Bit-sequence based features: We posit that the randomness due to encryption can be best leveraged by comparing the FFTs of two consecutive packets from a source app. In other words, we determine how similar or dissimilar the FFT vectors of two consecutive app packets are. The similarity (or lack thereof) in randomness is captured using 2 standard metrics employed in measuring the similarity between 2 *distributions*: (1) Pearson's Correlation Coefficient (PCC), and (2) Kullback-Leibler Divergence (KLD). In our case, these *distributions* are the Fourier transformed bit-sequences of encrypted packets generated by a cryptosystem.

In terms of implementation, we first convert the bit-sequence of each network packet into its corresponding bit-sequence in the frequency domain, by performing FFT. Thereafter, we compute the PCC and KLD of such bit-sequences of 2 consecutive packets. In order to not get restricted by sudden changes in PCC and KLD values, we also consider the moving average and moving variance of these values, which are smoother and more consistent. The entire mechanism is illustrated in Fig. 1.

Specifically, we define the following features to quantify bit-sequence similarity (or difference) between packets originating from a cryptosystem:

(1) *Pearson's Correlation Coefficient (PCC)* between the Fast Fourier Transform (FFT) of bit-sequences of 2 consecutive packets.
(2) *Pearson's Correlation Coefficient Average (PCCA)*, which is the moving average of the PCC values obtained.
(3) *Pearson's Correlation Coefficient Variance (PCCV)*, which is the moving variance of the PCC values obtained.
(4) *Kullback-Leibler Divergence (KLD)* between the FFTs of bit-sequences of 2 consecutive packets.
(5) *Kullback-Leibler Divergence Average (KLDA)*, which is the moving average of the KLD values obtained.
(6) *Kullback-Leibler Divergence Variance (KLDV)*, which is the moving variance of the KLD values obtained.

Table 2 Classification results (precision ($\mathcal{P}$), recall ($\mathcal{R}$), f1-score ($\mathcal{F}$), accuracy ($\mathcal{A}$)) obtained using 3 different classifiers for 3 variations of packet-sizes, for packets originating from 11 sources (10 encrypted using different ciphers, and 1 unencrypted). Best classification performance is achieved using the Random Forest Classifier (highlighted in green).

Let us denote the FFT vectors corresponding to the n^{th} packet and $(n-1)^{th}$ packet as p^n and p^{n-1} respectively. Pearson's correlation coefficient (PCC) between the FFTs corresponding to the n^{th} and the $(n-1)^{th}$ packets is defined as:

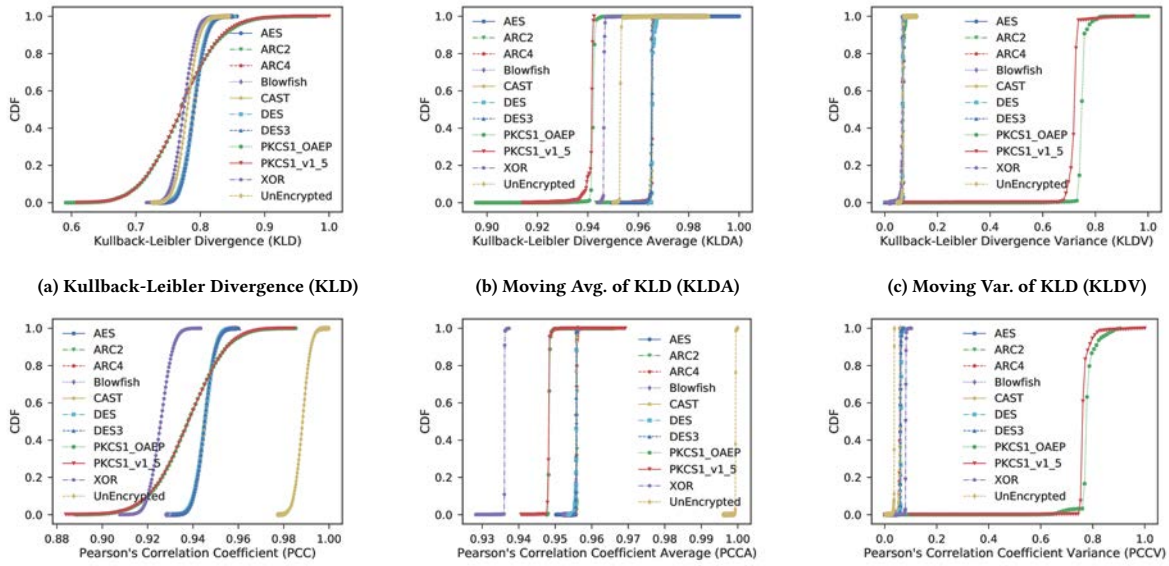
$$PCC_n = \frac{\sum_i (p_i^n - \overline{p^n}).(p_i^{n-1} - \overline{p^{n-1}})}{\sqrt{\sum_i (p_i^n - \overline{p^n})^2 . \sum_i (p_i^{n-1} - \overline{p^{n-1}})^2}} \quad (1)$$

The features derived from PCC, i.e. PCCA and PCCV, corresponding to the n^{th} packet in sequence, are defined as follows:

$$PCCA_n = \frac{1}{n} \sum_{i=0}^{i=n} PCC_i \quad (2) \qquad PCCV_n = \frac{1}{n} \sum_{i=0}^{i=n} (PCC_i - PCCA_i)^2 \quad (3)$$

Kullback-Leibler divergence between the FFTs corresponding to the n^{th} and the $(n-1)^{th}$ packets, is defined as follows:

$$KLD_n = \sum_i p_i^n . log \frac{p_i^n}{p_i^{n-1}} \quad (4)$$

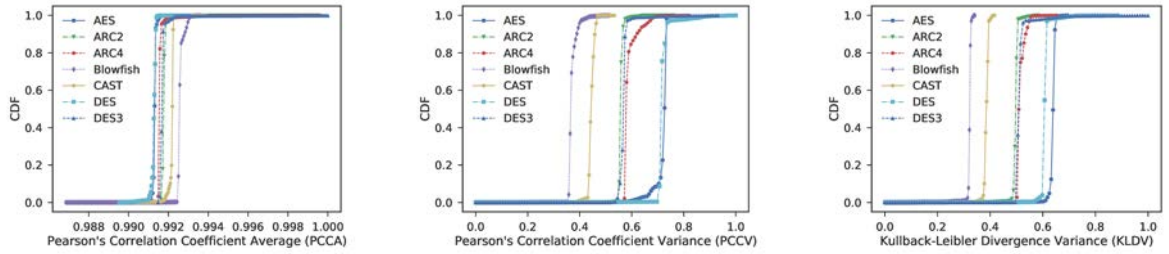


The features derived from KLD, i.e. KLDA and KLDV, corresponding to the n^{th} packet in the traffic flow, are defined as follows:

$$KLDA_n = \frac{1}{n} \sum_{i=0}^{i=n} KLD_i \quad (5) \qquad KLDV_n = \frac{1}{n} \sum_{i=0}^{i=n} (KLD_i - KLDA_i)^2 \quad (6)$$

2.4 Cipher and Key-Size Classification

In this subsection, we present two validation experiments, i.e., cipher classification (expt. 1) and key-size classification (expt. 2), to establish the efficacy of the aforementioned bit-sequence based features.



Ciphers: For expt. 1, we consider the same sources as in § 2.2, i.e., 7 symmetric-key ciphers (e.g., AES, ARC2, ARC4, Blowfish, CAST,

(a) Kullback-Leibler Divergence (KLD) (b) Moving Avg. of KLD (KLDA) (c) Moving Var. of KLD (KLDV)

(d) Pearson's Correlation Coeff. (PCC) (e) Moving Avg. of PCC (PCCA) (f) Moving Var. of PCC (PCCV)

Figure 2 Distribution (CDF) of bit-sequence based features: All 6 features – KL divergence (KLD), moving average of KL divergence (KLDA), moving variance of KL divergence (KLDV), Pearson's correlation coefficient (PCC), moving average of Pearson's correlation coefficient (PCCA), and moving variance of Pearson's correlation coefficient (PCCV) – are defined on the FFTs of the bit-sequences of packet payloads. These features capture the similarities (or dissimilarities) among bit-sequences of packet payloads generated using different ciphers (note that PKCS#1 v1.5 and PKCS#1 OAEP are represented as PKCS1_v1_5 and PKCS1_OAEP, respectively, in the plots).

(a) Moving Avg. of PCC (PCCA) (b) Moving Avg. of KLD (KLDA) (c) Moving Var. of KLD (KLDV)

Figure 3 Distribution (CDF) of bit-sequence based features PCCA, KLDA, and KLDV for 7 encryption algorithms, namely AES, ARC2, ARC4, Blowfish, CAST, DES, DES3. It can be observed that the packets generated for one encryption algorithm can be differentiated from others, on the basis of these 3 features.

DES, and DES3), 2 asymmetric ciphers (e.g., PKCS#1 OAEP and PKCS#1 v1.5), the XOR cipher, and unencrypted data acting as the 11^{th} source. We consider only the strongest cipher, i.e., AES, for expt. 2.

Key-sizes: In expt. 1, we use a fixed 128 bit key for symmetric ciphers, and a RSA public key extracted from a 1024 bit public/private key pair for asymmetric ciphers, as described in § 2.2. For expt. 2, we consider 3 different key-sizes of AES, i.e., 128 bits, 192 bits, and 256 bits. The keys are randomly generated using the Python `random.SystemRandom` class.

Setup: As in § 2.2, we used the Python package `PyCrypto` to encrypt each synthesized packet [3]. For both expts. 1 and 2, we generated 10,000 packets from each aforementioned source. In case of expt. 1, we repeated the experiments for 3 variations in terms of packet-size: (1) equal packet-size for all 11 sources, (2) equal packet-size for each source (different for different sources), and (3) random packet-size for each packet, irrespective of the packet source.

Results for cipher classification: We present the classification results for 8 different classifiers in Table 2. Multi-class (11 classes) classification is performed, all 6 features based on bit-sequence similarity are used, and 10-fold cross validation is employed to guard against over-fitting. We observe that the Random Forest Classifier (RFC) achieves best classification performance, with a worst-case accuracy of 89%. We also observe that the distribution of packet-sizes has an impact on classification, i.e., the packets can be more easily distinguished (96% in the best case) when packet-sizes are same across the packets from one source but different from the packets of other sources.

Results for key-size classification: Best performance is once again achieved by RFC, with an accuracy of 83% (with precision,

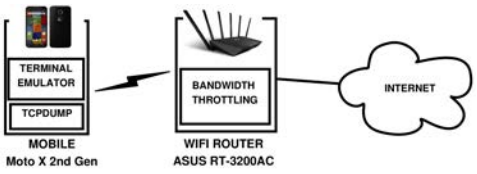


Figure 4 In-laboratory testbed setup for data collection: An ASUS RT-3200AC router connected to the Internet, acts as the gateway device. Bandwidth throttling is performed by setting router configuration parameters appropriately. A Moto X 2^{nd} generation Android smartphone running on Android 6.0 (Marshmallow) is connected to the router over WiFi. Mobile applications are executed on this phone, and data is collected using the *tcpdump* tool.

recall, and F1-score all at 0.83). We omit rest of the results (which are similar as for expt. 1) for brevity.

2.5 Bit-Sequence Features: Detailed Analysis

Having established that our proposed features are able to distinguish among data encrypted with different ciphers and different key-sizes, we perform a deeper analysis of those features. We plot the CDF for all 6 features for packets generated using each of the 11 sources in Fig. 2 (case (2), i.e., equal packet-size for each source is considered; the observations are similar in the other 2 cases). We observe that the distributions for PKCS#1 OAEP, PKCS#1 v1.5, XOR, and unencrypted can be easily differentiated from the rest of the cases (KLDV and PCCA showing the most prominent distinguishability). In order to analyze the other 7 encryption algorithms more closely, we normalize for those and plot the CDF of PCCA, PCCV, and KLDV in Fig. 3. We observe that even these 7 algorithms can be easily distinguished from each other with a classifier of higher arithmetic precision, on the basis of these 3 features.

So far, we have analyzed the effectiveness of our proposed set of features in classifying data encrypted with multiple ciphers/key-sizes. However, this ability is not merely limited to varying ciphers and key-sizes, but generalizes to any customizable parameter in a cryptosystem implementation that may give rise to a discernible difference in the randomness of the encrypted data. Other parameters (besides cipher and key-size) include the default OS library, the TLS library and its version being used, etc. In the following sections, we illustrate how these bit-sequence based features may be used to classify encrypted data generated from a large number of mobile apps, based on their ability to leverage variability in cryptosystem implementations.

3 EXPERIMENTAL SETUP AND DATASET

In this section, we explain our experimental setup for performing large-scale app traffic classification, and also describe the dataset collected using this setup.

3.1 Experimental Setup

We describe the experimental setup adopted by us, and the driving factors behind it, in this subsection.

Setup considerations: In order to generalize our results on mobile app traffic, we collected traffic traces under controlled operating conditions. Important control parameters included background traffic, channel conditions, and traffic from advertisements embedded in the traffic of the intended application. Even if all possible care is taken to avoid background traffic, it can still occur from services that the OS runs for optimizations and communications with the server. Also, variation in channel conditions may lead to differences in the way certain apps behave, e.g., video streaming apps may adapt to a different bit-rate when bandwidth varies. Similarly, advertisements running within the app may contaminate data collected from it. Keeping these factors in mind, we implemented an in-laboratory testbed to enable controlled collection of packet traces from a large number of mobile applications.

Testbed setup: The testbed setup is shown in Fig. 4. The end device connects to the ISP's network through a wireless router. The wireless router is instrumented such that we can control the bandwidth between the router and the end device. We used a Motorola Moto X 2^{nd} generation Android smartphone as the end device where we execute each mobile app separately. This device is rooted to allow trace collection using `tcpdump`. Android `Terminal Emulator` app provides the interface to execute `tcpdump`. The router is an ASUS RT-3200AC router with IEEE 802.11ac Wi-Fi standard. This router provides the *Adaptive QoS* feature, which allows manual configuration of the *Download Bandwidth* field to specify a controlled download rate.

Bandwidth scenarios: We collect data for each app under 4 bandwidth scenarios (by throttling at the router) – 0.5 Mbps, 1 Mbps, 4 Mbps, and 16 Mbps – to capture changes in app behaviour, if any, under varying bandwidth conditions.

Logs maintained during trace collection: We log the following information during data collection:

- ***Log 1:*** IPs for all client devices used in our experiments, and the corresponding app playing on each IP.
- ***Log 2:*** Start and end time for embedded advertisements, during execution of the app.

The aforementioned information enables us to discard noisy data from the accumulated traffic, in the manner described next.

Packet labeling: In order to associate each packet with a distinct label for our experiments, we first differentiate the video traffic flows based on 5-tuple information <*source IP, source port, destination IP, destination port, transport protocol*>, present in the header of each packet. Based on our knowledge of client IP addresses from ***Log 1***, we selectively preserve flows which correspond to download traffic, i.e., from the content server to the client app. We ensure that network control packets are eliminated from our dataset – such packets include ARP, DNS, IGMP, ICMP, NTP, DB-LSP-DISC (Dropbox Lan Sync Protocol), SYN, ACK (non-piggybacked), etc. – these packets do not carry any useful content, but appear in large numbers in the traces. Furthermore, we utilize the logged timing information in ***Log 2*** to discard packets which do not correspond to the actual app content, but to associated events (such as ads). Subsequently, we tag each packet with its source application, based on our knowledge of the client IP-app correspondence – cumulatively, this forms our dataset.

3.2 Android Application Dataset

In this subsection, we describe the dataset collected by us using the setup introduced in § 3.1.

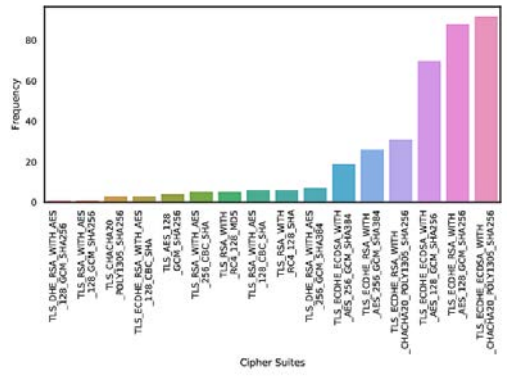

Figure 5 Distribution of cipher suites used by applications in our dataset.

Android app selection: We select 175 Android applications based on the *Top Free in Android Apps* selection in the Google Play Store[3]. The apps comprise a variety of categories, including but not limited to, video, audio, games, messaging, social networking, news, health, and static content-based apps.

Diversity in cipher suites: Razaghpanah et al. established in their analysis that different applications in the Android app store use different cipher suites, TLS libraries, OS defaults, etc. [41]. We perform a similar analysis of our dataset in terms of ciphers suites used and supported. We segregate out the `Server Hello` and `Client Hello` TLS handshake messages from our dataset, and parse them to find out cipher suites used by different applications. Fig. 5 shows the distribution of cipher suites used for encrypting traffic during the course of data collection. Fig. 6 on the other hand, shows the distribution of cipher suites which are supported by the application and may be used depending upon platform support, preference, or random choice. We observe from the figures that there is significant diversity in the cipher suites used for different mobile apps, which corroborates with the analysis in [41]. Furthermore, it is also important to note that cipher suites are not the only encryption parameters which affect randomness induced in the data; OS and TLS libraries, various configurable parameters on the client and server sides, etc. also impacts it. Our features are designed to leverage any such randomness occuring due to any combination of parameters in the cryptographic implementation of an application.

Choosing pairs of packets: We mentioned in § 2.3 that the ideal way of choosing pairs of packets in order to compute our proposed bit-sequence based features is to choose consecutive packets in a flow. We employ this idea (of consecutive packets) in the experiments conducted in this paper. The rationale is that in a real system, even if the client port is common (80 for HTTP and 443 for HTTPS) and the IPs are unrecognized for multiple simultaneously running applications, it would still be possible to segregate a flow based on its 5-tuple combination in most situations. There may be two exceptions, however: (1) when the first packet in a flow is encountered and it cannot be readily attributed to an application, and (2) when simultaneous flows end up with the same 5-tuple combination (e.g., when using a proxy). In both cases, we propose storing and using recent *reference* packets from all candidate applications, and using those for computation of the bit-sequence based features. The application for which the values correlate most closely (as returned by a trained classifier), is the likely target application.

In order to illustrate the frequency of case 1 (first packet of a flow) in our dataset, we plot the number of packets per flow for each application in Fig. 7. We observe that most (above 90%) of apps send atleast 100 packets in a flow, while around 50% send at least 1,000 packets. Around 15% of applications send upward of 10,000 packets in a single flow. This illustrates that in case of most applications the computation of bit-sequence based features does not incur any additional overhead, i.e., first packet instances are few and far between.

[3]This list changes frequently based on Google's app ranking system. Our selection was based on the status of this list on 15-April-2018.

4 EVALUATION

In this section, we evaluate the efficiency of our proposed bit-sequence based features in classifying traffic from a large number of applications.

4.1 Baseline (Packet-Level) Features

We introduce packet-level features in this subsection, such as those based on packet-size and packet inter-arrival time, which have been widely used in the literature for app-traffic classification [7, 27, 42, 46]. These features serve as baselines in our study. Along with the raw packet-size and inter-arrival time, we also consider the moving average and moving variance of these features. This is to account for sudden changes in the raw values, e.g., when the last packet in a burst is sent, it may be of an uncharacteristically lower size, or the first packet in a burst may have a significantly higher inter-arrival time. Moving average and variance values, which are more regular and smoothened, better capture the characteristic nature of app traffic.

Packet-Size Based Features: We use the following packet-size based features:

(1) *Packet-size (PS)*, which is directly the packet-size observed at the network (IP) layer.
(2) *Packet-size Moving Average (PSMA)*, which is the moving average of PS values for a traffic flow.
(3) *Packet-size Moving Variance (PSMV)*, which is the moving variance of PS values for a specific traffic flow.

PSMA and PSMV corresponding to the n^{th} packet in sequence of traffic flow, are formulated as follows:

$$PSMA_n = \frac{1}{n}\sum_{i=0}^{i=n} PS_i \quad (7) \qquad PSMV_n = \frac{1}{n}\sum_{i=0}^{i=n} (PS_i - PSMA_i)^2 \quad (8)$$

Packet Inter-Arrival Time Based Features: We use the following parameters based on temporal traffic behavior:

(1) *Inter-arrival time (IAT)*, which is merely the difference between arrival time of two consecutive packets belonging to the same flow.
(2) *Inter-packet timing average (IPTA)*, which is the moving average of IAT values for a traffic flow.
(3) *Inter-packet timing variance (IPTV)*, which is the moving variance of IAT values for a particular traffic flow.

The features identified above, i.e., IAT, IPTA, and IPTV, of the n^{th} packet in sequence within the flow, are formulated as follows:

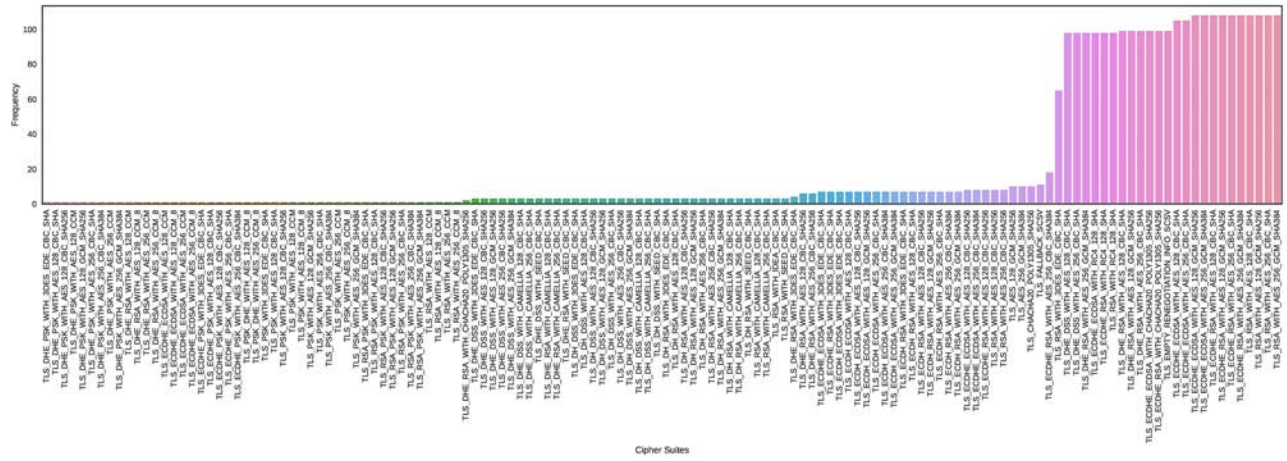

Figure 6 Distribution of cipher suites supported by applications in our dataset.

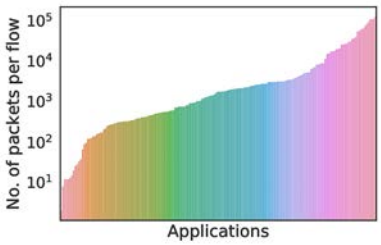

Figure 7 Distribution of number of packets per flow for applications

Table 3 Classification performance (precision ($\mathcal{P}$), recall ($\mathcal{R}$), f1-score ($\mathcal{F}$), accuracy ($\mathcal{A}$)) for classification of traffic from 175 mobile apps. Bit-sequence based features perform better than the baselines in terms of both F1-score and accuracy. The scores boost significantly when our proposed features are used in conjunction with baseline packet-level features.

Features / Classifier	**Random Forest**	**Decision Tree**
Metrics	$\mathcal{P}$, $\mathcal{R}$, $\mathcal{F}$, $\mathcal{A}$	$\mathcal{P}$, $\mathcal{R}$, $\mathcal{F}$, $\mathcal{A}$
Packet-Size Features (PSF)	0.32, 0.27, 0.27, **0.27**	0.35, 0.29, 0.29, **0.29**
Inter-Arrival Time Features (ITF)	0.33, 0.10, 0.12, **0.10**	0.37, 0.11, **0.13**, **0.11**
Packet-Level Features (PSF+ITF)	0.76, 0.62, 0.65, **0.62**	0.78, 0.60, **0.64**, **0.60**
Bit-Sequence Features (BSF)	0.68, 0.71, 0.69, **0.71**	0.66, 0.69, 0.67, **0.69**
Bit-Sequence + Packet-Level Features (PSF+ITF+BSF)	0.97, 0.96, 0.96, **0.96**	0.95, 0.95, 0.95, **0.95**

$$IAT_n = t_n - t_{n-1} \quad (9) \qquad IPTA_n = \frac{1}{n}\sum_{i=0}^{i=n} IAT_i \quad (10)$$

$$IPTV_n = \frac{1}{n}\sum_{i=0}^{i=n} (IAT_i - IPTA_i)^2 \quad (11)$$

where t_n and t_{n-1} are arrival time instances for the n^{th} and $(n-1)^{th}$ packets respectively.

4.2 Classification Methodology

We discuss the classification methodology employed for classification of packets from 175 mobile apps, followed by results.

Overcoming class imbalance: We train our classifiers on 10,000 packets from each app. In order to avoid bias due to class imbalance, we random-sample an equal number of packets (10,000) from the data collected for all those apps, where the total number of packets is higher than 10,000. In the few cases (5 apps) where lesser than 10,000 packets are available, we employ SMOTE [14] and oversample the datasets, so as to balance them.

Guarding against overfitting: In order to minimize the chances of over-fitting the data, we employ k-fold cross validation (we set $k = 10$ in our experiments).

4.3 Classification Results

Overall classification: The classification results for data collected from 175 apps are presented in Table 3. We present results for the following baselines: (1) Packet-size based features only (PS, PSMA, PSMV), (2) Inter-arrival time based features only (IAT, IPTA, IPTV), (3) Bit-sequence based features only (PCC, PCCA, PCCV, KLD, KLDA, KLDV), and (3) All packet-level features, i.e., a combination of packet-size based features and inter-arrival time based features (PS, PSMA, PCCV, IAT, IPTA, IPTV). Results for only the two best performing classifiers (Random Forest and Decision Tree) have been reported. We observe that using only packet-size based features results in an accuracy score of 0.29, while only inter-arrival time based features result in an ever lower accuracy of 0.11 (in the best cases, i.e., using the Decision Tree classifier). When combined, however, the packet-level features together result in a much higher accuracy of 0.60, which is still, however, not satisfactorily high.

Our proposed bit-sequence based features perform significantly better than either packet-size based or inter-arrival time based features, in terms of both F1-score and accuracy. In fact, they perform even better than all packet-level features combined (69% vs. 65% in terms of F1-score, and 71% vs. 62% in terms of accuracy). Considering that we perform multi-class classification with 175 classes, this is a significant result, and substantiates the effectiveness of our proposed features in differentiating apps based on differences in TLS implementations. The classification results are boosted heavily – in fact to 95% F1-score as well as accuracy, in the best case – when packet-level features are employed in conjunction with bit-sequence based features, which is our recommended strategy for mobile app traffic classification. A classifier performing with such

accuracy may be used by a network administrator in fingerprinting and monitoring heterogenous traffic from a vast number of apps.

Category-wise evaluation: We evaluate our proposed features for another important practical use-case. Instead of aggregate traffic, a network administrator may only be interested in identifying traffic from a specific category. For example, in an enterprise setting, she may try to enforce a policy where all video traffic is allocated lesser bandwidth to avoid overburdening critical applications. In this vein, we divide the entire dataset of apps into 5 categories, namely, video, audio, browsing, gaming, and messaging. The *browsing* category consists of apps used for email, download, sync, etc. apart from web browsing; the other 4 category names are self-explanatory. We then attempt to perform inter-category classification (i.e., classify among the 5 categories), as well as intra-category classification (i.e., classify among apps belonging to one particular category). The classification results are presented in Table 4.

We observe that we can achieve 90% accuracy (using only bit-pattern based features) in classifying heterogenous traffic into categories (row 1). Classification performance further improves when traffic from apps within a particular category are classified; minimum accuracy (using RFC) is 93%, which once again is a significant results considering the scale of classification.

Classification running time: Since the classifier needs to run as part of a live system, it is also important to evaluate the running time for per-packet classification. We executed a separate batch of experiments, where we trained the classifiers with 90% of the data, and tested with the remaining 10%. This enabled fine-grained time-keeping, which we achieved using the Python `timeit` module. These experiments were executed in a Ubuntu 16.04 workstation, with 64 GB RAM, and a 3.0 GHz Intel Core i5 processor. We observe that while RFC consumed 14.16 microseconds per packet, the Decision Tree classifier consumed only 0.84 microsecond. We note that these time quanta are well within the bounds of the RTT of packets arriving from a distant content server, which implies that our classification strategy can be employed in a real-life setting, such as in a smart-QoS enabled modern home router.

5 DISCUSSION

In this section, we discuss some of the major learnings from and limitations of this work, as well as the potential impact it may have in inducing further research in the area.

Real-time implementation: We show in § 4.3 that classification at per-packet granularity is compliant with the timing requirements of a live networked system. However, we do not comment on the time consumed in the training process, when either training frequency is high, or training data volume is extremely large. For example, network administrators intent on classifying and blocking malicious apps may need to avail frequent rounds of training, since new apps crop up everyday on the app store. Optimizations such as implementing FFT in hardware could be availed to speed up computations in such scenarios [6].

Attacks around bit-sequence based features: While our use-cases in this paper revolve around the opportunities bit-sequence based features could provide network administrators, the flip-side of the coin is that the same opportunities may be exploited by attackers. For example, these features could be leveraged to infer user actions from mobile phone traffic, which could lead to severe breach of privacy for users [18, 37, 49]. Applications which authenticate users based on their app activity history [21, 30], may also be fooled if app activities could be gleaned out using our proposed features.

Protection against obfuscation: Some works have pointed out the privacy risks involved when statistical analysis of packet-level features is used to differentiate traffic [32, 51]. These studies, including a recent work [13] propose obfuscating such features so that classifiers may not be able to extract useful information out of application traffic. The obfuscation is implemented in a proxy, which fragments incoming packets and regulates arrival rate to make one class of traffic look like another. Our classification mechanism based on randomness of security implementations, is however, immune to such packet-level obfuscation.

Tool for side-channel attacks: It follows from the previous discussion, therefore, that along with packet-level and traffic meta-data (e.g., direction of traffic) based features [17, 45, 48], bit-sequence based features can also pose threats via side-channel attacks. It is important therefore, to further the research agenda in this direction, and devise methods to either exploit or alleviate such attacks, as necessary for the application.

Impact of app updates: App updates may include updates to their encryption implementations as well. While such updates can affect classification performance of our trained model, as long as there exist differences in such implementations, it is possible to retrain the classifier to recover performance. We argue that such differences will continue to exist due to the non-standard nature of app stores, and deficiencies in computational capabilities of low-end devices.

6 RELATED WORK

Classifying traffic from mobile applications has spurred active research recently due to its practical necessity, as well as, the challenges arising from lack of features suitable for traffic classification. First, we look at classification strategies which have addressed generic web traffic. Next, we present studies specific to mobile traffic, and discuss their advantages and limitations.

6.1 Generic Web Traffic Classification

A large body of work has addressed traffic classification on the Internet over a number of years. Continuously changing landscapes in the way data is delivered to the end-users (e.g., content delivery networks (CDNs), cloud), have prompted researchers to revisit old techniques, and invent newer approaches more commensurate with the trends prevalent during the time of their studies.

Deep Packet Inspection (DPI) based Techniques: Several approaches have been suggested for web traffic classification using packet-inspection based methods. Finsterbusch et al. compiled a comprehensive survey of these techniques – however, they note, like many others, that DPI based approaches either perform abysmally, or fail entirely when traffic is encrypted [26].

Statistical Information based Techniques: Most studies which do not rely on packet-inspection, suggest exploiting side-channel information, and statistical properties of traffic, which remain unaffected by encryption. An MIT tech review article highlighted the importance of statistical tricks in extracting user footprints from encrypted communications [5]. Some statistical approaches rely on

Table 4 Classification results (precision ($\mathcal{P}$), recall ($\mathcal{R}$), f1-score ($\mathcal{F}$), accuracy ($\mathcal{A}$)) using only bit-sequence based features for 2 classification tasks: (1) classification of aggregate traffic into app categories (shown in the first row), and (2) classification of category traffic into constituent applications. Best classification performance is achieved using the Random Forest Classifier (highlighted in green).

carefully constructed rules for classification, while others employ machine learning – we report these cases separately.

Rule based Approaches: Sun et al. presented a method for statistical identification of browsed web applications, by studying the various unique web objects (e.g., images, stylesheets, etc.) fetched during the launch of a webpage [47]. This approach is clearly outdated, since most websites serve dynamic content nowadays, where fetched objects would continually change, sometimes even within seconds. Gong et al. proposed using side-channel attacks to determine round-trip times (RTTs), and then clustering traffic with similar RTTs [29]. A similar approach was adopted by Chen et al., where side-channel leaks in terms of packet-size, arrival time, and stateful interactions between servers and clients of web applications, were exploited [15]. Piskac et al. suggested protocol detection from web traffic, again using packet-size and arrival time values [40]. Detection of Domain Generation Algorithm (DGA) based botnets was proposed using DNS traffic analysis in a recent work by Wang et al. [50]. Another recent work studied privacy vulnerabilities in a IoT based smart home system, made possible by traffic analysis [9].

Machine Learning based Approaches: Traffic classification using supervised learning has been a popular approach – the major task in such an approach is to identify discriminative features from encrypted network traffic. Some of the earlier works can be found in a survey by Nguyen et al. in [39], and references therein. Jesudasan et al. identified generic features (based on packet-size and arrival time) across different versions of Skype that could be used to classify Skype flows [33]. Bujlow et al. proposed a learning model with features based on individual and aggregate payload sizes, along with IP and port no. based rules [11]. Recently, Shi et al. have also shown that encrypted, and even tunneled (using a Virtual Private Network (VPN)) video sources, can be identified by analyzing simple features derived from packet-sizes and temporal patterns of packet arrival [10, 43]. As an application of network traffic analysis, a recent work by Das et al. proposed privacy-aware localization using a supervised learning approach [22].

While some statistical observations for generic web traffic may still hold true in case of mobile traffic, there are differences due to buffer and bandwidth constraints on a mobile device, and how service providers tend to optimize traffic for mobile accordingly. We leverage upon the common statistical properties by identifying those (with careful analysis of mobile app traffic), and address the differences by defining novel features that can aid in classification.

6.2 Mobile Traffic Classification

Studies on mobile traffic classification can be broadly divided based on whether those targeted unencrypted or encrypted traffic.

Unencrypted Traffic: Approaches that assume unencrypted traffic rely on inspection of fields in the HTTP header. Hur et al. exploited the user agent field, and other common strings found in the HTTP headers of packets generated by the same application [31]. Dai et al. showed that by executing different apps in an emulator and gathering corresponding network traces, it is possible to build signatures for identifying specific traffic sources [20]. Yao et al. reduced the overhead of building signatures where they used context of signatures to improve identification accuracy and scalability [54]. Automatic generation of classifiers for traffic identification has been presented in [16, 53]. AppPrint also uses extensive traffic observations to build signatures based on header fields [38]. Since these works rely on information that must be read from the packets, they are ill-suited for classifying encrypted traffic.

Encrypted Traffic: Stöber et al. proposed classification of background traffic generated from a smartphone, by studying patterns in packet level features (e.g., packet-size and packet arrival instances), and burst level features (e.g., mean, median, etc. of packet level features) [46]. Alan et al. limited their study to using only launch time traffic for building supervised classifiers for Android app identification [7]. Mobile messaging apps were studied by Fu et al., and a machine learning based solution was provided using packet-level features [27]. Another work defined an end-to-end system to enable fine-grained bandwidth provisioning for video app traffic in absence of background traffic [42].

7 CONCLUSION

Mobile traffic classification is an important task for network administrators in order to achieve policy enforcement and service provisioning. However, due to lack of unique signatures and especially due to encryption, mobile app traffic classification is rendered difficult. While statistical analysis based on packet-size and arrival time of packets has shown a lot of promise, existing techniques do not scale well to traffic from a large number of applications. In this paper, we worked on the notion of exploiting encryption itself (more specifically, TLS implementations) to classify mobile app traffic at a large scale. We proposed a set of novel bit-sequence based features, which can classify data encrypted with different ciphers and key-sizes, with 89% and 83% accuracy (best case), respectively. We show that using these features in conjunction with existing packet-level based features, it is possible to classify traffic from 175 Android applications with a best case accuracy of 95% (as opposed to a baseline accuracy of 62%). The features also perform well in achieving inter-category (90% accuracy) and intra-category traffic classification (min. accuracy of 93%), using only bit-sequence based features.

ABSTRACT

Group detection is gaining popularity as it enables various applications ranging from marketing to urban planning. The group information is an important social context which could facilitate a more comprehensive behavior analysis. An example is for retailers to determine the right incentive for potential customers. Existing methods use received signal strength indicator (RSSI) to detect co-located people as groups. However, this approach might have difficulties in crowded urban spaces since many strangers with similar mobility patterns could be identified as groups. Moreover, RSSI is vulnerable to many factors like the human body attenuation and thus is unreliable in crowded scenarios. In this work, we propose a behavior-aware group detection system (BaG). BaG fuses people's mobility information and smartphone usage behaviors. We observe that people in a group tend to have similar phone usage patterns. Those patterns could be effectively captured by the proposed feature: number of bursts (NoB). Unlike RSSI, NoB is more resilient to environmental changes as it only cares about receiving packets or not. Besides, both mobility and usage patterns correspond to the same underlying grouping information. The latent associations between them cannot be fully utilized in conventional detection methods like graph clustering. We propose a detection method based on collective matrix factorization to reveal the hidden associations by factorizing mobility information and usage patterns simultaneously. Experimental results indicate BaG outperforms baseline approaches by 3.97% ∼ 15.79% in F-score. The proposed system could also achieve robust and reliable performance in scenarios with different levels of crowdedness.

1 INTRODUCTION

Group detection plays an important role in many applications including marketing [29], healthcare [22, 35], and urban planning [3, 39]. The grouping information is an essential contextual feature in multi-target tracking [26] and behavior analysis [12]. This social context facilitates better interpretation of observed events and detection of abnormal behaviors [13]. A typical scenario is for retailers to determine the right incentive for potential customers. For example, "Buy X get Y free" promotions would be more attractive to group customers than individual customers [29]. It is commonly assumed a group could be discerned by people's physical locations and behaviors [6, 23, 29, 34]. Therefore, *group detection* is defined as a task of clustering a set of people into disjoint subsets based on their locations and behaviors.

Existing works exploit *probe requests*[1] to detect co-located people as a group [12, 19]. Co-location is achieved through received signal strength indicator (RSSI) contained in probe requests. Besides, those probes could be collected without difficulty since they are broadcast automatically to seek information about nearby access points (APs). Compared with other approaches, this method requires neither high deployment cost (e.g., deploy cameras [9, 34]) nor user intervention (e.g., carry wearable devices or install apps [18, 24, 29]). The probe-based methods are thus capable of detecting large-scale spontaneous groups in naturalistic environments.

However, current probe-based methods might have some difficulties in crowded environments. First, many strangers are close to each other in crowded spaces [29]. For example, two strangers might walk closely along an aisle. This indicates detecting co-located people as a group in crowded areas is error-prone. Second, RSSI is vulnerable to many factors like device diversity, multipath fading, and body attenuation [30]. It is unreliable to use RSSI to detect groups in dynamic environments crowded with people moving around.

We ask the following question: *can we reliably detect groups with WiFi probes in crowded urban spaces?* In this paper, we provide an affirmative answer by proposing a Behavior-aware Group detection (BaG) system that integrates both mobility information and phone usage behaviors. We have a key observation that people in the same group tend to have similar phone usage patterns. The observation is closely related to the concept of "phubbing" that is rife throughout the world. "Phubbing" is defined as the act of snubbing others in social interactions and instead focusing on one's smartphone [11].

[1] *Probe request*, *WiFi probe*, and *probe* are used interchangeably

According to a survey of 276 participants, the correlation of "phubbing" and "being phubbed" is 0.6 [4], which indicates individuals in a group would have similar phone usage patterns. The authors [4] explained this phenomenon occurs might due to false-consensus effects. Individuals assume that others think and do the same as themselves. Besides, we contribute a new feature (*number of bursts, NoB*) extracted from WiFi probes that could effectively capture phone usage patterns. A *burst* is a set of probes sent over a very short period of time (less than 1 second) [8]. The higher frequency a phone is used, the more NoB is generated. Unlike RSSI, NoB is resilient to crowded environments since it only cares about whether there are probes or not.

The vision of BaG, however, entails sparsity and fusing challenges when applied to real conditions.

1) How to handle spatiotemporal sparsity of WiFi data? First, an area is usually covered by a limited number of APs (spatial sparsity). Second, the probing frequency of a smartphone is affected by many factors like operating systems and users' usage patterns [8] (temporal sparsity). The data in common of two users could be much sparser. Measuring user similarity with such data could lead to highly biased and unreliable results.

2) How to cluster users fusing mobility and behaviors? The integration of mobility and behaviors remains an open issue. Mobility and behaviors have latent associations since both of them are different perspectives of the real grouping information. Simply combing them like calculating their arithmetic mean might limit the potential of hidden associations and thus derive unsatisfactory results.

For the sparsity challenge, we first represent mobility and behavior information into two matrices respectively. Then we apply matrix factorization (MF) to handle data sparsity by decomposing an input matrix into the product of several factor matrices. For the fusing challenge, we consider sparsity-constrained collective nonnegative MF (SCNMF). The advantages are two-fold. First, collective MF (CMF) takes the correlation of both input matrices into consideration by factorizing them simultaneously. Second, the sparsity constraint of CMF makes it an alternative for clustering so that grouping results could be derived directly without extra clustering processes.

According to our experimental evaluation with 82 volunteer groups in a large shopping mall, BaG achieves robust and reliable performance in scenarios with different levels of crowdedness. Compared with baseline approaches, BaG improves F-score of detection by 3.97% $\sim$ 15.79% in labeled data and 6.67% $\sim$ 20.69% in synthetically labeled data, respectively.

Our main contributions are summarized as follows.

- We introduce a new improvement of group detection in crowded environments: phone usage behaviors.
- A new feature (NoB) is extracted from WiFi probes that could effectively capture phone usage behaviors.
- We propose a new group detection method (SCNMF) that fuses mobility and behaviors and derives the grouping results without extra clustering processes.

The remainder of this paper is organized as follows. We present preliminaries in Section 2. Section 3 introduces design details of BaG, followed by experimental evaluation of the system in Section 4. Related work is introduced in Section 5. We conclude this paper and introduce the future work in the last section.

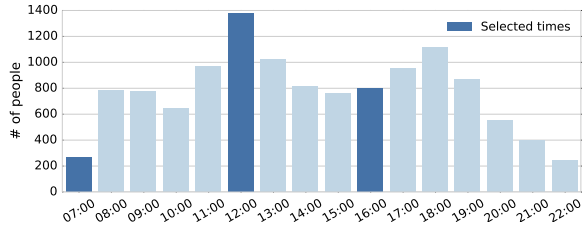

Figure 1: Average number of people in a day in the mall.

2 PRELIMINARIES

First of all, we use a two-day pilot study to illustrate relationships of the following variables in crowded environments: 1) RSS difference vs. groups 2) Phone usage behaviors vs. groups ; 3) Phone usage behaviors vs. NoB.

Experiments are conducted in a large shopping mall where we have deployed 20 APs to sniff WiFi probes. More detailed settings could be found in Section 4. Although it is difficult to define crowdedness directly, different numbers of onsite people could reflect different levels of crowdedness. Figure 1 highlights selected times of the experiment and the average number of people in the mall. The order of crowdedness is 12:00 > 16:00 > 7:00.

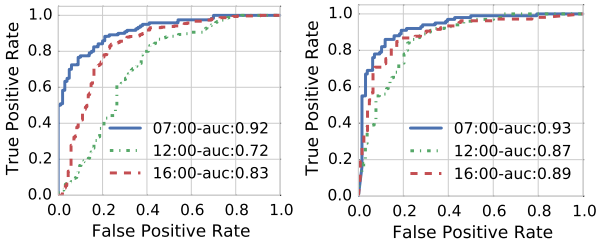
In each experiment, we recruit around 10 volunteer groups (each group consists of 2 $\sim$ 5 people) and record their grouping information and MAC addresses. We install an app on their smartphones to record screen on-off states as phone usage events. To ensure the authenticity, volunteers are only told to keep WiFi enabled and behave as normal without knowing the purposes of the experiment.

2.1 RSS Difference vs. Groups

RSSI methods calculate RSS (received signal strength) difference of two users. To this end, we first process users' WiFi data with an interval of 60 seconds, as probes are sent in a granularity of minutes [12]. Then user i's WiFi data in the t-th minute is represented as a vector:

$$\mathbf{v}_i^t = [rss_1, rss_2, \cdots, rss_N], \tag{1}$$

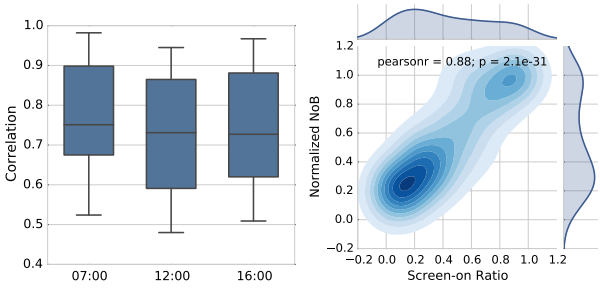
where rss_n represents received signal strength of the n-th AP, N is the number of total APs. If no RSS is available for AP n, then rss_n is set to 0. According to [37], RSS difference of users i and j at time t could be calculated with Eq. 2 and 3:



$$d(\mathbf{v}_i^t, \mathbf{v}_j^t) = \frac{1}{|A_i \cap A_j|} \cdot \sum_{a \in A_i \cap A_j} \left| rss_a^i - rss_a^j \right| \tag{2}$$

$$A_i = \left\{ k \middle| rss_k^i \neq 0, k \in [1, N] \right\} \tag{3}$$

The averaged RSS difference $D(i, j)$ over all common time slots is calculated with Eq. 4, where T is a set of common time slots of user i and j.



$$D(i, j) = \frac{1}{|T|} \sum_{t \in T} d(\mathbf{v}_i^t, \mathbf{v}_j^t), \tag{4}$$

Then we derive a distribution $\mathbf{X}_g(k)$ of $D(i, j)$ for all group pairs appear in time slot $k \in \{7{:}\,00, 12{:}\,00, 16{:}\,00\}$. Formal definition

(a) RSS difference (b) Behavior difference

Figure 2: ROC curves of different features at selected times. (a) With RSS difference; (b) With behavior difference.

(a) (b)

Figure 3: (a) Boxplot of the correlation for all users at selected times; (b) An example of correlation analysis of *screen-on ratio* and *normalized NoB* for a single user.

of $\mathbf{X}_g(k)$ is shown in Eq. 5, where boolean function $g(i,j)$ returns 'True' when user i and j are from the same group and U_k is a set of users appear in time slot k. Similarly, for all non-group pairs, we have another distribution $\mathbf{X}_{\tilde{g}}(k)$.

$$\begin{aligned}\mathbf{X}_g(k) &= \left\{D(i,j)\middle|g(i,j) = True; i,j \in U_k\right\}\\ \mathbf{X}_{\tilde{g}}(k) &= \left\{D(i,j)\middle|g(i,j) = False; i,j \in U_k\right\}\end{aligned} \tag{5}$$

Usually, $\mathbf{X}_g(k)$ and $\mathbf{X}_{\tilde{g}}(k)$ overlap to some extent, so we cannot easily find a cut-off point that completely separates both distributions. However, the smaller the overlap, the better the separation performance. To compare the effectiveness of using RSS difference more objectively, we exploit Receiver Operating Characteristic (ROC) curve, which is usually used to illustrate the diagnostic ability of a binary classifier system as its discrimination threshold varies. The curve is created by plotting the true positive rate (TPR) against the false positive rate (FPR) at various threshold settings.

Figure 2a shows the comparison of ROC curves using RSS difference at selected times. It is clear that the effectiveness of different times varies significantly, indicating RSS difference is not a consistent feature in crowded environments. Besides, the order of effectiveness is 7:00 > 16:00 > 12:00, which is exactly the opposite order of the crowdedness. This implies crowded environment might have a significant negative impact on RSSI methods.

2.2 Smartphone Usage Behaviors vs. Groups

To represent phone usage behaviors, we use a straightforward way. If a smartphone is in use, the screen must be on. Otherwise, the screen is off. To represent user i's usage behaviors, we use a behavior vector $\mathbf{b}_i$:

$$\mathbf{b}_i = \left[\frac{s_1}{60}, \frac{s_2}{60}, \cdots, \frac{s_t}{60}, \cdots\right], \tag{6}$$

where s_t is a total number of seconds when the screen is on in the t-th minute. Behavior difference $D'(i,j)$ of user i and j is measured with Euclidean distance in Eq. 7.

$$D'(i,j) = \frac{1}{60}\sqrt{\sum_{t=1}(s_t^i - s_t^j)^2} \tag{7}$$

The behavior difference distributions $\mathbf{Y}_g(k)$ and $\mathbf{Y}_{\tilde{g}}(k)$ at time k are defined as:

$$\begin{aligned}\mathbf{Y}_g(k) &= \left\{D'(i,j)\middle|g(i,j) = True; i,j \in U_k\right\}\\ \mathbf{Y}_{\tilde{g}}(k) &= \left\{D'(i,j)\middle|g(i,j) = False; i,j \in U_k\right\}\end{aligned} \tag{8}$$

Similarly, we draw ROC curves for $\mathbf{Y}_g(k)$ and $\mathbf{Y}_{\tilde{g}}(k)$. As shown in Figure 2b, the ROC curves at different times are close to each other, indicating behavior difference is stable in different crowdedness settings. Besides, the performance (AUC, area under curve, are all over 0.85) proves behavior difference is effective for group detection.

2.3 Smartphone Usage Behaviors vs. NoB

Although different smartphones have different probing patterns, it is reported that a smartphone will send more probes when the screen is on [8]. Therefore, the more frequently a smartphone is used, the more NoB is generated. A recent research work [15] uses the number of wireless packets to predict the screen on-off states and achieves an accuracy ranging from 93% to 100%. NoB is different from the work in two aspects. First, only WiFi probes are used here. Second, we use the number of bursts instead of the number of packets.

We represent user i's NoB feature with a NoB vector:

$$\mathbf{n}_i = [n_1, n_2, \cdots, n_t, \cdots], \tag{9}$$

where n_t is the number of bursts in the t-th minute. To handle the impact of device diversity, we further calculate a normalized NoB vector with Eq. 10, where $max(.)$ find the largest element of an input vector.

$$\hat{\mathbf{n}}_i = \mathbf{n}_i / max(\mathbf{n}_i) \tag{10}$$

To analyze the correlation between smartphone usage behaviors and NoB, we calculate the Pearson Correlation Coefficient of the normalized NoB vector ($\hat{\mathbf{n}}_i$) and the behavior vector ($\mathbf{b}_i$) for users in all experiments. Figure 3a shows the boxplot of the correlation from all users. It is clear that smartphone usage behaviors and NoB are closely correlated in different crowdedness settings. Furthermore, an example of correlation analysis for a single user is illustrated in Figure 3b. The correlation coefficient and the p-value are 0.88 and $2.1e^{-31}$, respectively, which shows it is significant that screen-on ratio is positively correlated with NoB for the user. Furthermore, we could find that the correlation is higher when both variables are small. This means if the screen is on, it is more likely that the smartphone will send probes.

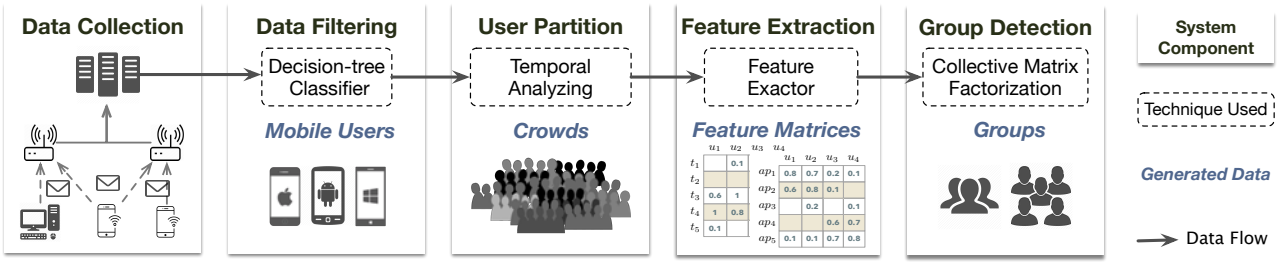


Figure 4: System overview of BaG.

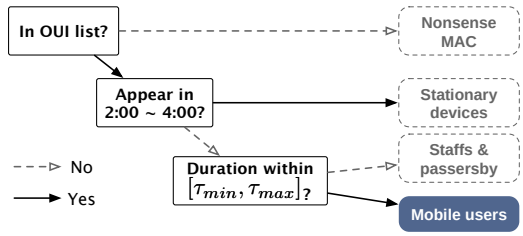

Figure 5: Filtering out WiFi data from non-mobile users.

3 SYSTEM DESIGN

In this section, we elaborate on design details of BaG. The overview of the proposed system is illustrated in Figure 4. First, we passively sniff WiFi probes from different devices (Data Collection). Then we filter out data from non-mobile users (Data filtering) and separate the filtered data into several crowds (User Partition). Besides, mobility and behavior related features are extracted and represented in matrices (Feature Extraction). Last, we use collective matrix factorization to fuse two matrices and derive grouping results (Group Detection) without extra clustering processes.

3.1 Data Collection

We exploit off-the-shelf WiFi APs to sniff WiFi probes from nearby devices and upload the data to a server. The AP configurations are as follows: AR9341 (WLAN chip), 64M (RAM), and 8M (Flash Memory). We use those APs for collecting probe requests only since they have limited computational and storage capacity.

Each AP works under OpenWrt[2] with a virtual network interface enabled in monitor mode. We use Tcpdump (a utility for capturing network traffic) to sniff WiFi probes and upload the collected data to the server at 2:00 AM when the bandwidth is fully available. Once the upload process is complete, local WiFi data will be deleted to make space for the new coming data.

3.2 Data Filtering

Data filtering services as a preprocessing of the raw WiFi data including three steps: combat with MAC randomization, filter out data from non-mobile users, and extract useful data fields.

To prevent third parties from tracking devices with MAC (Media Access Control) address, several vendors have implemented MAC address randomization which implies that probe requests no longer use the real MAC address of the device. However, this mechanism may not work as expected in reality since it is reported defeated in several recent works [8, 21, 38]. Besides, this randomization mechanism is not activated in the majority of old devices, especially for Android systems. We follow the practice described in [21] to defeat MAC randomization.

As the collected data may come from stationary devices (like desktops and IP cameras) and mobile devices, we remove the data of non-mobile users devices with a simple decision-tree classifier as illustrated in Figure 5. If a MAC is not in OUI (Organizationally Unique Identifier) list, it might be a forged MAC or from unregistered companies which makes no sense to us. Then we use the routine of human activities to filter out stationary devices as during 2:00 ~ 4:00, most public places are closed, and most of the people are in sleep. Last, with the help of two scenario-dependent parameters τ_{min} and τ_{max} which represent the minimum and maximum dwell time, we could filter out data from staffs and passersby. In our system, we empirically set $\tau_{min} = 10$ and $\tau_{max} = 240$ which means people stay for at least 10 minutes and up to 4 hours. This setting is based on our observation and is intended to identify customer groups. If we want to detect staff groups, both parameters should be relatively larger. More details could be found in Reference [32].

Lastly, we extract desired fields from WiFi probes. For each WiFi probe, we can get the following data entry:

$$< \text{Timestamp, Device_MAC, AP_MAC} >,$$

where *Timestamp* indicates the time of receiving a probe, *MAC* is MAC address which uniquely represents a smartphone or an AP.

3.3 User Partition

Instead of detecting groups out of all mobile users in a whole day, we first utilize temporal constraint of groups to separate users into different *crowds* and then identify groups out of each crowd. The main advantage of user partition is that the efficiency of group detection can be greatly improved since it breaks down the original problem into many subproblems which can be solved independently.

The idea of the temporal constraint is very simple. The time gap of the appearance of groups members would never be too large. An illustration is shown in Figure 6. For an extreme example, group members would not appear separately in the morning and in the night. Formally, the temporal constraint is defined as

$$max(|ta_i - ta_j|) \leq \psi, \tag{11}$$

[2]OpenWrt is a highly extensible GNU/Linux distribution for embedded devices (typically wireless routers).

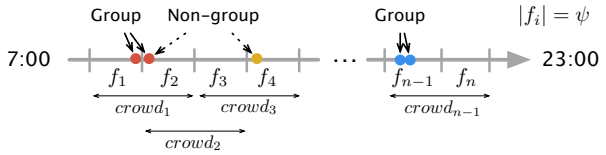

Figure 6: Partitioning users of a day into crowds.

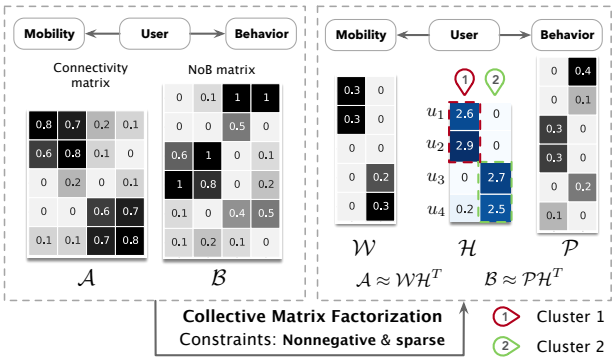

Figure 7: Illustration of using CMF to cluster users.

where ta_i means the appearance time of user i and ψ is a threshold. The physical meaning of parameter ψ is the dwell time of the most people. The selection of ψ is discussed in Section 4.

Then we equally partition the daytime into non-overlapping fragments using ψ. The partition process is depicted in Figure 6. For any two sequential fragments f_i and f_{i+1}, we take out WiFi data entries of users whose start time falls in both fragments. Those users are regarded as a *crowd* and their WiFi data entries are denoted as $crowd_i$. If a person appears in f_i, his/her group mate may appear in the same fragment or the next fragment, but it is barely possible to appear in f_{i+2} since ψ restricts the dwell time of most people.

3.4 Feature Extraction

Given data entries of a crowd, we represent two features as two feature matrices. The first feature is NoB that indicates a user's phone usage behaviors. The other is *AP connectivity* which indicates a user's mobility information.

As introduced in Section 1, NoB refers to how many times a device has sent WiFi probes. AP connectivity means how long a user has been in the coverage area of an AP. It reflects where a user has been to and how long they have stayed. Compared to RSSI, although AP connectivity is more coarse-grained, it is also more robust and reliable. Both AP connectivity and NoB are insensitive to crowded environments as they only care about whether a smartphone sends WiFi probes or not which cannot be readily affected.

We first group WiFi data entries by users' MAC addresses. For each user, we raise the granularity of the data from seconds to minutes, as this practice reduces the impact of sparse WiFi probes. To eliminate the negative impact of device diversity, we normalize connectivity vector and NoB vector for each user. Lastly, we combine all users' connectivity and NoB vectors and generate corresponding matrices.

3.5 Group Detection

Group detection is essentially a *hard clustering* problem which means each user can only belong to a cluster or not. Previous works [12, 29] need to measure pairwise user similarity and then construct a user graph with nodes representing users and the edge between nodes indicating their similarity. After that, an explicit graph clustering process like Markov Cluster Algorithm is applied to the graph to detect groups.

However, it would be inefficient and cumbersome to construct the graph by measuring pairwise user similarity. Instead, we use nonnegative matrix factorization (NMF) to derive the group results directly without extra clustering processes. We choose NMF rather than other matrix factorization like singular value decomposition (SVD) as entries in both original matrices have physical meaning (number of bursts and duration time). Positive factors facilitate direct physical connections. Besides, collective nonnegative matrix factorization (CNMF) is used to jointly factorize connectivity and NoB matrices to get better results as both matrices share the same latent feature: the grouping information. An illustration of the whole process is shown in Figure 7. We have two relation matrices $\mathcal{A}$ (user-mobility matrix) and $\mathcal{B}$ (user-behavior matrix) as input. After collective matrix factorization, there are three factors corresponding to three entities. The user entity matrix $\mathcal{H}$ contains the group results. Each row of $\mathcal{H}$ indicates a potential group with $\mathcal{H}_{ij}$ representing the strength that user i belongs to group j. From $\mathcal{H}$ we can see clearly that the group results are $(u_1, u2)$ and (u_3, u_4).

In the following subsections, we first briefly review the rationale of using NMF for clustering. Then we focus on solving the group detection problem using CNMF.

3.5.1 ***NMF and k-means.*** Given an input matrix $\mathcal{A} \in \mathbb{R}^{m \times n}$ and an integer $k < \min(m, n)$, NMF aims to find two nonnegative factors $\mathcal{W} \in \mathbb{R}^{m \times k}$, $\mathcal{H} \in \mathbb{R}^{n \times k}$ such that $\mathcal{A} \approx \mathcal{W}\mathcal{H}^T$. $\mathcal{W}$ and $\mathcal{H}$ can be found by solving the optimization problem:

$$\min_{\mathcal{W},\mathcal{H}} F_k(\mathcal{W},\mathcal{H}) = \frac{1}{2}\left\|\mathcal{A} - \mathcal{W}\mathcal{H}^T\right\|_F^2 s.t. \quad \mathcal{W},\mathcal{H} \geq 0, \tag{12}$$

where $F_k(\cdot)$ is the loss function and k is the reduced dimension. $\|\mathcal{A}\|_F$ means Frobenius Norm of matrix $\mathcal{A}$. The reasons of using Frobenius Norm are that it has a Guassian noise interpretation and the objective function can be easily transformed to a matrix trace version.

Existing works [17] provide evidence that sparsity constrained NMF is a viable alternative as a clustering method. The objective of k-means is to minimize the sum of squared distances from each data point to its centroid. With $\mathcal{A} = [a_1, ..., a_n] \in \mathbb{R}^{m \times n}$, the objective function J_k with given integer k can be written as:

$$J_k = \sum_{j=1}^{k} \sum_{a_i \in C_j} \left\|a_i - c_j\right\|^2 = \left\|\mathcal{A} - C\mathcal{B}^T\right\|_F^2, \tag{13}$$

where $\mathcal{B} \in \mathbb{R}^{n \times k}$ denotes the clustering assignment. If the i-th observation is assigned to the j-th cluster $\mathcal{B}_{ij} = 1$, otherwise $\mathcal{B}_{ij} = 0$. $C = [c_1, ..., c_k] \in \mathbb{R}^{n \times k}$ is the centroid matrix where c_j is the cluster centroid of cluster C_j. C can also be written as $C = \mathcal{A}\mathcal{B}\mathcal{D}^{-1}$

Algorithm 1 Alternating nonnegative least squares

Require: Initialize $\mathcal{H}$ and $\mathcal{P}$ with random nonnegative values.

1: **while** the convergence criterion is not satisfied **do**

2: $\mathcal{W} \leftarrow \arg\min_{\mathcal{W}} \left\| \begin{pmatrix} \sqrt{\alpha}\mathcal{H} \\ \sqrt{\eta}\mathbf{I}_k \end{pmatrix} \mathcal{W}^T - \begin{pmatrix} \sqrt{\alpha}\mathcal{A}^T \\ \mathbf{0}_{k\times m} \end{pmatrix} \right\|_F^2$

3: $\mathcal{P} \leftarrow \arg\min_{\mathcal{P}} \left\| \begin{pmatrix} \sqrt{1-\alpha}\mathcal{H} \\ \sqrt{\eta}\mathbf{I}_k \end{pmatrix} \mathcal{P}^T - \begin{pmatrix} \sqrt{1-\alpha}\mathcal{A}^T \\ \mathbf{0}_{k\times l} \end{pmatrix} \right\|_F^2$

4: $\mathcal{H} \leftarrow \arg\min_{\mathcal{H}} \left\| \begin{pmatrix} \sqrt{\alpha}\mathcal{W} \\ \sqrt{1-\alpha}\mathcal{P} \\ \sqrt{\beta}\mathbf{e}_{1\times k} \end{pmatrix} \mathcal{H}^T - \begin{pmatrix} \sqrt{\alpha}\mathcal{A} \\ \sqrt{1-\alpha}\mathcal{B} \\ \mathbf{0}_{1\times n} \end{pmatrix} \right\|_F^2$

5: **end while**

where $\mathcal{D}^{-1}$ is a diagonal matrix defined in:

$$\mathcal{D}^{-1} = diag(\frac{1}{|C_1|}, \frac{1}{|C_2|}, ..., \frac{1}{|C_k|}) \in \mathbb{R}^{k\times k} \tag{14}$$

$|C_j|$ denotes the number of data points in cluster j. Since a diagonal matrix can be factored as any two diagonal matrices $\mathcal{D}^{-1} = \mathcal{D}_1\mathcal{D}_2$. Defining $\mathcal{F} = \mathcal{B}\mathcal{D}_1$ and $\mathcal{H} = \mathcal{B}\mathcal{D}_2$, the objective function J_k can be rephrased as:

$$J_k = \left\|\mathcal{A} - \mathcal{A}\mathcal{B}\mathcal{D}_1\mathcal{D}_2\mathcal{B}^T\right\|_F^2 = \left\|\mathcal{A} - \mathcal{A}\mathcal{F}\mathcal{H}^T\right\|_F^2 \tag{15}$$

where $\mathcal{F}$ and $\mathcal{H}$ have exactly one positive element in each row. Factor $\mathcal{H}$ has exactly one nonzero element for each row which represents a hard clustering result of the corresponding data point. If we let $\mathcal{W} = \mathcal{A}\mathcal{F}$, J_k is similar to objective function F_k of NMF. The difference is that NMF formulation does not have the constraints that $\mathcal{H}^T$ is a sparse matrix. To this end, sparse NMF (SNMF) is proposed. The idea is to use ℓ_1-norm regularization to achieve sparsity of the factorization [36].

3.5.2 ***SCNMF for Group Detection***. Now we provide our formulation and solution to the group detection problem. Given two input matrices: connectivity matrix $\mathcal{A} \in \mathbb{R}^{m\times n}$ and NoB matrix $\mathcal{B} \in \mathbb{R}^{l\times n}$, and an integer $k < \min\{m, n, l\}$, sparsity-constrained collective nonnegative matrix factorization (SCNMF) aims to find three nonnegative factors $\mathcal{W} \in \mathbb{R}^{m\times k}$, $\mathcal{H} \in \mathbb{R}^{n\times k}$ (sparse matrix), and $\mathcal{P} \in \mathbb{R}^{l\times k}$ such that:

$$\begin{cases} \mathcal{A} \approx \mathcal{W}\mathcal{H}^T \\ \mathcal{B} \approx \mathcal{P}\mathcal{H}^T \end{cases} \tag{16}$$

The solutions $\mathcal{W}, \mathcal{H}, \mathcal{P}$ can be found by solving the optimization problem:

$$\min_{\mathcal{W},\mathcal{H},\mathcal{P}} \frac{1}{2}\Big[\alpha\left\|\mathcal{A} - \mathcal{W}\mathcal{H}^T\right\|_F^2 + (1-\alpha)\left\|\mathcal{B} - \mathcal{P}\mathcal{H}^T\right\|_F^2 + \beta\sum_{j=1}^{n}\left\|\mathcal{H}_j\right\|_1^2 + \eta(\|\mathcal{W}\|_F^2 + \|\mathcal{P}\|_F^2)\Big] \text{ s.t. } \mathcal{W},\mathcal{H},\mathcal{P} \geq 0, \tag{17}$$

where $\mathcal{H}_j$ is the j-th row vector of $\mathcal{H}$. Parameter $\alpha \in [0, 1]$ is scenario-dependent which weights the relative importance of two input matrices. Parameter $\beta > 0$ balances the trade-off between the accuracy of approximation and the sparseness of $\mathcal{H}$. Parameter $\eta > 0$ controls the size of the elements of $\mathcal{W}$ and $\mathcal{P}$ respectively. It is usually determined by the largest element of input matrices [17].

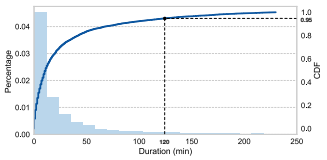

Figure 8: Distribution and CDF of dwell time in the mall.

Although solving Eq. 17 is a non-convex problem [10], it is convex separately in each factor, i.e., finding the optimal factor $\mathcal{W}$ corresponding to fixed factors $\mathcal{H}$ and $\mathcal{P}$ reduce to a convex optimization problem. Algorithms based alternating nonnegative least squares (ANLS) are often used for sparse NMF. Then we use Algorithm 1 to iterate the ANLS until a convergence criterion, which is set to iterate for 200 times [16], is satisfied. In the algorithm, $\mathbf{I}_k$ is an identity matrix of size $k \times k$, $\mathbf{0}_{k\times m}$ is a zero matrix of size $k \times m$, and $\mathbf{e}_{1\times k}$ is a row vector with all components equal to one. More details can be found in [16].

3.5.3 ***Determine the correct number of*** k. Parameter k is an input of the system which corresponds to the potential number of groups. In [17], consistency of clustering algorithms is used to determine the correct number of k from data. Consistency means the consistency clustering results under random initializations. To measure consistency, we construct a matrix $C_k \in \mathbb{R}^{n\times n}$ where n is the number of all users and k is the number of clusters. For pairwise users i and j, $C_k(i, j) = 1$ if they are assigned to the same cluster, otherwise $C_k(i, j) = 0$. Then we calculate the averaged $\hat{C}_k$ over trails. $\hat{C}_k(i, j)$ represents the possibility user i and user j being assigned to the same cluster. If the clustering results were consistent throughout all trails, each element in $\hat{C}_k$ would be close to either 0 or 1. A general quality of consistency is proposed by dispersion coefficient:

$$\rho_k = \frac{1}{n^2}\sum_{i=1}^{n}\sum_{j=1}^{n} 4\Big[\hat{C}_k(i, j) - \frac{1}{2}\Big]^2 \tag{18}$$

where $\rho_k \in [0, 1]$ and $\rho_k = 1$ indicates the perfect consistent clustering results. After obtaining the values of ρ_k for various k, the number of clusters could be determined by the point k' where $\rho_{k'}$ drops. More detailed information can be found in [17].

4 EXPERIMENTAL EVALUATION

4.1 Settings

4.1.1 ***Setup***. We conduct experiments in a large shopping mall with 4 floors covering an area of $4890m^2$. The experiments here and the experiments conducted in Section 2 are different in terms of purposes and scales.

There are originally 20 APs installed in the mall for customers to access the Internet. We use those APs to collect the WiFi data. Within one week, we recruit 82 volunteer groups including 294 volunteers during 28 experiments at different times of a day. For each experiment, we recruit $2 \sim 4$ volunteer groups with each group containing $2 \sim 5$ people and record their MAC addresses and grouping information. The majority of experiments last from 0.5 hour to 1.5 hours. To ensure authenticity, volunteers are only

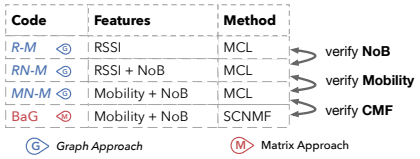

Figure 9: Illustration of baseline approaches.

told to keep their WiFi enabled without knowing the purpose of experiments.

4.1.2 ***Collected data.*** During the week, 4, 184, 778 WiFi probes are received from 59, 282 devices a day on average. According to our data filtering (Section 3.2), only 6.66% (3, 951) of them are from customers' mobile devices.

Figure 8 depicts the distribution of customers' dwell time which obeys the power law distribution. We also draw cumulative distribution function (CDF) of dwell time in Figure 8. It shows that 95% customers stay in the mall for less than 2 hours. This finding is useful because it helps to determine the value of parameter ψ (in Section 3.3).

4.1.3 ***Ground truth.*** BaG takes the collected data of each day as input and output the detected groups. We have no ways of knowing the grouping information for everyone in the collected data. However, we could know the relationships of a subset of those people.

Based on the information of our volunteers, we have prepared two evaluation datasets. The difference between two datasets is the number of non-group pairs. We call the first dataset as *labeled dataset* as it is entirely contributed by volunteers. In other words, we know the relation (group and non-group) of every pair of users. This dataset consists of 438 group pairs (positive samples) and 1, 135 non-group pairs (negative samples).

The second dataset is *synthetically labeled dataset* which includes some non-volunteers. When recruiting volunteer groups, we engage all group members in the experiment. Therefore, user pairs consisting of volunteer and non-volunteers must be non-group. Eventually, we get a dataset of 438 positive samples, and 2, 311 negative samples.

Even though we could find significantly more negative samples, we carefully control such negative samples. One reason is that such synthetic negative sample should also obey the temporal constraint as mentioned in Section 3.3, otherwise it could be too easy to detect. Another reason is that the difference of numbers between positive and negative samples should not be too large, otherwise the evaluation metrics might be affected.

4.1.4 ***Metrics.*** There is no consensus on which metrics should be used to evaluate groups detection [34]. Here we use *Precision*, *Recall* and *F-score* to measure the performance of group detection, which are defined as follows.

$$\begin{cases} \text{Precision(P)} = \dfrac{tp}{tp + fp} \\ \text{Recall(R)} = \dfrac{tp}{tp + fn} \\ \text{F-score} = 2 \cdot \dfrac{\text{P} \cdot \text{R}}{\text{P} + \text{R}} \end{cases}$$

Truth / Detection	g	$\tilde{g}$
g	tp	fp
$\tilde{g}$	fn	tn

g : Group
$\tilde{g}$: Non-group

.3	.829	.915	.870
.4	.813	.905	.857
.5	.817	.896	.855

4.1.5 ***Baseline approaches.*** As mentioned in Introduction, two of our contributions are an effective feature (NoB) and a clustering method (CMF) for detecting groups. To verify the effectiveness of both NoB and CMF, we set three baselines R-M, RN-M, and MN-M. A baseline has two important components: feature(s) and method. Figure 9 shows detailed configurations of all approaches. According to the clustering methods used, those approaches can be further classified as graph approach (using Markov Cluster algorithm, MCL) and matrix approach (using SCNMF). Steps of graph approaches: 1) Measure user similarity based on some features. 2) Construct a user graph with users as nodes and their similarities as edge weights. 3) Run graph clustering algorithms to derive clusters or groups.

For different graph approaches, different feature combinations are used to measure user similarity. For multiple features, we combine them with arithmetic mean to measure similarity. Finally, MCL is applied to the constructed graph to detect groups. MCL is a popular graph clustering algorithm used by many existing works [12, 29]. It works well when the cluster size is small and it does not require the number of clusters as an input.

For matrix approach, BaG is a typical one. Therefore, it is unnecessary to repeat the steps again here. The precondition of this approach is to have matrices as input. That is why we do not have a matrix approach with RSSI and NoB since it is non-trivial to find an appropriate way of representing RSSI in the matrix format.

Table 3: Performance in labeled dataset.

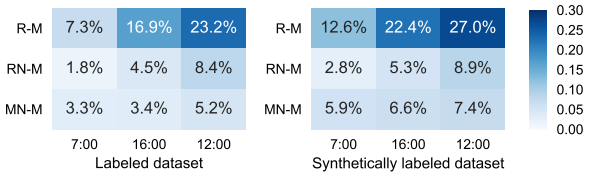

Figure 10: Performance gain ratios of BaG.

4.1.6 ***Parameter selection.*** In this system, there are 3 parameters to determine: ψ for user partition (Section 3.3) and α, β for group detection (Section 3.5).

In user partition, ψ represents the maximum duration time of onsite customers. As discussed in Section 3.3, the physical meaning of ψ is the dwell time of customers. While Figure 8 shows that 95% customers stay in the mall for less than 2 hours. Therefore, we set ψ to 120 minutes in our system.

For group detection, parameter α controls the relative importance of connectivity matrix over NoB matrix. According to the results shown in Table 1, we set α to 0.3. Generally, small α is preferred since connectivity matrix contains coarse-grained mobility information that has limited capacity to detect groups in crowded environments. Parameter β balances the trade-off between accuracy of approximation and sparseness. The performance of different β is illustrated in Table 2. Even though the performance is not that sensitive to β, too big β is undesirable since that might lead to worse approximation [17], so β is set to 0.2.

4.2 Evaluation

As explained in Section 2.1, we use the number of onsite people to represent different crowdedness settings. To have a comprehensive understanding of the performance of BaG, the evaluation is further explained with two datasets, four approaches, three feature combinations, and two clustering methods.

4.2.1 ***Two datasets.*** According to Figure 1, the order crowdedness for selected hours is 12:00 > 16:00 > 7:00. Detailed performance of all approaches on labeled and synthetically labeled datasets are shown in Table 3 and 4, respectively.

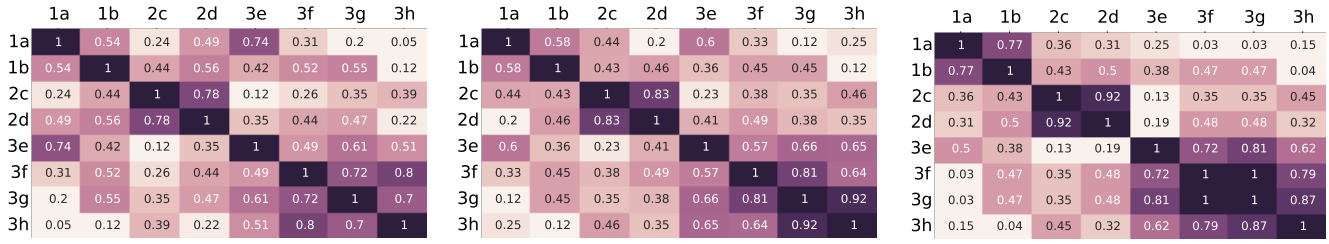
Compared with labeled dataset, all approaches have worse performance on the synthetically labeled dataset. This is reasonable since changes of the number of people to be detected might alter the clustering results. Besides, the probability that strangers are close to each other or have similar smartphones usage patterns are likely to increases with the number of people.

Interestingly, the average change of precision (−11.1%) is more significant than that of recall (−0.7%) over all approaches and times. One possible reason is the boost of negative samples increases false detections especially false positive detections (non-groups are detected as groups) and leads to a significant decline in precision.

4.2.2 ***Four approaches.*** Averaging the performance over all times, BaG improves F-score by 3.97% ∼ 15.79% and 6.67% ∼ 20.69% in labeled and synthetically labeled datasets, respectively.

We further demonstrate the performance of BaG by showing the *F-score gain ratio* over baselines. The ratio is defined in Eq. 19 where bl represents a baseline approach.

$$F\text{-score gain ratio} = \frac{F_{\text{BaG}} - F_{\text{bl}}}{F_{\text{bl}}}, \tag{19}$$



As shown in Figure 10, the ratio increases with the crowdedness indicating BaG is more accurate and reliable in crowded environments. Besides, the improvement is slightly higher in synthetically labeled data.

4.2.3 ***Three feature combinations.*** R-M, RN-M, and MN-M are all based on the same clustering method, so we could match them to compare the performance of different feature combinations.

From the performance tables, we have identified two issues on both datasets. First, the performance of feature combinations with NoB (RN-M and MN-M) are consistently higher than the other approach (R-M) over all times. The reasons might be two-fold. On one hand, the additional feature NoB has been used. On the other, it also proves NoB has the capability to capture the underlying grouping information in different crowdedness settings.

The second issue is that in the least crowded setting RN-M slightly outperforms MN-M, but the situation is just the opposite in the most crowded setting. This phenomenon results from different recall declining rates. When the crowdedness increases, both methods become worse, but recall of RN-M declines faster than that of MN-M. Potential reasons for different declining rates might be as follows. RSSI is more fine-grained than mobility but it is also more unreliable when the environment gets crowded since people frequently move around and hold their smartphones in different ways. In crowded environments, group users might have low similarity based on RSSI distance measurement and thus generate more false negative detections (groups are detected as non-groups) that degrade recall.

To support this, in Figure 11 we show an example of similarity matrices from a single experiment in 12:00 with 3 groups. As we can see in Figure 11a, some group users (like e and f) have low similarity

(a) RSSI **(b) RSSI+NoB** **(c) Mobility+NoB**

Figure 11: User similarity matrix from a single experiment in 12:00 using different feature combinations. Alphabets represent people, numbers reveal their grouping information. For example, $1a$ means user a is in group 1.

using RSSI. Although NoB has a certain effect, the improvement is quite limited as illustrated in Figure 11b. As a contrast in Figure 11c, the combination of mobility and NoB measures user similarity in a better way as mobility is more coarse-grained and thus insensitive to environmental changes.

4.2.4 ***Two clustering methods.*** Two clustering methods refer to graph approach and matrix approach. We could compare them by matching the performance of BaG and MN-M from performance tables and Figure 10. Overall, BaG slightly outperforms MN-M in all situations ranging from 3.3% $\sim$ 7.4%.

The main advantage of the matrix approach relies on the fusion of mobility and NoB. Mobility and NoB are two different perspectives of the real grouping information and thus have some hidden associations. With collective matrix factorization, we could simultaneously factorize them to reveal their hidden associations. While in the graph approach mobility and NoB are simply combined using arithmetic mean which might have limited the potential of the latent association.

5 RELATED WORK

Group detection can be classified as vision-based approaches, sensor-based approaches, and WiFi-based approaches according to different means.

Vision-based approaches regard group detection as a task of clustering set of users' trajectories into disjoint subsets [9, 34]. However, this kind of methods have some apparent limitations. First of all, the biggest issue is privacy erosion. Besides, video surveillance suffers from environmental issues such as non-line-of-sight, and low brightness.

Sensor-based approaches use wearable devices or install apps on smartphones to collect users' behavioral data. Groups are detected through correlation analysis of multiple sensor data. For instance, MIT researchers use specially designed wearable devices called "Sociometric Badges" [24, 25, 33] to measure group behavior through face-to-face interaction and physical proximity. Some research works [18, 20, 29] combine several sensor modalities (WiFi, accelerometer, compass, etc) to measures users similarity. However, these methods might be difficult to collect data on a scale, as they require user intervention which would be cumbersome in some scenarios. Besides, engaging multiple sensors drains smartphone battery more quickly.

WiFi-based approaches utilize the information contained in probe request to detect groups. Compared to other approaches, WiFi-based approaches do not require high deployment cost or user intervention. The probe contains significant information like time stamp, smartphone MAC address, RSSI, and SSID, which enables a wide range of applications like passive tracking [7], crowd counting[28, 40], and facility utilization analysis [27]. SSID and RSSI are two frequently used information to detect groups. Cunche et. al. [1, 2, 5] link different smartphones through SSID similarity. However, 80% of the devices reply with empty SSID list [14], approaches that rely on SSID may not work well anymore. Then researchers' focus transfer to RSSI which indicate users' mobility. Kjærgaard et. al. [19] extract spatial features, signal-strength features, and pseudo-spatial features from signal strength to detect social groups which they call pedestrian flocks. It is found that the performance of spatial features is unreliable, since mapping RSSI into locations is not accurate enough. Besides, the mapping process itself is usually time-consuming and labor-intensive. To avoid the cumbersome mapping process, directly measure the similarity of RSSI fingerprints to detect co-located mobile users. These methods get rid of absolute locations, thus eliminate labor-intensive calibration and protect users' privacy. SocialProbe [12] considers the hardware diversity and uses the normalized RSSI vector to achieve co-location detection. However, hardware difference is not the only factor, other factors like body attenuation, environmental disturbance, and multipath fading can also significantly affect RSSI. Therefore, RSSI based approach may not achieve reliable performance in some scenarios, especially in crowded urban spaces like shopping malls. SNOW [31] focuses on a certain type of group in shopping malls using WiFi data from associated devices rather than WiFi probes.

6 CONCLUSION

In this paper, we present a group detection system (BaG) that is verified reliable and accurate in different crowdedness settings. One of our main contributions is a new feature (NoB) extracted from WiFi probes. NoB could effectively capture phone usage patterns which is a new perspective for detecting groups. The second contribution is a new detection method (SCNMF) that fuses mobility information and usage behaviors. SCNMF could reveal the hidden associations between mobility and behaviors by decomposing them simultaneously. The experimental evaluation in a large shopping

mall demonstrates the effectiveness and robustness of BaG in scenarios with different levels of crowdedness. Compare to baseline approaches, BaG shows a significant improvement by increasing F-score of detection by 3.97% $\sim$ 15.79% in labeled dataset and 6.67% $\sim$ 20.69% in synthetically labeled dataset respectively.

ABSTRACT

Given a terabyte-scale graph distributed across multiple machines, how can we summarize it, with much fewer nodes and edges, so that we can restore the original graph exactly or within error bounds?

As large-scale graphs are ubiquitous, ranging from web graphs to online social networks, compactly representing graphs becomes important to efficiently store and process them. Given a graph, *graph summarization* aims to find its compact representation consisting of (a) a *summary graph* where the nodes are disjoint sets of nodes in the input graph, and each edge indicates the edges between all pairs of nodes in the two sets; and (b) *edge corrections* for restoring the input graph from the summary graph exactly or within error bounds. Although graph summarization is a widely-used graph-compression technique readily combinable with other techniques, existing algorithms for graph summarization are not satisfactory in terms of speed or compactness of outputs. More importantly, they assume that the input graph is small enough to fit in main memory.

In this work, we propose SWeG, a fast parallel algorithm for summarizing graphs with compact representations. SWeG is designed for not only shared-memory but also MapReduce settings to summarize graphs that are too large to fit in main memory. We demonstrate that SWeG is **(a) Fast:** SWeG is up to *5400× faster* than its competitors that give similarly compact representations, **(b) Scalable:** SWeG scales to graphs with *tens of billions* of edges, and **(c) Compact:** combined with state-of-the-art compression methods, SWeG achieves up to *3.4*× better compression than them.

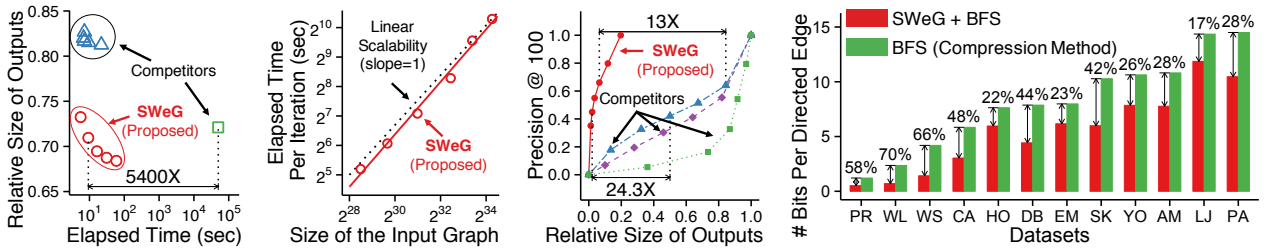
1 INTRODUCTION

Large-scale graphs are everywhere. Graphs are natural representations of the web, social networks, collaboration networks, internet topologies, citation networks, to name just a few. The rapid growth of the web and its applications has led to large-scale graphs of unprecedented size, such as 3.5 billion web pages connected by 129 billion hyperlinks [36], online social networks with 300 billion connections [11], and 1.15 billion query-URL pairs [30].

Consequently, representing graphs in a storage-efficient manner has become important. In addition to the reduction of hardware costs, compact representation may allow large-scale graphs to fit in main memory of one machine, eliminating expensive I/O over the network or to disk. Moreover, it can lead to performance gains by allowing large fractions of the graphs to reside in cache [7, 48].



To compactly represent graphs, a variety of graph-compression techniques have been developed, including relabeling nodes [2, 5, 9, 11], employing integer-sequence encoding schemes (e.g., reference, gap, and interval encodings) [5], and encoding common structures (e.g., cliques, bipartite-cores, and stars) with fewer bits [7, 22, 43]. These techniques are either *lossless* and *lossy* depending on whether the input graph can be reconstructed exactly from their outputs.

Graph summarization [38] is a widely-used graph-compression technique. It aims to find a compact representation of a given graph $\mathcal{G}$ consisting of a summary graph and edge corrections. The *summary graph* $\overline{\mathcal{G}}$ is a graph where the nodes are disjoint sets of nodes in $\mathcal{G}$ and each edge indicates the edges between all pairs of nodes in the two sets. The *edge corrections* (i.e., edges to be inserted, and edges to be deleted) are for restoring $\mathcal{G}$ from $\overline{\mathcal{G}}$ exactly (in cases of lossless summarization) or within given error bounds (in cases of lossy summarization). The outputs can be considered as graphs: (a) the summary graph, (b) the graph consisting of the edges to be inserted, and (c) the graph consisting of the edges to be deleted.

As a graph-compression technique, graph summarization has the following desirable properties: **(a) Combinable**: since graph summarization produces three graphs, as explained in the previous paragraph, each of them can be further compressed by any other graph compression technique, **(b) Adjustable**: the trade-off between compression rates and information loss can be adjusted by given error bounds, and **(c) Queryable**: neighbor queries (i.e., finding the neighboring nodes of a given node) can be answered efficiently on the outputs of graph summarization (see Appendix A).

However, existing algorithms for graph summarization are not satisfactory in terms of speed [38, 44] or compactness of output representations [20]. These serial algorithms either have high computational complexity or significantly sacrifice compactness of outputs for lower complexity. Moreover, they assume that the input graph is small enough to fit in main memory. The largest graph used in the previous studies has just about 10 million edges [20, 38, 44]. As

(a) Fast and Compact (Lossless Summarization)

(b) Scalable (Lossless Summarization)

(c) Compact and Accurate (Lossy Summarization)

(d) Compact (Lossless Compression)

Figure 1: SWeG is fast and scalable with compact and accurate representations. (a) SWeG is faster with more compact representations than the other lossless-summarization methods. (b) SWeG scales linearly with the size of the input graph, successfully scaling to graphs with over 20 billions edges. (c) The lossy version of SWeG yields more compact and accurate representations than the other lossy-summarization methods. (d) Combining SWeG and an advanced compression technique [2] yields up to 3.4× more compact representations than using the technique alone. See Section 4 for details.

large-scale graphs often do not fit in main memory, improving the scalability of graph summarization remains an important challenge.

To address this challenge, we propose SWeG (**S**ummarizing **We**b-Scale **G**raphs), a fast parallel algorithm for summarizing large-scale graphs with compact representations. SWeG is designed for both shared-memory and MapReduce settings. In a nutshell, SWeG repeats (a) dividing the input graph into small subgraphs and (b) processing the subgraphs in parallel without having to load the entire graph in main memory. SWeG also adjusts, in each iteration, how aggressively it merges nodes within subgraphs, and this turns out to be crucial for obtaining compact representations.

Extensive experiments with 13 real-world graphs show that SWeG significantly outperforms existing graph-summarization methods and enhances the best compression techniques, as shown in Figure 1. Specifically, SWeG provides the following advantages:

- **Speed**: SWeG is up to *5, 400× faster* than its competitors that give similarly compact representations (Figure 1(a)).
- **Scalability**: SWeG scales to graphs with *tens of billions* of edges, showing near-linear data and machine scalability (Figure 1(b)).
- **Compression**: Combined with advanced graph-compression methods, SWeG yields up to *3.4× better* compression than the methods (Figure 1(d)).

In Section 2, we provide notations and a formal problem definition. In Section 3, we present our proposed algorithm, SWeG. In Section 4, we provide our experimental results. After discussing related work in Section 5, we offer conclusions in Section 6.

2 NOTATIONS AND PROBLEM DEFINITION

Notations and Concepts. See Table 1 for frequently-used symbols and Figure 2 for an illustration of concepts. Consider a simple undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with nodes $\mathcal{V}$ and edges $\mathcal{E}$. We denote each node in $\mathcal{V}$ by a lowercase (e.g., v) and each edge in $\mathcal{E}$ by an unordered pair (e.g., $\{u, v\}$). We denote the set of neighbors of a node $v \in \mathcal{V}$ in $\mathcal{G}$ by $N_v \subset \mathcal{V}$.

A *summary graph* of $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, denoted by $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, is a graph whose nodes are a partition of $\mathcal{V}$ (i.e., disjoint and exhaustive subsets of $\mathcal{V}$). That is, each node $v \in \mathcal{V}$ belongs to exactly one node in $\mathcal{S}$. We call nodes and edges in $\overline{\mathcal{G}}$ *supernodes* and *superedges*. We denote each supernode by an uppercase (i.e., A). $\mathcal{P}$ may include self-loops, and we let $\mathcal{P}^* \subset \mathcal{P}$ be the set of non-loop superedges.

Given a summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and *corrections* $\mathcal{C} =< \mathcal{C}^+, \mathcal{C}^- >$, where $\mathcal{C}^+$ denotes the set of edges to be inserted and $\mathcal{C}^-$ denotes the set of edges to be deleted, a graph $\hat{\mathcal{G}} = (\mathcal{V}, \hat{\mathcal{E}})$, which we call a *restored graph*, is created by the following steps:

(1) For each superedge $\{A, B\} \in \mathcal{P}$, all pairs of distinct nodes in A and B (i.e.,. $\{\{u, v\} : u \in A, v \in B, u \neq v\}$) are added to $\hat{\mathcal{E}}$,
(2) Each edge in $\mathcal{C}^+$ is added to $\hat{\mathcal{E}}$,
(3) Each edge in $\mathcal{C}^-$ is removed from $\hat{\mathcal{E}}$.

We let the neighbors of each node $v \in \mathcal{V}$ in $\hat{\mathcal{G}}$ be $\hat{N}_v \subset \mathcal{V}$. On $\overline{\mathcal{G}}$ and $\mathcal{C}$, neighbor queries (i.e., finding $\hat{N}_v$ for a query node $v \in \mathcal{V}$) can be answered rapidly without restoring entire $\hat{\mathcal{G}}$ (see Appendix A).

Problem Definition. The large-scale graph summarization problem, which we address in this work, is defined in Problem 1.

Problem 1 (Large-scale Graph Summarization).

(1) **Given**: *a large-scale graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, which may or may not fit in main memory, and an error bound ϵ (≥ 0)*
(2) **Find:** *a summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, and corrections $\mathcal{C} =< \mathcal{C}^+, \mathcal{C}^- >$*

Table 1: Table of frequently-used symbols.

Symbol	Definition
$\mathcal{G} = (\mathcal{V}, \mathcal{E})$	input graph with nodes $\mathcal{V}$ and edges $\mathcal{E}$
N_v	set of neighbors of node v in $\mathcal{G}$
$\mathcal{C} =< \mathcal{C}^+, \mathcal{C}^- >$	edge corrections (i.e., edges insertions and deletions)
$\mathcal{C}^+$	set of edges to be inserted
$\mathcal{C}^-$	set of edges to be deleted
$\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$	summary graph with supernodes $\mathcal{S}$ and superedges $\mathcal{P}$
$\mathcal{P}^*$	non-loop superedges in $\mathcal{P}$
$\hat{\mathcal{G}} = (\mathcal{V}, \hat{\mathcal{E}})$	graph restored from $\overline{\mathcal{G}}$ and $\mathcal{C}$
$\hat{N}_v$	set of neighbors of node v in $\hat{\mathcal{G}}$
ϵ	error bound
T	number of iterations
$\theta(t)$	merging threshold in the t-th iteration

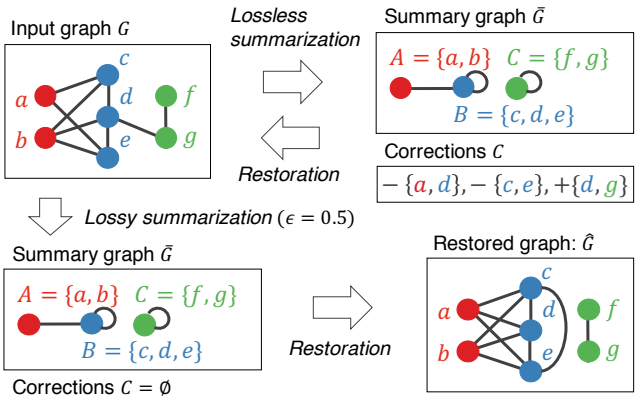

Figure 2: Illustration of graph summarization. Lossless summarization of the input graph (upper left) yields a summary graph and corrections (upper right) from which the input graph is restored exactly. Lossy summarization of the input graph (upper left) yields a summary graph and corrections (lower left). The restored graph (lower right) satisfies Eq. (2). Note that the outputs of the lossless and lossy graph summarization have fewer edges than the input graph.

(3) **to Minimize:**

$$|\mathcal{P}^*| + |C^+| + |C^-| \tag{1}$$

(4) **Subject to:** *the restored graph* $\hat{\mathcal{G}} = (\mathcal{V}, \hat{\mathcal{E}})$ *satisfies*

$$|N_v - \hat{N}_v| + |\hat{N}_v - N_v| \leq \epsilon |N_v|, \ \forall v \in \mathcal{V}. \tag{2}$$

The objective (Eq. (1)), which we aim to minimize, measures the size of the output representation by the count of non-loop (super) edges. We exclude all self-loops in $\mathcal{P}$ from the objective since they can be encoded concisely using 1 bit per supernode regardless of their count. The constraints (Eq. (2)) [38] states that the neighbors N_v of each node $v \in \mathcal{V}$ in the input graph and the node's neighbors $\hat{N}_v$ in the restored graph $\hat{\mathcal{G}}$ should be similar enough so that the size of their symmetric difference (i.e., $(N_v \cup \hat{N}_v) - (\hat{N}_v \cap N_v)$) is at most a certain proportion of the size of the node's neighbors N_v in the input graph. The proportion is given as a parameter ϵ, which we call an *error bound*, and it controls the trade-off between compression rates and the amount of information loss. If $\epsilon = 0$, then $N_v = \hat{N}_v$ holds for every node $v \in \mathcal{V}$ and thus the restored graph $\hat{\mathcal{G}}$ is equal to the input graph $\mathcal{G}$. Thus, Problem 1 is **lossless summarization** if $\epsilon = 0$ and **lossy summarization** if $\epsilon > 0$. See Figure 2 for lossless and lossy summarization of a toy graph.

3 PROPOSED ALGORITHM: SWEG

We present our proposed algorithm, SWeG (**S**ummarizing **We**b-Scale **G**raphs). SWeG provides approximate solutions to the lossless and lossy graph summarization problems (i.e., Problems 1). In Section 3.1, we provide an overview of SWeG then describe each step of it in detail. In Sections 3.2 and 3.3, we discuss parallelizing SWeG in shared-memory and MapReduce settings. In Section 3.4, we analyze its time complexity and memory requirements. In Section 3.5, we present SWeG+, an algorithm for further compression.

Algorithm 1 Overview of SWeG

Input: input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, number of iterations T, error bound ϵ
Output: summary graph $\bar{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, corrections C
1: initialize supernodes $\mathcal{S}$ to $\{\{v\} : v \in \mathcal{V}\}$
2: **for** $t = 1 \ldots T$ **do**
3: divide $\mathcal{S}$ into disjoint groups ▷ Algorithm 2
4: merge some supernodes within each group ▷ Algorithm 3
5: encode edges $\mathcal{E}$ into superedges $\mathcal{P}$ and corrections C ▷ Algorithm 4
6: **if** $\epsilon > 0$ **then** drop some (super) edges from $\mathcal{P}$ and C ▷ Algorithm 5
7: **return** $\bar{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and C

Algorithm 2 Dividing Step of SWeG

Input: input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, current supernodes $\mathcal{S}$
Output: disjoint groups of supernodes: $\{\mathcal{S}^{(1)}, \ldots, \mathcal{S}^{(k)}\}$
1: generate a random bijective hash function $h : \mathcal{V} \to \{1, \ldots, |\mathcal{V}|\}$
2: **for each** supernode $A \in \mathcal{S}$ **do**
3: **for each** node $v \in A$ **do**
4: $f(v) \leftarrow \min(\{h(u) : u \in N_v \text{ or } u = v\})$ ▷ shingle of node v
5: $F(A) \leftarrow \min(\{f(v) : v \in A\})$ ▷ shingle of supernode A
6: divide the supernodes in $\mathcal{S}$ into $\{\mathcal{S}^{(1)}, \ldots, \mathcal{S}^{(k)}\}$ by their $F(\cdot)$ value
7: **return** $\{\mathcal{S}^{(1)}, \ldots, \mathcal{S}^{(k)}\}$

3.1 Description of the Algorithm

We first give an overview of SWeG, and then describe each step of it in detail. In this subsection, for simplicity, we assume that SWeG is executed serially and the input graph is small enough to fit in main memory of one machine. Parallelization and distributed processing are discussed in Sections 3.2 and 3.3.

3.1.1 **Overview (Algorithm 1).** SWeG requires an input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, the number of iterations T, and an error bound ϵ, as in Problem 1. SWeG first initializes the set $\mathcal{S}$ of supernodes so that (a) each supernode consists of a node in $\mathcal{V}$ and (b) each node in $\mathcal{V}$ belongs to one supernode (line 1 of Algorithm 1). Then, SWeG updates $\mathcal{S}$ by repeating the following steps T times (line 2):

- **Dividing step (line 3, Section 3.1.2)**: divides $\mathcal{S}$ into disjoint groups, each of which is composed of supernodes with similar connectivity. Different groups are obtained in each iteration.
- **Merging step (line 4, Section 3.1.3)**: merges some supernodes within each group in a greedy manner.

Dividing $\mathcal{S}$ into small groups makes SWeG faster and more memory efficient by allowing it to process different groups in parallel without having to load entire $\mathcal{G}$ in memory (see Sections 3.2 and 3.3). After updating $\mathcal{S}$, SWeG performs the following steps:

- **Encoding step (line 5, Section 3.1.4)**: encodes the edges $\mathcal{E}$ into superedges $\mathcal{P}$ and corrections C so that the count of non-loop (super) edges (i.e., Eq. (1)) is minimized given supernodes $\mathcal{S}$.
- **Dropping step (line 6, Section 3.1.5)**: makes $\mathcal{P}$ and C more compact by dropping some (super) edges from them within the error bounds (i.e., Eq. (2)) in cases of lossy summarization.

Lastly, SWeG returns the summary graph $\bar{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and the corrections C as its outputs (line 7).

3.1.2 **Dividing Step (Algorithm 2).** The dividing step aims to divide the supernodes $\mathcal{S}$ into disjoint groups of supernodes with similar connectivity. To this end, we extend the shingle of nodes, for which it is known that two nodes have the same shingle with

Algorithm 3 Merging Step of SWeG

Input: input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, current supernodes $\mathcal{S}$, current iteration t, disjoint groups of supernodes $\{\mathcal{S}^{(1)}, \ldots, \mathcal{S}^{(k)}\}$
Output: updated supernodes $\mathcal{S}$

1: **for each** group $\mathcal{S}^{(i)} \in \{\mathcal{S}^{(1)}, \ldots, \mathcal{S}^{(k)}\}$ **do**
2: $\quad Q \leftarrow \mathcal{S}^{(i)}$
3: $\quad$ **while** $|Q| > 1$ **do**
4: $\quad\quad$ pick and remove a random supernode A from Q
5: $\quad\quad B \leftarrow \arg\max_{C \in Q} \textit{SuperJaccard}(A, C)$ ▷ Eq. (4)
6: $\quad\quad$ **if** $\textit{Saving}(A, B, \mathcal{S}) \geq \theta(t)$ **then** ▷ Eq. (3) and Eq. (5)
7: $\quad\quad\quad \mathcal{S} \leftarrow (\mathcal{S} - \{A, B\}) \cup \{A \cup B\}$ ▷ merge A and B
8: $\quad\quad\quad \mathcal{S}^{(i)} \leftarrow (\mathcal{S}^{(i)} - \{A, B\}) \cup \{A \cup B\}$
9: $\quad\quad\quad Q \leftarrow (Q - \{B\}) \cup \{A \cup B\}$ ▷ replace B with $A \cup B$
10: **return** $\mathcal{S}$

probability equal to the jaccard similarity of their neighbor sets [6], to supernodes. Specifically, we define the *shingle* $F(A)$ of each supernode $A \in \mathcal{S}$ as the smallest shingle of the nodes in A. Then, two supernodes $A \neq B \in \mathcal{S}$ are more likely to have the same shingle if the nodes in A and those in B have similar connectivity. Formally, given a random bijective hash function $h : \mathcal{V} \to \{1, ..., |\mathcal{V}|\}$,

$$F(A) := \min_{v \in A}(f(v)),$$

where $f(v) := \min_{u \in N_v \text{ or } u=v} h(u)$ is the shingle of node $v \in \mathcal{V}$, and N_v is the set of neighbors of node $v \in \mathcal{V}$ in the input graph $\mathcal{G}$. SWeG generates such a hash function h by shuffling the order of the nodes in $\mathcal{V}$ and mapping each i-th node to i (line 1 of Algorithm 2) and computes the shingle of every supernode in $\mathcal{S}$ (lines 2-5). Lastly, SWeG divides the supernodes $\mathcal{S}$ into disjoint groups $\{\mathcal{S}^{(1)}, ..., \mathcal{S}^{(k)}\}$ by their shingle and returns the groups (lines 6-7). In cases where large groups exist, Algorithm 2 can be applied recursively to each of the large groups with a new hash function h.

3.1.3 **Merging Step (Algorithm 3).** To describe this step, we first define several concepts. We define the *cost* of each supernode $A \in \mathcal{S}$ given supernodes $\mathcal{S}$, denoted by $\textit{Cost}(A, \mathcal{S})$, as the amount of increase in Eq. (1) (i.e., the count of non-loop (super) edges in outputs) due to the edges adjacent to any node in A (see the encoding step in Section 3.1.4). Then, we define the *saving* due to the merger between supernodes $A \neq B \in \mathcal{S}$ given supernodes $\mathcal{S}$ as

$$\textit{Saving}(A, B, \mathcal{S}) := 1 - \frac{\textit{Cost}(A \cup B, (\mathcal{S} - \{A, B\}) \cup \{A \cup B\})}{\textit{Cost}(A, \mathcal{S}) + \textit{Cost}(B, \mathcal{S})}, \quad (3)$$

where $\textit{Cost}(A, \mathcal{S}) + \textit{Cost}(B, \mathcal{S})$ is the cost of A and B before their merger, and $\textit{Cost}(A \cup B, (\mathcal{S} - \{A, B\}) \cup \{A \cup B\})$ is their cost after their merger. That is, $\textit{Saving}(A, B, \mathcal{S})$ is the ratio of the cost reduction due to the merger and the cost before the merger. Lastly, we define the *supernode jaccard similarity* between supernodes $A \neq B \in \mathcal{S}$ as

$$\textit{SuperJaccard}(A, B) := \frac{\sum_{v \in N_A \cup N_B} \min(w(A, v), w(B, v))}{\sum_{v \in N_A \cup N_B} \max(w(A, v), w(B, v))}, \quad (4)$$

where $N_A := \bigcup_{v \in A} N_v$ is the set of nodes adjacent to any node in supernode $A \in \mathcal{S}$, and $w(A, v) := |\{u \in A : \{u, v\} \in \mathcal{E}\}|$ is the number of nodes in supernode $A \in \mathcal{S}$ adjacent to node $v \in \mathcal{V}$. $\textit{SuperJaccard}(A, B)$ measures the similarity of A and B in terms of their connectivity. Notice that it is 1 if A and B have the same connectivity (i.e., $w(A, v) = w(B, v)$ for every $v \in N_A \cup N_B$) and it is 0 if their nodes have no common neighbors (i.e., $N_A \cap N_B = \emptyset$).

Given disjoint groups of supernodes $\{\mathcal{S}^{(1)}, ..., \mathcal{S}^{(k)}\}$, the merging step merges some pairs of supernodes within each group $\mathcal{S}^{(i)}$ in a greedy manner, as described in Algorithm 3. Notice that, in line 5, SWeG uses $\textit{SuperJaccard}(A, B)$ instead of $\textit{Saving}(A, B, \mathcal{S})$, which is a more straightforward choice, to find a candidate pair of supernodes $A \neq B \in \mathcal{S}^{(i)}$. This is because (a) $\textit{SuperJaccard}(A, B)$ is cheaper to compute than $\textit{Saving}(A, B, \mathcal{S})$ and (b) intuitively, $\textit{Saving}(A, B, \mathcal{S})$ tends to be high when A and B have similar connectivity. Computing $\textit{SuperJaccard}(A, C)$ instead of $\textit{Saving}(A, C, \mathcal{S})$ for every supernode $C \in Q$ in line 5 leads to a significant improvement in speed with small loss in the compactness of outputs, as shown empirically in Section 4.2. In line 6, the *merging threshold* $\theta(t)$ is set as in Eq. (5) so that SWeG gradually shifts from exploration (of supernodes in the other groups) to exploitation (of supernodes in the same group).

$$\theta(t) := \begin{cases} (1 + t)^{-1} & \text{if } t < T, \\ 0 & \text{if } t = T \end{cases} \quad (5)$$

This decreasing threshold is crucial for obtaining compact output representations, as shown empirically in Section 4.2.

3.1.4 **Encoding Step (Algorithm 4).** Given the supernodes $\mathcal{S}$ from the previous steps, the encoding step encodes the edges $\mathcal{E}$ of the input graph into superedges $\mathcal{P}$ and corrections $C =< C^+, C^- >$. We first describe how to encode edges that connect different supernodes (lines 3-5 of Algorithm 4). For each supernode pair $A \neq B \in \mathcal{S}$, we let $\mathcal{E}_{AB} \subset \mathcal{E}$ be the set of edges connecting A and B, and π_{AB} be the set of all pairs of nodes in A and B. That is,

$$\mathcal{E}_{AB} := \{\{u, v\} \subset \mathcal{V} : u \in A, v \in B, \{u, v\} \in \mathcal{E}\}, \quad (6)$$

$$\pi_{AB} := \{\{u, v\} \subset \mathcal{V} : u \in A, v \in B\}. \quad (7)$$

Recall how a graph is restored from $\mathcal{P}$ and C in Section 2. Then, the two options to encode the edges in $\mathcal{E}_{AB}$ are as follows:

(a) *without superedges*: merge $\mathcal{E}_{AB}$ into C^+,
(b) *with a superedge*: add $\{A, B\}$ to $\mathcal{P}$; merge $(\pi_{AB} - \mathcal{E}_{AB})$ into C^-.

Since (a) and (b) increase our objective (i.e., Eq. (1)) by $|\mathcal{E}_{AB}|$ and $(1 + |\pi_{AB}| - |\mathcal{E}_{AB}|)$, respectively, SWeG chooses (a) if $|\mathcal{E}_{AB}| \leq |\pi_{AB}|/2 = |A| \cdot |B|/2$ (line 4). Otherwise, it chooses (b) (line 5).

SWeG encodes edges between nodes within each supernode in a similar manner (lines 6-7). For each supernode $A \in \mathcal{S}$, we let $\mathcal{E}_{AA} \subset \mathcal{E}$ be the set of edges between nodes within A, and π_{AA} be the set of all pairs of distinct nodes within A. That is,

$$\mathcal{E}_{AA} := \{\{u, v\} \subset \mathcal{V} : u \neq v \in A, \{u, v\} \in \mathcal{E}\}, \quad (8)$$

$$\pi_{AA} := \{\{u, v\} \subset \mathcal{V} : u \neq v \in A\}. \quad (9)$$

Then, the two options to encode the edges in $\mathcal{E}_{AA}$ are as follows:

(c) *without superloops*: merge $\mathcal{E}_{AA}$ into C^+,
(d) *with a superloop*: add $\{A, A\}$ to $\mathcal{P}$; merge $(\pi_{AA} - \mathcal{E}_{AA})$ into C^-.

Since (c) and (d) increase our objective (i.e., Eq. (1)) by $|\mathcal{E}_{AA}|$ and $(|\pi_{AA}| - |\mathcal{E}_{AA}|)$, respectively, SWeG chooses (c) if $|\mathcal{E}_{AA}| \leq |\pi_{AA}|/2 = |A| \cdot (|A| - 1)/4$ (line 6). Otherwise, it chooses (d) (line 7).

3.1.5 **Dropping Step (Algorithm 5).** The dropping step is an optional step for lossy summarization (i.e., when $\epsilon > 0$). This step is skipped if lossless summarization is needed (i.e., when $\epsilon = 0$). Given the summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and corrections $C =< C^+, C^- >$ from the previous step, the dropping step drops some (super) edges from $\mathcal{P}$ and C to make the output representation

Algorithm 4 Encoding Step of SWeG

Input: input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, supernodes $\mathcal{S}$
Output: summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, corrections $C =< C^+, C^- >$

1: $\mathcal{P} \leftarrow \emptyset$; $C^+ \leftarrow \emptyset$; $C^- \leftarrow \emptyset$;
2: **for each** supernode $A \in \mathcal{S}$ **do**
3: **for each** supernode B ($\neq A$) where $\mathcal{E}_{AB} \neq \emptyset$ **do** ▷ Eq. (6)
4: **if** $\mathcal{E}_{AB} \leq \frac{|A|\cdot|B|}{2}$ **then** $C^+ \leftarrow C^+ \cup \mathcal{E}_{AB}$
5: **else** $\mathcal{P} \leftarrow \mathcal{P} \cup \{\{A, B\}\}$; $C^- \leftarrow C^- \cup (\pi_{AB} - \mathcal{E}_{AB})$ ▷ Eq. (7)
6: **if** $\mathcal{E}_{AA} \leq \frac{|A|\cdot(|A|-1)}{4}$ **then** $C^+ \leftarrow C^+ \cup \mathcal{E}_{AA}$ ▷ Eq. (8)
7: **else** $\mathcal{P} \leftarrow \mathcal{P} \cup \{\{A, A\}\}$; $C^- \leftarrow C^- \cup (\pi_{AA} - \mathcal{E}_{AA})$ ▷ Eq. (9)
8: **return** $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and $C =< C^+, C^- >$

more compact (i.e., to further reduce our objective Eq. (1)) without changing more than ϵ of the neighbors of each node (i.e., within the error bounds given in Eq. (2)). SWeG first initializes the *change limit* c_v of each node $v \in \mathcal{V}$ to $\epsilon \cdot |N_v|$, which is the right-hand side of Eq. (2) (line 1 of Algorithm 5). Then, within the change limit of each node, SWeG drops some adjacent edges from C^+, C^-, and $\mathcal{P}$, as described in lines 2-4, lines 5-7, and lines 8-12, respectively. Notice that, when a superedge $\{A, B\}$ is dropped, the total decrement in the change limits is proportional to $|A| \cdot |B|$, which is used to sort the superedges in line 8. Lastly, SWeG returns the updated summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and corrections $C =< C^+, C^- >$ that satisfy the error bounds given in Eq. (2), as shown in Theorem 3.1 (line 13).

Theorem 3.1 (Error Bounds). *Given an input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, a summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, and corrections $C =< C^+, C^- >$ satisfying that the restored graph $\hat{\mathcal{G}}$ is equal to $\mathcal{G}$, Algorithm 5 returns $\overline{\mathcal{G}}$ and C that satisfy Eq. (2).*

Proof. From $\hat{\mathcal{G}} = \mathcal{G}$, $\hat{N}_v = N_v$ holds for every node $v \in \mathcal{V}$ at the beginning of the algorithm. Thus, after the change limit c_v of each node $v \in \mathcal{V}$ is initialized to $\epsilon \cdot |N_v|$ in line 1, Eq. (10) holds.

$$c_v \leq \epsilon \cdot |N_v| - |\hat{N}_v - N_v| - |N_v - \hat{N}_v|, \forall v \in \mathcal{V}. \tag{10}$$

Recall how $\hat{\mathcal{G}}$ is constructed from $\overline{\mathcal{G}}$ and C in Section 2. Eq. (10) still holds after C^+ is processed in lines 2-4 since dropping an edge from C^+ decreases c_v by 1, increases $|N_v - \hat{N}_v|$ by at most 1, and keeps $|\hat{N}_v - N_v|$ the same for each adjacent node $v \in \mathcal{V}$. Likewise, Eq. (10) still holds after C^- is processed in lines 5-7 since dropping an edge in C^- decreases c_v by 1, increases $|\hat{N}_v - N_v|$ by at most 1, and keeps $|N_v - \hat{N}_v|$ the same for each adjacent node $v \in \mathcal{V}$. Similarly, we can show that Eq. (10) still holds after $\mathcal{P}$ is processed in lines 8-12. Eq. (11) is enforced by lines 3, 6, and 9.

$$c_v \geq 0, \forall v \in \mathcal{V}. \tag{11}$$

Eq. (10) and Eq. (11) imply Eq. (2). ■

3.2 Parallelization in Shared Memory

We describe how each step of SWeG (Algorithm 1) is parallelized in shared-memory environments. In the dividing step (Algorithm 2), the supernodes in line 2 are processed independently in parallel. In the merging step (Algorithm 3), the groups of supernodes in line 1 are processed in parallel. In lines 6 and 7, the accesses and updates of $\mathcal{S}$ are synchronized. In the encoding step (Algorithm 4), the supernodes in line 2 are processed independently in parallel. Specifically, each thread has its own copies of $\mathcal{P}$, C^+, and C^-; and the copies are merged once, after all supernodes are processed. Lastly, in the dropping step (line 5), parallel merge sort [24] is used when sorting $\mathcal{P}$ in line 8. Although the other parts of the dropping step are executed serially, they take a negligible portion of the total execution time because they are executed only once, while the dividing and merging steps are repeated multiple times.

Algorithm 5 Dropping Step of SWeG (Optional)

Input: input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, error bound ϵ
summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, corrections $C =< C^+, C^- >$
Output: updated summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$,
updated corrections $C =< C^+, C^- >$

1: $c_v \leftarrow \epsilon \cdot |N_v|$ for each node $v \in \mathcal{V}$ ▷ change limits of nodes
2: **for each** edge $\{u, v\} \in C^+$ **do**
3: **if** $c_u \geq 1$ and $c_v \geq 1$ **then**
4: $C^+ \leftarrow C^+ - \{\{u, v\}\}$; $c_u \leftarrow c_u - 1$; $c_v \leftarrow c_v - 1$
5: **for each** edge $\{u, v\} \in C^-$ **do**
6: **if** $c_u \geq 1$ and $c_v \geq 1$ **then**
7: $C^- \leftarrow C^- - \{\{u, v\}\}$; $c_u \leftarrow c_u - 1$; $c_v \leftarrow c_v - 1$
8: **for each** superedge $\{A, B\} \in \mathcal{P}$ in the increasing order of $|A| \cdot |B|$ **do**
9: **if** $A \neq B$ and ($\forall v \in A$, $c_v \geq |B|$) and ($\forall v \in B$, $c_v \geq |A|$) **then**
10: $\mathcal{P} \leftarrow \mathcal{P} - \{\{A, B\}\}$;
11: **for each** $v \in A$ **do** $c_v \leftarrow c_v - |B|$
12: **for each** $v \in B$ **do** $c_v \leftarrow c_v - |A|$
13: **return** $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and $C =< C^+, C^- >$

3.3 Distributed Processing with MapReduce

We describe how each step of SWeG is implemented in the MapReduce framework for large-scale graphs not fitting in main memory. We assume that the input graph $\mathcal{G}$ is stored in a file in a distributed file system where each record describes the nodes in a supernode and the neighbors of the nodes in $\mathcal{G}$. Specifically, the record $R(A)$ for a supernode $A \in \mathcal{S}$ is in the following format:

$$R(A) := (\text{id of } A, |A|, \underbrace{(u, |N_u|, (\overbrace{v, \ldots, w}^{|N_u|})), \ldots, (x, |N_x|, (\overbrace{y, \ldots, z}^{|N_x|}))}_{|A|}), \tag{12}$$

where $(u, |N_u|, (v, \ldots, w))$ describes the neighbors of node $u \in A$.

Dividing and Merging Steps: First, each iteration of the dividing and merging steps (Algorithms 2 and 3) is performed by the following MapReduce job:

- **Map-1**: The hash function h is broadcast to the mappers. Each mapper repeats taking a record $R(A)$, computing $F(A)$ (lines 3-5 of Algorithm 2), and emitting $< F(A), R(A) >$.
- **Reduce-1:** The supernodes $\mathcal{S}$ are broadcast to the reducers. Each reducer repeats taking $\{R(A) | A \in \mathcal{S}^{(i)}\}$ for a group $\mathcal{S}^{(i)}$, updating $\mathcal{S}^{(i)}$ (lines 2-9 of Algorithm 3), and emitting $R(A)$ for each supernode A in the updated $\mathcal{S}^{(i)}$. In the end, each reducer writes the updates in $\mathcal{S}$ to the distributed file system.

Note that updates in $\mathcal{S}$ are not shared among the reducers during the reduce stage. However, in our experiments, the effect of this lazy synchronization on the compactness of output representations was negligible.

Encoding Step: Next, the following map-only job performs the encoding step (Algorithm 4):

- **Map-2:** The supernodes $\mathcal{S}$ are broadcast to the mappers. Each mapper repeats taking a record $R(A)$, encoding the edges adjacent to any node in A (lines 3-7 of Algorithm 4), and emitting

the new (super) edges in $\mathcal{P}$, C^+, and C^-. Different output paths are used for $\mathcal{P}$, C^+, and C^-.

Dropping Step: Lastly, for the dropping step (Algorithm 5), Map-3 initializes the change limit of each node (line 1); and Map-4 and Reduce-4 sort the superedges in $\mathcal{P}$ (line 9).

- **Map-3**: Each mapper repeats taking a record $R(A)$ and emitting $< v, \epsilon \cdot |N_v| >$ for each node $v \in A$.
- **Map-4**: The input file, which is an output of Map-2, lists the superedges in $\mathcal{P}$. Each mapper repeats taking a superedge $\{A, B\}$ and emitting $< (|A| \cdot |B|, \{A, B\}), \emptyset >$.
- **Reduce-4**: A single reducer repeats taking a superedge $\{A, B\} \in \mathcal{P}$ and emitting it. The superedges are sorted in the shuffle stage.

The other parts of the dropping step are processed serially. Specifically, after loading the nodes' change limits (the output of Map-3) in memory, our implementation repeats reading a (super) edge in C^+ (an output of Map-2), C^- (an output of Map-2), and $\mathcal{P}$ (the output of Reduce-4) and writing the (super) edge to the output file if it is not dropped. Note that entire C^+, C^-, or $\mathcal{P}$ is not loaded in memory at once. These serial parts take a small portion of the total execution time because they are executed only once, while the dividing and merging steps are repeated multiple times.

3.4 Complexity Analysis

We analyze the time complexity and memory requirements of SWeG. To this end, we let $\mathcal{E}_A := \{\{u, v\} \in \mathcal{E} : u \in A\}$ be the set of edges adjacent to any node in supernode $A \in \mathcal{S}$ and $\mathcal{E}^{(i)} := \bigcup_{A \in \mathcal{S}^{(i)}} \mathcal{E}_A$ be the set of edges adjacent to any node in any supernode in group $\mathcal{S}^{(i)}$. We also let k be the number of groups of supernodes from the dividing step. Since the groups are disjoint,

$$\sum_{i=1}^{k} |\mathcal{E}^{(i)}| \leq \sum_{A \in \mathcal{S}} |\mathcal{E}_A| \leq 2|\mathcal{E}|. \tag{13}$$

Since the encoding step (Algorithm 4) yields outputs with no more (super) edges than ($\mathcal{P} \leftarrow \emptyset, C^+ \leftarrow \mathcal{E}, C^- \leftarrow \emptyset$),

$$|C^+| + |C^-| + |\mathcal{P}| \leq |\mathcal{E}|. \tag{14}$$

Lastly, we assume that $|\mathcal{V}| \leq |\mathcal{E}|$, for simplicity.

3.4.1 Time Complexity. The dividing step (Algorithm 2) takes $O(|\mathcal{E}|)$ time since its computational bottleneck is to compute the shingles of all supernodes (lines 2-5), which requires accessing every edge in $\mathcal{E}$ twice. The merging step (Algorithm 3) takes $O(\sum_{i=1}^{k} |\mathcal{S}^{(i)}| \cdot |\mathcal{E}^{(i)}|)$ time, since when each group $\mathcal{S}^{(i)}$ is processed (lines 2-9), the number of iterations is $|\mathcal{S}^{(i)}| - 1$ and each iteration takes $O(|\mathcal{E}^{(i)}|)$ time. The encoding step (Algorithm 4) takes $O(\sum_{A \in \mathcal{S}} |\mathcal{E}_A|) = O(|\mathcal{E}|)$ time since to process each supernode A (lines 3-7) takes $O(|\mathcal{E}_{AA}| + \sum_{B(\neq A):\mathcal{E}_{AB} \neq \emptyset} |\mathcal{E}_{AB}|) = O(|\mathcal{E}_A|)$ time. This follows from $|\pi_{AB}| < 2 \cdot |\mathcal{E}_{AB}|$ and $|\pi_{AA}| < 2 \cdot |\mathcal{E}_{AA}|$ in lines 5 and 7, which are due to the conditions in lines 4 and 6. Lastly, the dropping step (Algorithm 5) takes $O(|\mathcal{E}| + |C^+| + |C^-| + |\mathcal{P}|) = O(|\mathcal{E}|)$ time (see Eq. (14)). Note that $\mathcal{P}$ (line 8) can be sorted in $O(|\mathcal{P}| + |\mathcal{E}|)$ time using any linear-time integer sort (e.g., counting sort) since $|A| \cdot |B| \in \{1, ..., 2 \cdot |\mathcal{E}|\}$ for every $\{A, B\} \in \mathcal{P}$ due to the conditions in lines 4 and 6 of Algorithm 4. Thus, all the steps except for the merging step take $O(|\mathcal{E}|)$ time. The merging step, whose complexity is $O(\sum_{i=1}^{k} |\mathcal{S}^{(i)}| \cdot |\mathcal{E}^{(i)}|)$, also takes $O(|\mathcal{E}|)$ time if $\mathcal{S}$ is divided finely in the dividing step so that the size of each group is less than a constant (see Eq. (13)). In such cases, the overall time complexity of SWeG (Algorithm 1) is $O(T \cdot |\mathcal{E}|)$ since the dividing and merging steps are repeated T times. This linear scalability is shown experimentally in Section 4.4.

3.4.2 Memory Requirements. The space required for storing $\mathcal{S}$, $\{\mathcal{S}^{(1)}, ..., \mathcal{S}^{(k)}\}$, $\{h(v) : v \in \mathcal{V}\}$, and $\{c_v : v \in \mathcal{V}\}$ is $O(|\mathcal{V}|)$, and the space required for storing $\mathcal{G}$, $\overline{\mathcal{G}}$, and C is $O(|\mathcal{E}|)$ (see Eq. (14)). Thus, in shared-memory settings, where all of them are stored in memory, the memory requirements of SWeG (Algorithm 1) are $O(|\mathcal{V}| + |\mathcal{E}|) = O(|\mathcal{E}|)$. In MapReduce settings, as described in Section 3.3, each mapper or reducer requires $O(|\mathcal{V}|)$ memory, which is used to store $\mathcal{S}$, $\{h(v) : v \in \mathcal{V}\}$, or $\{c_v : v \in \mathcal{V}\}$, in all the stages except for Reduce-1. In Reduce-1, in addition to $O(|\mathcal{V}|)$ memory for $\mathcal{S}$, each reducer requires $O(\max_{1 \leq i \leq k} |\mathcal{E}^{(i)}|)$ memory to load $\{R(A) : A \in \mathcal{S}^{(i)}\}$ for each group $\mathcal{S}^{(i)}$ at once. Thus, the memory requirements are $O(|\mathcal{V}| + \max_{1 \leq i \leq k} |\mathcal{E}^{(i)}|)$ per reducer. In real-world graphs, $\max_{1 \leq i \leq k} |\mathcal{E}^{(i)}|$ is much smaller than $|\mathcal{E}|$, as shown experimentally in Appendix B.

Algorithm 6 SWeG+: Algorithm for Further Compression

Input: input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, number of iterations T, error bound ϵ
graph-compression method ALG
Output: compressed $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, $\mathcal{G}^+ = (\mathcal{V}, C^+)$, and $\mathcal{G}^- = (\mathcal{V}, C^-)$
1: run SWeG to get $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and $C =< C^+, C^- >$ ▷ Algorithm 1
2: run ALG on each of $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, $\mathcal{G}^+ = (\mathcal{V}, C^+)$, and $\mathcal{G}^- = (\mathcal{V}, C^-)$
3: **return** the compressed $\overline{\mathcal{G}}$, $\mathcal{G}^+$, and $\mathcal{G}^-$

3.5 Further Compression: SWeG+

We propose SWeG+, an algorithm for further compression. The outputs of SWeG (i.e., $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and $C =< C^+, C^- >$) can be represented as three graphs: $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, $\mathcal{G}^+ = (\mathcal{V}, C^+)$, and $\mathcal{G}^- = (\mathcal{V}, C^-)$. As described in Algorithm 6, SWeG+ further compresses each of the graphs using a given graph-compression method ALG. Any graph-compression method, such as [2, 5, 7, 9, 11, 43], can be used as ALG depending on the objectives of compression.[1] In Section 4.6, we empirically show that for many graph-compression methods, SWeG+ gives significantly more compact representations than directly compressing the input graph using the methods.

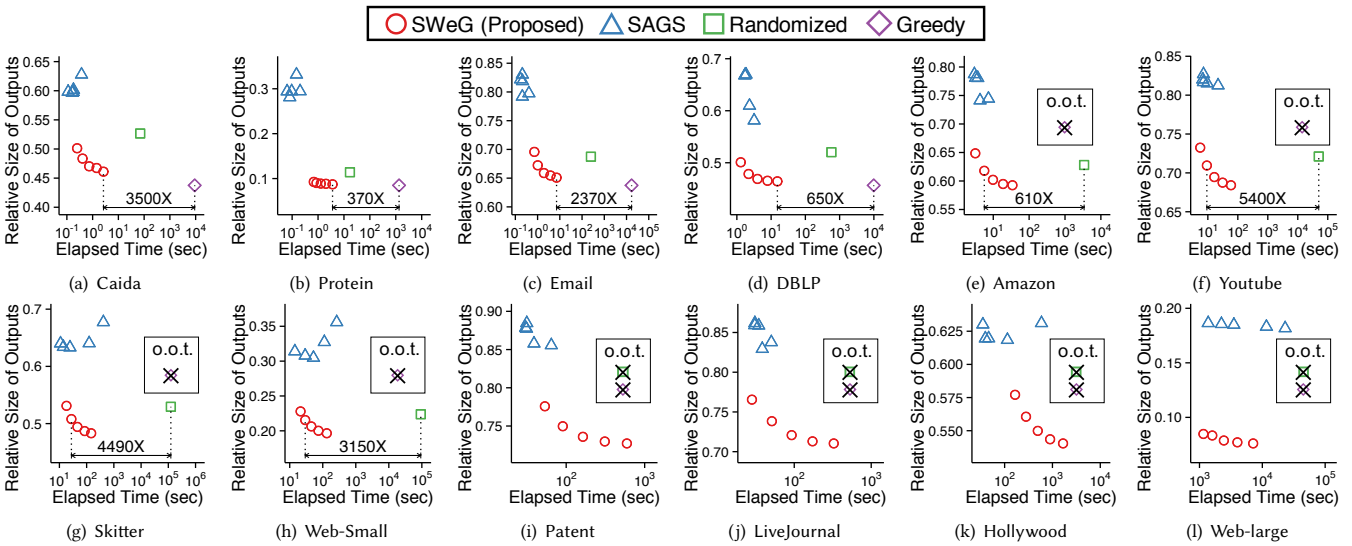

Figure 3: SWeG (lossless and shared-memory) significantly outperforms existing lossless summarization methods. o.o.t.: out of time (> 48 hours). Specifically, SWeG was up to $5,400\times$ faster than the others that give similarly compact outputs.

4 EXPERIMENTS

We review our experiments for answering the following questions:

- **Q1. Lossless Summarization**: Does the lossless version of SWeG yield more compact representations faster than its competitors?
- **Q2. Lossy Summarization**: Does the lossy version SWeG yield more compact and accurate representations than baselines?
- **Q3. Scalability**: How well does SWeG scale as the size of the input graph, the number of machines, and the number of cores grow?
- **Q4. Effects of Parameters**: How do the number of iterations T and the error bound ϵ affect the compactness of outputs?
- **Q5. Further Compression**: How much does SWeG+ improve the compression rates of combined compression methods?

4.1 Experimental Settings

Machines: We ran single instance experiments on a machine with 2.10GHz Intel Xeon E6-2620 CPUs (with 6 cores) and 64GB memory. We ran MapReduce experiments on a private Hadoop cluster.

Datasets: We used the graphs listed in Table 2. We ignored the direction of edges in all of them.

Implementations: We implemented all the considered algorithms in Java 1.8. We implemented the shared-memory version of SWeG using standard Java multithreading, and we set the number of threads to 8 unless otherwise stated. We implemented the MapReduce version of SWeG using Hadoop 2.6.1, and we set the numbers of mappers and reducers to 40 unless otherwise stated. In both implementations, we ran the dividing step recursively so that each group had at most 500 supernodes, as described in Section 3.1.2.

Evaluation Metric: Given an output representation $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and $C = < C^+, C^- >$ of a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we measured its compactness using the *relative size of outputs*, defined as

$$(|\mathcal{P}^*| + |C^+| + |C^-|)/|\mathcal{E}|, \tag{15}$$

where the numerator is our objective function (i.e., Eq. (1)) and the denominator is a constant for a given input graph.

[1] If ALG relabels nodes, to keep the labels of $\mathcal{V}$ in $\mathcal{G}^+$ and $\mathcal{G}^-$ the same, the labels obtained when compressing $\mathcal{G}^+$ are used for $\mathcal{G}^-$, which tends to be smaller than $\mathcal{G}^+$.

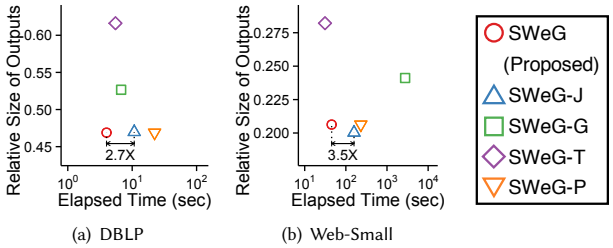

Figure 4: SWeG (lossless and shared-memory) significantly outperforms its variants. This justifies our design choices.

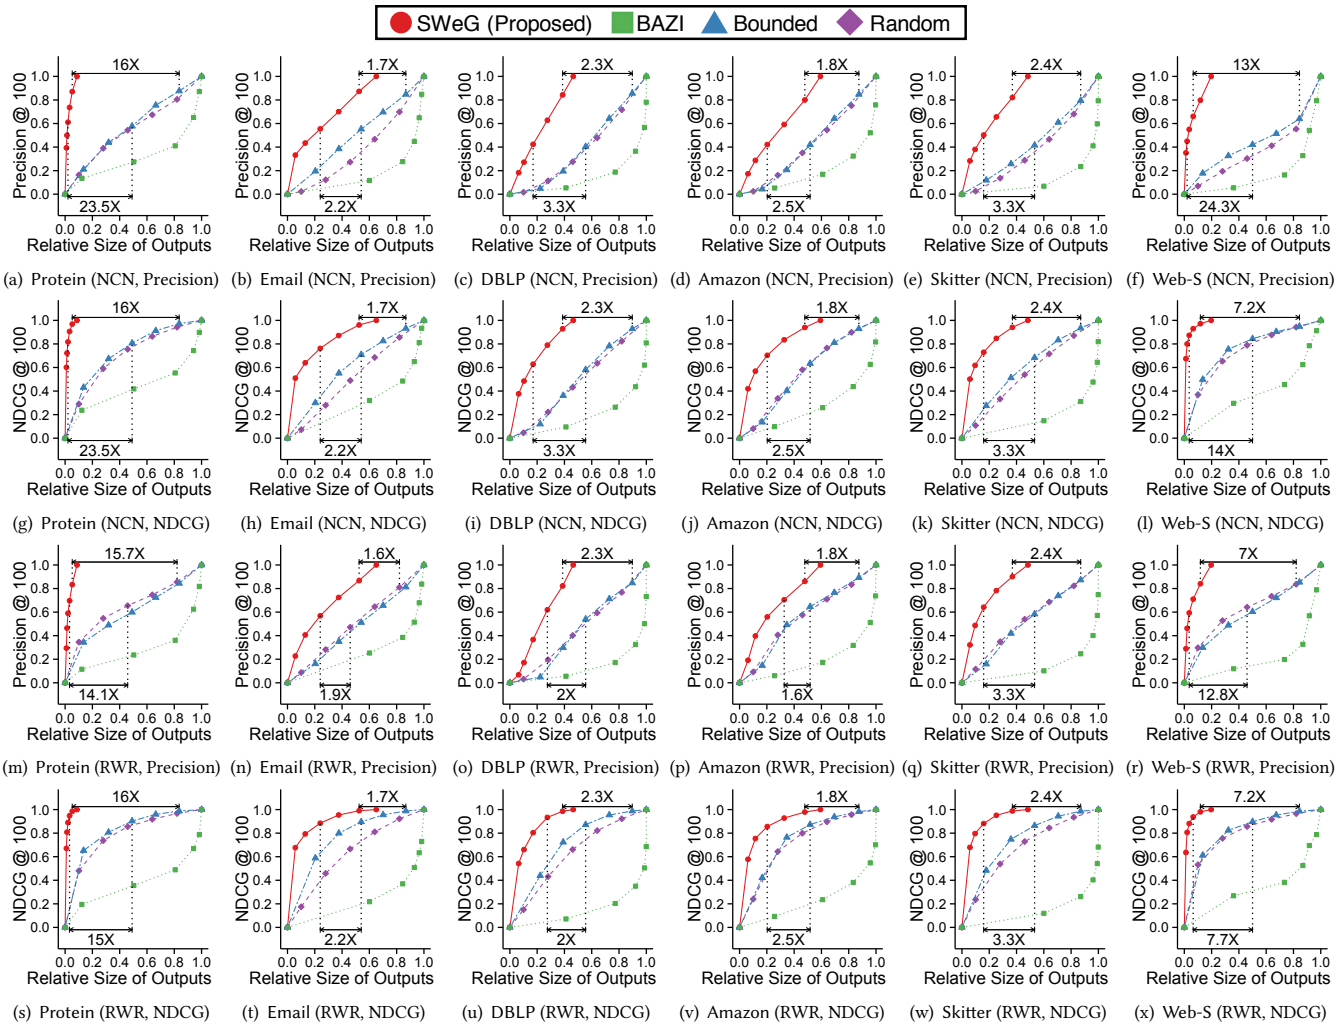
4.2 Q1. Lossless Summarization



We compared the following lossless graph-summarization methods in terms of speed and compactness of representations: [2]

(a) SWeG (proposed): the shared-memory and lossless version of SWeG with $\epsilon = 0$ and $T = \{5, 10, 20, 40, 80\}$.
(b) SAGS [20]: SAGS with five different parameter settings. [3]
(c) Randomized [38].
(d) Greedy [38].
(e) SWeG-P: a variant of (a) without **p**arallelization.
(f) SWeG-G: a variant of (a) that does not **g**roup the supernodes.
(g) SWeG-J: a variant of (a) that chooses supernodes to merge based on the exact savings instead of **j**accard similarity.
(h) SWeG-T: a variant of (a) where the merging **t**hresohld $\theta(t)$ is 0.

To this end, we measured the elapsed time and the relative size of the outputs (i.e., Eq. (15)) of each algorithm.

SWeG gave the best trade-off between speed and compactness of outputs on all the datasets, as seen in Figure 3. For example, on the Youtube dataset, SWeG was **5,400× faster** with 2% smaller outputs than Randomized and 18% faster with 10% smaller outputs than SAGS. Greedy did not terminate within a reasonable

[2] We slightly modified (b)-(d) so that they aim to minimize the same objective of SWeG (i.e., Eq. (1)). We fixed T to 20 in (e)-(h). (b)-(e) are serial, and the others are parallel.
[3] $\{h = 28, b = 7, p = 0.3\}$, $\{h = 28, b = 7, p = 0.1\}$, $\{h = 28, b = 7, p = 0.2\}$, $\{h = 30, b = 10, p = 0.3\}$,$\{h = 30, b = 15, p = 0.3\}$. p denotes the overlap ratio.

Figure 5: SWeG (lossy) significantly outperforms baseline methods for lossy graph summarization. Specifically, SWeG yielded up to 24.3× more compact and similarly accurate representations than the other methods.

time (48 hours). In Figure 4, we show that SWeG (with $T = 20$) also outperformed its variants, justifying our design choices in Section 3.

4.3 Q2. Lossy Summarization

We compared the following lossy graph-summarization methods in terms of the compactness and accuracy of output representations:

(a) SWeG (proposed): the shared-memory and lossy version of SWeG with $T = 80$ and $\epsilon = \{0, 0.18, 0.36, 0.54, 0.72, 0.9\}$.
(b) BAZI [3]: BAZI with $s = \log^2 |\mathcal{S}|$, $w = 50$, and $k = \{0.1 \cdot |\mathcal{V}|, 0.28 \cdot |\mathcal{V}|, 0.46 \cdot |\mathcal{V}|, 0.64 \cdot |\mathcal{V}|, 0.82 \cdot |\mathcal{V}|, |\mathcal{V}|\}$.
(c) Bounded: a baseline that performs only the dropping step of SWeG, i.e., SWeG with $T = 0$ and $\epsilon = \{0.18, 0.36, 0.54, 0.72, 0.9\}$.
(d) Random: a baseline that randomly drops $\epsilon = \{0.18, 0.36, 0.54, 0.72, 0.9\}$ of the edges from the input graph.

To this end, for each method, we measured the relative size of outputs (e.g., Eq. (15)) and measured how accurately the outputs preserve the relevances between nodes as follows:

S1. randomly choose 100,000 seed nodes in the input graph.
S2. compute the **true relevances** between each seed node and the other nodes in the input graph.
S3. compute the **approximate relevances** between each seed node and the other nodes in the graph restored from the outputs.
S4. measure how accurate the approximate relevances from S3 are.

In **S2** and **S3**, we used one of the following relevance scores:

- *Random Walk with Restart (RWR)* [53]: each node's RWR score with respect to a seed node is defined as the stationary probability that a random surfer is at the node. The random surfer either moves to a neighboring node of the current node (with probability 0.8) or restarts at the seed node (with probability 0.2).
- *Number of Common Neighbors (NCN)*: each node's NCN score with respect to a seed node is defined as the number of common neighbors of the node and the seed node.

In **S4**, we computed one of the following accuracy measures for every seed node and then averaged them.

- *Precision@100*: Precision@100 is defined as the fraction of the 100 most relevant nodes in terms of the true relevances among those in terms of the approximate relevances.

- *NDCG@*100 [17]: Let $r(i)$ be the true relevance of the i-th most relevant node in terms of the approximate relevances. Then,

$$\text{NDCG@100} := \frac{1}{Z}\sum_{i=1}^{100}\frac{2^{r(i)}}{\log_2(1+i)},$$

where Z is a constant normalizing NDCG@100 to be within $[0, 1]$.

SWeG yielded the most compact and accurate representations on all the considered datasets, as seen in Figure 5. For example, on the Web-Small dataset, SWeG gave a **24.3× more compact** and similarly accurate representation than the other methods. BAZI tended to yield representations with most (super) edges since it aims to reduce the number of supernodes instead of minimizing the number of (super) edges (see Section 5).

4.4 Q3. Scalability

We evaluated the scalability of the shared-memory and MapReduce implementations of SWeG. Specifically, we measured how rapidly their running times change depending on the size of the input graph, the number of threads, and the number of machines (i.e., the numbers of mappers and reducers in the MapReduce framework). In the shared-memory setting, we used graphs with different sizes obtained by sampling different numbers of nodes from the Web-Large dataset. In the MapReduce setting, we used graphs obtained in the same manner using the LinkedIn dataset. When measuring the data scalability, we fixed the number of threads to 8 and the number of machines to 40. When measuring the machine and multi-core scalability, we fixed the size of the input graph.

SWeG scaled linearly with the size of the input graph, as seen in Figures 6(a) and 6(b). The lossless summarization by SWeG as well as the additional dropping step for lossy summarization (with $\epsilon = 0.1$) scaled near linearly with the number of edges in the input graph in both settings. Note that the largest graph used had more than **20 billion edges**.

SWeG achieved significant speedup in the shared-memory and MapReduce settings. As seen in Figure 6(c), the speedup, defined as T_1/T_N where T_N is the running time of SWeG with N threads, increased near linearly with the number of threads in the shared-memory setting. Specifically, SWeG provided a speedup of 3.3 with 4 threads and 5.7 with 8 threads. As seen in Figure 6(d), the speedup of SWeG, defined as T_1/T_N where T_N is the running time of SWeG with N machines, increased near linearly with the number of machines in the MapReduce setting. Specifically, SWeG provided a speedup of 8.3 with 10 machines and 26.4 with 40 machines.

4.5 Q4. Effects of Parameters

We measured how the number of iterations T and the error bound ϵ in SWeG affect the compactness of its output representation using the relative size of outputs (i.e., Eq. (15)). When measuring the effect of T, we fixed ϵ to 0 and changed T from 1 to 80. When measuring the effect of ϵ, we fixed T to 80 and changed ϵ from 0 to 0.5.

The larger the number of iterations, the more compact the output representation. As seen in Figure 7, the size of outputs decreased over iterations and eventually plateaued. **The larger the error bound, the more compact the output representation**. As seen in Figure 8, the size of outputs decreased near linearly as the error bound increased. The relative size of outputs was especially small in web graphs and protein-interaction graphs, where nodes tend to have similar connectivity [10, 23].

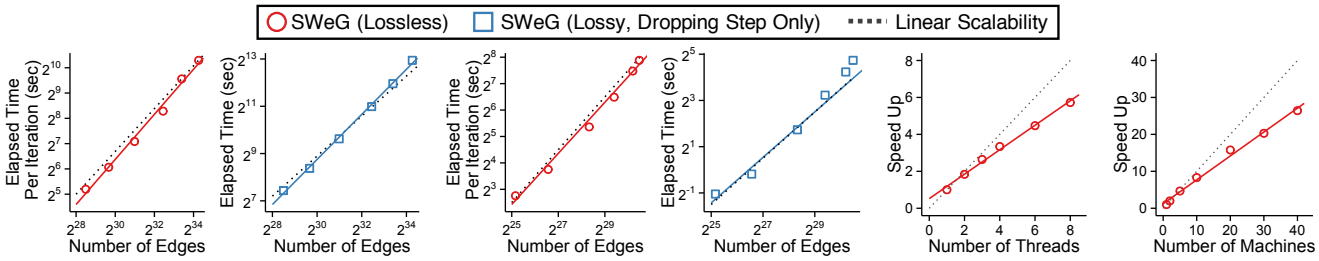
4.6 Q5. Further Compression

We measured how much SWeG+ improves the compression rates of the following advanced graph-compression methods:

(a) BP [11]: reordering nodes as suggested in [11] with 20 iterations and using the webgraph framework [5].
(b) Shingle [9]: reordering nodes as suggested in [9] and using the webgraph framework [5].
(c) BFS [2]: running BFS with the default parameter setting at https://github.com/drovandi/GraphCompressionByBFS.
(d) VNMiner [7]: running VNMiner with 80 iterations.

For the webgraph framework in (a)-(b), we used the default parameter setting (i.e., $r = 3$, $W = 7$, $L_{min} = 7$, and ζ_3). We measured the compression rates using the objective function of each compression method. That is, we used the number of bits per directed edge[4] for (a)-(c) and the relative size of outputs (i.e., Eq. (15)) for (d).

SWeG+ achieved significant further compression. As seen in Figures 1(d) and 9, the lossless version of SWeG+ with $T = 80$ and $\epsilon = 0$ yielded up to **3.4× more compact** representations than all the input compression methods on all the datasets. Especially, SWeG+ with ALG = BFS represented the Web-Large dataset using less than **0.7 bits per directed edge** without loss of information.



5 RELATED WORK

While this paper addresses Problem 1, the term "graph summarization" has been used for a wider range of problems related to concisely describing static plain graphs [12, 22, 28, 33–35, 38, 39, 42, 46, 52, 58], static attributed graphs [8, 13, 16, 19, 41, 47, 49, 51, 55, 57], and dynamic graphs [1, 29, 40, 45, 50]. We refer the reader to an excellent survey [32] for a review on these problems. In this section, we focus on previous work closely related to Problem 1.

Lossless Graph Summarization. Greedy [38] repeatedly finds and merges a pair of supernodes so that savings in space are maximized given the other supernodes. If there is no pair whose merger leads to non-negative savings, then Greedy creates a summary graph and corrections so that the number of (super) edges is minimized given the current supernodes. Greedy is computationally and memory expensive because it maintains and updates savings for $O(|\mathcal{V}|^2)$ pairs of supernodes. Without maintaining any precomputed savings, Randomized [38], whose time complexity is $O(|\mathcal{V}| \cdot |\mathcal{E}|)$, randomly chooses a supernode first and then chooses another supernode to be merged so that savings in space are maximized given the other supernodes. SAGS [20] chooses supernodes to be merged using locality sensitive hashing without computing savings in space, which are expensive to compute. We empirically show in Section 4.2 that all these serial algorithms are not satisfactory in terms of speed or compactness of outputs. They either have high computational complexity or significantly sacrifice compactness of outputs for lower complexity. More importantly, they cannot handle large-scale graphs that do not fit in main memory.

Lossy Graph Summarization. Apxmdl [38] reduces the problem of choosing edges to be dropped from outputs of Greedy to a maximum b-matching problem and uses GabowâĂŹs algorithm [14], whose time complexity is $O(\min(|\mathcal{E}|^2 \log|\mathcal{V}|, |\mathcal{E}| \cdot |\mathcal{V}|^2))$. Due to this high computational complexity, Apxmdl does not scale

[4]We regarded undirected graphs as symmetric directed graphs.

(a) Data Scalability (MapReduce) (b) Data Scalability (Shared Memory) (c) Multi-Core Scalability (Shared Memory) (d) Machine Scalability (MapReduce)

Figure 6: SWeG is scalable. (a-b) SWeG scaled linearly with the size of the input graph. (c-d) SWeG achieved significant speedup as more machines and CPU cores were used. Note that the largest graph used had more than 20 billion edges.

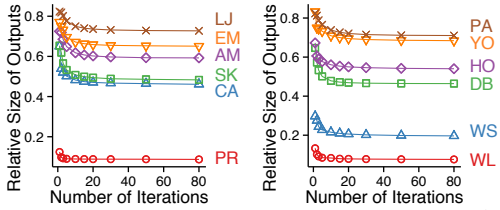


Figure 7: As the number of iterations in SWeG (lossless) increases, the output representations become compact.

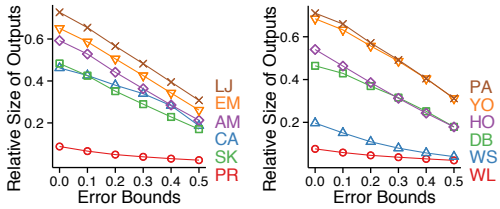

Figure 8: As the error bound in SWeG (lossy) increases, the output representations become compact.

even to moderately-sized graphs. For the same problem, the dropping step of SWeG takes $O(|\mathcal{E}|)$ time (see Section 3.4.1) without sacrificing the compactness of outputs (see Appendix C). In [38], combining Greedy and Apxmdl into a single step was also discussed. Several algorithms [3, 25, 31, 42] have been developed for a problem that is similar but not identical to Problem 1. They aim to find a weighted summary graph with a given number of supernodes so that the difference between the original and restored graphs is minimized without edge corrections. The way of restoring a graph is also different from that in Problem 1. Since these algorithms aim to reduce the number of supernodes, instead of (super) edges, they are not effective for Problem 1 (see Section 4.3).

Combination with Other Compression Techniques. In addition to graph summarization, numerous graph-compression techniques have been developed, including relabeling nodes [2, 5, 9, 11], utilizing encoding schemes for integer sequences (e.g., reference, gap, and interval encodings) [5], and encoding common structures (e.g., cliques, bipartite-cores, and stars) with fewer bits [7, 22, 43]. See [4] for a comprehensive survey on these techniques. As described in Section 3.5 and Section 4.6, SWeG is readily combinable with any compression technique for static plain graphs. In [44], tightly combining two specific summarization and compression algorithms [38, 54] into a single process was presented.

Algorithm 7 Neighbor Query Processing on $\overline{\mathcal{G}}$ and C

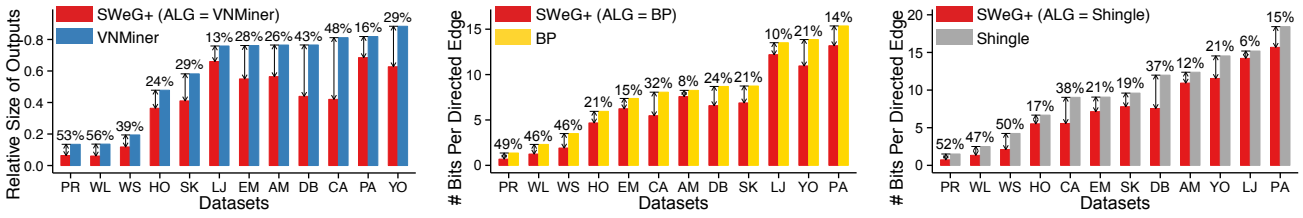
Input: summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$, corrections $C =< C^+, C^- >$, query node $v \in \mathcal{V}$
Output: the set $\hat{N}_v$ of v's neighbors in the restored graph $\hat{\mathcal{G}}$

```
1: N̂_v ← ∅; S_v ← the supernode in S where v ∈ S_v
2: if S_v has a self-loop in Ḡ then N̂_v ← N̂_v ∪ (S_v − {v})
3: for each neighbor A (≠ S_v) of S_v in Ḡ do N̂_v ← N̂_v ∪ A
4: N̂_v ← (N̂_v ∪ N_v^+) − N_v^−        ▷ N_v^+: v's neighbors in C^+
5: return N̂_v                          ▷ N_v^− : v's neighbors in C^−
```

6 CONCLUSIONS

We propose SWeG, a fast parallel algorithm for lossless and lossy summarization of large-scale graphs, which may not fit in main memory. We present efficient implementations of SWeG in shared-memory and MapReduce environments. We also propose SWeG+ where SWeG and other graph-compression methods are combined to achieve better compression than individual methods. We theoretically and empirically show the following strengths of SWeG:

- **Speed**: SWeG provides similarly compact representations up to *5, 400× faster* than existing summarization methods (Figure 3).
- **Scalability**: SWeG scales near linearly with the size of the input graph, the number of machines, and the number of CPU cores. It successfully scales to graphs with over *20 billion* edges (Figure 6).
- **Compression**: SWeG+ achieves up to *3.4× better* compression than individual state-of-the-art graph-compression methods that are combined with SWeG (Figures 1(d) and 9).



A APPENDIX: NEIGHBOR QUERIES

Algorithm 7 describes how to answer neighbor queries (i.e., finding the neighbors $\hat{N}_v$ of a given node $v \in \mathcal{V}$) efficiently on a summary graph $\overline{\mathcal{G}} = (\mathcal{S}, \mathcal{P})$ and corrections $C =< C^+, C^- >$ without restoring entire $\hat{\mathcal{G}}$. Let N_v^- be the neighbors of node $v \in \mathcal{V}$ in C^-. If there is no redundant edge[5] in C^+ and we use a hash table for $\hat{N}_v$ and adjacency lists for C^+, C^-, and $\mathcal{P}$, then the running time of Algorithm 7 is proportional to $|\hat{N}_v| + 2|N_v^-|$. In every dataset listed in Table 2 in Section 4, when SWeG ($T = 80$) was used, $|C^-|$ was at most 6% of the number of edges in the input graph, regardless of the error bound ϵ. Thus, since $|\hat{N}_v| \leq (1+\epsilon) \cdot |N_v|$ from Eq. (2), $|\hat{N}_v| + 2|N_v^-|$ was at most $(1.12 + \epsilon) \cdot |N_v|$ on average.

B APPENDIX: SIZE OF SUBGRAPHS

We measured the size of the largest subgraphs that need to be loaded in main memory at once in our MapReduce implementation of SWeG (with $T = 80$). As seen in Figure 10, the largest subgraphs had

[5] As in the outputs of SWeG, if $\{A, B\} \in \mathcal{P}$, $u \in A$, and $v \in B$, then $\{u, v\} \notin C^+$.

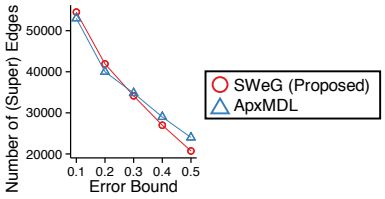

Figure 11: While SWeG has much lower time complexity than Apxmdl, they give similarly compact results.

up to **1,209× fewer** edges than the entire graphs. The experimental settings were the same with those in Section 4.1.

C APPENDIX: COMPARISON WITH APXMDL

To compare SWeG and Apxmdl [38] in terms of the compactness of their output representations, we measured how the number of (super) edges in their outputs, which Apxmdl aims to minimize, changes depending on the error bound ϵ. We used the same small-scale graph used in [38], which is a web graph with 40,000 nodes [5]. SWeG (with $T = 80$) and Apxmdl yielded similarly compact outputs, as seen in Figure 11, where we compare with the numbers reported in [38]. Specifically, SWeG gave more compact outputs than Apxmdl when ϵ was large, while the opposite happened when ϵ was small. SWeG has much lower time complexity than Apxmdl. Specifically, the dropping step of Apxmdl takes $O(\min(|\mathcal{E}|^2 \log |\mathcal{V}|, |\mathcal{E}| \cdot |\mathcal{V}|^2))$ time, while that of SWeG takes $O(|\mathcal{E}|)$ time (see Section 3.4.1).

Generative Graph Models based on Laplacian Spectra*

Alana Shine
University of Southern California

David Kempe
University of Southern California

ABSTRACT

We present techniques for generating random graphs whose Laplacian spectrum approximately matches that of a given input graph. The motivation for matching the Laplacian spectrum is that it naturally encodes high-level connectivity information about the input graph; most existing models (e.g., variants of the Configuration Model, Stochastic Block Model, or Kronecker Graphs) focus on local structure or limited high-level partitions.

Our techniques succeed in matching the spectrum of the input graph more closely than the benchmark models. We also evaluate our generative model using other global and local properties, including shortest path distances, betweenness centrality, degree distribution, and clustering coefficients. The graphs produced by our model almost always match the input graph better than those produced by the benchmark models with respect to shortest path distance and clustering coefficient distributions. The performance on betweenness centrality is comparable to the benchmarks, while a worse match on the degree distribution is a price our method pays for more global similarity.

Our results suggest that focusing on spectral properties may lead to good performance for other global properties, at a modest loss in local similarity. Since global connectivity patterns are usually more important than local features for processes such as information flow, spread of epidemics, routing, etc., our main goal is to advocate for a shift in focus from graph generative models matching local properties to those matching global connectivity patterns.

1 INTRODUCTION

Random graph models for generating "realistic-looking" graphs play a number of important roles in network science and network data mining. Their uses include:

- Produce graphs to evaluate the computational performance of algorithms or protocols (see, e.g., [32]).
- Produce graphs to evaluate the correctness or quality of the *output* of algorithms in a controlled setting.
- Formally prove that certain graphs are likely to have certain properties, and derive (descriptive or prescriptive) insights about real-world networks from these proofs.

In all cases, the insights gained from the model can only be useful if the generated graphs resemble the class of real-world networks about which one is aiming to make statements [46]. More specifically, this resemblance must apply to graph parameters that are *relevant* to the kinds of structures or processes that the algorithm depends on, or the theorem reasons about.

To illustrate this issue, consider the following example. A researcher seeks insight into the spread of epidemics in social networks, many of which he has observed to follow particular degree distributions. He proves (or observes from simulations) that when a graph is drawn uniformly at random subject to this degree distribution, with high probability, an epidemic will spread very fast on it. He concludes that social networks are very susceptible to epidemics.

The concern with this inference is that social networks may have additional properties beyond the observed degree distribution; these properties may be exceedingly rare among the sampled graphs. For instance, it is well known (see, e.g., [8, 15]) that even subject to most fixed degree distributions, almost every graph has high expansion; in turn, high expansion facilitates epidemic spread under many natural models [6, 26]. On the other hand, high expansion is also nearly synonymous with a lack of pronounced community structure, whereas social networks typically do have pronounced community structure. As a result, the observation that epidemics spread fast on a random graph subject to a given degree distribution is likely more due to the expansion of random graphs than the given degree distribution.

With some exceptions (e.g., [52, 53, 55]) discussed below, most[1] generative graph models draw a graph (nearly) uniformly from an ensemble, subject to local properties such as (expected) degrees, joint degrees, or triangle counts, and/or a global partition into communities [5, 8, 14, 15, 27, 29, 30, 34, 41, 43, 44, 46, 49]. Going beyond those basic models, exponential random graph models (ERGMs) [24, 47] draw graphs from a distribution that rewards or penalizes user-specified local features; the Kronecker Graph Model [36] allows recursive specification of "community" structure in a generalization of stochastic block models (SBM). Another line of work

[1] An orthogonal class of models prescribe a generative (growing or rewiring) process based upon a plausible real-world dynamic [4, 37, 50].

uses deep neural networks (DNNs) to generate graphs. The hope is that using DNNs, one can avoid explicitly specifying the (local or global) properties one desires to replicate, instead learning them automatically from a training data set of enough "similar" graphs [17, 39, 54, 56]. An exception is the NetGAN approach [7]. NetGAN trains a deep network from a single input graph, with the goal of reproducing "realistic-looking" random walks, i.e., sequences of node visits. From these sequences, NetGAN then extracts empirical edge frequencies, and uses these to generate random graphs resembling the input graph.

While most constraints imposed by such models are typically[2] *local* in nature, most network properties and dynamics of interest to researchers are *global*. These include the spread of epidemics or information, the prevalence or strength of communities in graphs, the distribution of distances between individuals, or the capacity for information flow, among many others. These graph properties are all closely affected by the graph's expansion; hence, if the random graph model overwhelmingly generates expander graphs, the effects due to other parameters may be overshadowed.

The main high-level point of this paper is the following: *If one is interested in global network properties, then a generative model should try to match these global properties with those of the real-world networks the model is trying to mimic.*

1.1 Approximately Matching Graph Spectra

Our approach to "matching global structure" focuses on the *spectrum* (eigenvalues $0 = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$) of the (normalized) graph Laplacian of the input graph. (Definitions of all key concepts are given in Section 2.) The spectrum of the graph Laplacian is known to capture connectivity properties [21, 23]. Best known is Cheeger's Inequality [13], which relates the spectral gap λ_2 with the graph's conductance. More intricate results [13, 35] show that small values of $\lambda_3, \lambda_4, \ldots$ indicate additional node sets that are sparsely connected to each other.

Concretely, given an (undirected) input graph G^* with spectrum $0 = \lambda_1^* \leq \lambda_2^* \leq \cdots \leq \lambda_n^*$, our goal is to generate random graphs G with spectrum $0 = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$ such that $\lambda_i \approx \lambda_i^*$ for all i. The intuition is that a similar spectrum should result in similar global connectivity properties.[3]

We propose intricate heuristics for randomly generating such graphs, and evaluate the heuristics extensively. The central viewpoint exploited throughout is that a (symmetric) matrix is naturally characterized by its spectrum and orthonormal eigenbasis. Since the spectrum is given, finding a graph Laplacian reduces to finding a suitable orthonormal basis. The problem is that for most bases, the resulting "graph adjacency matrix" A will have entries far from the set $\{0, 1\}$. Our approach is to produce the actual adjacency matrix gradually, using the following steps (detailed in Section 3):

(1) Sample a random orthonormal basis to construct a candidate Laplacian matrix with the desired spectrum. Use linear programming to find a matrix M whose Laplacian is approximately the candidate matrix.
(2) Keeping the spectrum fixed, perform a walk on possible orthonormal bases, guided by an objective function that pushes the entries of M close to 0 or 1.
(3) Use an LP-based algorithm to minimally perturb the entries of M to end up inside $[0, 1]$, while maintaining the row sums. This may perturb the spectrum, but the LP's objective is designed to keep the perturbation small.
(4) Use a combination of deterministic rounding across eigencuts with small eigenvalues and randomized rounding of other edges to round M to a graph G.

In Section 7, we evaluate this algorithm on multiple real-world networks. We generate samples using our approach, and compare them to the graphs generated according to the configuration model, stochastic block model, and Kronecker graph model. The comparison is based on the following global and local graph parameters: the spectrum itself, betweenness centralities, clustering coefficients, degree distribution, and the distribution of shortest path lengths.

We observe (not surprisingly) that the spectrum is in fact matched significantly better by our approach. For the other metrics, the spectral approach typically performs comparably (sometimes slightly better, sometimes slightly worse) to the best of the other approaches; for shortest path lengths, it outperforms the other models significantly most of the time.

Our work raises many concrete questions and big-picture directions for future work, discussed in more detail in Section 8. Perhaps most immediately, our algorithms currently scale to graphs of a few thousand nodes, but not beyond. In order to apply them to realistic networks, it is important to speed up the generation by several orders of magnitude. We therefore view this work not as a complete or final solution to the problem, but as a first step. Our goal in this work was to show that (1) it is computationally feasible to generate graphs matching a given graph's spectrum fairly well, and (2) doing so also helps in matching other important global graph properties. We expect future work to yield faster heuristics and different approaches which will allow these ideas to be applied to even more practical instances. Beyond the running time of the algorithm, there are also many natural questions for future work regarding provable guarantees for the objectives we pursue. Our algorithms do not come with provable approximation guarantees, and obtaining such guarantees would be desirable — though it also appears very challenging.

1.2 Related Work

Our goal is directly related to *inverse eigenvalue problems*: constructing matrices with a given spectrum, subject to other structural properties [12]. Ours is an *inexact* inverse eigenvalue problem, because the spectrum only needs to be matched approximately. On the other hand, our task is to generate a *diverse* collection of matrices, making a deterministic construction inadequate.

[2] The SBM prescribes a high-level partition, but typically only into a constant number of partitions; the recursive structure prescribed by the Kronecker model is more intricate, but depends only on a small number of parameters.

[3] It may appear natural to aim to match the eigenvalues exactly: $\lambda_i = \lambda_i^*$ for all (or some) i. There are two reasons to prefer an approximation instead. The first is computational — we are not aware of any way to efficiently decide if *any* graph has a given spectrum, let alone find one. Second, while there are non-isomorphic pairs of graphs with the same spectrum, such pairs are exceedingly rare: for example, Butler and Grout [10], based on computational enumeration, estimate that only roughly one in 10^{23} graphs has a non-isomorphic cospectral graph. Thus, most of the time, a generative model would be forced to always return the input graph G^*.

Typical structural properties considered in the context of inverse eigenvalue problems include symmetric non-negative and self-adjoint matrices, both of which have known constructions [20, 22, 33]. Deciding if a spectrum is realized by a real non-negative matrix is NP-hard [9].

Inverse eigenvalue *graph* problems ask whether a graph exists such that a given associated matrix (e.g., adjacency, random walk, Laplacian) has a given spectrum. Godsil and McKay present a method for generating non-isomorphic co-spectral graphs with respect to the adjacency matrix [28]. There has also been work on generating certain families of co-spectral graphs with respect to the Laplacian matrix [40]. We are interested in the (inexact) inverse eigenvalue graph problem with respect to the symmetric normalized Laplacian; with respect to the normalized Laplacian, Butler and Grout [10] have shown how to construct some families of (exactly) cospectral graphs with special structure.

Spectral graph generative approaches have been proposed in some prior work, e.g., [52, 53, 55]. The idea in these approaches is to consider spectral embeddings of the means and covariances of a *set* of graphs, then interpret these embeddings as samples from a distribution, and sample from this distribution, with the goal of interpolating between graphs. The sampling produces a candidate "Laplacian matrix." As discussed above, in general, it is not guaranteed that such a candidate matrix is the Laplacian of any matrix resembling a graph adjacency matrix, and indeed, a lot of our effort here is focused on actually producing a suitable adjacency matrix, and on choosing a "Laplacian matrix" that lends itself to this transformation.

As far as we can tell, [55] does not describe any such procedure. [52] suggests thresholding the values of the matrix, including as edges of the graph those pairs (i, j) for which the entries of the Laplacian are most negative. We compare two different thresholding approaches in this vein to our algorithms in Section 7.3, and find that they perform significantly inferior in matching the spectrum of the input graph.

In very recent work, [3] proposed an approach very similar to ours. Their goal is also to generate graphs whose spectrum approximately matches that of a given input graph; however, [3] use the Modularity matrix [42] instead of the normalized Laplacian. They use a low-rank approximation of the Modularity matrix, which is then transformed back to an adjacency matrix, noised, scaled, and truncated, to define edge probabilities $p_{i,j}$; subsequently, each edge (i, j) is included independently with probability $p_{i,j}$. The rank of the approximation is a user-specified feature, capturing how different the output graphs are likely to be from the input graph.

2 MODEL AND PRELIMINARIES

Throughout this paper, all graphs are undirected, and all matrices (except basis matrices) are real and symmetric. Vectors are denoted by boldface, including $\mathbf{0}$ and $\mathbf{1}$ for the all-0 and all-1 vectors. Graphs have n nodes, and matrices are of dimension $n \times n$.

For any matrix (adjacency or otherwise) $A = (a_{i,j})_{i,j} \in \mathbb{R}^{n \times n}$, we use $\lambda(A)$ to denote the set of A's eigenvalues $\lambda(A) = \{\lambda_1(A) \leq \lambda_2(A) \leq \cdots \leq \lambda_n(A)\}$, also called the *spectrum* of A. We use $\Lambda(A) = \mathrm{diag}(\lambda_1(A), \lambda_2(A), \ldots, \lambda_n(A))$ to denote the diagonal matrix whose diagonal entries are $\lambda_1(A), \lambda_2(A), \ldots, \lambda_n(A)$.

For any matrix A (in particular, an adjacency matrix), we let $d_i(A) = \sum_j a_{i,j}$, and call it the *degree* of node i in A. The degree matrix D for A is $D(A) = \mathrm{diag}(d_1(A), d_2(A), \ldots, d_n(A))$. The identity matrix is denoted by $I = \mathrm{diag}(1, 1, \ldots, 1)$.

Definition 2.1 (Symmetric Normalized Laplacian Matrix). The symmetric normalized Laplacian matrix $L(A)$ for the symmetric $n \times n$ matrix A is $L(A) = I - (D(A))^{-1/2} A (D(A))^{-1/2}$.

We call $\lambda(L(A))$ the *Laplacian spectrum* of A. It is well known that $\lambda_1(L(A)) = 0$, and $\lambda_n(L(A)) \leq 2$ [13]. Throughout this paper, all eigenvalues we consider will be of Laplacians of matrices; when there is no risk of confusion, we then simply refer to the Laplacian eigenvalues as $\lambda_1, \lambda_2, \ldots, \lambda_n$, omitting the dependence on A. In that case, the corresponding (normalized) eigenvectors are denoted by $\boldsymbol{x}_1, \boldsymbol{x}_2 \ldots, \boldsymbol{x}_n$, and the (orthonormal) matrix of eigenvectors is $X(A) = (\boldsymbol{x}_1, \boldsymbol{x}_2 \ldots, \boldsymbol{x}_n)$. The set of all such matrices, i.e., $n \times n$ matrices of orthonormal column vectors, is called the *Stiefel manifold* [18], and denoted by $\mathcal{S}_n$.

The difference $\lambda_2 - \lambda_1 = \lambda_2$ is called the *spectral gap of* $L(A)$. The corresponding eigenvector $\boldsymbol{x}_2$ is called the *Fiedler vector* [21, 23] of A, and plays an important role in identifying low-conductance cuts.

Given a diagonal matrix Λ of eigenvalues, we can obtain a matrix A with spectrum Λ from any basis matrix X simply as $A = W_\Lambda(X) := X \Lambda X^\intercal$; this is nothing but the standard *eigendecomposition* of A. Conversely, given a symmetric real matrix A, there is always a basis (of A's eigenvectors) such that $A = X \Lambda(A) X^\intercal$.

Definition 2.2 (Computational Goal). The given (undirected and connected) graph on n nodes is denoted by G^*, and has (symmetric) adjacency matrix $A^* \in \{0, 1\}^{n \times n}$. The eigenvalues of $L(A^*)$ are $0 = \lambda_1^* \leq \lambda_2^* \leq \cdots \leq \lambda_n^* \leq 2$.

The goal is to randomly sample a graph G with adjacency matrix $A \in \{0, 1\}^{n \times n}$ whose Laplacian spectrum $0 = \lambda_1(L(A)) \leq \lambda_2(L(A)) \leq \cdots \leq \lambda_n(L(A)) \leq 2$ is similar to that of A^*, in the sense that $\lambda_i(L(A)) \approx \lambda_i^*$ for all i.

Definition 2.2 is not formal, in that it does not quantify the meaning of "$\approx$", i.e., it does not specify how close is "close enough" in terms of the Laplacian spectrum of A. It would be desirable to do so, but we are not aware of ways to sample graphs whose spectrum is *provably* close to a given spectrum. Indeed, the following result of Borobia and Canogar [9] suggests that this may be difficult:

Theorem 2.3 ([9]). *The following problem is NP-hard: given a sequence of n real numbers $\lambda_1, \ldots, \lambda_n$, decide if there exists a real nonnegative matrix A of order n with eigenvalues $\lambda_1, \ldots, \lambda_n$.*

Theorem 2.3 does not apply directly to our problem, in that it (1) asks about the spectrum of A, rather than of $L(A)$, and (2) only requires that all entries of A be non-negative, rather than from $\{0, 1\}$. Typically, requiring integrality of a solution makes problems harder (e.g., linear programming), so we expect the hardness result to apply to our problem as well; however, at this time, we have no proof of NP-hardness with the integrality restriction.

3 ALGORITHM OUTLINE

Our graph generative algorithms can be divided into two stages:

(1) **Relaxed Spectrum Fitting:** Find a *template matrix* M whose Laplacian spectrum $\lambda(L(M))$ is very close to the target spectrum $\lambda(L(G^*))$; the entries $m_{i,j}$ may in principle be far from $\{0,1\}$ (including fractional, negative, or larger than 1), but the goal is for them to be close to $\{0,1\}$.
(2) **Template Matrix Perturbation:** Gradually "round" M, first to a matrix $P \in [0,1]^{n\times n}$, then to an actual adjacency matrix. In the process, aim to minimize perturbations to the Laplacian spectrum.

3.1 Relaxed Spectrum Fitting

The Relaxed Spectrum Fitting phase makes heavy use of the correspondence between matrices with a given spectrum and basis matrices. Its goal is to identify a good candidate orthonormal basis X so that the template matrix M defined by $L(M) = W_{\Lambda^*}(X) = X\Lambda^* X^\intercal$ has entries in (or close to) the interval $[0,1]$; or, even better, close to 0 or 1.

Our method starts by generating a random graph $\hat{G}$ from the configuration model [5] with the degree distribution of G^*. Let $\hat{A}$ be the adjacency matrix of $\hat{G}$, and $\hat{X}$ its eigenbasis. In the basic version of the Relaxed Spectrum Fitting phase, we use a linear programming (LP) based approach to find a template matrix M with $L(M) \approx W_\Lambda(\hat{X})$ (see Section 4).

The matrix M could have many entries far from $[0,1]$. Thus, rather than simply using $\hat{X}$, the extended version of our algorithm uses continuous optimization techniques to search the Stiefel manifold for a basis X such that the corresponding template matrix M has entries closer to 0 and 1. This optimization does not scale to large graphs, but more often than not makes small improvements.

3.2 Template Matrix Rounding

As a first step to rounding the template, M is converted to a matrix $P \in [0,1]^{n\times n}$, whose entries can be viewed as edge strengths or probabilities for randomized rounding. We use the following proxy problem: find an "error" matrix E such that $p_{i,j} = m_{i,j} + e_{i,j} \in [0,1]$ for all i,j and the spectrum of M is close to that of P. We show (in Section 6) how to cast the problem of finding E as a linear program, and prove that the objective function gives an upper bound on the sum of eigenvalue perturbations.

Finally, P needs to be converted to an adjacency matrix A. Small eigenvalues λ_k are particularly sensitive to changes going from M to P or from P to A. We therefore treat them separately. Our goal is to make initial edge modifications judiciously to counteract such effects, and to prevent large changes in λ_k for small k. To do so, we focus on the first approximately balanced[4] *eigencut* $(S_k, \overline{S_k})$, defined by $S_k = \{i \mid x_{k,i} < 0\}$ and $\overline{S}_k = \{i \mid x_{k,i} \geq 0\}$, where $\boldsymbol{x}_k$ are eigenvectors of $L(P)$. For each edge crossing $(S_k, \overline{S_k})$, we estimate how much its addition or removal would affect λ_k. We then select edges (i,j) to round $p_{i,j}$ up or down to correct λ_k as well as possible. We observe experimentally that when $k \neq 2$, if rounding edges across $(S_k, \overline{S}_k)$ shrinks λ_k, the spectral gap is typically lowered as well. There could be other candidate cuts that provide valuable connectivity information, but we restrict our search to eigencuts to keep the computational cost manageable.

In a final step, we round all remaining edges, independently including edge (i,j) with probability $p_{i,j}$.

3.3 Randomness

There are two sources of randomness in our generative process: the random initial generation of an orthonormal matrix X via a configuration model graph $\hat{G}$, and the independent random edge inclusions in the final part of the Template Matrix Rounding phase.

Naturally, the process does not guarantee sampling a graph *uniformly* from an ensemble of graphs with approximately correct spectra; however, experimentally, it leads to significant variation in the graphs that are generated, obviously an important criterion for graph generative processes [48].

4 RELAXED SPECTRUM FITTING

We are given a basis X and associated matrix $A = W_{\Lambda^*}(X)$, and would like to identify a matrix M whose normalized Laplacian is $L(M) = A$; ideally M, should be the adjacency matrix of a graph or close to one. It is obvious how to compute $L(M)$ from M. However, we need to compute M given a candidate $L(M)$. The transformation requires knowing the degrees d_i of nodes in M. The following lemma motivates our LP-based approach for finding d_i:

Lemma 4.1. *The matrix A is the Laplacian of some symmetric matrix M with positive row sums if and only if there exists a vector $\boldsymbol{y} > \mathbf{0}$ (all entries are strictly positive) such that $A\boldsymbol{y} = \mathbf{0}$.*

Proof. For the first direction, assume that $A = L(M) = I - D^{-1/2}MD^{-1/2}$ for some symmetric matrix M with positive row sums. Let $d_i = \sum_j m_{i,j} > 0$ be the degree of i in M, and let $\boldsymbol{y}$ be the vector with $y_i = d_i^{1/2}$. Clearly, $\boldsymbol{y} > \mathbf{0}$, and

$$A\boldsymbol{y} = \boldsymbol{y} - D^{-1/2}MD^{-1/2}\boldsymbol{y} = \boldsymbol{y} - D^{-1/2}M\cdot\mathbf{1} = \boldsymbol{y} - D^{-1/2}\boldsymbol{d} = \mathbf{0}.$$

For the converse direction, let $\boldsymbol{y} > \mathbf{0}$ be a solution to $A\boldsymbol{y} = \mathbf{0}$. Let $Y = \mathrm{diag}(y_1, y_2, \ldots, y_n)$, and define $M = Y^2 - YAY$. The vector of row sums of M is

$$M\cdot\mathbf{1} = (y_i^2)_i - YAY\cdot\mathbf{1} = (y_i^2)_i - YA\boldsymbol{y} = (y_i^2)_i > \mathbf{0}.$$

And because

$$L(M) = I - Y^{-1}MY^{-1} = I - Y^{-1}(Y^2 - YAY)Y^{-1} = I - I + A = A,$$

A is indeed the symmetric normalized Laplacian of M. □

The vector entries y_i in Lemma 4.1 are the square roots of the degrees of node i. During the computation, the basis X may be such that the associated matrix $W_{\Lambda^*}(X)$ is not the Laplacian of any matrix M with positive row sums.[5] In order to compute an approximate and usable matrix M, we relax the constraint that $M\boldsymbol{y} = \mathbf{0}$, and instead aim to minimize $||M\boldsymbol{y}||_\infty$. We approximate the positivity constraint by requiring that $y_i \geq \epsilon$ for all i, for a very small positive constant $\epsilon > 0$; we then obtain the following linear program:

[4] For most inputs, $k = 2$ and we round edges across the Fiedler cut. Occasionally, the Fiedler cut is very unbalanced. In those cases, rounding edges across the Fiedler cut very judiciously is largely misspent effort, since later steps are likely to disconnect the smaller side (plus some nodes) from the rest of the graph.

[5] Because $\lambda_1^* = 0$, the matrix $W_{\Lambda^*}(X)$ is always singular. However, the corresponding eigenvector $\boldsymbol{x}_1$ will typically have negative entries, so we are not guaranteed a vector $\boldsymbol{y} > \mathbf{0}$.

$$\begin{array}{lll} \text{Minimize} & b & \\ \text{subject to} & |\sum_{j=1}^{n} a_{i,j} y_j| \le b & i = 1, \ldots, n \\ & y_j \ge \epsilon & j = 1, \ldots, n. \end{array} \quad (1)$$

The procedure for fitting a graph M is now as follows:

(1) Given an orthonormal basis X, compute $A = W_{\Lambda^*}(X)$.
(2) Solve the LP (1), obtaining a solution $(b, \boldsymbol{y})$.
(3) Output the *template matrix* $M = Y^2 - YW_{\Lambda^*}(X)Y$, where $Y = \text{diag}(\boldsymbol{y})$.
(4) To match the edge density of M to that of the target, set $M := \frac{\sum_i d_i^*}{\sum_i d_i} \cdot M$, where d_i^* are the node degrees in the target graph, and $d_i = \sum_j m_{i,j}$.

If $b = 0$, then $L(M) = W_{\Lambda^*}(X)$, and we have found a template matrix M such that $L(M)$ has exactly the desired spectrum Λ^*. We note that the spectrum is invariant to the scaling in Step (4). We perform the scaling to match the target edge density before perturbing the edges, in order to avoid having to perturb the matrix twice to yield entries in the interval $[0, 1]$. Even in this case, individual entries $m_{i,j}$ of the template matrix may be negative or larger than 1 (and of course fractional): the solution $\boldsymbol{y}$ only guarantees that the *total* degree of each node is positive.

When $b > 0$, we have that $L(M) \neq W_{\Lambda^*}(X)$, meaning that typically $\Lambda(M) \neq \Lambda^*$ as well, i.e., the spectrum can be perturbed. We show that the deviation in spectrum can be bounded using the LP objective b; the lemma also motivates our choice of LP objective.

Lemma 4.2. *Let δ be such that $b \le \delta y_i$ for all i. Then, the perturbed eigenvalues satisfy $|\lambda_i(L(M)) - \lambda_i(A)| \le \frac{\delta}{1-\delta} \cdot |\lambda_i(A)|$.*

Proof. The degrees under M are $d_i = \sum_k m_{i,k} = y_i^2 - y_i \sum_k a_{i,k} y_k$, so the perturbed Laplacian matrix $L = L(M)$ has entries

$$\ell_{i,j} = \frac{a_{i,j} y_i y_j}{(y_i^2 - y_i \sum_k a_{i,k} y_k)^{1/2} (y_j^2 - y_j \sum_k a_{j,k} y_k)^{1/2}}.$$

Writing $z_i = \frac{y_i}{(y_i^2 - y_i \sum_k a_{i,k} y_k)^{1/2}}$ and $Z = \text{diag}(z_1, z_2, \ldots, z_n)$, the perturbed Laplacian therefore satisfies $L = ZAZ^\intercal$.

Applying Theorem 4.3 (below) with $D = D^\intercal = Z$, we get that the relative perturbation in eigenvalues is at most

$$|\lambda_i(L(M)) - \lambda_i(A)| \le |\lambda_i(A)| \cdot ||Z^\intercal Z - I||_2.$$

The norm of a diagonal matrix is its maximum entry, so

$$||Z^\intercal Z - I||_2 = \max_i \frac{\sum_k a_{i,k} y_k}{y_i - \sum_k a_{i,k} y_k} \le \max_i \frac{b}{y_i - b},$$

by the LP's first constraint. Because $b \le \delta y_i$ for all i by assumption, we obtain the claimed bound. □

Theorem 4.3 (Theorem 2.1 of [19]). *Let $\tilde{A} = D^\intercal A D$, where D is a nonsingular matrix. Let λ_i and $\tilde{\lambda}_i$ be the eigenvalues of A and $\tilde{A}$, respectively. Then, $|\tilde{\lambda}_i - \lambda_i| \le |\lambda_i| \cdot ||D^\intercal D - I||_2$, for all i.*

5 STIEFEL MANIFOLD OPTIMIZATION

While the techniques in Section 4 find a good M so $L(M) \approx X\Lambda X^\intercal$, if X was a bad basis, no M will be satisfactory, and the entries will lie far outside $[0, 1]$, or the Laplacian eigenvalues will be perturbed. To improve the basis before committing to it, we can perform a walk on the Stiefel manifold, using known techniques to locally optimize an objective function that rewards template matrices M with entries close to 0 or 1. Specifically, we define the objective function $F(M) = \sum_{i<j} (1 - m_{i,j})^2 m_{i,j}^2$, which has minima when all $m_{i,j}$ are in $\{0, 1\}$ and steeply penalizes entries far from 0 and 1.

For any basis $X \in \mathcal{S}_n$, let $\boldsymbol{y}_X$ be the solution to the linear program (1) (applied to $A = X\Lambda^* X^\intercal$), and $Y_X = \text{diag}(\boldsymbol{y})$. Then, $M(X) = Y_X^2 - Y_X X \Lambda^* X^\intercal Y_X$ is the candidate template matrix for X. The objective is then to find a basis $X \in \mathcal{S}_n$ (approximately) minimizing $F(M(X))$.

While the objective function F itself is differentiable (which would allow for a straightforward application of existing manifold optimization techniques), the transformation $X \mapsto M(X)$ is computed via the solution to a linear program. It is not clear how optimal solutions to the linear program (1) change with X, and in particular whether $X \mapsto F(M(X))$ is continuous or differentiable. Therefore, few guarantees for known optimization techniques apply in our setting. To compensate, we use a small maximum step size of .0001 in the optimization.

To perform optimization over the Stiefel manifold, we use known iterative optimization techniques. Specifically, we use the *Polar Decomposition retraction scheme* [2][6]. Retraction schemes in each step t identify a search direction $\boldsymbol{\eta}_t$ in the tangent bundle of the current basis X_t, such that moving in the direction $\boldsymbol{\eta}_t$ minimizes F. (See [1] for definitions of the notions of *tangent bundle* and *retraction*.) The scheme moves X_t by a step size τ_t in the direction $\boldsymbol{\eta}_t$, then projects it back onto the manifold using a retraction $R_X(\tau)$. A retraction scheme specifies both the retraction $R_X(\tau)$ and search direction $\boldsymbol{\eta}$ such that $R_X(\tau)$ is a descent direction: the derivative $R'_X(\tau)$ must be equal to the projection of $-\text{grad}(F(M(X_t)))$ onto the tangent bundle at X. The step size τ_t is typically chosen according to the *Armajiro-Wolfe Conditions*, which ensure that at the point $X_t + \tau_t$, the decrease $F(X_t) - F(X_t + \tau_t)$ is proportional to τ (*sufficient-decrease*), but also that τ_t is sufficiently large such that one cannot decrease $F(X_t + \tau_t)$ by taking a larger step (*curvature condition*) [45]. One iteration of the Stiefel manifold optimization can be summarized as follows:

(1) Using X_t, solve the template fit LP (1) to compute $M(X_t)$.
(2) Treat the y_{X_t} computed from LP (1) as constant, and using $\text{grad}(F(M(X_t)))$, compute a search direction $\boldsymbol{\eta}_t$ using a retraction method.
(3) Perform a line search technique to find a step size τ_t that obeys the Armajiro-Wolfe conditions [45].
(4) Set $X_{t+1} = X_t + \tau_t \boldsymbol{\eta}_t$.
(5) Repeat until a local optimum is reached.

We implemented and experimented with two different retraction methods: the Cayley Transform Retraction [51] and the Polar-Decomposition Retraction [2]. Our experiments showed that the Polar-Decomposition Retraction performed better most of the time.

6 ROUNDING THE TEMPLATE MATRIX

6.1 Perturbing the Template Matrix

The next step is to compute an additive perturbation matrix E that leaves the row sums (i.e., degrees) of M intact (first constraint of

[6] Manifold optimization techniques can generally be divided into two categories: retraction schemes and geodesic schemes. We use retractions as geodesics are often difficult to compute [1].

LP (2)), and ensures that all entries of $P = M + E$ are in $[0, 1]$ (third constraint). Subject to this, we aim to minimize the weighted sum of absolute perturbations. The variables are $e_{i,j}$ and $q_{i,j} = |e_{i,j}|$ (second constraint) for $i \neq j$ (with $e_{i,i} = 0$ implicitly). $d_i = \sum_j m_{i,j}$ denotes the (fractional) degree of i.

$$\begin{array}{lll} \text{Minimize} & \sum_{i \neq j} \frac{q_{ij}}{d_i^{1/2} d_j^{1/2}} & \\ \text{subject to} & \sum_j e_{i,j} = 0, & i = 1, \ldots, n \\ & q_{i,j} \geq |e_{i,j}| & \text{for all } i \neq j \\ & 0 \leq m_{i,j} + e_{i,j} \leq 1 & \text{for all } i \neq j \\ & e_{i,j} = e_{j,i} & \text{for all } i \neq j \end{array} \tag{2}$$

Keeping the degrees constant ensures that the normalization factors for the Laplacian are the same for P and M. The choice of objective function is justified by the following lemma.

Lemma 6.1. *Let $(e_{i,j})$ be an optimal solution of the LP (2), with objective value b. Then, the eigenvalues of the Laplacians of M and $P = M + E$ are close: $\sum_i |\lambda_i(L(M)) - \lambda_i(L(P))| \leq b$.*

Proof. Consider the perturbation $\Delta = L(M) - L(P)$ of the Laplacian matrix. Applying Theorem 6.2 (below) with $\Phi(x) = |x|$, we obtain that $\sum_i |\lambda_i(L(M)) - \lambda_i(L(P))| \leq \sum_i |\lambda_i(\Delta)|$. In the remainder of the proof, we will show that $\sum_i |\lambda_i(\Delta)| \leq b$.

Because Δ is symmetric and real-valued, $\Delta = U^\intercal \Lambda U$ for a diagonal matrix $\Lambda = \mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ of eigenvalues λ_i of Δ, and orthonormal U. Let $\hat{\Lambda} = \mathrm{diag}(|\lambda_1|, \ldots, |\lambda_n|)$ be the diagonal matrix of absolute values of Δ's eigenvalues, and $\hat{\Delta} = U^\intercal \hat{\Lambda} U$. Define $\sigma_i = \mathrm{sgn}(\lambda_i)$ (with $\mathrm{sgn}(0) := 1$), and $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_n)$ to be the diagonal matrix of signs of λ_i, so that $\hat{\Lambda} = \Sigma\Lambda$. Then, $\hat{\Delta} = U^\intercal \Sigma U \Delta = U'\Delta$, where $U' = U^\intercal \Sigma U$ is a unitary matrix. Because U' is unitary, its entries are bounded by 1 in absolute value. We can therefore bound

$$\sum_i |\lambda_i(\Delta)| = \mathrm{tr}(\hat{\Delta}) = \mathrm{tr}(U'\Delta) = \sum_i \sum_j u'_{i,j} \delta_{j,i} \leq \sum_{i,j} |\delta_{j,i}|.$$

We have shown that the sum of absolute eigenvalues of a (real symmetric) matrix is bounded by the sum of absolute values of its entries[7]. It remains to bound the sum of absolute entries of Δ. Because the degrees (row sums) are the same, i.e., d_i, for M as for P, we obtain that $\delta_{i,j} = \frac{m_{i,j} - p_{i,j}}{d_i^{1/2} d_j^{1/2}}$. Summing their absolute values over all i, j, this is exactly the objective function of the LP (2), which we assumed to be bounded by b. □

Theorem 6.2 (Theorem 1 of [31]). *If A, B are $n \times n$ Hermitian matrices, their eigenvalues can be enumerated in such a way that for every real-valued convex function Φ on $\mathbb{R}$, we have $\sum_i \Phi(\lambda_i(A) - \lambda_i(B)) \leq \sum_i \Phi(\lambda_i(B - A))$.*

6.2 Cut Rounding

As outlined in Section 3, the cuts corresponding to small λ_k are particularly important for global connectivity properties. Our rounding procedure therefore first focuses on matching those eigenvalues. The main point of comparison is the Fiedler cut $(S^*, \bar{S^*})$ of the input graph G^*; without loss of generality, we assume that $|S^*| \leq n/2$. Ideally, we would like to focus on rounding edges across the Fiedler cut of the fractional graph P, so as to match $\lambda_2(G^*)$. However, it is possible[8] that the Fiedler cut of P is extremely unbalanced, with one side only having a handful of nodes. Efforts to round such unbalanced cuts are largely misplaced.

Instead, we focus on the first approximately balanced cut defined by an eigenvector of P. Let $k \geq 2$ be smallest such that the smaller side of the cut defined by $S_k = \{i \mid x_{k,i} < 0\}$ (again, w.l.o.g. S_k rather than its complement) satisfies $|S_k| \geq \frac{1}{2}|S^*|$. We let $\boldsymbol{x} = \boldsymbol{x}_2, \boldsymbol{x'} = \boldsymbol{x}_k$ and refer to $(S_k, \bar{S}_k)$ as the *critical cut*. We write $d_i = \sum_j p_{i,j}$. Our heuristic is guided by the standard characterization $\lambda_2 = \boldsymbol{x} L(P) \boldsymbol{x}^\intercal = \sum x_i^2 - \sum_{i \neq j} x_i x_j \frac{p_{i,j}}{\sqrt{d_i d_j}}$.

When i and j are on opposite sides of the Fiedler cut,[9] their signs in $\boldsymbol{x}$ are opposite, making the term $-x_i x_j \frac{p_{i,j}}{\sqrt{d_i d_j}}$ positive in $\boldsymbol{x} L(P) \boldsymbol{x}^\intercal$. This motivates scoring each edge (i, j) based on $x_i x_j$ as candidates for removal (rounding $p_{i,j}$ down to 0) or addition (rounding $p_{i,j}$ up to 1). However, the heuristic of rounding edges in such a way suffers from two drawbacks:

(1) The degrees d_i and d_j are affected when the edge (i, j) is removed or added; the changes in the terms for edges (i', j) or (i, j') could offset the rounding progress.
(2) The Fiedler vector (and other eigenvectors) may change after removing or adding an edge (i, j), making it difficult to compute a set of edges to remove or add one by one.

Ideally, after each small change to some $p_{i,j}$, one should recompute the eigenbasis before continuing. This is computationally expensive, so instead we adapt an idea of the *NetMelt* algorithm, which was designed to identify good edge removals/additions to decrease/increase the spectral gap of an *adjacency* matrix [11]. We assign scores for each edge removal and edge addition. When working with the adjacency matrix, each edge removal/addition affects only one entry of the perturbation matrix E. For the Laplacian matrix, an edge removal or addition can change the spectrum also through the changes in the nodes' degrees (and thus the normalization).

To help safeguard against the possibility of perturbing many edges adjacent to the same node, thereby changing the degrees drastically and misestimating additional rounding effects, we designate a *budget* b for how many edges can be removed; once the budget has been exceeded, the Fiedler vector $\boldsymbol{x}$, eigenvector $\boldsymbol{x'}$, and scores are recomputed. In addition, if the (fractional) number of edges crossing the Fiedler cut is below 1, we stop the procedure. To keep the overall edge density reasonably constant, we alternate between edge removals (across the cut) and additions (on some side of the cut).

The central part of the rounding algorithm is the following *Critical Cut Rounding* procedure. It is called repeatedly from the overall rounding procedure (described further below), which handles special cases such as "disconnected" probability matrices P and very unbalanced Fiedler Cuts.

(1) Compute $L(P)$, the Fiedler vector $\boldsymbol{x}_2$, the spectral gap $\lambda_2(L(P))$, $\boldsymbol{x'}$ and $\lambda_k(L(P))$, and let $\delta = \lambda_k(L(P)) - \lambda_k^*(L(P))$ be the

[7] We suspect that this must be a well-known fact, but could not find a reference.

[8] We found that this only happened on input graphs with spectral gap less than .01 and with sparse edge density (for example, the Euro Road graph).

[9] The intuition behind the reasoning applies to $\boldsymbol{x'}$ as well, although the variational characterization of λ_k is more complex.

amount by which we would like to decrease λ_k. If $\delta < c$ (where c is a small constant) or the number of (fractional) edges crossing the critical cut or the Fiedler cut is less than 1, exit the Critical Cut Rounding procedure.

(2) For all (i,j) with $x'_i x'_j < 0$ (on opposite sides of the critical cut), let the score be $s_{i,j} = -\frac{x'_i x'_j p_{i,j}}{\sqrt{d_i d_j}} \geq 0$. All such edges (i,j) are removal candidates; we consider them in order from highest to lowest score.

(3) For all (i,j) with $x'_i x'_j > 0$ (on the same side of the critical cut), let the score be $s_{i,j} = \frac{x'_i x'_j (1-p_{i,j})}{\sqrt{d_i d_j}} \geq 0$. All such edges (i,j) are addition candidates; we consider them in order from highest to lowest score.

(4) Keep track of the following quantities: q is the sum of $p_{i,j}$ for all edges (i,j) that have been rounded, s the sum of all scores of alterations, and y the total change in entries in P (where positive and negative changes cancel out). Initially, all of q, s, y are 0.

(5) Until $q \geq b$ or $s \geq \delta/2$, or all addition and removal candidates have been processed:
- If $y \geq 0$, consider the removal candidate (i,j) with largest score $s_{i,j}$; otherwise, consider the addition candidate (i,j) with largest score $s_{i,j}$. (In either case, remove (i,j) from the candidates for the future.)
- If $s + s_{i,j} \leq \delta$ and (i,j) is not the last candidate edge keeping the critical cut connected, update the values as follows (otherwise, skip (i,j)):
  - If (i,j) was a candidate for removal, then set $p_{i,j} = 0$ and $y = y - p_{i,j}$; otherwise, set $p_{i,j} = 1$ and $y = y + (1 - p_{i,j})$.
  - In both cases, update $s = s + s_{i,j}$ and $q = q + p_{i,j}$.

(6) If any changes were made to P, repeat from Step (1).

$L(P)$ and the eigenvectors are computed only once for each overall iteration of the critical cut rounding procedure. An iteration terminates once the approximate score s reaches $\delta/2$, or the algorithm has reached its budget b. At this point, the critical cut and Fiedler cut are recomputed to check whether the algorithm has indeed reached its goal of ensuring $\lambda_k^* \leq \lambda_k \leq \lambda_k^* + c$, and to adapt should the cuts have changed. In our implementation, we use a constant of $c = .0001$ and a budget b equal to $\frac{1}{4}$ of the number of edges crossing the critical cut. When the Critical Cut Rounding procedure terminates, either all edges across the critical cut have been considered, or λ_k is a good approximation to the target: $\lambda_k^* \leq \lambda_k \leq \lambda_k^* + c$.

While Critical Cut Rounding is the key component to our rounding approach, we need to take care of special cases: disconnected template matrices P and extremely unbalanced Fiedler cuts. This is accomplished by the following *Cut Rounding* procedure.

(1) Consider the graph with edges (i,j) iff $p_{i,j} > 0$. If this graph is disconnected, then permanently discard everything except its largest connected component. For the remainder, consider only the remaining nodes.

(2) Compute $L(P)$, the Fiedler vector $\boldsymbol{x}_2$, and the spectral gap $\lambda_2(L(P))$. While the Fiedler cut is severely unbalanced (having fewer than five vertices on the smaller side of the cut), permanently discard the vertices on the smaller side, and recompute $L(P)$, $\boldsymbol{x}_2$, and $\lambda_2(L(P))$.

(3) If $\lambda_2(L(P)) - \lambda_2^*(L(P)) \geq c$ and the number of (fractional) edges crossing the Fiedler cut is at least 1, then perform Critical Cut Rounding, as described above. If Critical Cut Rounding made any changes to P, then repeat from Step (1).

(4) While the (fractional) number of edges crossing the Fiedler Cut is less than 1, round the largest fractional edge $p_{i,j}$ crossing the Fiedler cut up to 1.

In our experiments, the largest fraction of nodes ever disconnected was .5% (including nodes removed due to unbalanced Fiedler cuts).

When the Critical Cut Rounding procedure made the sum of fractional edges crossing the Fiedler cut less than one, the graph would be likely to become disconnected in the later independent rounding step. To prevent this, the final step rounds the largest fractional entry up to 1.

When there are remaining edges to round, we include them in the independent rounding stage described next; this does not change the expected density of edges across the critical cut.

We also experimented with using a dependent rounding scheme [25] that includes each edge with probability $p_{i,j}$, but correlates the random choices so that the the number of edges crossing the Fiedler cut exactly matches the expectation (up to fractional parts). Experimentally, we found the performance of both approaches comparable, so we did not include dependent rounding in our final algorithm.

6.3 Independent Rounding

The final step is to include each remaining edge (i,j) independently with probability $p_{i,j}$, akin to the generation of $G(n,p)$, SBM, or Kronecker graphs. The following theorem by Chung and Radcliffe bounds the resulting spectral perturbations.

Theorem 6.3 (Theorem 2 of [16]). *Let G be a random graph, generated by including each edge (i,j) independently with probability $p_{i,j}$. Let A be the adjacency matrix of the random graph, and $\delta = \min_i \sum_j p_{i,j}$ the minimum expected degree of any node. For every $\epsilon > 0$, there exists a constant $k = k(\epsilon)$ such that if $\delta > k \ln n$, then with probability at least $1-\epsilon$, all eigenvalues of $L(A)$ and $L(P)$ satisfy $|\lambda_i(L(A)) - \lambda_i(L(P))| \leq 3\sqrt{\frac{3\ln(4n/\epsilon)}{\delta}}$.*

7 EXPERIMENTAL EVALUATION

We evaluated our generative model (*SpectralGen*) against the Configuration Model (*Config.*), Stochastic Block Model (*SBM*), and Kronecker graph model (*Kronecker*), based on many real-world data sets, and using a number of metrics.

7.1 Data, Models, and Metrics

Data Sets. We report on results[10] from running on several standard network data sets, available for download from https://icon.colorado.edu/#!/networks, and https://tuvalu.santafe.edu/~simon/styled-9/styled-10/. They are a network of flights between 500 commercial airports in the US, weights representing the number of

[10] We also ran experiments on several other (smaller) network data sets from the Colorado repository: Political books, Football, High School dynamic contacts, Computer Science Faculty Hiring, Physicians social network, Irvine student forum, Jazz. The results were similar to those reported here.

seats (*Airport*), an email exchange network between members of a university (*Email*), self-reported friendships between high school students (*Health*), a road network made up of European cities and roads (*Euro Road*), and links between Wikipedia pages on editorial norms (*Wiki*). Even when the input network was directed (e.g., Wikipedia), we treated the edges as undirected. In addition to these real-world networks, we include a grid graph in our evaluation to test if our method can prevent generating an expander when the target is far from one.

For all networks (input graphs and generated networks), we focused on the the largest connected component rather than the entire graph. This avoids difficulties in comparing spectra or assigning arbitrary distances to disconnected pairs of nodes. We also removed all self loops. The input graphs used and their basic parameters (of the largest connected component) are summarized in Table 1.

	Num Vertices	Num Edges	Spectral Gap	Fiedler Cut Conductance

Email	1133	5452	0.1211	0.1617
Health	2535	10455	0.0379	0.0654
Euro Road	1039	1305	0.0005	0.0093
Grid 900	900	1740	0.0029	0.0299
Wiki	1872	15367	0.1295	0.5135

Table 1: Basic properties of the input graphs.

Generative Models. We generated networks using the following four models. For the first three, we implemented the models ourselves in MATLAB.

SpectralGen. Our own model, as described in Sections 3–6.[11]

Config. The configuration model [5, 41], matching the input degree sequence.

SBM. For the SBM [29], we used the Fiedler cut to find a high-level bipartition, then fit the edge densities across this partition and within each set to the input graph. Without knowledge of the number of clusters that best fit the SBM to the ground truth graphs, we use two blocks, and choose the edge densities so as to match the conductance across the Fiedler cut in expectation.

Kronecker. The Kronecker model [36], fit and generated using the Stanford Network Analysis Platform (SNAP) [38], to generate a network of size 2^k which is closest to n (the input graph's size). We used the default initial gradient descent matrix and initiator matrix size and 100 gradient descent iterations.

Evaluation Metrics. We compared the four models along multiple network properties.

Spectrum. The difference between the spectra of the generated graphs and the spectrum of the input graph. Doing well for this metric was the main goal of our work.

Path Length Distribution. Distribution of lengths of shortest paths from s to t for all vertex pairs (s, t).

Clustering Coefficient Distribution. Writing $T(v)$ for the number of triangles that v participates in, the clustering coefficient of v is $\frac{T(v)}{d_v(d_v-1)}$, the fraction of pairs of neighbors of v that are neighbors of each other.

Betweenness Centrality Distribution. Letting $\sigma_{s,t}$ denote the number of shortest paths between s and t, and $\sigma_{s,t}(v)$ the number of shortest paths from s to t that pass through v, the betweenness centrality of v is $\sum_{s,t\neq v} \frac{\sigma_{s,t}(v)}{\sigma_{s,t}}$.

Degree Distribution. Frequency for each degree.

All graph properties were computed using the Python Networkx library. For betweenness centrality, clustering coefficients, degree distributions, and path length distributions, we evaluated how close the distribution of the generated graph was to the distribution of the input graph using the (one-dimensional) Earth Mover's Distance (EMD). EMD is a well-suited distance measure between distributions for our purpose because it increases when more probability mass needs to be shifted, or it needs to be shifted larger distances. For example, we want to consider graphs more similar if path distances are mostly off by 1 than when they are mostly off by 5.

To compare EMD results across different graph properties, we normalized each distribution to the unit interval: more specifically, when computing the EMD between two empirical distributions, we normalized the elements in the supports of both distributions by dividing them by the largest element in the union of their supports. We compute the loss reductions (or increases) of our method as

$$\Delta = (\text{mean EMD BB} - \text{mean EMD SpecGen})/(\text{mean EMD BB}),$$

where "BB" is the *best* benchmark (having the smallest average EMD).

7.2 Results

Figure 1 shows plots of the first 50 eigenvalues of the graphs generated according to the different models; we plot the average and standard deviation for each eigenvalue across 20 runs. The eigenvalues tend to be tracked closer by our method than by the other generative models.

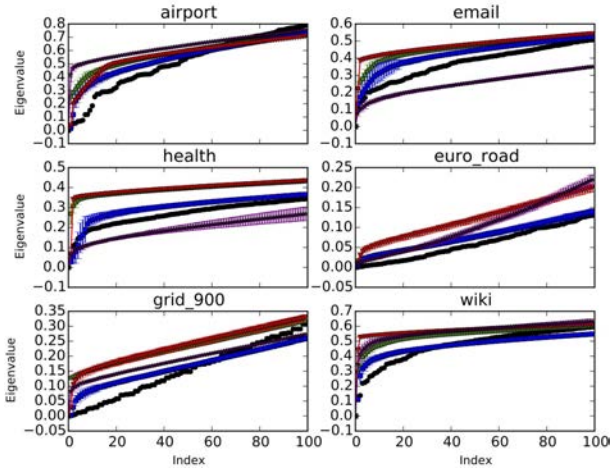

Figure 1: Comparison of spectra. Input graph (black circles), SpectralGen (blue squares), Config (green hexagons), SBM (red triangles), Kronecker (purple stars).

[11] The code is online at https://github.com/alanadakotashine/spectral_generation.

Next, we report the mean and standard deviation EMD[12] of each graph property discussed above for each generative model. These data are reported in Table 2. The spectral generation approach generally outperforms the benchmarks for shortest path lengths and clustering coefficients; however, there are two exceptions.

Our method does not match shortest path lengths on the Wikipedia graph well. This is likely due to the large discrepancy (.384) between the conductance across the Fiedler cut and the spectral gap of the Wikipedia graph, since we observed similar behavior on other graphs with this discrepancy. For graphs with such a large discrepancy, using the density of the Fiedler cut as a stand-in for the graph conductance is a poor approximation.

We included the grid graph in our evaluation, because it is explicitly *not an expander*, while most graph models tend to generate expander graphs. Indeed, our method matches path lengths and betweenness centrality significantly better. It does not do well on clustering coefficients, because it generates too many triangles.

The results are mixed on betweenness centrality. The EMDs for betweenness centrality are smaller than the EMD for other graph properties, which indicates that all methods, including ours, track betweenness centrality reasonably well relative to other graph properties.

The spectral generation approach does not match the degree distribution as well as the configuration model. This is unsurprising considering that the configuration model is designed explicitly to match the degree distribution, making mistakes only when it generates self-loops or multi-edges.

7.3 Evaluating Algorithm Components

Our approach utilizes multiple heuristics. To study the contribution of each heuristic to the final result, in Figure 2, we plot (for two graphs) the spectra obtained by leaving out various steps. We also compare the spectra against those of simple thresholding approaches as they seem to be utilized by [52]. In addition to the spectra of the input graphs, we show the spectra of six matrices.

(1) The result of using the initial template matrix C from the configuration model (with entries $c_{i,j} = d_i d_j / m$), and applying our rounding procedure from Section 6, without first applying LP (1). C is a reasonable candidate for rounding because it matches the degrees of G^*, and all its entries are already in $[0, 1]$.
(2) The template matrix output by the LP (1). This matrix may have entries outside $[0, 1]$.
(3) The matrix output by the LP (2), which forced entries from the template inside $[0, 1]$.
(4) The final rounded output using the Stiefel manifold optimization along with the LP (1) for relaxed spectrum fitting.
(5) The final rounded output without using the Stiefel manifold optimization, but only using the LP (1) for relaxed spectrum fitting.
(6) We derive the following random graph using methods similar to [52]. We combine the spectrum of the target graph and a uniformly random orthonormal matrix X to define the Laplacian matrix $L = X \Lambda X^\intercal$. A graph is produced by simple thresholding: the edge (i, j) is included iff $l_{i,j} < \theta$ (recall that a Laplacian matrix has negative off-diagonal entries for (i, j) that correspond to edges), with the threshold θ chosen so that the number of edges matches the target.
(7) Again in the spirit of [52], we consider a thresholding of our template matrix M. In this case, we include all edges (i, j) with $m_{i,j} > \theta$, again choosing θ such that the number of edges matches the target.

[12]Statistics are taken over $k = 20$ runs for all graphs.

Table 2: Models' Performance for matching graph property distributions and loss reduction.

Our experimental results show that the template matrix spectrum closely matches the desired spectrum; thus, the deviation in the final spectrum is mostly a result of pushing the template matrix entries into $[0, 1]$, then rounding them. Using C as a template and using our rounding scheme normally suffices to produce strong performance on the spectral *gap*, but fails to match the other eigenvalues. This demonstrates that a careful choice in template helps preserve more of the spectrum. Thresholding the Laplacian and adjacency matrices performs poorly not only on the overall spectrum, but even on the spectral gap. This confirms that a more careful rounding procedure and generation of a suitable template are necessary to generate graphs matching a desired spectrum.

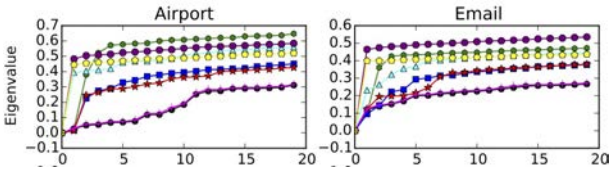

Figure 2: Spectra of matrices produced by employing different sets of heuristics. Input graph (black circles), rounding an unfitted matrix (green hexagons), fitted template matrix (magenta plus), fractional graph (cyan triangles), output graph without Stiefel (blue squares), output graph with Stiefel (red stars), thresholding the Laplacian (yellow pentagons), thresholding the adjacency matrix (purple octagons).

We observe that the Stiefel manifold optimization did not always improve performance of the final result, but more often than not provided small improvements. However, for large graphs, the computation becomes expensive.

8 CONCLUSION

We developed heuristics for randomly generating graphs whose Laplacian spectra approximately match that of a given input graph. Our experiments on multiple real-world network data sets show that for other graph parameters of interest, too, the graphs generated in this way match their real-world counterpart as well as or better compared to several widely used generative models.

Our work is nowhere near the final word on the subject, but should instead be considered as an invitation to the community to focus on spectral properties as an important criterion in random graph generative models.

Among the most obvious directions for future work is to devise faster heuristics. While our approach scales to graphs of several thousand nodes, real-world networks of interest often have millions of nodes; we would like to generate graphs of this size that match global spectral properties of given networks.

A second natural direction is to derive sampling algorithms with *provable* guarantees. The most obvious desirable guarantee would be that the spectrum of the generated graphs be "close" to Λ^* *provably*, or alternatively, that the distribution of deviations can be characterized. An even stronger type of guarantee would be to show that the generated graphs be drawn (nearly) *uniformly* from a suitable class of graphs with spectra similar to Λ^*.

A (perhaps more likely) alternative would be to prove hardness results. Paralleling the two tasks described in the previous paragraph, hardness results could come in two varieties: (1) show that deciding whether graphs exist whose Laplacian spectrum is close to a given Λ^* is hard, or (2) show that sampling nearly uniformly from graphs with the desired Laplacian spectra is hard.

The motivation for our work was that the spectrum naturally characterizes global connectivity properties. However, it is not the only graph metric to do so, and one could consider several others. For example, an alternative approach would be to sample graphs G such that for every partition $(S, \bar{S})$ of the vertices, the conductance (or expansion, or number of edges, or some other parameter) is approximately the same as in G^*. An obvious downside of this approach is that even to verify whether G is similar to G^* in this sense requires inspecting exponentially many cuts instead of linearly many eigenvalues, unless more efficient algorithms are designed.

Finally, the initial motivation for our work raises a very intriguing general direction. We implied (in Section 1) that even when local properties (such as degree distributions, triangle counts, other motifs) of a graph are fixed, generating graphs under such constraints still produces expander graphs with high probability[13]. Without any qualifications, this claim is definitely false — for example, a 3-regular graph in which each node participates in 3 triangles must be the union of disjoint 4-cliques, not an expander. However, under a careful formalization, we believe that such a claim should hold true, and it would be desirable to corroborate the intuition that local motifs do not constrain global structure enough to prevent most graphs from being expanders.

ACKNOWLEDGMENTS

ABSTRACT

Modern enterprises rely on Data Leakage Prevention (DLP) systems to enforce privacy policies that prevent unintentional flow of sensitive information to unauthorized entities. However, these systems operate based on rule sets that are limited to syntactic analysis and therefore completely ignore the semantic relationships between participants involved in the information exchanges. For similar reasons, these systems cannot enforce complex privacy policies that require temporal reasoning about events that have previously occurred.

To address these limitations, we advocate a new design methodology for DLP systems centered on the notion of Contextual Integrity (CI). We use the CI framework to abstract real-world communication exchanges into formally defined information flows where privacy policies describe sequences of admissible flows. CI allows us to decouple (1) the syntactic extraction of flows from information exchanges, and (2) the enforcement of privacy policies on these flows. We applied this approach to built VACCINE, a DLP auditing system for emails. VACCINE uses state-of-the-art techniques in natural language processing to extract flows from email text. It also provides a declarative language for describing privacy policies. These policies are automatically compiled to operational rules that the system uses for detecting data leakages. We evaluated VACCINE on the Enron email corpus and show that it improves over the state of the art both in terms of the expressivity of the policies that DLP systems can enforce as well as its precision in detecting data leakages.

1 INTRODUCTION

Modern enterprises rely on Data Leakage Prevention (DLP) systems [12, 20, 27, 28, 39] to prevent the flow of sensitive information such as credit card and other business data to unauthorized entities. Rather than combating malicious behavior by end users, the goal of these systems is to prevent unintentional data leakage. This goal is accomplished by monitoring whether information flows (e.g. extracted from emails) adhere to a set of rules [35] that encode the organizational data handling policies, industry-specific regulations, and general privacy laws, and block or flag those flows that violate the rules. This monitoring process may be performed online as data is in motion, or offline to audit data that is in rest.

We will argue later that a key issue in the design of existing DLP systems is that they conflate the problem of extracting information flows from information exchanges and the problem of checking whether these flows are admissible. As a consequence, the tremendous progress made in natural language processing and machine learning techniques had little impact on modern DLP systems. Moreover, the rules that can be expressed in these systems fail to meet the demands imposed by the increasingly complex privacy policies and regulations that they must enforce. Specifically, they cannot account for contextual information such as consent, which involves reasoning about histories of information flows. The recent General Data Protection Regulation (GDPR) by the European Union is just one example of a privacy policy where such contextual notions are prevalent.

To address these limitations, we advocate a new design methodology for DLP systems centered on the notion of Contextual Integrity

(CI) [30]. The key idea behind this methodology is to view real-world communication exchanges as sequences of information flows as defined by the CI framework. A CI flow represents an atomic information exchange unit identified by the sender, recipient, attribute (i.e. data) being exchanged, and the subject associated with the attribute. CI flows carry the essential information being communicated in information exchanges while abstracting from the low-level details of these exchanges. Privacy policies are modeled as contextual norms that describe flow sequences admissible in a particular privacy context. DLP systems based on this view allow one to take advantage of advances in natural language processing techniques for extracting CI flows on one hand, and advances in formal methods for specifying and automatically enforcing privacy policies on the other hand.

The main technical contribution of this paper is VACCINE, a DLP auditing system for emails that follows this new CI-based design methodology. VACCINE provides users with a simple but expressive language for the declarative specification of complex privacy policies. In particular, it supports policies that require a DLP system to reason about the history of past information flows, which is not supported by other existing DLP systems in this general form. The policies are automatically compiled to sound-by-construction rules, implemented as SQL queries. These queries are used to check the admissibility of the extracted information flows.

VACCINE further leverages advanced techniques in natural language processing [23], such as syntactic dependency parsing [13], name entity recognizers [26], and question answering models [34], to efficiently extract contextual flows from complex email corpora. It combines rule-based and model-based techniques into a single combined model learned end-to-end in a generator-discriminator setting using distant supervision techniques.

We have evaluated VACCINE by applying it to the Enron email corpus [9, 36]. Compared to flow extraction used in existing DLP systems, we achieve improvements in F1 accuracy in detecting attributes by 4% and subject pairs by 32%. We have also used VACCINE to describe and enforce Enron privacy policies extracted from corporate privacy handbooks on the flows extracted from the email corpus. Our experiments demonstrate that VACCINE is effective at detecting violations of complex privacy policies in a real-world corporate setting.

2 DESIGN METHODOLOGY

In this section, we discuss the limits of commercial DLP systems and outline our new design methodology. For a detailed comparison with related work, see Section 5.

To check whether a particular information exchange such as sending an email is admissible, a DLP system has to solve two subproblems, as illustrated in Figure 1. First, it has to extract the (implicit) information flows from the information exchange. For instance, suppose Bob sends an email to Alice containing the phrase: *"You can find Mary's address below. Her credit card number is..."*. This email, thus, contains the implicit flow that Bob sends Mary's credit card data to Alice. Once this flow has been extracted, the second subproblem is then to check whether it is admissible according to the specified rules. For example, if a rule can disallow *any* flow of credit card data via email whatsoever, then Bob's email would be blocked or flagged as a data leakage. However, a more refined rule could include an additional relevant contextual information that, e.g., only disallowed flows with *Alice's* credit card data from Bob to Mary. In this case, the information flow would not be blocked.

Hence, the administrator of a DLP system has to provide two types of inputs to the system: (1) a specification of the information flows to be extracted from information exchanges, and (2) a specification of the rules that determine which of these extracted flows are admissible.

The issue with the design of current DLP systems is that, from the perspective of the administrator, these two types of information are conflated. The rules are specified directly in terms of the underlying information exchange format using combinations of regular expressions, templates, keywords, or text patterns. This severely limits the capabilities of these systems. In particular, the focus on regular expressions means that these systems cannot easily deploy more sophisticated flow extraction techniques based on natural language processing. For instance, the fact that the credit card data sent in Bob's email belongs to Mary cannot be captured by a regular expression because the flow extractor has to establish the identity of "Mary" and the possessive adjective "her" in the two consecutive sentences of the email, which involves a more complex analysis of the grammatical structure of these sentences.

It is therefore not surprising that current DLP systems only consider very basic notions of information flows and rules. While they can reason about senders and receivers of information flows like Bob and Alice, which can be easily extracted from the header of the email, there is no notion of a subject whose information is being transmitted, like Mary in our example. This, in turn, limits the expressivity of the rules that can be checked by these systems. For example, a more sophisticated DLP policy could demand that the flow from Bob to Alice is admissible as long as it is Bob's credit card number that Bob is sharing. Without the notion of a subject of the transferred information, such policies cannot be expressed.

A related limitation of existing systems is that their rules can only refer to a single information exchange (the email from Bob to Alice in our example). This means that they can only take into account very limited contextual information. For instance, a reasonable privacy policy could demand that the flow from Bob to Alice is only admissible if Mary has given explicit consent to sharing her information. Checking such policies requires reasoning about the history of information flows that happened in the past, which cannot be done in existing systems. However, such policies are common in privacy laws such as GDPR [1], which these systems are meant to enforce.

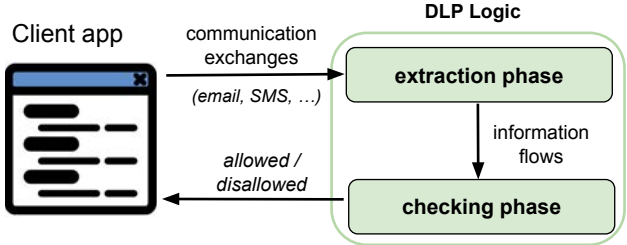

Figure 1: Illustration of an the enforcement mechanism that comprises two main phases: extraction and checking

2.1 Solving the Conflation Problem

Naturally, to solve the conflation problem, we need to separate the extraction and checking phases to make way for a modular DLP system architecture that is parameterized by the solutions to the two phases. A key technical challenge in achieving such separation is in defining a suitable information flow abstraction between the two phases. This abstraction will need to support seamless integration of customized solutions for each of the phases and needs to encompass relevant aspects of the communication exchanges and be amendable to different types of policies. Furthermore, the separation of extraction and checking phases in policy enforcement enables a natural division of labor in the process of implementing rules. For instance, on the one side, NLP experts can focus on devising techniques for extracting information flows from communication exchanges. On the other side, legal scholars and lawyers can focus on the task of checking that information flows obey the policies of interest, not worrying about the low-level details involving actual communication exchanges.

In this regard, the account of privacy [30] as contextual integrity offers a compelling answer to the question of how to tackle the aforementioned issues. It offers a) a suitable abstraction to decouple and interface between the extraction and checking mechanisms, and b) a common language for encoding legal policy and regulations such as FEPRA, HIPAA, and DLP rules into privacy rules. Moreover, CI overcomes the conflation problem by enabling the use of existing techniques tailored for the flow extraction and flow checking phases.

Next, we give a brief introduction to CI and also discuss how the theory and framework can be used to model the data leakage problem.

2.2 Contextual Integrity Overview

The theory of contextual integrity (CI) postulates that informational privacy is not all about secrecy (blocking information) [31] or control [44] but about the appropriateness of information flow within a particular context. Appropriateness of flow means flow that is compliant with contextual norms governing informational flows. To express an informational norm one must specify key parameters: *actors* (senders, recipients and subjects), *attributes* (the type of information at hand) and *transmission principles* (the constraints imposed on a particular information flow). Taken together, these components constitute context-relative informational norms. For instance, in the health context, the patient, acting in his capacity as both the sender and subject of an information flow, could be telling his doctor, the recipient, about his health issues, the attribute. The information flow would be constrained by the transmission principle of confidentiality, which restricts the onward flow of this information to other parties. Exchange the doctor for a friend, and the transmission principle might be reciprocity instead, since friends tend to expect to hear about each other's problems. A patient, by contrast, does not expect to hear about the health issues of his doctor. This is because the context of health and the context of friendship have different overarching goals: the doctor is there to promote the patient's health; friends are there to support each other. An informational norm is breached when an action or practice disrupts the actors, attributes, or transmission principles within a given information flow. Contextual integrity "is preserved when informational norms are respected and violated when informational norms are breached" [30].

It is worth emphasizing one of the most fundamental aspects of CI, namely that, in order to determine whether or not information flows respect or violate privacy expectations within a given context, one must address all three parameters: actors, information types, and transmission principles. Omitting any one of them may lead to an inconclusive or ambiguous description. Accordingly, any formal rendering of information flows, for the purpose of assessing their appropriateness, needs to include independent variables for these parameters. Defining privacy [30] in terms of CI is now a well-established approach in the privacy and computer science research communities. It is used to describe contextual informational norms, to detect infractions of these norms, and in approaches to accountability and enforcement [5, 17].

2.3 Data Leakage Detection using CI

In its core, the theory of CI offers a way to reason about the appropriateness of an information exchange. An *information flow* is the atomic unit of an information (*attribute*) exchange between *actors*. Information flow is formally defined by a tuple:

```
[sender, recipient, subject, attribute]
```

Actors (sender, recipient, subject) take on different roles/objectives that define the capacity in which they function in a given context such as doctors, teachers, or network middleware. Appropriateness of information flow, within a particular context, is defined using contextual informational *norms*. A norm consists of:

```
[Sender, Recipient, Subject, Attribute,
                    Transmission principle]
```

Here `Sender`, `Recipient`, and `Subject` refer to roles and `Attribute` to the type of information exchange under a specified `Transmission principle` condition. For instance, in the educational setting, where information exchange between actors is regulated by the FERPA policies, *a teacher* (sender role) would be allowed to share *grades* (attribute) of a *student* (subject role) to her *parents* (recipient role) if the student has given *explicit written permission* (transmission principle) [42]. If the student has not given such a permission, flows from the teacher to a student's parents involving her grades must not be allowed, i.e., such information exchanges are not appropriate. Thus, it is important to realize that contextual norms specify the appropriateness of a flow subject to conditions that may depend on the history of previous information flows.

We can use the above CI model to define a data leakage. In CI terms, a data leakage occurs within a particular context when an information exchange (flow sequence) is not deemed appropriate by any of the specified contextual norms. We use the above as a system abstraction for building real-world DLP systems that prevent data leakage by only allowing sequences that are consistent with the norms. More formally, we denote the flow sequences that the system deems admissible with T_s and the contextual informational norms of a privacy context as a set of flow sequences, T_n. A DLP system is designed to *correctly* enforce a privacy context by guaranteeing that $T_s \subseteq T_n$. i.e., the system exhibits flow sequences allowed by the given norms.

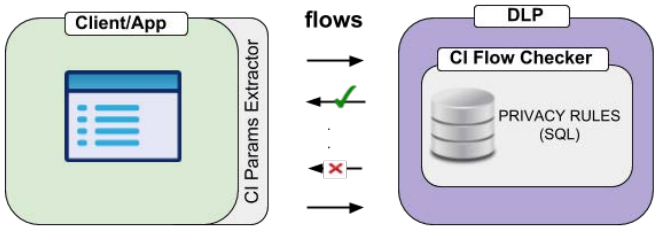

Figure 2: *VACCINE:* Information exchanges are processed by the CI Parameters Extractor that forms corresponding CI flows that are then fed into CI Flow Checker to check for violations with respect to existing privacy norms

3 VACCINE

We next describe our Verifiable and ACtionable Contextual Integrity Norms Engine (VACCINE), a DLP system for email communication based on CI. As illustrated by Figure 2, VACCINE maps information exchanges at the application level to the corresponding CI flows and checks them against the specified CI norms. The information flow abstraction is used to communicate the required contextual information to the checking mechanism.

Specifying norms. Norms can originate from a combination of external sources such as privacy handbooks and context specifications. Other external sources may also be used as a base for CI norms in a specific domain, such as legal and policy documents, professional codes of conduct, findings of empirical social scientists, privacy advocates, ethicists, stipulations of sponsoring organizations, etc. To express contextual norms, VACCINE provides a logic for specifying what flows are admissible based on past events. For example, a norm might state "Allow information flows from Alice to Bob with Mary's credit card information, *provided Mary previously gave Alice permission to do so*".

Enforcing norms. For this task, VACCINE operationalizes norms into a set of actionable privacy rules by automatically compiling norms into SQL queries which then check if a given flow is admissible taking into account the history of previously observed flows. To enforce the norms, VACCINE first extracts the respective flows from the email text with the help of the CI Parameter Extractor and then uses the CI Flow Checker to see whether the extracted flows are admissible by running the respective SQL queries.

VACCINE's approach offers intrinsic benefits to the design of DLP systems. First, it achieves *modularity in design* as a result of decoupling the extraction and checking phases in policy enforcement. Second, it increases the *expressiveness of privacy rules* due to its support for CI based norm enforcement. Finally, it supports *obfuscation of sensitive information* through the use of the CI framework that only captures the type of information being conveyed, not the actual data.

In the following, we describe the two key components of the system in more detail. We also briefly describe the temporal logic that we use for expressing the CI norms that are enforced by the CI Flow Checker.

3.1 CI Flow Extractor

The CI flows comprise the CI parameters extracted by the CI parameter extractor. As depicted in Figure 2, the parameter extractor detects the relevant CI parameters associated with each information exchange such as actors (sender, recipient, subject) and the type of information (attribute) and map them onto CI flows. The extractor retrieves the sender and the intended recipients from the underlying protocol's metadata. This is the straightforward bit compared to the task of identifying attributes and the corresponding subjects, which requires a more sophisticated approach. For example, if the policy states that "John's financial information" should not be transferred without his permission, the CI extractor needs to identify all patterns of text that correspond to financial information like, *bank accounts, SSN*, etc. Similarly, for each attribute type mentioned in the privacy policy text, the CI extractor needs to identify the CI subject, in this case *John*. The resulting CI flow will comprise of the extracted parameters:

```
[sender,
        financial information (attribute),
                John (subject),
                                recipient]
```

To tackle the attribute-subject task, we combine a suite of natural language models using recent advances in distant supervision techniques to identify the mentioned attributes and link them to the appropriate subjects. We assume that the relevant CI parameters are retrieved from the policy either manually or with the assistance of an automatic CI parameter detection algorithm [37].

Extracting attributes. The CI extractor needs to identify the instances of the abstract information types included in the rules (policy). For example, if the rule applies to financial information, the extractor needs to detect all possible related instances in the text such as SSN, bank information, credit card number and so forth. This many-to-one mapping makes it difficult to use a single model to detect all instances of a given attribute. To tackle this issue, we adopt the Snorkel [32] framework to generate a large amount of training data using a small number of annotators with weak supervision to increase accuracy. This approach helps to bootstrap our model to annotate CI parameters in emails using a small number of human curated annotators. As Figure 3 shows, we use the labels outputs of multiple models to train a generative annotator choice model. Namely, we import regular expressions corresponding to each attribute[1]. Secondly, we include name entity recognizers which use a dictionary mapping to known types of nouns to identify numeric and non-numeric attributes [23]. Lastly, we use the syntactic structure to identify the nouns associated with subjects. The outputs from each of the models is used to train a simple logistic classifier on these labels. The resulting unsupervised annotator choice model performs better than the majority vote of all annotators by modeling the agreement between various annotators. The high precision, low coverage probabilistic labels provided by the generative model is trained to discriminate by a fully connected feedforward neural network against gold labels annotated by humans on a small set of information flows.

[1]There can be more than one pattern for attribute like "phone number". See http://regexlib.com/Search.aspx?k=phone

Extracting subjects. For this task, similarly to attribute detection, we use the output of a three model mixture to train a generative annotator choice model for subjects. The annotator models set comprise: 1) a heuristic model that matches the entity closest in syntactical proximity to the attribute using a name entity recognizer (NER) 2) a model to detect matching subject-object using syntactic dependency parse trees, 3) a state-of-the-art conversational question answering model (BiDAF) [34] which encodes the email text and a question whose answer is the desired subject of an attribute into an embedding to perform semantic dimensionality reduction. For example, if the attribute detected is a phone number, the question posed to the QA model is "Who should we call?".

3.2 CI Logic

As explained in Section 2.2, a system execution in VACCINE can be abstractly seen as a timed sequence of CI flows. That is, a set of contextual informational norms describes those flow sequences that are allowed in a given privacy context. We next introduce a logic, `TFlow`, for expressing privacy norms that can be automatically converted into actionable rules used to check whether given information flows obey the specified norms.

Syntax. `TFlow` allows the declarative specification of CI flow sequences where the admissibility of a flow in a sequence can depend on whether other flows have or have not been observed. More precisely, `TFlow` is a variant of metric linear temporal logic [3, 15, 22, 40], which has been used to formalize CI-based privacy frameworks in other settings. We here adapt this logic to the specific setting of DLP and identify several important restrictions that enable the efficient checking of these norms in a DLP system. One important restriction is that we allow only temporal operators that can reason about flows that have happened in the past, which makes the logic suitable for both offline and online monitoring. The syntax of the logic is as follows:

$$\phi \in \texttt{TFlow} ::= \phi_1 \textbf{ and } \phi_2 \mid \phi_1 \textbf{ or } \phi_2 \mid \textbf{not } \phi \mid \textbf{exists } x.\ \phi \mid \phi_1 \textbf{ since } \phi_2 \mid \textbf{flow}(x_1, x_2, x_3, x_4) \textbf{ where } P(\vec{x})$$

Atomic formulas $\textbf{flow}(x_1, x_2, x_3, x_4)$ **where** $P(\vec{x})$ are used to describe flows from a sender x_1 to a receiver x_2 concerning attribute x_3 of subject x_4 such that the formula $P(\vec{x})$ holds. Here P is a Boolean combination of basic predicates, such as equality between variables $x \in Var$ and constants $c \in C$. In the case that $P(\vec{x})$ is simply *true*, we omit the **where** clause for convenience. Constants include numbers, strings, and other common data structures encoding agents and attributes of the target CI context. Temporal formulas of the form ϕ_1 **since** ϕ_2 are used to express that at some point in the past the formula ϕ_2 held after which all later time steps satisfied the formula ϕ_1. The semantics of existential quantification (**exists** $x.\phi$), logical conjunction (**and**), disjunction (**or**), and negation (**not**) are as expected.

Contextual norms are typically expressed as `TFlow` formulas of the form

$$\textbf{flow}(snd, rcp, att, sub) \textbf{ and } \phi(snd, rcp, att, sub)$$

where *snd*, *rcp*, *att*, and *sub* refer to the parameters (agents and attribute) of the flow being checked for admissibility, and ϕ is a formula specifying the transmission principle of the norm.

Examples. As a first example, let us consider a simple generic norm $norm_g$ stating that everybody can send their own data to themselves. This norm can be expressed in `TFlow` as

$$norm_g(snd, rcp, att, sub) \stackrel{\text{def}}{\equiv} \textbf{flow}(snd, rcp, att, sub) \textbf{ where } snd = sub \textbf{ and } snd = rcp.$$

As another example, suppose we want to express the $norm_p$ stating that an agent *snd* can share an attribute of an agent *sub* if *sub* has previously given *snd* an explicit permission to do so, and *sub* has not revoked the permission since then. This norm can be formulated in `TFlow` as

$$norm_p(snd, rcp, att, sub) \stackrel{\text{def}}{\equiv} \textbf{flow}(snd, rcp, att, sub) \textbf{ and } ((\textbf{not flow}(sub, snd, \langle -, permission, att\rangle, sub)) \textbf{ since } \textbf{flow}(sub, snd, \langle +, permission, att\rangle, sub)).$$

Here, we use the term $\langle +, permission, att\rangle$ to indicate that permission of sharing *att* has been granted, and similarly $\langle -, permission, att\rangle$ to indicate that this permission has been revoked.

We point out that existing DLP systems cannot handle the second norm because it involves reasoning about flows that occurred in the past. It is also instructive to point out that the above formulation of the norms does not depend or involve lower-level details of communication exchanges, thereby achieving the level of abstraction needed for separating the checking phase from the extraction phase.

Formal semantics. The formal semantics of `TFlow` formulas can be defined in terms of timed sequences of flows. In this work, we take an equivalent approach where a flow sequence is modeled as a table of flows where each row in the table contains the arguments of one flow in the sequence together with its timestamp indicating when the associated flow occurred. Hence, the flow sequence can be reconstructed from the flow table using this timestamp information.

The satisfiability of a `TFlow` formula ϕ is defined by a satisfiability relation $T, \Gamma, i \models \phi$ which states that ϕ holds at time point i in the flow trace given by flow table T and subject to the variable assignment Γ, which maps the free variables of ϕ to values. For instance, here are the formal definitions of the satisfaction relation for the two most important constructs in the logic:

$$T, \Gamma, i \models \textbf{flow}(x, y, z, w) \textbf{ where } P(\vec{x}) \quad \text{iff } f \in T(i) \text{ and } \Gamma[x \mapsto f(1), y \mapsto f(2), z \mapsto f(3), w \mapsto f(4)](\vec{x}) \in I(P)$$

$$T, \Gamma, i \models \phi_1 \textbf{ since } \phi_2 \quad \text{iff } T, \Gamma, j \models \phi_2 \text{ or } i > 0 \text{ and } T, \Gamma, i \models \phi_1 \text{ and } T, \Gamma, i-1 \models \phi_1 \textbf{ since } \phi_2$$

In the above, we use $T(i)$ to denote the flows in T with the timestamp i. Similar notation is used for accessing constituent elements of a flow f. Lastly, we assume that the function I provides the interpretation for basic predicates expressing constraints on variables

and constants. We omit the full details of the semantics as it is standard [15, 22]. We note that the above semantics directly supports extensions of TFlow to metric temporal logics where formulas can explicitly refer to time points.

3.3 CI Flow Checker

We have implemented our flow checker on top of an SQL database. The database maintains a table FH of all the flows that have been accepted so far. Checking whether a new flow f obeys the norms expressed in TFlow amounts to checking if FH extended with f satisfies any of the norms. Each norm $\phi(\vec{x})$ is automatically compiled to an SQL query that produces a table with one column per free variable in $\vec{x}$ as well as a timestamp column. This table contains one row per timestamp i and valuation Γ for $\vec{x}$ such that $\mathsf{FH}, \Gamma, i \models \phi$ holds. Thus, if the query for any of the norms contains an entry for the current timestamp i, then the new flow is accepted and permanently added to FH. Otherwise, it is rejected.

The algorithm for generating the SQL queries is defined recursively on the structure of formulas and closely follows from the semantics of TFlow. However, a naive encoding into SQL yields queries that do not scale well, in particular if we must deal with nested **since** formulas and unconstrained negation. We therefore discuss several restrictions and optimizations to a naive encoding that considerably improves the performance.

Syntactic restrictions. In order to support the automatic compilation of TFlow formulas into efficient SQL queries, we impose some restrictions on TFlow. First, the free variables in the subformulas of disjunctions have to be identical. Further, all variable must occur as a parameter in some **flow** predicate. Finally, we require that every negative formula **not** ϕ_1 that occurs in a positive context is guarded by a positive formula ϕ_2. A formula is positive if it contains no unguarded negative formulas and a formula occurs in a positive context if it occurs under an even number of **not** operators. A negative formula **not** ϕ_1 is guarded by ϕ_2 if these formulas occur either as (**not** ϕ_1) **and** ϕ_2 or as (**not** ϕ_1) **since** ϕ_2 where all the free variables of ϕ_1 also occur free in ϕ_2.

For instance, in the norm $norm_p$ given in § 3.2, the negative formula (**not** **flow**$(sub, snd, \langle -, permission, att\rangle, sub)$) is guarded by the positive formula **flow**$(sub, snd, \langle +, permission, att\rangle, sub)$ below the **since** operator. This restriction of the logic to a *guarded fragment* is particularly important because it ensures that negative subformulas can only be used to prune the result tables obtained from positive subformulas. This restriction enables us to cache the evaluation of subformulas in dedicated tables which can then be updated incrementally using simple queries as new flows are added to the history table FH. We describe this process in more detail below. Without this restriction, the evaluation of temporal formulas involving the **since** operator cannot be done efficiently (i.e. without reevaluating the entire history of flows each time the norm is checked). For otherwise, to enable caching we would have to know in advance the entire universe of values for agents and attributes that may appear in a future flow. We found that these syntactic restriction did not affect the expressivity of the logic in practice.

Compiling norms to efficient SQL. Our optimized compilation process associates a unique SQL table T_ϕ with every subformula of a norm that needs to be checked. These tables cache the satisfaction relation for ϕ with respect to the current history table FH. Thus, when we check a norm ϕ, we can simply query the associated cache table T_ϕ directly. These cache tables are updated whenever a new flow is added to the history table and time advances to a new timestamp. The updates are computed recursively according to the structure of the subformulas.

For instance, suppose ϕ is of the form (ϕ_1 **since** ϕ_2) and we extend the history table FH with a new incoming flow f at time i. Then we first update the caches for the subformulas ϕ_1 and ϕ_2 recursively to account for the update. To update the cache for ϕ itself, note that according to the semantics of **since**, FH extended with f satisfies ϕ at timestamp i iff either ϕ_2 is satisfied at i or ϕ_1 is satisfied at i and ϕ already holds at the previous timestamp i'. In effect, this means that the table for ϕ can be updated as $T_\phi \triangleq T_\phi \cup T_{\phi_2}(i) \cup (\pi_t(T_\phi(i')) \circ T_{\phi_1}(i))$. Here, $\circ$ stands for inner join (on the common columns), and π_t projects out the timestamp column in a given table. The cache table for an atomic formula $\phi \triangleq$ **flow**(x, y, z, w) **where** $P(\vec{x})$ is updated with the results of the following generic SQL query:

```
SELECT snd AS x, rcp AS y, att AS z, sub AS w
FROM FH WHERE P(x⃗)
```

Here, we assume the case where $\vec{x} = (x, y, z, w)$. If P has free variables other than x, y, z, w, these variables are additionally added as columns in the SELECT clause. Those columns are then populated with all possible values in FH using appropriate subqueries. The syntactic restrictions on free variables in norm formulas ensure that this encoding is both sound and complete.

4 EVALUATION

In this Section, we present results of evaluating the key components of VACCINE in a corporate setting. We first evaluated the CI parameter extractors that form the basis of the combined CI extractor individually on the emails from the Jeb Bush Presidential campaign. We then present an end-to-end case study of data leakage protection using VACCINE on the corpus of emails associated with the Enron corporation [9, 36]. We detail the accuracy of VACCINE parameter extraction techniques on the Enron email dataset, the extraction of contextual norms (expressed in TFlow) for the Enron corporate privacy context, performance numbers on evaluating the norms using the VACCINE SQL-based flow checker, and the benefits of using VACCINE for real-world data leakage protection.

4.1 Extraction Microbenchmark

We compared the efficiency of the CI flow extraction against manually annotated emails from the Jeb Bush Presidential campaign [2]. We manually annotated 436 attributes and 72 subject parameters. Table 1 summarizes the performance of the components used in the Snorkel based CI parameter extraction. Some of the failures of the model can be attributed to genuinely ambiguous natural language in the email. A typical example is the following sentence: *"Can you tell me if you have plans to amend the drivers license laws, so that as I, Florida homeowner from the UK, can have a drivers license for*

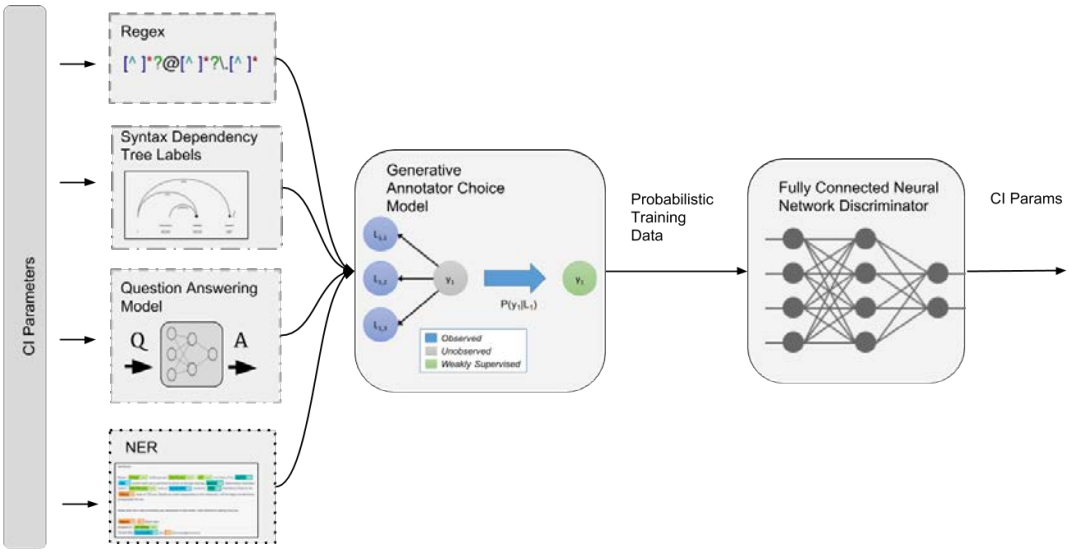

Figure 3: CI Parameters Extractor. We combine outputs from multiple models to train a generative annotator choice model, which we subsequently use to train a fully-connected neural network discriminator for extracting relevant CI parameters.

6 years as I used to have". Here, the manually annotated subject was *"I"*, but the model's output was *"Florida"*. Similarly, for attribute detection, many of the failures are due to the jargons used within an organization which can be confused for affiliations. This makes the case for continuous improvement of the model through active learning once a system like VACCINE is deployed to keep up with the evolving language patterns.

Table 1: Benchmark of CI parameter extraction from Jeb Bush's emails

Model Type	Parameter Type	F1 Accuracy (%)
Regex	Attribute	71.56
NER	Subject	56.94
QA	Subject	61.11
QA+Query Rewrite	Subject	63.88

4.2 Enron Case Study

We have evaluated VACCINE's DLP system performance for offline auditing of email communication. For this experiment, we used the Enron corporation email corpus [9, 36]. Specifically, we aimed to answer the following questions:

(1) How effective is the VACCINE framework in preventing potentially unauthorized flows in a real-world emulated context?
(2) How efficiently can CI flows be checked against the privacy rules automatically generated from `TFlow` norm descriptions?

We chose the Enron corporation for our enterprise context since both its code of ethics [43] as well its email dataset are publicly available [9, 36]. From Enron's code of ethics we extracted CI parameters for an enterprise context. We identified 145 agents with 12 company roles, such as director, manager, and regular employee. We assigned roles to employees, identified by their email addresses, using publicly available data sources [18, 41]. We also identified 13 attributes, such as social security number, visa number, address, etc. Our focus was on emails containing the exchange of sensitive information such as passwords, bank account information, phone numbers, etc. We thus identified 73 emails involving exchange of such information and extracted 87 corresponding CI flows. We used these flows to evaluate the effectiveness and efficiency of VACCINE. All of the experiments were carried out on an `Intel(R) Xeon(R)` machine with eight 3.6GHz cores.

4.2.1 Norm Extraction. We identified 40 Enron contextual norms that focus on access and disclosure of personal identifiable information (PII) in a corporate setting. The norm creation process was conducted over the available documentation of Enron's code of ethics and its organizational structure. Due to the lack of a publicly available (Enron) enterprise privacy handbook that specifies precise norms, we created norms to enforce a simulated *ethical wall* on email communication between Enron employees. An ethical wall [29] refers to establishing an environment that will prevent information exchange between specific departments within the organization to avoid any conflicts of interest. Our norm extraction process focused on each type of PII and how agents in the various enterprise roles can exchange the corresponding attributes. A typical example of a norm is: *Enron employees can send their social security number to administrative managers.* This norm in our policy language `TFlow` is expressed as

$$norm_{SSN}(s,r,a,b) \stackrel{\text{def}}{\equiv} \textbf{flow}(s,r,a,b) \textbf{ where } s = b \wedge a = \text{“}SSN\text{”} \textbf{ and } in_role(s, \text{“}employee\text{”}) \textbf{ and } in_role(r, \text{“}manager\text{”}).$$

Here, the *in_role* predicate is defined using the **since** construct in a similar fashion to the predicate of having a permission in Section 3.2. In contrast, employees are allowed to send their less sensitive information, such as phone number and addresses to anyone without restrictions. This norm is captured in `TFlow` as

$$norm_{PII}(s,r,a,b) \stackrel{\text{def}}{\equiv} \textbf{flow}(s,r,a,b) \textbf{ where } s = b \wedge (a = \text{“}phone_number\text{”} \vee a = \text{“}address\text{”}).$$

Also, the distribution of information belonging to other Enron employees can be done if the subject employee gave a permission for the disclosure of such information. This norm specified in `TFlow` is essentially the norm $norm_g$ introduced in Section 3.2.

4.2.2 Identifying Contextual Information. To evaluate the extraction of CI parameters, we manually annotated our corpus of selected emails (73) with attributes such as phone number and conference call codes and CI subjects corresponding to them. As a baseline accuracy for extracting relevant attributes without taking any contextual information into account, we used regular expression based models (regex) for detecting attributes. These models are similar to the ones currently available in tools like Google DLP and Microsoft Exchange.

Results Table 2 shows that by aggregating multiple regular expressions using a distant supervised framework called Snorkel [32], gives an improvement of 4% points in F1 accuracy. For subjects detection, it is close to 1% F1 accuracy. Combining results from the QA model using the “Who should we call?” question with other NER based models increases the accuracy by almost 4%. Narrowing context by posing a question that includes an attribute, e.g., "Whose phone number is 123-456-7890?", leads to increased accuracy by a further 9%.

Table 2: Accuracy of CI parameter extraction from Enron emails

Model Type	Parameter Type	F1 Accuracy (%)
Regex	Attribute	90.20
Snorkel	Attribute	**94.80**
NER	Subject	48.35
QA	Subject	67.12
Snorkel	Subject	71.83
QA+Query Rewrite	Subject	**80.82**

4.2.3 Leakage Detection Performance. The purpose of our next experiment was to measure the general performance of checking flows against the extracted norms. First, we automatically compiled the extracted Enron norms to SQL queries that we then evaluated against approximately 6700 Enron flows, consisting of our manually extracted flows and initial flows used to set up the organizational structure of the company. For instance, the fact that agent a is an employee is modeled as the flow

$$(enron_inc, enron_inc, \langle +, in_role, employee\rangle, a).$$

Intuitively, this flow encodes that a has been previously given a role of a regular employee in the Enron corporation. We also use the initial flows to incorporate reasonable assumptions about disclosure privileges for PII information, say, that within each department (i.e., role), employees can disclose each other’s phone numbers.

Our implementation of the SQL flow checking engine follows the high-level algorithm introduced in Section 3.3 except that we cache only since formulas in auxiliary tables. We only maintain the rows with the latest timestamp in cache tables as they are the only once needed for proper updating in the future. We use Sqlite3 as our relational database. Lastly, we compressed 40 Enron norms into 12 succinct ones as many of them shared the same structure except that they differ slightly in the specific **where** conditions. For instance, consider a norm stating that managers can disclose employee phone numbers to CEOs and a norm stating that managers can disclose employee phone numbers to directors. We compress these two norms into a single one where managers can disclose employee phone numbers to either CEOs or directors.

Results The performance times are reported in Table 3. We provide measurements for flow checking in general and its breakdown subject to accepted and blocked flows. We also provide information on time spent performing cache updates while checking flows. As it can be seen, average time spent analyzing a flow is reasonable. We point out that rejecting a flow takes more time than accepting it. This is because we implement a form of short-circuit evaluation of the norms where a flow is accepted as soon as we encounter a norm that is satisfied. The remaining norms then no longer need to be evaluated. We note that the initial flows for setting up the organizational structure are always accepted, accounting for the high number of accepted flows.

Table 3: Performance times (in seconds) for SQL checking of flows against the Enron norms

	total	avg	med	min	max	sd
flows (6706)	184	0.027	0.027	0.004	0.054	0.012
accepted (6658)	181	0.027	0.026	0.004	0.053	0.012
blocked (48)	2.54	0.052	0.052	0.051	0.054	0.001
cache upd.	95	0.007	0.0003	0.0002	0.0001	0.008

We also measured how flow checking times vary depending on how the history flow table grows. The results are shown in Figure 4. Flow checking times grow linearly with the size of the table, i.e., the number of accepted flows in the past. The outliers in the graph mostly correspond to the checking of flows that occur at the end of the experiment where we check the flows extracted from the Enron emails containing sensitive information. On the other hand, initial flows are always accepted by exactly the same norm, so the performance of analyzing such flows is more stable. The reported numbers can be improved by employing more sophisticated algorithms used in work on runtime policy monitoring [15, 22].

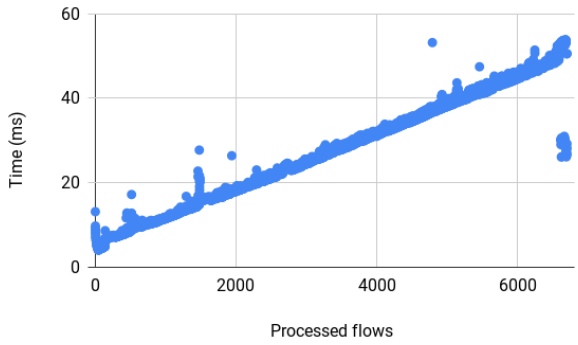

Figure 4: Flow checking performance (in miliseconds) through time

4.2.4 Detecting Information Leakages. The flows rejected in the previous experiment constitute data leakages subject to the identified contextual Enron norms. We note that the flow checking experiment does not suffer from false positives or false negatives. This is due to the fact that the flows used in the experiment were manually extracted and SQL queries implementing the norms are sound by construction (as described in Section 3.3).

In our next experiment, we have analyzed the nature of emails from which the rejected flows were extracted.

Results Arguably, the most interesting case of rejected flows involves visa information. VACCINE rejected a flow between two Enron employees where the sender was sharing visa information about a third party subject. More precisely, the sender was sharing the type of the visa in question, its expiration date, and the information that the subject was granted multiple entries to the United States. To the best of our understanding, the subject had not previously granted the sender with a permission to share such confidential information.

The vast majority (44) of rejected flows involves distribution of passcodes/passwords and phone numbers for company conference calls. Our implementation of VACCINE rejected such flows as we did not extract or create any contextual norms governing the distribution of conference call metadata. In effect, VACCINE conservatively treats such flows as data leakages. VACCINE also prevented a flow where a third party resumé was shared between two Enron employees. Our current norms only allow agents to share their own resumes. Lastly, our implementation also blocked a flow between a third party and one of the higher-ranked Enron employees where the flow subjects were Enron bank accounts. Although careful inspection of the corresponding email did not show any actual leakage of sensitive company information, our norms were deliberately designed to contain the communication exchanges involving confidential company data within Enron.

These experiments show that VACCINE provides an effective tool for data leakage prevention, modulo an effective flow extractor.

4.2.5 Complexity of Email Communication Exchanges. In our last experiment, we measured how many CI flows are typically generated in an email conversation. We note that a single email can generate multiple flows between different participants. This is because an email often quotes other emails that have been sent earlier in the same conversation. In such cases, the new email also generates *transitive flows* involving subjects and attributes from the quoted emails to the new recipients.

Table 4: Statistics for each of the 2000 Enron email conversations

	Total	Min	Avg	Max
Emails	78,386	1	39	15,555
Participants	11,609	1	17	2,428
Threads	4,082	1	2	196
Flows	218,070	1	109	85,280

We grouped the emails in the Enron data set into conversations. We then defined an email conversation as a set of emails with the same email subject (modulo reply and forwarding prefixes, etc.). We extracted from each email a set of quadruples (one per recipient) consisting of the sender email address, a recipient email address, the time the email was sent, and the recipient type which can be `TO`, `CC`, and `BCC`, omitting the email content and other metadata. Here is an example of such a tuple:

```
(tracy.geaccone@enron.com,
 sarah.taylor@enron.com,
                2001-11-27 12:48:05,TO)
```

We identified every unique email address with a unique participant. For emails sent to mailing lists, we simply simulated broadcasting the email to all of the active conversation participants.

Out of the whole Enron email data set, we randomly chose 2,000 email conversations involving approximately 80,000 emails and 11,500 participants in total, as shown in Table 4 (first and second row). We used the email time and recipient type fields to recreate email threads for each conversation. There are two email threads per conversation on average, as shown in Table 4 (third row). Due to some missing information in the data set, we observed cases where participants sent emails in the middle of the conversation although they never received any emails in the conversation up to that point. In our analysis, such emails start a new conversation thread, which explains multiple threads per conversation. We used the extracted email threads to generate CI information flows. To model the worst case scenario in terms of the information flow complexity, whenever an email is sent by some sender in a conversation, we assume the sender creates new content and also transitively sends all of the emails in the conversation up to that point. Also, a CI flow has a subject and attribute. For the purposes of this experiment, the actual subject and attribute values are not important. For transitive flows, however, the subject is the sender of the corresponding email that is being quoted.

Results Given the above dataset, we measure how many flows an email yields in practice. As it can be already inferred from Table 4, a single email yields 2.78 flows on average. Moreover, Figure 5 shows the frequency distribution of emails depending on the number of flows they generate. It can be seen that the flow-per-email ratio is in general low, reaching 15 at maximum. This suggests that the load on a DLP (auditing) system created using VACCINE will be tolerable in practice. This is further evidenced by Figure 6 showing a linear increase in the number of generated flows subject to a total number of thread emails.

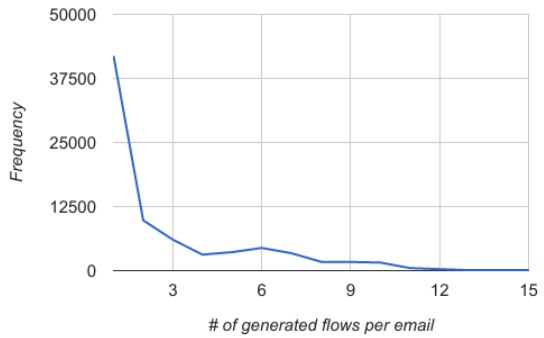

Figure 5: Email frequency distribution based on the number of generated flows per email

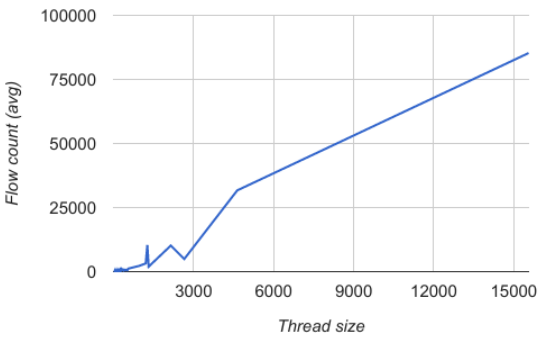

Figure 6: Average number of generated flows per size of the conversation thread

5 RELATED WORK

We already discussed how VACCINE compares to existing commercial DLP solutions in Section 2. The research community has explored sophisticated email DLP methods mostly relying on a combination of machine learning and related classification techniques. These approaches roughly fall under content- and behavior-driven methodologies [35]. Content-based approaches [10, 11, 21, 25] determine the sensitivity of a message based on textual content analysis, either through keyword, regex pattern matching, or machine learning techniques. Behavior-based approaches [24, 38, 45] analyze the organizational structure, common roles and duties, as well as past interaction to identify "normal" behavior patterns and use them to detect unlikely information flows between a pair of sender and recipient. Our work is largely orthogonal to these approaches. While prior solutions explored advancing techniques in identifying insensitive data and malicious behavior patterns, VACCINE instead focuses on providing a robust way to express, administer, and enforce complex DLP policies.

Early work by Armour et.al., looked at designing a privacy compliance engine for emails [4, 7] to prevent privacy violations in large enterprise settings. Similar to our system, their engine comprises an information extraction and violation detection module. The information extraction module relied on an enterprise domain ontology, part-of-speech and semantic tagging to find relevant information in the email text. While the work positions itself as a privacy compliance tool, it does not go beyond facilitating role-based access control to information. Namely, the implicit assumption here is that roles and ownership determine the right to access. In particular, it does not support complex policies involving e.g. notions of consent that require reasoning about the history of observed emails. Furthermore, VACCINE takes advantage of the advances in NLP techniques since this pioneering work. We are not aware of other work that took the ideas in [4, 7] and developed them beyond the preliminary proposal explored there.

Related Work using CI. Defining privacy [30] in terms of CI is now a well-established approach in the privacy and computer science research communities. It is used to describe contextual informational norms, to detect infractions of these norms, and in approaches to accountability and enforcement [5, 17]. Much of the prior work in this space has focused on sophisticated formal logics for describing CI norms that involve complex temporal properties of sequences of information flows such as those involved in HIPAA [6, 14, 16, 19]. We build on these earlier works and adapt them to the specific needs of the DLP setting. Our observation is that in this setting, a simpler logical framework is sufficient to express the relevant norms. With these restrictions, norms can be automatically compiled into SQL queries. The encoding into SQL enables the use of our system in applications where both robustness and efficiency of the DLP engine are important factors.

Compliance-based Approaches. Numerous approaches have been invented to map system constraints to privacy policies that are generated external to these systems. Two examples, are due to Sen, et al. [33] and Breaux and Anton [8]. Sen, et al. have developed LEGALEASE, a language with precise semantics that enables enterprises to express privacy policies against which practices can be checked for compliance. With similar goals, Breaux and Anton have proposed a methodology for extracting implementable software requirements from privacy and security regulatory requirements expressed in legal language that is sometimes vague and ambiguous. The intention in both systems is similar to our own in that it seeks to translate privacy requirements expressed in natural language (assuming this covers legal language) into formally expressed rules that allow for compliance checking. The threat scenarios, however, are quite different.

6 CONCLUSIONS

We presented a new design methodology for building DLP systems based on the theory of Contextual Integrity that offers more precise and modular detection of information flow violations compared to traditional DLP systems.

Using our methodology, we built VACCINE, a system for auditing email communication corpora. VACCINE supports a powerful declarative language for specifying expressive privacy policies that are automatically compiled to sound-by-construction actionable rules, implemented as SQL queries. Furthermore, VACCINE

leverages advanced NLP techniques to efficiently extract relevant information omitted by the existing DLP systems.

In our evaluation, we used VACCINE to audit the Enron emails corpus and achieved significant improvement compared to the methods used by state-of-the-art systems.

7 ACKNOWLEDGEMENTS

We thank Paula Kift and Schrasing Tong for their help in the initial stage of this work. This work is supported by the following National Science Foundation (NSF) under grants CCF-1350574, CNS-1514422, CNS-1801501, CNS-1704527, SES-1537324, SES-1650589, the National Security Agency grant H98230-18-D-006 and the Cisco CG-653005 Research Award. We are also grateful to the NSF I-CORPS 1650769 grant that allowed us to discuss the data leakage problem with large number of companies and ultimately helped us with articulating the VACCINE problem.

ABSTRACT

One of the central challenges in online advertising is attribution, namely, assessing the contribution of individual advertiser actions including emails, display ads and search ads to eventual conversion. Several heuristics are used for attribution in practice; however, there is no formal justification for them and many of these fail even in simple canonical settings. The main contribution in this work is to develop an axiomatic framework for attribution in online advertising. In particular, we consider a Markovian model for the user journey through the conversion funnel, in which ad actions may have disparate impacts at different stages. We propose a novel attribution metric, that we refer to as *counterfactual adjusted Shapley value*, which inherits the desirable properties of the traditional Shapley value. Furthermore, we establish that this metric coincides with an adjusted "unique-uniform" attribution scheme. This scheme is efficiently computable and implementable and can be interpreted as a correction to the commonly used uniform attribution scheme.

1 INTRODUCTION

With the rise of the Internet, the digital economy has become a trillion dollar industry accounting for over 6% of the U.S. GDP [19]. A multitude of retailers reach consumers through online sources with the goal of acquiring new customers and managing relationships with the existing ones. Such wide range of economic activities taking place in the digital world has enabled data collection at a massive scale, allowing retailers to better understand customer behavior and enhance service quality using data-driven decisions. With over a billion people with access to the Internet, it is not surprising that advertising has moved to the digital space. The global digital marketing sector witnessed a growth of 21% in 2017, which increased its market size to USD 88 billion [44]. Key decisions in this space include allocating budget to various ad channels and media (e-mail, display media platforms, and paid search for instance) and bidding for ads to push one's product towards the desired customer demographic at the right time. Such problems require the retailer to understand the value of showing an ad via a specific channel at a given time. How can an advertiser assign or *attribute* value to the advertising actions taken across the different channels and media? *Attribution* is one of the central questions in online advertising today. The value of each channel is an important input to media mix optimization, helps build an understanding of the customer journey, and also helps a company to justify its marketing spend [38, 45]. Incorrect understanding of the effectiveness of online channels can result in sub-optimal budget allocation, possibly resulting in lost revenue. Recognizing the importance of this problem, the Marketing Science Institute identifies attribution as the topmost research priority for the period 2016-2018 [23]. Though there exist multiple articles in this domain, there lacks a systematic approach that is both theoretically-sound and tractable.

Attribution is inextricably linked to causality since it involves quantifying the added value of showing an ad over the baseline value of what *would have* happened if no ad was shown (*counterfactual*). In this work, we take the following view of causality, which comes from the pioneering work of Rubin [41]:

> *"Intuitively, the causal effect of one treatment, E, over another, C, for a particular unit and an interval of time from t_1 to t_2 is the difference between what would have happened at time t_2 if the unit had been exposed to E initiated at t_1 and what would have happened at t_2 if the unit had been exposed to C initiated at t_1."*

In the context of digital advertising, treatments E and C are the advertiser showing, and not showing an ad, respectively. Accordingly, attribution involves capturing the causal effect of an ad where the baseline corresponds to not showing an ad.

Causality is an active research area, and there exist paradigms for capturing the causal effect of a treatment. See, e.g. Chockler and Halpern [11], Collins et al. [13], Eells [16], Halpern and Pearl [20], Hitchcock [21], Hume [22], Morgan and Winship [35], Pearl [37] and Rubin [41]. We comment on some of these alternative approaches in our concluding remarks.

As with the existing work in attribution, we also consider the setting where an advertiser is interested in understanding the contributions of various ads to a single product they are promoting. Even with a single product, attribution is a challenging problem. It involves distributing the value generated by a network of actions to each individual action. Such a network might have a mix of interaction effects that one needs to account for when decomposing the network value. Capturing such (possibly non-linear) interaction effects is quite non-trivial.

1.1 Related literature

There exists a large and diverse literature on the attribution problem in online advertising. We present a brief overview of existing approaches and refer the reader to existing surveys [12, 28] for a more complete treatment. Attribution methodologies can be classified into two broad classes: *rule-based* or *algorithmic*. We discuss both the classifications below.

1.1.1 ***Rule-based heuristics.*** Rule-based heuristics include approaches such as *last touch attribution* (LTA), *uniform weights*, and *customized weights* [6, 38–40]. In LTA, an advertiser allocates all the value generated by a user to the last ad directed at her whereas under a uniform weights scheme, all the ads are allocated an equal credit. Ads receive tailored weights under a custom weights scheme. Although such heuristics are transparent and tractable, there is no rationale justifying their appropriateness as a measure for attribution. Metrics such as LTA appear unfair since they do not value the contribution of channels that build product awareness. Uniform or customized weights might appear to be a fix but there is no a priori reason to believe that attribution should be linear.

1.1.2 ***Algorithmic approaches.*** The algorithmic approaches can be classified as using either *incremental value heuristic (IVH)* (or *removal effect*) or *Shapley value (SV)* as a measure for attribution.

IVH. IVH computes the change in the eventual *conversion*[1] probability of a user when a specific ad is removed from her path. This is the most common metric for attribution [2–5, 15, 27, 29, 30]. In this approach, one calibrates a model that predicts the conversion probability as a function of the ad exposure and then, uses the estimated model to compute the incremental value of each ad. The novelty comes from the model proposed to describe user behavior, e.g., an HMM [2] or a neural network [4]. Irrespective of the prediction model's level of complexity, attribution is measured via IVH. There exists little (if any) formal justification for why IVH serves as a good approximation to attribution. In fact, in Section 3.2, we show that IVH can result in inappropriate allocations.

SV. SV [43] is a well-accepted concept for assigning credit to individual players in a cooperative game. The value generated by online advertising can be viewed as the outcome of a cooperative effect of the channels and media platforms. Dalessandro et al. [14] pose attribution as a causal estimation problem and propose SV as an approximation scheme for the causally motivated problem. They also show that SV generalizes the probabilistic model of Shao and Li [42]. Using a stylized model, Berman [8] shows the use of SV for attribution can be beneficial to the advertiser.

Other works. Attribution has been tackled from various other angles. Jordan et al. [26] use a Markovian model to motivate a payment scheme that satisfies incentive compatibility for the advertiser and is fair from the publisher's point-of-view. Xu et al. [46] propose a mutually exciting point process to capture dynamic interactions among various ads. Zhang et al. [47], Ji et al. [25], and Ji and Wang [24] provide an interesting view of attribution via the lens of survival theory. Under a stylized setting, Abhishek et al. [1] analyze attribution contracts used by an advertiser to incentivize two publishers that affect customer acquisition. Zhao et al. [48] propose a regression-based relative importance method to compute the marginal contributions.

1.2 Our approach and contributions

With almost a decade of research, it remains unclear as to what is an "appropriate" or "best" attribution measure. IVH appears to be the most popular; but, to the best of our knowledge, there exists little rationale supporting it. On the other hand, SV has a strong theoretical justification. It has a number of desirable properties such as *efficiency*, *symmetry*, *linearity*, and *null player*; in fact, SV is the unique solution to a cooperative game that has all these properties. However, estimating SV exactly is computationally intractable, and one has to resort to approximations [7, 10, 17, 31–34, 36]. In addition, as we show in Section 4.2, SV is not counterfactual in nature. We seek a metric that has the desirable properties of SV, and yet is tractable and able to accommodate counterfactual reasoning.

Our main contributions are as follows. First, we construct an abstract Markov chain model for the user journey through the conversion funnel that generalizes most of the existing Markovian models in the attribution literature. At every period, the user is in one of the finitely many *states*. The advertiser observes the state and takes an *action*. The user transitions to a random state distributed according to a probability mass function that depends on the current state and the advertising action. We propose attributing value to each state-action pair, which is a generalization of the existing approaches that attribute only to advertising actions. This extension allows us to capture state-specific attribution for each action, the need for which is motivated by Bleier and Eisenbeiss [9].

Second, using our Markovian model, we develop a series of intuitive canonical network structures that serve as a robustness check for any attribution scheme. Using these networks, we show the current attribution metrics (LTA, IVH, and uniform) have serious limitations. Furthermore, we show how one can compute state-specific SV for each action in our Markovian model and highlight that it does not adjust for the counterfactual and hence, is an inappropriate metric for attribution. To the best of our knowledge, this is the first work in the literature to analyze the various existing attribution metrics using a common framework.

Third, we develop an axiomatic framework for attribution in online advertising, which forms the main contribution of this work.

[1] Conversion refers to the event in which a user buys the underlying product.

In particular, we propose a new metric for attribution in the Markovian model of user behavior, that we refer to as *counterfactual adjusted Shapley value*. We show that our proposed metric inherits the desirable axioms of the classical SV. We also demonstrate its robustness to a mix of network structures that highlighted limitations of the existing metrics. In addition, we establish that our metric admits a crisp characterization under our Markovian model. It coincides with a *unique-uniform attribution scheme* that explicitly adjusts for the counterfactual. In turn, it can be interpreted as a correction to the commonly used uniform attribution scheme. Furthermore, we exploit this characterization to shed light on the ease of computability of our metric.

The remainder of this paper is organized as follows. In Section 2, we introduce the Markovian model that describes the user journey as a function of ad exposure. We discuss how the existing attribution schemes (LTA, IVH, and uniform) can be captured on the Markovian model and highlight their limitations in Section 3. In Section 4, we showcase the drawback of directly applying SV to measure attribution and then present our novel metric along with the axioms it satisfies. We then characterize our metric as an adjusted unique-uniform attribution scheme in Section 5 and discuss its ease of computability. We conclude in Section 6 where we also discuss some directions for ongoing and future research. Some technical results are deferred to Appendix A.

2 MODEL

We propose a Markovian model for user behavior. The transitions in user's state are stochastic, and are a function of only the current state and the advertiser action. This process ends when the user quits (leaves the system) or converts (buys the product). In Section 2.1, we define the components of the Markov chain (denoted by $\mathcal{M}$). When constructing the Markov chain, we keep most of its elements abstract to showcase its flexibility. In Section 2.2, we shed light on the abstractness through practical examples. We conclude this section by defining the attribution problem over our Markovian model (Section 2.3).

2.1 Markovian model of user behavior

We first discuss the state space of the Markov chain followed by the arrival process of the users. We then elaborate on the action space of the advertiser. Finally, we define the transition probabilities.

State space. We define $\mathbb{S} := \{s\}_{s=1}^{m}$ as the set of states excluding the two absorbing states (quit q and conversion c) and $\mathbb{S}^+ := \mathbb{S} \cup \{q, c\}$. In order to highlight the flexibility of our model, we do not yet give a concrete meaning to a state.

Arrival process. External traffic arrives at state $s \in \mathbb{S}$ w.p. λ_s (*initial state probability*). We define the vector $\lambda \in \mathbb{R}^m$ as $[\lambda_s]_{s\in\mathbb{S}}$. We assume no external traffic arrives at c and q.

Action space. We define $\mathbb{A} := \{a\}_{a=1}^{n}$ as the set of actions the advertiser can take, such as sending an email or showing a display ad. We include the no-ad action ($a = 1$)[2] in $\mathbb{A}$ and define β_s^a to be the probability that an advertiser takes action $a \in \mathbb{A}$ at state $s \in \mathbb{S}$. We denote by β the collection of all β_s^a values and assume it is known.

Transition probabilities. We denote by $p_{ss'}^a$ the probability a user moves from $s \in \mathbb{S}$ to $s' \in \mathbb{S}$ in one transition given the advertiser takes action $a \in \mathbb{A}$ at s. Also, for all $(s, s') \in \mathbb{S}^2$, we define $p_{ss'}^\beta := \sum_{a\in\mathbb{A}} \beta_s^a p_{ss'}^a$, which denotes the *average* transition probability. To keep the notation concise, for each $a \in \mathbb{A}$, we define the matrix $P^a := [p_{ss'}^a]_{(s,s')\in\mathbb{S}^2} \in \mathbb{R}^{m\times m}$. Furthermore, $P^\beta := [p_{ss'}^\beta]_{(s,s')\in\mathbb{S}^2} \in \mathbb{R}^{m\times m}$ and $B^a := \text{diag}([\beta_s^a]_{s\in\mathbb{S}}) \in \mathbb{R}^{m\times m}$ for each $a \in \mathbb{A}$ is a diagonal matrix. Clearly, P^β represents the transition matrix over the *partial* state space $\mathbb{S}$ and $P^\beta = \sum_{a\in\mathbb{A}} B^a P^a$. For all $s \in \mathbb{S}$, we define the vector $p_s^a \in \mathbb{R}^m$ as the s-th row of P^a for all $a \in \mathbb{A}$ and $p_s^\beta \in \mathbb{R}^m$ as the s-th row of P^β. Next, we state the only assumption we make on our problem primitives.

Assumption 2.1. *The Markov chain with P^β as its transition matrix is absorbing, i.e., the probability each user will eventually either quit or convert from any state equals 1.*

We note that Assumption 2.1 is very mild. So far, we have not discussed the transitions to and from states q and c. We use the notation p_{sc}^a and p_{sc}^β to denote the action-specific and average one-step transition probabilities from $s \in \mathbb{S}$ to c for all $a \in \mathbb{A}$. (For transitions from $s \in \mathbb{S}$ to q, replace the index c by q.) Since both q and c are absorbing states, the transitions from them are self-loops w.p. 1. We define $p_c^a := [p_{sc}^a]_{s\in\mathbb{S}} \in \mathbb{R}^m$ for each $a \in \mathbb{A}$ and $p_c^\beta := [p_{sc}^\beta]_{s\in\mathbb{S}} \in \mathbb{R}^m$. (Note that p_s^a and p_s^β for $s \in \mathbb{S}$ correspond to the probabilities of *leaving* s whereas p_c^a and p_c^β correspond to the probabilities of *entering* c.) Next, we shift our focus to three quantities of interest for this Markov chain.

Expected number of visits. We define $F^\beta \in \mathbb{R}^{m\times m}$ as the *fundamental matrix* of $\mathcal{M}$, i.e., its (i, j)-th entry equals the expected number of visits to state j if the initial state is i. Results in Markov chain theory [18] imply that $F^\beta = (I - P^\beta)^{-1}$ and Assumption 2.1 ensures that F^β exists and is finite.

Effective arrival rate. Let μ_s^β denote the *effective* arrival rate into state $s \in \mathbb{S}$ and $\mu^\beta := [\mu_s^\beta]_{s\in\mathbb{S}} \in \mathbb{R}^m$. It is easy to show that $\lambda^\top + (\mu^\beta)^\top P^\beta = (\mu^\beta)^\top$; hence, $(\mu^\beta)^\top = \lambda^\top F^\beta$.

Eventual conversion probability. We define h_s^β as the probability of eventually being absorbed in c from state $s \in \mathbb{S}$ and the vector $h^\beta := [h_s^\beta]_{s\in\mathbb{S}} \in \mathbb{R}^m$. It is easy to show that $h^\beta = P^\beta h^\beta + p_c^\beta$. Thus, $h^\beta = F^\beta p_c^\beta$. We set $h_q^\beta = 0$ and $h_c^\beta = 1$.

2.2 Model discussion

We have so far defined the state and action spaces in abstract terms. Now, we provide some possible mappings from physical quantities to these.

As a first possibility, the state may be composed of past interactions with the user, e.g., the number of visits to the product website, number of emails received, number of emails opened, number of display ads seen, number of display ads clicked, etc. The number of states may become too large, resulting in potential tractability issues. However, one can quantize the counts to control the size of the state space. The advertiser's action space includes doing nothing (no ad), or sending an email, or showing a display ad, etc.

[2] We are reserving $a = 0$ for future use as it will become transparent in Section 4.2.

As another possibility, the state space may correspond to the widespread conversion funnel used in the marketing literature which captures the journey of the user to the state of being unaware of the product to eventually becoming interested and finally purchasing. Given the fine granularity of data available to advertisers, we believe the advertiser can infer such states using an appropriate statistical model. The action space remains the same as above.

We note that the definitions of state and action spaces can be customized as per the needs of the advertiser (since our attribution framework is developed for the abstract Markovian model). In fact, the state space should very much be context-specific and driven by the user features that are relevant to a particular advertiser.

2.3 The attribution problem

The total value[3] generated by the network equals $\lambda^\top h^\beta$. The goal of an attribution model is to allocate this value to the underlying *agents* (state-action pairs)[4] in the system while accounting for the counterfactual. For any given $(s,a) \in \mathbb{S} \times \mathbb{A}$, we use π_s^a to denote the corresponding attribution. Naturally, a desirable property is that the total value in the system should be credited back to the agents, i.e., $\sum_{s\in\mathbb{S}} \sum_{a\in\mathbb{A}} \pi_s^a = \lambda^\top h^\beta$.

3 CURRENT APPROACHES & LIMITATIONS

We now define in our context the commonly used attribution schemes (LTA, IVH, and uniform) and illustrate their limitations. At a high-level, both LTA and uniform are "backward looking" in the sense that they split the value of a path after observing its realization (from the initial state to the end). LTA allocates all the value to the last interacting agent whereas uniform allocates it equally to all the agents that appeared in the path. On the other hand, IVH is "forward looking" since it attributes to a given agent based on what will happen in the future. It does not require the knowledge of how the actual path will unfold. All it requires is a model that can output the change in eventual conversion probability that results if the agent is removed from the path.

3.1 LTA

In LTA, all the value generated due to a purchase is attributed to the last state-action pair in the path. Denote by $\mathcal{P}$ a random path (over state-action pairs) sampled uniformly from $\mathcal{M}$. For $(s,a) \in \mathbb{S} \times \mathbb{A}$, define

$$\hat{w}_s^a(\mathcal{P}) := \begin{cases} 1 & \text{if } \mathcal{P} \text{ converts and } (s,a) \text{ is the last agent in } \mathcal{P} \\ 0 & \text{otherwise.} \end{cases}$$

The attribution to $(s,a) \in \mathbb{S} \times \mathbb{A}$ under the LTA scheme equals

$$\pi_s^{a,\text{LTA}} := \mathbb{E}_{\mathcal{P}\sim\mathcal{M}} \left[\hat{w}_s^a(\mathcal{P})\right].$$

In other words, (s,a) receives complete credit of each *converted* path it is the last agent of. Trivially, LTA attributes exactly all the value generated by the network (*efficient*) and is easy to implement. However, LTA appears "unfair" since the states are not rewarded for moving the user up in the conversion funnel. We demonstrate this limitation next.

[3]We assume that the sale of one unit of the product generates a value of 1. If the true number is different from 1, the numbers can be scaled accordingly.

[4]One might want to consider actions as the agents. However, we view the state-action pairs as the agents, because the impact of an action is likely to be state dependent.

Example 3.1 (LTA is unfair). Consider the network in Figure 1 with self-loop probability $p = 0$ (*line*). Under LTA, all the value goes to the ad action at state m although state 1 brings in all the traffic and the ad action at each state pushes the user towards conversion.

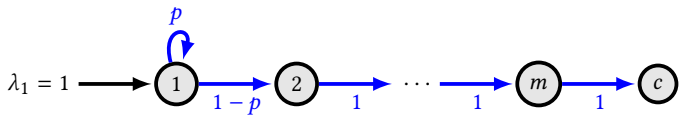

Figure 1: Network for Examples 3.1 and 3.4. The action space consists of two actions: show no-ad and show an ad. The lines denote transitions if an ad is shown. For brevity, we do not show the transitions if an ad is not shown (to quit state w.p. 1). The advertiser shows an ad at all states w.p. 1.

3.2 IVH

IVH allocates to each state-action pair (s,a) the increase in the eventual conversion probability by taking action a in state s as opposed to the no-ad action. For each $a \in \mathbb{A}$, we first define an auxiliary variable that captures the corresponding forward looking increment *conditioned* on the user being at a given state:

$$z^{a,\text{IVH}} := \underbrace{P^a h^\beta + p_c^a}_{\text{action } a} - \underbrace{(P^1 h^\beta + p_c^1)}_{\text{no-ad action}} = \underbrace{(P^a - P^1)h^\beta}_{\text{eventual}} + \underbrace{(p_c^a - p_c^1)}_{\text{immediate}},$$

where $z^{a,\text{IVH}} = [z_s^{a,\text{IVH}}]_{s\in\mathbb{S}} \in \mathbb{R}^m$. The scalar $z_s^{a,\text{IVH}}$ can be interpreted as the allocation at a "trace" level, i.e., if the advertiser observes a user at state s and decides to take action a, the corresponding allocation would be $z_s^{a,\text{IVH}}$. However, we need to scale this metric for it to be seen as attribution over the entire population. In particular, given that at state s, the effective arrival rate is μ_s^β and action a is taken w.p. β_s^a, the IVH attribution is given by

$$\pi_s^{a,\text{IVH}} := \mu_s^\beta \beta_s^a z_s^{a,\text{IVH}}.$$

Although IVH is tractable and somewhat adjusts for the counterfactual, a serious limitation is that it can distribute more value than the network generates because it pays for both eventual and immediate conversions; consequently, each conversion is accounted for several times. We now show that this is, indeed, possible.

Example 3.2 (IVH can over-allocate). Consider the network in Figure 1 with $p = 0$. Under IVH, all states receive an attribution of 1 for the show ad action and 0 for the no-ad action, resulting in a total allocation of m even though the value generated equals 1.

A common workaround to ensure IVH in budget-balanced is to normalize the output by an appropriate constant (*normalized IVH*). Normalizing the numbers in Example 3.2 results in the ad action at each state receiving $1/m$, which appears reasonable. However, as we illustrate in Example 3.3, even normalized IVH can be problematic.

Example 3.3 (Normalized IVH can be unjustified). Consider the network in Figure 2. IVH attributes 1 to state 1 and 1/2 for all other states. Thus, normalized IVH attributes

$$\begin{cases} \frac{1}{1+(m-1)/2} & \text{if state equals 1} \\ \frac{1/2}{1+(m-1)/2} & \text{otherwise.} \end{cases}$$

Clearly, as $m \to \infty$, all the value goes to states 2 to m. This appears inappropriate as state 1 "deserves" at least half the total value since 50% of the users convert immediately after state 1.

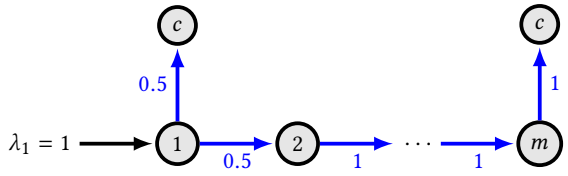

Figure 2: Network for Example 3.3. The action space consists of two actions: show no-ad and show an ad. Solid blue lines denote transitions if an ad is shown. For brevity, we do not show the transitions if an ad is not shown (to quit state w.p. 1). The advertiser shows an ad at all states w.p. 1.

3.3 Uniform attribution

Under a uniform attribution scheme, the credit generated is attributed equally to all the state-action pairs that are encountered in a path. Denote by $\mathcal{P}$ a random path (over state-action pairs) sampled uniformly from $\mathcal{M}$. For $(s, a) \in \mathbb{S} \times \mathbb{A}$, define

$$\bar{w}_s^a(\mathcal{P}) := \begin{cases} \frac{n_s^a}{|\mathcal{P}|} & \text{if } \mathcal{P} \text{ converts and } (s,a) \in \mathcal{P} \\ 0 & \text{otherwise,} \end{cases}$$

where n_s^a equals the number of times (s, a) appears in $\mathcal{P}$ and $|\mathcal{P}|$ denotes the number of state-action pairs in $\mathcal{P}$ (not necessarily unique). The uniform attribution for $(s, a) \in \mathbb{S} \times \mathbb{A}$ is

$$\pi_s^{a,\text{uni}} := \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[\bar{w}_s^a(\mathcal{P})\right]. \tag{1}$$

In other words, (s, a) receives an "equal cut" of each *converted* path it contributes to. Such a scheme is efficient and scalable. On the line network, it attributes $1/m$ to the ad action at each state, which seems reasonable. However, it does not account for the counterfactual. Furthermore, it creates undesired incentives, which we show next.

Example 3.4 (Undesired incentive). Consider the network in Figure 1 with $p < 1$. For a given path with n_1 occurrences of state 1, the uniform attribution scheme attributes $n_1/(n_1 + m - 1)$ to state 1. As p increases, state 1 receives more credit. However, this seems inappropriate since it gives an undesired incentive to the ad action at state 1 to "game the system" via self-loops. Ideally, an attribution scheme should incentivize the ads to push the user towards conversion.

Remark 3.1 (Unique-uniform). A simple fix to the above drawback is to attribute based on the number of unique agents. For instance, in the example above, the *unique-uniform* scheme would attribute $1/m$ to the ad action at each state. However, this scheme still does not account for the counterfactual, and there is no formal rationale for it. (In the following sections, we will see that adjusting for uniqueness is in fact supported by a strong mathematical rationale and will be part of our prescribed method.)

To summarize this section, the above examples highlight some limitations of existing heuristics but also point to the fact that no single heuristic "dominates the other." In some way, IVH possesses a counterfactual form giving it some practical appeal. At the same time, it is only forward looking, ignoring all past actions and their potential contributions. Uniform, on the other hand, accounts for past actions, but is not counterfactual. Ideally, an attribution scheme would provide the best of both worlds, properly accounting for past actions while also accounting for the counterfactual associated with not advertising.

4 SHAPLEY VALUE

We now study SV as a measure for attribution. We first present a primer on SV (Section 4.1) followed by a discussion on why a direct application to our context does not suffice (Section 4.2). We then adapt SV accordingly (Section 4.3) and conclude this section by discussing the performance of our proposed measure on all the motivating examples (Section 4.4). In this section, we hope to convince the reader that, leaving computational tractability aside, SV (adjusted for the counterfactual) is an appropriate metric for attribution.

4.1 Primer

SV is a well-accepted concept from cooperative game theory that is used to distribute the payoff generated by a *coalition* to the *players* in the coalition [43]. Given a finite set $\mathbb{P}$ of players, the *characteristic function* $v(\cdot)$ maps a coalition $\mathcal{X} \subseteq \mathbb{P}$ to the value (a real number) generated by the coalition. The value $v(\emptyset)$ of the empty coalition is normalized to 0. SV distributes the value $v(\mathbb{P})$ of the grand coalition to a player $r \in \mathbb{P}$ as follows:

$$\pi_r^{\text{Shap}} := \sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|} \times \{v(\mathcal{X}\cup\{r\}) - v(\mathcal{X})\},$$

where

$$w_{|\mathcal{X}|} := \frac{|\mathcal{X}|!(|\mathbb{P}| - |\mathcal{X}| - 1)!}{|\mathbb{P}|!}.$$

The attractiveness of SV is rooted in the fact that it is the *only* solution to a cooperative game that has the following four desirable properties:

1. **Efficiency**: $\sum_{r\in\mathbb{P}} \pi_r = v(\mathbb{P})$.
2. **Symmetry**: Consider players $r, r' \in \mathbb{P}$ such that for any $\mathcal{X} \subseteq \mathbb{P} \setminus \{r, r'\}$, r and r' are *equivalent*, i.e., $v(\mathcal{X} \cup \{r\}) = v(\mathcal{X} \cup \{r'\})$. Then, $\pi_r = \pi_{r'}$.
3. **Linearity**: Consider two characteristic functions $v(\cdot)$ and $w(\cdot)$. Linearity states that for all players $r \in \mathbb{P}$, $\pi_r(v + w) = \pi_r(v) + \pi_r(w)$ and $\pi_r(\alpha v) = \alpha\pi_r(v)$ for all $\alpha \in \mathbb{R}$.
4. **Null player**: Suppose player $r \in \mathbb{P}$ does not add any value to any coalition, i.e., for all $\mathcal{X} \subseteq \mathbb{P}$, $v(X \cup \{r\}) = v(\mathcal{X})$. Then, $\pi_r = 0$.

4.2 Direct application

SV is a natural candidate for decomposing network value because the state-action pairs can be viewed as players participating in a cooperative game to achieve a common goal of converting the users. In particular, given the action intensities β, the network generates a value of $\lambda^\top h^\beta$ and the state-action specific SV $\pi_s^{a,\text{Shap}}$ represents the credit allocated to each state-action pair $(s, a) \in \mathbb{S}\times\mathbb{A}$. We first define the underlying components (players, coalition, and characteristic function) in our context and then discuss an important drawback of such a naive application.

Player. We view each state-action pair $(s, a) \in \mathbb{S} \times \mathbb{A}$ as an underlying player in the cooperative game. Consequently, our SV will not just be action-specific, but also state-specific.

Coalition. A coalition $\mathcal{X} \subseteq \mathbb{S}\times\mathbb{A}$ refers to a collection of players (state-action pairs). We construct a coalition by starting with the *empty coalition*, which corresponds to the Markov chain containing all the states but no action (not even the no-ad action), i.e., the traffic is directed to the quit state w.p. 1. Equivalently, one can view the empty coalition as the one with all the states but *action 0* ("zero-value action") being taken at all of them[5]. If a state-action pair, say (s, a), is added to the empty coalition, then the advertiser takes action a at state s w.p. β_s^a and so on. Therefore, for each coalition $\mathcal{X}$, we obtain a corresponding β, which we denote by $\beta^{\mathcal{X}}$.

Characteristic function. Given $\mathcal{X} \subseteq \mathbb{S} \times \mathbb{A}$, we define

$$v(\mathcal{X}) := \lambda^\top h^{\beta^{\mathcal{X}}}.$$

We define the action probabilities collections $\beta^\emptyset$ and β^* such that they correspond to the empty coalition $\emptyset$ and complete coalition $\mathbb{S} \times \mathbb{A}$, respectively. Thus, $\beta^\emptyset = 0$ and $\beta^* = \{\beta_s^a\}_{(s,a)\in\mathbb{S}\times\mathbb{A}}$. We satisfy $v(\emptyset) = 0$ and $v(\mathbb{S} \times \mathbb{A}) = \lambda^\top h^{\beta^*}$ is the total network value.

Shapley value. The SV for each $(s, a) \in \mathbb{S} \times \mathbb{A}$ is

$$\pi_s^{a,\text{Shap}} := \sum_{\mathcal{X}\subseteq\{\mathbb{S}\times\mathbb{A}\}\setminus\{(s,a)\}} w_{|\mathcal{X}|} \times \{v(\mathcal{X} \cup \{(s, a)\}) - v(\mathcal{X})\}, \quad (2)$$

where

$$w_{|\mathcal{X}|} := \frac{|\mathcal{X}|!(mn - |\mathcal{X}| - 1)!}{(mn)!}. \quad (3)$$

SV depends on our choice of the characteristic function $v(\cdot)$ and the underlying Markov chain $\mathcal{M}$ and hence, we will use the notation $\pi_s^{a,\text{Shap}}(v)$ and $\pi_s^{a,\text{Shap}}(\mathcal{M})$ when the emphasis on $v(\cdot)$ and $\mathcal{M}$ is necessary. Though this view of attribution inherits the desirability of SV, it suffers from a critical flaw: it does not adjust for the counterfactual (Example 4.1).

Example 4.1 (Need for counterfactual). Consider the network in Figure 3. Clearly, showing an ad should not get any attribution since it provides no *additional* value over the counterfactual action (no ad). However, (2) attributes all the value to the ad action. Furthermore, even LTA and uniform attribution fail this sanity check.

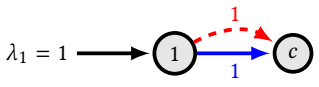

Figure 3: Network for Example 4.1. The action space consists of two actions: show no-ad and show an ad. Solid blue (dashed red) lines denote transition if an ad is shown (not shown). The advertiser shows an ad w.p. 1.

[5] An alternate candidate for the empty coalition is to have the no-ad action being taken at all the states. In other words, the no-ad action fills the "void" left due to the absence of other actions. However, we believe such a view is inappropriate since the no-ad action itself can have some value (either in terms of network effect or in terms of direct conversions). Therefore, using the no-ad action as the "default" action would allow the other actions to free ride on the value generated by the no-ad action, and hence, undermine the contribution due to the no-ad action.

4.3 Our approach

As we alluded to earlier, we seek a measure that provides the best of two worlds: (1) appropriately captures the contributions of the past actions (capturing the feature of, e.g., uniform and SV)[6] and (2) exhibits counterfactual reasoning (capturing a feature of IVH). To this end, we focus on adapting SV to account for the counterfactual and we do so by adhering to the causality framework of Rubin [41]. We first define a *counterfactual player* followed by our novel definition of *counterfactual adjusted Shapley value (CASV)*. We then show the desirability of CASV.

Counterfactual player. Following Rubin [41], the counterfactual to taking action a at state s w.p. β_s^a is to take the no-ad action (action 1) at state s w.p. β_s^a (instead of β_s^1). Accordingly, for a given player $(s, a) \in \mathbb{S} \times \mathbb{A}$, we denote the counterfactual player as $(s, 1)^a$, where the "a" in the superscript captures the dependence on β_s^a.

Counterfactual adjusted Shapley value. The game theoretic setup (player, coalition, characteristic function) is the same as in Section 4.2. For each $(s, a) \in \mathbb{S} \times \mathbb{A}$, we define CASV as

$$\psi_s^{a,\text{Shap}} := \sum_{\mathcal{X}\subseteq\{\mathbb{S}\times\mathbb{A}\}\setminus\{(s,a)\}} w_{|\mathcal{X}|} \times \{v(\mathcal{X} \cup \{(s, a)\}) - v(\mathcal{X} \cup \{(s, 1)^a\})\}, \quad (4)$$

where $w_{|\mathcal{X}|}$ is the same as in (3). We use the symbol ψ instead of π to differentiate CASV from SV. The only change we make in going from $\pi_s^{a,\text{Shap}}$ to $\psi_s^{a,\text{Shap}}$ is that we replace $v(\mathcal{X})$ by $v(\mathcal{X} \cup \{(s, 1)^a\})$, i.e., CASV captures the value added by a player over its counterfactual. Intuitively, it is unclear whether CASV under the current cooperative game is equivalent to SV under a different cooperative game. However, it is possible to view CASV as the difference between two SVs:

$$\psi_s^{a,\text{Shap}}(\mathcal{M}) = \pi_s^{a,\text{Shap}}(\mathcal{M}) - \pi_s^{a,\text{Shap}}(\mathcal{M}_s^a), \quad (5)$$

where $\mathcal{M}$ denotes the original Markov chain and $\mathcal{M}_s^a$ denotes the *counterfactual network* for (s, a), i.e., it is identical to $\mathcal{M}$ except that we replace the transition probabilities of (s, a) by those of $(s, 1)$. Clearly, $\pi_s^{a,\text{Shap}}(\mathcal{M}_s^a)$ is the *counterfactual value* of (s, a), i.e., the value generated if no-ad was shown instead of ad a at state s.

Obviously, it is of interest to check how CASV performs with respect to the desirable properties that motivated SV in the first place. However, one needs to be careful when discussing these axioms in the counterfactual context. To be specific, efficiency should now pertain to the redistribution of additional value generated over the counterfactual value. Similarly, the definition of equivalent players should be adjusted (discussed in Remark 4.1) and null player should correspond to a player with zero value-add. We formalize the desirability of CASV in Theorem 4.2, the proof of which is in Appendix A.

Theorem 4.2 (Axioms). *CASV satisfies the following axioms:*

1. ***Counterfactual efficiency****: The sum of CASVs equals the additional value generated over the counterfactual value, i.e.,*

$$\sum_{(s,a)\in\mathbb{S}\times\mathbb{A}} \psi_s^{a,\text{Shap}} = v(\mathbb{S} \times \mathbb{A}) - \sum_{(s,a)\in\mathbb{S}\times\mathbb{A}} \pi_s^{a,\text{Shap}}(\mathcal{M}_s^a).$$

[6] We will see in Section 5 that uniform and SV are closely linked.

2. ***Counterfactual symmetry***: *If* $(s,a) \in \mathbb{S} \times \mathbb{A}$ *and* $(s',a') \in \mathbb{S} \times \mathbb{A}$ *are counterfactual equivalent, i.e.,*
(A) $v(\mathcal{X} \cup \{(s,a)\}) - v(\mathcal{X} \cup \{(s,1)^a\}) = v(\mathcal{X} \cup \{(s',a')\}) - v(\mathcal{X} \cup \{(s',1)^{a'}\})$ *and*
(B) $v(\mathcal{X} \cup \{(s,1)^a, (s',a')\}) = v(\mathcal{X} \cup \{(s',1)^{a'}, (s,a)\})$
for all $\mathcal{X} \subseteq \{\mathbb{S} \times \mathbb{A}\} \setminus \{(s,a),(s',a')\}$*, then*

$$\psi_s^{a,\,Shap} = \psi_{s'}^{a',\,Shap}.$$

3. ***Linearity***: *Consider two characteristic functions* $v(\cdot)$ *and* $w(\cdot)$*. For all* $(s,a) \in \mathbb{S} \times \mathbb{A}$*, we have*

$$\psi_s^{a,\,Shap}(v+w) = \psi_s^{a,\,Shap}(v) + \psi_s^{a,\,Shap}(w)$$

and for all $\alpha \in \mathbb{R}$*,*

$$\psi_s^{a,\,Shap}(\alpha v) = \alpha \psi_s^{a,\,Shap}(v).$$

4. ***Counterfactual null player***: *Consider a player* $(s,a) \in \mathbb{S} \times \mathbb{A}$ *that has a zero value-add to all coalitions that do not contain* (s,a)*, i.e., for all* $\mathcal{X} \subseteq \{\mathbb{S} \times \mathbb{A}\} \setminus \{(s,a)\}$*,*

$$v(\mathcal{X} \cup \{(s,a)\}) = v(\mathcal{X} \cup \{(s,1)^a\}).$$

Then, $\psi_s^{a,\,Shap} = 0$.

Furthermore, CASV is the unique solution to satisfy these four counterfactual axioms.

Remark 4.1 (Counterfactual equivalent players). In Theorem 4.2, we define $(s,a) \in \mathbb{S} \times \mathbb{A}$ and $(s',a') \in \mathbb{S} \times \mathbb{A}$ to be counterfactual equivalent if they satisfy (A) and (B). To develop an intuitive understanding of these conditions, one can consider the following three conditions for all $\mathcal{X} \subseteq \{\mathbb{S} \times \mathbb{A}\} \setminus \{(s,a),(s',a')\}$:

(A1) $v(\mathcal{X} \cup \{(s,a)\}) = v(\mathcal{X} \cup \{(s',a')\})$,
(A2) $v(\mathcal{X} \cup \{(s,1)^a\}) = v(\mathcal{X} \cup \{(s',1)^{a'}\})$, and
(B) $v(\mathcal{X} \cup \{(s,1)^a, (s',a')\}) = v(\mathcal{X} \cup \{(s',1)^{a'}, (s,a)\})$.

In simple words, consider a coalition that does not contain either of the two given players. Condition (A1) states that adding either of the two players has the same effect on the network value and condition (A2) says so for the counterfactual players. The remaining case of interest is what happens when, on one hand, we add the first player and the counterfactual of the second player whereas, on the other hand, we do the opposite (add the second player and the counterfactual of the first player). Condition (B) states that doing either is equivalent in terms of the characteristic function. Note that we only need conditions (A) and (B) for two players to be counterfactual equivalent, and (A1) and (A2) are sufficient conditions for (A). It is worth mentioning that our definition of counterfactual equivalent players is a generalization of equivalent players from Section 4.1. In particular, equivalent players only need to satisfy condition (A1) and since the notion of a counterfactual player does not exist in the SV context, conditions (A2) and (B) are irrelevant.

We conclude this subsection with a discussion regarding the attribution to the no-ad action. By definition of CASV, the no-ad action at each state receives zero counterfactual credit. However, one can attribute the counterfactual value $\sum_{(s,a)\in\mathbb{S}\times\mathbb{A}} \pi_s^{a,\,\text{Shap}}(\mathcal{M}_s^a)$ ("residual") to the no-ad action in a post hoc fashion. In other words, the post hoc attribution to the no-ad action at state $s \in \mathbb{S}$ equals

$$\sum_{a\in\mathbb{A}} \pi_s^{a,\,\text{Shap}}(\mathcal{M}_s^a) = \pi_s^{1,\text{Shap}}(\mathcal{M}) + \sum_{a=2}^{n} \pi_s^{a,\,\text{Shap}}(\mathcal{M}_s^a), \tag{6}$$

where we use the fact that $\mathcal{M}_s^1 = \mathcal{M}$. The two terms in (6) have an intuitive interpretation. The first term captures the value generated by the no-ad action due to a positive value of β_s^1 whereas the second term captures the value that *would have* been generated if the no-ad action was used in place of the other actions.

4.4 Revisiting canonical examples

We now revisit the networks discussed so far and show that our CASV measure does not suffer from the same limitations as existing heuristics.

Example 4.3. For the network in Figure 1 with $p < 1$, CASV at every state equals $1/m$ for the ad action and 0 otherwise.

Example 4.4. For the network in Figure 2, CASV attributes 0 to the no-ad action at all the states and the following to the ad action:

$$\begin{cases} \frac{1}{2} + \frac{1}{2m} & \text{if } s = 1 \\ \frac{1}{2m} & \text{otherwise.} \end{cases}$$

This seems sensible as half of the paths convert just due to the ad action at state 1 whereas the other half of the paths convert with the help of the ad action at all the m states.

Example 4.5. For the network in Figure 3, CASV allocates zero credit to the ad action, which seems appropriate. However, CASV of the no-ad action also equals zero, which raises the following question: which player gets credit for the value in the system? The answer is, as discussed at the end of Section 4.3, the no-ad action.

In sum, CASV appears to be an appealing measure for attribution: it has a number of desirable properties and appears robust to various network structures. However, similar to SV, computing CASV using (4) requires an exponential runtime in the number of underlying players. This is an important tractability concern that could render CASV impractical in settings with moderately-sized state and action spaces. In the next section, we focus on representing CASV in a manner that is amenable to being computed efficiently, under our Markovian model.

5 CHARACTERIZING COUNTERFACTUAL ADJUSTED SHAPLEY VALUE

We now focus on characterizing CASV by exploiting the structure of the underlying cooperative game. In doing so, we use the fact that CASV can be expressed as a difference of two SVs (see (5)) and hence, analyze SV first. Proposition 5.1 connects the coalition-oriented game-theoretic construct of SV to the paths sampled from $\mathcal{M}$. In particular, we show that, under our Markovian setup, SV is (surprisingly) identical to the unique-uniform attribution scheme (motivated in Remark 3.1). We present the formal proof of Proposition 5.1 in Appendix A and highlight the intuition here.

Proposition 5.1 (SV equals unique-uniform). *Consider* $(s,a) \in \mathbb{S} \times \mathbb{A}$ *and the Markov chain* $\mathcal{M}$*. The SV of* (s,a) *as defined in* (2)

equals

$$\pi_s^{a,\,Shap} = \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[w_s^a(\mathcal{P})\right],$$

where

$$w_s^a(\mathcal{P}) := \begin{cases} \frac{1}{u(\mathcal{P})} & \text{if } \mathcal{P} \text{ converts and } (s,a)\in\mathcal{P} \\ 0 & \text{otherwise.} \end{cases}$$

The function $u(\cdot)$ returns the number of unique players and $\mathcal{P}$ is a path over players, i.e., state-action pairs.

Proof sketch. There are two keys ideas at interplay here. First, to characterize SV, we observe that the characteristic function for a given coalition $\mathcal{X}\subseteq\mathbb{S}\times\mathbb{A}$ can be expressed as an expectation over the paths sampled from the Markov chain $\mathcal{M}(\mathcal{X})$ in which only the players in $\mathcal{X}$ are "active", i.e.,

$$v(\mathcal{X}) = \mathbb{E}_{\mathcal{P}\sim\mathcal{M}(\mathcal{X})}\left[\mathbb{I}_{\{\mathcal{P}\text{ converts}\}}\right].$$

Using this observation allows us to express SV $\pi_s^{a,\,\text{Shap}}$ as an expectation over the paths from the original Markov chain $\mathcal{M}$:

$$\pi_s^{a,\,\text{Shap}} = \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[\mathbb{I}_{\{\mathcal{P}\text{ converts}\}}\,(\star)\right],$$

where

$$(\star) := \sum_{\mathcal{X}\subseteq\{\mathbb{S}\times\mathbb{A}\}\setminus\{(s,a)\}} w_{|\mathcal{X}|}\left(\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\cup\{(s,a)\}\}} - \mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}}\right).$$

The second key idea is to analyze $(\star)$ rigorously, which forms the bulk of our analysis. We show that $(\star)$ admits the following remarkably simple form:

$$(\star) = \begin{cases} \frac{1}{u(\mathcal{P})} & \text{if } (s,a)\in\mathcal{P} \\ 0 & \text{otherwise.} \end{cases}$$

Putting the two pieces together allows us to finish the proof. □

The above result enables one to characterize CASV, which constitutes the main result of this work.

Theorem 5.1 (CASV equals unique-uniform minus counterfactual). *Consider $(s,a)\in\mathbb{S}\times\mathbb{A}$, the Markov chain $\mathcal{M}$, and the counterfactual Markov chain $\mathcal{M}_s^a$. The CASV of (s,a) as defined in* (4) *equals*

$$\psi_s^{a,\,Shap} = \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[w_s^a(\mathcal{P})\right] - \mathbb{E}_{\mathcal{P}\sim\mathcal{M}_s^a}\left[w_s^a(\mathcal{P})\right],$$

where $w_s^a(\cdot)$ and $u(\cdot)$ are as defined in Proposition 5.1.

There is a striking resemblance between this characterization of CASV and uniform attribution as defined in (1). In particular, the two expressions are identical except the definition of the weight function and the counterfactual adjustment. The weight function in CASV does not provide an incentive for players to "game the system" as it only rewards based on whether a player appears in the path or not (as opposed to the number of times it appears). In other words, if an ad a had to be shown multiple times (say n_s^a) at the *same* state s to make the user move to another state s', then the CASV weight function only rewards it once (as opposed to rewarding it n_s^a times). This seems very reasonable and, in fact, is the simple fix we proposed in Remark 3.1.

It is noteworthy that the coalition-oriented construct of CASV, which on the surface does not seem to be related to the paths of the underlying Markovian model, reduces to being expressed as a remarkably simple function of such paths. This connection is quite valuable as it helps to gain deeper insights regarding the structure of CASV and hence, build a better understanding. Next, we conclude this section by using this connection to highlight that our scheme is efficiently computable and implementable.

Given a set of user paths $\mathcal{D} := \{\mathcal{P}_i\}_{i=1}^N$ where each user path $\mathcal{P}_i$ consists of various state-action-state (s,a,s') tuples, the action-specific transition probabilities can be estimated using empirical frequencies. To estimate CASV for player (s,a), one can sample paths from the estimated Markov chains $\mathcal{M}$ and $\mathcal{M}_s^a$ and use Theorem 5.1 directly. However, this involves sampling from a different Markov chain $\mathcal{M}_s^a$ to estimate CASV for each player, which we address next.

A simple change of measure allows CASV to be expressed as

$$\psi_s^{a,\,\text{Shap}} = \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[w_s^a(\mathcal{P})\left(1 - \frac{g_s^a(\mathcal{P})}{g(\mathcal{P})}\right)\right], \tag{7}$$

where $g(\mathcal{P})$ and $g_s^a(\mathcal{P})$ denote the probabilities of observing path $\mathcal{P}$ under Markov chains $\mathcal{M}$ and $\mathcal{M}_s^a$, respectively. The ratio $g_s^a(\mathcal{P})/g(\mathcal{P})$ denotes the *importance weight* and it is easy to show that

$$\frac{g_s^a(\mathcal{P})}{g(\mathcal{P})} = \prod_{s'\in\mathbb{S}^+}\left(\frac{p^1_{ss'}}{p^a_{ss'}}\right)^{n^a_{ss'}(\mathcal{P})},$$

where $n^a_{ss'}(\mathcal{P})$ denotes the number of occurrences of the tuple (s,a,s') in $\mathcal{P}$ for each $s'\in\mathbb{S}^+$. Given (7), it suffices to sample paths from just one Markov chain ($\mathcal{M}$) to estimate CASV for all the players. In fact, each sample can be recycled for multiple players and the scheme can be implemented using a parallel (over both players and samples) architecture.

It is possible to use a Bayesian version of the approach described above. In particular, one can maintain a belief over the transition probability vector $[p^a_{ss'}]_{s'\in\mathbb{S}^+}$ in the form of a Dirichlet distribution for each $a\in\mathbb{A}$. Using Dirichlet-multinomial conjugacy and real data $\mathcal{D}$, the belief can be updated easily. The posterior belief can be used to generate samples of the Markov chain $\mathcal{M}$ itself. For each sample of $\mathcal{M}$, one can use (7) to estimate CASV, resulting in posterior samples of CASV. Naturally, these posterior samples quantify the uncertainty in CASV that arises due to the noise in data and/or lack of data. Furthermore, this Bayesian approach is amenable to parallelization over the samples of $\mathcal{M}$.

6 CONCLUSIONS & FURTHER RESEARCH

In this paper, using a Markovian model for user behavior, we have proposed a new metric (counterfactual adjusted Shapley value) for the attribution problem in online advertising. We have established its grounding and appropriateness in two ways. First, we have shown the robustness of the proposed measure over various canonical settings in which the existing metrics fail. Second, we have provided an underlying axiomatic framework motivated by game theory and causality that supports our choice. Furthermore, we have established a characterization of the proposed metric as a remarkably simple function of the user paths. In particular, we have established, in our Markovian model, that the proposed attribution metric is an adjustment to the unique-uniform attribution scheme. Finally, we have proposed multiple approaches to efficiently estimate our metric.

There are many potential directions for future research, most of which we are pursuing at the present. First, it is of interest to develop more canonical settings to further verify the appropriateness of our proposed measure. Second, though we have briefly touched upon algorithms to estimate the proposed metric, a thorough treatment would involve understanding their statistical efficiency. In addition, it is worthwhile to explore algorithms to estimate the counterfactual adjusted Shapley value that can be implemented in an online fashion while maintaining strong approximation guarantees. Third, with the help of an industry partner, we are working on comparing the output of our scheme to the existing ones on a real world dataset composed of millions of user paths. Fourth, we are interested in applying the methodology developed in this paper to other domains. In particular, the abstract Markovian model presented here can be used to model other applications, where one wishes to understand the contributions of the underlying agents. Finally, it is worthwhile to explore whether attribution metrics can be constructed from other notions of causality. In this work, we modified Shapley value using Rubin's definition of causality [41]. However, there exist several alternative formulations for causality. See, e.g. Chockler and Halpern [11], Collins et al. [13], Eells [16], Halpern and Pearl [20], Hitchcock [21], Morgan and Winship [35], Pearl [37] and Hume [22] for approaches to causality in the computer science and philosophy literature. Chockler and Halpern [11] proposed metrics such as "degree of responsibility" and "blame" in order to *quantify* the causal effect of one variable on another. However, computing these metrics is computationally expensive. Furthermore, these metrics lack axiomatic support. In particular, similar to IVH, these metrics are not budget balanced. In fact, Chockler and Halpern [11] mention adjusting their notions using Shapley value as a potential future work. Accordingly, though we have unified the existing attribution literature in this work, there is more to explore in terms of the set of counterfactuals to consider.

A TECHNICAL RESULTS

Theorem 4.2 (Axioms). *CASV satisfies the following axioms:*

1. ***Counterfactual efficiency**: The sum of CASVs equals the additional value generated over the counterfactual value, i.e.,*
$$\sum_{(s,a)\in\mathbb{S}\times\mathbb{A}} \psi_s^{a,\,Shap} = v(\mathbb{S}\times\mathbb{A}) - \sum_{(s,a)\in\mathbb{S}\times\mathbb{A}} \pi_s^{a,\,Shap}(\mathcal{M}_s^a).$$
2. ***Counterfactual symmetry**: If $(s,a)\in\mathbb{S}\times\mathbb{A}$ and $(s',a')\in\mathbb{S}\times\mathbb{A}$ are counterfactual equivalent, i.e.,*
(A) $v(\mathcal{X}\cup\{(s,a)\}) - v(\mathcal{X}\cup\{(s,1)^a\}) = v(\mathcal{X}\cup\{(s',a')\}) - v(\mathcal{X}\cup\{(s',1)^{a'}\})$ *and*
(B) $v(\mathcal{X}\cup\{(s,1)^a,(s',a')\}) = v(\mathcal{X}\cup\{(s',1)^{a'},(s,a)\})$
for all $\mathcal{X}\subseteq\{\mathbb{S}\times\mathbb{A}\}\setminus\{(s,a),(s',a')\}$, then
$$\psi_s^{a,\,Shap} = \psi_{s'}^{a',\,Shap}.$$
3. ***Linearity**: Consider two characteristic functions $v(\cdot)$ and $w(\cdot)$. For all $(s,a)\in\mathbb{S}\times\mathbb{A}$, we have*
$$\psi_s^{a,\,Shap}(v+w) = \psi_s^{a,\,Shap}(v) + \psi_s^{a,\,Shap}(w)$$
and for all $\alpha\in\mathbb{R}$,
$$\psi_s^{a,\,Shap}(\alpha v) = \alpha\psi_s^{a,\,Shap}(v).$$
4. ***Counterfactual null player**: Consider a player $(s,a)\in\mathbb{S}\times\mathbb{A}$ that has a zero value-add to all coalitions that do not contain (s,a), i.e., for all $\mathcal{X}\subseteq\{\mathbb{S}\times\mathbb{A}\}\setminus\{(s,a)\}$,*
$$v(\mathcal{X}\cup\{(s,a)\}) = v(\mathcal{X}\cup\{(s,1)^a\}).$$
Then, $\psi_s^{a,\,Shap} = 0$.

Furthermore, CASV is the unique solution to satisfy these four counterfactual axioms.

Proof. Counterfactual efficiency and linearity follow from (5) when used with the efficiency and linearity of SV, respectively. Counterfactual null player follows from (4). For counterfactual symmetry, consider $(s,a)\in\mathbb{S}\times\mathbb{A}$ and $(s',a')\in\mathbb{S}\times\mathbb{A}$ satisfying (A) and (B), define the set $\diamond := \{\mathbb{S}\times\mathbb{A}\}\setminus\{(s,a),(s',a')\}$, and observe that

$$\begin{aligned}
\psi_s^{a,\,\text{Shap}} &= \sum_{\mathcal{X}\subseteq\{\mathbb{S}\times\mathbb{A}\}\setminus\{(s,a)\}} w_{|\mathcal{X}|}\times\{v(\mathcal{X}\cup\{(s,a)\}) - v(\mathcal{X}\cup\{(s,1)^a\})\}\\
&= \sum_{\mathcal{X}\subseteq\diamond} w_{|\mathcal{X}|}\times\{v(\mathcal{X}\cup\{(s,a)\}) - v(\mathcal{X}\cup\{(s,1)^a\})\}\\
&+ \sum_{\mathcal{X}\subseteq\diamond} w_{|\mathcal{X}|+1}\times\{v(\mathcal{X}\cup\{(s,a),(s',a')\}) - v(\mathcal{X}\cup\{(s,1)^a,(s',a')\})\}\\
&= \sum_{\mathcal{X}\subseteq\diamond} w_{|\mathcal{X}|}\times\left\{v(\mathcal{X}\cup\{(s',a')\}) - v(\mathcal{X}\cup\{(s',1)^{a'}\})\right\}\\
&+ \sum_{\mathcal{X}\subseteq\diamond} w_{|\mathcal{X}|+1}\times\left\{v(\mathcal{X}\cup\{(s,a),(s',a')\}) - v(\mathcal{X}\cup\{(s',1)^{a'},(s,a)\})\right\}\\
&= \sum_{\mathcal{X}\subseteq\{\mathbb{S}\times\mathbb{A}\}\setminus\{(s',a')\}} w_{|\mathcal{X}|}\times\left\{v(\mathcal{X}\cup\{(s',a')\}) - v(\mathcal{X}\cup\{(s',1)^{a'}\})\right\}\\
&= \psi_{s'}^{a',\,\text{Shap}}.
\end{aligned}$$

This proves that CASV satisfies the four axioms. To be concise, we defer the uniqueness proof to the journal version of this paper. □

Proposition 5.1 (SV equals unique-uniform). *Consider $(s,a)\in\mathbb{S}\times\mathbb{A}$ and the Markov chain $\mathcal{M}$. The SV of (s,a) as defined in (2) equals*
$$\pi_s^{a,\,Shap} = \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[w_s^a(\mathcal{P})\right],$$
where
$$w_s^a(\mathcal{P}) := \begin{cases}\frac{1}{u(\mathcal{P})} & \text{if } \mathcal{P} \text{ converts and } (s,a)\in\mathcal{P}\\ 0 & \text{otherwise.}\end{cases}$$
The function $u(\cdot)$ returns the number of unique players and $\mathcal{P}$ is a path over players, i.e., state-action pairs.

Proof. For convenience, we use linearized notation such that $r := (s, a)$ and $\mathbb{P} := \mathbb{S} \times \mathbb{A}$ with the understanding that $\pi_r^{\text{Shap}} := \pi_s^{a,\text{Shap}}$, and $w_r(\cdot) := w_s^a(\cdot)$. The proof is split into three parts.

Step 1: Express $v(\mathcal{X})$ as an expectation over paths:

$$\begin{aligned} v(\mathcal{X}) &= \lambda^\top h^{\beta^{\mathcal{X}}} \\ &= \lambda^\top \left(I + P^{\beta^{\mathcal{X}}} + (P^{\beta^{\mathcal{X}}})^2 + \ldots\right) p_c^{\beta^{\mathcal{X}}} \\ &= \mathbb{E}_{\mathcal{P}\sim\mathcal{M}(\mathcal{X})}\left[\mathbb{I}_{\{\mathcal{P} \text{ converts}\}}\right] \\ &= \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[\mathbb{I}_{\{\mathcal{P} \text{ converts}\}}\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}}\right], \end{aligned}$$

where $\mathcal{M}(\mathcal{X})$ denotes the Markov chain in which only the players in coalition $\mathcal{X}$ are "active".

Step 2: Use the representation from Step 1 in the definition of SV π_r^{Shap} as stated in (2):

$$\begin{aligned} \pi_r^{\text{Shap}} &= \sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|} \times \{v(\mathcal{X}\cup\{r\}) - v(\mathcal{X})\} \\ &= \sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|} \left\{\mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[\mathbb{I}_{\{\mathcal{P} \text{ converts}\}}\left(\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\cup\{r\}\}} - \mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}}\right)\right]\right\} \\ &= \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[\mathbb{I}_{\{\mathcal{P} \text{ converts}\}} \sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|}\left(\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\cup\{r\}\}} - \mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}}\right)\right]. \end{aligned}$$

Step 3: Use Lemma A.1, which states

$$\sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|}\left(\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\cup\{r\}\}} - \mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}}\right) = \begin{cases} \frac{1}{u(\mathcal{P})} & \text{if } r \in \mathcal{P} \\ 0 & \text{otherwise,} \end{cases}$$

to conclude that

$$\pi_r^{\text{Shap}} = \mathbb{E}_{\mathcal{P}\sim\mathcal{M}}\left[w_r(\mathcal{P})\right]. \tag{8}$$

This completes the proof. □

Lemma A.1 (Unique players). *For any player $r \in \mathbb{P}$ and any path $\mathcal{P}$ over players in $\mathbb{P}$, we have*

$$\sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|}\left(\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\cup\{r\}\}} - \mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}}\right) = \begin{cases} \frac{1}{u(\mathcal{P})} & \text{if } r \in \mathcal{P} \\ 0 & \text{otherwise,} \end{cases}$$

where the function $u(\cdot)$ returns the number of unique players.

Proof. First, suppose $r \notin \mathcal{P}$. Then, $\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\cup\{r\}\}} = \mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}}$ for all $\mathcal{X} \subseteq \mathbb{P}\setminus\{r\}$ and hence, the l.h.s. equals 0, which equals the r.h.s.

Second, suppose $r \in \mathcal{P}$. Assume w.l.o.g. that path $\mathcal{P}$ has $u+1$ unique players: $r, r_1, \ldots, r_u$. Observe that $\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\}} = 0$ for all $\mathcal{X} \subseteq \mathbb{P}\setminus\{r\}$ and hence, the l.h.s. equals $\sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|}\mathbb{I}_{\{\mathcal{P}\subseteq\mathcal{X}\cup\{r\}\}}$. Furthermore, since $r \in \mathcal{P}$, we can define a new path $\mathcal{P}' := \mathcal{P}\setminus\{r\}$ and express the l.h.s. as $\sum_{\mathcal{X}\subseteq\mathbb{P}\setminus\{r\}} w_{|\mathcal{X}|}\mathbb{I}_{\{\mathcal{P}'\subseteq\mathcal{X}\}}$. Now, we will count the number of times the combination $(r_1, \ldots, r_u)$ appears in the l.h.s. and weight it by $w_{|\mathcal{X}|}$ to compute the coefficient corresponding to $\mathcal{P}$ in the l.h.s. Trivially, if $|\mathcal{X}| < u$, then the combination will not appear (since there will not be enough number of unique players). For $|\mathcal{X}| \in \{u, \ldots, |\mathbb{P}|-1\}$, the contribution to the combination $(r_1, \ldots, r_u)$ equals

$$\underbrace{w_{|\mathcal{X}|}}_{\text{weight}} \times \underbrace{\binom{|\mathbb{P}|-1-u}{|\mathcal{X}|-u}}_{\#\text{ of times the combination appears in the summation over } \mathcal{X} \text{ for a fixed } |\mathcal{X}|}.$$

Summing over $|\mathcal{X}|$, the total contribution (which is the coefficient we are interested in) equals

$$\sum_{|\mathcal{X}|=u}^{|\mathbb{P}|-1} w_{|\mathcal{X}|} \times \binom{|\mathbb{P}|-1-u}{|\mathcal{X}|-u} = \frac{1}{|\mathbb{P}|-u} \sum_{|\mathcal{X}|=u}^{|\mathbb{P}|-1} \prod_{i=0}^{u-1} \frac{|\mathcal{X}|-i}{|\mathbb{P}|-i} = \frac{1}{u+1},$$

where the last equality follows Lemma A.2. This agrees with the r.h.s. and completes our proof. □

Lemma A.2. *Let k_1 be a non-negative integer and k_2 be a positive integer such that $k_2 \geq k_1 + 1$. Then,*

$$\frac{1}{k_2-k_1} \sum_{j=k_1}^{k_2-1} \prod_{i=0}^{k_1-1} \frac{j-i}{k_2-i} = \frac{1}{k_1+1}.$$

Proof. We will prove this via induction on k_2. For the base case, consider $k_2 = k_1 + 1$. The l.h.s. equals

$$\begin{aligned} \frac{1}{k_1+1-k_1} \sum_{j=k_1}^{k_1+1-1} \prod_{i=0}^{k_1-1} \frac{j-i}{k_1+1-i} &= \prod_{i=0}^{k_1-1} \frac{k_1-i}{k_1+1-i} \\ &= \frac{1}{k_1+1}, \end{aligned}$$

which is what we wanted. For the induction step, we show that if the statement is true for some $k_2 \geq k_1 + 1$, then it is also true for $k_2 + 1$, that is,

$$\frac{1}{k_2+1-k_1} \sum_{j=k_1}^{k_2} \prod_{i=0}^{k_1-1} \frac{j-i}{k_2+1-i} = \frac{1}{k_1+1}.$$

The l.h.s. of the above equation equals

$$\begin{aligned} &\frac{1}{k_2+1-k_1} \sum_{j=k_1}^{k_2} \prod_{i=0}^{k_1-1} \frac{j-i}{k_2+1-i} \\ &= \frac{1}{k_2+1-k_1}\left\{\sum_{j=k_1}^{k_2-1} \prod_{i=0}^{k_1-1} \frac{j-i}{k_2+1-i} + \prod_{i=0}^{k_1-1} \frac{k_2-i}{k_2+1-i}\right\} \\ &= \frac{1}{k_2+1-k_1}\left\{\sum_{j=k_1}^{k_2-1} \prod_{i=0}^{k_1-1} \frac{j-i}{k_2+1-i} + \frac{k_2-k_1+1}{k_2+1}\right\} \\ &= \frac{1}{k_2+1-k_1}\left\{\sum_{j=k_1}^{k_2-1} \prod_{i=0}^{k_1-1} \left(\frac{j-i}{k_2-i} \times \frac{k_2-i}{k_2+1-i}\right) + \frac{k_2-k_1+1}{k_2+1}\right\} \\ &= \frac{1}{k_2+1-k_1}\left\{\sum_{j=k_1}^{k_2-1} \left[\left(\prod_{i=0}^{k_1-1} \frac{j-i}{k_2-i}\right)\left(\prod_{i'=0}^{k_1-1} \frac{k_2-i'}{k_2+1-i'}\right)\right] + \frac{k_2-k_1+1}{k_2+1}\right\} \\ &= \frac{1}{k_2+1-k_1}\left\{\sum_{j=k_1}^{k_2-1} \left[\left(\prod_{i=0}^{k_1-1} \frac{j-i}{k_2-i}\right)\left(\frac{k_2-k_1+1}{k_2+1}\right)\right] + \frac{k_2-k_1+1}{k_2+1}\right\} \\ &= \frac{\frac{k_2-k_1+1}{k_2+1}}{k_2+1-k_1}\left\{\sum_{j=k_1}^{k_2-1} \prod_{i=0}^{k_1-1} \frac{j-i}{k_2-i} + 1\right\} = \frac{1}{k_2+1}\left\{\frac{k_2-k_1}{k_1+1} + 1\right\} = \frac{1}{k_1+1}, \end{aligned}$$

where the second-last equality is true due to the induction hypothesis. This completes the proof. □

ABSTRACT

We investigate spatial patterns in mobile service consumption that emerge at national scale. Our investigation focuses on a representative case study, *i.e.*, France, where we find that: (*i*) the demand for popular mobile services is fairly uniform across the whole country, and only a reduced set of peculiar services (mainly operating system updates and long-lived video streaming) yields geographic diversity; (*ii*) even for such distinguishing services, the spatial heterogeneity of demands is limited, and a small set of consumption behaviors is sufficient to characterize most of the mobile service usage across the country; (*iii*) the spatial distribution of these behaviors correlates well with the urbanization level, ultimately suggesting that the adoption of geographically-diverse mobile applications is linked to a dichotomy of cities and rural areas. We derive our results through the analysis of substantial measurement data collected by a major mobile network operator, leveraging an approach rooted in information theory that can be readily applied to other scenarios.

1 INTRODUCTION

As mobile data traffic keeps surging worldwide [9], knowledge of where, when, how and why mobile services are consumed by network subscribers becomes increasingly relevant across research and technology domains, including sociology [4], demography [10], urban planning [18], economy [30], transportation engineering [34], or network management [23]. Despite the importance of the problem and some recent efforts discussed in Section 2, our comprehension of mobile service adoption is currently limited, and many questions remain unanswered, especially when considering the phenomenon at very large geographical scales. In this paper, we focus on one such open question, namely: *"how similar (or different) are demands for mobile services across a whole country?"* We answer by analyzing a real-world dataset of mobile network traffic collected by a major operator that describes the demands for individual services in 10,000 *communes* (*i.e.*, administrative areas) in France. Our study yields the following insights:

- what sets communes apart are not usage patterns of the most popular services, which tend to be similar everywhere in the country, but those of a small set of specific services that still figure in the top-50 services in terms of generated traffic, including operating system updates and long-lived video streaming;
- just 9 (respectively, 50) service consumption patterns are sufficient to retain 23% (respectively, 35%) of the overall usage diversity, implying that a small number of distinct behaviors is sufficient to characterize the many thousands of areas in the whole of France;
- clear correlations exist between different patterns in mobile service consumption and demographics features, which are rooted in higher (or lower) than average usage of specific types of service.

Deriving these results requires overcoming methodological and computational challenges. We face a clustering problem, where communes are to be grouped based on how their inhabitants use mobile services. However, our clustering operates in a multidimensional space of hundreds of mobile services, where a suitable notion of similarity is to be defined. In addition, working at a national scale implies potentially disentangling billions of pairwise relationships between tens of thousands of geographical areas.

We address these issues by adopting an information theoretic approach that builds on the notion of *mutual information* between mobile service demands and geographical locations. The mutual

information measures how much can be inferred about the consumed services by knowing the location, and vice versa. We first leverage it to limit the problem dimension in the mobile service space, by identifying *informative services* that maximize the mutual information, *i.e.*, exhibit significant spatial diversity. Also, we measure the similarity of usage distributions of such informative services between two communes in terms of the loss of mutual information incurred when their distributions are merged. Finally, the fraction of retained mutual information is used to assess the quality of clustering results obtained via a scalable two-phase approach.

Overall, our work sheds light on the limited set of services that are responsible for diversity in mobile data demands across a whole developed country, and on their relation to demographics features. It also provides the research community with a tool[1] for the analysis of patterns in mobile data traffic usage at national scales.

2 RELATED WORK

The vast majority of the literature on mobile network traffic analysis investigates patterns in the aggregate demand, without differentiating among services. In this context, early works have revealed the heterogeneity that characterizes the offered load at radio access in space and time, leading to strong fluctuations of the demand across diverse regions of a same city and during different periods of the day [26]. Especially relevant to our study are works that established links between the temporal dynamics of aggregate traffic and the land use, *i.e.*, the type of human infrastructures and activities present in a given area [8, 16, 32]. Although they focus on aggregate traffic at city scale, these studies have demonstrated for the first time the strong impact that user centric aspects can have on the adoption of mobile applications.

At the individual mobile service level, several works have studied specific applications in depth. Investigations have focused on services such as adaptive-bit-rate video streaming by over-the-top providers [12], Facebook and WhatsApp [15], or cloud storage [22]. These studies address the network-level performance of the examined services, and do not provide insights in terms of the geographical diversity of their usage. Related to these works is also a thorough analysis of web browsing behaviors by mobile users, which finds that a limited number of profiles are sufficient to capture most of the patterns in website visits [20]. However, similarly to the papers above, also in this case the spatial dimension is not considered.

Geographical diversity has been often overlooked also in prior explorations of mobile data traffic considering multiple services. Most works in the literature have a different focus, including differences in mobile application usage in time [35] or across the subscriber population [21]. Attention has also been paid to patterns in the utilization of apps by individual users, finding, *e.g.*, that mobile service usage is very heterogeneous among the user base [13], strongly depends on context [6], is characterized by brief bursts of interactions [14], and is influenced by the type of device used [19]. However, these are orthogonal problems to that of the spatial diversity of the demands for mobile services that we target. Finally, several previous works have observed a strong locality in the usage of applications within a given urban area, *i.e.*, a significant spatial diversity of usage across different city neighborhoods [29, 31]. Our investigation suggests that these dissimilarities in service usage are not significant at a national scale, where the consumption of mobile services is relatively uniform.

Only two previous works investigate the spatial dimension of mobile application usage at a national scale. In a study carried out in the US [33], the authors hint at the existence of local (*i.e.*, US state-related) and nationwide services. We do not find such a dichotomy in our case study, and ascribe it to the federal organization of the US into states, which is not reflected in France. Interestingly, however, the differences in the consumption of nationwide apps is fairly limited in the USA (between 2% and 20%), which is consistent with our findings. The second work is a recent study of mobile service usage in France [24], which unveils the existence of a strong temporal diversity in mobile service demands, but somewhat lower geographical differences. Our in-depth analysis substantiates the observations in [24] with stronger evidence of the limited nationwide diversity of mobile service consumption patterns. Finally, we remark that both works above only provide preliminary geographical results via baseline statistical measures, and do not perform a rigorous analysis based on spatial clustering as the one we propose. Moreover, none investigates the existence of informative services whose distribution is geographically varied, or offers interpretations of the results based on side information.

3 SYSTEM MODEL

As stated at the outset, our framework builds on information theory. In this section we introduce the notation and fundamentals of the proposed approach, and show how they apply to our scenario.

3.1 Probabilistic rendering of service demands

Let $C = \{1, \ldots, N_C\}$ and $\mathcal{S} = \{1, \ldots, N_S\}$ be the set of geographical areas in the target region and the set of mobile services under study, respectively, having cardinality N_C and N_S. A total mobile data traffic of t_i bytes is generated in area i, $i = 1, \ldots, N_C$, over the system observation time, *i.e.*, the time period during which network measurements are performed[2]. Let C be a random variable, with outcome in C, representing the selection of an area with a certain probability. Similarly, let S be a random variable, with outcome in $\mathcal{S}$, representing the selection of a service. In the considered period of time, the probability that a given byte of traffic was generated by service j in area i is the joint probability distribution of services and areas, denoted by $p_{S,C}(j, i)$, $j = 1, \ldots, N_S$, $i = 1, \ldots, N_C$.

Given an area i, the probability of observing a byte generated by service j is denoted by the conditional probability $p_{S|C}(j|i) = \rho_{j,i}$. The vector $\boldsymbol{\rho}_i = [\rho_{1,i}, \ldots, \rho_{N_S,i}]$ thus represents the *service usage distribution* in area i and is such that $\sum_{j=1}^{N_S} \rho_{j,i} = 1$.

Overall, the probability of observing traffic generated by service j, $j = 1, \ldots, N_S$, is represented by the marginal distribution of traffic among services:

$$p_S(j) = \sum_{i=1}^{N_C} p_{S,C}(j, i) = \sum_{i=1}^{N_C} p_C(i)\rho_{j,i},$$

[1] Available at https://github.com/rajkarn/mobdiv.

[2] As our interest is in the spatial diversity of mobile service usage, we primarily consider data accumulated over time. However, we also carried out experiments by partially disaggregating data in time, as discussed at the end of Section 6.2.

where $p_C(i)$, $i = 1, \ldots, N_C$ is the fraction of traffic in area i, among all areas, and so is given by:

$$p_C(i) = \frac{t_i}{\sum_{k=1}^{N_C} t_k}.$$

The amount of information that random variables S and C share is measured by the *mutual information*:

$$I(S;C) = H(S) - H(S|C), \tag{1}$$

where $H(S)$ and $H(S|C)$ are the entropy of S and the conditional entropy of S given C, respectively, expressed as:

$$H(S) = -\sum_{j=1}^{N_S} p_S(j) \log p_S(j),$$

and

$$H(S|C) = -\sum_{i=1}^{N_C} p_C(i) \sum_{j=1}^{N_S} p_{S|C}(j|i) \log p_{S|C}(j|i).$$

The mutual information $I(S;C)$ is a measure of the correlation between how traffic is distributed among services in S and among areas in C; *i.e.*, it captures how much can be inferred about the consumed services by knowing C, or vice versa. As a result, $I(S;C)$ measures how much mobile service usage depends on geographical location. $I(S;C) = 0$ when S and C are independent, *i.e.*, the exact same distribution of mobile service traffic is observed across all areas in C, and the spatial diversity is nil. Non-zero yet low values of mutual information of services and areas imply that sampling a unit of traffic from those services still carries little information on the area it was sampled from, *i.e.*, that services tend to have a quite uniform usage distribution across areas. As $I(S;C)$ grows, the knowledge of C increasingly helps to anticipate the value of S, *i.e.*, geographical regions are characterized by more and more distinctive mobile service usage, hence the spatial diversity rises.

3.2 Application to the France case study

We apply the probabilistic model above to the nationwide case study of France. The information on the traffic demands for individual mobile services in France was collected by a major network operator during one continuous week in late 2016. Deep packet inspection and proprietary fingerprinting techniques[3] were employed on traffic sniffed on the GPRS Tunneling Protocol (GTP), so as to associate single IP-level flows to applications. Overall, the dataset captures the usage of thousands of mobile services by 30 million subscribers in 10,000 *communes*, *i.e.*, local administrative zones with a mean surface of 16 km^2, in France.

The left plot in Fig. 1 provides an illustration of the joint probability $p_{S,C}(j,i)$, where $\mathcal{S}$ is the set of the 50 most popular mobile services[4], and C is the set of 10,000 communes. We remark the high unbalance in the traffic recorded across communes, as well as among services, underscored by the logarithmic scale of the z axis.

The middle plot in Fig. 1 shows the evolution of the mutual information $I(S_k;C)$, computed by limiting the joint distribution to a subset $\mathcal{S}_k \subseteq \mathcal{S}$ of the k services that generate the highest total traffic; equivalently, S_k denotes the random variable representing the selection of a service in $\mathcal{S}_k$. The number k of considered services is on the x-axis. We note that the mutual information remains very low, close to zero, for all top-50 services: according to our previous discussion, this implies that there is very little correlation between the two variables, hence the distribution of mobile service traffic does not vary in a sensible manner across communes.

A more detailed view is provided in the right plot in Fig. 1, which shows the joint distribution $p_{S,C}(j,i)$ in a linearized form where each "period" represents the probabilities associated to one service over all communes. The product of the marginal distributions $p_S(j) \cdot p_C(i)$ is also displayed according to the same format. There is a substantial overlap between the two curves, which confirms that spatial diversity is low also when inspecting the system on a more detailed per-service basis. Indeed, matching curves imply $p_{S,C}(j,i) = p_S(j) \cdot p_C(i)$, hence independence between S and C, or, equivalently, $I(S;C) = 0$ in (1). As discussed previously, such a condition indicates that service consumption is identical everywhere.

Overall, these results lead to our first takeaway message: ***usage patterns of the most popular mobile services tend to be very similar across the whole country under study***. This is quite a surprising outcome, considering the spatial differences in demographic, social and economic features that characterize France. It also leads us to investigate next if specific individual services are in fact geographically diverse in their usage characteristics.

4 DETECTING INFORMATIVE SERVICES

An interesting observation from the right plot of Fig. 1 is that, although the overlap between $p_{S,C}(j,i)$ and $p_S(j) \cdot p_C(i)$ is generally good, some services (denoted by specific "periods") show especially noisy joint distribution curves that are not well captured by the simple product of the marginal distributions. Such services thus appear to be adopted less homogeneously across the country than most other mobile applications. Next, we investigate the existence of *informative services* that are characterized by a non-negligible diversity of usage across geographical areas in the target region.

4.1 Maximizing the mutual information

Consider a subset $\mathcal{S}' = \{j_1, \ldots, j_{|\mathcal{S}'|}\} \subseteq \mathcal{S}$ of services and define the service usage distribution in area i restricted to $\mathcal{S}'$ as $\boldsymbol{\rho}_i(\mathcal{S}') = [\rho_{i1}(\mathcal{S}'), \ldots, \rho_{i,|\mathcal{S}'|}(\mathcal{S}')]$, where

$$\rho_{ik}(\mathcal{S}') = \frac{\rho_{i,j_k}}{\sum_{k'=1}^{|\mathcal{S}'|} \rho_{i,j_{k'}}}.$$

Considering only services that are in $\mathcal{S}'$, let us define the traffic within area i, denoted by $t_i(\mathcal{S}')$, as the sum of the demands within area i for each service in $\mathcal{S}'$. The joint probability of sampling area i and service $j_k \in \mathcal{S}'$ is then given by $p_C(i,\mathcal{S}')\rho_{ik}(\mathcal{S}')$, where we suppose $p_C(i,\mathcal{S}')$ to be the fraction of traffic in area i, *i.e.*,

$$p_C(i,\mathcal{S}') = \frac{t_i(\mathcal{S}')}{\sum_{i'=1}^{N_C} t_{i'}(\mathcal{S}')}.$$

[3] Confidential agreements with the network operator do not allow us to disclose the details of the traffic classification procedure. However, we can mention that 88% of the sessions were correctly detected, according to the operator's performance evaluations. Also, we underscore that the data collection occurred in compliance with regulations in force, and was approved by the French national authority for data privacy (CNIL). All data was aggregated by the operator at the commune level before we could access it, which ensures strong privacy protection as mobile traffic is accumulated over thousands of subscribers. No individual data is used in our study.

[4] We limit plots to the 50 services that generate the highest demands, for the sake of clarity. Such services account for over 93% of the total mobile data traffic in France.

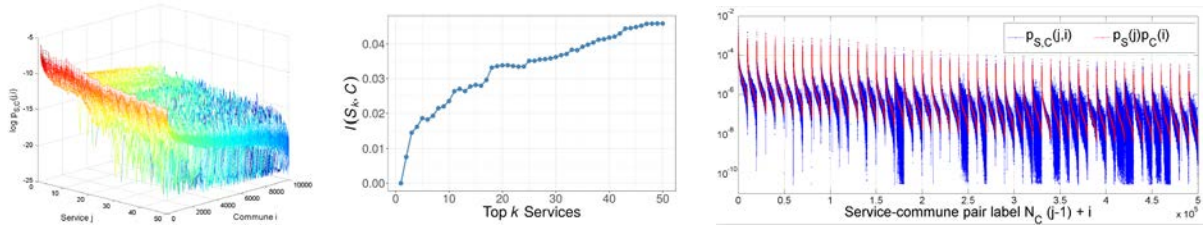

Figure 1: Probabilistic view of mobile service demands in France. Left: joint distribution $p_{S,C}(j,i)$ of services in S and communes in C. Middle: mutual information $I(S_k;C)$ computed on subsets $\mathcal{S}_k$ of the k services generating the most traffic. Right: unidimensional rendering of $p_{S,C}(j,i)$ (blue) and marginal distributions product $p_S(j) \cdot p_C(i)$ (red). Figure best viewed in colors.

We can now define informative services as a subset of all mobile services such that their mutual information with respect to the target spatial areas is maximized. Formally, the subset of informative services defined as above maps to the optimal choice of $\mathcal{S}' \subseteq \mathcal{S}$ that solves the following problem:

$$\mathcal{S}'_{\text{opt}} = \arg \max_{\mathcal{S}' \subseteq \mathcal{S}} I(C|_{\mathcal{S}'}; S|_{\mathcal{S}'}),$$

where $C|_{\mathcal{S}'}$ and $S|_{\mathcal{S}'}$ are the random variables representing the sampled area and service in the restricted scenario where only services in $\mathcal{S}'$ are considered.

Unfortunately, the above combinatorial problem is too complex to be solved exactly for typical data sizes. We thus adopt the following heuristic approach to determine $\mathcal{S}'$. Let us consider the whole set of services and sample service j from an arbitrary probability distribution $p_S(j)$. Then, along the lines of (1), we consider $I(C;S) = H(S) - H(C|S)$, where

$$H(C|S) = -\sum_{j=1}^{N_S} p_S(j) \sum_{i=1}^{N_C} p_{C|S}(i|j) \log p_{C|S}(i|j),$$

and area i is sampled with probability

$$p_{C|S}(i|j) = \frac{t_{i,j}}{\sum_{i'=1}^{N_C} t_{i',j}}.$$

The optimal service distribution p_S^* that weights services according to their informativeness is the one that solves

$$p_S^* = \arg \max_{p_S(j)} I(C;S),$$

which we obtain via the Blahut-Arimoto algorithm [1, 3]. We then sort the services according to decreasing values of p_S^* and we set a threshold θ. Then, $\mathcal{S}'$ contains those services for which $p_S^* > \theta$. The value of θ can be empirically chosen by inspecting the shape of p_S^*, as we will see next in the context of our reference scenario.

4.2 Application to the France case study

When applied to the France reference scenario, the approach returns the result in Fig. 2. Here, mobile services in $\mathcal{S}$ (x axis) are ranked based on their associated weights p_S^*. The differences in weights is striking, and spans tens of orders of magnitude: this implies that some services are significantly more informative than others. Specifically, there is a clear gap in the ranked values after the 13$^{\text{th}}$ service, highlighted by the vertical line, which indicates a substantial reduction of informativeness beyond that point. As the

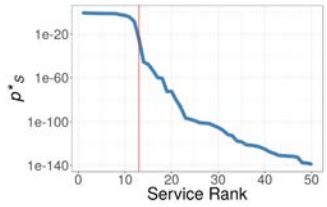

Figure 2: Mobile services ranked by the weighting distribution p_S^* returned by the Blahut-Arimoto approach in France.

Table 1: Set $\mathcal{S}'$ of informative services in France. Values within parentheses denote OS-specific traffic, while the absence of such values indicates OS-independent traffic.

p_S^* rank	Service name	Weekly traffic	/ Overall rank
1	torrent (Android)	8,070 GB	/ 43
2	Netflix (Android)	8,244 GB	/ 42
3	Netflix (iOS)	13,100 GB	/ 33
4	streaming (Android)	6,989 GB	/ 47
5	OS updates (iOS)	10,100 GB	/ 38
6	streaming (Windows Mobile)	11,800 GB	/ 35
7	streaming (iOS)	20,503 GB	/ 25
8	OS updates (Windows Mobile)	42,900 GB	/ 18
9	WhatsApp	8,821 GB	/ 40
10	OS updates (Android)	6,993 GB	/ 46
11	blogging	11,100 GB	/ 37
12	cloud storage (iOS)	11,300 GB	/ 36
13	SoundCloud	7,814 GB	/ 45

first 13 mobile services in the p_S^* ranking yield nearly equivalent informativeness, we include them all in the set $\mathcal{S}'$. These informative services are listed in Tab. 1, where we remark that:

- there exists a notable pattern in the selected mobile services, as they belong to specific classes, *i.e.*, operating system (OS) updates, and audio/video streaming;
- none of these informative services are among the top 15 in terms of total generated traffic, but they are all within the top 50, and amount to substantial network traffic loads of Terabytes per week.

Overall, those identified above are the mobile services that show substantial diversity in usage across France. Indeed, if S' is the random variable representing the selection of a service in $\mathcal{S}'$, the mutual information $I(S';C)$ is equal to 0.236, which is between 5 and 25 times that recorded from the top-k services in $\mathcal{S}_k$, for any $k \leq 50$, in the middle plot of Fig. 1. The findings above convey our second takeaway message: ***there exist a small set of applications that are actually informative of the geographical diversity in mobile service consumption, and which belong to fairly specific service categories.***

5 CLUSTERING MOBILE SERVICE USAGES

In order to understand how the informative services in $\mathcal{S}'$ are linked to the actual geography of France, we cluster the communes in C based on their mobile service usage distribution. Clustering based on distributions itself is non-trivial, and the scale of our scenario adds a layer of complexity. We build upon a recent breakthrough in social segregation analysis [7] to define the *weighted diversity* of two distributions, and use it in a scalable two-phase process.

5.1 Weighted diversity

Our problem essentially involves clustering geographical areas according to their service usage distribution. In our context, a clustering of areas with N_K clusters ($N_K \leq N_C$) is a map $\mathfrak{K} : C \to \mathcal{K}$ where $\mathcal{K} = \{1, \ldots, N_K\}$. We then define $J_{\mathfrak{K}}(k)$, $k = 1, \ldots, N_K$ as

$$J_{\mathfrak{K}}(k) = \{c \in C : \mathfrak{K}(c) = k\},$$

which is the set of geographical areas grouped into cluster k. Also, a clustering $\mathfrak{K}_1$ is a *refinement* of another clustering $\mathfrak{K}_2$ if and only if, for any two $c_1, c_2 \in C$, $\mathfrak{K}_1(c_1) = \mathfrak{K}_1(c_2)$ implies $\mathfrak{K}_2(c_1) = \mathfrak{K}_2(c_2)$.

Let $K = \mathfrak{K}(C)$ be the random variable representing the cluster in which a sampled area belongs to. The distribution p_K of clusters is induced by the distribution of areas p_C in a trivial way, *i.e.*,

$$p_K(k) = \sum_{i \in J_{\mathfrak{K}}(k)} p_C(i).$$

We can now define the mutual information between cluster and service random variables, denoted by $I(K, S)$. By the data processing inequality, we have $I(K; S) \leq I(C; S)$, since K is a deterministic function of C so that the knowledge of C implies the knowledge of K but not vice versa. More generally, we have the proposition:

Proposition 5.1. *If $\mathfrak{K}_1$ is a refinement of $\mathfrak{K}_2$ and $K_i = \mathfrak{K}_i(C)$, $i = 1, 2$, then*

$$I(K_2; S) \leq I(K_1; S)$$

Proof: For the proof, we first consider that $\mathfrak{K}_1$ has $N_K + 1$ clusters, $\mathfrak{K}_2$ has N_K clusters, $J_{\mathfrak{K}_1}(k) = J_{\mathfrak{K}_2}(k)$ for $k = 1, \ldots, N_K - 1$ and $J_{\mathfrak{K}_2}(N_K) = J_{\mathfrak{K}_1}(N_K) \cup J_{\mathfrak{K}_1}(N_K + 1)$. Then, the difference $I(K_1; S) - I(K_2; S)$ is given in (2), where $p_{K_2}(N_K) = p_{K_1}(N_K) + p_{K_1}(N_K + 1)$. Now, since mutual information is convex, we have as a consequence (3). This implies that $I(K_1; S) - I(K_2; S) \geq 0$.

When $\mathfrak{K}_1$ is a general refinement of $\mathfrak{K}_2$, we can always imagine a chain of refinements that starts from $\mathfrak{K}_2$ and ends to $\mathfrak{K}_1$, in which each step consists in splitting a cluster into two. For each of such steps, we can apply the argument above, and conclude again that $I(K_1; S) - I(K_2; S) \geq 0$. ∎

In the above proposition, the information loss $I(K_1; S) - I(K_2; S)$ can be seen as the price to pay for merging two clusters of $\mathfrak{K}_1$ into a single cluster of $\mathfrak{K}_2$. Based on this observation, and given a clustering $\mathfrak{K}$, we can introduce a pairwise cost measure for the joining of any two clusters $J_{\mathfrak{K}}(k_1)$ and $J_{\mathfrak{K}}(k_2)$, which will be central to the design of our information theory-based clustering algorithm. We name such a measure *weighted diversity*, and define it as follows.

Definition 5.1. *Given a spatial clustering $\mathfrak{K}$ with clusters $J_{\mathfrak{K}}(1)$, $\ldots$, $J_{\mathfrak{K}}(N_K)$, let us define a new clustering $\mathfrak{K}_{i,i'}$, with $N_K - 1$ clusters, obtained from $\mathfrak{K}$ by merging clusters $J_{\mathfrak{K}}(i)$ and $J_{\mathfrak{K}}(i')$. Moreover, let $K = \mathfrak{K}(C)$ and $K_{i,i'} = \mathfrak{K}_{i,i'}(C)$. We define the weighted diversity between $J_{\mathfrak{K}}(i)$ and $J_{\mathfrak{K}}(i')$ as*

$$d(i, i') = I(K; S) - I(K_{i,i'}; S). \tag{4}$$

In the above proposition, the information loss $I(K_1; S) - I(K_2; S)$ can be seen as the cost entailed by passing from a more refined description of service usage distribution given by clustering $\mathfrak{K}_1$ to a coarser description corresponding to $\mathfrak{K}_2$. Next, we employ the measure in (4) as the basis for a clustering algorithm.

5.2 Practical clustering algorithm

The weighted diversity measure can be leveraged as a distance metric for practical algorithms that aim at clustering geographical areas based on mobile service usage. It has the following desirable features: (*i*) it depends only on the two considered clusters i and i', and not on the other components of clustering $\mathfrak{K}$, as per (2), hence it is a suitable distance metric for clustering; (*ii*) its definition and properties are independent of how $\mathfrak{K}$ is obtained, hence it can be used in combination with any clustering algorithm; and, (*iii*) it is specifically designed for computing the dissimilarity of two distributions, *i.e.*, the data representation that characterizes our system. In addition, the metric has a clear interpretation in information theory terms, as it maps to the loss of information incurred by merging the mobile service usage distributions of two geographical areas into one. Two areas with identical service usage will be characterized by a null weighted diversity, and merging them into the same cluster will preserve the original distributions without any loss of information. Instead, two areas with very diverse service consumption will have a high weighted diversity, and joining them in a same cluster will lose the specificity of the original distributions.

According to (*ii*) above, we can embed weighted diversity as a similarity measure in any clustering algorithm. In this work, we opt for a greedy *divide-et-impera* solution, which, unlike legacy (*e.g.*, spectral, agglomerative, modularity-based) clustering techniques, avoids computing pairwise weighted diversities for the billion edges in the complete mesh of geographical areas. The algorithm, outlined in Alg. 1, separates the problem in two phases as follows.

5.2.1 Phase I. In the first phase, we start by initializing the clustering $\mathfrak{K}$ to the set of communes **C**, *i.e.*, considering each commune in a separate cluster (line 2). We then compute the dissimilarity matrix **D** among all communes in **C** by initializing all values to ∞ (line 3), and then updating the actual weighted diversity via the expression in (4) only between pairs of adjacent communes (lines 4-6). An important remark is that the matrix **D** is very sparse, since communes typically have a fairly small number of neighboring areas (*e.g.*, less than ten), which is orders of magnitude lower than the cardinality of **C**: therefore, populating **D** with weighted diversities is dramatically faster than computing the weighted diversity for all pairs of areas in the target region. At this point, matrix **D** represents a sparse, weighted graph on which we can run any practical algorithm `cluster` to produce the desired grouping of the original communes in the starting $\mathfrak{K}$ into N_{K_1} clusters (line 7). In our implementation, we opt for a simple hierarchical clustering technique also presented in Alg. 1. This is a traditional greedy approach [2, 11]: until the desired number of clusters is obtained (line 16), it proceeds by identifying the two areas (or clusters) with minimum weighted

$$I(K_1;S) - I(K_2;S) = H(S|K_2) - H(S|K_1)$$
$$= \sum_{k=1}^{N_K} p_{K_2}(k) H(S|K_2 = k) - \sum_{k=1}^{N_K+1} p_{K_1}(k) H(S|K_1 = k)$$
$$= p_{K_2}(N_K) H(S|K_2 = N_K) - p_{K_1}(N_K) H(S|K_1 = N_K) - p_{K_1}(N_K + 1) H(S|K_1 = N_K + 1) \quad (2)$$
$$H(S|K_2 = N_K) \geq \frac{p_{K_1}(N_K)}{p_{K_1}(N_K) + p_{K_1}(N_K + 1)} H(S|K_1 = N_K) + \frac{p_{K_1}(N_K + 1)}{p_{K_1}(N_K) + p_{K_1}(N_K + 1)} H(S|K_1 = N_K + 1) \quad (3)$$

diversity (line 17), removing them from the current set of clusters (line 18), performing a merge of the geographical areas and associated mobile service usage distributions (line 19), and finally adding the new cluster to the updated $\mathfrak{K}$ (line 20). The dissimilarity matrix is also updated, by removing the weighted diversity values associated to the two merged areas, and computing and adding to **D** the weighted diversities between the newly created cluster J and all adjacent (merged) regions in the current $\mathfrak{K}$ (line 21-26).

At the end of this phase, a specific clustering $\mathfrak{K}_1$ of N_{K_1} merged communes is selected. Typical approaches for picking N_{K_1} rely on expert knowledge of the system, or stopping rules [25]. Instead, we opt for a simple and pragmatic strategy. Each iteration of the `cluster` algorithm decreases N_K by generating a refinement of the previous clustering, which, according to Definition 5.1, retains lower or equal information than that available at the previous step. Thus, a larger N_{K_1} is always a better choice, and N_{K_1} can be straightforwardly set to the order of the largest graph that is computationally manageable during the second phase.

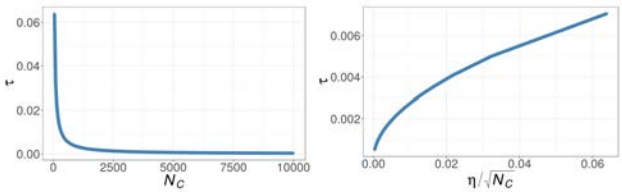

Figure 3: France scenario. Left: variation of τ with number of communes. Right: relationship between τ and $1/\sqrt{N_C}$.

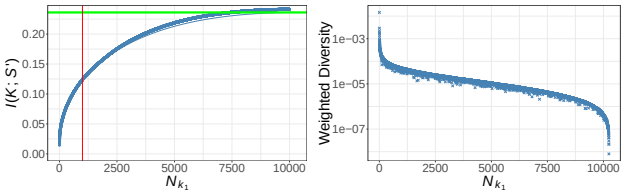
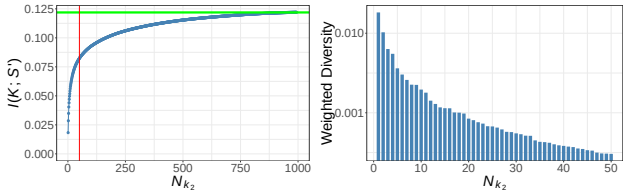
5.2.2 Phase II. In the second phase, we build a clique, *i.e.*, fully connected mesh, of the clusters received from the first phase, and compute the weighted diversity for all pairs of clusters in $\mathfrak{K}_1$ (lines 8-11). Note that, unlike in the first phase, this is now a feasible operation, as N_{K_1} is selected by accounting for computational feasibility.



We then run the `cluster` algorithm again on the new graph (line 12). This operation allows breaking the spatial proximity constraint imposed during phase I: areas that are geographically distant and yet show similar mobile service distributions can now be grouped together in a scalable way. Using the weighted diversity as an edge weight metric returns an easily interpretable view of the information loss at each refinement, and allows for an educated choice of the eventual number of clusters to retain, N_{K_2}. We provide an example of this property in the France case study, in Section 5.3.

5.2.3 Complexity analysis. The function `weightedDiversity` operates on the conditional distributions $p_{S|C}(j|i) = \rho_{j,i}$ of S on C. Thus, its complexity is linear with respect to the size of the outcome set of S, *i.e.*, $O(N_S)$ for any pair of geographical areas.

During phase I, the calculation of `weightedDiversity` is first repeated for all non-zero elements of the adjacency matrix $\mathbf{A} \in \mathbb{R}^{N_C \times N_C}$ to obtain **D**, which yields a complexity $O\left(N_S(\tau N_C)^2\right)$. Here, τ is the squared fractional average degree in the adjacency graph described by matrix **A**: it denotes the sparsity of the matrix due by the geographical topology of the target region. Then, each iteration of the `cluster` algorithm requires recomputing all weighted diversities for the neighboring areas of those selected for merging, with complexity $O\left(N_S(\tau N_C)\right)$. Overall, this leads to a complexity of the first phase $O\left(N_S(\tau N_C)^2 + N_S(\tau N_C)\right) = O\left(N_S(\tau N_C)^2\right)$.



In phase II, the same operations above are repeated on a different, fully connected graph with a reduced number of nodes equal to the clusters from the first phase. Hence, the complexity is $O\left(N_S N_{K_1}^2\right)$. As $N_{K_1} \ll N_C$, we can approximate the total complexity of the algorithm in the two phases as $O\left(N_S(\tau N_C)^2\right)$.

A key remark is that, in planar spatial graphs such as those we consider, τ is typically an extremely low number that scales approximately as $1/\sqrt{N_C}$ when N_C grows [5]. This effectively reduces the complexity of the proposed two-phase algorithm to $O\left(N_S N_C\right)$,

(a) Mutual Information (b) Weighted diversity

Figure 4: Phase I of the clustering algorithm. Left: Mutual information $I(K;S')$ retained by the clustering versus the number of returned clusters N_{K_1}. Right: weighted diversity of the two communes (or clusters) aggregated at each step.

(a) Mutual Information (b) Weighted diversity

Figure 5: Phase II of the clustering algorithm. Left: Mutual information $I(K;S')$ retained by the clustering versus the number of returned clusters N_{K_2}. Right: weighted diversity of the two communes (or clusters) aggregated at each step.

making it extremely efficient in large-scale scenarios. Evidence of the scalability of the approach in is provided in Fig. 3, for the France nationwide scenario. The left plot shows the evolution of τ with respect to N_C in the case of the adjacency matrix of communes in France, when considering an increasingly larger portion of the country, *i.e.*, higher N_C. The curve confirms the scaling property indicated above, which is even more clearly seen in the right plot of Fig. 3, where τ is shown to scale as $\eta/\sqrt{N_C}$ with $\eta = 0.05$.

5.3 Results in the France case study

The two-phase clustering introduced in Section 5.2 above enables the investigation of mobile service usage across the whole country of France. In the light of the results in Section 4.2, it makes sense to limit the analysis to the set of informative services $\mathcal{S}'$ that yield non-negligible geographical diversity.

5.3.1 Phase I analysis. Fig. 4 shows the mutual information $I(K;S')$ retained by all clusterings $\mathfrak{K}_1$ in the hierarchical structure formed by the greedy approach during the first phase of the algorithm. Looking at each of these plots from right to left allows imagining how the algorithm works. Specifically, $I(K;S')$ is illustrated as a function of N_{K_1}, *i.e.*, the number of clusters. In the left plot, we note that $I(K;S')$ grows with N_{K_1}, as expected from Definition 5.1, until it reaches the complete mutual information $I(C;S')$ (green horizontal line) that characterizes the system of $N_{S'}$ (*i.e.*, 13) services and N_C (*i.e.*, 10,000) communes in France, when $N_{K_1} = N_C$.

The curve grows faster at first, to slow down afterwards: this means that the majority of the information is retained by the very first clusters, or, equivalently, that the latest iterations of the agglomerative clustering are those that lose the highest informations. This is highlighted in the right plot of Fig. 4, where the merging of the few tens of clusters (on the left) results in an information loss, quantified by the weighted diversity, which is orders of magnitude higher than that incurred at earlier stages of the algorithm (to the right). The diversity gently degrades across the vast majority of N_{K_1} values, with the exception of the last clusterings: this implies that only the opening aggregations do not lose information.

5.3.2 Phase II analysis. As recommended in Section 5.2, we retain the maximum number of clusters for which we can afford the computationally expensive processing of the second phase. We thus consider $N_{K_1} = 1,000$, which is highlighted by the vertical line in Fig. 4, and captures 52% of the original mutual information. This means that we are bounding the computational complexity of the analysis in phase II to operations on graphs with 500,000 edges.

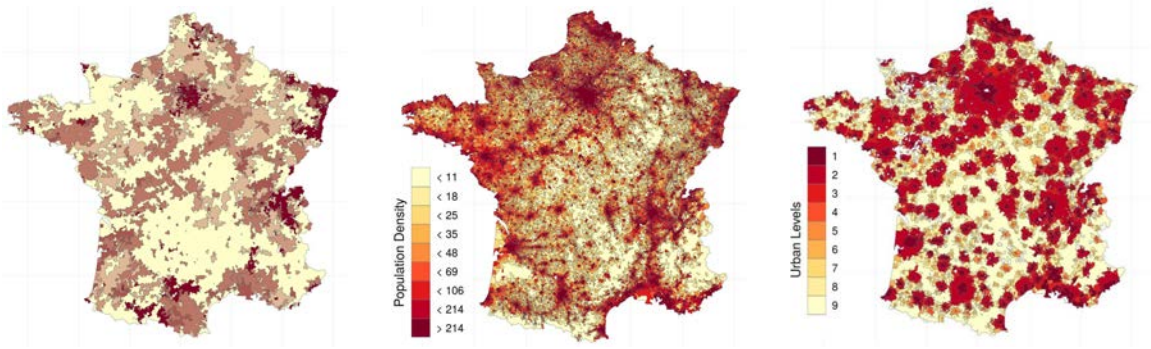
Table 2: Urbanization levels categorizing French communes. Metropolis, medium- and small-sized cities are based on the number of workplaces. Intermediate classes are obtained by geographical adjacency to the three types of urban areas.

Level	*Urbanization class*	*Workplaces*	*Adjacency*
1	Large metropolis	10,000 and more	-
2	Large metropolis suburbs	-	to 1
3	Large metropolis influence area	-	to 2
4	Medium-sized city	5,000 - 10,000	-
5	Medium-sized city suburbs	-	to 4
6	Small-sized city	1,500 - 5,000	-
7	Small-sized city suburbs	-	to 6
8	Town	-	to 7
9	Rural area	-	-

Equivalent curves to those for the first phase, illustrating the output of the clustering on the fully connected mesh of 1,000 clusters of communes from the first phase, are shown in Fig. 5. Interestingly, the mutual information curve, in the left plot, grows much faster with N_{K_2} than it did with N_{K_1} during phase I. We ascribe this phenomenon to the fact that the clique representation removes all geographical constraints, and grants higher flexibility during the clustering process, allowing matching and merging (clusters of) communes that are spatially distant but showing fairly correlated mobile service distributions. Therefore, the result implicitly proves that similar mobile application usages often occur in areas located at significant geographical distance in France.

The sudden increase of the mutual information also lets us take an easy, informed choice about a reasonable number of clusters: *e.g.*, by selecting $N_{K_2} = 50$ (the red vertical line in Fig. 5), it is possible to retain 67.5% of the mutual information of the 1,000 clusters considered after first phase, and 35% of the total mutual information of the system. Or, a very small $N_{K_2} = 9$ preserves 44% and 23% of the mutual information in the two cases. The detailed weighted diversity values are in the right plot of Fig. 5.

Overall, the observations above let us formulate our third takeaway message: ***a small number of commune clusters (e.g., 9, equal to a fraction 0.0009 of around 10,000 communes considered in the analysis) is sufficient to retain a substantial percentage (e.g., over 20%) of the diversity observed in the usage of mobile services in France***. These figures refer to the set $\mathcal{S}'$ of services that yield the highest spatial heterogeneity. Then, the takeaway above implies that there exists a fairly limited set of typical behaviors in the usage of mobile services across the whole country, even when considering only those applications that show substantial geographic diversity.



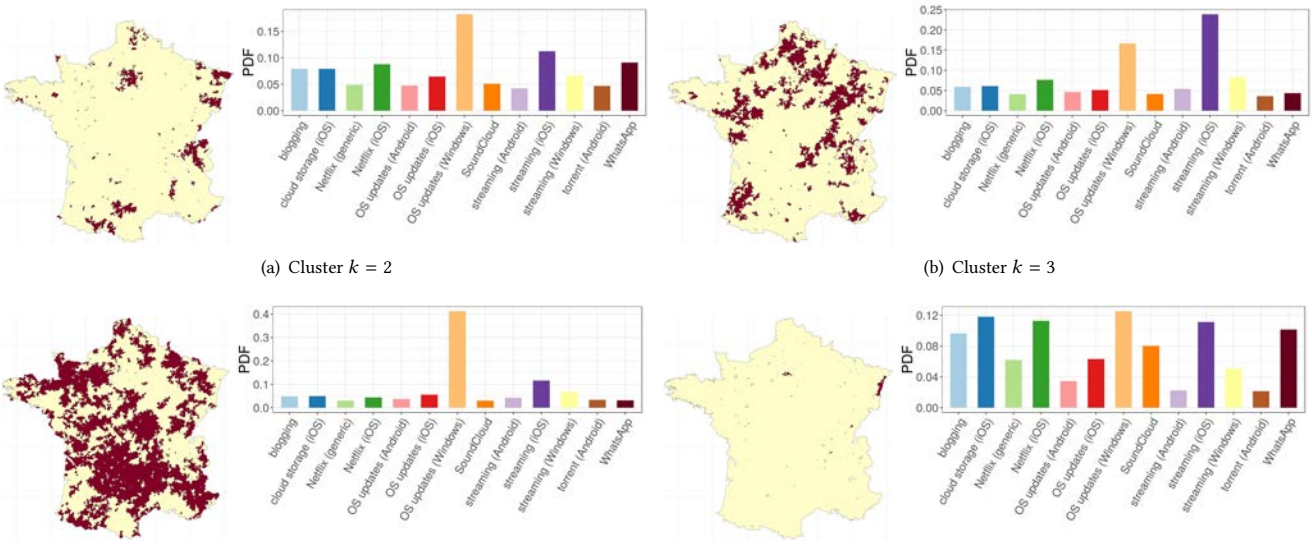


Figure 6: Maps of France. Left: geographical layout of the $N_{K_2} = 9$ clusters produced by our algorithm, each identified by a color. Middle: population density levels (in people per square kilometer). Right: urbanization levels. Figure best viewed in colors.

(b) Cluster $k = 3$

(c) Cluster $k = 5$

(d) Cluster $k = 9$

Figure 7: Geographical coverage of four representative clusters, and associated PDF $\rho_{j,k}$ of the informative service demands.

6 INTERPRETATION OF RESULTS

In order to better understand the results obtained so far, we investigate the links between the clustered mobile service usages and the country demographics in the representative case of $N_{K_2} = 9$.

6.1 French geography of mobile service usage

The left plot in Fig. 6 provides an illustration of how clusters are associated to different geographical areas in France. The spatial pattern of clusters is not random. For instance, one cluster clearly tells apart the Paris metropolitan area from its surroundings (dark patch at the center top of the map); or, most of the areas in central France are clustered together in a large continuous region (wide light territory at center bottom of the map).

In fact, a simple visual inspection reveals that the map of clusters yields substantial resemblances to those of two important demographic measures: (*i*) population density, *i.e.*, the number of dwelling units per commune, measured in inhabitants/Km^2; (*ii*) the urbanization level, *i.e.*, a categorization of communes based on number of workplaces and mutual geographical adjacency, which results in the nine categories in Tab. 2 [17]. The likeness is evident when comparing the left plot in Fig. 6 with the middle and right plots in the same figure, which respectively portray the population density and urbanization levels for all communes in France.

Also, it is interesting to observe how the most informative services are consumed in these clusters. Fig. 7 shows the Probability Density Function (PDF) $p_{S'|K}(j|k) = \rho_{j,k}$ of services $j \in \mathcal{S}'$ in a selected subset of clusters $k \in \mathcal{K}$. For the sake of clarity, the PDFs are accompanied by maps displaying the regions included in each cluster. We observe that the distributions yield significant differences, and characterize very heterogeneous surfaces. For instance, clusters 3 and 5 cover large regions all over France that appear to be fairly complementary; the former happens to be characterized by a distinctively high usage of streaming services, while the latter has a high incidence of background traffic generated by smartphones that run Windows Mobile as the operating system. Instead, clusters 2 and 9 cover much smaller areas in France, and have more balanced distributions across all services.

6.2 Linking services and demographics

The qualitative analysis above suggests: (*i*) an apparent correlation between the geographical layout of the clusters and the intensity of human presence (captured by the population density and urbanization level); and (*ii*) striking differences in the way specific services are consumed across clusters. By combining these observations, the identified clusters allow bonding mobile services to demographics.

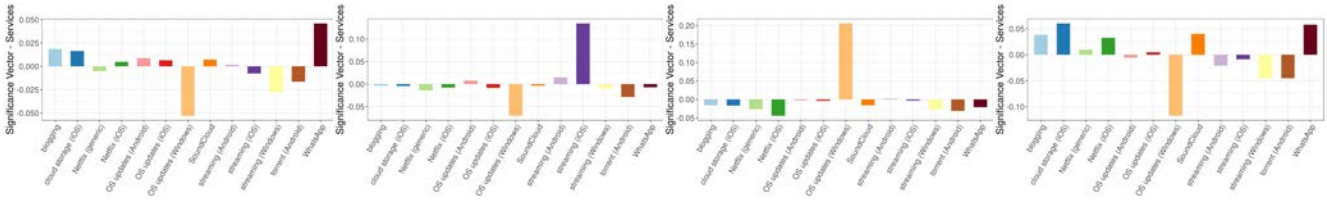
6.2.1 Methodology. Let $\mathcal{D} = \{1, \ldots, N_D\}$ be a set of demographics levels (either discretized population density levels, or urbanization levels), with cardinality N_D. All geographical areas $i \in C$ are assigned a unique level in $d \in \mathcal{D}$. We can then define as D the random variable with outcome in $\mathcal{D}$ that denotes the probability that a given area i is characterized by a specific demographics level. The joint distribution of demographics levels and clusters is $p_{D,K}(d,k)$, and we can compute conditional probabilities $p_{D|K}(d|k)$ that describe the distribution of individual demographics levels within cluster k.

We now define *significance vectors* $\boldsymbol{\rho}_k^D(d)$ and $\boldsymbol{\rho}_k^{S'}(j)$ from the distributions $p_{D|K}(d|k) = \rho_{d,k}$ and $p_{S'|K}(j|k) = \rho_{j,k}$, as:

$$\boldsymbol{\rho}_k^D(d) = \rho_{d,k} - \frac{1}{N_K - 1} \sum_{k' \in \mathcal{K}, k' \neq k} \rho_{d,k'}, \quad \forall k \in \mathcal{K},$$

$$\boldsymbol{\rho}_k^{S'}(j) = \rho_{j,k} - \frac{1}{N_K - 1} \sum_{k' \in \mathcal{K}, k' \neq k} \rho_{j,k'}, \quad \forall k \in \mathcal{K}.$$

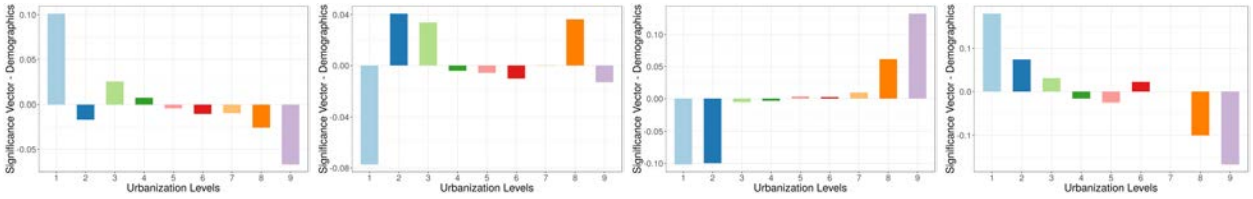
The significance vector $\boldsymbol{\rho}_k^D(d)$ (respectively, $\boldsymbol{\rho}_k^{S'}(j)$) associated to cluster k thus assigns a weight bounded in $[-1, 1]$ to each demographics level (respectively, service). Such weight indicates how much the fraction of communes in the clusters associated to one demographics level (respectively, the demand for a specific service in the cluster) differ, positively or negatively, from the average across all clusters. Example illustrations are provided in Fig. 8 and Fig. 9. Fig. 8 shows the significance vectors $\boldsymbol{\rho}_k^{S'}(j)$ derived from the conditional service distributions at the four representative clusters in Fig. 7. Fig. 9 portrays the significance vectors $\boldsymbol{\rho}_k^D(d)$ of the same four clusters, with respect to urbanization levels. We can observe, for instance, that clusters 2 and 9 show similar patterns in $\boldsymbol{\rho}_k^{S'}(j)$ and are much more present in dense urban areas. Instead, cluster 5 is characterized by very high incidence of Windows Mobile updates, as well as by a striking presence in rural regions.



The extent of inter-dependency among services and demographics levels can be computed in a rigorous way for each cluster $k \in \mathcal{K}$, by means of the matrix multiplication $\boldsymbol{\rho}_k^D(d) \left[\boldsymbol{\rho}_k^{S'}(j)\right]^T$, where $[\cdot]^T$ is the matrix transposition operation. This returns an *incidence matrix* $\mathbf{M}_k(d,j) \in \mathbb{R}^{N_D \times N_{S'}}$, where element (d,j) is a value in $[-1,1]$ that indicates the peculiarity of demands for service j in demographics level d, as conveyed by cluster k. Highly positive (resp., negative) values point at abnormally high (resp., low) incidence of the service in the demographics level. Finally, it is possible to derive a single incidence matrix for the overall clustering $\mathfrak{K}$, by simply averaging over all clusters $k \in \mathcal{K}$, *i.e.*, $\mathbf{M}(d,j) = \frac{1}{N_{K_2}} \sum_{k \in \mathcal{K}} \mathbf{M}_k(d,j)$.

6.2.2 Results and discussion. Examples of the matrices $\mathbf{M}(d,j)$ obtained with the clustering $\mathfrak{K}$ portrayed in the left plot of Fig. 6, where $N_{K_2} = 9$, are in the left and middle plots of Fig. 10, for demographics levels obtained with population density percentiles and urbanization levels, respectively. The matrices confirm that some informative services are prone to an higher-than-average use in areas characterized by specific demographics levels; for instance, Windows system updates and streaming services have higher incidence in rural areas, and a lower impact on urbanized areas; conversely, WhatsApp is widely adopted in metropolitan areas, but shows lower-than-average usage in the countryside. Interestingly, the two metrics used to derive demographics levels, in the left and middle plots of Fig. 10, appear to yield consistent views across services. We provide a joint representation in the right plot of Fig. 10, where application $j \in \mathcal{S}'$ is located in the bidimensional space of population density and urbanization levels, by assigning to it coordinates $\frac{1}{N_D} \sum_{d \in \mathcal{D}} d \cdot \mathbf{M}(d,j)$, one for each notion of $\mathcal{D}$. The plot confirms our observation of a clear association of specific informative services to different demographics, providing an interesting and consistent ranking of applications versus urbanization.

Specifically, it is apparent that people living in rural regions of France have a preference to use Windows Mobile devices. Automatic updates for such OS are especially characterizing of the spatial diversity, due to a lower overall traffic per user in rural regions, which makes background traffic stand out. Instead, inhabitants of French metropolitan areas prefer Apple iPhones, as iOS-only services have a higher incidence than normal in cities. Residents in French cities also display a remarkable tendency to significantly use WhatsApp, a popular messaging application, and long-lived streaming services such as Netflix.



We underscore that the diversity of mobile service usage observed above is not an artifact of the different availability of radio access technolologies in urban and rural areas of France. The observed diversity of OS-specific traffic is a first evidence: there is no reason why lower or higher mobile datarates should affect adoption of Windows Mobile devices rather than Apple iPhones. To further prove our point, we leverage 2G, 3G, and 4G coverage maps provided by ARCEP, the French agency in charge of regulating telecommunications in France[5], as well as data on the deployment of 1.8 million Wi-Fi home access points owned by Free, an incumbent Internet service provider in the country [28]. Both datasets refer to around the same period of the mobile service traffic collection. The left plot in Fig. 11 shows that 4G coverage (dark blue) was already pervasive in France at the end of 2016: most of the national territory enjoyed broadband mobile access, including many regions tagged as suburban and rural by the demographics levels in Fig. 6. In the relatively small portion of geographic surface without 4G access, 3G was available, and 2G-only coverage areas were basically absent. Therefore, the cellular access technology cannot be considered as a discriminant for the geographical diversity of usages observed in our study for specific services. Also, the right plot in Fig. 11 shows that Wi-Fi presence, measured in available access points per person, is largely uniform across communes; it ranges between 10 and 50 people per one Free Wi-Fi router, without any clear correlation with population density. The limited heterogeneity of Wi-Fi presence lets us conclude that also Wi-Fi access alone is insufficient to justify the differences in mobile service consumption across urban and rural areas that we find in the France scenario.

Demographics levels in $\mathcal{D}$ are derived from discretized population density in terms of number of people per square kilometer (left) and urbanization levels (middle). Services are from the informative set $\mathcal{S}'$. Right: relative positioning of informative mobile services in the space of population density and urbanization levels.

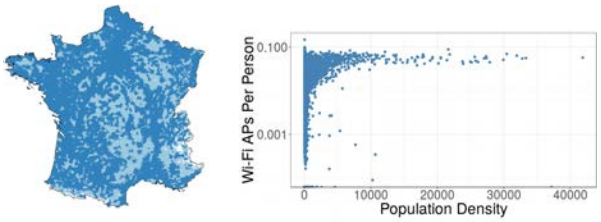

Figure 11: Left: 3G (light) and 4G (dark) coverage in France. Right: Scatterplot of the population density and Wi-Fi access point per person recorded in all communes of France.

Overall, the results in this section lead to our final takeaway message: ***there exist clear interplays between the usage of a specific set of mobile services and the demographics features of the territory, i.e., people tend to consume differently some applications in cities and in the countryside***. Such relationships are time-invariant: tests not detailed here due to space limitations return nearly identical results to those in Fig. 10 when disaggregating the data into night, morning, afternoon, and evening hours.

7 CONCLUSIONS

We unveil that most mobile services are typically consumed in very similar ways across a whole country like France. This suggests that heterogeneity in mobile service usage is observable at citywide scale due to land use [16], and at worldwide scale due to cultural and language differences [27], but it is much weaker at nationwide scale. In the latter case, we show that only a few specific services display spatial diversity, in a way that is strongly linked to urbanization. While our results are for France, the methods used to derive them are general. Also, they are ductile, which leaves space for fine tuning and improvements: for instance, the two-phase algorithm can accommodate any clustering technique as the `cluster` procedure, including more complex solutions than a greedy strategy. Our insights and approach can be useful in mobile networking (for infrastructure planning), sociology (to understand relationships between digital activity and social segregation), or urban planning (to correlate mobile service usage and city structures).

ABSTRACT

JavaScript has been used for various attacks on client-side web applications. To hinder both manual and automated analysis from detecting malicious scripts, code minification and code obfuscation may hide the behavior of a script. Unfortunately, little is currently known about how real-world websites use such code transformations. This paper presents an empirical study of obfuscation and minification in 967,149 scripts (424,023 unique) from the top 100,000 websites. The core of our study is a highly accurate (95%-100%) neural network-based classifier that we train to identify whether obfuscation or minification have been applied and if yes, using what tools. We find that code transformations are very widespread, affecting 38% of all scripts. Most of the transformed code has been minified, whereas advanced obfuscation techniques, such as encoding parts of the code or fetching all strings from a global array, affect less than 1% of all scripts (2,842 unique scripts in total). Studying which code gets obfuscated, we find that obfuscation is particularly common in certain website categories, e.g., adult content. Further analysis of the obfuscated code shows that most of it is similar to the output produced by a single obfuscation tool and that some obfuscated scripts trigger suspicious behavior, such as likely fingerprinting and timing attacks. Finally, we show that obfuscation comes at a cost, because it slows down execution and risks to produce code that changes the intended behavior. Overall, our study shows that the security community must consider minified and obfuscated JavaScript code, and it provides insights into what kinds of transformations to focus on. Our learned classifiers provide an automated and accurate way to identify obfuscated code, and we release a set of real-world obfuscated scripts for future research.

1 INTRODUCTION

JavaScript has become the dominant programming language for client-side web applications and nowadays is used in the vast majority of all websites. The popularity of the language makes JavaScript an attractive target for various kinds of attacks. For example, cross-site scripting attacks try to inject malicious JavaScript code into websites [14, 17, 28]. Other attacks aim at compromising the underlying browser [6, 7] or extensions installed in a browser [11, 12], or they abuse particular web APIs [19, 26, 30].

An effective way to hide the maliciousness of JavaScript code are code transformations that preserve the overall behavior of a script while making it harder to understand and analyze. Such transformations affect both manual code inspection, e.g., because the code becomes harder to understand, and automated code analysis, e.g., because the malicious behavior is disguised as apparently harmless operations. There exist a variety of code transformations, ranging from renaming of local variables to more complex code changes that affect the control flow and data flow. We refer to transformations aimed at reducing code size, typically by renaming local variables to shorter names, as *minification*. In contrast, we refer to more complex transformations aimed at hindering the understanding and analysis of code as *obfuscation*. It is important to note that minification and obfuscation may be used for legitimate reasons, such as reducing code size or protecting intellectual property. However, independently of what the reason for transforming code is, it affects the ability of human and automated security analysis.

Despite the potential impact that minification and obfuscation may have on security analysis, little is currently known about how real-world websites use such transformations. A better understanding of what kinds of code transformations are applied in the wild could guide future efforts on making the web more secure. In particular, knowing how widespread minification and obfuscation are helps future analyses to focus on relevant problems. Moreover, understanding what kinds of transformation tools are the most popular enables the development of targeted defense techniques. Unfortunately, to the best of our knowledge, there currently is no comprehensive study of code transformations in the web.

This paper presents a large-scale empirical study of minification and obfuscation in client-side web code. The study involves 967,149 JavaScript files gathered from the top 100,000 websites. We analyze how many of these scripts are transformed through minification and obfuscation, respectively, and which tools are used for these transformations. Moreover, we study which kinds of scripts are transformed particularly often and inspect the runtime behavior

of some obfuscated scripts. Finally, we analyze which costs code transformation may incur by assessing to what extent popular transformation tools influence the performance and correctness of JavaScript code.

Given the large-scale nature of our study, we rely, at least in parts, on automation to answer the above questions. To this end, we present a neural network-based classifier that identifies JavaScript code with particular properties. For example, the classifier can be trained to distinguish transformed from non-transformed code, minified from obfuscated code, and to identify code transformed with particular tools. We show that the classification has very high accuracy for these tasks, providing an effective way to identify particular kinds of scripts across all studied websites.

The study addresses six research questions.

RQ1: How prevalent are minification and obfuscation in client-side JavaScript code? Answering this question is important to determine whether code transformations should be considered by security analyses at all, and what kinds of transformations such analyses should focus on. We find that code transformations are very widespread, affecting 38% of all client-side scripts. The vast majority of the transformed code has been minified, whereas less than 1% of all code is obfuscated. Even though the percentage of obfuscated code is low, the absolute number of obfuscated scripts (2,842) still motivates work on de-obfuscation, as these scripts arguably are the most interesting for security analysis.

RQ2: Which tools are used to obfuscate code in the web? There is a variety of tools available for obfuscating JavaScript code. Understanding which tools and transformation techniques are used most often in practice helps prioritize efforts toward dealing with transformed code. Our study finds that a single obfuscation tool accounts for most obfuscated scripts in the web: 2,551 obfuscated scripts resemble the output of the *Daft Logic Obfuscator*, an online tool that is available free of charge, motivating future work to consider obfuscation techniques implemented by this tool.

RQ3: Does the prevalence of code transformations differ across different kinds of scripts or websites? Since there are many possible reasons for minifying and obfuscating code, it is interesting to ask whether specific kinds of scripts are transformed more often than others. We find that third-party scripts, i.e., code loaded from another website than the one visited by a user, is about twice as likely to be transformed than scripts loaded from the visited website. Possible reasons for this distribution include that content delivery networks minify libraries to reduce network traffic, and that advertisement and tracking code is transformed to protected intellectual property. Studying the prevalence of obfuscation in different categories of websites shows that some categories, e.g., sites with adult content, contain more obfuscated scripts than an average website.

RQ4: What kind of behavior do developers hide behind obfuscation? To further understand the reasons for obfuscating code, we analyze the execution behavior of obfuscated scripts and manually inspect a subset of them. We find that many of the obfuscated scripts access APIs that are typically used for tracking, fingerprinting, cookie syncing, or cookie theft. We also identify a script with an unusually high number of calls to `performance.now`, which could be because the script is exploiting some timing channel.

The final two questions are about potential costs that applying code transformations may incur.

RQ5: How do code transformations affect the performance of code? We find that most obfuscation tools negatively affect performance, i.e., they slow down the execution of the code. In contrast, most minification tools either have no effect on performance or speed up the execution of the code. These findings show that complex code transformations may come at a non-negligible cost, motivating future work on performance-invariant obfuscation.

RQ6: How do code transformations affect the correctness of code? Developers applying an automated code transformation tool may naively assume that the transformation preserves the overall semantics of the code. However, we find that existing tools for both minification and obfuscation often produce corrupt code that behaves differently from the original code. Only about half of the transformed code completely preserves the original semantics, motivating future work on more reliable transformation tools.

The results of our work are relevant for at least four groups of people. First, the study provides insights for developers of security-related program analyses, e.g., static malware checkers and de-obfuscators. In particular, we show that transformed code must be considered by any analysis aimed at real-world, client-side JavaScript code, and we show what kinds of transformations are the most important in practice. Second, the study affects developers of obfuscation and minification tools by highlighting the costs that using state-of-the-art tools imply. Third, the study informs users of transformation tools about the effects that using such tools may have on the performance and correctness of code. Finally, the classifier that we develop to conduct our study enables researchers interested in analyzing real-world JavaScript code to focus on code relevant for their research. For example, the classifier can accurately identify obfuscated code among hundreds of thousands of scripts.

In summary, this paper contributes the following:

- The first large-scale study of minification and obfuscation in real-world, client-side web application code.
- Insights about how code transformations are used in practice, including evidence that minification is widespread, that more complex obfuscation is rather rare yet non-negligible, and that particular obfuscation techniques clearly dominate.
- An automated classification technique that accurately identifies different kinds of transformed code. The technique is useful to select particular scripts, e.g., those with obfuscated code, for further analysis.
- A benchmark of obfuscated JavaScript files gathered from various popular websites, which we provide for future work on de-obfuscating, analyzing, and understanding obfuscated code.

2 CLASSIFICATION OF SCRIPTS

Addressing RQ1, RQ2, RQ3, and RQ4 at the scale of hundreds of thousands of scripts requires an automated technique to determine whether a script has been transformed, and if yes, in what way. While a skilled human could manually label files with high accuracy, that approach does not scale to the amount of JavaScript code considered in our study. One approach to address this challenge would be to define a set of heuristics, e.g., based on idiosyncrasies

of specific transformation tools, and to determine the properties of code based on these heuristics. Unfortunately, the heuristics-based approach relies on human expertise for identifying code properties that are unique to specific transformation techniques, and it cannot be easily adapted to other transformation tools. Instead, we address the challenge of determining properties of code through machine learning. This section presents two machine learning-based approaches for classifying JavaScript code. We use the more effective of the two approaches as the basis of our study.

2.1 Classification Tasks

We address three classification tasks.

TRANS. The first task, called *TRANS*, is to determine whether a given piece of JavaScript code has been transformed by any minification or obfuscation tool. We train classifiers for this task with examples of regular code, which has not been processed by any transformation tool, and with examples of transformed code, which has been processed by a minification or obfuscation tool.

OBFUS. The second task, called *OBFUS*, is to determine whether a given piece of JavaScript code has been obfuscated. We train OBFUS classifiers with examples of regular code, examples of minified but not obfuscated code, and examples of obfuscated code.

TOOL-X. The third task, called *TOOL-X*, is to determine for a given piece of transformed JavaScript code what tool has been used to transform the code. Because popular minification tools apply very similar transformations, we focus on obfuscation tools for this task.

2.2 Training Data for Learning Classifiers

To train the classifiers, we start with a set of human-written, or *regular*, JavaScript files and then create transformed variants of these files.

2.2.1 Corpus of Regular Code. The regular code examples are a subset of a corpus of 150,000 JavaScript files provided by others [24], which consists of human-written, non-transformed code from open-source projects. We remove from this corpus all files with a size less than 1kB, as they provide very little information for the classifiers to make an informed decision, and files with a size greater than 10kB, to keep the memory consumption during training at a manageable level.

2.2.2 Program Transformation Tools. Our study is based on popular minification and obfuscation tools. We select tools that are publicly available and widely used, as reported, e.g., by publicly visible download numbers.

Minification. We consider seven minification tools (the names in parentheses are the abbreviation we use throughout the paper): UglifyJS (uglify), babel-minify (babel), Google Closure Compiler (closure), javascript-minifier.com (jsmincom), Matthias Mullie Minify (mmminify), and YUI Compressor (yui). These tools reduce the program size mainly by performing white spaces reduction and identifiers shortening. In addition, some tools, e.g., closure, also perform optimizations, such as inlining or constant folding.

Table 1: Obfuscation tools and transformation techniques.

Transformation techniques	Obfuscation tools				
	jsobf	jsobfcom	jfogs	JSObfu	daft-logic
String splitting	✓				✓
Keyword substitution					
String concatenation				✓	
Encoding the entire code					✓
Encrypting the entire code					
Identifier encoding	✓	✓	✓	✓	✓
String encoding	✓	✓		✓	
Dead code injection	✓				
Control flow flattening	✓				
String array	✓	✓	✓		✓
Code protecting techniques	✓				

Obfuscation. We consider five obfuscation tools: javascript-obfuscator (jsobf), javascriptobfuscator.com (jsobfcom), DaftLogic Obfuscator (daft-logic), jfogs, and JSObfu. The result of our tool search also included JSFuck and javascript2img.com, but we exclude them as they either are unable to process large code files or produce invalid JavaScript code. Table 1 shows which transformation techniques the tools use, as reported in previous work and in the tool's documentation. The two most common obfuscation techniques are identifier encoding, usually using HEX encoding, and storing strings in a global array.

Configurations. Most tools provide options to configure which transformation techniques to apply. Since different configurations may result in a different transformed code, we use multiple configurations for each tool. In total, we consider 15 configurations for the obfuscation tools and 31 configurations for the minification tools. Together with the regular version of a JavaScript file, this setup yields 47 variants of each file.

2.2.3 Generation of Training Data. As training data for a specific classifier, we randomly sample 10,000 files from the corpus of regular files and apply transformations tools to these files. For all three tasks, we train the classifiers with an even split of two classes of code, i.e., half of the training examples are expected to be classified as positive and negative, respectively. For the TRANS classifier, we apply the minification and obfuscation tools to each code example, using each tool equally often. For the OBFUS classifier, we obtain examples of obfuscated code by applying one of the obfuscation tools to each code example, using each tool equally often. To obtain examples of non-obfuscated code, we use regular and minified code. Since OBFUS gets trained to distinguish obfuscated code from both minified code and regular code, it can be used not only to identify obfuscated code among any code, but also to classify transformed code into minified versus obfuscated code. For the TOOL-X classifiers, we use examples of code transformed by tool X and code examples that are either not transformed or transformed by other tools.

2.3 Classification via Identifier Frequencies

The following describes the first of two approaches to learn classifiers. The approach exploits the fact that both minification and obfuscation tools replace the original identifiers, e.g., names of local variables, with other identifiers. Because many transformation tools use specific identifiers, a skilled human can determine whether a tool has been used and if yes, which tool. The learning approach is based on this observation.

The approach consists of two main steps. The first step is to extract a feature vector for a given JavaScript file. The feature vector summarizes what identifier names occur in the file and how frequent each name is. To this end, we tokenize the code and extract all identifiers. Based on all identifiers that occur in the training data, we determine a vocabulary of the 30,000 most common identifiers. Then, we transform each script into a feature vector of length 30,000, where each element represents a specific identifier. The element that represents a specific identifier is the *tf-idf* value of the identifier, i.e., the result of multiplying the *term frequency* with the *inverted document frequency* of an identifier. To compute the term frequency for a given script, we count the occurrences of each identifier and normalize these with the number of occurrences of the most frequent identifier in the script. For the inverted document frequency we divide, for each identifier, the total number of scripts in the training dataset by the number of scripts that contain the identifier and compute the logarithm of the resulting value.

The second step is to classify the feature vector of a JavaScript file using a support vector machine (SVM). We use SVMs because they are effective for binary classification problems. We achieve the best results for the SVM when using the *radial basis function kernel* and setting the penalty term C to 5. The classifier is implemented in Python using the machine learning library scikit-learn[1].

2.4 Classification via AST Convolution

The identifier-based classifier described above is conceptually simple but limited to a single feature of source code, i.e., identifier names. Our second classification approach addresses this limitation through a neural network that classifies abstract syntax trees (ASTs). ASTs are a useful representation of code because they preserve all relevant information while making the structural relationships between code elements explicit. To classify ASTs, we build upon a neural network architecture proposed by Mou et al. [18]. We adapt their approach by enriching traditional ASTs with additional information that proves useful for our classification tasks.

2.4.1 Background: Tree-based Convolutional Neural Network. We build upon an existing machine learning architecture for classifying trees, e.g., ASTs, based on a convolutional neural network. The network transforms a given tree into a continuous vector representation and then performs the actual classification task on the vector representation. The vector representation is learned in such a way that similar trees are represented by similar vectors. Figure 1 shows the five main steps involved in classifying trees. First, each node is transformed into a vector, where nodes with the same label, e.g., two CallExpression nodes, are mapped to the same vector. Second, a neural network layer ("coding layer") summarizes the children of a node and the node itself into the parent's vector. Third, several convolution layers extract features from the tree by sliding a feature detector over fixed-depth subtrees of the tree, which yields several trees of features. Fourth, a pooling layer summarizes these trees of features into a single tree again. Finally, all nodes of the new tree are passed through a fully connected hidden layer that outputs the classification result. During training with stochastic gradient descent, the parameters of the network are adapted to minimize a loss function that expresses how much the network's classification differs from the expected classification. Our implementation of the tree-based convolutional neural network is based on an implementation by Creston Bunch[2]. The architecture has previously been shown to be effective for identifying code that implements a particular algorithm [18]. We are the first to use it for identifying minified and obfuscated code.

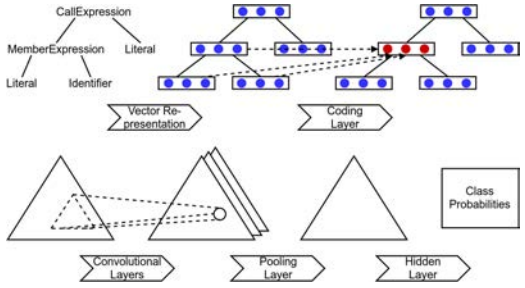

Figure 1: Tree-based convolutional neural network [18]. Rectangles with dots are vector representations of AST nodes; triangles represent trees.

2.4.2 Enriched ASTs. One possible approach is to apply the neural network to standard JavaScript ASTs. During initial experiments, we find this approach to provide a classifier with promising yet not fully satisfying accuracy. In particular, the classifiers struggle to learn from two features that are useful for a human but not well represented in standard ASTs: whitespace and specific properties of identifier names. Motivated by this observation, we enrich the standard JavaScript ASTs in two ways.

Whitespace. The first enrichment is to add information about whitespace into ASTs. Usually, this information is abstracted away as it is irrelevant for most scenarios where ASTs are used. To recognize minified and obfuscated code, though, whitespace is relevant because both minification and obfuscation tools often remove all or at least some whitespace. We enrich ASTs with whitespace information as follows: Whenever two nodes in the AST correspond to successive elements in the source code, we check whether any whitespace exists between the two code elements. If no such whitespace exists, then we insert a new "no whitespace" node between the two adjacent nodes; otherwise, we leave the nodes unchanged.

Length of identifiers. The second enrichment of ASTs is to add information about the length of identifiers, i.e., the number of characters of an identifier name. The motivation is that several obfuscation tools replace identifiers with less understandable identifiers of a fixed length that differs from tool to tool. In contrast, regular code

[1] http://scikit-learn.org/stable

[2] https://github.com/crestonbunch/tbcnn

Table 2: Testing accuracies for different classifiers and classification tasks.

Classifier	Task		
	TRANS	OBFUS	TOOL-X
Identifier frequencies	76.40%	80.07%	64.44%–82.86%
AST convolution	95.06%	99.96%	99.68–100.00%

usually consists of natural identifiers that have variable lengths. We encode this information by modifying every "Identifier" AST node by appending the length of the identifier to the node label, e.g., "Identifier3" for an identifier `foo`. To deal with unusually long identifiers, any length exceeding 30 characters is simply represented by a single, special label.

2.5 Accuracy of Classifiers

To decide which of the two classifiers to use for the study, we measure their classification accuracy on previously unseen sets of validation data. To this end, we randomly select 2,500 files from the non-transformed code (disjoint from the files used for generating training data), and create transformed variants of them, as described in Section 2.2.3. We then measure the accuracy for each classifier and task, i.e., the percentage of predictions that match the expected classification.

Table 2 summarizes the accuracy results for the two classifiers presented in Sections 2.3 and 2.4. Overall, the results show that both classifiers are effective (for comparison, a random decision would achieve 50% accuracy) and that the AST convolution-based classifier has the by far highest accuracy for all three tasks. In particular, the AST convolution-based classifier achieves more than 95% accuracy for all three tasks, and at least 99.68% accuracy for the OBFUS and TOOL-X tasks. In contrast, the classifier based on identifier frequencies performs poorly for some of the TOOL-X tasks, with an accuracy as low as 64.44% for one of the obfuscation tools.

To better understand why one classifier performs better than the other, we check how many of the different kinds of training examples the classifiers identify correctly. We find that the identifier frequency-based classifier is successful at identifying minified and obfuscated code but often fails to correctly identify regular code. For example, for the OBFUS task, the classifier correctly labels 99.92% of all obfuscated examples, but classifies only 59.47% of all non-obfuscated examples correctly. A detailed analysis of the identifiers that occur in obfuscated and non-obfuscated code explains these results: Many obfuscation tools use very characteristic identifiers, whereas regular code contains a wide range of natural identifiers. For example, jfogs creates many variables names `$fog$` followed by some number, and jsobf uses a similar pattern but also hex-encodes the identifiers.

To validate that enriching AST is beneficial over running the neural network on default JavaScript ASTs, we compare the accuracies of both variants of the AST-based classifier. We find that the default ASTs yield significantly lower accuracies than the enriched ASTs. For example, for the OBFUS task, the default ASTs give only 75.43% accuracy, which is not only much lower than with enriched ASTs but also lower than the classifier based on identifier frequencies.

Overall, we conclude from the accuracy results that the AST convolution-based classifier is highly effective at identifying transformed code, obfuscated code, and code obfuscated with a particular tool, making it a solid basis for studying JavaScript code at a large scale.

3 STUDYING DEPLOYED CLIENT-SIDE CODE

Based on the classifiers described above, this section presents the setup and results of our study of minification and obfuscation in deployed, client-side JavaScript code.

3.1 Study Data: Deployed, Client-Side JavaScript Code

To gather a representative set of JavaScript code used in real-world websites, we crawl the top 100,000 most popular websites, as listed by the Majestic Million[3] service. Our crawler visits each website, waits five seconds to enable dynamically loaded code to arrive, and then saves all scripts. We consider both code loaded via .js files and code loaded via inline scripts, i.e., via `<script>` tags without a `src` attribute. For the latter, the crawler copies the code between the tags into a new file. To speed up the loading of websites, we do not fetch resources other than scripts and HTML code.

The crawling yields 2,335,207 scripts from 85,001 websites in total. 14,999 websites are not accessible due to timeout errors and other reasons. Due to the limited size of ASTs that the classifiers can handle in reasonable time, we remove scripts with a size exceeding 40kB. This results in 1,861,489 scripts. We further remove scripts that are smaller than 512 bytes because we observe that such small scripts are hard to classify even for human subjects due to the limited number of clues that can aid the distinction between transformed and original scripts. Finally, we remove all those scripts for which the AST does not contain at least one "CallExpression" node. This is because such scripts are very often just configuration files in the JSON format. Applying these filters yields a set of 967,149 scripts. However, different websites may use the same JavaScript code, e.g., third-party libraries, thus the set of scripts contains duplicate files. In this study we are mostly concerned with the nature of the code on the web and not so much with its frequency on different websites, hence we remove all duplicates. This filtering leaves **a final set of 424,023 unique JavaScript files**, which we use for the study.

3.2 Accuracy of Classifiers on Study Data

Section 2.2.2 has established that our classifiers are highly accurate on code transformed by the tools used to generate the training data. To validate that the classifiers are effective also on the study data, for which we do not know which (if any) tools have been used, and to validate that the classification results match the classification that a skilled human could produce, we perform an experiment with JavaScript developers. The experiment involves five advanced developers, who have extensive experience in writing JavaScript and in understanding real-world JavaScript code.

[3] https://de.majestic.com/reports/majestic-million

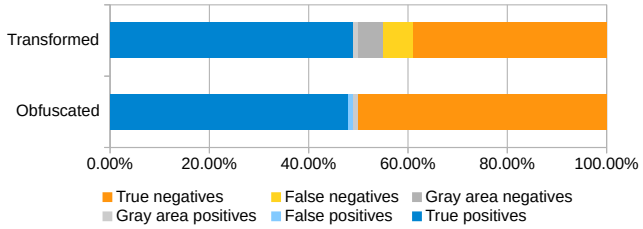

Figure 2: Effectiveness of the TRANS and OBFUS classifiers judged against the ground truth obtained from experienced JavaScript developers. The gray area depicts scripts for which the developers did not agree on the classification label.

The goal of the experiment is to gather ground truth to compare our classifiers against. During the experiment, each developer performs two tasks, which validate the TRANS and OBFUS classifiers, respectively. First, to validate the TRANS classifier, we show to each developer 50 scripts labeled by the classifier as transformed and 50 scripts labeled by the classifier as not transformed. We randomly sample the scripts from all 424,023 scripts in the study data. For each script, the developers are asked to answer the following question: "Is this human-written or generated/transformed code?" Second, to validate the OBFUS classifier, we repeat the same setup with 50 scripts labeled as obfuscated by the classifier and 50 scripts labeled as not obfuscated by the classifier. For these scripts, the developers are asked to answer the question: "Is this obfuscated or not obfuscated code? If the file is transformed but you are not sure if it is obfuscated, try to decide whether the developer transformed it for hindering understanding." To avoid any influence from file names, such as "jquery.min.js", we hide the original file names from the developers and assign some generic names to the files.

After aggregating the results of the experiment, we compute the inter-rater agreement, which quantifies the extent to which the participants agree with each other. More precisely, we compute Cohen's kappa for each pair of participants. The pairwise agreement ranges between 0.64 and 0.93, with an average of 0.81, which is considered a very high agreement. To account for possible mistakes made by individual developers, we consider a 4-out-of-5 majority vote. That is, if at least four of the developers agree on whether a given script is transformed/obfuscated, then we consider this decision as the ground truth. If no such majority is reached, then we consider the scripts to be in a *gray area*, where even humans have a hard time judging whether the script has been transformed/obfuscated.

Figure 2 shows the results of the developer experiment. The blue area depicts true positives, i.e., scripts where the classifier and the developers agree on the scripts being transformed/obfuscated. Likewise, the orange area depicts true negatives, i.e., scripts where the classifier and the developers agree on the scripts being not transformed/obfuscated. Overall, the automated classifiers largely match the decisions by the developers. In addition, the TRANS classifier has 13% false negatives, i.e., it misses a few scripts that developers consider to be transformed, and the OBFUS classifier has 2% false positives, i.e., it sometimes incorrectly labels a non-obfuscated script as obfuscated. The gray parts in the middle of the figure, six scripts for TRANS and one for OBFUS, are the gray area, where the developers disagreed with each other.

Table 3: Prevalence of transformed code.

TRANS on all scripts:	Regular	61.5%
	Transformed	38.5%
OBFUS on all scripts:	Regular or minified	99.33%
	Obfuscated	0.67%
OBFUS on transformed scripts:	Minified	98.31%
	Obfuscated	1.69%

Table 4: Tools used to obfuscate scripts.

Classifier	% detected scripts	% other scripts	# detected scripts
TOOL-JSObfu	0.01%	99.99%	3
TOOL-jsobfcom	0.04%	99.96%	149
TOOL-jfogs	0.02%	99.98%	0
TOOL-daft-logic	0.60%	99.40%	2,551
TOOL-jsobf	0.02%	99.98%	71

Overall, we conclude from the experiment with developers that our automated classifiers match human classifications for the overwhelming majority of scripts. Given the 13% false negative rate of TRANS, one should interpret our results about the number of transformed scripts as a slight under-approximation of the actual number.

3.3 RQ1. Prevalence of Transformed Code

To address the question of how prevalent minified and obfuscated code is in client-side JavaScript code, we classify all downloaded scripts using the TRANS and OBFUS classifiers. Table 3 summarizes the results. We find that 38.5% of all scripts have gone through some kind of transformation, including both minification and obfuscation. In contrast, only 0.67% of all scripts (2,842 scripts) have been obfuscated. Applying the OBFUS classifier to those scripts that are classified as transformed confirms the above numbers: The vast majority of transformed scripts are not obfuscated, i.e., they have only been minified. These numbers show that minification is popular in the web. This finding is in line with the fact that many JavaScript libraries and frameworks include a minification step in their deployment pipeline to reduce the file size and hence the transmission time. A possible explanation for the low number of obfuscated scripts is that obfuscation comes at a cost (discussed in detail in Section 3.7 and 3.8), and therefore it is used only when developers want to hide some behavior. Despite the surprisingly low number of obfuscated scripts, these scripts provide an interesting target for further analysis, and we provide them as a benchmark for future work.[4]

> **Finding 1.** Around 38% of the scripts in the web are transformed, most of which are minified but not obfuscated. Overall, we find a total of 2,842 obfuscated scripts.

3.4 RQ2. Prevalence of Obfuscation Tools

Given the non-negligible number of obfuscated scripts, we next address the question which tools and techniques developers use for obfuscation. Table 4 shows for each tool X how many scripts are detected as obfuscated by this tool according to the corresponding TOOL-X classifier. The by far most popular obfuscator in the web

[4] http://software-lab.org/projects/obfuscation_study.html

Table 5: Overlap between different classifiers.

Pair of classifiers	Number of scripts
TOOL-jsobfcom ∩ OBFUS	147 (98% of TOOL-jsobfcom)
TOOL-daft-logic ∩ OBFUS	2,474 (97% of TOOL-daft-logic)
TOOL-jsobf ∩ OBFUS	71 (100% of TOOL-jsobf)

is DaftLogic Obfuscator, with 2,551 scripts in total. As the only tool that encodes the entire code using the `eval` function, it clearly stands out among the other tools. The study data does not contain any scripts obfuscated with jfogs. A surprising fact from these results is that the apparent popularity on npm of tools like javascript-obfuscator and JSObfu does not transfer to client-side obfuscated code. One reason may be that these obfuscators are more popular for JavaScript code running on Node.js than for client-side code.

> **Finding 2.** DaftLogic Obfuscator is the by far most popular obfuscation tool. The most popular obfuscation technique is to load code at runtime via `eval`.

Having a set of classifiers related to obfuscation (OBFUS and several TOOL-X classifiers) raises the question to what extent the scripts detected by these classifiers overlap. Table 5 shows the overlap of scripts identified by the different obfuscation-related classifiers. We can make three observations. First, the TOOL-X classifiers do not overlap with each other, i.e., each of them precisely identifies scripts originating from a specific tool. This result is particularly remarkable for javascriptobfuscator.com and javascript-obfuscator, as these tools share a list of common obfuscation techniques. Second, almost all scripts detected as obfuscated by a specific tool are also detected as obfuscated by the general OBFUS classifier. Third, some scripts are classified as obfuscated but none of our TOOL-X classifiers can identify the tool used for obfuscating them.

> **Finding 3.** Our generic obfuscation detection classifier successfully identifies most of the obfuscated scripts found by the individual tool classifiers and several additional scripts.

3.5 RQ3. Transformations vs. Kinds of Scripts

3.5.1 Categories of Scripts. We associate scripts with website categories, such as "News", "Travel", and "Education". To this end, we use the *Juniper Test-a-Site*[5] service, which yields a category for a given URL. We associate a category with a script based on the top-level domain from which the script was loaded.

Obfuscated code. We first analyze the prevalence of obfuscated code loaded by websites in specific categories. Figure 3 shows for ten of the categories the percentage of obfuscated scripts among all scripts loaded by a site and an additional entry with the average across all other categories. The results show that the prevalence of obfuscation differs significantly across website categories. Categories with a particularly high percentage of obfuscated scripts include "Adult/Sexually Explicit" and "Glamour & Intimate Apparel", i.e., sites with content that careful users may trust less than an average website.

Transformed code. Figure 4 shows the ratio between transformed and regular code within all script categories in the study data.

[5]http://mtas.surfcontrol.com/mtas/JuniperTest-a-Site.asp

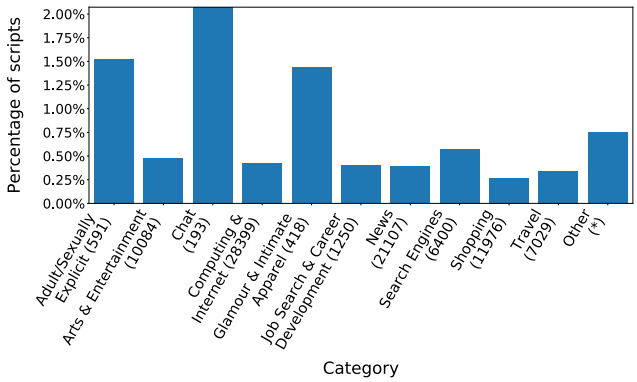

Figure 3: Prevalence of obfuscated code within categories of websites. In parenthesis on the x-axis we show the number of scripts in each category.

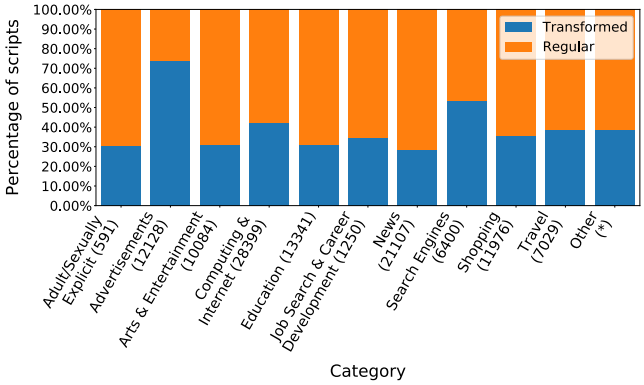

Figure 4: Prevalence of transformed code within categories of websites. In parenthesis on the x-axis we show the number of scripts in each category.

The percentage of transformed code ranges between 28% and 73%. The most significant categories are "Search engines" with 71.7% transformed code and "Advertisements" with 73.7%. We hypothesize that this is the case because websites in these categories serve scripts to many other domains, e.g. tracking scripts, and the size of the delivered scripts has a direct impact in the cost of using these services.

> **Finding 4.** Code obfuscation is particularly common in certain website categories, e.g., adult content. Other code transformations occur particularly often in scripts delivered to many other websites.

3.5.2 Third-party Scripts. The following studies whether transformations are particularly common for scripts loaded from third-party sites. As first-party scripts, we consider all inline scripts and all scripts loaded from the top-level domain of the visited website itself.

All remaining scripts are considered third-party scripts. [6] Based on this grouping of scripts, we analyze how the results of the TRANS and OBFUS classifiers relate to where a script is loaded from.

We find that third-party scripts, with a percentage of 55.38%, are almost twice as frequently transformed than scripts loaded directly from the visited website, which have a percentage of only 30.18% transformed code. These findings seem natural because providers of third-party scripts, e.g., content-delivery networks, often provide a minified version to reduce loading time. For scripts labeled as obfuscated, we do not find a significant difference between third-party and first-party scripts.

> **Finding 5.** Third-party scripts are almost twice as frequently transformed than first-party scripts (55.38% versus 30.18%). Obfuscation is equally uncommon within both categories.

3.6 RQ4. Runtime Behavior of Obfuscated Code

To better understand what the obfuscated scripts actually do, we run them in a custom environment and observe what APIs they try to access. The custom environment consists of self-replicating proxy objects that emulate the browser APIs and other well-known frameworks required by the analyzed scripts. For example, we create a globally accessible `document` proxy object that returns another proxy each time one of its properties is accessed. This environment provides a simple and effective technique for inspecting the behavior of obfuscated scripts.

In total, we analyze 2,924 unique obfuscated scripts which include all scripts classified as obfuscated by either OBFUS or one of the TOOL-X classifiers. We use 13 self-replicating proxies to mock the browser API and we run our analysis in Node.js. After each run, we collect a trace summarizing the property writes, property reads, and function calls observed via the proxies. In total, we collect 3.6 million property accesses, 10,400 writes and 1.4 million function calls. 2,231 scripts access at least one property via the proxies and 1,263 scripts set globally accessible properties. These numbers show that our setup is effective at running the obfuscated scripts and at extracting meaningful information about the APIs they call and the properties they access.

Out of the 2,924 scripts, 341 access the `cookie` object, 316 the `userAgent`, 287 the `location` and 101 the `referrer`. These are all privacy-sensitive APIs that may be accessed to perform cookie theft, cookie syncing, referrer sniffing, or browser fingerprinting. However, a more detailed analysis is needed to confirm this hypothesis. The most frequently invoked method is by far `document.createElement`, used by 346 scripts. This means that in order to fully understand a given obfuscated script, an analysis needs to reason about the HTML code injected in the page, which seem to be a popular idiom. Moreover, we observe that 295 scripts call `document.createElement('script')`, i.e., inject code at runtime, a technique commonly used by malware.

We manually inspect some of the traces and find two security-relevant behavioral patterns. First, several traces contain various API calls known to be used for browser fingerprinting, such as `location.href`, `screen.width`, `screen.colorDepth`, `navigator.plugins` or `window.devicePixelRatio`. There is even a trace in which after multiple such property accesses, a call to `document.createElement('img')` is made, which suggests that the obfuscated script is sending this information over the network. The second interesting case is of a trace containing 336,000 invocations to `performance.now`, which is likely to be part of a timing attack.

An additional observation we make after our sampling-based manual analysis is that some scripts set global properties, such as `SHA256_init`, `jQueryPath`, `mtTracking` or `Fingerprint2`. Their names suggest that some of the scripts register benign functionality, such as SHA hash functions or jQuery, while others register tracking and fingerprinting functionality.

> **Finding 6.** Multiple obfuscated scripts access privacy-sensitive APIs and use dynamic code loading.

[6] This classification may be wrong for websites that split their files across multiple top-level domains. Finding more accurate ways to identify third-party scripts is left for future work.

Table 6: Libraries used to measure performance and correctness.

Library	Category	Number of tests
Bacon	Reactive programming	7,492
async	Asynchronous programming	513
immutable	Immutable data structures	557
lodash	General utility	6,685
math	Math utility	4,063
moment	Date utility	3,232
ramda	Functional programming	954
underscore	General utility	1,569
voca	String utility	409
when	Promise implementation	872

3.7 RQ5. Performance of Transformed Code

Code transformations may not only influence the understandability of code but also its efficiency. To better understand the cost-benefit tradeoff of transformations, we study to what extent transformations affect the performance of code.

3.7.1 Benchmarks. Addressing RQ5 and RQ6 requires JavaScript code for which we can measure both the performance and the correctness. For this purpose, we gather a set of popular client-side JavaScript libraries that have extensive test suites. These tests include assertions to check the correctness of execution behavior, and they provide a reliable way to measure the execution time of code. Table 6 presents the ten libraries we consider, along with the number of tests they provide. All libraries are frequently used in client-side web applications. We execute their unit tests on Node.js, though, because it facilitates the performance measurements, as they are not influenced by opening and initializing a browser.

To study how transformations affect the performance and correctness of the libraries, we apply all 46 transformations (Section 2.2.2) to each library. To measure the performance of a given, possibly transformed, library, we execute its test suite 20 times and measure the overall wall-clock time of each execution. We do not perform a separate warm-up phase before measuring performance, as is common for longer-running benchmarks, to include the time for parsing code into our measurements, as this time affects the user experience on websites. Since closure injects code that is not compatible with our environment and prevents us from running the library tests, we omit this transformation tool for RQ5 and RQ6.

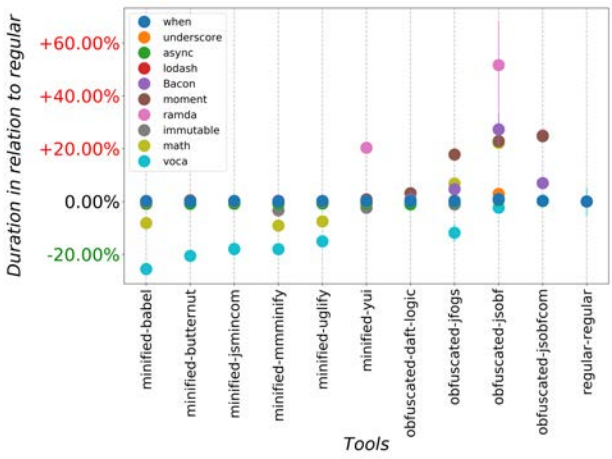

Figure 5: Execution time of transformed code relative to regular code. Each data point shows the average across 20 repetitions and the 95% confidence interval (which is too small to be visible for most libraries).

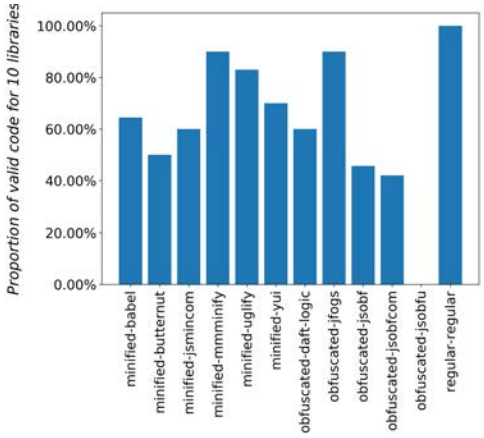

Figure 6: Percentage of correct code among all code transformed by a specific tool.

We run all our performance and correctness measurements on an AMD Phenom II X6 1100T CPU with 16GB of RAM.

3.7.2 Results. Figure 5 shows the execution time of transformed code relatively to regular code for eleven different transformation tools. The figure presents results from the ten libraries listed in Section 3.7.1. Each data point shows the average execution time across 20 repetitions and the 95% confidence interval. The first six columns of data points are for minification tools, whereas the following four columns are for obfuscation tools. The last column shows the baseline, i.e. the performance of the original code.

For minification, the figure shows an overall improvement of efficiency. In particular, for two libraries, voca and math, minification causes performance improvements of over 20% and 8%, respectively. For most of the other libraries, minification causes a measurable but small performance improvement.

In contrast to minification, we observe an overall performance degradation after obfuscating code. For at least four libraries (ramda, moment, math, and Bacon), obfuscation significantly increases the execution time, with average increases between 16% to 37%. For eight out of the ten libraries, the obfuscated code is measurably slower than the regular code. The only outlier is voca, which executes faster for two of the applied obfuscation tools.

> **Finding 7.** Minification either improves performance or has no noticeable effect. In contrast, obfuscation can cause significant performance degradations.

3.8 RQ6. Correctness of Transformed Code

Besides affecting the performance of code, there is another potential cost of applying code transformations: the impact of transformations on the correctness of the code. To assess this impact, we run the test suites of the benchmarks from Section 3.7.1 before and after applying different transformations and measure the percentage of tests that still succeed after the transformation. We say that transformed code is *correct* if this percentage is 100%, i.e., the transformed code passes all tests.

Figure 6 shows the percentage of correct code among all code transformed with a specific tool. Overall, only about 70% of the minified code is correct, and even worse, less than 50% of the obfuscated code is correct. The original code, shown in the right-most column, is by definition 100% correct. A manual analysis of transformed code that fails test cases shows two root causes. First, some transformation tools have implementation-level bugs that get triggered by some code. For example, JSObfu, which consistently creates incorrect code extensively uses the `String.fromCharCode()` method to encode constant string occurring in the code. However, in some cases the method is applied on an undefined object instead of a string, which causes an exception. Second, some transformation tools change the semantics of code in ways that affect rather subtle corner-cases of the JavaScript language. For example, some configurations of UglifyJS replace non-global function names with short and meaningless names. If such a function is a constructor function, this transformation affects code that creates an object with this function and then checks the name of the constructor using JavaScript's reflection APIs. Some of the tests trigger this corner case, e.g., a test of the "immutable" benchmark checks whether objects of type `Record` have a constructor with the same name.

> **Finding 8.** A large portion of code transformed both by minification and obfuscation does not fully preserve the correctness of the code.

We conclude from these results that transformation tools may not only impose a performance cost, but even worse, risk to change the semantics of code. A practical take-away from this finding is that users of such tools must carefully check the correctness of transformed code, instead of blindly relying on the transformation tool. Our results also motivates future work on validating and improving minification and obfuscation tools, e.g., through automated testing.

4 RELATED WORK

This work relates to two active research fields: (i) detection of obfuscated and malicious code and (ii) empirical studies of the web.

4.1 Obfuscated and Malicious Code Detection

Tellenbach et al. [33] propose multiple classifiers for detecting obfuscation. However, they manually specify features of code files, such as the Shannon entropy or the number of characters per line. Similar, Likarish et al. [15] manually extract 60 features from code and propose four different classifiers. In contrast to both, our AST-based classifier does not require any feature engineering.

Wang et al. [36] present a neural network-based classifier for detecting malicious JavaScript code. Since attackers often hide the malicious intent of their scripts using obfuscation, a significant proportion of the dataset used for training their classifier consists of obfuscated code. Comparable to our approach, instead of defining explicit features, they learn the features automatically from the code with the help of multiple layers of stacked denoising autoencoders in the neural network. They transform the code files by replacing each character with a unique binary vector. The vectors require 20,000 dimensions to represent all characters of the dataset. Therefore, Wang et al. reduce the dimensionality to 480 using a dimensionality reduction algorithm. In contrast, we learn a vector representation for AST nodes which only requires 45 dimensions.

Al-Taharwa et al. [1] present a Bayesian-based obfuscation detector aimed at manually performed obfuscation. In contrast, we consider automatically transformed code. Kaplan et al. [10] and Curtsinger et al. [7] extract features from AST nodes while preserving the context of nodes. Their classifiers specialize on obfuscated and on malicious code, respectively. The context-based feature extraction mechanism is comparable to the concept we follow by processing entire ASTs of code files to preserve the context of all AST nodes. However, all three approaches limit the number of allowed contexts and reduce the number of features by applying feature selection. In our case, we do not discard any information from the ASTs so that the neural network can extract the most descriptive features.

There are further static classifier-based approaches which are less related to our approach. Jodavi et al. [9] address the detection of obfuscation with an ensemble of multiple one-class SVM classifiers which are trained to recognize non-obfuscated code using a set of structural and lexical features, such as the number of dynamic code evaluations and the maximum entropy of strings.

Certain researchers address the problem of detecting obfuscated code by using techniques other than machine learning. Xu et al. [38] propose an approach to detect malicious obfuscated code using both static and dynamic analysis. They mostly focus on obfuscation techniques which require the usage of the `eval` function, the `unescape` function, or other related functions. Using static analysis, they gather information about function definitions and invocations in the code. At runtime, they examine if new function definitions and invocations are present to reveal the potentially malicious part of the code. By comparison, we detect if code is obfuscated without assuming a malicious intent because obfuscation allows for different goals, e.g. the protection of intellectual property of code. Furthermore, we include all techniques offered by the obfuscation tools we use for this study instead of focusing only on `eval` based obfuscation. As discovered in Section 2.2.2, most JavaScript obfuscators do not implement `eval` based techniques.

Ceccato et al. [5] propose using out of the box obfuscators for hindering portability of attacks. We also use readily available obfuscators, but for generating training data, not for software diversification.

Deobfuscation is the process of reverse engineering obfuscated code. Techniques for purpose include learning-based approaches [3, 25] and semantics-preserving rewriting of the obfuscated code [16, 39]. This work is complementary to our work and can be applied after detection obfuscated code.

4.2 Empirical Studies

There are a few obfuscation related studies in other programming language contexts. Ceccato et al. [4] analyze the impact of different obfuscation patterns on Java code in terms of the difference between the obfuscated and the original code with the help of metrics. Wang et al. [35] examine the characteristics of obfuscated iOS Apps, the popularity of different obfuscation patterns, and the difficulty of reverse engineering the obfuscated apps. Hammad et al. [8] perform a study concerning the effect of obfuscated Android apps on anti-malware products. They find that the performance of most anti-malware products is significantly impacted by obfuscated apps. Moreover, they report that the tools used for obfuscating the apps frequently result in corrupt apps. Depending on the tool, only 0% to 62% of all 250 apps are runnable after the obfuscation is applied. We observe a similar outcome in the case of JavaScript obfuscation.

Visaggio et al. [34] compare obfuscated and regular JavaScript code using several metrics, including n-gram, entropy, and word size. They find that the two kinds of code differ from each other, in particular, when combining multiple metrics. XU et al. [37] study 510 samples of malicious JavaScript code, its use of obfuscation, and how obfuscation influences whether an anti-virus checker detects the code as malicious. In contrast, our study considers many more scripts, goes beyond obfuscated code, and addresses different research questions.

There have been various JavaScript and web security related studies recently, including a study on the prevalence of the `eval` function [27], on trust relationships between websites that include remote libraries and their corresponding library providers [21], on the communication between websites and embedded frames with 3rd-party content [30], on outdated libraries in the web [13], on XSS vulnerabilities [17], on ReDoS vulnerabilities in JavaScript-based web servers [31], and on performance issues in JavaScript [29]. However, there has been no study focusing on obfuscation and minification in the web outside of malicious code. We conduct the first comprehensive study examining the prevalence, the performance, and the validity of obfuscated and minified JavaScript code in the web.

4.3 JavaScript Analysis

Our work relates to program analyses for JavaScript [2], e.g., to detect conflicts between libraries [22], type inconsistencies [23], code injection attacks [32], or data races [20]. In contrast to that work,

we here address an analysis task by training a machine learning instead of implementing an analysis by hand.

5 CONCLUSION

This paper presents the first large-scale study of minified and obfuscated JavaScript in client-side website applications. Our study leads to several findings that should be of interest for both the web community and the security community. In particular, we show that transformed code is surprisingly common, whereas obfuscation aimed at hindering understanding remains an exception. Yet, there is a non-negligible number of obfuscated scripts, which typically occur in specific website categories and which sometimes expose security-relevant behavior, e.g., fingerprinting or timing attacks. Moreover, we show that obfuscation not only provides benefits to its users but also imposes a cost by negatively impacting both the performance and the correctness of the code. Besides these findings we are releasing the obfuscated code detected during the study to stimulate future research in this area.

ABSTRACT

This paper describes, develops, and validates SciLens, a method to evaluate the quality of scientific news articles. The starting point for our work are structured methodologies that define a series of quality aspects for manually evaluating news. Based on these aspects, we describe a series of indicators of news quality. According to our experiments, these indicators help non-experts evaluate more accurately the quality of a scientific news article, compared to non-experts that do not have access to these indicators. Furthermore, SciLens can also be used to produce a completely automated quality score for an article, which agrees more with expert evaluators than manual evaluations done by non-experts. One of the main elements of SciLens is the focus on both content and context of articles, where context is provided by (1) explicit and implicit references on the article to scientific literature, and (2) reactions in social media referencing the article. We show that both contextual elements can be valuable sources of information for determining article quality. The validation of SciLens, done through a combination of expert and non-expert annotation, demonstrates its effectiveness for both semi-automatic and automatic quality evaluation of scientific news.

1 INTRODUCTION

Scientific literacy is broadly defined as a knowledge of basic scientific facts and methods. Deficits in scientific literacy are endemic in many societies, which is why understanding, measuring, and furthering the public understanding of science is important to many scientists [6].

Mass media can be a potential ally in fighting scientific illiteracy. Reading scientific content has been shown to help align public knowledge of scientific topics with the scientific consensus, although in highly politicized topics it can also reinforce pre-existing biases [27]. There are many ways in which mass media approaches science, and even within the journalistic practice there are several sub-genres. Scientific news portals, for instance, include most of the categories of articles appearing traditionally in newspapers [21] such as *editorial*, *op-ed*, and (less frequently) *letters to the editor*. The main category of articles, however, are scientific *news* articles, where journalists describe scientific advances.

Scientific news articles have many common characteristics with other classes of news articles; for instance, they follow the well-known *inverted pyramid* style, where the most relevant elements are presented at the beginning of the text. However, they also differ in important ways. Scientific news are often based on findings reported in scientific journals, books, and talks, which are highly specialized. The task of the journalist is then to *translate* these findings to make them understandable to a non-specialized, broad audience. By necessity, this involves negotiating several trade-offs between desirable goals that sometimes enter into conflict, including appealing to the public and using accessible language, while at the same time accurately representing research findings, methods, and limitations [46].

The resulting portrayal of science in news varies widely in quality. For example, the website "Kill or Cure?"[1] has reviewed over 1,200 news stories published by The Daily Mail (a UK-based tabloid) finding headlines pointing to 140 substances or factors that cause cancer (including obesity, but also Worcestershire sauce), 113 that prevent it (including garlic and green tea), and 56 that both cause and prevent cancer (including rice). Evidently, news coverage of cancer research that merely seeks to classify every inanimate object into something that either causes or prevents cancer does not help to communicate effectively scientific knowledge on this subject.

Our contribution. In this paper we describe *SciLens,* a method for evaluating the quality of scientific news articles. The technical contributions we describe are the following:

- a framework, depicted in Figure 1, for semi-automatic and automatic article quality evaluation (§3);
- a method for contextual data collection that captures the contents of an article, its relationship with the scientific literature, and the reactions it generates in social media (§4);
- a series of automatically-computed *quality indicators* describing:
  - the content of a news article, where we introduce a method to use quotes appearing on it as quality indicators (§5.1),
  - the relationship of a news article with the scientific literature, where we introduce content-based and graph-based similarity methods (§5.2), and

  - the social media reactions to the article, where we introduce a method to interpret their stance (supporting, commenting, contradicting, or questioning) as quality signals (§5.3);
- an experimental evaluation of our methods involving experts and non-experts (§6).

2 RELATED WORK

In this section, we present background information that frames our research (§2.1), previous work on evaluating news quality (§2.2), and methods to extract quality indicators from news articles (§2.3). This is a broad research area where results are scattered through multiple disciplines and venues; our coverage is by no means complete.

2.1 Background on Scientific News

A starting point for understanding communication of science has historically been the "deficit model," in which the public is assumed to have a deficit in scientific information that is addressed by science communication (see, e.g., Gross [25]). In a simplified manner, scientific journalism, as practiced by professional journalists as well as science communicators and bloggers from various backgrounds, can be seen as a translation from a discourse inside scientific institutions to a discourse outside them. However, there are many nuances that make this process much more than a simple translation. For instance, Myers [44], among others, notes that (i) in many cases the gulf between experts and the public is not as large as it may seem, as many people may have some information on the topic; (ii) there is a continuum of popularization through different genres, i.e., science popularization is a matter of degree; and (iii) the scientific discourse is intertwined with other discourses, including the discussion of political and economic issues.

Producing a high-quality article presenting scientific findings to the general public is unquestionably a challenging task, and often there is much to criticize about the outcome. In the process of writing an article, "information not only changes textual form, but is simplified, distorted, hyped up, and dumbed down" [44]. Misrepresentation of scientific knowledge by journalists has been attributed to several factors, including "a tendency to sensationalize news, a lack of analysis and perspective when handling scientific issues, excessive reliance on certain professional journals for the selection of news, lack of criticism of powerful sources, and lack of criteria for evaluating information" [13].

In many cases, these issues can be traced to journalists adhering to journalistic rather than scientific norms. According to Dunwoody [15], this includes (i) a tendency to favor conflict, novelty, and similar news values; (ii) a compromise of accuracy by lack of details that might be relevant to scientists, but that journalists consider uninteresting and/or hard to understand for the public; and (iii) a pursuit of "balance" that mistakenly gives similar coverage to consensus viewpoints and fringe theories. Journalists tend to focus on events or episodic developments rather than long-term processes, which results in preferential coverage to initial findings even if they are later contradicted, and little coverage if results are disconfirmed or shown to be wrong [14]. Furthermore, news articles typically do not include caveat/hedging/tentative language, i.e., they tend to report scientific findings using a language expressing certainty, which may actually have the opposite effect from what is sought, as tentative language makes scientific reporting more credible to readers [32].

2.2 Evaluation of Quality of News

There are many approaches for evaluating the quality of articles on the web; we summarize some of these approaches in Table 1.

Manual Evaluation. The simplest approach for evaluating news article quality relies on the manual work of domain experts. This is a highly subjective task, given that quality aspects such as credibility are to a large extent perceived qualities, made of many dimensions [20]. In the health domain, evaluations of news article quality have been undertaken for both general health topics [53] and specific health topics such as Pancreatic Cancer [57].

Independent, non-partisan *fact-checking portals* perform manual content verification at large scale, typically employing a mixture of professional and volunteer staff. They can cover news articles on general topics (e.g., Snopes.com) or specific topics such as politics (e.g., PolitiFact.com). In the case of science news, ClimateFeedback.org is maintained by a team of experts on climate change with the explicit goal of helping non-expert readers evaluate the quality of news articles reporting on climate change. Each evaluated article is accompanied by a brief review and an overall quality score. Reviews and credibility scores from fact-checking portals have been recently integrated with search results [36] and social media posts [40] to help people find accurate information. Furthermore, they are frequently used as a ground truth to build systems for rumor tracking [54], claim assessment [50], and fake multimedia detection [8]. Articles considered by fact-checking portals as misinformation have been used as "seeds" for diffusion-based methods studying the spread of misinformation [56].

Our approach differs from previous work because it is completely automated and does not need to be initialized with labels from expert- or crowd-curated knowledge bases. For instance, in the *diffusion graph*, which is the graph we construct during contextual data collection (§4) from social media posts and scientific papers, we do not need prior knowledge on the quality of different nodes.

Automatic and Semi-Automatic Evaluation. Recent work has demonstrated methods to automate the extraction of signals or indicators of article quality. These indicators are either expressed at a

conceptual level [58] (e.g, *balance of view points*, *respect of personal rights*) or operationalized as features that can be computed from an article [62] (e.g., *expert quotes* or *citations*). Shu et al. [55] describe an approach for detecting fake news on social media based on social and content indicators. Kumar et al. [37] describe a framework for finding hoax Wikipedia pages mainly based on the author's behavior and social circle, while Ciampaglia et al. [11] use Wikipedia as ground truth for testing the validity of dubious claims. Baly et al. [5] describe site-level indicators that evaluate an entire website instead of individual pages.

Our work differs from these by being, to the best of our knowledge, the first work that analyzes the quality of a news article on the web combining its own content with context that includes social media reactions and referenced scientific literature. We provide a framework, *SciLens*, that is scalable and generally applicable to any technical/scientific context at any granularity (from a broad topic such as "health and nutrition" to more specific topics such as "gene editing techniques").

2.3 Indicator Extraction Techniques

Our method relies on a series of indicators that can be computed automatically, and intersects previous literature that describes related indicators used to evaluate article quality or for other purposes.

Quote Extraction and Attribution. The most basic approach to quote extraction is to consider that a quote is a "block of text within a paragraph falling between quotation marks" [16, 51]. Simple regular expressions for detecting quotes can be constructed [45, 52]. Pavllo et al. [48] leverages the redundancy of popular quotes in large news corpora (e.g., highly controversial statements from politicians that are intensely discussed in the press) for building unsupervised bootstrapping models, while Pareti et al. [47] and Jurafsky et al. [34] train supervised machine learning models using corpora of political and literary quotes (Wikiquote, https://www.wikiquote.org, is such a corpus that contains general quotes).

Our work does not rely on simple regular expressions, such as syntactic patterns combined with quotations marks, which in our preliminary experiments performed poorly in quote extraction from science news; instead we use regular expressions based on classes of words. We also do not use a supervised approach as there is currently no annotated corpus for scientific quote extraction. For the research reported on this paper, we built an information extraction model specifically for scientific quotes from scratch, i.e., a "bootstrapping" model, which is based on word embeddings. This is a commonly used technique for information extraction when there is no training data and we can manually define a few high-precision extraction patterns [33].

Semantic Text Similarity. One of the indicators of quality that we use is the extent to which the content of a news article represents the scientific paper(s) it is reporting about. The Semantic Text Similarity task in Natural Language Processing (NLP) determines the extent to which two pieces of text are semantically equivalent. This is a popular task in the *International Workshop on Semantic Evaluation* (SemEval). Three approaches that are part of many proposed methods over the last few years include: (i) *surface-level similarity* (e.g., similarity between sets or sequences of words or named entities in the two documents); (ii) *context similarity* (e.g., similarity between document representations); and (iii) *topical similarity* [26, 38].

In this paper, we adopt these three types of similarity, which we compute at the document, paragraph, and sentence level. The results we present suggest that combining different similarity metrics at different granularities results in notable improvements over using only one metric or only one granularity.

Social Media Stance Classification. Our analysis of social media postings to obtain quality indicators considers their *stance*, i.e., the way in which posting authors position themselves with respect to the article they are posting about. Stance can be binary ("for" or "against"), or be described by more fine-grained types (supporting, contradicting, questioning, or commenting) [28], which is what we employ in this work. Stance classification of social media postings has been studied mostly in the context of online marketing [35] and political discourse and rumors [63].

In our work, we build a new stance classifier based on textual and contextual features of social media postings and replies, annotated by crowdsourcing workers. To the best of our knowledge, there is no currently available corpus covering the scientific domain. As part of our work, we release such corpus.

3 SCILENS OVERVIEW

The goal of SciLens is to help evaluate the quality of scientific news articles. As Figure 1 shows, we consider a contextual data collection, a computation of quality indicators, and an evaluation of the results.

Contextual Data Collection (§4). First, we consider a set of keywords that are representative of a scientific/technical domain; for this paper, we have considered a number of key words and phrases related to health and nutrition. Second, we extract from a social media platform (in this case, Twitter), all postings matching these keywords, as well as public replies to these postings. Third, we follow all links from the postings to web pages, and download such pages; while the majority of them are news sites and blogs of various kinds, we do not restrict the collection by type of site at this point. Fourth, we follow all links from the web pages to URLs in a series of pre-defined domain names from scientific repositories, academic portals and libraries, and universities. Fifth, we clean-up the collection by applying a series of heuristics to de-duplicate articles and remove noisy entries.

Quality Indicators (§5). We compute a series of quality indicators from the content of articles, and from their referencing social media postings and referenced scientific literature.

Regarding the content of the articles, we begin by computing several content-based features described by previous work. Next, we perform an analysis of quotes in articles, which are a part of journalistic practices in general and are quite prevalent in the case of scientific news. Given that attributed quotes are more telling of high quality than unattributed or "weasel" quotes, we also carefully seek to attribute each quote to a named entity which is often a scientist, but can also be an institution.

Regarding the scientific literature, we would like to know the strength of the connection of articles to scientific papers. For this, we consider two groups of indicators: content-based and graph-based. Content-based indicators are built upon various metrics of text similarity between the content of an article and the content of scientific papers, considering that the technical vocabulary is unlikely to be preserved as-is in articles written for the general public. Graph-based indicators are based on a diffusion graph in which scientific papers and web pages in academic portals are nodes connected by links. High-quality articles are expected to be connected through many short paths to academic sources in this graph.

Regarding social media postings, we measure two aspects: reach and stance. Reach is measured through various proxies for attention, that seek to quantify the impact that an article has in social media. The stance is the positioning of posting authors with respect to an article, which can be positive (supporting, or commenting on an article without expressing doubts), or negative (questioning an article, or directly contradicting what the article is saying).

Evaluation (§6). We evaluate the extent to which the indicators computed in SciLens are useful for determining the quality of a scientific news article. We consider that these indicators can be useful in two ways. First, in a semi-automatic setting, we can show the indicators to end-users and ask them to evaluate the quality of a scientific news article; if users that see these indicators are better at this task that users that do not see them, we could claim that the indicators are useful. Second, in a fully automatic setting, we can train a model based on all the indicators that we computed. In both cases, the ground truth for evaluation is provided by experts in communication and science.

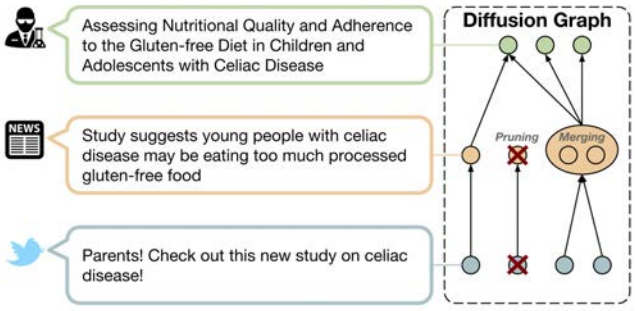

Figure 2: Contextual data collection, including social media postings, which reference a series of news articles, which cite one or more scientific papers. In our diffusion graph, paths that do not end up in a scientific paper or paths that contain unparsable nodes (e.g., malformed HTML pages) are *pruned*, and articles with the same content in two different outlets (e.g., produced by the same news agency) are *merged*.

4 CONTEXTUAL DATA COLLECTION

The contextual data collection in our work seeks to capture all relevant content for evaluating news article quality, including referenced scientific papers and reactions in social media. This methodology can be applied to any specialized or technical domain covered in the news, as long as: (i) media coverage in the domain involves "translating" from primary technical sources, (ii) such technical sources can be characterized by known host/domain names on the web, and (iii) social media reactions can be characterized by the presence of certain query terms. Examples where this type of contextual data collection could be applied beyond scientific news include news coverage of specialized topics such as law or finance.

We consider two phases: a crawling phase, which starts from social media and then collects news articles and primary sources (§4.1), and a pruning/merging phase, which starts from primary sources and prunes/de-duplicates articles and postings (§4.2). This process is depicted in Figure 2 and explained next.

4.1 Crawling of Postings, Articles, and Papers

The crawling phase starts with social media postings, which are identified as candidates for inclusion based on the presence of certain topic-related keywords in them. In the case of this study, we selected "health and nutrition" as our main topic: this is among the most frequent topics in scientific news reporting, which is known to have a medical/health orientation [4, 15, 61]. The initial set of keywords was obtained from Nutrition Facts (https://nutritionfacts.org/topics), a non-commercial and non-profit website that provides scientific information on healthy eating. The list contains over 2,800 keywords and key phrases such as "HDL cholesterol," "polyphenols" and the names of hundreds of foods from "algae" to "zucchini". We further expanded this list with popular synonyms from WordNet [42].

We harvest social media postings from DataStreamer.io (formerly known as Spinn3r.com), covering a 5-year period from June 2013 through June 2018. In this collection, we find 2.5M candidate postings matching at least one of our query terms from which we discard postings without URLs.

Next, we crawl the pages pointed to by each URL found in the remaining postings. These pages are hosted in a wide variety of domains, the majority being news outlets and blogging platforms. We scan these pages for links to scientific papers, which we do identify by domain names. We use a predefined list of the top-1000 universities as indicated by CWUR.org plus a manually curated list of open-access publishers and academic databases obtained from Wikipedia[2] and expanded using the "also visited websites" functionality of SimilarWeb.com. Overall, we obtained a diffusion graph of **2.4M** nodes and **3.7M** edges.

4.2 Pruning and Merging

The initial data collection described in §4.1 is recall-oriented. Now, we make it more precise by pruning and merging items.

Pruning. During the pruning phase, we keep in our collection only documents that we managed to successfully download and parse (e.g., we discard malformed HTML pages and PDFs). We also prune paths that do not end up in a scientific paper i.e., articles that do not have references and all the tweets that point to these articles. This phase helps us eliminate most of the noisy nodes of the diffusion graph that were introduced due to the generic set of seed keywords that we used in the crawling phase (§4.1).

Merging. We notice a large number of duplicate articles across news outlets, which we identify by text similarity i.e, by cosine similarity of more than 90% between the bag-of-words vectors representing the articles. This happens when one outlet re-posts an article originally published in another outlet, or when both syndicate from the same news agency. Once we find such duplicates or near-duplicates, we keep only one of them (the one having more out-links, breaking ties arbitrarily) and remove the redundant ones. Social media postings that point to the duplicates are re-wired to connect to the one that survived after merging, hence we do not lose a potentially important signal of article quality.

The resulting collection is large and mostly composed of elements that are closely related to the topic of health and nutrition: **49K** social media postings, **12K** articles (most of them in news sites and blogs), and **24K** scientific links (most of them peer-reviewed or grey-literature papers). Even after pruning, our collection is possibly more comprehensive than the ones used by systems used to appraise the impact of scientific papers. For instance, when compared to Altmetric.com [1] we find that our collection has more links to scientific papers than what Altmetric counts. In their case, referencing articles seem to be restricted to a controlled list of mainstream news sources, while in our case we often find these references plus multiple references from less known news sources, blogs, and other websites.

[2]https://en.wikipedia.org/wiki/List_of_academic_databases_and_search_engines

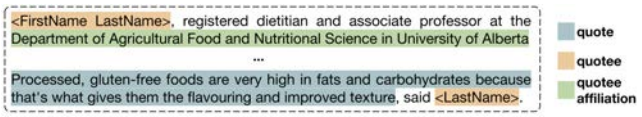

Figure 3: Example of quote extraction and attribution (best seen in color). Quotee has been anonymized.

5 QUALITY INDICATORS

We compute indicators from the content of news articles (§5.1), from the scientific literature referenced in these articles (§5.2), and from the social media postings referencing them (§5.3). The full list of indicators is presented on Table 2.

5.1 News Article Indicators

These indicators are based on the textual content of a news article.

5.1.1 Baseline Indicators. As a starting point, we adopt a large set of content-based quality indicators described by previous work. These indicators are: (i) title deceptiveness and sentiment: we consider if the title is "clickbait" that oversells the contents of an article in order to pique interest [41, 60]; (ii) article readability: indicator of the level of education someone would need to easily read and understand the article [19]; and (iii) article length and presence of author byline [62].

5.1.2 Quote-Based Indicators. Quotes are a common and important element of many scientific news articles. While selected by journalists, they provide an opportunity for experts to directly present their viewpoints in their own words [12]. However, identifying quotes in general is challenging, as noted by previous work (§2.3). In the specific case of our corpus, we observe that they are seldom contained in quotation marks in contrast to other kinds of quotes (e.g., political quotes [51]). We also note that each expert quoted tends to be quoted once, which makes the problem of *attributing* a quote challenging as well.

Quote Extraction Model. To extract quotes we start by addressing a classification problem at the level of a sentence: we want to distinguish between quote-containing and non-containing sentences. To achieve this, we first select a random sample from our dataset, then manually identify quote patterns, and finally, we generalize automatically these patterns to cover the full dataset. As we describe in the related work section (§2.3), this is a "bootstrapping" model built from high-precision patterns, as follows.

The usage of *reporting verbs* is a typical element of quote extraction models [47]. Along with common verbs that are used to quote others (e.g., "say," "claim") we used verbs that are common in scientific contexts, such as "prove" or "analyze." First, we manually create a seed set of such verbs. Next, we extend it with their nearest neighbors in a word embedding space; the word embeddings we use are the *GloVe* embeddings, which are trained on a corpus of Wikipedia articles [49]. We follow a similar approach for nouns related to studies (e.g., "survey," "analysis") and nouns related to scientists (e.g., "researcher," "analyst"). Syntactically, quotes are usually expressed using indirect speech. Thus, we also obtain part-of-speech tags from the candidate quote-containing sentences.

Using this information, we construct a series of regular expressions over *classes* of words ("reporting verbs," "study-related noun," and part-of-speech tags) which we evaluate in §6.1.

Quote Attribution. For the purposes of evaluating article quality, it is fundamental to know not only that an article has quotes, but also their provenance: *who* or *what* is being quoted. After extracting all the candidate quote-containing sentences, we categorize them according to the information available about their quotee.

A quotee can be an *unnamed scientist* or an *unnamed study* if the person or article being quoted is not disclosed (e.g., "researchers believe," "most scientists think" and other so-called "weasel" words). Sources that are not specifically attributed such as these ones are as a general rule considered less credible than sources in which the quotee is named [62].

A quotee can also be a *named entity* identifying a specific person or organization. In this case, we apply several heuristics for quote attribution. If the quotee is a *named person*, if she/he is referred with her/his last or first name, we search within the article for the full name. When the full name is not present in the article, we map the partial name to the most common full name that contains it within our corpus of news articles. We also locate sentences within the article that mention this person together with a named organization. This search is performed from the beginning of the article as we assume they follow an *inverted pyramid* style. In case there are several, the most co-mentioned organization is considered as the affiliation of the quotee.

If the quotee is an *organization*, then it can be either mentioned in full or using an acronym. We map acronyms to full names of organizations when possible (e.g., we map "WHO" to "World Health Organization"). If the full name is not present in an article, we follow a similar procedure as the one used to determine the affiliation of a researcher, scanning all the articles for co-mentions of the acronym and a named organization.

An illustrative example of the extraction and the attribution phase can be shown in Figure 3.

Scientific Mentions. News articles tend to follow journalistic conventions rather than scientific ones [15]; regarding citation practices, this implies they seldom include formal references in the manner in which one would find them in a scientific paper. Often there is no explicit link: journalists may consider that the primary source is too complex or inaccessible to readers to be of any value, or may find that the scientific paper is located in a "pay-walled" or otherwise inaccessible repository. However, even when there is no explicit link to the paper(s) on which an article is based, good journalistic practices still require to identify the information source (institution, laboratory, or researcher).

Mentions of academic sources are partially obtained during the quote extraction process (§5.1.2), and complemented with a second pass that specifically looks for them. During the second pass, we use the list of universities and scientific portals that we used during the *crawling phase* of the data collection (§4.1).

5.2 Scientific Literature Indicators

In this section, we describe content- and graph-based indicators measuring how articles are related to the scientific literature.

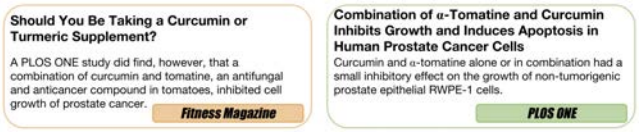

Figure 4: A news article (left) and a scientific paper (right) with Semantic Text Similarity of 87.9%. Indicatively, two passages from these documents, whose conceptual similarity is captured by our method, are presented. In these two passages we can see the effort of the journalist on translating from an academic to a less formal language, without misrepresenting the results from the paper.

5.2.1 Source Adherence Indicators. When there is an explicit link from a news article to the URL where a scientific paper is hosted, we can measure the extent to which these two documents convey the same information. This is essentially a computation of the *Semantic Text Similarity* (STS) between the news article and its source(s).

Supervised Learning for STS. We construct an STS model using supervised learning. The **features** that we use as input to the model consist of the following text similarity metrics: (i) the Jaccard similarity between the sets of named entities (persons and organizations), dates, numbers and percentages of the two texts; (ii) the cosine similarity between the *GloVe* embeddings of the two texts; (iii) the Hellinger similarity [30] between topic vectors of the two texts (obtained by applying LDA [7]); and (iv) the relative difference between the length in words of the two texts. Each of them is computed three times: (1) considering the entire contents of the article and the paper; (2) considering one paragraph at a time, and then computing the average similarity between a paragraph in one document and a paragraph in the other; and (3) considering one sentence at a time, and then computing the average similarity between a sentence in one document and a sentence in the other. In other words, in (2) and (3) we compute the average of each similarity between the Cartesian product of the passages.

The **training data** that we use is automatically created from pairs of documents consisting of a news article and a scientific paper. Whenever a news article has exactly one link to a scientific paper, we add the article and the paper to training data in the positive class. For the negative class, we sample random pairs of news articles and papers. The **learning schemes** used are Support Vector Machine, Random Forests and Neural Networks. Details regarding the evaluation of these schemes are provided in §6.1.2. An example of a highly related pair of documents, as determined by this method, is shown in Figure 4.

Handling Multi-Sourced Articles. When an article has a single link to a scientific paper, we use the STS of them as an indicator of quality. When an article has multiple links to scientific papers, we select the one that has the maximum score according to the STS model we just described. We remark that this is just an indicator of article quality and we do not expect that by itself it is enough to appraise the quality of the article. Deviations from the content of the scientific paper are not always wrong, and indeed a good journalist might consult multiple sources and summarize them in a way that re-phrases content from the papers used as sources.

5.2.2 Diffusion Graph Indicators. We also consider that referencing scientific sources, or referencing pages that reference scientific sources, are good indicators of quality. Figure 2 showing a graph from scientific papers to articles, and from articles to social media postings and from them to their reactions, suggests this can be done using graph-based indicators. We consider the following:

(1) personalized PageRank [29] on the graph having scientific articles and universities as root nodes and news articles as leaf nodes; and
(2) betweenness and degree on the full diffusion graph [22, 23].

Additionally, we consider the traffic score computed by Alexa.com for the website in which each article is hosted, which estimates the total number of visitors to a website.

5.3 Social Media Indicators

We extract signals describing the quantity and characteristics of social media postings referencing each article. Quantifying the amount of reactions in various ways might give us signals about the interest in different articles (§5.3.1). However, this might be insufficient or even misleading, if we consider that false news may reach a larger audience and propagate faster than actual news [59]. Hence, we also need to analyze the content of these postings (§5.3.2).

5.3.1 Social Media Reach. Not every social media user posting the URL of a scientific news article agrees with the article's content, and not all users have sufficient expertise to properly appraise its contents. Indeed, sharing articles and reading articles are often driven by different mechanisms [2]. However, and similarly to citation analysis and to link-based ranking, the volume of social media reactions to an article might be a signal of its quality, although the same caveats apply.

Given that we do not have access to the number of times a social media posting is shown to users, we extract several proxies of the *reach* of such postings. First, we consider the total number of postings including a URL and the number of times those postings are "liked" in their platform. Second, we consider the number of followers and followees of posting users in the social graph. Third, we consider a proxy for international news coverage, which we operationalize as the number of different countries (declared by users themselves) from which users posted about an article.

Additionally, we assume that a level of attention that is sustained can be translated to a larger exposure and may indicate long-standing interest on a topic. Hence, we consider the temporal coverage i.e., the length of the time window during which postings in social media are observed. To exclude outliers, we compute this period for 90% of the postings, i.e., the article's "shelf life" [9].

5.3.2 Social Media Stance. We consider the stance or positioning of social media postings with respect to the article they link to, as well as the stance of the responses (replies) to those postings. According to what we observe in this corpus, repliers sometimes ask for (additional) sources, express doubts about the quality of an article, and in some cases post links to fact-checking portals that contradict the claims of the article. These repliers are, indeed, acting as "social media fact-checkers," as the example in Figure 5 shows. Following

Figure 5: Example in which the stance of social media replies (bottom row) indicates the poor quality of an article promoted through a series of postings (top row).

a classification used for analyzing ideological debates [28], we consider four possible stances: supporting, commenting, contradicting, and questioning.

Retrieving replies. Twitter's API does not provide a programmatic method to retrieve all the replies to a tweet. Thus, we use a web scraper that retrieves the text of the replies of a tweet from the page in which each tweet is shown on the web. The design of this web scraper is straightforward and allows us to retrieve all the *first-level* replies of a tweet.

Classifying replies. To train our stance classifier, we use: (i) a general purpose dataset provided in the context of *SemEval 2016* [43], and (ii) a set of 300 tweets from our corpus which were annotated by crowdsourcing workers. From the first dataset we discard tweets that are not relevant to our corpus (e.g., debates on *Atheism*), thus we keep only debates on *Abortion* and *Climate Change*. The second set of annotated tweets is divided into 97 contradicting, 42 questioning, 80 commenting and 71 supporting tweets. We also have 10 tweets that were marked as "not-related" by the annotators and thus we exclude them from our training process. The combined dataset contains 1,140 annotated tweets. The **learning scheme** we use is a Random Forest classifier based on **features** including the number of: (i) total words, (ii) positive/negative words (using the Opinion Lexicon [31]), (iii) negation words, (iv) URLs, and (v) question/exclamation marks. We also computed the similarity between the replies and the tweet being replied to (using cosine similarity on *GloVe* vectors [49]), and the sentiment of the reply and the original tweet [39]. Details regarding the evaluation are provided in § 6.1.3.

6 EXPERIMENTAL EVALUATION

We begin the experimental evaluation by studying the performance of the methods we have described to extract quality indicators (§6.1). Then, we evaluate if these indicators correlate with scientific news quality. First, we determine if publications that have a good (bad) reputation or track record of rigor in scientific news reporting have higher (lower) scores according to our indicators (§6.2). Second, we use labels from experts (§6.3) to compare quality evaluations done by non-experts with and without access to our indicators (§6.4).

6.1 Evaluation of Indicator Extraction Methods

6.1.1 Quote Extraction and Attribution. The evaluation of our quote extraction and attribution method (§5.1.2) is based on a manually-annotated sample of articles from our corpus. A native English speaker performed an annotation finding 104 quotes (37 quotes attributed to persons, 33 scientific mentions and 34 "weasel" or unattributed quotes) in a random sample of 20 articles.

Table 2: Summary of all the quality indicators provided by the framework SciLens.

Context	Type	Indicator
Article	Baseline	Title [Clickbait, Subjectivity, Polarity], Article Readability, Article Word Count, Article Bylined
	Quote-Based	#Total Quotes, #Person Quotes, #Scientific Mentions, #Weasel Quotes
Sci. literature	Source Adherence	Semantic Textual Similarity
	Diffusion Graph	Personalized PageRank, Betweenness, [In, Out] Degree, Alexa Rank
Social media	Reach	#Likes, #Retweets, #Replies, #Followers, #Followees, [International News, Temporal] Coverage
	Stance	Tweets/Replies [Stance, Subjectivity, Polarity]

We compare three algorithms: (i) a baseline approach based on regular expressions searching for content enclosed in quote marks, which is usually the baseline for this type of task; (ii) our quote extraction method without the quote attribution phase, and (iii) the quote extraction and attribution method, where we consider a quote as correctly extracted if there is no ambiguity regarding the quotee (e.g., if the quotee is fully identified in the article but the attribution finds only the last name, we count it as incorrect).

As we observed, although the baseline approach has the optimal precision, it is unable to deal with cases where quotes are not within quote marks, which are the majority (**100%** precision, **8.3%** recall). Thus, our approach, without the quote attribution phase, improves significantly in terms of recall (**81.8%** precision, **45.0%** recall). Remarkably, the heuristics we use for quote attribution work well in practice and serve to increase both precision and recall (**90.9%** precision, **50.0%** recall). The resulting performance is comparable to state-of-the-art approaches in other domains (e.g., Pavllo et al. [48] obtain **90%** precision, **40%** recall).

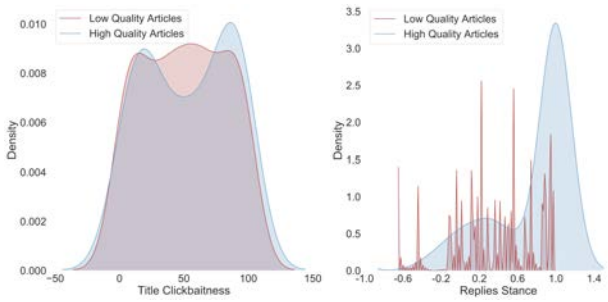
6.1.2 Source Adherence. We use the supervised learning method described on §5.2.1 to measure Semantic Text Similarity (STS). We test three different learning models: Support Vector Machine, Random Forests and Neural Networks. The three classifiers use similarities computed at the document, sentence, and paragraph level, and combining all features from the three levels. Overall, the best accuracy (**93.5%**) was achieved by using a Random Forests classifier and all the features from the three levels of granularity, combined.

6.1.3 Social Media Stance. We evaluate the stance classifier described in §5.3.2 by performing 5-fold cross validation over our dataset. When we consider all four possible categories for the stance (supporting, commenting, contradicting and questioning), the accuracy of the classifier is **59.42%**. This is mainly due to confusion between postings expressing a mild support for the article and postings just commenting on the article, which also tend to elicit disagreement between annotators. Hence, we merge these categories into a "supporting or commenting" category comprising postings that do not express doubts about an article. Similarly, we consider "contradicting or questioning" as a category of postings expressing doubts about an article; previous work has observed that indeed false information in social media tends to be questioned more often (e.g., [10]). The problem is then reduced to binary classification.

To aggregate the stance of different postings that may refer to the same article, we compute their weighed average stance considering supporting or commenting as +1 (a "positive" stance) and contradicting or questioning as −1 (a "negative" stance). As weights we consider the popularity indicators of the postings (i.e., the number of likes and retweets). This is essentially a text quantification task [24], and the usage of a classification approach for a quantification task is justified because our classifier has nearly identical pairs of true positive and true negative rates (**80.65%** and **80.49%** respectively), and false positive and false negative rates (**19.51%** and **19.35%** respectively).

6.2 Correlation of Indicators among Portals of Diverse Reputability

We use two lists that classify news portals into different categories by reputability. The first list, by the American Council on Science and Health [3] comprises 50 websites sorted along two axes: whether they produce evidence-based or ideologically-based reporting, and whether their science content is compelling. The second list, by Climate Feedback [17], comprises 20 websites hosting 25 highly-shared stories on climate change, categorized into five groups by scientific credibility, from very high to very low.



We sample a few sources according to reputability scores among the sources given consistent scores in both lists: high reputability (The Atlantic), medium reputability (New York Times), and low reputability (The Daily Mail). Next, we compare all of our indicators in the sets of articles in our collection belonging to these sources. Two example features are compared in Figure 6. We perform ANOVA [18] tests to select discriminating features. The results are shown on Table 3. Traffic rankings by Alexa.com, scientific mentions, and quotes, are among some of the most discriminating features.

6.3 Expert Evaluation

We ask a set of four external experts to evaluate the quality of a set of articles. Two of them evaluated a random sample of 20 articles about the gene editing technique CRISPR, which is a specialized topic being discussed relatively recently in mass media. The other two experts evaluated a random sample of 20 articles on the effects of Alcohol, Tobacco, and Caffeine (the "ATC" set in the following), which are frequently discussed in science news.

Experts were shown a set of guidelines for article quality based on previous work (§2). Then, they read each article and gave it a score in a 5-point scale, from very low quality to very high quality. Each expert annotated the 20 articles independently, and was given afterwards a chance to cross-check the ratings by the other expert and revise her/his own ratings if deemed appropriate.

The agreement between experts is distributed as follows: (i) *strong agreement*, when the rates after cross-checking are the same (7/20 in ATC, 6/20 in CRISPR); (ii) *weak agreement*, when the rates differ

(a) (b)

Figure 6: Kernel Density Estimation (KDE) of a traditional quality indicator (*Title Clickbaitness* on the left) and our proposal quality indicator (*Replies Stance* on the right). We observe that for both high and low quality articles the distribution of *Title Clickbaitness* is similar, thus the indicator is non-informative. However, most of the high quality articles have *Replies Stance* close to 1.0 which represents the *Supporting/Commenting* class of replies, whereas low quality articles span a wider spectrum of values and often have smaller or negative values representing the *Contradicting/Questioning* class of replies. Best seen in color.

by one point (12/20 in ATC, 10/20 in CRISPR), and (iii) *disagreement*, when the rates differ by two or more points (1/20 in ATC, 4/20 in CRISPR). Annotation results are show on Figure 7, and compared to non-expert evaluations, which are described next.

6.4 Expert vs Non-Expert Evaluation

We perform a comparison of quality evaluations by experts and non-experts. Non-experts are workers in a crowdsourcing platform. We ask for five non-expert labels per article, and employ what our crowdsourcing provider, *Figure Eight* (figure-eight.com), calls tier-3 workers, which are the most experienced and accurate. As a further quality assurance method, we use the agreement among workers to disregard annotators producing consistently annotations that are significantly different from the rest of the crowd. This is done at the worker level, and as a result we remove on average about one outlier judgment per article.

We consider two experimental conditions. On the first condition (**non-expert without indicators**), non-experts are shown the exact same evaluation interface as experts. On the second condition (**non-expert with indicators**), non-experts are shown 7 of the quality indicators we produced, which are selected according to Table 3. Each indicator (except the last two) is shown with stars, with ★☆☆☆☆ indicating that the article is in the lowest quintile according to that metric, and ★★★★★ indicating the article is in the highest quintile. The following legend is provided to non-experts to interpret the indicators:

> **Visitors per day of this news website** (more visitors = more stars)
> **Mentions of universities and scientific portals** (more mentions = more stars)
> **Length of the article** (longer article = more stars)
> **Number of quotes in the article** (more quotes = more stars)
> **Number of replies to tweets about this article)** (more replies = more stars)
> **Article signed by its author** (✓= signed,✗= not signed)
> **Sentiment of the article's title** (☺☺= most positive, ☹☹= most negative)

Results of comparing the evaluation of experts and non-experts in the two conditions we have described are summarized in Figure 7. In the figure, the 20 articles in each set are sorted by increasing expert rating; assessments by non-experts differ from expert ratings, but this difference tends to be reduced when non-experts have access to quality indicators.

In Table 4 we show how displaying indicators leads to a decrease in these differences, meaning that non-expert evaluations become closer to the average evaluation of experts, particularly when experts agree. In the ATC set the improvement is small, but in CRISPR

Table 3: Top five discriminating indicators for articles sampled from pairs of outlets having different levels of reputability (p-value: < 0.005 *, < 0.01 **, < 0.05 *).**

The Atlantic vs. Daily Mail (very high vs. very low)	NY Times vs. Daily Mail (medium vs. very low)
Alexa Rank***	Alexa Rank***
#Scientific Mentions***	Article Bylined***
Article Readability**	#Scientific Mentions***
#Total Quotes*	Article Readability***
Title Polarity	#Total Quotes**
The Atlantic vs. NY Times (very high vs. medium)	**All Outlets (from very high to very low)**
Alexa Rank***	Alexa Rank***
Article Bylined***	Article Bylined***
Article Word Count*	Article Word Count***
#Replies*	#Scientific Mentions***
#Followers	Article Readability***

Table 4: Differences among expert evaluations, evaluations provided by non-experts and fully automatic evaluations provided by the SciLens framework, measured using RMSE (lower is better). ATC and CRISPR are two sets of 20 articles each. Strong agreement indicates cases where experts fully agree, weak agreement when they differed by one point, and disagreement when they differed by two or more points. No-Ind. is the first experimental condition for non-experts, in which no indicators are shown. Ind. is the second experimental condition, in which indicators are shown.

	Experts by agreement	#	Non-Experts No ind.	Non-Experts Ind.	Fully automated
ATC	Strong agreement	7	0.80	**0.45**	1.41
	Weak agreement	12	1.28	1.18	**0.76**
	Disagreement	1	0.40	1.30	**0.00**
	All articles	20	1.10	**1.00**	**1.00**
CRISPR	Strong agreement	6	1.40	1.17	**1.00**
	Weak agreement	10	0.86	0.76	**0.67**
	Disagreement	4	**0.96**	1.22	1.03
	All articles	20	1.96	0.96	**0.85**

(a) Articles on Alcohol, Tobacco, and Caffeine

(b) Articles on CRISPR

Figure 7: Evaluation of two sets of 20 scientific articles. The line corresponds to expert evaluation, while the bars indicate fully automatic evaluation (red), assisted evaluation by non-experts (light blue), and manual evaluation by non-experts (dark blue). Best seen in color.

it is large, bringing non-expert scores about 1 point (out of 5) closer to expert scores.

Table 4 and Figure 7 also includes a fully automated quality evaluation, built using a weakly supervised classifier over all the features we extracted. As weak supervision, we used the lists of sites in different tiers of reputability (§6.2) and considered that *all articles* on each site had the same quality score as the reputation of the site. Then, we used this classifier to annotate the 20 articles in each of the two sets. Results show that this achieves the **lowest** error with respect to expert annotations.

7 CONCLUSIONS

We have described a method for evaluating the quality of scientific news articles. This method, SciLens, requires to collect news articles, papers referenced in them, and social media postings referencing them. We have introduced new quality indicators that consider quotes in the articles, the similarity and relationship of articles with the scientific literature, and the volume and stance of social media reactions. The approach is general and can be applied to any specialized domain where there are primary sources in technical language that are "translated" by journalists and bloggers into accessible language.

In the course of this work, we developed several quality indicators that can be computed automatically, and demonstrated their suitability for this task through multiple experiments. First, we showed several of them are applicable at the site level, to distinguish among different tiers of quality with respect to scientific news. Second, we showed that they can be used by non-experts to improve their evaluations of quality of scientific articles, bringing them more in line with expert evaluations. Third, we showed how these indicators can be combined to produce fully automated scores using weak supervision, namely data annotated at the site level.

Limitations. Our methodology requires access to the content of scientific papers and social media postings. Regarding the latter, given the limitations of the data scrapers we have used only replies to postings and not replies-to-replies. We have also used a single data source for social media postings. Furthermore, we consider a broad definition of "news" to build our corpus, covering mainstream media as well as other sites, including fringe publications. Finally, our methodology is currently applicable only on English corpora.

Reproducibility. Our code uses the following `Python` libraries: `Pandas` and `Spark` for data management, `NetworkX` for graph processing, `scikit-learn` and `PyTorch` for ML, and `SpaCy`, `Beautiful Soup`, `Newspaper`, `TextSTAT` and `TextBlob` for NLP. All the data, code as well as the expert and crowd annotations used in this paper are available for research purposes in ***http://scilens.epfl.ch***.

ACKNOWLEDGMENTS

We would like to thank the external experts who helped us on the evaluation of our framework: **Aina Crosas** (Communication

Officer at the Barcelona Biomedical Research Park), **Andreu Prados** (Pharmacist and Registered Dietitian Nutritionist specialized in Health Communication), **Jose F. Rizo** (Biologist and President of the Fundación Ñamku), and **Dimitra Synefiaridou** (PhD Student in Microbiology at the Veening Lab). ABSTRACT

Request latency is a critical metric in determining the usability of web services. The latency of a request includes service time – the time when the request is being actively serviced – and waiting time – the time when the request is waiting to be served. Most existing works aim to reduce request latency by focusing on reducing the mean service time (that is, shortening the critical path).

In this paper, we explore an alternative approach to reducing latency – *using variability as a guiding principle when designing web services*. By tracking the service time variability of the request as it traverses across software layers within the user and kernel space of the web server, we identify the most critical stages of request processing. We then determine control knobs in the OS and application, such as thread scheduling and request batching, that regulate the variability in these stages, and demonstrate that tuning these specific knobs can significantly improve end-to-end request latency. Our experimental results with Memcached and Apache web server under different request rates, including real-world traces, show that this alternative approach can reduce mean and tail latency by 30–50%.

1 INTRODUCTION

Web applications provide important services, such as online retail, messaging, and search, to end-users on a daily basis [3, 5, 8, 13]. A critical metric for determining the usability of such web applications is the *latency* of user requests; different service providers employ different measures of latency, such as mean, median, 95%ile, and 99%ile [7, 37, 47]. A delay of even a few milliseconds in request latency can lead to significant revenue loss for service providers due to user abandonment [14, 44].

Conceptually, request latency can be broken down into two distinct components, *service time* and *waiting time* [27]. Service time is defined as the time during which the request is being actively serviced. Waiting time is then defined as the remaining time during which the request is waiting to be served. To maintain acceptable latencies, service providers often optimize their web servers to reduce the mean service time of requests, that is, shorten the critical path of request processing. For example, Chronos [24] uses user-level networking with NIC-level request dispatch to reduce lock contention and lower the latency of web applications; Jose et al. [53] make Memcached RDMA-capable to shorten the critical path; Li et al. [31] advocate using a real-time scheduler to reduce request scheduling delay.

An alternative approach to reducing web latencies that we explore in this paper is to minimize the *variability* in request processing. Queuing models show that, in addition to mean service time, the variability of the service time is also important when trying to reduce latency. Surprisingly, there has been very little work on actually reducing the variability in the system [7, 19, 49]. While much of the variability is intrinsic to the workload (e.g., burstiness in customer traffic), some of the variability is due to the *application and software design* (e.g., garbage collection, context switches, CPU scheduling policies, etc.), and can be regulated by making subtle changes to the system.

In this paper, we investigate the following system design question – "*is it worth reducing variability in request processing times at the potential expense of lengthening its critical path?*". While theoretical analysis suggests that this is indeed the case, especially for heavy-tailed distributions (see Section 2), evaluating this idea in practice for web applications is challenging for several reasons:

- Web applications have a *complex processing lifetime*, going through several paths of processing in the kernel, including the TCP stack, parsing of requests, and scheduling of the request on server cores. Identifying the most likely culprit(s) that contributes to service time variability will require low-overhead yet accurate and fine-grained *request tracing* in the user and kernel space.
- There are several control knobs within a web server that can be tuned to reduce service time variability, such as the OS scheduler, page allocation strategy, etc. Prior work has also shown that new application-specific control knobs can be dynamically generated [18]. Given the numerous choices, efficiently finding the right control knob to mitigate variability is challenging, especially since the choice of the optimal control knob may depend on the server and web application configuration. Worse, employing the wrong control knob can *hurt* request latency.
- Most control knobs within the system that can be tuned to reduce service time variability *invariably hurt mean service*

time. For example, prior work has shown that admission control can reduce service time variability by preventing server overload [21]. But this reduction comes at the expense of lengthening the critical path (since requests are held back), and possibly hurting latency. It is thus important to carefully tune the control knob to balance the trade-off between variability and mean service time.

We address the above challenges in the context of web services and demonstrate the benefits of *using service time variability as a guiding principle* to improve request latency. We employ lightweight, fine-grained request profiling to track service time variability; this allows us to identify components on the critical path of the request-response cycle that exacerbate service time variability. Using variability as our guiding principle, we then determine control knobs in the system and/or application that can be tuned to mitigate service time variability in the identified components. We evaluate our approach by investigating variability in Memcached, a popular in-memory (key-value store) caching service used to speed up web applications [12], and the Apache web server [45], a widely deployed http server application. Specifically, we explore the following use cases:

(1) *Request batching at the Memcached client*: To reduce the network overhead of sending short packets, the Linux kernel at the client batches incoming requests until it gets a response back from the server saying it has received the previous batch (Nagle's algorithm [40]). However, since network conditions can be variable, this default batching behavior leads to bursts of processing at the server, followed by idle times, resulting in significant service time variability. We modify this default batching behavior to closely regulate the time between batches, lowering the variability (by as much as 76%) and improving tail latency by up to 40%.
(2) *Redesigning the LRU management on the Memcached server*: To maintain the Least-Recently-Used (LRU) ordering of items in the cache, the Memcached server needs to constantly reorder items. To shorten the critical path, Memcached moves the LRU maintenance off the request processing path and delegates this responsibility to an LRU management thread that is run periodically. When this thread is active, it interferes with the Memcached request processing, resulting in high service time variability. We redesign the LRU management functionality and include it on the critical path of Memcached request processing in the form of fine-grained slices of LRU work. This counter-intuitive redesign reduces variability and improves latency by about 30%.
(3) *Application thread pinning for the Apache web server*: The Apache web server schedules its various worker threads and processes on any available idle CPU core opportunistically to start serving customer requests as soon as possible. Consequently, threads may move between cores, resulting in context switch overheads and state migration. We explore thread pinning to reduce this overhead and associated variability, though at the expense of possibly delaying request processing when the pinned core is busy. We show that, at high load, this approach can reduce latency by 50%.

We experimentally evaluate the performance improvements for the above three use cases under various workload scenarios, including different levels of load, different inter-arrival time distributions, and different (time-varying) arrival traces. While existing approaches, such as exclusively focusing on reducing mean service time or employing ad-hoc control knobs, can end up *hurting* request latency, we use our alternative approach of focusing on service time variability to substantially reduce mean and tail latency (by up to 30–50%) in all three cases. Importantly, we do so by simply changing the metric that we use to identify the critical stage of request processing and determine the appropriate control knob.

2 MOTIVATION AND SCOPE OF OUR WORK

To motivate our approach of focusing on service time variability, we leverage queueing theory to analyze request latency for a server as a function of variability. Although models are only approximations of today's complex applications, the resulting analysis is instructive [16, 33, 36, 48], and guides our system design in later sections.

2.1 Request latency versus variability

Recent studies at Bing [15, 19], Google [23, 24, 43], and Facebook [3], suggest that modern web applications often experience high variability in inter-arrival time (IAT) and service time (ST). Variability in IAT represents workload variability, such as bursty arrivals. ST variability represents variability in processing times due to differences in work requirements (e.g., reads vs. writes) or differences in the request path (e.g., due to batching or TLB misses), or due to misconfigurations at the server that lead to anomalous behavior or "jitters" [31]. Note that ST is the amount of service required by a request to complete processing; alternatively, ST is the minimum possible request latency, assuming no delays.

To investigate the impact of variability on request latency, we consider a web server with a given inter-arrival time (IAT) distribution and a given service time (ST) distribution. To parameterize variability, we use the squared coefficient of variation (C^2), defined as the ratio of variance and square of the mean. Then, we have:

$$C^2_{IAT} = Var(IAT)/E^2[IAT], \text{ and} \quad (1)$$

$$C^2_{ST} = Var(ST)/E^2[ST], \quad (2)$$

where $E[]$ is the mean and $Var()$ is the variance of the random variable. To examine the full range of variability ($[0, \infty)$), we consider the following distributions:

- D (Deterministic), with $C^2 = 0$, is the ideal case of no variability.
- M (Exponential), with $C^2 = 1$, represents nominal variability.
- H_2 (Hyper-exponential), with $C^2 > 1$ (customizable), represents the case of high variability.

The $M/G/1$ queueing model, with Exponential IAT and generic ST distributions, allows us to analyze mean request latency, $E[T]$, as a function of ST variability, $Var(ST)$, and mean ST, $E[ST]$, via the Pollaczek-Khinchin (P-K) formula [27]:

$$E[T] = Var(ST) \cdot \frac{\lambda}{2(1-\rho)} + E[ST] \cdot \frac{2-\rho}{2(1-\rho)}, \quad (3)$$

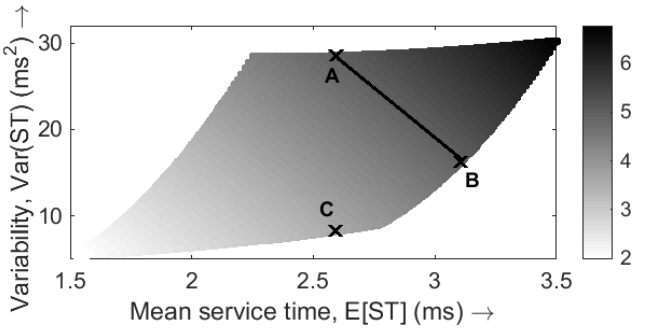

Figure 1: Heatmap of mean latency as a function of mean service time ($E[ST]$) and variability in service time ($Var(ST)$). The black diagonal line denotes the equi-latency line of $5ms$.

where $\lambda = 1/E[IAT]$ is the mean request arrival rate and $\rho = \lambda \cdot E[ST]$ is the normalized system load [27]. Clearly, both $E[T]$ *and* $Var(ST)$ impact request latency.

Consider the $M/G/1$ model where all parameters, including $E[ST]$, are fixed, and only $Var(ST)$ is varied. Let the workload have a mean ST, $E[ST]$, of 1 millisecond, and system load of, say, 60%; thus, request rate, $\lambda = 0.6 \cdot E[ST] = 600$ req/s. Using Eq. (3), we find that $E[T] = 1.7ms$ under Deterministic ST ($C^2_{ST} = 0$). For comparison, for a system with Deterministic IAT and ST, we get $E[T] = 1ms$. Thus, the added variability due to an Exponential IAT already increases mean latency by 70%. For the $M/G/1$ system, if we now consider Exponential ST ($C^2_{ST} = 1$), we get $E[T] = 2.5ms$, a 250% increase over the baseline. If we further increase the variability in ST to $C^2_{ST} = 2$ using a H_2 distribution, we get $E[T] = 3.3ms$, a 330% increase! The increase in request latency with variability is even more pronounced at higher loads.

While the above results highlight the importance of reducing variability in ST, we note that making changes to a system to reduce variability may lead to other performance overheads, resulting in higher $E[ST]$. For example, the OS scheduler may opportunistically move threads between cores to leverage idle cores. However, this introduces ST variability due to the associated state migration and context switches. Disabling this opportunistic behavior can mitigate variability, but may lead to scenarios where threads are waiting on a busy core even though other cores are idle. There is thus a trade-off between reducing $Var(ST)$ and increasing $E[ST]$, which is captured by Eq. (3).

Figure 1 illustrates the impact on mean request latency of the trade-off between $E[ST]$ and $Var(ST)$ for the $M/G/1$ model. We set $\lambda = 100$ req/s, and use an H_2 distributed ST whose variability can be controlled. To highlight the trade-off, we show the equi-latency line of $5ms$ in black. Point B on this line has a *higher* $E[ST]$ but *lower* $Var(ST)$ compared to point A; nonetheless, both have the same $5ms$ latency. Thus, we can afford some overhead in $E[ST]$ when reducing $Var(ST)$ of a system. Finally, point C has the same $E[ST]$ as A, but has much lower $Var(ST)$; as a result, the mean request latency for C is almost 30% lower than that for A.

Key takeaways: *(i) Reducing service time variability can significantly lower request latency (by 2× or higher), and (ii) It is beneficial to reduce variability even if doing so increases the mean service time.*

2.2 Objective and scope of this work

The design of today's web server systems is primarily driven by the intent to shorten the critical path of requests, that is, reducing the mean ST. However, our analytical results above suggest an alternative solution to improving request latencies in systems – *reducing variability*. Variability is often assumed to be intrinsic to the hardware and the workload, and thus not easily controllable. However, this is not always true. While variability in IAT depends on customer request behavior, variability in ST can be regulated to some extent by modifying the application and software stack. The objective of our work is to demonstrate that this alternative viewpoint of "focusing on ST variability for designing web servers" can reveal viable solutions to reduce latency. Note, however, that we are *not* arguing against solutions that focus on reducing ST.

3 SOLUTION OVERVIEW

Given a web application, our goal is to improve its latency by targeting a reduction in service time (ST) variability. However, web applications can be complex, consisting of several processes and threads that work asynchronously. Further, web requests typically pass through several software layers before completing service. Thus, we must first identify the potential software layers or components that significantly contribute to ST variability, and then determine control knobs that can be tuned to reduce ST variability in the identified software layers. Some control knobs are readily available, such as OS thread scheduler, TCP congestion control, etc. However, in some software layers, effective control knobs may not be available, necessitating modifications to existing software.

We use the following methodology to achieve our goal:

(1) *Fine-grained, unobtrusive request tracing*: We employ low-overhead tracing for the web requests. Our tracing encompasses all layers of the software stack that a request goes through during its processing lifetime, including the OS and network stack.
(2) *Identifying the source(s) of service time variability*: We aggregate the tracing information across all requests using low-overhead histograms to identify the software layers with the highest variability that are amenable to modification.
(3) *Modifying the system software to mitigate variability and reduce request latency*: We explore available control knobs in the system that can reduce the observed ST variability in the target software layer, even if this reduction comes at the expense of an increase in mean ST (see Section 2.1). Once the knob is determined, we investigate its optimal setting to minimize end-to-end request latency.

Our choice of "variability of service time" as the guiding principle in our methodology is important. We demonstrate, in Sections 6 – 8, that our methodology allows us to uncover the critical stages of request processing for two popular web applications and guides our selection of control knob. We show later, in Section 9, that naïvely

employing request tracing (for example, by using mean ST as the metric instead of variability) or selecting control knobs in an ad-hoc manner can actually *hurt* application performance.

4 REQUEST TRACING

Our request tracing works by timestamping the request through several layers starting from when it arrives at the host from the server's NIC until immediately before the application transfers the response packet back to the OS. Given our focus on variability in service times, we only trace the request at the host server, and not the client.

To store the timestamps, we append an empty 64-byte buffer to the original request packet, similar to prior works [31]. Then, as the request goes through different stages of processing on the client and the server, timestamps are recorded at appropriate offsets for the stage of processing by writing the system clock time into the buffer; we use the system clock with nanosecond precision to record timestamps within the server. By appending the small buffer to the request, we can record multiple timestamps and track the request to which they correspond without requiring any additional post-processing. The above tracing implementation required modification to the Linux kernel source, network drivers, and the application protocols to write timestamps into the appended buffer at the right offset. The overhead on request latency through all layers is low, about 5%; this overhead is incurred by both the baseline and our approach.

To choose the timestamping locations, we consider all possible components within the host server that may contribute to service time variability; these are locations where significant request processing may occur. For this study, we timestamp at the following locations/events at the host server:

- **e1**: In the host network driver when the packet arrives at the NIC.
- **e2**: At the end of TCP processing.
- **e3**: When the application drains the requests from the socket.
- **e4**: When the application starts processing an individual request.
- **e5**: When the application hands off the response to the kernel.
- **e6**: When the response is dispatched from the host server's NIC.

Timestamping at these different event boundaries provides us an opportunity to analyze the time spent by the requests at different stages, T_{ei}, for $i = 1, 2, \ldots 6$, as shown in Figure 2. However, other fine grained events are used when required, see Section 7.3.

- **driver-to-tcp**: $(T_{e2} - T_{e1})$ is the time spent by the request from driver to TCP layer, representing the network stack processing delay.
- **tcp-to-socket**: $(T_{e3} - T_{e2})$ is the time spent between the TCP layers and the socket, and represents the wakeup/scheduling delay.
- **socket-to-parse**: $(T_{e4} - T_{e3})$ is the time between application processing and socket, and represents the queuing delay at the application level caused by batching of requests.
- **parse-to-response**: $(T_{e5} - T_{e4})$ is the user-space application processing time.

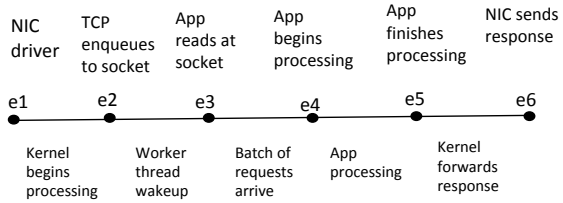

Figure 2: Timestamping locations in our request tracing.

- **response-to-send**: $(T_{e6} - T_{e5})$ is the network stack processing time to dispatch the response from the host server.

To efficiently compute variability at each stage, we maintain a running sum (across requests) of X and X^2, where X is the time spent in a stage. At the end of an experiment, we compute the sample moments $E[X]$ and $E[X^2]$ by dividing the running sums by the number of requests. Finally, we compute $Var(X) = E[X^2] - (E[X])^2$.

In our evaluation, we find that the most significant stages, in terms of variability, are the tcp-to-socket, socket-to-parse, and parse-to-response. We will discuss their role in request processing in detail in the evaluation sections. We also traced the request on the outgoing send path (server socket to driver), but the variability on this path is much smaller, only about 20% of the variability on the incoming path from client to server. Unless otherwise noted, we report $(T_{e6} - T_{e1})$ as the latency of a given request. This definition only includes the server-side latency, which is the focus of our current work.

5 EXPERIMENTAL SETUP

Testbed: We employ two servers in our experiments, one as the client to generate the workload and the other as the server hosting the web application. Each server is equipped with two sockets of Intel Xeon E5-2620 6-core (12 threads, 2.4 GHz) processors, running Ubuntu Linux 14.04 with kernel version 3.16.7. The servers each have 64GB of DRAM (1333 MHz) divided into two 32GB NUMA nodes. The servers each have an Intel I210 1Gb NIC, and are connected via a Quanta LB4M switch. Hyper-threading and power saving mechanisms such as DVFS and sleep states have been disabled in both machines as they are known to cause variability [31].

Web applications: We employ two popular web applications, Memcached [12] and Apache web server [45], for our evaluation.

- *Memcached* is a lightweight and scalable in-memory key-value store, primarily used for accelerating dynamic web applications by acting as a cache for the back-end database. Memcached is employed by several web services, including Facebook [3, 42], Twitter [46], Wikipedia [35], and YouTube [9]. Memcached maintains a list of least-recently-used (LRU) active items in memory to aid the memory reclamation process when an item expires or needs to be evicted. Memcached, from version 1.5.0, has overhauled its LRU maintenance mechanism by using a *dedicated LRU maintainer thread* that speeds up the release of expired items and the allocation of new items [38]. While the dedicated LRU thread

is not on the critical path of request processing, it may interference with requests by requiring a core to run at frequent intervals.

Our Memcached server hosts six million key-value pairs, with the key and value size for each pair set to 20 bytes and 50 bytes, respectively. The workload consists of 90% get and 10% set requests. We use Memcached version 1.5.1 and test two different throughput configurations (Sections 6 and 7).

- *Apache* is a modular, process based web server used by more than 43% of the websites [34]. The Apache web server forks identical processes and can serve a request independent of others. Apache in its newer versions from v2.0 can run in a hybrid multi-process, multi-threaded mode, which improves scalability. We use a newer version (v2.3.4) in our evaluation (Section 8).

Request rate traces: We employ request rate traces in many of our evaluations to drive the application load. Specifically, we use three digitized Memcached traces from Facebook [3], appropriately scaled for our setup, to mimic the load variation experienced by real-world web services. The VAR trace has a gradual drop in request rate, followed by a gradual rise. The APP trace has a steep rise, followed by a relatively constant request rate, and ends with a steep drop. The ETC trace is similar to APP, but is much more bursty. The peak-to-min request rate ratio in all three traces is about 2.

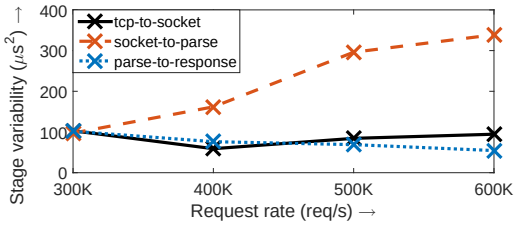
6 EVALUATION 1: REQUEST BATCHING AT THE MEMCACHED CLIENT

Our first evaluation focuses on the Memcached application. In our experiments, we find that Memcached has different sources of variability under high and low throughput configurations. We thus evaluate these configurations separately, starting with high throughput. All the results we report are averaged over 5 experimental runs each.

6.1 Application setup and tracing results

In the high throughput configuration, we run Memcached on the server with six worker threads on six cores of a socket. We use a custom client load generator that sends read/write requests at controllable request rates. In addition to the request rate traces described in Section 5, we also experiment with different inter-arrival time (IAT) distributions, motivated by prior studies on web IATs [2–4, 25]: Deterministic ($C^2_{IAT} = 0$), Exponential ($C^2_{IAT} = 1$), and Bounded Pareto ($C^2_{IAT} = 20$, IAT range of (5μs, 100ms)). The load generator emulates multiple clients by opening several connections sequentially for each worker thread, and sends multiple requests on each connection with the configured IAT. The load generator also supports different popularity distributions for the requested data (keys); unless stated otherwise, we use the random (discrete uniform) distribution.

Figure 3 shows the results of our request tracing for the three stages with the highest variability under Memcached. We see that the *socket-to-parse* stage has the highest variability, by far, compared to others. The socket-to-parse stage at the server involves parsing the drained batch of requests from the socket one request at a time



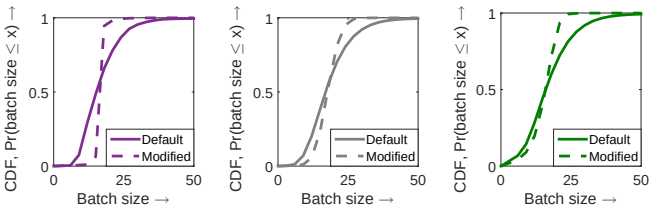


Figure 3: Variability at various request processing stages for Memcached under high throughput setting.

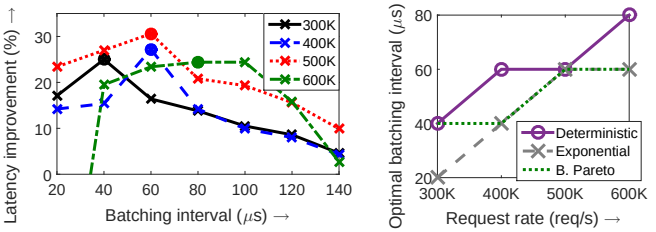
(see Section 4). The time taken in this stage is thus proportional to the size of the batch being served by the application. Consequently, the variability in this stage suggests that there is variability in the request batch sizes as observed by the application at the host server.

6.2 Determining the control knob

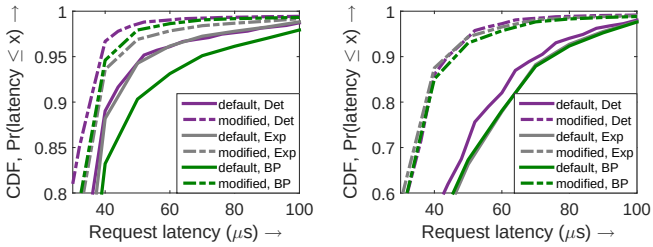
To reduce variability in socket-to-parse stage due to request batching, we need to consider the *source* of batching. Requests at the client are batched by the Linux kernel before being sent out so as to avoid the network processing overhead required for each request that is sent ("small-packet problem"). This batching is regulated by Nagle's algorithm [40]. While there are various conditions in the algorithm that trigger the sending of the next batch, we find that it is the condition of getting a response back from the server (kernel) saying it has received the previous batch that triggers the sending of a new batch in our experiments with Memcached. Since network conditions can be variable, the request batch sizes may be variable as well.



(a) Deterministic IAT. (b) Exponential IAT. (c) Bounded Pareto IAT.

Figure 4: CDF of batch sizes for default and modified Nagle's algorithm under different IAT distributions for 600K req/s.

The solid lines in Figure 4 show our empirical observations for batch sizes under 600K request rate for different IAT distributions. We see that the batch sizes vary from 5 to about 50, with the distribution being more variable for Bounded Pareto IAT. This variance in batch sizes leads to instances where the application is overwhelmed by a large batch of requests, resulting in high tail latencies. Note that once the application finishes serving a large batch of requests and returns to the socket, multiple client-side batches of requests may be waiting in the socket to be drained, resulting in the application finding (server-side) batches as large as 50 requests.



We *modify Nagle's algorithm on the client OS to force batches to be sent out at regular intervals.* This will result in less variable units of work received by the server, indirectly benefiting request latency. Rather than controlling the batch size, we instead control the time between batches, which is easier to implement. When a new request arrives at the client TCP, we append it to the existing

(a) Impact of batch size on request latency improvement under Deterministic IAT.

(b) Optimal batch size for different IAT distributions.

Figure 5: Optimizing the batch size for modified Nagle's.

(a) Request rate: 300K req/s.

(b) Request rate: 600K req/s.

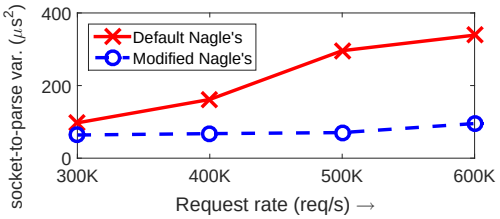

Figure 7: Variability of socket-to-parse stage under the default and modified Nagle's algorithm for Deterministic IAT.

batch and check whether the specified batching interval time has passed since the previous batch was sent. If yes, then we dispatch the current batch; else, we wait for the next request. This modification to Nagle's algorithm reduces the variability in batch sizes, as shown by the dashed lines in Figure 4 that represent the CDF of batch sizes after applying our modification and setting specific batching intervals for 600K req/s. For less variable IAT distributions, such as Deterministic, our modification eliminates almost all variability in batch sizes, as represented by the near-vertical CDF (dashed line) in Figure 4(a). Note that we still batch requests, and so preserve the Nagle's algorithm's functionality of preventing small packets from overwhelming the TCP/IP stack [40].

The "batching interval" length that we specify for sending out batches is a parameter that can be tuned. A large batching interval will result in numerous requests being sent simultaneously in a batch, overwhelming the server. On the other hand, a small interval can overwhelm the network stack with frequent packets. The batching interval must thus be carefully chosen, as we discuss next.

6.3 Evaluation results

Figure 5(a) shows the improvement in mean latency (over default Nagle's batching) for different batching intervals in our experiments under Deterministic IAT. We see that the batching interval does have a significant impact on latency. The optimal batching interval, indicated by the solid circles on each line, improves mean request latency by about 27%, on average, compared to the default Nagle's algorithm.

Figure 5(b) shows the optimal batching interval as a function of request rate for different IAT distributions. In general, the optimal batching interval length increases with request rate. An increase in batching interval leads to larger batch sizes being dispatched to the server, but also results in the server having longer to service each batch. With increasing load, it is likely that the server benefits more from having a longer duration of time to ensure that all requests in the batch are served before taking on a new batch. We find that, compared to the default Nagle's algorithm, our optimal batching leads to more frequent but smaller batches of requests being sent out at predictable intervals.

Figure 6 shows the CDF of request latency under the default and our modified Nagle's algorithm (using the optimal batching interval) for fixed request rates, but with different IAT distributions. Solid lines show the latency for default Nagle's and dashed lines show the latency for our modified algorithm. Given our focus on tail latencies, we intentionally show higher latencies in the CDF figures. For illustration, we show results for the smallest and largest request rate settings in our experiments; results are qualitatively similar for other request rates. We see that the latency reduction is higher for larger request rates. This is because the variable batch sizes overwhelm the server more under high load, and thus our modified batching algorithm has greater opportunity for improvement. The reduction in tail latency (80^{th}–99^{th} percentile) for all distributions ranges from 34-40% for 600K req/s, and from 14-35% for 300K req/s. The improvement in mean request latency likewise ranges from 24-26% for 600K req/s, and from 17-25% for 300K req/s. In general, the improvement is largest for Bounded Pareto IAT (which also has the largest IAT variability), followed by Exponential and Deterministic. This ordering is likely because of the relative variability in batch sizes (dictated by the IAT distribution) for the default case under these distributions.

To validate the efficacy of our chosen control knob in reducing variability, we analyze the socket-to-parse stage variability for the default and modified Nagle's algorithm in Figure 7, for Deterministic IAT; results are similar for other IAT distributions. We see that our modified batching algorithm maintains low variability throughout the request rate range, while the default Nagle's has much higher variability. The reduction in variability in Figure 7 ranges from 34-76%. We find a similar reduction in batch size variability as a function of request rate as well. Note that the reduction in stage variability in Figure 7 is correlated with the latency improvement in Figure 6.

Content popularity: The above results are for random content (key) popularity distribution. We also experiment with the Generalized Pareto distribution using similar parameters as reported by Facebook [3]. In this case, our modified batching reduces tail latency (80^{th}–99^{th} %ile) by about 20-24% and mean latency by about 17%.

Multiple clients: We also experiment with multiple clients, with each new client sending a fixed number of requests over a new connection. Note that only requests within a connection get batched. We vary the number of (sequential) clients per thread from 1 to 50, and the number of requests per client from 100 to 1000. Under our modified batching, the reduction in tail latency (80^{th}–99^{th} %ile) ranges from 13-21% and that for mean latency ranges from 15-17%, across all cases.

Trace-driven: Finally, we also experiment with dynamic trace-driven request rates (see Section 5), with the request rate ranging from 260K–610K req/s. Our modified batching reduces tail latency by about 26-39% and mean latency by about 14-20%, across all traces. The improvement is more pronounced for the ETC trace, likely because it has the highest mean request rate (500K req/s) among all traces.

Our focus on variability of service time in this section led us to request batching as the right control knob for Memcached under high throughput. We show, in Section 9, that request batching is *not* effective for the Apache web server; this is because the socket-to-parse stage variability for Apache is low (see Section 8). It is thus important to consider variability when deciding the right control knob.

7 EVALUATION 2: REDESIGNING THE LRU MANAGEMENT THREAD IN MEMCACHED

7.1 Application setup and tracing results

In the low throughput configuration, we run Memcached with different worker thread and core counts, starting with two worker threads on two cores of a socket. This configuration is representative of typical VM sizes requested by customers in public clouds [6]. We again employ our custom Memcached load generator (see Section 6.1) to vary the request rate (including via traces) and IAT distribution. Unless otherwise stated, we report results for the Deterministic IAT.

Figure 8 shows the results of our request tracing; note the much higher magnitude of variability values here (two core) when compared to the six core configuration in Figure 3. We see that the *tcp-to-socket* stage now has much higher variability compared to the other stages, and the socket-to-parse stage has much lower variability, in contrast to Figure 3. We do not employ the modified batching algorithm here so as to preserve the default application behavior and identify the most significant source of variability under the low throughput configuration. We evaluate the impact of modified batching for the low throughput configuration in Section 9.

The tcp-to-socket stage denotes the time between the TCP processing and the application picking up requests from the socket. Specifically, at the start of this stage, the TCP has enqueued the request(s) in socket, and the kernel now attempts to wake up/schedule the application's worker thread on a core so it can pick up the enqueued requests from the socket. The high variability in this stage indicates that there is variability in the time it takes the application to be scheduled, suggesting that the application is either busy elsewhere or has been scheduled out for other processes. Possible

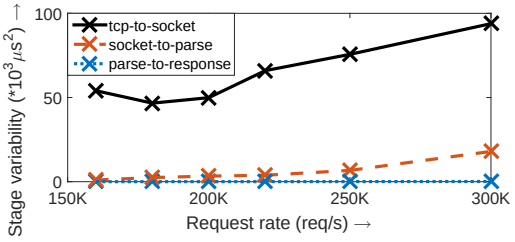

Figure 8: Variability at various request processing stages for Memcached under low throughput setting.

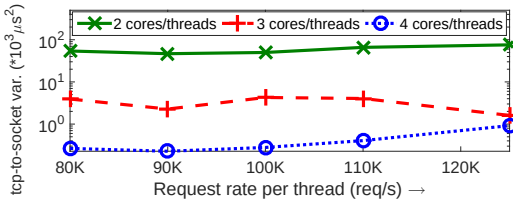

Figure 9: tcp-to-socket variability for different Memcached server configurations. Note the log scale on y-axis.

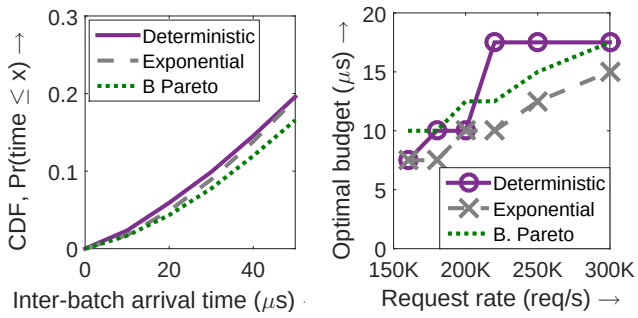
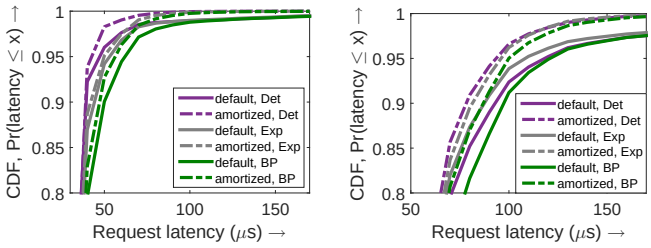


sources of this variability include the application scheduling overhead and competing background threads, such as the dedicated Memcached LRU thread (see Section 5).

To precisely determine the most likely source of variability, we study the change in tcp-to-socket variability as we change the number of cores and threads assigned to Memcached, as shown in Figure 9. Note that the x-axis denotes the request rate *per thread*. We see that the tcp-to-socket variability goes *down* as the number of cores/Memcached threads increases, suggesting that the source of variability is mitigated by increasing the number of cores. This suggests that the dedicated LRU thread interfering with the Memcached worker threads is the likely cause for the increased tcp-to-socket variability. If the source of variability was instead the application scheduling overhead, then the tcp-to-socket variability should not have decreased with the number of threads (since we scale request rate with number of threads), which is contrary to the findings in Figure 9.

7.2 Creating a new control knob

The dedicated LRU thread is an application-specific function and does not expose any tunable knobs. While we can modify the application to do less LRU maintenance work, this would impact the application's functionality. Instead, we wish to preserve the LRU maintenance functionality while reducing variability by mitigating the interference between the LRU thread and the Memcached worker threads.



Our key idea is to *offload the LRU maintenance work to the Memcached worker threads and disable the dedicated LRU thread entirely* so it does not cause high variability for the tcp-to-socket stage. Specifically, at the end of each request processing phase and before being scheduled out, we leverage the worker thread itself do some controllable amount of LRU maintenance work. In other words, we *amortize* the LRU maintenance work over all worker thread invocations. We refer to our LRU maintenance approach as the *amortized LRU*.

(a) CDF of inter-batch arrival times at the server for different IAT distributions.

(b) Optimal budget for amortized LRU as a function of request rate.

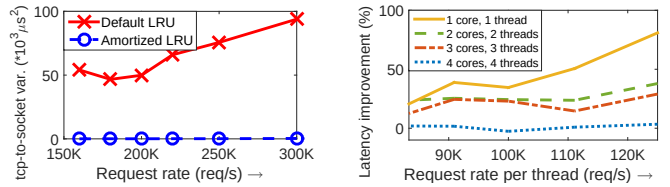


Figure 10: Optimizing the budget for our amortized LRU.

(a) Request rate: 160K req/s.

(b) Request rate: 300K req/s.

Figure 11: CDF of request latency for the default and our amortized LRU mechanisms for different IAT distributions.

(a) Variability of tcp-to-socket stage under the default LRU and our amortized LRU.

(b) Improvement in mean latency under amortized LRU for different configurations.

Figure 12: Reduction in variability and sensitivity analysis.

While it may appear that the LRU maintenance work is now on the critical path, this is not entirely true. By scheduling LRU maintenance only *after* a batch of requests is processed, we are leveraging the idle time between batches to do LRU work. Of course, it is possible that a new batch of requests arrives before our LRU work is completed. To minimize this overstepping, we *regulate the amount of LRU work* done by each worker thread before being scheduled out. We refer to this controllable amount of work as the "budget" of our amortized LRU.

The budget for our amortized LRU must be carefully chosen so as to (i) ensure that the same amount of LRU maintenance work is being done as the dedicated LRU thread, and (ii) minimize the overlap with future request arrivals. While the former constraint implies a larger budget, the latter concern suggests a smaller budget.

7.3 Evaluation results

To determine the optimal budget for our amortized LRU, we analyze the idle time at the server between processing of successive request batches by the application. We timestamp two additional events– e7: When a batch of requests has finished processing (or event e5 for the last request in a batch, see Section 4), and e8: When a new batch of requests has completed its TCP processing and is ready to be serviced (or event e2 for a new batch). Figure 10(a) shows the CDF of inter-batch arrival times, $(T_{e8} - T_{e7})$, for 300K req/s request rate under different IAT distributions; we intentionally focus on a small region of the CDF. We see that almost 90% of the batches have an inter-batch arrival time of at least 30μs. The percentage is even higher for smaller request rates. This suggests that as long as the LRU work is scheduled for no more than 30μs, the negative impact on latency should be small. We thus consider budget values smaller than 30μs to investigate the benefits of amortizing LRU.

We find that the exact value of the budget does not significantly impact request latency. As a result, we seek the *smallest* budget that can still provide an equivalent amount of LRU maintenance as the default dedicated LRU thread. Figure 10(b) shows the optimal budget for different request rates under different IAT distributions. We see that the optimal budget increases with load, as expected, since the amount of LRU maintenance required for items (even in case of the default LRU thread) is proportional to the rate at which they are accessed.

Figure 11 shows the CDF of request latency for the default LRU and our amortized LRU mechanism (using the optimal budget for each request rate) for different IAT distributions and for the smallest and largest request rate setting. Solid lines show the latency for default LRU and dashed lines show the latency for our amortized LRU. The difference in latencies is more pronounced for the higher percentiles, and so we focus on this region in the figures. We see that the latency improvement afforded by our amortized LRU is slightly higher for larger request rates. This is because the default LRU thread interferes with more requests per second when the request rate is higher, and also because the LRU thread has to run for a longer time (to do more maintenance) when the request rate is high; thus, there is more opportunity for improvement at high request rates.

The reduction in tail latency (80^{th}–99^{th} percentile) for all IAT distributions ranges from 4-32% for 300K req/s, and from 6-31% for 160K req/s, with the improvement being slightly higher for Bounded Pareto IAT in general. The improvement in mean request latency across all experiments is about 28%. We also experiment with the Generalized Pareto content popularity distribution. In this case, our amortized LRU reduces tail latency by about 6-23% and mean latency by about 7%. Finally, we also experiment with request rate traces, with the request rate ranging from 90K-200K req/s. Under our amortized LRU, the reduction in tail and mean latency ranges from 7-42% and 22-31%, respectively, across all traces.

Figure 12(a) shows the variability of the target tcp-to-socket stage for the default and amortized LRU mechanisms, for Deterministic IAT. Our amortized LRU significantly reduces the stage variability, with the reduction being more prominent at higher request rates. This is in agreement with the latency improvement trends in Figure 11.

The above results are for the Memcached configuration of 2 cores and 2 threads. We now investigate the results under different configurations of cores and threads, since the impact of interference by the default LRU thread depends on these settings. Figure 12(b) shows the mean latency improvement under Deterministic IAT using our amortized LRU for n cores and n threads, where $n = 1, 2, 3, 4$. The improvement decreases with the number of cores/worker threads; this is because the interference caused by the default LRU thread is shared among all cores, so higher the number of cores, lesser is the impact.

In this section, we demonstrated how non-trivial control knobs can be developed to reduce variability in the critical stages of request processing. By only adding tens of lines of code to change LRU maintenance, we are able to reduce Memcached request latency by about 30%, a significant performance benefit. The evaluations in this and the previous section also highlight the need for request profiling, as different configurations of an application can have different sources of variability and thus different control knobs and solution strategies.

8 EVALUATION 3: APPLICATION THREAD PINNING FOR THE APACHE WEB SERVER

8.1 Application setup and tracing results

We use Apache v2.3.4 with mpm-event module configured to use 6 child processes, running on 6 CPU cores of a socket. We vary the number of threads per process from 5 to 25; unless otherwise stated, we use 25 threads/process. The server hosts a static web page, resulting in a response of 280 bytes. We use httperf [39] as our client driver to experiment with different request rates, including traces. We vary the load by changing the rate at which connections are opened; each connection issues 75 requests using Deterministic IAT. We report load in terms of the total request rate (across all connections).

Figure 13 shows the results of our request tracing for the three stages with the highest variability. We see that the parse-to-response and tcp-to-socket stages have the highest variability; further, the variability increases rapidly with request rate. The parse-to-response stage represents the time taken by the application to process the request, and the tcp-to-socket stage represents the application thread scheduling latency. The high variability in these stages suggests that the worker threads are experiencing unpredictable delays which is affecting their ability to complete the application processing on time (thus the high variability in parse-to-response), and is also delaying their return to pick up requests from the socket. Given that Apache does not have a dedicated maintenance thread like the LRU thread in Memcached, we instead focus on *application thread scheduling* as a possible source of variability. The increase in stage variability with request rate in Figure 13 strengthens our hypothesis since we expect scheduling overhead to increase with load.

8.2 Determining the control knob

By default, the Apache worker threads are not pinned to the cores, and can thus be migrated between cores by the OS scheduler. The

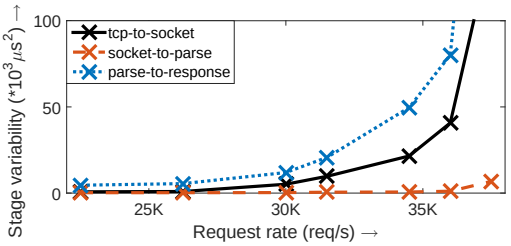

Figure 13: Variability at various stages for Apache web server.

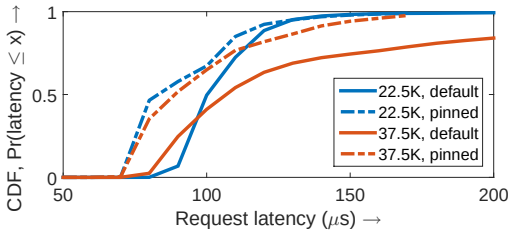

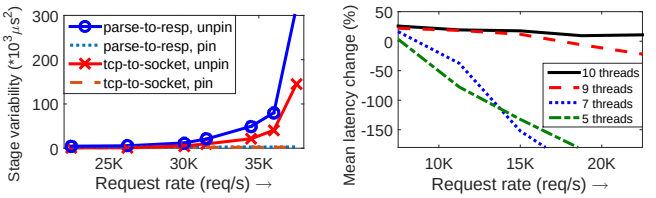

Figure 14: CDF of request latency when threads are unpinned (default) and when threads are pinned.

OS scheduler (CFS, in our case) decides on thread migration based on core availability, cache placement, NUMA affinity, etc. While not pinning the threads has the advantage of leveraging idle cores to reduce mean service time, there is the potential overhead of context switching and associated state migration when migrating threads across cores. This overhead may hinder the progress of worker threads, resulting in unpredictable delays. To reduce variability, we thus *pin the Apache application threads to cores* to prevent thread migration. Specifically, we pin all threads of a process on one core each; thus, each of the six cores handles threads from a specific process.

8.3 Evaluation results

Figure 14 shows the CDF of request latency under the default unpinned case and under the pinned case for the smallest and largest request rate settings in our experiments. We see that pinning threads significantly improves latency over the default case when threads are unpinned (i.e., can run on any of the 6 cores of the socket). The reduction in median and 90%ile latency for 37.5K request rate is 19% and 52%, respectively; the corresponding reduction for 22.5K request rate is 20% and 9%, respectively. The mean latency improvement varies from 15% at low request rates to 50% at high request rates. The higher improvement at high request rates stems from the larger potential in reducing variability (as discussed later). We also experiment with request rate traces, with the request rate ranging from 18K-37K req/s. Pinning threads improves tail latency by about 36-62% and mean latency by about 27-49%; the improvement is highest for the ETC trace.

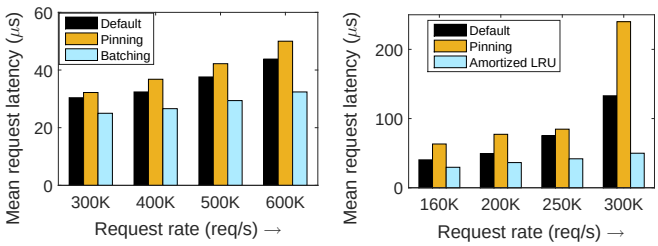

Figure 15(a) shows the variability of the target parse-to-response and tcp-to-socket stages for the unpinned and pinned cases. We see that pinning threads significantly reduces the stage variabilities. This is because pinning reduces the context switching and thread migration penalty, resulting in more predictable delays for

(a) Variability of parse-to-response and tcp-to-socket under unpinned vs pinned.

(b) Change in mean latency under pinning for different number of threads/process.

Figure 15: Reduction in variability and sensitivity analysis.

(a) Memcached, high throughput config.

(b) Memcached, low throughput config.

Figure 16: Using the wrong control knob can hurt latency.

the worker threads. For example, pinning reduces the dTLB and L1-dcache load misses by about 87% and 22%, respectively, compared to the default unpinned case. The reduction is more pronounced at higher request rates. This is likely because the impact of context switching and thread migration penalty under the default unpinned case increases with load. Note the correlation between stage variability reduction in Figure 15(a) and improvement in latency in Figure 14.

The above results for Apache are for the high-throughput case with 25 worker threads/process. We now study the sensitivity of the configuration – number of threads/process – to the improvement in mean latency. Figure 15(b) shows our evaluation results as a function of request rate; we intentionally focus on lower number of threads. We clearly see that the thread configuration has a significant impact on the benefits of pinning over not pinning. For the case of 5 threads/process, pinning does not help for any of the request rates we experiment with, and can lead to a significant increase in latency; this is in contrast to the case of 25 threads/process where pinning is always beneficial. As we increase the number of worker threads, pinning starts outperforming the unpinned case for low request rates. The inflection point occurs at 10 threads, where pinning always helps. This is because the penalty of thread migration under unpinning is higher when there are more threads being scheduled in and out across cores, resulting in cache contents being constantly disrupted; pinning avoids this penalty.

The results in this section highlight the importance of analyzing the sensitivity of the control knob to the application configuration to understand *when* the control knob should be employed, since the benefits (50% latency reduction) and consequences (150% latency increase) of the choice can be significant, as shown in Figures 14 and 15(b). In the next section, we discuss the consequences of selecting the *wrong* control knob for a given application.

9 SIGNIFICANCE OF USING VARIABILITY IN SERVICE TIME AS GUIDING PRINCIPLE

The two key components of our approach, identifying the critical stage and determining the control knob, both rely on using "variability in service time (ST)" as the guiding principle. We now discuss the importance of this metric by comparing with alternative approaches.

Using variability to identify the critical stage:
A natural question to consider in our request profiling approach is – what if we employ "mean ST" as the metric when identifying the target stage instead of "variability of ST"? Consider the Memcached application under low throughput configuration, from Section 7. When employing mean ST as the metric for request profiling, we find that the socket-to-parse stage has the highest ST. Using the arguments from Section 6, we then employ batching as our control knob. However, the impact on request latency when using batching is inconsistent. For low request rates, the optimal batching does improve mean latency by about 28%. However, for higher request rates, even the optimal batching ends up *hurting* mean latency by as much as 32%. By contrast, when using variability of ST as the guiding metric, we consistently reduce mean latency by 26-61% by employing amortized LRU to mitigate variability in the tcp-to-socket stage. This shows that exclusively focusing on reducing mean ST may not always improve latency; a more robust approach is to also consider ST variability.

Using variability to determine the control knob:
Selecting control knobs in an ad-hoc manner is an alternative and sometimes easier approach. Thus, an obvious question is how important is it to select the right control knob?

Consider the Memcached application; an alternative control knob is to pin application threads. Figure 16 shows the resulting mean latency when using the incorrect knob (pinning) and our chosen control knob under Deterministic IAT. For the high throughput configuration, the incorrect knob *hurts* mean latency by about 11.5%, whereas our chosen control knob (batching) improves latency by about 20.9%. Likewise, for the low throughput configuration, the incorrect knob *hurts* latency by about 51.1%, whereas our chosen control knob (amortized LRU) improves latency by about 35.4%.

Similarly, for the Apache web server, another option is to batch requests by modifying the Nagle's algorithm, as in Section 6. However, even under the optimal batching interval for Apache, the improvement in mean request latency is only about 2.7%, whereas that under our chosen control knob (pinning) is about 21.1%.

10 RELATED WORK

Reducing the variability of end-to-end request latency
Dean et al. [7] analyze tail latencies in a production data center that supports their Google search system. The authors acknowledge that latency variability is a problem, and propose application-specific solutions, such as differentiating service classes and reducing head-of-line blocking. While this seminal work established the importance of variability and tail latency in production systems, it focuses on variability in request latency as a whole, and not on specific stages.

Li et al. [31] study sources of tail latency in interactive services by instrumenting applications and the kernel. While our request

profiling approach is inspired by the authors' work, we focus on variability at individual stages of request processing whereas the above work focuses on end-to-end latency. Focusing on per-stage variability can reveal system design opportunities that may otherwise be overlooked. In particular, while the above work also studies the Memcached application, they do not uncover request batching or LRU maintenance as potential optimizations.

Jalaparti et al. [19] focus on the tail latency of Bing web search, and propose application-specific strategies such as reissuing stragglers and speeding up stragglers. Each of these strategies applies to a different "stage", where the concept of stage here refers to a step in the application's workflow and may span thousands of servers; this is in contrast to our definition of "stage" which refers to a fine-grained section of the request's processing path within a single server.

Reducing the latency variability for specific components
Hocko et al. [17] show that making the physical page allocation cache-aware reduces performance non-determinism without significantly increasing mean latency. Pusukuri et al. [30] show that changing the scheduling and migration policies to be aware of cache misses and context switches simultaneously reduces performance variation and improves performance. In addition, several techniques have been developed for promoting fairness in multi-threaded processor cores, shared caches [20, 26, 52], and memory controllers [10, 41], for improving performance by minimizing resource interference.

The above works focus on reducing variability in specific components (such as the OS scheduler), which are known a priori to be the performance bottlenecks. In our work, we profile the request processing path to first determine the potential bottlenecks. Thus, the above works can be employed as control knobs by our approach to reduce the variability at specific stages, *after* those stages have been identified as the potential source of variability.

Shortening the critical path of request processing
Kanev et al. [23] perform a detailed analysis of Google's data center jobs and find that CPU stalls and cache misses are the main causes of low core utilization. To improve utilization, the work calls for shortening the critical path of request processing by employing hardware specialization. Kapoor et al. [24] analyze data center applications and find that kernel overheads contribute significantly to request latency. The authors propose Chronos, a communication framework that bypasses the kernel by employing user-level, zero-copy network functionality, thus shortening the critical path.

The above works are classic examples of approaches that improve performance by reducing the mean ST (shortening the critical path). Our work presents a complementary approach that improves performance by reducing the *variability* of ST.

Request batching
SEDA [51] proposes a staged event-driven architecture for web applications with event batching and thread pool sizing. Yaksha [21] is a control-theoretic admission control proxy for internet services that prevents overload while maintaining high throughput. Elnikety et al. [11] propose black-box admission control for internet services by measuring execution costs and differentiating between request types. While the above works employ batching or admission control to avoid server overload, we precisely control when new requests start being processed by the server to minimize ST variability.

Thread pinning
Kumar et al. [28, 29] consider thread migration to exploit power-performance-area tradeoffs in multi-core machines. Li et al. [32] propose OS scheduling algorithms based on predicting the thread migration overheads. Wang et al. [50] study the interaction between various microarchitectural resources and thread characteristics to efficiently map threads. Thread migration has also been explored for changing thread-level parallelism [1] and for software data spreading [22]. Our work employs thread pinning to specifically reduce ST variability by avoiding state migration across cores.

11 CONCLUSION

Latency is a critical metric for user-facing web services. Existing work typically focuses on shortening the critical path (or mean service time) to improve performance. This paper takes an alternative approach to improving application performance - reducing the variability in request processing. By using "reduction in service time variability" as the guiding principle in web server design, we reveal control knobs that improve request latency (both mean and tail) by up to 28-50% across different scenarios.

Our end-goal is to make the case for using service time variability as a metric to guide system design. The three use cases presented in this paper demonstrate the validity of this approach.

ABSTRACT

In this paper, we investigate the task of aggregating search results from heterogeneous sources in an E-commerce environment. First, unlike traditional aggregated web search that merely presents multi-sourced results in the first page, this new task may present aggregated results in all pages and has to dynamically decide which source should be presented in the current page. Second, as pointed out by many existing studies, it is not trivial to rank items from heterogeneous sources because the relevance scores from different source systems are not directly comparable. To address these two issues, we decompose the task into two subtasks in a hierarchical structure: a high-level task for *source selection* where we model the sequential patterns of user behaviors onto aggregated results in different pages so as to understand user intents and select the relevant sources properly; and a low-level task for *item presentation* where we formulate a slot filling process to sequentially present the items instead of giving each item a relevance score when deciding the presentation order of heterogeneous items. Since both subtasks can be naturally formulated as sequential decision problems and learn from the future user feedback on search results, we build our model with hierarchical reinforcement learning. Extensive experiments demonstrate that our model obtains remarkable improvements in search performance metrics, and achieves a higher user satisfaction.

1 INTRODUCTION

The process of aggregating search results from heterogeneous sources is usually referred to as *aggregated search* [17]. Different from a meta-search engine or search federation which assumes that all distributed sources contain homogeneous content and applies the same ranking function to each source for result fusion [1], an aggregated search system is expected to support **heterogeneous information seeking** from different sources. When a user issues a query, the search system should integrate relevant results from each specialized search system, called *vertical*, into one Search Engine Result Page (SERP).

Existing research on search result aggregation has focused on web search [4, 11, 21], while in this paper, we study the task in E-commerce search with one of the largest E-commerce search services in the world: *Taobao.com*. Fig. 1 illustrates that traditional E-commerce search can be augmented with *blog posts* that share purchasing experiences, or *topic groups* that cluster products with the same brand or from the same shop to facilitate finding similar products. As a matter of fact, user study in Taobao Search shows that mixing products with topic groups and blog posts in a SERP can greatly improve the user experiences of product search and online shopping. In this study, we aggregate two other verticals in product search, namely the topic and blog verticals. Given a query, these verticals return topic groups and blog posts respectively.

In web search [4, 11, 21], result aggregation is performed only once at the first page for each query. While in E-commerce search, aggregation is performed multiple times for a query, one for each

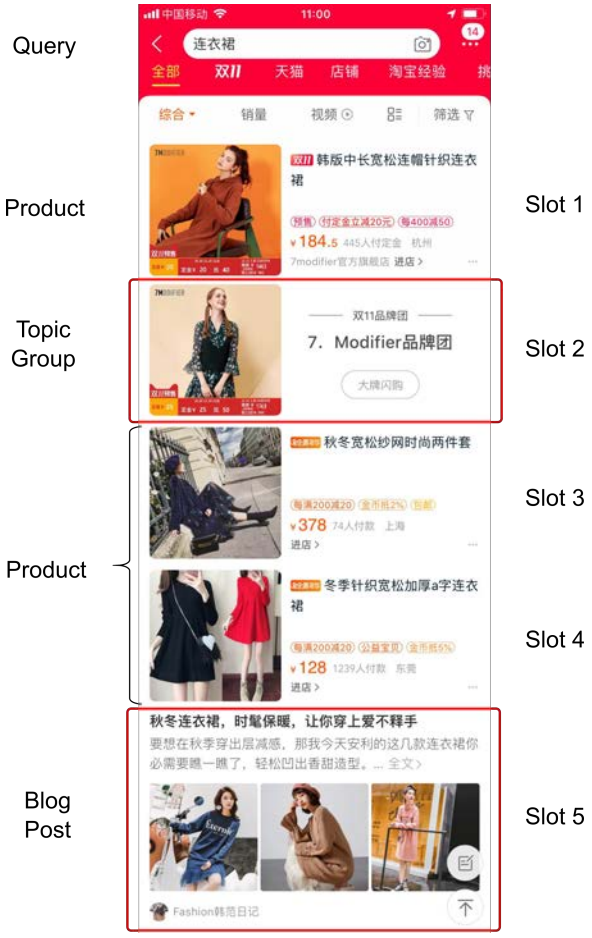

Figure 1: An aggregated search example for the query "dress", where the topic group from the *topic* vertical is shown in the 2nd position, and the blog post from the *blog* vertical in the 5th position.

page. The aim of page-wise aggregation in E-commerce search is to keep diversity to attract and retain diverse customers. This is a major difference from previous web search aggregation in which a single decision is made only for the first page.

In this paper, we decompose search result aggregation in E-commerce search into two subtasks: *source selection* and *item presentation*. *Source selection* decides whether to present the search results of a certain source type in the current page, which depends on the user behaviors onto the items that have been already presented in previous pages. For example, if a user issued the query "sport shoes", and clicked several products with the same brand, presenting a topic group with the same brand in the next page may be a good decision. Then the validity of search results can be examined afterwards by analyzing the long-term gains like click through rate (CTR). So this process is a sequence of decisions and can be modeled with reinforcement learning (RL) [32], which helps better understand user intents to present more relevant aggregated search results.

The other subtask, *item presentation*, is to decide the presentation order of the items from heterogeneous sources, which requires to estimate the relevance scores of all items in a unified way. However, items from different sources have different relevance estimation models [2, 16, 28], thereby making the scores not comparable between different sources. This is termed the *relevance ranking* issue. To avoid this, we formulate the item presentation task as a *slot filling* problem where the training signal comes directly from the user feedback. In this formulation, each display position in a page is regarded as a slot, and the slots in a page will be filled sequentially. At each position, an *item presenter* is trained to choose the most relevant item from the candidate sources, and then fills in the slot with the selected item. Once again, the slot filling process is consistent with the sequential nature of user behaviors, which can be viewed as a sequential decision problem and handled by RL.

Given the above decomposition, we propose a hierarchical reinforcement learning (**HRL**) model [5] consisting of two components: a source selector that decides which sources should be selected at the current page, and an item presenter that decides the presentation order of the items selected from the selected sources in a page. The model fully utilizes the sequential characteristics of user behaviors across different pages to decide both the sources and items to be presented. The hierarchical framework enables the model to utilize the immediate user feedback in the current page as well as the future user feedback on the entire search session.

To summarize, our main contributions are as follows:

- We propose a novel search result aggregation method that formulates a semi-Markov decision process which is composed of a high-level policy for *source selection* and a low-level policy for *item presentation*.
- We present aggregated search results for each page during source selection and capture the sequential patterns of user behaviors onto aggregated items in different pages.
- We formulate the item presentation subtask as a slot filling problem in order to avoid the relevance ranking issue on displaying heterogeneous items.

Results demonstrate that our proposed model can improve user experience and make significant advancement on marketing metrics like CTR and GMV over other baselines.

2 PRELIMINARIES

2.1 Reinforcement Learning

Reinforcement learning (RL) [32] is a learning paradigm that an agent learns from the interactions with the environment through sequential exploration and exploitation. Generally, RL follows a Markov Decision Process (MDP) formulation.

Let an MDP be defined as $< \mathcal{S}, \mathcal{A}, \mathcal{P}, r, \gamma >$, where $\mathcal{S}$ denotes the state space, $\mathcal{A}$ denotes the set of possible actions, $\mathcal{P} : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow [0, 1]$ denotes the transition function to generate the next state from current state-action pair, $r : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$ denotes the reward function and $\gamma \in [0, 1]$ is an discount factor . Given an MDP, a trajectory $\tau = s_0, a_0, r_0, s_1, \cdots$ that starts from state s_0 is sampled from a policy $\pi : \mathcal{S} \times \mathcal{A} \rightarrow [0, 1]$ that specifies the action. The aim of RL is to find an optimal policy π^* which maximizes the expected cumulative reward (return) $R_t = \mathbb{E}[\sum_{k=0}^{\infty} \gamma^k r_{t+k}]$ at

each time step t. For an agent following a policy π, the Q-value of the state-action pair (s, a) is defined as $Q_\pi(s, a) = \mathbb{E}[R_t|s_t = s, a_t = a, \pi] = \mathbb{E}_{s' \sim \mathcal{P}(\cdot|s,a)}[r + \gamma \mathbb{E}_{a' \sim \pi(s')}[Q_\pi(s', a')]|s, a]$, which measures the average discounted long-term rewards. In the practice of training, the action is often selected by an $\epsilon - greedy$ policy that follows the greedy policy $a = \arg\max_{a'} Q(s, a')$ with probability $1 - \epsilon$ for exploitation and selects a random action with probability ϵ for exploration, in order to collect desired transitions for learning.

With the advance of deep neural networks, deep reinforcement learning (DRL) has been widely used in various search tasks in recent two years [12, 25, 41].

2.2 Options Framework

Options framework [33] extends the usual MDP so that it involves temporal abstractions over the action space in the context of HRL. At each step, the HRL agent chooses either a "one-step" action (primitive action) or a "multi-step" action (option). An option $o = (\pi, \mathcal{I}, \beta) \in O$ defines a policy π over actions (either primitive or option), includes an initiation set $\mathcal{I} \subset \mathcal{S}$ that option o is available *iff* state $s \in \mathcal{I}$, and can be terminated according to a stochastic function $\beta : \mathcal{S} \rightarrow [0, 1]$. An MDP endowed with a set of options is extended to a Semi-Markov Decision Process (SMDP). Given an SMDP, a trajectory τ is sampled from a policy μ over options. Each option o_k launches a new subtask where a sub-trajectory τ_k is sampled from the corresponding policy π over actions. The agent cannot select next option (possibly in a recursive way) until current option terminates according to the termination function β.

Recently, several studies have demonstrated that combining DRL with predefined subgoals delivers promising results in challenging environments like Atari [18], Minecraft [35], relation extraction [34] and task-oriented dialogues [26].

3 RELATED WORK

In recent years, search engines are able to search heterogeneous sources that contain different types of contents (e.g. news, maps, videos, images). Studies have shown that the aggregated view helps expose the content in other sources, thus offering the chance for the user to explore different sources in search[7, 10]. Existing aggregated search systems, which merge all heterogeneous results from various search services in one SERP, mostly adopt a pipeline architecture as illustrated in Fig. 2. In general, the architecture contains two key components, one is source selection which decides the vertical sources from which items should be ranked, and the other is item presentation which decides the presentation order of the heterogeneous items.

3.1 Vertical Selection

The first subtask of aggregated search is vertical selection, also called source selection. The goal of vertical selection is to decide which verticals are to be presented in a SERP, e.g. whether it is necessary to present the videos of "violin" when a user types query "violin". Several works [20, 37, 44] have found that participants rated the system negatively when irrelevant vertical results were presented in an aggregated SERP. It is thus essential to evaluate the relevance of a source to a query.

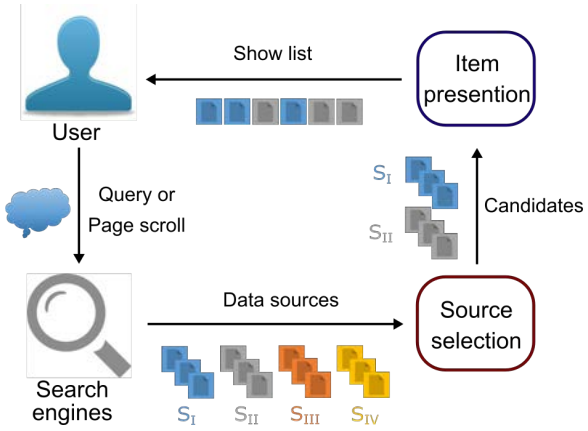

Figure 2: Task flow of search aggregation on heterogeneous sources.

Most existing approaches use a binary classifier for each vertical to make a decision on whether to present a vertical result in a page [15, 19, 36]. From this perspective, each classifier can adopt a different feature representation and focus on the features that are uniquely predictive for its corresponding vertical. Human judges are employed to generate ground-truth labels for the verticals in some approaches [4, 11]. Other approaches [16, 28] leverage user search logs and assign a binary label based on user behaviors.

As previous studies focused on web search, vertical selection is only launched one time when a user issues a query. For instance, the *video* vertical will only appear once in the first SERP for query "Titanic", but no vertical will be shown again in the following pages unless the user types a new query. However, the goal of E-commerce search is quite different from web search [45]. With respect to aggregated search, the main difference between web and E-commerce lies in that the latter needs to present the aggregated search results in each page to meet user search demand, which requires the system to capture the sequential patterns of user behaviors onto aggregated results.

3.2 Vertical Presentation

The second subtask, vertical presentation, or item presentation, is to rank the candidate items selected from verticals. For instance, should the videos of "violin" be positioned above or below the web links in a page? In general, the system presents the most relevant items at the top, which are more likely to be viewed by users [9, 31]. Existing approaches to vertical presentation can be classified into three types: *pointwise*, *pairwise* and *attention-based* approaches.

Pointwise approaches train an independent classifier per vertical to predict the relevance of the corresponding vertical. *Click models* were proposed to predict the user response (i.e. click or skip) to vertical results [16, 38, 39]. FCM [8] considered the rank of the verticals, their visual salience, and the distance between them and the current item. Markov et al. [22] proposed a click model that estimated different probabilities for results above or below the vertical as well. Others directly trained *vertical-specific classifiers* to predict the relevance score of a source to a query, which was used to decide

the position of each vertical [6, 27, 30]. Ponnuswami et al. [28] trained a gradient boosted decision tree to learn relevance scores and ranked each vertical individually using a computed threshold. Although it is simple and intuitive to implement pointwise models, they suffer from the *relevance ranking* issue that the prediction scores from individual classifiers are not directly comparable.

Pairwise approaches learn to predict the *relative preference* between candidate sources to be displayed in a SERP. Arguello et al. [2] trained one binary classifier for user preference per vertical pair, and derived a final ranking from the predicted preferences. The pairwise method solves the *relevance ranking* issue, but in return, it requires a complex ranking principle among verticals and results in a large number of pairwise classifiers.

The recent study [42] adapted an **attention-based** method that applied different weights to different information sources for relevance estimation. It has gained a significant improvement on ranking relevance, however, it requires a large number of data annotations on relevance score to support model training.

4 HIERARCHICAL SEARCH AGGREGATION

We develop a deep hierarchical reinforcement learning algorithm for aggregated search in this paper. The model consists of a high-level source selection policy and a low-level item presentation policy. The entire process works as shown in Fig. 3. When a new search request arrives, the source selector decides which sources to present on the current page. The item presenter then decides the presentation order of the relevant items from selected sources. The user search session continues when the user scrolls to the next page, and ends when he leaves the platform or types a new query. Both policies are trained with the DQN [24] algorithm. The rewards for policy training come from implicit user feedback, instead of any artificial metrics [3, 43], so that it can learn from user behaviors straightforwardly.

In the following subsections, we will present the details of the two policies, deep Q network architecture, and model optimization. The notations used in this paper are summarized in Table 1.

Notation	Description
x	Search request
$\mathcal{SR}_j$	Set of all items of source type j
m_j^k	K-th item of source type j
$n_j(x)$	The number of items of type j given the request x
p, P	Slot position on the SERP, Result presentation
s, $\mathcal{S}$	State, State set
a, $\mathcal{A}$	Primitive action, Primitive action set
o, O	Option, Option set
r^e, r^i	Extrinsic reward, Intrinsic reward
γ	Discount factor
R	Return (discounted cumulative reward)
μ, π	Source selector policy, Item presenter policy

Table 1: Notations of aggregated search and HRL.

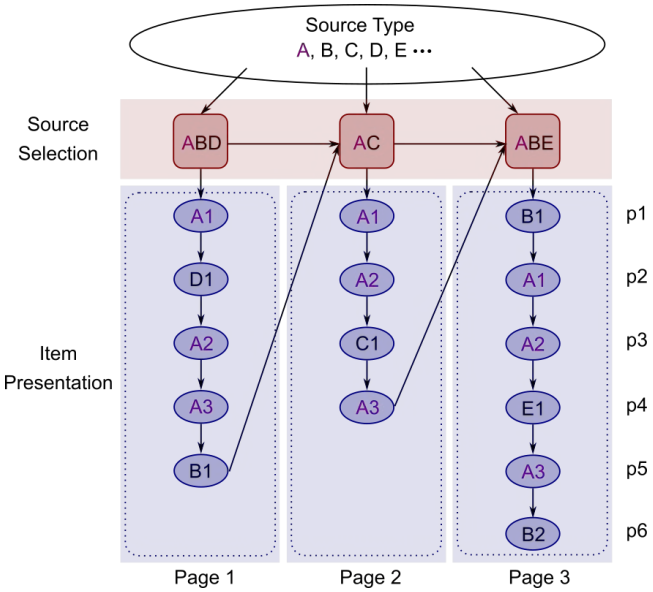

Figure 3: The hierarchical architecture on aggregated search. This example of user search session is composed of three search requests (page 1 to 3). A stands for the products, and $B, C \cdots$ for the items of other source types.

4.1 Source Selection with High-level Policy

The high-level RL process aims to decide which sources should be selected in each page. The high-level policy μ perceives the high-level state s^e and selects an option o that tells what sources to display. The option o will trigger the low-level policy to decide how to present the items from these selected sources. The high-level source selector tries to capture the sequential patterns of user behaviors onto aggregated results in different pages.

4.1.1 Option. An option $o \in O$ refers to a multi-step action [33] that selects the relevant sources to display. The core search, which is the product search in our case, must be selected, while verticals can either be selected or not. So if there are N verticals, the size of the option set is $|O| = 2^N$. The agent samples an option o according to μ, then the control of the agent transfers to the low-level policy. The option lasts until the low-level RL process terminates, then the source selector continues to execute the next option.

4.1.2 State. The state $s_t^e \in \mathcal{S}$ of the high-level RL process at time step t is represented by: 1) the search request x, 2) the triggered search source results $\mathcal{SR}(x)$, and 3) the *latest* option $o_{t'}$ where $t - t'$ is the duration of $o_{t'}$. Then the state vector $\phi(s_t^e)$ is the concatenation of the embedding vector of each part. It should be noted that the vector of source type $\mathcal{SR}_j$ is represented by the mean value of all item vectors of that type, i.e. $\mathbf{e}(\mathcal{SR}_j(x)) = \frac{1}{n_j(x)} \sum_k \mathbf{e}(m_j^k(x))$ where $\mathbf{e}(m)$ is the item vector of m. In particular, the vector of a certain source is represented by zeros if the result of that type is empty. Then the vector of entire source results $\mathbf{e}(\mathcal{SR})$ is derived from the concatenation of $\mathbf{e}(\mathcal{SR}_j)$ from all source types.

4.1.3 Extrinsic reward. The extrinsic reward r^e is given to the source selector to evaluate the global performance. It is derived from the mean value of the intrinsic return from the low-level process, which can be formulated as follows:

$$r_t^e = \frac{1}{l} R_t^i = \frac{1}{l} \sum_{k=0}^{l-1} \gamma^k r_{t+k}^i, \tag{1}$$

where l is the duration of the option o_t. The average return is calculated to prevent the tendency that the source selector greedily chooses all triggered sources to obtain more rewards. The definition of intrinsic reward will be introduced soon later.

4.2 Item Presentation with Low-level Policy

The low-level RL process aims to decide the presentation order of the items from the candidate sources $\overline{\mathcal{SR}}(x)$ chosen by the high-level source selector. Note that the items from each source have been ranked according to its private vertical, and all items from verticals can be interleaved with results from other sources. Each display position is regarded as a slot and the entire presentation subtask starts by filling an item into the top slot of the page, and then the second slot, etc. At each step, the low-level RL policy π takes the corresponding option o and the low-level state s^i as input, and outputs a primitive action a that tells which source to display at the current position. As a result, the agent does not give a relevance score to each item thus avoiding the relevance ranking issue.

Considering that the source selector has notified which sources are selected to display, the number of slots on the page can be determined by $l = \sum_{\mathcal{SR}_j \in \overline{\mathcal{SR}}} n_j(x)$. The agent reaches the subgoal when all the slots in a page have been filled, thus the number of slots is equal to the time duration of the option, and the termination function $\beta : \mathcal{S} \rightarrow \{0, 1\}$ is deterministic in our setting. Once it is terminated, the control of the agent will return to the high-level process.

4.2.1 Primitive action. A primitive action $a \in \mathcal{A}$ refers to a one-step action that chooses a certain source type, so $|\mathcal{A}| = 1 + N$ given the core search and N verticals. Each source can be seen as a stack with its items in descending order of relevance to the search request x. If a certain source is selected according to π, the top item at the stack of this source is displayed in the current position, as shown in Fig. 4. When a source stack is empty, the source is excluded from the action space. In this way, we simplify the relevance ranking problem into a slot filling process to mix different sources: we only need to decide from which source the top item should be selected, instead of evaluating the relevance of each source item. Note that the relative order of the items within the same source type remains unchanged, the agent simply utilizes the existing ranking list.

4.2.2 State. The state $s_t^i \in \mathcal{S}$ of the low-level RL process at time step t is represented by: 1) the search request x, 2) the *top items* of candidate sources $top(\overline{\mathcal{SR}}(x))$, 3) the last primitive action a_{t-1}, and 4) the option o that launches the current subtask, and the state vector $\phi(s_t^i)$ is the concatenation of all vectors of each corresponding part. In order to give an intuitive understanding of *top items*, we take Fig. 4 as an instance. $top(\overline{\mathcal{SR}}) = [A5; B1; C2]$ before the agent presents the item at 6th slot position, then $top(\overline{\mathcal{SR}}) = [A5; B2; C2]$ after it chooses the source type B. So naturally, the vector of candidate sources $\mathbf{e}(top(\overline{\mathcal{SR}}))$ is represented by the concatenation of the top item vector $\mathbf{e}(m_j^{top})$ from each selected source. In addition, similar to [29], we put options into the low-level state representation as an additional input throughout the low-level RL process, to make the selected sources available for the policy π.

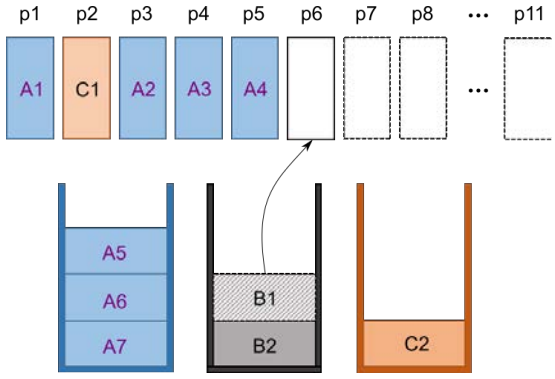

Figure 4: Illustration of the proposed slot filling scheme. There are three sources (A,B,C) and 7+2+2=11 slots in this example.

4.2.3 Intrinsic reward. The intrinsic reward r^i is provided for the item presenter to indicate how well a particular subtask is completed. User clicks and transactions are used to form the intrinsic reward, which is computed as below:

$$r_t^i = \lambda * click + (1 - \lambda) * \min(ln(1 + pay), \delta), \tag{2}$$

where λ is a weight factor, $click \in \{1, -1\}$ indicates whether the user clicks or skips the current slot, and $pay \in [0, +\infty)$ is the price of the product that the user buys. When the user does not buy anything, the second term is zeroed as $pay = 0$. The second term is also clipped by the value δ to reduce the impact of extreme observations. In addition, if there is no click or transaction during the current subtask, a small negative value is added to the intrinsic reward at the last time step as a penalty.

4.3 Q Network Framework

Deep Q-learning uses a multi-layer neural networks with parameters θ to estimate the Q function. Given an n-dimensional state s, it outputs a vector of Q-values over the actions $Q(s, \cdot; \theta) : \mathbb{R}^n \rightarrow \mathbb{R}^{|\mathcal{A}|}$.

In our algorithm, both high-level and low-level policies leverage the same Q network framework, as shown in Fig. 5. We apply DRQN [14] by considering the previous context with a recurrent structure to integrate the underlying correlation between the previous state and current observation. Eq. 3 refers to the hidden layer and RNN layer in Fig. 5.

$$\begin{aligned} \mathbf{w}_t &= \beta(\mathbf{W}_\phi \cdot \phi(s_t) + b_\phi), \\ \mathbf{h}_t &= GRU(\mathbf{w}_t, \mathbf{h}_{t-1}), \end{aligned} \tag{3}$$

where $\phi(s)$ is the vector representation of the state s, β is *Leaky ReLU* activation function.

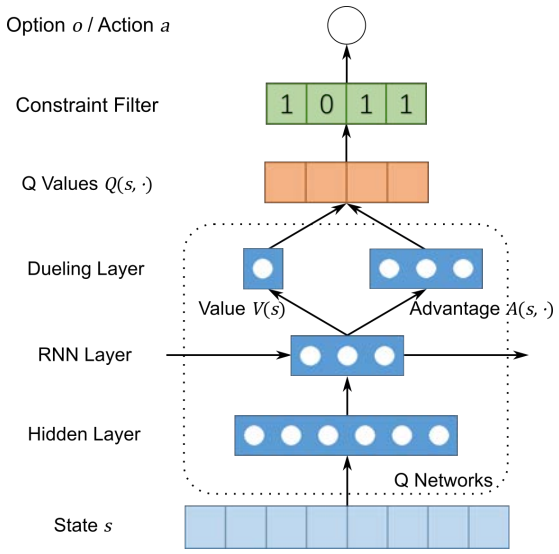

Figure 5: Q network framework used in both high and low level policies.

Besides, the dueling architecture [40] is introduced as well to get a more precise policy evaluation in the presence of many similar-valued actions. It consists of two streams that represent the value and advantage functions, and the two streams are combined afterward to provide a better estimate of Q-values, i.e. the dueling layer of Fig. 5.

$$Q(s,a;\theta) = V(s;\theta) + (A(s,a;\theta) - \frac{1}{|\mathcal{A}|}\sum_{a'} A(s,a';\theta)). \quad (4)$$

The *constraint filter* is to explicitly perform an element-wise mask operation on the Q-values to meet some complicated commercial needs. In this way, commercial constraints in a special situation can be easily satisfied in this framework. For instance, not displaying any blog posts in the first page can be dealt with by the source selector via excluding the corresponding source type from the action space. Similarly, displaying a particular source item at a pre-specified position can be handled by the item presenter via excluding the corresponding slot from the slot sequence.

4.4 Hierarchical Policy Learning

Standard DQN is used to minimize the squared error between the target (Bellman optimality condition) $r + \gamma \max_{a'} Q(s', a'; \theta)$ and its estimate $\hat{Q}(s, a; \theta)$. In the context of HRL, the top-level policy μ tries to minimize the following loss function at each time step t:

$$\begin{aligned} L_\mu(\theta_t^e) &= \mathbb{E}_{(s,o,r,s')\sim D^e}[(y_t^e - Q_\mu(s,o;\theta_t^e))^2], \\ y_t^e &= r + \gamma^l Q_\mu(s', \arg\max_{o'} Q_\mu(s',o';\theta_t^e);\theta_t^{e-}), \end{aligned} \quad (5)$$

where l is the number of steps the option o lasts. Here we apply experience buffer [23] to smooth over changes in the data distribution. We also employ a target Q network [24] with parameters θ^- to decrease the possibility of divergence or oscillations during the training process, and double Q-learning [13] to reduce the observed over-estimations caused by traditional Q-learning. Similarly,

Algorithm 1: Deep hierarchical policy learning for aggregated search

Input: Item sets with multiple source types $\mathcal{SR}$ and their search services.

Initialize the two policies with parameters $\{\theta^e, \theta^i\}$
Initialize replay memories $\{D^e, D^i\}$ respectively
$\theta^{e-} = \theta^e$, $\theta^{i-} = \theta^i$
foreach *user search session* **do**
  Initialize high-level state s^e with current search request x
  repeat
    // Page-level source selection
    Set option $o =$
    $\begin{cases} \text{random sample option } o \text{ from } \mathcal{O}, & random() < \epsilon^e \\ \arg\max_{o'} Q^\mu(s^e, o'; \theta^e), & otherwise \end{cases}$
    Initialize low-level state s^i and option duration l according to o
    for $k = 0$ **to** $l - 1$ **do**
      // Slot-level item presentation
      Set primitive action $a =$
      $\begin{cases} \text{random sample action } a \text{ from } \mathcal{A}, & random() < \epsilon^i \\ \arg\max_{a'} Q^\pi(s^i, o, a'; \theta^i), & otherwise \end{cases}$
      Execute action a, observe intrinsic reward r^i (cf. Eq. 2) and next state s'^i
      Store transition (s^i, o, a, r^i, s'^i) in D^i
      Randomly sample mini-batches from D^i
      Perform gradient descent on $L_\pi(\theta^i)$ (cf. Eq. 6 & 8)
      $s^i = s'^i$
      Assign $\theta^{i-} = \theta^i$ every C^i steps
    end
    Obtain extrinsic reward r^e (cf. Eq. 1) and next state s'^e
    Store transition (s^e, o, r^e, s'^e) in D^e
    Randomly sample mini-batches from D^e
    Perform gradient descent on $L_\mu(\theta^e)$ (cf. Eq. 5 & 7)
    $s^e = s'^e$
    Assign $\theta^{e-} = \theta^e$ every C^e steps
  until *the session ends*
end

we learn the low-level policy π by minimizing the following loss function:

$$\begin{aligned} L_\pi(\theta_t^i) &= \mathbb{E}_{(s,o,a,r,s')\sim D^i}[(y_t^i - Q_\pi(s,o,a;\theta_t^i))^2], \\ y_t^i &= r + \gamma Q_\pi(s', o, \arg\max_{a'} Q_\pi(s',o,a';\theta_t^i);\theta_t^{i-}), \end{aligned} \quad (6)$$

given the option o from μ.

Differentiating the loss function with respect to the weights, we arrive at the following gradient for the high-level policy:

$$\nabla_{\theta_t^e} L_\mu = \mathbb{E}_{(s,o,r,s')\sim D^e}[(y_t^e - Q_\mu(s,o;\theta_t^e))\nabla_{\theta_t^e} Q_\mu(s,o;\theta_t^e)], \quad (7)$$

and similarly, the gradient for the low-level policy yields as below:

$$\nabla_{\theta_t^i} L_\pi = \mathbb{E}_{(s,o,a,r,s')\sim D^i}[(y_t^i - Q_\pi(s,o,a;\theta_t^i))\nabla_{\theta_t^i} Q_\pi(s,o,a;\theta_t^i)]. \quad (8)$$

Note that the initial hidden state of RNN layer should be carried forward from its previous values $\mathbf{h}_{t-1}$ when sampling actions, but we zero it at the start of the update so that we do not need to save $\mathbf{h}_{t-1}$ into replay buffers. The convergence and performance of such complexity reduction are guaranteed [14]. In addition, we clip the error term through *Huber Loss* to improve the stability of the algorithm.

The entire training process is described in Algo. 1.

5 EXPERIMENTAL SETUP

To evaluate the performance of our proposed approach, we carried out experiments on the Taobao Search platform, which is one of the largest E-commerce search services in the world, with over 1 billion user clicks every day. All models in this paper adopt the online-learning paradigm and are trained on the hourly real-time search log streaming data.

The online experiment methodology we adopted is called bucket testing, also known as A/B test. In the bucket testing system of Taobao Search, several test buckets are set up. And all users are randomly hashed into these buckets based on their user ids. Each bucket has the same number of users, and the same distribution of users. Then each algorithm is deployed on one bucket. The performance of an algorithm is estimated using the metrics calculated on the bucket it is deployed on. In this paper, our online bucket testing lasted for two weeks, a period long enough to ensure the statistical stability of our test results.

5.1 Features and Parameter Settings

We aggregated two verticals, namely topic and group verticals, into the results of product search. For each RL policy in our model, the components of state s (i.e. search request x, search source results $\mathcal{SR}(x)$, etc.) are represented by a number of features, which mainly contains 1) the query features: including the word-segmented tokens of the query; 2) user features: including user gender, age, items user clicked in the previous page; 3) page features: the current page number; 4) source features obtained from each search services, including the type and title of a topic group or a blog post.

The parameter settings for the high-level source selector and low-level item presenter are provided in Table 2.

Hyper-parameter	Setting	
	Source selector	Item presenter
Learning rate	1e-2	1e-4
Optimization algorithm	RMSProp	RMSProp
Memory D size	5e4	5e5
Mini-batch size	32	32
Target θ^- update period C	1e3	1e4
State feature vector size	48	56
Hidden layer size	28	24
RNN layer size	16	12
Discount factor γ	0.95	
Weight factor λ in Eq. 2	-	0.3
Clipped to δ in Eq. 2	-	3

Table 2: Hyper-parameter settings

5.2 Baselines and Evaluation Metrics

In order to show the effectiveness of our HRL model, we implemented several aggregation methods for comparison, which can be grouped into two categories: *rule-based* and *learning to aggregate* methods, while the latter can be separated into two types: *one-stage* and *two-stage* methods according to the process flow. The *one-stage* method is introduced to verify the hierarchical decomposition in the aggregate search, and the *two-stage* method is carried out to validate the RL formulation in each subtask. The details of our baselines are introduced as follows:

Rule: a rule-based method, where the rule is manually made for search aggregation according to abundant experience in search product design. The rule claims that the first page should not present aggregated results, and the topic and blog verticals will be alternately displayed at fixed positions from the second page when a topic group or a blog post is available from backends. In a page, the rule displays a topic group at the 4th position, and a blog post at the 9th position. Note that this simple rule is the benchmark for comparison with other methods.

Flat RL: a one-stage method. In this paradigm, the aggregation task is simplified into one stage: for each aggregation request, just choose the optimal template from a set of predefined templates. Seven templates are used in this method and are provided in Fig. 6. Each template clarifies exactly what to fill in each slot. These templates are designed by human experts familiar with Taobao Search to ensure good customer experience. The aggregation problem is solved by a single DQN agent. The state representation and the reward of this DQN are the same with the high-level state and the extrinsic reward defined in subsection 4.1 respectively.

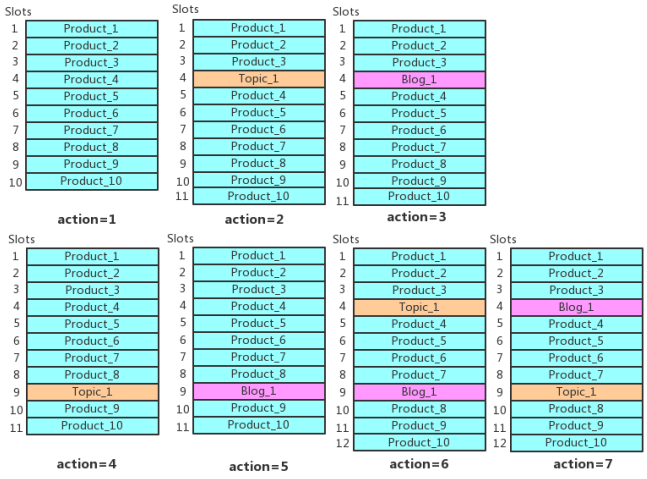

Figure 6: The SERP templates for our 1-stage DQN baseline.

BC+RM: a two-stage method similar to [28]. For *vertical selection*, it uses a binary classifier for each source to decide whether to present this source in a page. The binary classifiers are Neural Networks with 3 hidden layers. The training data for the binary classifiers come from online search log, where each page view is a sample. For a vertical in the page, if it is clicked by a user, then

Method	Topic group						Blog post					
	CTR		ADT		COV		CTR		ADT		COV	
	value (1e-2)	gain	value	gain	value (1e-2)	gain	value (1e-2)	gain	value	gain	value (1e-2)	gain
Rule	5.24	-	10.56	-	5.60	-	3.43	-	75.78	-	6.47	-
Flat RL	6.08	15.99%	10.62	0.54%	5.98	6.79%	3.92	14.29%	76.69	1.20%	6.76	4.48%
BC+RM	5.59	6.76%	10.68	1.09%	6.03	7.68%	3.69	7.58%	76.99	1.59%	6.75	4.33%
BC+RL	5.60	6.77%	10.66	0.92%	6.00	7.32%	3.73	8.75%	76.69	1.21%	6.82	5.41%
RL+RM	5.52	5.29%	10.75	1.75%	6.09	8.75%	3.60	6.12%	76.46	0.91%	6.87	6.18%
HRL	7.34	**40.07**%	10.65	0.89%	5.95	6.25%	4.25	**23.91**%	76.53	0.98%	6.86	6.03%

Table 3: Metrics of online bucket testing on two verticals.

it is a positive sample, otherwise a negative sample. For *vertical presentation*, it uses a 3-hidden-layer Neural Network regression model to score each item. The regression target of the regression model is the same with the intrinsic reward in Eq. 2.

BC+RL: a two-stage method similar to *HRL*, which replaces the high-level source selector with multiple binary classifiers as described in *BC+RM*, but the RL policy for the item presenter remains unchanged.

RL+RM: a two-stage method similar to *HRL*, which replaces the low-level item presenter with a regression model as described in *BC+RM*, but the RL policy for the source selector remains unchanged.

Note that all *learning to aggregate* methods were pre-trained on offline data by *behavioral cloning* prior to online experiments, so as to mitigate the slow learning and poor performance in the early stage of online training. The offline data, which contain 60,000 search sessions covering a broad query topics with an average of 11.3 items per page and 13.4 pages per session, were collected from the user search logs on the Taobao platform.

To evaluate the performance of the algorithms, we use some common evaluation metrics in search aggregation, including:

Click Through Rate (CTR): the ratio of users who click on a specific vertical to the number of total users who view the vertical on a page.

Average Dwell Time (ADT): the mean value of a user's dwell time in seconds on a specific vertical.

Coverage (COV): the ratio of the number of slots occupied by a specific vertical to the total number of slots.

Moreover, we also include an important metric in the E-commerce industry: the *Gross Merchandise Volume* (GMV) of each search service, which is the total revenue of sales made by the product search, or induced by a vertical in SERPs within a fixed time period.

6 RESULTS

6.1 Online Performance

We show the results of online bucket testing in terms of CTR, ADT and COV of different verticals in Table 3. Among these three metrics, the most important one is CTR, which indicates whether users clicked the verticals in the aggregated SERP. For each metric in Table 3, we present its value in the "value" column, and its relative improvement over the *Rule* baseline in the "gain" column. The results in Table 3 show that all the baselines and our HRL model achieve similar improvement rate on ADT and COV. However, it is worth noting that the result on CTR differs remarkably among all the methods.

In general, **HRL** achieves much better CTR improvement than all the baselines on both topic and blog verticals. The comparison to **Flat RL** shows that our hierarchical decomposition of the RL process is very effective, achieving better CTR from the historical user behaviors across different pages as well as the immediate user feedback in the current page. And the result also indicates that it is more sensible to allow a model to choose from any positions when displaying heterogeneous items, rather than restrict the positions where a vertical can be presented in a page. While the *one-stage* method can only use limited aggregation templates to meet the trade-off between the model performance and the exponential number growth of templates due to the number of sources, the hierarchical decomposition of *HRL* overcomes the exponentially large action space problem and allows the agent to explore all possible source combination and item permutation.

The comparisons to *BC+RM*, *BC+RL*, *RL+RM* show that the sequential RL modeling in both high-level and low-level aggregation subtasks is critical for a good performance. A common feature of these discriminant models is that they all follow the vertical selection and presentation pipeline, but make point-wise decisions, without the passing of states between sequential decisions as in *HRL*. **BC+RL** considers the user feedback only based on the current page, while *HRL* tracks the user behaviors from page to page to understand user intents. The result verifies that it is essential to capture sequential patterns of user behavior in aggregated E-commerce search. Similarly, the comparison to **RL+RM** demonstrates that *HRL* also consistently outperforms the baseline that simply ranks items from heterogeneous sources since it suffers from relevance ranking issue by giving scores to each vertical, which concludes that our slot filling process aggregates a more reasonable SERP.

Another important metric, the GMV of the aggregated E-commerce search, that we care about is shown in Table 4. It should be noted that, due to Alibaba's business policy, we temporarily cannot expose the absolute values of GMV. Hence, we report relative GMV increase over *Rule* instead, and this will not affect performance comparison. Because the GMV of aggregated search is the total merchandised volume of all sources, we report not only the GMV of topic and blog verticals, but also the GMV of product search in Table 4.

Method	Topic group	Blog post	Products
Flat RL	38.4%	12.31%	-0.47%
BC+RM	19.32%	5.83%	-0.41%
BC+RL	20.78%	6.00%	-0.37%
RL+RM	17.60%	5.54%	-0.20%
HRL	**56.49%**	**16.93%**	**0.56%**

Table 4: The relative GMV increase over *Rule*. The GMV of a vertical is computed through the sales value guided by the presented items of that vertical.

As shown in Table 4, *HRL* is the only method that increases the GMV of product search. Although other baselines achieve GMV increase on the topic and blog verticals, their GMVs on product search all decrease. For example, *Flat RL* brings a marked GMV improvement on topic and blog verticals, at the expense of the largest GMV drop on product search though. This means that *HRL* provides the best user experience in its aggregated SERP, because even a growth on the COV of topic and blog verticals does not reduce users' purchases in product search. Moreover, *HRL* also achieves the best GMV increase on the topic and blog verticals, leading to the best overall GMV increase among all methods.

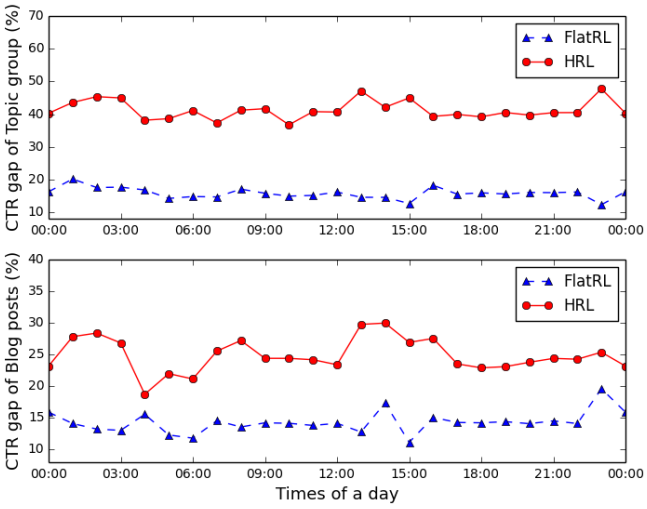

Figure 7: The relative CTR increase over *Rule* in different hours. Each mark indicates the result in the time span between the current time and next full hour.

To provide more insights on the online experiments, we group the two-week statistics by different hours of a day to observe the performance variation over time. For simplicity, we only compare the relative CTR increase of the two most competitive methods: *Flat RL* and *HRL*. Fig. 7 shows the trend of their CTR increase over the baseline *Rule* during different time periods of a day. It can be seen that the CTR increase does not variate too much at different hours of a day, and *HRL* has consistently better CTR improvement than *Flat RL*.

6.2 User Evaluation

In order to study the user experience change caused by our HRL aggregation method, we invite 50 users of Taobao Search to evaluate the quality of our aggregated result against that of the rule-based baseline: *Rule*, which is the old online aggregation method of Taobao Search and has been online serving for several years. The evaluation is performed on a fixed query set: 200 popular queries covering 13 salient product categories in Taobao. This query set is selected by third-party experts on Taobao platform. A user is asked to search each query in both our and the old aggregation environments simultaneously, without knowing which environment is the old one. And the aggregated results of the two environments, designated by A and B, are presented to the user side-by-side. The user can browse the results, click items, scroll to the next page, and so on. And the user provides a grade from {"System A better", "Same/cannot judge", "System B better"} on each vertical for this query. Then we translate the user's grade to {"New System better", "Same/cannot judge", "Old System better"}, where the "New System" refers to *HRL* and the "Old System" refers to *Rule*. The distribution of user grades on each vertical is shown in Table 5.

Vertical	New system better	Same	Old system better
Topic	30.35%	67.98%	1.67%
Blog	26.14%	72.53%	1.33%

Table 5: The distributions of user evaluation grades.

The results in Table 5 show that user experience grades are the same on about 70% of the queries. In spite of this, *HRL* provides better user experience than the baseline most of the times on the rest 30% of the queries.

To understand how *HRL* improves user experience, every time when a user thinks the new system is better, we inquire about his reason for this preference. And we also ask them to group their reasons into three groups as follows:

- Better **behavior relevance**: In *HRL*, the presented verticals are more relevant to the user's previous behaviors.
- Better **query relevance**: In *HRL*, the presented verticals are more relevant to the query.
- **Others**: other reasons.

Vertical	Behavior relevance	Query relevance	Others
Topic	42%	33%	25%
Blog	37%	35%	28%

Table 6: Distributions of reasons why new system is better.

The results in Table 6 show that *HRL* contributes to both user behavior relevance and query relevance. We present two cases here to give some clue that how user experience is improved.

A case for better user behavior relevance is as follows: a user issues the query "running shoes", and clicks several products with the same brand: "Nike" on the first page, then on the next page the topic group titled "Nike shops with discounts" is presented at the

second position in our HRL aggregated result, which is very relevant to the user's behavior. In contrast, no topic group is presented by the baseline in the aggregated result on the next page. In *HRL*, user behaviors in previous pages are encoded into the RNN layer hidden states in the Q network shown in Fig. 5. So user behaviors in previous pages are passed on to the next page for decision making in *HRL*, which helps perceive user behavior relevance. Besides, *HRL* can also capture sequential patterns of user behavior by learning from the long-delayed user feedback across the whole user search session.

A case for better query relevance is as follows: a user issues the query "women's long dress autumn Vero Moda", which is very specific in brand, season and style. The blog post titled "Introduction to the world of women's dresses", which gives a general introduction to women's dresses, is not presented in the aggregated result of *HRL*, whereas it is presented in the baseline's aggregated result. The user prefers our aggregated result because she thinks the blog post is too general thus not meeting her specific needs. With query and blog title features as input, *HRL* is able to identify that the general introduction of the blog post is not relevant enough to the query she inputs.

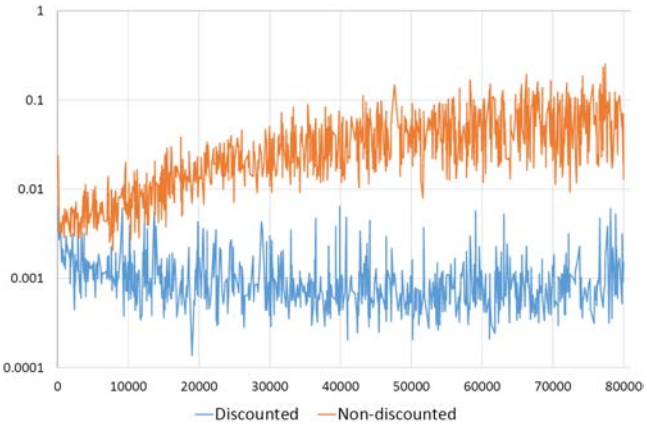

Figure 8: Loss curve of high-level source selector between different training strategies. Blue curve for strategy (I) and orange curve for strategy (II). The horizontal axis is the training iteration, and the vertical axis is the loss value in log scale.

6.3 Training Analysis

To offer a detail training analysis of HRL, we investigate the training procedure of the high-level RL process that takes multi-step actions. Two strategies are designed for the source selector. (I) One is the proposed one in section 4.1 & 4.4 that the extrinsic reward is the mean value of the intrinsic return from the item presenter, i.e. the same as Eq. 1, and the optimization target of Q network (y_t^e in Eq. 5) is discounted by γ^l. (II) The other is to regard the high-level RL process as a simple RL process that takes one-step actions. Under this setting, the extrinsic reward is directly equivalent to the mean value of the intrinsic rewards, i.e. $r_t^e = \frac{1}{l}\sum_{k=0}^{l-1} r_{t+k}^i$, then the training target of source selector policy in Eq. 5 is similar to that in Eq. 6: $y_t^e = r + \gamma Q_\mu(s', \arg\max_{o'} Q_\mu(s', o'; \theta_t^e); \theta_t^{e-})$.

The learning curves of the two strategies are demonstrated in Fig. 8, where the blue and orange curves correspond to strategy (I) and (II) respectively. It is clear that the proposed strategy (I) converges well as the training procedure proceeds while the strategy (II) diverges dramatically. This result shows that it is necessary to handle a multi-step RL process in a proper way to guarantee its convergence. From another perspective, the strategy (I) puts more weight on the items presented in the top slots, which is consistent with the position bias in most search area that top-ranked search results attract more clicks, so the agent can better understand the sequential patterns of user behavior and learn from such data effectively.

7 CONCLUSION AND DISCUSSION

We have studied the search aggregation problem in a large E-commerce search service and proposed an effective HRL aggregation method. Different from web search aggregation, the E-commerce aggregation needs to be performed for each page, leading to multiple and sequential aggregation decisions for one query. In light of this, we propose a hierarchical aggregation model for E-commerce search aggregation. Our HRL model naturally fits the two-stage decomposition of the aggregated search task: a high-level RL for source selection and a low-level RL for item presentation. The source selector models user interactions on aggregated results across pages to capture the sequential patterns of user behavior, and the item presenter formulates a slot filling process that sequentially presents the heterogeneous items to avoid the relevance ranking issue. In this manner, the HRL model can fully learn from user feedback in the current page as well as in the entire search session.

We perform online bucket testing on Taobao Search platform and compare our HRL method with several baselines. The results show that our method contributes a substantial improvement over the baselines for all verticals. Moreover, it also boosts the GMV of product search and achieves the best overall GMV among all the models. User study also demonstrates that it improves user experience by displaying better aggregated results that are relevant to user behaviors and needs. Note that our method can easily combine new verticals into an aggregated search system.

One limitation of the proposed algorithm may lie in the automatic offline evaluation. All we can get from the offline data is the records of user behaviors on the presented results, so it is difficult to infer the user feedback on the unseen SERPs without full annotations of the heterogeneous item relevance as we train our model in a RL setting. However, sufficient experiments including bucket testing and user study indicate that our method indeed shows its effectiveness on the search aggregation. Future research will be focused on the application of our HRL model in different E-commerce verticals and other scenarios.

ABSTRACT

Understanding temporal dynamics has proved to be highly valuable for accurate recommendation. Sequential recommenders have been successful in modeling the dynamics of users and items over time. However, while different model architectures excel at capturing various temporal ranges or dynamics, distinct application contexts require adapting to diverse behaviors.

In this paper we examine how to build a model that can make use of different temporal ranges and dynamics depending on the request context. We begin with the analysis of an anonymized Youtube dataset comprising millions of user sequences. We quantify the degree of long-range dependence in these sequences and demonstrate that both short-term and long-term dependent behavioral patterns co-exist. We then propose a neural Multi-temporal-range Mixture Model (*M3*) as a tailored solution to deal with both short-term and long-term dependencies. Our approach employs a mixture of models, each with a different temporal range. These models are combined by a learned gating mechanism capable of exerting different model combinations given different contextual information. In empirical evaluations on a public dataset and our own anonymized YouTube dataset, *M3* consistently outperforms state-of-the-art sequential recommendation methods.

1 INTRODUCTION

Across the web and mobile applications, recommender systems are relied upon to surface the right items to users at the right time. Some of their success can be attributed to advances in modeling as well as the ingenuity of applied researchers in adopting and inventing new techniques to solve this important problem [19, 30, 44, 46]. Fundamentally, recommenders match users in a particular context with the best personalized items that they will engage with [17, 34]. In order to do this effectively, recommenders need to understand the users, typically based on their previous actions, and to understand items, most often based on the users who previously interacted with them. This presents a fundamental challenge: users' preferences and items' perception are continuously changing over time, and the recommender system needs to understand these dynamics.

A significant amount of research has recognized forms of this problem. Sequence information has been generally shown to improve recommender performance [18, 45]. Koren [29] identified multiple user and item dynamics in the Netflix Prize competition, and incorporated these dynamics as biases in a collaborative filtering model. [7, 56] demonstrated that Recurrent Neural Networks (RNNs) could learn many of these patterns, and likewise [20] demonstrated that RNNs can learn patterns in individual sessions. Despite these successes, RNNs are known to have difficulties learning long-range dependent temporal patterns [4].

We observe and study an open challenge for such sequential recommender systems: *while different applications and contexts require different temporal ranges and patterns, model architectures are typically designed to capture a particular temporal dynamic.* For

example, when a user comes to the Amazon home page they may be looking for something new to buy or watch, but on an item specific page they may be looking for other items that are closely related to recently browsed items. *How can we design a model that works, simultaneously, across all of these contexts and temporal ranges?*

Contributions: We address the issue of providing a single model adapted to the diversity of contexts and scales of temporal dependencies in sequential recommendations through data analysis and the design of a Multi-temporal-range Mixture Model, or *M3* for short. We make the following contributions to this problem:

- **Data-driven design:** We demonstrate that in real world recommendation tasks there are significant long-range temporal dependencies in user sequence data, and that previous approaches are limited in their ability to capture those dynamics. M3's design is informed by this quantitative analysis.
- **Multi-range Model:** We offer a single model, M3, which is a mixture model consisting of three sub-models (each with a distinct manually designed architecture) that specialize in capturing different ranges of temporal dependencies. M3 can learn how to dynamically choose to focus on different temporal dynamics and ranges depending on the application context.
- **Empirical Benefits and Interpretability:** We show on both public academic and private data that our approach provides significantly better recommendations. Further, using its interpretable design, we analyze how M3 dynamically switches between patterns present at different temporal ranges for different contexts, thus showing the value in enabling context-specific multi-range modeling. Our private dataset consists in anonymized user sequences from YouTube. To the best of our knowledge this paper is the first to focus on sequential patterns in such a setting.

2 RELATED WORK

Before we describe our sequential recommendation problem and provide the quantitative insights orienting the design of a novel sequential neural model based on a mixture of models, we briefly introduce the reader to some key pre-existing related work.

Matrix factorization [30] is among the most popular techniques used in classic recommender research, in which a similarity score for each user-item pair is learned by building latent user and item representations to recover historical user-item interactions. The predicted similarity score is then used to indicate the *relatedness* and find the most relevant items to recommend to a user. Followup work on introducing auxiliary sources of information beyond user-item interactions have been proven successful [11], especially for cold-start problems. Pazzani and Billsus [39] use item content (*e.g.,* product image, video's visual/audio content, etc) to provide a better item representation.

Neural Recommender Systems. Deep neural networks have gained tremendous success in the fields of Computer Vision [28, 31] and Natural Language Processing [2, 36]. In recommender research, we have witnessed growing interest of using deep neural networks to model complex contextual interactions between user and items, which surpass classic factorization-based methods [30, 43]. Auto-encoders[33, 47, 57] constitute an early example of success for a framework based on neural networks to better infer un-observed user/item affinities in a recommendation problem. He et al. [19] also proved that traditional Collaborative Filtering methods can be effectively generalized by a deep neural network. Besides,

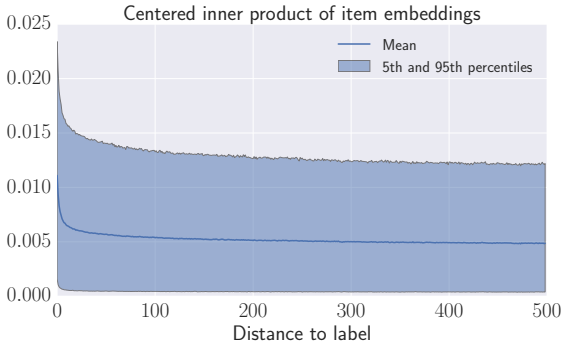

Figure 1: Trace of covariance (i.e. centered inner product similarity) of item embeddings between the last item in user sequence and the item located L steps before (100K samples).

For the specific problem of sequential recommendation using neural networks, RNNs [20, 56] have become a common choice. Other methods based on Convolutional Neural Networks (CNNs) [51, 59], Attention Models [61] have also been explored. While most of existing methods developed for sequential recommendations perform well [18, 20, 45, 49, 51], they still have some limitations when dealing with long user sequences found in production recommender systems. As we shall discuss in Section 3, such approaches do not scale well to very long sequences.

Mixture of Models. Despite being simpler and more elegant, monolithic models are in general less effective than mixtures of models to take advantage of different model capacities and architectural biases. Gehring et al. [15] used an RNN in combination with an attention model for neural machine translation which provided a substantial performance gain. Pinheiro and Collobert [40] proposed to combine a CNN with an RNN for scene labeling. In the field of sequential recommendation, an earlier work on mixing of a Latent Factor Model (LFM) and a Factorized Markov Chain (FMC) has been shown to offer superior performance than each individual one [45]. A similar trend was observed in [18, 60]. While sharing similar spirit to these aforementioned methods, we designed our mixture of models with the goal to model varying ranges of dependence in long user sequences found in real production systems. Unlike model ensembles [13, 62, 63] that learn individual models separately prior to ensembling them, a mixture of models learns individual models as well as combination logic simultaneously.

3 QUANTIFYING LONG RANGE TEMPORAL DEPENDENCIES IN USER SEQUENCES

We first present some findings on our anonymized proprietary dataset which uncover properties of behavioral patterns as observed in extremely-long user-item interaction sequences. We then pinpoint some limitations of existing methods which motivate us to design a better adapted solution.

Sequential Recommendation Problem: We consider a sequential recommendation problem [18, 20, 45, 49, 51] defined as follows: assume we have a set of users $u \in \mathcal{U}$, a set of items $v \in \mathcal{V}$, and for each user we have access to a sequence of user historical events $\mathcal{E}^u = (e_1^u, e_2^u, \cdots)$ ordered by time. Each e_τ^u records the item consumed at time τ as well as context information of the interaction. Given the historical interactions, our goal is to recommend to each user a subset of items in order to maximize a performance metric such as user satisfaction.

3.1 Hidden Values in Long User Sequences

We now describe how we developed a better understanding of long user sequences in our proprietary dataset through quantitative data exploration. To quantify how past events can influence a user's current behavior in our internal dataset, *i.e.* measure the range of temporal dependency within a sequence of events, one can examine the covariance matrix of two events L-step apart [5, 41], where step denotes the relative order of events within sequence. In particular, we look at the trace of the covariance matrix as a measurement of dependency:

$$\mathrm{Dep}_L = \mathrm{tr}\left(\mathrm{Cov}\left(Q_{e_N}, Q_{e_{N-L}}\right)\right)$$

where e_N is the item in last event in a logged user/item interaction sequence and e_{N-L} is the item corresponding to the interaction that occurred L time steps before the last event. We focus on the trace of the covariance matrix as it equals the sum of the eigenvalues of the covariance matrix and its rate of decay is therefore informative of the rate of decay of these eigenvalues as a whole.

We utilize the embeddings Q that have been learned by a pre-existing model—in our case an RNN-based sequential recommender which we describe later as one of M3's sub-models. Dep_L here measures the similarity between the current event and the event L steps back from it. To estimate Dep_L for a particular value of L we employ a classic empirical averaging across user sequences in our dataset. From Figure 1, we can extract multiple findings:

- The dependency between two events decreases as the time separating their consumption grows. This suggests that recent events bear most of the influence of past user behavior on a user's future behavior.
- The dependency slowly approaches zero even as the temporal distance becomes very large (*i.e.* $L > 100$). The clear hyperbolic-decay of the level of temporal dependencies indicates the presence of long-range-dependent patterns existing in user sequences [41]. In other words, a user's past interactions, though far from the current time step, still cumulatively influence their current behavior significantly.

These findings suggest that users do have long-term preferences and better capturing such long-range-dependent pattern could help predicting their future interests. In further work, we plan to use off-policy correction methods such as [8, 16] to remove presentation bias when estimating correlations.

3.2 Limitations of Existing Sequential Models

The previous section has demonstrated the informational value of long-range temporal patterns in user sequences. Unfortunately, it is still generally challenging for existing sequential predictive models to fully utilize information located far into the past.

Most prior models have difficulties when learning to account for sequential patterns involving long-range dependence. Existing sequential recommenders with factorized Markov chain methods [18] or CNNs [51] arguably provide reliable sequential recommendation strategies. Unfortunately they are all limited by a short window of significant temporal dependence when leveraging sequential data to make a recommendation prediction. RNNs [7, 20, 24] and their variants [12, 42] are widely used in sequential recommendation. RNN-based models, though effective for short user sequences (*e.g.* short event sequences within a session), are challenged by long-range dependent patterns in long user sequences. Because of the way they iterate over sequential items [36] and their use of saturating non-linear functions such as tanh to propagate information through time, RNNs tend to have difficulties leveraging the information contained in states located far into the past due to gradient propagation issues [4, 38]. Even recent architectures designed to facilitate gradient propagation such as Gated Recurrent Unit [10] and Long-short Term Memory [21, 50] have also been shown to suffer from the same problem of not being able to provably account for long-range dependent patterns in sequences [4].

A second challenge in sequential recommendations is learning user latent factors P_u explicitly from data, which has been observed to create many difficulties [9, 18, 45, 51]. In the corresponding works, users' long-term preferences have been modeled through learning a set of latent factors P_u for each user. However, learning P_u explicitly is difficult in large-scale production systems. As the number of users is usually several magnitudes higher than the number of items, building such a large user vocabulary and storing the latent factors in a persistent manner is challenging. Also, the long-tail users (*a.k.a* cold users) and visitor users (*i.e.* users who are not logged in) could have much worse recommendations than engaged users [6].

3.3 Limitations of Single Monolithic Models

Figure 1 clearly indicates that although the influence of past user events on future interactions follows a significant decaying trend, significant predictive power can still be carried by events located arbitrarily far in the past. Very recent events (*i.e.* $1 \leq L \leq 10$) have large magnitude similarities with the current user behavior and this similarity depends strongly on the sequential order of related events. As the distance L grows larger, the informative power of previously consumed items on future user behavior is affected by more uncertainty (*e.g.* variance) and is less sensitive to relative sequential position. That is, the events from 100 steps ago and from 110 steps ago may have a generally similar influence on future user decisions regardless of their relative temporal location. Therefore, *for the kind of sequential signals we intend to leverage, in which different scales of temporal dependencies co-exist, it may be better to no longer consider a single model.* While simple monolithic models such as Deep Neural Network (DNN) with pooling and dropout [11, 55] are provably robust to noise, they are unfortunately not sensitive to sequential order (without substantial modifications). On the other hand, RNNs [7, 20] provide cutting-edge sequential modeling capabilities but they are heavily sensitive to noise in sequential patterns. Therefore, it is natural to choose a mixture of diverse models which would then complement each other to provide better overall predictive power.

4 MULTI-TEMPORAL-RANGE MIXTURE MODEL FOR LONG USER SEQUENCES

Motivated by our earlier analyses, we now introduce a novel method aimed at addressing the shortcoming of pre-existing approaches for long user/item interaction sequences: Multi-temporal-range Mixture Model (M3) and its two variants (M3R/M3C). For simplicity, we omit the superscripts related to users (*i.e.* e_τ^u will now be denoted e_τ) and use a single user sequence to describe the neural architecture we introduce.

4.1 Overview

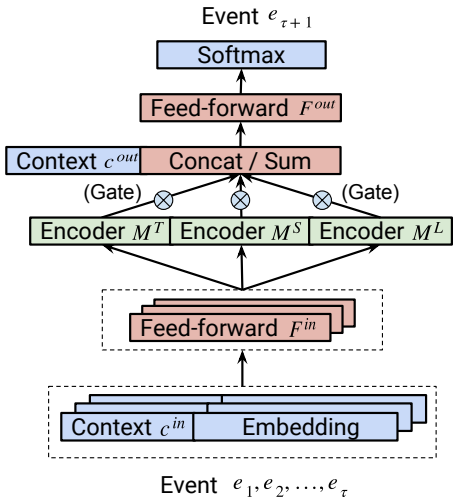

Figure 2: An overview of the proposed M3 model.

Figure 2 gives a general schematic depiction of M3. We will now introduce each part of the model separately in a bottom-up manner, starting from the inputs and progressively abstracting their representation which finally determines the model's output. When predicting the behavior of a user in the next event $e_{\tau+1}$ of their logged sequence, we employ item embeddings and context features (optional) from past events as inputs:

$$x_\tau = [Q_\tau \oplus c_\tau^{\text{in}}], \tag{1}$$

where $\oplus$ denotes the concatenation operator. To map the raw context features and item embeddings to the same high-dimensional space for future use, a feed-forward layer F^{in} is used:

$$Z_\tau^{\text{in}} = \{z_i^{\text{in}}\}_{i=1\cdots\tau} \text{ where } z_\tau^{\text{in}} = F^{\text{in}}(x_\tau) \tag{2}$$

here $z_\tau^{\text{in}} \in \mathbb{R}^{1\times d_{\text{in}}}$ represents the input processed at step τ and $Z_\tau^{\text{in}} \in \mathbb{R}^{\tau\times d_{\text{in}}}$ stands for the collection of all processed inputs before step τ (included). Either the identity function or a ReLU [37] can be used to instantiate the feed-forward layer F^{in}.

In the previous section, we assessed the limitations of using a single model on long user sequence. To circumvent the issues we highlighted, we employ in M3 three different sequence models (encoders) in conjunction, namely M^T, M^S and M^L, on top of the processed input Z_τ^{in}. We will later explain their individual architectures in details. The general insight is that we want each of these sub-models to focus on different ranges of temporal dependencies in user sequences to provide a better representation (*i.e.,* embedding) of the sequence. We want the sub-models to be architecturally diverse and address each other's shortcomings. Hence

$$SE_\tau^T = M^T(Z_\tau^{\text{in}}),\ SE_\tau^S = M^S(Z_\tau^{\text{in}}),\ SE_\tau^L = M^L(Z_\tau^{\text{in}}), \tag{3}$$

which yields three different representations, one produced by each of the three sequence encoders. The three different sub-model encoders are expected to produce outputs—denoted by d_{enc}—of identical dimension. By construction, each sequential encoder produces its own abstract representation of a given user's logged sequence, providing diverse latent semantics for the same input data.

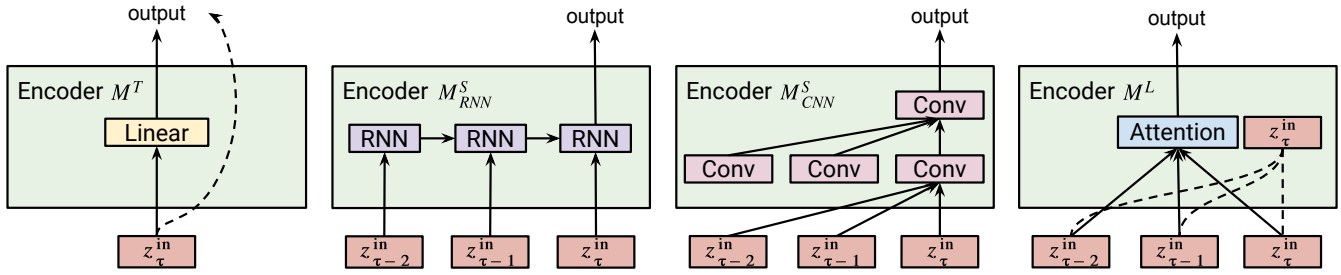
Our approach builds upon the success of Mixture-of-Experts (MOE) model [23]. One key difference is that our 'experts' are constructed to work with different ranges of temporal dependencies, instead of letting the cohort of 'experts' specialize by learning from data. As shown in [48], heavy regularization is needed to learn different experts sharing the same architecture in order to induce specialization and prevent starvation when learning (only one expert performs well because it is the only one to learn which creates a self-reinforcing loop when learning with back-propagation).

Informed by the insights underlying the architecture of MOE models, we aggregate all sequence encoders' results by weighted-concatenate or weighted-sum, with weights G_τ computed by a small gating network. In fact, we concatenate the outputs with

$$SE_\tau = (G_\tau^T \times SE_\tau^T) \oplus (G_\tau^S \times SE_\tau^S) \oplus (G_\tau^L \times SE_\tau^L), \tag{4}$$

where $G_\tau \in \mathbb{R}^3$ corresponds to the outputs of our gating network. We can also aggregate outputs with a weighted-sum:

$$SE_\tau = (G_\tau^T \times SE_\tau^T) + (G_\tau^S \times SE_\tau^S) + (G_\tau^L \times SE_\tau^L). \tag{5}$$



Note that there is no theoretical guarantee whether concatenation is better than summation or not. The choice of aggregation, as well as the choice of activation functions, is determined by observing a given model's performance from a validation set extracted from different datasets. Such a procedure is usual in machine learning and will help practitioners determine which variant of the model we propose is best suited to their particular application.

Because of its MOE-like structure, our model can adapt to different recommendation scenarios and provide insightful interpretability (as we shall see in Section 5). In many recommendation applications, some features annotate each event and represent the context in which the recommendation query is produced. Such features are for instance indicative of the page or device on which a user is being served a recommendation. After obtaining a sequence encoding at step τ (*i.e.* SE_τ), we fuse it with the annotation's context features (optional) and project them to the same latent space with another hidden feed-forward layer F^{out}:

$$z_\tau^{\text{out}} = F^{\text{out}}([SE_\tau \oplus c_\tau^{\text{out}}]) \tag{6}$$

where c^{out} is a vector encoding contextual information to use after the sequence has been encoded. Here the $z_\tau^{\text{out}} \in \mathbb{R}^{1\times d_{\text{out}}}$ is what we name *user representation*, it is computed based on the user's history as it has been gathered in logs. Finally, a user similarity score r_v is predicted for each item via an inner-product (which can be changed to another similarity scoring function):

$$r_v = z_\tau^{\text{out}} \cdot Q_v' \tag{7}$$

(a) Tiny-range encoder **(b) Short-range encoder (RNN)** **(c) Short-range encoder (CNN)** **(d) Long-range encoder**

Figure 3: The sequence encoders of *M3*. The solid lines are used to denote the data flow. The dotted line in (a) means an identity copy whereas in (d) it means the interaction of attention queries and keys.

where Q'_v is a vector representing the item. For a given user, item similarity scores are then normalized by a softmax layer which yields a recommendation distribution over the item vocabulary. After training M3, the recommendations for a user at step τ are served by sorting the similarity scores r_v obtained for all $v \in \mathcal{V}$ and retrieving the items associated with the highest scores.

4.2 Three Different Range Encoders

Item Co-occurrence as a Tiny-range Encoder The Tiny-range encoder M^T only focuses on the user's last event e_τ, ignoring all previous events. In other words, given the processed inputs from past events Z^{in}_τ, this encoder will only consider z^{in}_τ. As in factorizing Markov chain (FMC) models [45], M^T makes predictions based on item range-1 co-occurrence within observed sequences. For example, if most of users buy iPhone cases after purchasing an iPhone, then M^T should learn this item-to-item co-occurrence pattern. As shown in Figure 3a, we compute M^T's output as:

$$M^T(Z^{\text{in}}_\tau) = \phi(z^{\text{in}}_\tau), \text{ where } \phi(x) = \begin{cases} xW^{(T)} + b^{(T)}, & \text{if } d_{\text{in}} \neq d_{\text{enc}}, \\ x, & \text{otherwise.} \end{cases} \tag{8}$$

That is, when the dimensionality of processed input and encoder output are the same, the tiny-range encoder performs a role of residual for the other encoders in mixture. If $d_{\text{in}} \neq d_{\text{enc}}$, it is possible to down-sample (if $d_{\text{in}} > d_{\text{enc}}$) or up-sample (if $d_{\text{in}} < d_{\text{enc}}$) from z^{in}_τ by learned parameters $W^{(T)} \in \mathbb{R}^{d_{\text{in}} \times d_{\text{enc}}}$ and $b^{(T)} \in \mathbb{R}^{d_{\text{enc}}}$.

In summary, the tiny-range encoder M^T can only focus on the last event by construction, meaning *it has a temporal range of 1 by design*. If we only use the output of M^T to make predictions, we obtain recommendations results based on item co-occurrence.

RNN/CNN as Short-range Encoder As discussed in Section 3, the recent behavior of a user has substantial predictive power on current and future interactions. Therefore, to leverage the corresponding signals entailed in observations, we consider instantiating a short-range sequence encoder that puts more emphasis on recent past events. Given the processed input from past events Z^{in}_τ, this encoder, represented as M^S, focuses by design on a recent subset of logged events. Based on our quantitative data exploration, we believe it is suitable for M^S to be highly sensitive to sequence order. For instance, we expect this encoder to capture the purchasing pattern iPhone → iPhone case → iPhone charger if it appears frequently in user sequences. As a result, we believe the Recurrent Neural Network (RNN [36]) and the Temporal Convolutional Network ([3, 53, 59]) are fitting potential architectural choices. Such neural architectures have shown superb performances when modeling high-order causalities. Beyond accuracy, these two encoders are also order sensitive, unlike early sequence modeling method (*i.e.* Bag-of-Word [27]). As a result we develop two interchangeable variants of M3: *M3R* and *M3C* using an RNN and a CNN respectively.

To further describe each of these options, let us introduce our RNN encoder M^S_{RNN}. As shown in Figure 3b we obtain the output of M^S_{RNN} by first computing the *hidden state* of RNN at step τ:

$$h_\tau = \text{RNN}(z^{\text{in}}_\tau, h_{\tau-1}), \tag{9}$$

where RNN$(\cdot)$ is a *recurrent cell* that updates the hidden state at each step based on the previous hidden state $h_{\tau-1} \in \mathbb{R}^{1 \times d_{\text{in}}}$ and the current RNN input z^{in}_τ. Several choices such as Gated Recurrent Unit (GRU) [10] or Long Short Term Memory (LSTM) [21] can be used. The output is then computed as follows:

$$M^S_{\text{RNN}}(Z^{\text{in}}_\tau) = h_\tau W^{(R)}, \text{ where } W^{(R)} \in \mathbb{R}^{d_{\text{in}} \times d_{\text{enc}}} \tag{10}$$

where $W^{(R)}$ maps the hidden state to the encoder output space. We design our CNN encoder M^S_{CNN} as a Temporal Convolutional Networks which has provided state-of-art sequential modeling performance [3, 15, 53]. As shown in Figure 3c, this encoder consists of several stacked layers. Each layer computes

$$h^{(1)}_\tau = \text{Conv}(Z^{\text{in}}_\tau), \ldots, h^{(k)}_\tau = \text{Conv}(h^{(k-1)}_\tau), \tag{11}$$

where k indicates the layer number. The Conv$(\cdot)$ is a 1-D convolutional operator (combined with non-linear activations, see [3] for more details), which contains d_{enc} convolutional filters and operates on the convolutional inputs. With K layers in our CNN encoder, the final output will be:

$$M^S_{\text{CNN}}(Z^{\text{in}}_\tau) = h^{(K)}_\tau. \tag{12}$$

As highly valuable signals exist in the short-range part of user sequence, we propose two types of encoders to capture them. Our model can be instantiated in its first variant, *M3R*, if we use RNN encoder or *M3C* if a CNN is employed. Here M3C and M3R are totally interchangeable with each other and they show comparable results in our experiments (see Section 5.2.1). We believe such

flexibility will help practitioners adapt their model to the hardware they intend to use, *i.e.* typically using GPU for faster CNN training or CPU for which RNNs are better suited. In terms of temporal range, the CNN only considers a limited finite window of inputs when producing any output. The RNN, although it does not have a finite receptive field, is hampered by difficulties when learning to leverage events located further back into the past (to leverage an event located L observations ago the RNN needs $L-1$ steps). Regardless of the choice of a CNN or an RNN, our short-range encoder M^S *has a temporal range greater than 1, although it is challenging for this sub-model to capture signals too far away from current step.* This second encoder is specifically designed to capture sequence patterns that concern recent events.

Attention Model as Long-range Encoder The choice of an attention model is also influenced by our preliminary quantitative analysis. As discussed in Section 3, as the temporal distance grows larger, the uncertainties affecting the influence of item consumption on future events get larger as well. Moreover, as opposed to the recent part of a given user's interaction sequence, relative position does not matter as much when it comes to capturing the influence of temporally distant events. As we take these properties into account, we choose to employ *Attention Model* [2, 54] as our long-range sequence encoder. Usually, an attention model consists of three parts: attention *queries*, attention *keys* and attention *values*. One can simply regard an attention model as weighted-sum over attention values with weights resulting from the interaction between attention queries and attention keys. In our setting, we use (1) the last event's processed input z_τ^{in} as attention queries, (2) all past events' processed inputs Z_τ^{in} as keys and values and (3) scaled dot-product [54] as the similarity metric in the attention softmax. For instance, if a user last purchased a pair of shoes, the attention mechanism will focus on footwear related previous purchases.

So that all encoders have the same output dimensionality, we need to transform[1] our processed input first as follows:

$$\tilde{Z}_\tau^{\text{in}} = Z_\tau^{\text{in}} W^{(A)}, \tag{13}$$

where $W^{(A)} \in \mathbb{R}^{d_{\text{in}} \times d_{\text{enc}}}$ is a learned matrix of parameters. Then for each position $i \in [1, \tau]$, we obtain its raw attention weights, with respect to the processed input $\tilde{z}_i^{\text{in}}$, as follows:

$$\omega_{\tau,i} = \frac{\tilde{z}_\tau^{\text{in}} \cdot \tilde{z}_i^{\text{in}}}{\sqrt{d_{\text{enc}}}}, \tag{14}$$

where $\omega_{\tau,i}$ is the raw weight at position i. Similarly, we compute the raw attention weights $\boldsymbol{\omega}_\tau \in \mathbb{R}^{1\times\tau}$ for all positions $\boldsymbol{\omega}_\tau = \{\omega_i\}_{i=1..\tau}$ and normalize them with a softmax$(\cdot)$ function. Finally, we acquire the output of our long-range encoder as follows:

$$M^L(Z_\tau^{\text{in}}) = \text{softmax}(\boldsymbol{\omega}_\tau) Z_\tau^{\text{in}}. \tag{15}$$

Our long-range encoder borrows several advantages from the attention model. First, it is not limited by a certain finite temporal range. That is, *it has an unlimited temporal range and can 'attend' to anywhere in user's sequence with O(1) steps.* Second,because it computes its outputs as a weighted sum of inputs, the attention-based encoder is not as sensitive to sequential order as an RNN or a CNN as each event from the past has an equal chance of influencing the prediction. Third, the attention model is robust to noisy inputs due to its normalized attention weights and weighted-sum aggregation.

Gating Network Borrowing the idea from from Mixture-of-Experts model [23, 35], we build a gating network to aggregate our encoders' results. The gate is also helpful to better understand our model (see Section 5). To produce a simpler gating network, we use a feed-forward layer F^g on the gating network's inputs:

$$G_\tau = [G_\tau^T, G_\tau^S, G_\tau^L] = \text{sigmoid}(F^g(G_\tau^{\text{in}})), \tag{16}$$

where G_τ^{in} is the input we feed into our gating network. We will discuss how the model performs overall with different choices of gate inputs in Section 5.4. The resulting $G_\tau \in \mathbb{R}^3$ contains the gate value modulating each encoder. More importantly, an element-wise sigmoid function is applied to the gate values which allows encoders to 'corporate' with each other [4]. Note that a few previous works [26, 35, 48] also normalize the gate values, but we found this choice led to the degeneracy of our mixture model as it would learn to only use M^S which in turn hampers model performance.

Summary M3 is able to address limitations of pre-existing models as shown in Table 1: (1) M3 has a mixture of three encoders with different temporal ranges which can capture sequential patterns located anywhere in user sequences. (2) Instead of learning a set of latent factor P_u for each user, M3 represents the long-term user preferences by using a long-range sequence encoder that provides a representation of the entire history of a user. Furthermore, M3 is efficient in both model size and computational cost. In particular M3 does not introduce any extra parameters under certain settings (*i.e.* $d_{\text{in}} = d_{\text{enc}}$), and the computation of M^T and M^L are very efficient when using specialized hardware such as a GPU. With its simple gate design, M3 also provides good interpretability and adaptability.

- **Effectiveness.** Given our analysis on user sequences, we assume M3 to be effective. As compared to past works, M3 is capable to capture signals from the whole sequence, it also satisfies the properties we found in different parts of sequence. Moreover, our three encoders constitute a diverse set of sequential encoder and, if well-trained, can model user sequence in a multi-scale manner, which is a key to success in past literature [53, 58].
- **Efficiency.** In terms of model size, M3 is efficient. As compared to existing works which use short-range encoder only, though uses two other encoders, our M3 model doesn't introduce any extra parameters (if $d_{\text{in}} = d_{\text{enc}}$). In terms of computational efficiency, our M3 is good as well, as both M^T and M^L are nothing other than matrix multiplication, which is cheap when computed with optimized hardwares like Graphics Processing Unit (GPU).
- **Interpretability.** Model's interpretability is critical for diagnosing purpose. As we shall see later, with the gate network, we are able to visualize our network transparently by observing the gate values.
- **Adaptability.** One issue in production recommender system is modeling users for different recommendation scenarios, as people may behave very differently. Two typical scenarios are *HomePage* recommendation and product *DetailPage* recommendation. However, as we shall introduce in later

[1] It is unnecessary if d_{in} is same as d_{enc}.

Table 1: A summary of relationships and differences between sequence encoders in *M3*

	Base model	Temporal range	Model size	Sensitive to order	Robustness
M^T	Item Co-occurrence	1	small (or 0)	very high	no
M^S_{RNN}	Recurrent Neural Nets	unknown	large	high	no
M^S_{CNN}	Temporal Convolution Nets	limited	large	high	no
M^L	Attention Model	unlimited	small (or 0)	no	high

section, M3 is able to adapt to these scenarios if we use the scenario information as our gate input.

5 EXPERIMENTAL STUDIES

In this section, we study the two variants of M3 against several baseline state-of-the-art methods on both a publicly available dataset and our large-scale Youtube dataset.

Datasets We use MovieLens 20M[2], which is a publicly available dataset, along with a large-scale anonymized dataset from YouTube to which we have access because we are employees of Google working on improving YouTube as a platform. The dataset is private, anonymized and accessible only internally by few employees whose work is directly related to Youtube.

5.1 Experiments on MovieLens Dataset

As in previous works [18, 51], we process the MovieLens data by first converting numeric ratings to 1 values, turning them into implicit logged item consumption feedback. We remove the items with less than 20 ratings. Such items, because of how little user feedback is available for them, represent another research challenge — cold start — which is outside the scope of the present paper.

To focus on long user sequences, we filtered out users who had a sequence length of less than $\delta_{\text{min}} = 20$ item consumed, while we didn't filter items specifically. The maximum sequence length in the dataset being 7450, we follow the method proposed in [18, 51] and employ a sliding window of length $\delta_{\text{win}} = 300$ to generate similarly long sequences of user/item interactions in which we aim to capture long range dependent patterns. Some statistics can be found in the first row of Table 3.

We do not use contextual annotations for the MovieLens data.

Evaluation protocol We split the dataset into training and test set by randomly choosing 80% of users for training and the remaining 20% for validation (10%) and testing (10%). As with the training data, a sliding window is used on the validation and test sets to generate sequences. We measure the mean average precision (mAP) as an indicator for models' performances [6, 52]. We only focus on the top positions of our predictions, so we choose to use mAP@n with $n \in \{5, 10, 20\}$. There is only one target per instance here and therefore the mAP@n is expected to increase with n which is consistent with [4] but differs from [51].

Details on model architectures We keep architectural parameters consistent across all experiments on MovieLens. In particular, we use identical representation dimensions: $d_{\text{in}} = d_{\text{enc}} = d_{\text{out}} = 32$. Such a choice decreases the number of free parameters as the sub-models M^T and M^L will not have learned parameters. A GRU cell is employed for the RNN while 2 stacked temporal convolution layers [3] of width 5 are used in the CNN. A ReLU activation function is employed in the feed-forward layers F^{in} and F^{out}. Item embeddings of dimension 64 are learned with different weights on the input side (*i.e.,* Q in Eq. 1) and output side (*i.e.,* Q' in Eq. 7). Although previous work [18] has constrained such embeddings to be identical on the input and output side of the model, we found that increasing the number of degrees of freedom led to better results.

Baselines We compare our two variants, *i.e.,* M3R and M3C, with the following baselines:

- **FMC**: The Factorizing model for the first-order Markov chain (FMC) [45] is a simple but strong baseline in sequential recommendation task [7, 49, 51]. As discussed in Section 1, we do not want to use explicit user representations. Therefore, we do not compare the personalized version of this model (FPMC).
- **DeepBoW**: The Deep Bag-of-word model represent user by averaging item embeddings from all past events. The model then makes predictions through a feed-forward layer. In our experiments, we use a single hidden layer with size of 32 and ReLU as activation function.
- **GRU4Rec**: Originally presented in [20], this method uses a GRU RNN over user sequences and is a state-of-the-art model for sequential recommendation with anonymized data.
- **Caser**: The Convolutional Sequence Embeddings model [51] applying horizontal and vertical convolutional filters over the embedding matrix and achieves state-of-the-art sequential recommendation performance. We try $\{2, 4, 8\}$ vertical filters and $\{16, 32, 64\}$ horizontal filters of size $(3, 5, 7)$. In order to focus on the sequential encoding task, we discard the user embedding and only use the sequence embedding of this model to make predictions.

In the models above, due to the large number of items in input and output dictionaries, the learned embeddings comprise most of the free parameters. Therefore, having set the embedding dimension to 64 in all the baselines as well as in M3R and M3C, we consider models with similar numbers of learned parameters. The other hyperparameters mentioned above are tuned by looking at the mAP@20 on validation set. The training time of M3R/M3C is comparable with others and can be further improved with techniques like model compression [52], quantization [22], etc.

5.1.1 Overall Performances. We report each model's performance in Table 2. Each metric is averaged across all user sequences in test set. The best performer is highlighted in bold face. The results show that both M3C and M3R outperform other baselines by a large margin. Among the baselines, GRU4Rec achieves the best performance

[2] https://grouplens.org/datasets/movielens/20m/

and DeepBoW worst one, suggesting the sequence order plays a very important predictive role. FMC performs surprisingly well, suggesting we could get considerable results with a simple model only taking the last event into account. The poor results of Caser may be caused by its design which relies on vertical filters of fixed size. Caser performs better in the next subsection which considers sequences whose lengths vary less within the training data.

Table 2: Performance comparison on MovieLens 20M. M3C and M3R outperform the baselines significantly.

	mAP@5	mAP@10	mAP@20
FMC	0.0256	0.0291	0.0317
DeepBoW	0.0065	0.0079	0.0093
GRU4Rec	0.0256	0.0304	0.0343
Caser	0.0225	0.0269	0.0304
M3C	0.0295	0.0342	0.0379
M3R	**0.0315**	**0.0367**	**0.0421**
Improv.	+23.4%	+20.7%	+22.7%

5.1.2 Investigating the influence of sequence length through variants of MovieLens. The previous results have shown strong performance gains achieved by the models we intruced: M3C and M3R. We now investigate the origin of such improvements. The design of these models was inspired by an attempt to capture sequential patterns with different characteristic temporal extents. To check whether the models we introduced achieve this aim we construct multiple variants of MovieLens with different sequence lengths.

We vary the sequence length by having a maximum cutoff threshold $\delta_{\max}$ which complements the minimal sequence length threshold $\delta_{\min}$. A sequence with more than $\delta_{\max}$ only has its latest $\delta_{\max}$ observations remained. We vary the values of $\delta_{\min}$, $\delta_{\max}$ and the sequence generation window size. Table 3 summarizes the properties of the four variants of the MovieLens dataset we construct. It is noteworthy that such settings make Caser perform better as the sequence length is more consistent within each dataset variant.

GRU4Rec and Caser outperform the other baselines in the present setting and therefore we only report their performance. Figure 4 shows the improvements of M3C and M3R over the best baselines on four MovieLens variants. The improvement of each model is computed by its mAP@20 against the best baseline. In most cases, M3C and M3R can outperform the highest performing baseline. Specifically, on ML20M-S and ML20M-M, Caser performs similarly to GRU4Rec while both M3C and M3R have good performance. This is probably due to the contribution of the tiny-range encoder.

5.2 Anonymized YouTube dataset

For the YouTube dataset, we filtered out users whose logged sequence length was less than 150 ($\delta_{\min} = 150$) and keep each user's last 300 events ($\delta_{\max} = 300$) in their item consumption sequence. In the following experiments, we exploit contextual annotations such as user device (*e.g.,* from web browser or mobile App), time-based features (*e.g.,* dwelling time), etc. User sequences are all anonymized and precautions have been taken to guarantee that users cannot be re-identified. In particular, only public videos with enough views have been retained.

Neural recommender systems attempt at foreseeing the interest of users under extreme constraints of latency and scale. We define the task as predicting the next item the user will consume given a recorded history of items already consumed. Such a problem setting is indeed common in collaborative filtering [34, 46] recommendations. We present here results obtained on a dataset where only about 2 million items are present that correspond to most popular items. While the user history can span over months, only watches from the last 7 days are used for labels in training and watches in the last 2 days are used for testing. The train/test split is 90/10%. The test set does not overlap with the train set and corresponds to the last temporal slice of the dataset. In all, we have more than 200 million training sequences and more than 1 million test sequences, and with overall average sequence length approximately being 200.

The neural network predicts, for a sample of negatives, the probability that they are chosen and classically a negative sampling loss is employed in order to leverage observations belonging to a very large vocabulary [25]. The loss being minimized is

$$\sum_{l \in \text{Labels}} w_l \times \text{CrossEntropy}(\text{SampledSoftmax}(\xi(t+1)))$$

where the SampledSoftmax [25] uses 20000 randomly sampled negatives and w_l is the weight of each label.

Evaluation metrics To test the models' performances, we measure the mean average precision (mAP) as in [7, 51]. We only focus on the top positions of our predictions, so we choose to use mAP@n with $n \in \{5, 10, 20\}$. The mAP is computed with the entire dictionary of candidate items as opposed to the training loss which samples negatives. There is only one target per instance here and therefore the mAP@n is expected to increase with n which is consistent with [4] but differs from [51].

Baselines In order to make fair comparisons with all previous baselines, we used their contextual counterparts if they are proposed or compared in literature.

- **Context-FMC**: The Context-FMC condition the last event's embedding on last event's context features by concatenating them and having a feed-forward layer over them.
- **DeepYouTube**: Proposed by [11], the DeepYoutube model is a state-of-the-art neural model for recommendation. It concatenates: (1) item embedding from users' last event, (2) item embeddings averaged by all past events and (3) context features. The model then makes predictions through a feedforward layer composed of several ReLU layers.
- **Context-GRU**: We used the contextual version of GRU proposed in [49]. Among the three conditioning paradigms on context, we used the concatenation as it gives us better performances.

All models are implemented by TensorFlow [1] and by Adagrad [14] over a parameter server [32] with many workers.

Model details In the following experiments, we keep the dimensions of processed input d_{in} and encoder outputs d_{enc} identical for all experiments conducted on the same dataset. Once more, we also want to share some of our architectural parameters so that they are consistent across the two datasets. Again, by doing this, we make the parametrization of our models more parsimonious,

Table 3: Statistics of the variants of the MovieLens dataset.

	Min. Length	Max. Length	Window Size	Avg. Length	#Sequences	#Items
ML20M	20	∞	300	144.1	138.4K	13.1K
ML20M-S	20	50	20	42.8	138.4K	13.1K
ML20M-M	50	150	50	113.6	85.2K	13.1K
ML20M-L	150	300	150	250.7	35.8K	12.9K
ML20M-XL	300	∞	300	605.5	16.3K	12.5K

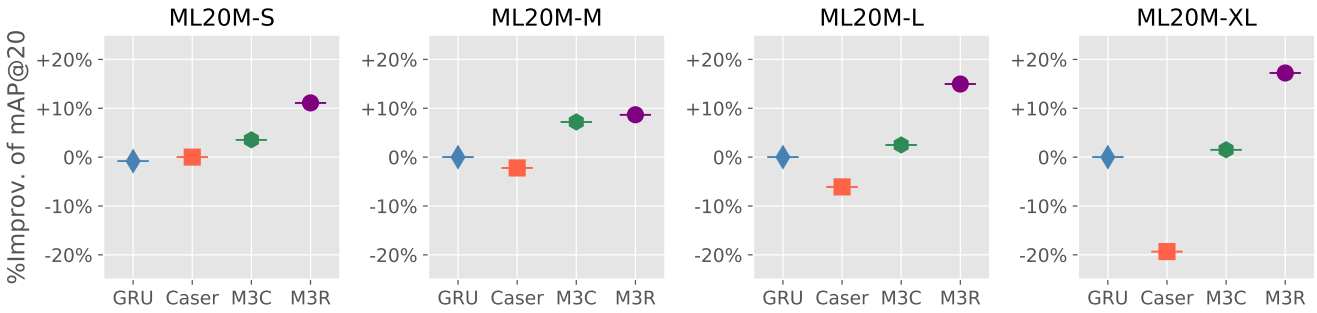


Figure 4: Uplifts with respect to the best baselines on four MovieLens variants. The improvement percentage of each model is computed by its relative mAP@20 gain against the best baseline. For all variants, M3R significantly outperforms the two baselines we consider according to a one-tail paired t-test at level 0.01, while M3C outperforms the other two significantly only on ML20M-M. Note that the standard error of all uplifts gets higher as we use a MovieLens variant with longer sequences. The standard error reaches 2.3% on ML20M-XL.

Table 4: Performance comparison on the anonymized YouTube dataset. M3C and M3R outperform the baselines significantly.

	mAP@5	mAP@10	mAP@20
Context-FMC	0.1103	0.119	0.1240
DeepYouTube	0.1295	0.1399	0.1455
Context-GRU	0.1319	0.1438	0.1503
M3C	0.1469	0.1591	0.1654
M3R	**0.1541**	**01670**	**0.1743**
Improv.	+16.8%	+16.1%	+16.0%

because the sub-models M^T and M^L will be parameter-free. For the RNN cell, we use a GRU on both datasets for its effectiveness as well as efficiency. For the CNN version, we stacked 3 layers of temporal convolution [3], with no dilation and width of 5. For the feed-forward layers F^{in} and F^{out}, we used ReLU as their activation functions, whereas they contains different number of sub-layers. For item embeddings on the input side (*i.e.,* Q in Eq. 1) and on the output side (*i.e.,* Q' in Eq. 7), we learn them separately which improves all results.

5.2.1 Overall Results. We report each model's performance on the private dataset in Table 4. The best performer is highlighted in bold face. As can be seen from this table, on our anonymized YouTube dataset, the Context-FMC performs worse followed by DeepYoutube while Context-GRU performs best among all baselines. The DeepYouTube and Context-GRU perform better than Context-FMC possibly because they have longer temporal range, which again shows that the temporal range matters significantly in long user sequences. One can therefore improve the performance of a sequential recommender if the model is able to leverage distant (long-range dependent) informantion in user sequences.

On both datasets, we observed our proposed two model variants M3R and M3C significantly outperform all other baselines. Within these two variants, the M3R preforms marginally better than the M3C, and it improves upon the best baselines by a large margin (more than 20% on MovieLens data and 16.0% on YouTube data).

5.3 Ablation Study of Mixture of Models

To demonstrate how each encoder contributes to the overall performance, we now present an ablation test on our M3R model (results from M3C are similar) on our proprietary data. We use T, S, L to denote M^T, M^S and M^L respectively. The results are described in Table 5. When we only enable single encoder for M3R, the best performer is M3R-T on MovieLens data and M3R-S on the YouTube data. This result is consistent with the results in Section 5.2.1. With more encoders involved in M3R the model performs better. In particular, when all encoders are incorporated, our M3R-TSL performs best on both datasets, indicating all three encoders matter for performance.

Table 5: mAP@20 vs. different components of M3R on both datasets, where T,S,L stands for M^T, M^S and M^L respectively.

	MovieLens 20M	YouTube Dataset
M3R-T	0.0269	0.1406
M3R-S	0.0363	0.1673
M3R-L	0.0266	0.1359
M3R-TS	0.0412	0.1700
M3R-TL	0.0293	0.1485
M3R-SL	0.0403	0.1702
M3R-TSL	0.0421	0.1743

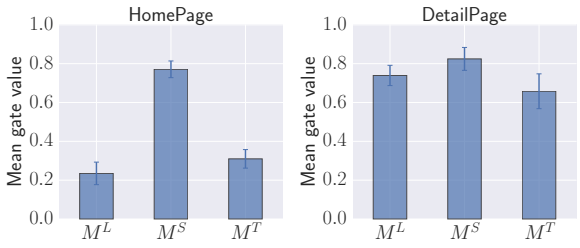

Figure 5: Average gate values of M3R in different scenarios. The model learns to use different combination of encoders in different recommendation scenarios.

5.4 Role of Gating Network

We now begin to study our gating network in order to answer the following questions: (1) Is the gating network beneficial to the overall model performance? (2) How do different gating network inputs influence the model performance? and (3) How can the gating network make our model more adaptable and interpretable?

Fixed gates versus learned gates: First of all, we examine the impact of our gating network by comparing it with a set of fixed gate values. More precisely, we fixed the gate values to be all equal to 1.0 during the model training: $G_\tau = \mathbf{1}$, here $\mathbf{1} \in \mathbb{R}^3$ is a vector. The first row of Table 6 shows the result of this fixed-gate model. We found that the fixed models are weaker than the best performing version of M3R (*i.e.,* mAP@20 of 0.1743) and M3C (*i.e.,* mAP@20 of 0.1654). This reveals that the gating network consistently improves M3-based models' performances.

Influence of different gate inputs: In this paragraph we investigate the potential choices of inputs for the gating network, and how they result in different performance scores. In the existing Mixture-of-Experts (MOE) literature, the input for the gating network G_τ^{in} can be categorized into Contextual-switch and Bottom-switch. The Contextual-switch, used in [4], uses context information as gate input:

$$G_\tau^{\text{in}} = [c_\tau^{\text{in}} \oplus c_\tau^{\text{out}}], \tag{17}$$

where c_τ^{in} and c_τ^{out} are context features from input and output side. Intuitively, this suggests how context may influence the choices of different encoders. If no context information is available, we can still use the output of a shared layer operating before the MOE layer [35, 48] as gate input, *i.e.,* Bottom-switch:

$$G_\tau^{\text{in}} = z_\tau^{\text{in}}. \tag{18}$$

The shared layer contains high-level semantic knowledge from the last event, which can also enable gate switching.

Table 6: mAP@20 vs. different types of gating network on the two datasets for M3R. 'Fixed' indicates we fix gate values to 1.0, 'Contextual-switch' means that we use context features c^{in} and c^{out} as gate input and 'Bottom-switch' corresponds to the use of z_τ^{in} as gate input.

	MovieLens	YouTube
Fixed	0.0413	0.1715
Bottom-switch	0.0421	0.1734
Contextual-switch	/	0.1743

On the MovieLens data, we used Bottom-switched gate for all the results above because of the absence of contextual annotations. On the YouTube dataset, the last two rows from Table 6 provide the comparison results between Contextual-switched gate and Bottom-switched gate. We observe that context information is more useful to the gates than a shared layer. In other words, the decision of whether to focus more on recent part (*i.e.* large gate values for M^T and M^S) or on the distant part (*i.e.* large values for M^L) from user sequence is easier to make based on contextual annotations.

5.5 Discussion on model architecture

The model architecture we design is based on quantitative findings and has two primary goals: capturing co-existing short-range and long-range behavioral patterns as well as serving recommendations given in different contexts with a single model.

We know for recommender systems in most applications (*e.g.* e-commerce like Amazon, streaming services like Netflix) that recommendations commonly occur in at least two different contexts: either a *HomePage* or a *DetailPage*. The Homepage is the page shown when users open the website or open the mobile App, while DetailPage is the page shown when users click on a certain item. User behaviors are different depending on which of these two pages they are browsing. Users are more likely to be satisfied by a recommendation related to recent events, especially the last event, when they are on a DetailPage. A straightforward solution to deal with these changing dynamics is to train two different models.

We now demonstrate that with the multi-temporal-range encoders architecture and gating mechanism in M3, we can have a single adaptive end-to-end model that provides good performance in a multi-faceted recommendation problem. To that end we analyze the behavior of our gating network and show the adaptability of the model as we gain a better understanding of its behavior.

What we observe in Figure 5 is that when contextual information is available to infer the recommendation scenario, the gating network can effectively automatically decide how to combine the results from different encoders in a dynamic manner to further improve performance. Figure 5 shows how gate values of M3R change *w.r.t.* across different recommendation scenarios. It is clear that M3R puts more emphasis on M^S when users are on the HomePage,

while it encourages all three encoders involved when users are on DetailPage. This result shows that the gating network uses different combinations of encoders for different recommendation scenarios.

As a result, we can argue that our architectural design choices do meet the expectations we set in our preliminary analysis. It is noteworthy that the gating mechanism we added on top of the three sub-models is helpful to improve predictive performance and ease model diagnosis. We have indeed been able to analyze recommendation patterns seamlessly.

6 CONCLUSION

M3 is an effective solution to provide better recommendations based on long user sequences. M3 is a neural model that avoids most of the limitations faced by pre-existing approaches and is well adapted to cases in which short term and long term temporal dependencies coexist. Other than effectiveness, this approach also provides several advantages such as the absence of a need extra parameters and interpretability. Our experiments on large public dataset as well as a large-scale production dataset suggest that M3 outperforms the state-of-the-art methods by a large margin for sequential recommendation with long user sequences. One shortcoming of the architecture we propose is that all sub-models are computed at serving time. As a next step, we plan to train a sparse context dependent gating network to address this shortcoming.

ABSTRACT

Crowdsourcing has become a popular tool for large-scale data collection where it is often assumed that crowd workers complete the work *independently*. In this paper, we relax such independence property and explore the usage of *peer communication*—a kind of direct interactions between workers—in crowdsourcing. In particular, in the crowdsourcing setting with peer communication, a *pair* of workers are asked to complete the same task together by first generating their initial answers to the task independently and then freely discussing the task with each other and updating their answers after the discussion. We first experimentally examine the effects of peer communication on individual microtasks. Our results conducted on three types of tasks consistently suggest that work quality is significantly improved in tasks with peer communication compared to tasks where workers complete the work independently. We next explore how to utilize peer communication to optimize the requester's total utility while taking into account higher data correlation and higher cost introduced by peer communication. In particular, we model the requester's online decision problem of whether and when to use peer communication in crowdsourcing as a constrained Markov decision process which maximizes the requester's total utility under budget constraints. Our proposed approach is empirically shown to bring higher total utility compared to baseline approaches.

1 INTRODUCTION

Crowdsourcing has gained increasing popularity recently as a scalable data collection tool for various purposes, such as obtaining labeled data for training machine learning algorithms and getting high-quality yet cheap transcriptions for audio files. On a typical crowdsourcing platform like Amazon Mechanical Turk (MTurk), task requesters can post small jobs (e.g., image labeling or audio transcription tasks) as "microtasks" along with the specified payment for completing each task. Workers then can browse all available tasks on the platform and decide which ones to work on. Crowd workers are often assumed to complete tasks *independently*, and a substantial amount of crowdsourcing research has been focused on how to make better use of the independent workers. For example, a rich body of research has explored how to aggregate independent contributions from multiple workers by inferring task difficulties, worker skills, and correct answers simultaneously [10, 41, 49, 53]. Moreover, given a limited budget, researchers have further examined how to intelligently decide the number of independent workers needed for each task at the first place [8, 21, 34].

However, the validity and value of this independence assumption in crowdsourcing has been challenged recently. Through a combination of ethnographic and experimental methodologies, researchers have found that crowd workers, in fact, communicate and collaborate with each other through both online forums (like TurkerNation[1] and MTurkCrowd[2]) and one-on-one channels [19, 20, 25, 37, 44, 51]. Different from such collaboration which is organically arisen within the crowd and mostly about exchanging meta-level information related to crowd work (e.g., how to find well-paid tasks), an increasing number of studies in the human-computer interaction community have started to design certain level of interactions between workers in their actual work, which is shown to improve crowdsourcing outcomes in many cases. For example, various *workflows* are developed to coordinate workers to work on *different* subtasks and interact with each other through the pre-defined input-output handoffs [4, 9, 30–32, 35, 40, 42], which enable the crowd to jointly complete complex tasks.

More recently, worker interactions are further introduced between workers of the *same* task: Drapeau et al. [18] and Chang et al. [7] showed that in image/text labeling tasks, workers can improve their labeling accuracy when *indirect* interactions—in the form of showing each worker the alternative answer and associated justification produced by another worker who works on the same task—are enabled, and Schaekermann et al. [45] observed that in text classification tasks, worker performance increases when they can debate their answers through *direct, real-time* deliberation with one another. While these research show the promise of an alternative way to structure crowd work that leads to higher performance, they also raise a number of open questions.

First, on the "micro" level, it is important to empirically examine whether adding interactions between workers working on the same task leads to an increase in work quality for *individual* tasks of *different* types, especially for those tasks with a large number of possible answers (rather than just a few options as in image labeling and text classification tasks). Indeed, when the number of possible

answers in a task becomes large, workers may hardly agree with each other so it is unclear whether interactions between them would be meaningful and effective. It is also impractical for workers to argue against all alternative answers during their interactions, which may imply the need for new formats of interactions beyond providing justification and argumentation.

Furthermore, from a more "macro" point of view, requesters typically have a *large batch* of tasks at hand and need to solicit answers from multiple workers for each task. Their goal is to optimize their *overall* utility such as maximizing the quality obtained across *all* the tasks under a fixed budget. Yet, compared to independent work, allowing worker interactions in a task can bring up not only work quality improvement in that task, but also higher cost and higher correlation in workers' answers. Thus, for requesters to make better use of worker interactions, a critical problem to address is that given a limited budget, *whether* and *when* should worker interactions be used in each task, such that after combining the possibly correlated answers together for each task, the work quality for the entire batch of tasks is maximized when the budget is exhausted.

In this paper, we attempt to answer these two questions. In particular, inspired by the concept of peer instruction in education [12], we focus on studying a specific format of worker interactions that we refer to as *peer communication*—a *pair* of workers working on the same task are asked to first provide an independent answer each, then freely discuss the task with each other, and finally provide an updated answer, again independently, after the discussion. Compared to worker interaction formats used in the early research (e.g., justification and argumentation), we consider peer communication as a kind of direct and synchronous interaction that can be generalized to different types of tasks more easily. Our goal is to better understand not only whether and how peer communication would affect the outcome of crowd work for various types of tasks, but also how requesters can use algorithmic approaches to better utilize the potential benefits brought up by peer communication.

To understand the effects of peer communication on crowd work, we design and conduct randomized experiments with three different types of tasks: image labeling, optical character recognition, and audio transcription. For all types of tasks in our experiments, regardless of how large the number of possible answers in the task is, we have consistently observed an increase in work quality when workers can talk with their peers in the task compared to workers who work independently. Yet, we do not observe any spillover effects of such quality improvement when workers who have engaged in peer communication work on similar tasks again independently.

Moreover, to examine how peer communication can be better utilized, we propose an algorithmic framework to help requesters make *online decisions* on whether and when to use peer communication for each task in their batch, with the goal of maximizing the overall work quality produced in all tasks given a budget constraint. One of the key challenges here is how to infer the correct answer for a task given multiple answers solicited from workers, where some of them may be produced following the peer communication procedure and thus may be correlated. To this end, we introduce the notions of *meta-workers* and *meta-labels* to describe a pair of workers who have engaged in a task with peer communication and the pair of answers produced by them. Such notions enable us to characterize the possible correlation in data, which further allow us to solve the requester's online decision-making problem by modeling it as a constrained Markov decision process.

We evaluate the effectiveness of the proposed algorithmic approach on real data collected through our experimental study. Results show that using our approach to decide the usage of peer communication in tasks, the requester can achieve higher overall quality across all her tasks when the budget is exhausted, compared to when baseline approaches are adopted where peer communication is always used in all tasks or never used in any of the tasks, or when correlation in data is not explicitly considered. In addition, through two sets of simulated experiments, we further examine how the proposed algorithmic approach performs in various scenarios when the differences in work quality and cost between hiring pairs of communicating workers and hiring independent workers vary, and when answers produced by pairs of communicating workers are correlated to different extent.

In summary, we make the following contributions:

- We introduce peer communication, a general mechanism adapted from the concept of peer instruction in education for including worker interactions in crowd work.
- We empirically show that on different types of tasks, compared to independent work, peer communication consistently leads to a 32%–47% improvement in work quality for individual tasks.
- We propose an algorithmic framework to help requesters dynamically decide whether and when to use peer communication for each task in their batch, so as to maximize the overall quality obtained across all tasks given a budget constraint.
- Through evaluations on both real data from crowd workers and synthetic data, we demonstrate that compared to baseline approaches, using our proposed algorithm to determine the deployment of peer communication leads to higher requester utility.

2 RELATED WORK

Our work joins a long line of research on improving the quality of crowd work. In traditional settings where it is assumed that workers independently complete tasks, various methods have been proposed to address this problem, including post-hoc aggregation of workers' answers [10, 14, 15, 26, 41, 49, 53], designing effective extrinsic incentives [23, 24, 38, 50] and intrinsic motivation [33, 43, 47], appropriate assignment of tasks to workers [22, 27, 28], etc.

We explore how to improve the quality of crowd work from a different angle, that is, by adding interactions between workers. Researchers have previously designed *workflows* for complex tasks to allow workers to work on different subtasks while indirectly interacting with one another through the pre-defined input-output handoffs [4, 9, 30–32, 35, 40, 42]. Different from these workflow-based approaches, we consider the addition of interactions between workers of the *same* task. A few previous studies [7, 18, 45] have showed that enabling interactions between workers working on the same task, in the form of asking workers to provide justification for their answers, can lead to improvement in work quality, but these studies only test this idea on classification tasks. We aim to extend this idea to a wider range of tasks, especially for tasks with a large number of possible answers.

In this paper, we study a specific format of interactions, *peer communication*, which is adapted from "peer instruction" [12] and

"think-pair-share" strategies [36] in the educational settings. There is a rich literature in the collaborative learning community suggesting that asking students to discuss conceptual questions with other students after they independently answer the questions leads to higher levels of understanding and post-test performance [11, 16, 48]. We thus design the peer communication procedure as first asking a pair of workers to provide an independent answer each, then allowing them to *freely* discuss the task with each other, and finally independently update their answers. While evidence in the collaborative learning community and results for adding argumentation in classification tasks seem to indicate peer communication would lead to higher work quality, other studies showed that allowing workers to chat during work doesn't change work quality [52]. Thus, it is necessary to re-examine the impact of peer communication on the quality of crowd work, if any. In addition, as prior research on inter-task effects [1, 6, 39] suggests that when working on a sequence of tasks, workers' responses for later tasks could be influenced by the earlier tasks, we further examine whether peer communication brings any "spillover" effect on work quality. That is, whether workers produce higher independent work quality after engaging in similar tasks with peer communication.

Besides empirically showing the benefits of peer communication on work quality, we further provide an algorithmic framework for helping requesters better utilize such benefits. Early work has explored how indirect interactions between workers of different tasks that are embedded in certain workflows can be algorithmically controlled in order to maximize requester utility [13]. In contrast, the purpose of our algorithmic framework is to dynamically decide whether and when to deploy peer communication between workers of the *same* task for each task in requesters' batch to maximize their utility. Our framework is built on top of the work by Chen et al. [8], in which they used a Markov decision process to sequentially decide which task in requesters' batch needs an additional worker to work on given a budget constraint. However, our framework has a few key differences: First, in addition to choose which task needs further work, we also decide on how to design that piece of work—hiring one independent worker or two communicating workers? Second, when making inference for each task, we need to consider the possible correlation in the answers for this task. Finally, since peer communication and independent work incurs *different cost*, this decision-making problem does *not* degenerate into a finite-horizon Markov decision process. Thus, we explicitly model the problem as a *constrained* Markov decision process.

3 EXAMINING PEER COMMUNICATION VIA REAL-WORLD EXPERIMENTS

In this section, we first present our experimental study, in which we carefully examine the effects of introducing peer communication between pairs of workers on the quality produced in individual tasks through a set of randomized experiments conducted on Amazon's Mechanical Turk (MTurk). In particular, we ask:

- **Question 1 (Q1)**: Do workers produce higher work quality in tasks with peer communication compared to that in tasks where workers work independently?

Previous studies on the effects of adding worker interactions in image and text classification tasks [7, 18, 45] seem to imply a positive answer for Q1. Compared to these studies, our study has two key differences that warrant a re-examination of Q1: (1) the main format of interaction in peer communication is a *synchronous, free-form chat* rather than required justification and argumentation; (2) we consider different types of tasks beyond classification, especially tasks with a large number of possible answers so workers can hardly agree with each other or argue against all alternative answers. Moreover, we are also interested in examining whether there is any "spillover" effects of the impact of peer communication on work quality. Specifically:

- **Question 2 (Q2)**: Do workers produce higher independent work quality after engaging in similar tasks with peer communication, compared to workers who always complete tasks on their own?

Both positive and negative answers might be possible for Q2: On the one hand, if communication between workers in tasks allow them to resolve misconception about the tasks or learn useful problem-solving strategies from each other, we might expect a positive answer; on the other hand, if the benefits of peer communication are mostly due to workers being able to exchange their confidence levels on a task and eventually converge to the more confident answer [2], the answer for Q2 would likely be negative.

3.1 Independent Tasks vs. Discussion Tasks

In our experiments, we considered two ways to structure the tasks:

- **Independent tasks** (tasks without peer communication). In an independent task, workers are instructed to complete the task on their own.
- **Discussion tasks** (tasks with peer communication). In discussion tasks, we designed a procedure which guides workers to communicate with each other and complete the task together. Specifically, each worker is paired with another "co-worker" on a discussion task. Both workers in the pair are first asked to work on the task and submit their answers independently. Then, the pair enters a chat room, where they can see each other's independent answer. Workers are instructed to freely discuss the task with their co-workers for two minutes; for example, they can explain to each other why they believe their answers are correct. After the discussion, both workers get the opportunity to independently update and submit their final answers.

3.2 Experimental Treatments

The most straight-forward experimental design would include two treatments, where workers in one treatment are asked to work on a sequence of independent tasks while workers in the other treatment complete a sequence of discussion tasks. However, if we adopt such a design, the different nature of independent and discussion tasks (e.g., discussion tasks require more time and effort from workers but can be more interesting to workers) implies the possibility of observing severe self-selection biases in the experiments (i.e., workers may self-select into the treatment that they can complete tasks faster or find more enjoyable).

To overcome the drawback of this simple design, we design our experiments in a way that each treatment consists of the same number of independent tasks *and* discussion tasks, so neither treatment appears to be obviously more time-consuming or enjoyable. Figure 1 illustrates the two treatments used in our experiments. In

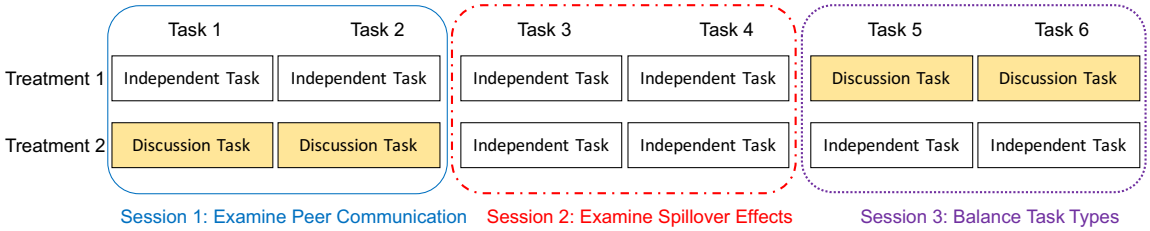

Figure 1: The two experimental treatments. This design enables us to examine whether peer communication improves the quality of crowd work (by comparing work quality in Session 1) and if so, does the improvement spill over to the following independent tasks (by comparing work quality in Session 2), while not creating significant differences between the two treatments (by adding Session 3 to make the two treatments containing equal number of independent and discussion tasks).

particular, we bundle 6 tasks in each HIT (i.e., Human Intelligence Task on MTurk). When a worker accepted our HIT, she was told that there are 4 independent tasks and 2 discussion tasks in the HIT. There are two treatments in our experiments:

- *Treatment 1*: Workers are asked to complete 4 independent tasks followed by 2 discussion tasks.
- *Treatment 2*: Workers are asked to complete 2 discussion tasks followed by 4 independent tasks.

Importantly, we did *not* tell workers the ordering of the 6 tasks, which helps us to minimize the self-selection biases as the two treatments look the same to workers. We refer to the first, middle, and last two tasks in the sequence as Session 1, 2, 3 of the HIT, respectively. Thus, we can answer Q1 by comparing the work quality produced in Session 1 between the two treatments, while a comparison of work quality in Session 2 between the two treatments would allow us to answer Q2. Finally, Session 3 is used for balancing the number of independent and discussion tasks in each HIT.

3.3 Experimental Tasks

We conducted our experiments on three types of tasks:

- **Image labeling.** In each task, the worker is asked to identify whether the dog shown in an image is a Siberian Husky or a Malamute. Dog images we use are collected from the Stanford Dogs dataset [29].
- **Optical character recognition (OCR).** In each task, the worker is asked to transcribe a vehicle's license plate numbers from photos. The photos are taken from the dataset provided by Shah and Zhou [46].
- **Audio transcription.** In each task, the worker is asked to transcribe an audio clip which contains about 5 seconds of speech. The audio clips are collected from VoxForge[3].

We decided to conduct our experiments on these three types of tasks for two main reasons: First, these tasks are all very common types of tasks on crowdsourcing platforms [17], so experimenting with them would allow us to better understand the effects of peer communication on typical kind of crowd work. Second, in terms of the number of possible answers, these tasks span a wide spectrum from two (image labeling) to infinitely many (audio transcription), enabling us to both confirm the effects of peer communication in tasks with just a few possible answers and explore its effects in tasks with many possible answers. As a final note, tasks we bundled in the same HIT had a certain degree of similarity[4], hence a spillover effect of peer communication on work quality is not impossible as knowledge/strategy that workers may learn in one task can potentially be transferred to another task.

3.4 Experimental Procedure

Enabling synchronous work among crowd workers is quite challenging, as discussed in previous research on real-time crowdsourcing [3, 5]. We address this challenge by dynamically matching pairs of workers and sending them to simultaneously start working on the same sequence of tasks. In particular, when each worker arrived at our HIT, we first checked whether there was another worker in our HIT who didn't have a co-worker yet—if yes, she would be matched to that worker and assigned to the same treatment and task sequence as that worker, and the pair then started working on their sequence of tasks together. Otherwise, the worker would be *randomly* assigned to one of the two treatments as well as a *random* sequence of tasks, and she would be asked to wait for another co-worker to join the HIT for a maximum of 3 minutes. In the case where no other workers arrived at our HIT within 3 minutes, we asked the worker to decide whether she was willing to complete all tasks in the HIT on her own (and we dropped the data for the analysis but still paid her accordingly) or get a 5-cent bonus to keep waiting for another 3 minutes.

We provided a base payment of 60 cents for all our HITs. In addition to the base payments, workers were provided with the opportunity to earn performance-based bonuses, that is, workers can earn a bonus of 10 cents in a task if the final answer they submit for that task is correct. Our experiment HITs were open to U.S. workers only, and each worker was only allowed to take one HIT for each type of tasks.

3.5 Experimental Results

In total, we have 388, 382, and 250 workers who successfully formed pairs and completed the image labeling, OCR, and audio transcription tasks in our experiments, respectively. We then answer Questions 1 and 2 separately for each type of task by analyzing experimental data from Session 1 and 2 in the HIT, respectively.[5]

[3] http://www.voxforge.org

[4] For example, image labeling tasks are all about the key concept of distinguishing Siberian Husky from Malamute, OCR tasks have similar image quality, and audio transcription tasks contain similar accents.

[5] On a side note, analyzing the data collected in Session 3 leads to conclusions that are consistent with our findings reported below, and including such data only strengthens our results. However, since we have decided not to use it in the experiment design phase, we do not include the data in the analysis. The reason of the decision is that

3.5.1 Work Quality Metrics. For all three types of tasks, we evaluate the work quality using the notion of *error*. In the image labeling task, we define error as the binary classification error—the error is 0 for correct labels and 1 for incorrect labels. For OCR and audio transcription tasks, we define error as the edit distance between the worker's answer and the correct answer, divided by the number of characters in the correct answer. Naturally, for all tasks, a lower rate of error implies higher work quality.

3.5.2 Q1: Peer Communication Improves Work Quality. In Figure 2, We plot the average error rate for workers' final answers in the first two tasks (i.e., Session 1) of Treatment 1 and 2 using white and black bars, respectively. Visually, it is clear that for all three types of tasks, the work quality is higher in discussion tasks (i.e., Session 1 of Treatment 2 HITs) when workers are able to communicate with others about the work, compared to that in independent tasks (i.e., Session 1 of Treatment 1 HITs) where workers need to complete the work on their own. Indeed, we observe a substantial 37%, 32%, and 47% deduction in the average error rate for image labeling, OCR, and audio transcription tasks when peer communication is enabled. We further conduct two-sample t-tests to check whether these changes are statistically significant, and p-values are 2.42×10^{-4}, 5.02×10^{-3}, and 1.95×10^{-11} respectively, suggesting that introducing peer communication in crowd work can significantly improve the work quality produced for various types of tasks.

We then look into the chat logs to gain some insights on how and what workers have communicated with each other during the discussion. On average, the length of the discussions in image labeling, OCR and audio transcription tasks are 4.2, 5.1 and 5.4 turns[6], yet the amount of discussion is not correlated to the quality of worker's final answers after discussion. Furthermore, by looking into the content of discussions, we find several types of information workers are exchanging during their communication:

- *Providing Justification*: e.g., "triangle ears that stand erect are traits of a Siberian Husky" (image labeling)
- *Communicating Confidence*: e.g., "I'm pretty sure about UR to start, but not very sure after that" (OCR); "I had no idea what the last word was" (audio transcription)
- *Exchanging Strategy*: e.g., "If you can zoom in on it you will see what I mean" (OCR); "He pronounces 'was' with a v-sound instead of the w-sound" (audio transcription)
- *Expressing Agreement*: e.g., "I agree"; "Listening to it again, I think you are right" (audio transcription)
- *Collaborative Work*: the pair of workers work together to solve the task, e.g., guessing a digit on the car plate for the OCR task that neither worker can recognize independently

Interestingly, as an anecdotal observation, we notice that in image labeling tasks the majority of workers tend to provide justifications for their answers. In OCR and audio transcription tasks, instead of "defending" their own answers, many more workers choose to team up with their co-workers to solve the task together.

workers' conditions in Session 3 of the two treatments differ to each other both in terms of whether they have communicated with other workers about the work in previous tasks and whether they can communicate with other workers in the current tasks, making it difficult to draw any causal conclusions on the effect of peer communication.

[6]We count each chunk of sentences a worker entered in the chat room as a "turn."

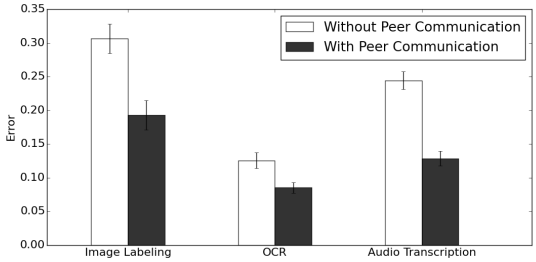

Figure 2: Comparisons of work quality produced in tasks with or without peer communication. Error bars indicate the mean ± one standard error.

3.5.3 Q2: There are no spillover effects. We now move on to Q2: Compared to workers who always complete tasks independently, do workers who have participated in tasks with peer communication continue to produce work of higher quality in future tasks of the same type, even if they need to complete those tasks on their own? To answer this question, we compare the work quality produced in Session 2 (i.e., the middle two independent tasks) of the two treatments for all three types of tasks. For image labeling, OCR, and audio transcription tasks, the average error rates for Session 2 in Treatment 1 (workers never engage in peer communication) are 0.324, 0.175, and 0.209 respectively, while the average error rates for Session 2 in Treatment 2 (workers have previously engaged in peer communication) are 0.334, 0.168, and 0.244. Thus, we do not observe any spillover for the effects of peer communication on work quality, that is, the quality improvement brought up by peer communication does not carry on to future independent work.

3.5.4 Discussions. Results of our experimental study suggest that peer communication improves the quality of crowd work for various types of tasks, even when the number of possible answers in the task is very large, yet such effect does not spill over to later independent work. Cautions should be used when generalizing these results to substantially different contexts, such as when workers can interact with each other for an extended period of time rather than just 2 minutes, when the tasks are significantly more complex or more subjective, or when workers engage in peer communication for a longer sequence of tasks. It is, thus, an important future direction to obtain an thorough understanding on how tuning various parameters of the design space (e.g., length of interactions, complexity/subjectivity of tasks) would change the effects of peer communication.

4 AN ALGORITHMIC FRAMEWORK FOR UTILIZING PEER COMMUNICATION

Our experimental study focuses on understanding the impact of peer communication on *individual tasks*. Now, we turn to our next question, that is, for a requester who has a *large batch* of tasks, how can he better utilize peer communication to improve the *overall utility* that he can obtain across all the tasks? In particular, we address the following research question: *Given a budget and a batch of tasks to complete, whether and when should a requester deploy peer communication in each task to maximize his total utility?*

To answer this question, there are two main challenges. First, when peer communication is deployed, workers communicate with

each other before submitting their answers. Therefore, their answers might be correlated. Yet, existing aggregation methods all assume each worker complete the work independently, making it necessary for us to develop new ways to address the data correlation issue. Second, deploying peer communication incurs higher cost, since it requires us to hire workers in pairs to work for longer period of time and may need additional effort for worker synchronizations. Therefore, even though peer communication produces higher work quality for individual tasks, it is not clear deploying peer communication is always beneficial for the overall utility.

In this section, we focus on the setting in which a requester aims to collect labels for a batch of binary classification tasks with a fixed budget, and the "utility" to maximize is the average accuracy the requester obtains across all classification tasks[7]. In the following, we first discuss how to deal with the data correlation issue, that is, how to infer the correct label for a task given multiple labels solicited from workers, where some of the labels may be correlated. We then describe our algorithmic framework, a constrained Markov decision process, which adaptively decides whether and when peer communication should be deployed in each task under the budget constraint while taking into account data correlation and differing cost in deploying peer communication.

4.1 Dealing with Data Correlation

When peer communication is used in a task, a pair of workers directly interact with each other. Naturally, their contributions (e.g., labels in image labeling tasks) might be correlated. For categorical tasks with a finite number of labels, we could use the covariance notion to measure the correlation of workers' contributions. Formally, let X, Y be the random variables representing the answers generated by a pair of workers for the same task. The correlation of workers' answers can be formulated using covariance $cov(X, Y)$, defined as $cov(X, Y) = E[XY] - E[X]E[Y]$. By definition, when a pair of answers X, Y are independent, the covariance should be 0.

4.1.1 Measuring Data Correlation. To see whether the answers from a pair of workers are correlated when they work together on a task with peer communication, we examine workers' answers in Session 1 of both treatments in our experiments on image labeling tasks. For each of the 20 images in the experiments (with labels in $\{0, 1\}$), we calculate the covariance between pairs of labels generated in independent tasks (Session 1 of Treatment 1) and discussion tasks (Session 1 of Treatment 2)[8], in which we use the empirical average to replace the expectation in the definition. The results are shown in Figure 3. Perhaps not surprisingly, data collected in independent tasks is mostly independent (with covariance close to 0), while data collected in discussion tasks is correlated to various degrees.

We also calculate the covariance of workers' answers in Session 2 of both treatments to see if the data correlation caused by peer communication has any spillover effect. We find the covariance is close to 0 for both treatments, indicating the correlation in data caused by peer communication does not carry on to later independent work.

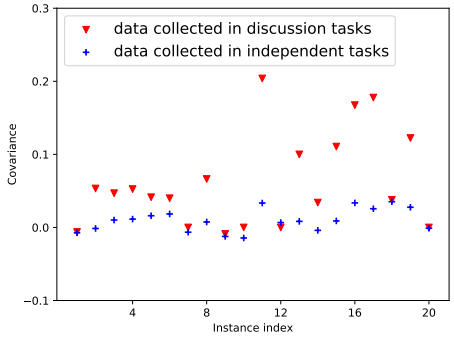

Figure 3: Covariance for data collected in independent tasks and discussion tasks in Session 1 in the image labeling HITs.

4.1.2 Meta-Workers and Meta-Labels. The above observations confirm that workers' answers are indeed correlated when peer communication is deployed. To deal with data correlation, we introduce the notions of *meta-workers* and *meta-labels*. In particular, we denote a pair of workers who talk with each other through the peer communication procedure as a meta-worker, and the pair of labels they generate as a meta-label. As no communication happens between different pairs of workers, we assume each meta-label is drawn independently.

Formally, for a binary classification task, let the true label $z \in \{0, 1\}$. When peer communication is deployed in a task, we obtain a pair of labels, which can be $\{1, 1\}$, $\{0, 1\}$, or $\{0, 0\}$, and we use the *meta-label* s_{11}, s_{01}, and s_{00} to denote them, respectively. Moreover, denote s_1 and s_0 as the label 1 and 0 obtained from a single worker who works independently.

To simplify the discussion, we assume workers are homogeneous. We propose a model to characterize the correlation in data produced in tasks with peer communication as follows: Denote p as the probability of independent workers providing correct labels, i.e., $p = P(s_1|z = 1) = P(s_0|z = 0)$. Additionally, we denote p_+, p_0, p_- as the probability for workers in tasks with peer communication to contribute two correct labels, one correct and one incorrect label, and two incorrect labels[9]:

$$p_+ = P(s_{11}|z = 1) = P(s_{00}|z = 0)$$
$$p_- = P(s_{00}|z = 1) = P(s_{11}|z = 0)$$
$$p_0 = P(s_{01}|z = 1) = P(s_{01}|z = 0)$$

This model provides a principled way to capture different levels of correlation. For example, when the pair of labels are independent, and the probability for each worker in the pair to submit a correct label is still p, we should have $p_+ = p^2, p_- = (1 - p)^2$, and $p_0 = 2p(1 - p)$. When the correlation between a pair of labels is 1 (i.e., the two labels are always the same), we have $p_0 = 0$.

4.1.3 Utilizing Meta-labels. The idea of introducing meta-workers and meta-labels are intuitive but powerful. Below we use maximum likelihood aggregation as an example to demonstrate how the

[7] Our discussion can be extended to classification tasks with any finite number of labels. Extending our results to general types of tasks (such as transcription tasks) requires a well-defined utility notion that can quantify the total utility for any given set of worker contributions. It is an interesting and important future direction.

[8] Recall that in our experiment, we always send a pair of workers to work on the same sequence of tasks. Thus, an independent task is also completed by a pair of workers except that they don't communicate with each other. This allows us to directly calculate the covariance for labels generated in independent tasks.

[9] This is the extension to the standard one-coin model in crowdsourcing literatures. Extending the discussion to model the confusion matrix (e.g., using two different probability values for $P(s_{11}|z = 1)$ and $P(s_{00}|z = 0)$) is straightforward. We do not include the discussion here due to space constraints.

concepts of meta-workers and meta-labels can be incorporated in standard aggregation methods, which provides us with key insights on how to utilize these concepts in our algorithmic framework (we will detail this in Section 4.2).

For a task with unknown true label $z \in \{0, 1\}$, given a set of N labels (or meta-labels) $\boldsymbol{L} = \{l_1, ..., l_N\}$, where $l_i \in \{s_{11}, s_1, s_{01}, s_0, s_{00}\}$, the maximum likelihood estimator for the value of z is defined as:

Definition 1. *Let the ground truth of the task be z. Given a set of labels $\boldsymbol{L} = \{l_1, \ldots, l_N\}$. $\hat{z}$ is a maximum likelihood estimator if*

$$\hat{z} = \begin{cases} 1 & \text{if } P(\boldsymbol{L}|z = 1) \geq P(\boldsymbol{L}|z = 0), \\ 0 & \text{otherwise.} \end{cases}$$

We assume p, p_+, p_0, and p_- are all known. Note that in our algorithmic framework as explained in Section 4.2, we adopt a Bayesian setting to learn how to aggregate the data over time without prior knowledge on values of these parameters. However, when such prior knowledge is available, a weighted majority voting rule can lead to maximum likelihood estimation:

Lemma 1. *Given a set of labels $\boldsymbol{L}$. Let $n_{11}, n_1, n_{01}, n_0, n_{00}$ denote the number of labels $s_{11}, s_1, s_{01}, s_0, s_{00}$ in $\boldsymbol{L}$. Consider the following weighted majority voting rule that generates an aggregation $\hat{z}$*

$$\hat{z} = \begin{cases} 1 & \text{if } w_{11}n_{11} + w_1 n_1 \geq w_{00}n_{00} + w_0 n_0 \\ 0 & \text{if } w_{11}n_{11} + w_1 n_1 < w_{00}n_{00} + w_0 n_0 \end{cases}$$

This weighted majority voting rule leads to maximum likelihood estimation when the weights are set as: $w_{11} = w_{00} = \ln \frac{p_+}{p_-}$, and $w_1 = w_0 = \ln \frac{p}{1-p}$.

Proof. We can write the probabilities on both sides as follows:

$$P(\boldsymbol{L}|z = 1) = p_+^{n_{11}} p^{n_1} p_0^{n_{01}} (1-p)^{n_0} p_-^{n_{00}}$$
$$P(\boldsymbol{L}|z = 0) = p_-^{n_{11}} (1-p)^{n_1} p_0^{n_{01}} p^{n_0} p_+^{n_{00}}$$

Therefore, we have

$$\frac{P(\boldsymbol{L}|z = 1)}{P(\boldsymbol{L}|z = 0)} = \left(\frac{p_+}{p_-}\right)^{n_{11}} \left(\frac{p}{1-p}\right)^{n_1} \left(\frac{1-p}{p}\right)^{n_0} \left(\frac{p_-}{p_+}\right)^{n_{00}}$$

Note that, in maximum likelihood estimator, $\hat{z} = 1$ if $P(\boldsymbol{L}|z = 1)/P(\boldsymbol{L}|z = 0) \geq 1$. Therefore, $\hat{z} = 1$ if

$$\left(\frac{p_+}{p_-}\right)^{n_{11}} \left(\frac{p}{1-p}\right)^{n_1} \geq \left(\frac{p}{1-p}\right)^{n_0} \left(\frac{p_+}{p_-}\right)^{n_{00}}$$

The proof is completed by taking logarithm on both sides. □

As a sanity check, we can see that when a pair of labels are independent (i.e., $p_+ = p^2$ and $p_- = (1-p)^2$), we have $w_{11} = w_{00} = 2w_1 = 2w_0$, implying that the weight of $\{1, 1\}$ label is twice as the weight of $\{1\}$ label, and this is essentially a simple majority voting.

Note that in the maximum likelihood aggregation, the number of meta-label s_{01} does *not* play a role in the aggregation process. In other words, we may interpret the generation of meta-labels as follows: with probability p_+ (or p_-), a meta-worker generates a correct label s_{11} (or incorrect label s_{00}), while with probability p_0 she generates *no* label at all. The above weighted majority voting rule then simply indicates that different weights need to be used for labels generated by independent workers or meta-workers. Following a similar idea, in the following algorithmic framework, we only take the meta-label s_{00} and s_{11} into consideration and discard the meta-label s_{01} when inferring the correct labels of a task from a collection of labels and meta-labels.

4.2 Our Algorithmic Framework

With the notions of meta-workers and meta-labels in place, we have a principled way to deal with correlated data in peer communication. However, we still need to address the second challenge of balancing the quality and cost. In particular, while introducing peer communication leads to a significant improvement in work quality for individual microtasks, such improvement comes with extra cost, such as the financial payment incurred to recruit more workers (e.g., at least two workers are needed for peer communication to happen), the compensation for longer task completion time due to discussions, and the additional administrative costs for synchronizing the work pace of worker pairs. As a result, a requester needs to face the quality-cost tradeoff when deploying peer communication.

We now describe our algorithmic framework, built on the constrained Markov decision process (CMDP), that adaptively decides for a requester with a limited budget, whether and when peer communication should be deployed in each of his tasks with the goal of maximizing his total utility (i.e., the average accuracy for all classification tasks), while taking into account data correlation and differing costs for deploying peer communication.

4.2.1 Problem Setup. Our problem setup is inspired by the method by Chen et al. [8] to optimally allocate budget among task instances in crowdsourcing data collection. Our setup differs from theirs in two fundamental ways due to the presence of peer communication strategy. First, they don't and don't need to consider the issue of data correlation. Second, in their setting, the cost for acquiring labels is fixed, while we need to deal with the differing costs when peer communication is deployed in a task. Therefore, instead of modeling the decision-making problem as a Markov decision process framework (as in Chen et al. [8]), we adopt a constrained Markov decision process framework and include the meta-label concept in our formulation.

Formally, suppose a requester gets a budget of $\mathcal{B}$ and a batch of K binary classification tasks, and he needs to estimate the label for each of these tasks. The goal of the requester is to maximize the average accuracy of the estimated labels across all tasks through spending the budget to solicit labels from crowd workers and then aggregating the collected labels. We describe the setting in which workers are homogeneous (however, their performance might be different when working independently or when working with peer communication). Extensions to settings with heterogeneous workers are straightforward as described by Chen et al. [8].

Assume the K tasks are independent from each other, and $Z_k \in \{0, 1\}$ represents the true label for task k ($1 \leq k \leq K$). We use the notations $\theta_k \in [0, 1]$, $\alpha_s \in [0, 1]$, and $\alpha_p \in [0, 1]$ to model the label generation process, where θ_k characterizes the difficulty of task k, α_s and α_p characterize workers' performance when working independently and working with peer communication. In particular, we denote $p_{k,s,1}$ (or $p_{k,s,0}$) as the probability for a single worker (who works independently) to provide label 1 (or 0) for task k. We define $p_{k,s,1} = \alpha_s\theta_k + (1-\alpha_s)(1-\theta_k)$ and $p_{k,s,0} = 1 - p_{k,s,1}$. To obtain intuition for the parameters of the model, assume $\alpha_s = 1$, we can see that θ_k captures the difficulty of task k: When θ_k is

close to 0.5, workers are effectively making random guess (hence the task is difficult), and when θ_k is close to 0 or 1, independent workers can consistently provide the same label (hence the task is easy). Similarly, α_s can then be interpreted as the worker skill and a larger α_s implies a higher skill. We assume θ_k is consistent with the label Z_k, which means $Z_k = 1$ if and only if $\theta_k \geq 0.5$.

Recall that we denote a meta-worker as a pair of workers in tasks with peer communication. We use α_p to denote the skill of meta-workers, and the probability for a meta-worker to generate a meta-label s_{01} for task k is denoted as q_k. Conditioned on a meta-worker contributing a meta-label other than s_{01}, α_p is similarly defined as α_s. That is, when $p_{k,p,1}$ and $p_{k,p,0}$ is the probability for a meta-worker to generate meta-labels s_{11} and s_{00}, we have $p_{k,p,1} = (1-q_k)(\alpha_p\theta_k + (1-\alpha_p)(1-\theta_k))$ and $p_{k,p,0} = 1 - p_{k,p,1} - q_k$.

After describing the data generation model, we formulate the online decision problem faced by the requester. The requester recruits workers to label his tasks in a sequential manner. Specifically, at each time step t, the requester decides on a task k_t to work on, and he can solicit label(s) from crowd workers on this task using one of the two strategies (the strategy is denoted as x_t): first, the requester can recruit a *single* worker to work on the task ($x_t = 0$), and thus obtain a label for that task; second, the requester may recruit a meta-worker (i.e., a *pair* of workers following the peer communication procedure) to work on the task ($x_t = 1$), and thus obtain a meta-label for the task. We denote c_s as the cost for recruiting a single worker and c_p ($c_p > c_s$) as the cost of recruiting a meta-worker through peer communication strategy.

Naturally, the requester's activity in each time step can be summarized through the tuple (k_t, x_t). We also denote y_t as the label (or meta-label) obtained by the requester at time t for task k_t. By the time $t_{\mathcal{B}}$ that the requester exhausts his budget, his activity history is $\mathcal{H}_{\mathcal{B}} = \{(k_0, x_0, y_0), ..., (k_{t_{\mathcal{B}}}, x_{t_{\mathcal{B}}}, y_{t_{\mathcal{B}}})\}$. The requester then aggregates the data he has collected and infers the true labels for each of the K tasks such that the expected accuracy across all K tasks, conditioned on the activity history $\mathcal{H}_{\mathcal{B}}$, is maximized.

4.2.2 A Constrained Markov Decision Process Formulation. We now formally model the requester's decision-making problem as a constrained Markov decision process:

- **States**: the state s_t is a $K \times 4$ matrix, where $s_t(k, \cdot)$ is a 1×4 vector with each entry representing before time t, the number of label (or meta-labels) s_0, s_1, s_{00}, s_{11} obtained for task k. Note that following the idea that we have discussed in Section 4.1.3, we consider the meta-label s_{01} to contributes zero utility to the requester and thus we do not include the count of it in the state.
- **Actions**: $a_t = (k_t, x_t)$, where k_t is the task to work on at time t, and $x_t \in \{0, 1\}$ represents the worker recruiting strategy, with 0 being recruiting a single worker working independently and 1 being recruiting a pair of workers to follow the peer communication procedure.
- **Transition probabilities**: When $a_t = (k_t, x_t = 0)$,

$$Pr(s_{t+1}|s_t, a_t) = \begin{cases} p_{k_t,s,1} & \text{if } s_{t+1} = s_t + (\mathbf{0}, \mathbf{e_{k_t}}, \mathbf{0}, \mathbf{0}) \\ p_{k_t,s,0} & \text{if } s_{t+1} = s_t + (\mathbf{e_{k_t}}, \mathbf{0}, \mathbf{0}, \mathbf{0}) \\ 0 & \text{otherwise} \end{cases}$$

where $\mathbf{e_{k_t}}$ is a $K \times 1$ vector with value 1 at the k_t-th entry and 0 at all other entries. On the other hand, when $a_t = (k_t, x_t = 1)$,

$$Pr(s_{t+1}|s_t, a_t) = \begin{cases} p_{k_t,p,1} & \text{if } s_{t+1} = s_t + (\mathbf{0}, \mathbf{0}, \mathbf{0}, \mathbf{e_{k_t}}) \\ 1 - p_{k_t,p,1} - q_{k_t} & \text{if } s_{t+1} = s_t + (\mathbf{0}, \mathbf{0}, \mathbf{e_{k_t}}, \mathbf{0}) \\ q_{k_t} & s_{t+1} = s_t \\ 0 & \text{otherwise} \end{cases}$$

- **Rewards**: We adopt the same reward function as that used by Chen et al. [8]. Specifically, we assume the parameters $\theta_k, \alpha_s, \alpha_p$ are sampled from three separate Beta prior distributions, and we update the posteriors of these distributions through variational approximation where hyper-parameters are decided by moment matching. Doing so, we can then define the reward as $R(s_t, a_t) = \mathbb{E}(h(P_{k_t}^{t+1}) - h(P_{k_t}^t))$, where P_k^t is the probability of the parameter θ_k taking on a value of at least 0.5 given the posterior of θ_k at time t, $h(x) = \max(x, 1-x)$, and the expectation is taken over all possible label y_t observed after action a_t.
- **Constraint**: Different from the setting in the work by Chen et al. [8], as different actions imply different costs, we need to explicitly characterize the budget constraint for our problem. Formally, the requester needs to ensure the budget constraint is satisfied. $\sum_{t=0}^{t_{\mathcal{B}}} c_s \mathbf{1}(x_t = 0) + c_p \mathbf{1}(x_t = 1) \leq \mathcal{B}$, where $\mathbf{1}(.)$ is the indicator function.

4.2.3 Proposed Algorithm. We adopt the method of Lagrangian multipliers to solve the above constrained optimization problem, which converts the problem of maximizing the total reward (i.e., $\sum_{t=0}^{t_{\mathcal{B}}} R(s_t, a_t)$) under the budget constraint into a simpler problem of maximizing the auxiliary function $\sum_{t=0}^{t_{\mathcal{B}}} R(s_t, a_t) - \lambda \sum_{t=0}^{t_{\mathcal{B}}} (c_s \mathbf{1}(x_t = 0) + c_p \mathbf{1}(x_t = 1))$. Notice this optimization problem is equivalent to solve a (unconstrained) Markov decision process where reward in each step is redefined as $R'(s_t, a_t) = R(s_t, a_t) - \lambda(c_s \mathbf{1}(x_t = 0) + c_p \mathbf{1}(x_t = 1))$. We use the optimistic knowledge gradient technique introduced by Chen et al. [8] to solve the optimal policy of this MDP, which produces a single-step look-ahead policy that maximizes the highest reward at each step. Note that in theory, we can compute the optimal value of λ by solving the dual of the constrained MDP. In practice, we have experimented with multiple different λ values and find that the choice of λ has limited influence on the performance of our algorithmic approach.

4.3 Evaluations

We evaluate the effectiveness of our algorithmic approach using both real-world data and synthetic data.

4.3.1 Experiments on Real Data. Using the real data that we collected in image labeling tasks of our experimental study, we compare the performance of our algorithm with a couple of baseline algorithms. In our evaluation, we set the cost of recruiting a single worker as $c_s = 1.0$ and the cost of recruiting a pair of workers to work on a task with peer communication (i.e., a meta-worker) $c_p = 2.5$. Note that we have examined a range of different values of c_p from 1.5 to 3.5 and the results are qualitatively similar. The prior distribution for θ_k is set as Beta(1, 1), where the prior distributions for α_s and α_p are all set to be Beta(4, 1). For this evaluation, we only considered the final labels that workers in our experimental

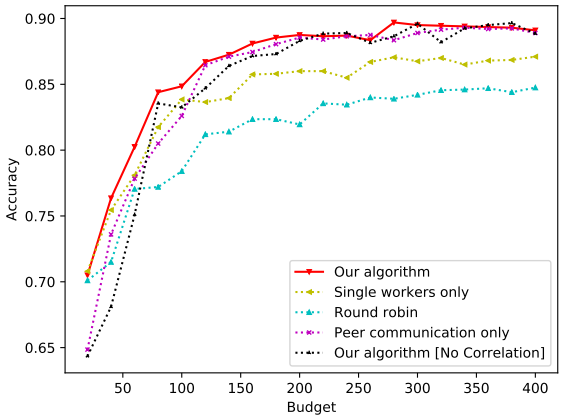
study submit in the *first two tasks* of the image labeling HIT[10]. Thus, when $a_t = (k_t, 0)$, we randomly sampled a label from Treatment 1 workers who had completed task k_t in their first two (independent) tasks, and when $a_t = (k_t, 1)$, we randomly sampled a label from Treatment 2 workers who had completed task k_t in their first two (discussion) tasks.

The performance of our algorithmic approach is compared against the following baseline approaches:

- *Round robin*: in each round, the requester decides which task to work on in a round robin fashion, and he always recruit a single worker to work on that task independently.
- *Single workers only*: in each round, the requester recruits a single worker to work on a task independently, and this task is optimally decided (effectively by considering only actions with $x_t = 0$ in our algorithm).
- *Peer communication only*: in each round, the requester recruits a pair of workers to work on a task with peer communication, and this task is optimally decided (effectively by considering only actions with $x_t = 1$ in our algorithm).
- *Our algorithm [No correlation]*: in each round, the requester uses our algorithm to decide whether to deploy peer communication and which task to work. The only difference is that this baseline treats the two labels from peer communication as two independent labels while our algorithm incorporates the concept of meta-labels to deal with data correlation.

We conduct this evaluation on a range of budget level from 20 to 400 with an interval of 20. At each budget level, we implement each of the decision-making strategies for 100 times, and we report the average level of overall accuracy the requester obtains across the 20 tasks when she exhausts the budget in Figure 4.

As shown in Figure 4, our proposed algorithm outperforms all baseline strategies. In particular, we make a few observations as follows. First, comparing the performance of our algorithm and that of the "No Correlation" strategy, it is clear that incorporating meta-labels to deal with data correlation has improved the requester's overall utility. In fact, even for the "peer communication only" strategy, we also implement two versions, and the version for which the idea of meta-labels is used also outperforms the other version treating two labels generated by pairs of workers as independent. In the following discussion, unless otherwise specified, we adopt the meta-worker ideas in our implementation when peer communication is used. Second, strategies involving peer communication converge to a better overall accuracy than strategies without peer communication does. This is due to the fact that for some tasks in our experiment, the majority of workers who work independently provide incorrect answers while the majority of workers with peer communication provide correct answers. Third, adaptively determining whether and when to deploy peer communication outperforms fixed recruiting strategies, as illustrated by the superior performance of our algorithm over both the "single workers only" and "peer communication only" strategies. Finally, adaptively deciding which task to label next significantly improves the total utility than random task assignment does, e.g., through observing the significantly worse performance of the baseline "round robin" strategy.



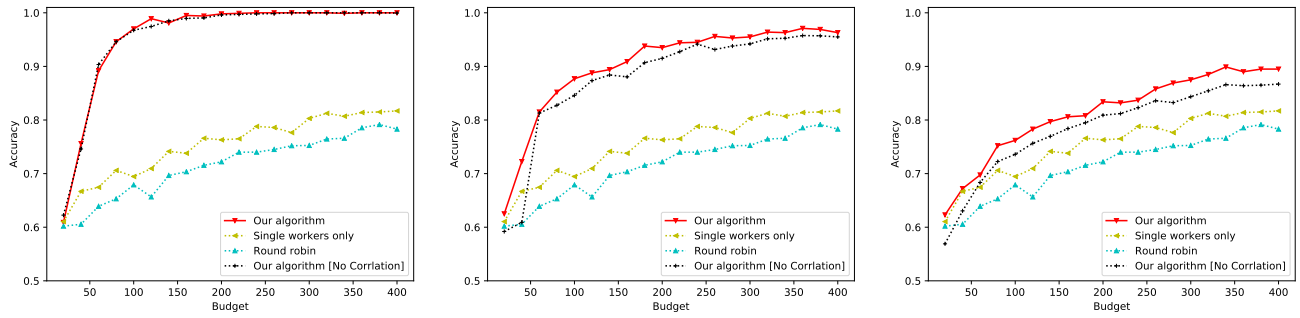


Figure 4: Evaluating the performance of the proposed approach on real datasets.

4.3.2 Experiments on Synthetic Data. To the best of our knowledge, our dataset is the only dataset that deploys peer communication for crowdsourcing data collection. Therefore, to further investigate the properties of our proposed algorithm, we generate synthetic data to evaluate our algorithm. In particular, we explore how the performance of our algorithm changes along the following three dimensions: 1) the level of data correlation of workers' answers in tasks with peer communication, 2) the performance gap between workers who work independently and workers who discuss with others via peer communication, and 3) the cost differences of hiring a single worker and hiring a pair of workers for peer communication. In the base setup, we set θ_k to be uniformly drawn from $[0.5, 1]$, α_s drawn from a normal distribution with mean 0.7 and variance 0.01, α_p drawn from a normal distribution with mean 0.9 and variance 0.1. We also set $c_s = 1$ and $c_p = 2.5$.

We first modify the level of data correlation of workers' answers in peer communication. This can be done by changing the value of q_k, i.e., the probability of a pair of workers in peer communication to generate the meta-label s_{01}. In strong correlation, we set $q_k = 0$, which means the two workers are entirely correlated (always generating the same label). In no correlation, we set q_k to the value such that the two labels in a meta-label are independently generated (i.e., $q_k = 2\sqrt{p_{k,p,1}p_{k,p,0}}$, which can be derived using our model discussed in Section 4.1.2). In weak correlation, q_k is uniformly drawn between the above two values. We compare the performance between our algorithm and "our algorithm [no correlation]", which treats the two labels from a meta-label as independent labels. As shown in Figure 5, the performance gap becomes larger as the correlation becomes stronger[11]. This validates the benefits of incorporating meta-labels in our framework when there is data correlation.

[10]Recall that we set out to examine the effects of peer communication using the first two tasks in each HIT.

[11]As a side note, the overall performance is lower in strong correlation since we fixed α_p in all three plots; two independent labels brings more information than two correlated labels. Since our goal is to measure the gap between two algorithms, we didn't tune the parameter to normalize the algorithm performance.

(a) No Correlation (b) Weak Correlation (c) Strong Correlation

Figure 5: The performance comparison under different levels of correlation in peer communication.

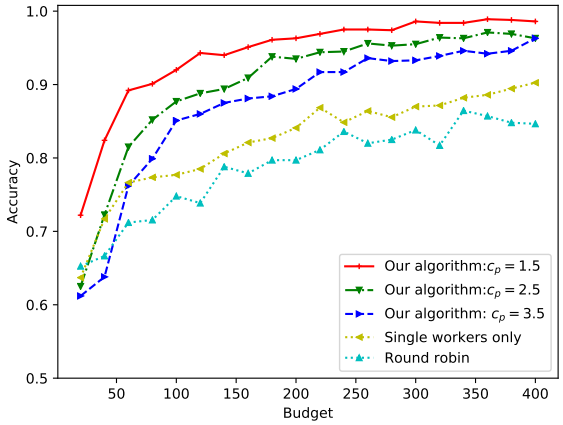

Figure 6: Modify the cost of peer communication.

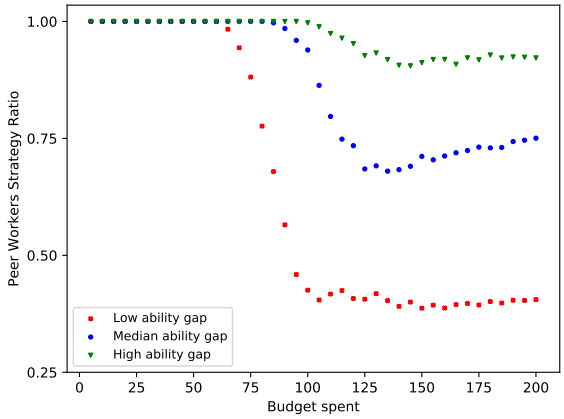

Figure 7: Ratio of peer communication strategies deployed.

We then change the cost of deploying peer communication c_p to be from $\{1.5, 2.5, 3.5\}$. As shown in Figure 6, our algorithm performance decreases as c_p increases. However, even when the cost of peer communication is pretty large (i.e., $c_p = 3.5$), utilizing peer communication is still beneficial. Next, we vary the performance gap between single workers (who work independently) and meta-workers by fixing the mean of α_p to be 0.9 and set the mean of α_s to be 0.8, 0.7, and 0.6. The results are qualitatively similar to changing c_p (e.g., larger skill gap corresponds to smaller c_p). To provide more insights for our algorithm, we demonstrate this result in a different plot. In particular, we fix the budget to be 200 and run our algorithm 100 times. We record the worker recruiting strategy (hiring single workers or deploying peer communication) our algorithm takes at every step, and then calculate the ratio of peer communication strategy as a function of the budget spent so far. As shown in Figure 7, our algorithm always starts by deploying peer communication. When the marginal rewards for hiring peer communication is not high enough to justify the higher cost, our algorithm gradually switches to hire single workers. These two figures demonstrate that our algorithm brings in benefits under a wide range of settings and has stronger benefits when c_p is small or when the performance gap between single workers and meta-workers (with peer communication) are higher.

5 CONCLUSION

In this paper, we relax the common assumption of data independence in crowdsouring data collection. In particular we explore peer communication, in which a pair of crowd workers directly communicate when producing the data. We first examine the effects of peer communication on the quality of crowd work produced. Randomized experiments conducted on Amazon Mechanical Turk demonstrate that the work quality significantly improves in tasks with peer communication. We then study how to utilize peer communication in crowdsourcing data collection. In particular, we introduce the notions of meta-workers and meta-labels to deal with data correlation caused by peer communication. We then develop an algorithmic framework, built on constrained Markov decision process, to optimally determine whether and when to deploy peer communication in crowdsourcing data collection, with the goal of maximizing the total utility of requesters while satisfying budget constraints. Experiments conducted on both real data and synthetic data demonstrate the advantage of our proposed algorithms over baseline approaches.

Our results suggest the potential benefits of incorporating peer communication in crowdsourcing and provide a framework for better utilizing these benefits. We hope this work could open more discussions on designing and leveraging more complex, useful worker interactions to further enhance crowdsourcing.

ABSTRACT

Real-time traffic volume inference is key to an intelligent city. It is a challenging task because accurate traffic volumes on the roads can only be measured at certain locations where sensors are installed. Moreover, the traffic evolves over time due to the influences of weather, events, holidays, etc. Existing solutions to the traffic volume inference problem often rely on dense GPS trajectories, which inevitably fail to account for the vehicles which carry no GPS devices or have them turned off. Consequently, the results are biased to taxicabs because they are almost always online for GPS tracking. In this paper, we propose a novel framework for the citywide traffic volume inference using both dense GPS trajectories and incomplete trajectories captured by camera surveillance systems. Our approach employs a high-fidelity traffic simulator and deep reinforcement learning to recover full vehicle movements from the incomplete trajectories. In order to jointly model the recovered trajectories and dense GPS trajectories, we construct spatiotemporal graphs and use multi-view graph embedding to encode the multi-hop correlations between road segments into real-valued vectors. Finally, we infer the citywide traffic volumes by propagating the traffic values of monitored road segments to the unmonitored ones through masked pairwise similarities. Extensive experiments with two big regions in a provincial capital city in China verify the effectiveness of our approach.

1 INTRODUCTION

With the vast deployment of sensors, such as loop detectors and surveillance cameras, and the rapid development of data storage techniques, an intelligent city can collect and store a large amount of traffic volume data on the daily basis. It is vital to not only monitor "visible" traffic volumes in real time but also infer those unseen by the sensors. Information extracted from the traffic volume data may contribute to a wide range of urban applications, such as route selection, traffic control, and urban planning, etc.

However, the sensors are often displaced away from each other to a certain distance, and some of them could fail now and then. As a result, the citywide traffic volume data inevitably have lots of missing values, causing challenges to many downstream applications. In this paper, we aim to develop techniques for the citywide traffic volume inference — in other words, to estimate the traffic volume of each and every road segment in every time interval in the city.

The citywide traffic volume inference is a very challenging problem for two major reasons. Firstly, sensors to monitor the traffic are not only sparse but also non-uniform, resulting in relatively low spatial coverage [15]. It is difficult to obtain any historic traffic data for the currently unmonitored roads. Secondly, traffic patterns evolve over time and could suddenly change rapidly due to big events. The high dynamism of traffic makes it difficult to infer the traffic volume data by drawing similarities between different road segments or across various time intervals.

Existing works on inferring the traffic volume mostly fall into the category of missing (spatiotemporal) data inference. A basic and representative framework is to estimate the missing values by linear interpolation [3, 9, 27, 44]. However, those approaches fail to maintain the global consistency of the inferred results and assume simple structures underlying the historic spatiotemporal data. Another frequently used method is collaborative filtering [40]. However, this approach fails for the unmonitored road segments which have no historical information.

Some recent studies use dense trajectories from mobile devices for traffic volume inference. Zhan et al. estimate the citywide traffic volume by combining GPS trajectories with road networks, point-of-interest information, and weather conditions. Meng et al. characterize the similarities between roads using travel speeds extracted from taxi trajectories. However, the dense trajectories, no matter extracted from GPS or taxi, are biased representations of the real traffic. After all, taxi is only a small portion of the total vehicles and not all vehicles carry or turn on the GPS devices.

Partially observed trajectories, which are captured by the static and discrete sensors (e.g., a vehicle tracked by a camera network), are notably under-explored by the existing works. Unlike the dense trajectories (e.g., generated by "active" GPS devices), the partially observed trajectories are incomplete because they are obtained from the "passive" static sensors (e.g., cameras). As a result, they are available for almost all kinds of vehicles no matter they have GPS devices installed or not. Compared with dense trajectories, such incomplete trajectories are collected in a much bigger scale everyday. For instance, the surveillance system recognizes and provides the incomplete trajectories of more than 1.1 million unique vehicles in a provincial capital city in China every single day at the time of this paper written. To the best of our knowledge, the incomplete trajectories have not been utilized before for the traffic volume inference.

Of course, it is more involved to model the spatiotemporal patterns of incomplete trajectories than their dense counterparts. The uncertainties between monitor points have to be taken care of, as well as the noisy measurements at the monitor points. There exist some research tackling the uncertainty problem. For example, Zheng et al. investigate how to reduce the uncertainty in low-sampling-rate trajectories by inferring the possible routes therein. Banerjee et al. employ road-network constraints to summarize all probable routes in a holistic manner. Li et al. use the GPS snippets to help recover the full trajectories. However, these methods require that every road segment has appeared at least once in the past in order to guide the recovering procedure of the full trajectories. Besides, their performance significantly degrades when the traffic pattern changes, e.g., due to big events or severe weather.

To address the aforementioned challenges, we propose a novel framework to **J**ointly **M**odel the **D**ense and **I**ncomplete trajectories (JMDI) for the citywide traffic volume inference. Specifically, we first recover detailed vehicle movements given the incomplete trajectories using a high-fidelity city traffic simulator. We tune the simulator's parameters using deep reinforcement learning so as to automatically identify the proper simulator state which matches the real data. After that, two spatiotemporal graphs are constructed using the recovered trajectories and the dense GPS trajectories, respectively. The graphs are a natural choice for modeling the dynamism of traffic volumes of road segments and over time. Meanwhile, the graphs enable us to conveniently embed the road segments (nodes of the graph) to continuous-value vectors. Finally, we use these embeddings to construct pairwise similarities between the road segments and then propagate the known traffic volumes to the road segments of unknown traffic.

We conduct extensive experiments on large-scale real-world traffic datasets collected from a provincial capital city in China. The dense trajectories are available for GPS-enabled taxi. For the incomplete trajectories, we extract partially observed information from the surveillance cameras as a result of the plate number identification technique [7]. We evaluate the proposed framework JMDI against competitive baselines on two selected regions of the city and during different time periods. We also study some ablations of our approach to highlight the effectiveness of main components of JMDI.

We summarize our main contribution as follows.

- We propose a novel framework, called JMDI, to infer citywide traffic volumes using both dense and incomplete traffic trajectories.
- We propose to use a high-fidelity traffic simulator to recover full vehicle movements from incomplete trajectories. Moreover, in order to efficiently tune the simulator towards the real data, we design a deep reinforcement learning algorithm to automatically set the parameters of the simulator.
- We present a joint embedding method to learn meaningful representations of road segments using spatiotemporal graphs. We further use a semi-supervised propagation method to infer citywide traffic volume values.
- We conduct extensive experiments on large-scale real-world traffic datasets to validate the proposed approach.

To the best of our knowledge, this work is the first to jointly model the dense and incomplete trajectories for the citywide traffic volume inference. Since the dense GPS trajectories are biased to taxi, the incomplete trajectories obtained from other sensors show strong complement to their dense counterparts. Jointly, they give rise to better results than either individually.

2 RELATED WORK

2.1 Traffic Volume Inference

Some studies [9, 27, 44] use linear regression models to infer missing traffic speed or travel time based on taxi trajectories. Aslam et al. [3] learn a regression model with taxi GPS trajectories to estimate traffic volume. *However, regression methods require a great amount of labeled training data, which is unavailable in our problem setting.*

Another category of prior studies apply principal component analysis (PCA) (e.g., [2, 13, 23, 24]) or collaborative filtering (CF) (e.g., [26, 31, 40]) to fill in missing values in spatiotemporal data. PCA-based methods extract traffic patterns from observed data using various PCA techniques, such as Bayesian PCA [24], Probabilistic PCA [13, 23] and FPCA [2]. CF-based methods recover missing values by decomposing spatiotemporal data into the product of low-rank matrices. Yi et al. [40] fill missing values in geo-sensory time series using CF from multiple spatial and temporal perspectives. Ruan et al. [26] use tensor completion to recover missing values in spatiotemporal sensory data. Wang et al. [31] propose a tensor

factorization method to estimate the missing travel time for drivers on road segments. *However, both PCA-based and CF-based methods rely on historical data when filling in. They are unable to handle our problem since the traffic volume of unmonitored road segments are totally missing.*

Graph-based Semi-supervised learning (SSL) method [6] has been widely applied for unlabeled data inference, which can be used for inferring missing values. Label propagation [47], a classic semi-supervised method, infers unobserved labels by propagating existing labels on an affinity graph. Other SSL based methods [1, 36, 46] have been proposed to model the similarities of vertices in the affinity graph. *Although Graph-based SSL methods can be applied to our problem, they only consider the similarities between vertices. Therefore, they fail to utilize rich traffic flow information for volume inference.*

Other existing work aim to infer traffic volume values of road segments using loop detector [12, 17, 35], surveillance cameras [41], or float car trajectories [3, 8, 42]. Studies [12, 35, 41] tackle the volume estimation of a single road segment with loop detectors or surveillance cameras. Thus their methods cannot infer citywide traffic volume. Zhan et al. [42] propose a method to estimate citywide traffic volume using probe taxi trajectories. They estimate travel speeds for volume inference using full taxi trajectories. Recently, Meng et al. [17] propose ST-SSL that predicts city-wide traffic volume values using loop detector incorporating taxi trajectories. They first build a spatiotemporal affinity graph based on travel speed pattern and spatial correlations extracted from loop detector and taxi trajectories. Then they infer traffic volume using semi-supervised learning method on the spatiotemporal affinity graph. *However, both [42] and ST-SSL [17] require full observation of trajectories, thus they are unable to utilize incomplete counterparts.*

2.2 Trajectory Recovery

Several methods (e.g., [4, 34, 45]) have been proposed to predict complete trajectories from partial observations. Zheng et al. [45] investigate how to reduce the uncertainty in low-sampling-rate trajectories. This approach requires every road segment appearing in historical data, which is impossible for incomplete trajectories. Banerjee et al. [4] infer uncertain trajectories from network-constrained partial observations by summarizing all probable routes in a holistic manner. However, their method ignores many important factors such as vehicle interaction and road constraints. *More important, these methods require historical trajectories as input, which cannot be applied to recovering routes in our problem.*

3 NOTATIONS AND PROBLEM STATEMENT

Let $\{r_1, r_2, \ldots, r_m\}$ denote road segments of a road network in a city region. Each road segment is a directed short portion of a road. The traffic volume of a road segment can be represented using the total number of vehicles traversing through it during a fixed time interval. We split the whole time period (e.g, one week) into equal-length continuous time intervals and use vector $\mathbf{x}_i = (x_{i1}, x_{i2}, \ldots, x_{in})$ to denote the traffic volume values of the road segment r_i during the past n continuous time intervals. Note that the traffic volume values are only available at monitored road segments.

Different sources of trajectories (i.e., incomplete observations from cameras or GPS trackers of taxi) are denotes by $\Delta^{\mathrm{S}} = \{\delta_i\}$, where the superscript S stands for the source S. A trajectory $\delta_i = p_{i,1} \rightarrow p_{i,2} \rightarrow \cdots \rightarrow p_{i,s}$ is a list of s points in chronological order, where each point $p = \langle l, t \rangle$ is a location coordinate l (i.e., latitude and longitude) and a time stamp t. We denote by Δ^{D} and Δ^{I} dense and incomplete trajectories, respectively. Note that points contained in the incomplete trajectories Δ^{I} are restricted to monitor points — therefore they form a fixed finite set.

The citywide traffic volume inference problem is defined as follows: Given the road network, observed traffic volume values $\{x_{it}\}$ at monitored road segments, and multiple sources of trajectories Δ^{S} ($\mathrm{S} \in \{\mathrm{D}, \mathrm{I}\}$), our goal is to infer the traffic volume values of any unmonitored road segment at any time interval.

4 APPROACH

Figure 1 illustrates the proposed framework JMDI. First, we design an algorithm to recover full trajectory from incomplete observations using a traffic simulator, whose parameters are tuned by deep reinforcement learning. Next, we construct spatiotemporal graphs from the dense and incomplete trajectories. In order to model the spatiotemporal dynamics of traffic volume, we then employ a multi-view graph embedding technique [25] to learn representation vectors for road segments. Finally, we present a propagation method which infers the citywide traffic volume values according to pairwise similarities between different road segments. In the following sections, we introduce each major component of our solution in detail.

4.1 Trajectory Recovery

In this section, we introduce the recovery process for incomplete trajectories. Instead of data-driven algorithms, we incorporate a high-fidelity traffic simulator [11] for the recovery. Different from previous trajectory recovery methods (e.g., [4, 45]), the simulator jointly models the influence of traffic rules as well as vehicle interactions. Furthermore, we propose a novel deep reinforcement learning [20] algorithm that improves the accuracy of trajectory recovery by tuning time-aware hyper-parameters of the simulator.

4.1.1 Trajectory Recovery via Simulator. We first estimate the missing portions of incomplete trajectories by using rich spatiotemporal movement patterns. Unlike the existing methods [4, 14, 37, 45], our solution relies on a traffic simulator [11], which naturally observes road network constraints (e.g., no turn on red at some intersections) and the global consistency of traffic in the road network. It also captures the influence of vehicle interactions.

Specifically, we simulate all vehicles simultaneously in real-world road networks using the traffic simulator named *SUMO* [11], conditioning on observations in the incomplete trajectories. Given an incomplete trajectory $\delta_i = p_{i,1} \rightarrow p_{i,2} \rightarrow \cdots \rightarrow p_{i,s}$, the simulator initializes a vehicle at the corresponding time and location of each point $p_{i,j}$. Then, the vehicle moves toward $p_{i,j+1}$ along the most possible route selected by the simulator. Multiple factors, such as distance, speed, traffic jams, etc., are considered jointly to find the best route. The simulated results for all points $p_{i,j} \rightarrow p_{i,j+1}$ are collected to fill in the missing values in the incomplete trajectories.

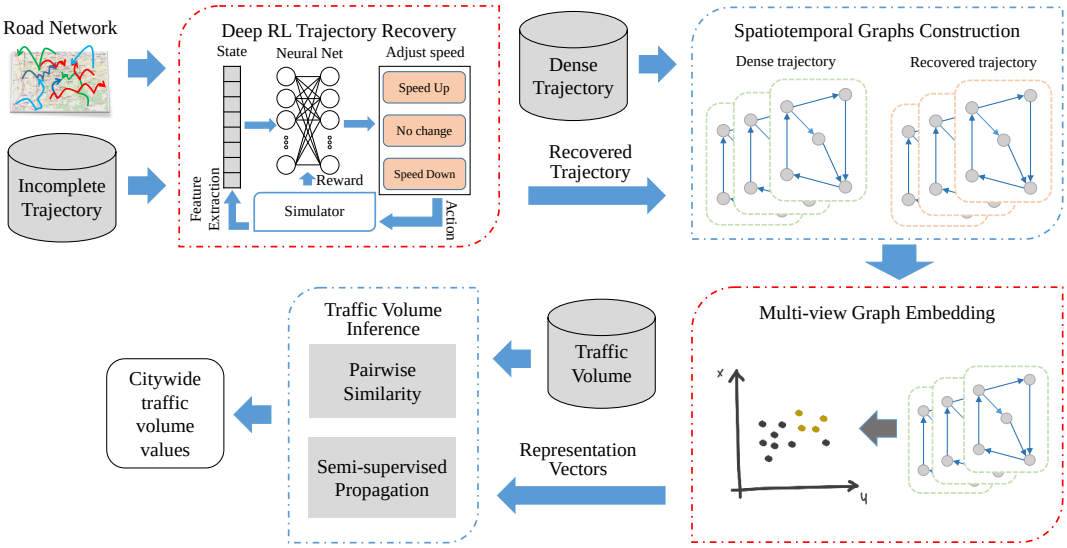

Figure 1: Overview of the proposed JMDI framework.

However, blindly using the simulator for trajectory recovery without careful validation is not rigorous. Therefore, a novel metric is proposed for trajectory recovery evaluation. Taking incomplete trajectory δ_i as an example, we first measure the relative arrival time $t_{i,j}$ for $p_{i,j} \in \delta_i$, using time stamps provided by δ_i. Here $t_{i,j}$ equals to the time consumption of traversing between $p_{i,j}$ and $p_{i,1}$ ($t_{i,1} = 0$) captured by real-world sensors. Since vehicles would traverse through each monitor point successively in the simulating environment, we compute the relative arrival time at each $p_{i,j}$ again, using time stamps from simulating results. Similarly, let $t^{\text{simu}}_{i,j}$ denote the relative arrival time at $p_{i,j}$ of the simulated vehicle. Given those two kinds of relative arrival time $t_{i,j}$ and $t^{\text{simu}}_{i,j}$, the trajectory recovery accuracy can be estimated using the following equation:

$$err = \sum_{\delta_i \in \Delta^{\text{I}}} \sum_{p_{i,j} \in \delta_i} |t^{\text{simu}}_{i,j} - t_{i,j}| / (\sum_{\delta_i \in \Delta^{\text{I}}} \sum_{p_{i,j} \in \delta_i} 1). \quad (1)$$

The intuition behind Equation 1 is that larger errors will be generated if the recovered trajectories differ a lot from the real ones (i.e., larger $|t^{\text{simu}}_{i,j} - t_{i,j}|$). And the recovered trajectories have low err if the simulated vehicles arrive at monitor points sharply.

4.1.2 *Deep Reinforcement Learning for Parameter Tuning.*

There are a few major parameters of the simulator (see Table 1) we have to tune in order to achieve good simulation results (in other words, small err). For example, changing the speed of vehicles could directly affect the arrival time at each monitored point in the simulating environment, and modifying the lane-changing rules could lead to traffic jams. In order to simulate as realistic as possible, parameter tuning is key. Unfortunately, it is nontrivial to tune the parameters because they are inter-correlated and their effects on the traffic volume are delayed. For example, we may speed up a vehicle anytime but the results of the acceleration cannot be validated until the vehicle arrives at the next monitor point. Besides, the change of speed of one vehicle may change the speed of others.

Table 1: Examples of parameters in *SUMO*.

Parameters	Descriptions
stop	Lets the vehicle stop at the given edge
change lane	Change to the lane with the given index
slow down	Change the speed smoothly
speed	Sets the vehicle speed to the given value
change target	Change the vehicle's destination edge
change route	Assigns the vehicle's new route
speed factor	Sets the vehicle's speed factor
max speed	Sets the vehicle's maximum speed

To address the above challenges, we propose a reinforcement learning (RL) algorithm to tune the simulator's parameters such that the simulated trajectories can better match the sparsely monitored real data. The RL algorithm successfully avoids the manual configuration of the simulator in a tedious trial-and-error manner.

The general goal of reinforcement learning is to maximize the expected cumulative rewards in a sequential decision making process. Given a set of states $\{s_i\}$ and actions $\{a_i\}$, an action a is taken by the agent following a certain policy π after seeing the current state s in each step. The expected return of each potential action a under state s is evaluated using the Bellmen equation [32],

$$Q_\pi(s, a) = \mathbf{E}(\sum_{i=1}^{\infty} \gamma^{i-1} R_i | S_0 = s, A_0 = a, \pi), \quad (2)$$

where γ is the discount factor for future rewards. The goal of reinforcement learning is to maximize the expectation of accumulative future rewards through the sequential process.

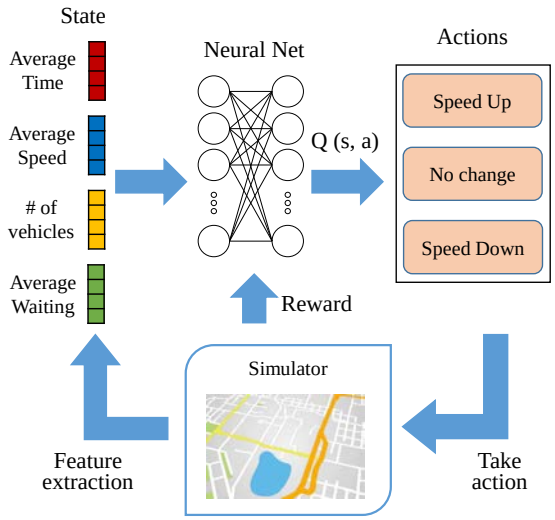

Figure 2: Deep reinforcement learning architecture for tuning the vehicles' speeds in the simulator.

Parameter tuning of the simulator can be naturally considered as a sequential decision making process, where states are the snapshots of the simulating environment and actions are all possible ways of parameter tuning. We learn a policy that continuously takes positive action to change the parameters of the simulator in each step. Note that it is intractable to use the Bellmen Equation (Equation 2) to directly optimize the Q-value as it has to track all possible state-action combinations. Instead, we employ Deep Q-Learning (DQN) [20] which approximates the Q-value using a deep neural network. Given a state s, the output of DQN is the approximated Q-values for the actions $Q(s, a; \theta)$, where θ are neural network weights in DQN. The greedy action is chosen as $\arg\max_{a \in A} Q(s, a; \theta)$. In our context, we use this action to tune the simulator's parameters.

Figure 2 illustrates the DQN framework for trajectory recovery. Real-valued feature vectors extracted from the simulator are used to describe the states. We construct a two-layer fully-connected neural network for DQN to approximate the Q-value. During the training process, weights of the neural network are optimized iteratively to reduce the discrepancy between the optimal Q-value and the predicted one, using gradient descent of the loss function. The details of states, actions, rewards, and the training are described below:

- **States**: Many existing deep reinforcement learning methods (e.g. [16, 30, 33, 43]) use real-valued vector to represent state. Following the same practice, we first extract representative features using the API of the simulator. Since the number of vehicles on the road segments directly describes the traffic volume distribution, we first retrieve their values from the simulator. Next, average traversing time and speed are acquired as the traversing speed and time are closely related to the traffic volume. In addition, we retrieve average waiting time, which measures the average stopping time of every vehicle in the immediate past simulating step. Those four types of values are retrieved from each road segment and then concatenated into a real-valued vector as the state representation. Given m road segments, the dimension of the state feature vector is $4m$.
- **Actions**: Recall that the action with the largest expected cumulative reward (Q-value) will be selected by the agent in each simulating step. To construct the action set, we change the speeds of vehicles which are one of the most important factors that affect the traversing trajectory. However, directly tuning the speed for every vehicle in the simulator is prohibitive because there could be thousands of vehicles traveling simultaneously. To simplify the setting, we do not change the speed continuously for every vehicle. Instead, the speed limits (meters/second) for different vehicles are modified within a certain range in each simulation step. The actions include increasing the speed limit by +1, 0, or −1 (i.e., decrease by 1) for each vehicle. To reduce the action space, we group the vehicles according to their sizes (i.e., sedans, SUVs, and large trucks) and assign the same speed limit to a group of vehicles. Hence, the action space consists of 9 possible actions pairing the speed limits with the groups. Such a setting actually changes the behavior of every group of vehicles by limiting their speeds into a certain range.
- **Rewards**: In reinforcement learning, positive or negative rewards are provided by the environment for each action by the agent. The agent can utilize the reward to calculate the optimal Q-value, and to optimize parameters in the neural network using the discrepancy induced by the Bellman equation. We construct short-term rewards according to the following equation:

$$R = \sum_{v \in \Omega} (e^{-|t_v^{\text{simu}} - t_v|}), \tag{3}$$

  where Ω denotes vehicles that have arrived at the monitor points at the simulating step. That is, the simulating results of those vehicles can be evaluated at this time. The arrival time stamps t_v^{simu} and t_v are of the simulated ones and the real vehicles, respectively. The definition is straightforward. Obviously, lower absolute time differences are received if and only if more vehicles arrive sharply, and the agent receives larger rewards under such conditions.
- **Training**: A simulating step is set to lasting for one minute. A two-layer neural network is initialized and trained to estimate the Q-value. Weights θ of the network are updated every step by gradient descent, using the discrepancy between estimated Q-value and the feedback from the simulating environment. Before the training, we first set up a replay memory $\mathcal{M}$ to store state transitions (i.e., (s, a, s', R) where s' denotes the next state following s after taking action a). The deep reinforcement learning algorithm keeps sampling mini-batches from the replay memory and updates its network weights in each simulating step by minimizing the following loss function:

$$\mathcal{L}(\theta) = \mathbf{E}_{s,a}[(Q^* - Q(s, a; \theta))^2], \tag{4}$$

Algorithm 1: Training of the Deep RL Architecture

Randomly initialize network parameters θ and the replay memory $\mathcal{M}$;
for *each episode* **do**
  for *each simulation step* **do**
    /* Action and simulating */
    if *random()* $< \epsilon$ **then**
      Select a random action a;
    else
      Select $a = \max_a Q(s, a; \theta)$;
    end
    Obtain short-term reward R and new state s' by executing a in the simulator;
    Store state transition (s, a, s', R) in $\mathcal{M}$;
    /* Updating Q-network parameters θ */
    Sample mini-batch state transitions $\{(s, a, s', R)\}$ from $\mathcal{M}$;
    if *simulator terminated* **then**
      $Q^* = R$;
    else
      $Q^* = R + \gamma \max_{a'} Q(s', a'; \theta)$;
    end
    Use Equation 5 to perform gradient descent on the loss $\mathcal{L}(\theta)$ based on Q^*;
  end
end

where $Q^* = R + \gamma \max_{a'} Q(s', a'; \theta)$ is the target optimal Q-value, which is the sum of the short-term reward R and the optimal Q-value of the next step. The decay term γ gives penalty to future rewards. The expectation is computed over the mini-batches. Furthermore, we adopt ϵ-greedy strategy [21] to balance the trade-off between exploration and exploitation. That is, with probability ϵ, a random action is selected for exploration during training, instead of the optimal one. After calculating the loss function, the network weights θ are updated using gradient descent. The gradient of θ is given as follows,

$$\nabla_\theta \mathcal{L}(\theta) = \mathbb{E}_{s,a}[(Q^* - Q(s, a; \theta))\nabla_\theta Q(s, a; \theta)]. \quad (5)$$

The overall training procedure of the deep reinforcement learning architecture is given in Algorithm 1. Once the simulator is stable, we fill in the missing values of the real and incomplete trajectories using the traffic volume values in the simulator *SUMO*. Compared with taxi trajectories collected from GPS devices, these recovered trajectories, denoted by Δ^{I+}, are more representative of a variety of vehicle types. Both kinds of trajectories will be employed in the following steps.

4.2 Spatiotemporal Graph Construction

Temporal correlations of different road segments change over time. For example, an expressway connecting business areas and residential areas may exhibit reversed traffic flows from morning to evening. Moreover, the spatial relationship between road segments is extremely complicated (e.g., overpasses at the intersection of the main road). To model such dynamism of traffic in the road network, we construct spatiotemporal graphs, as shown in Figure 3 and detailed below.

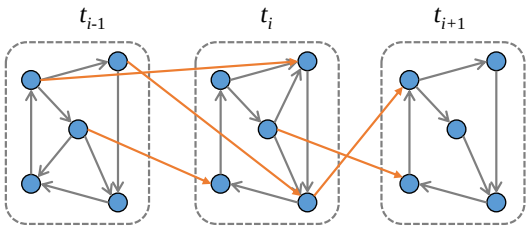

Figure 3: An example of spatiotemporal graph. Three layers are shown in the figure. Gray arrows denote edges within the same layer and yellow arrows denote edges between current and next layers.

A spatiotemporal graph in this paper is a multi-layer graph $G = \langle \mathcal{V}, \mathcal{E} \rangle$, where $\mathcal{V} = \{v_i^t\}$ denotes time-enhanced nodes representing road segments $\{r_i\}$, and $\mathcal{E}$ represents edges between nodes. Nodes in the same time interval are grouped to the same *layer*. To preserve spatial restrictions of the road network, edges in $\mathcal{E}$ are limited to $v_i^t \rightarrow v_j^{\{t+1\}}$ where vehicles could travel from the road segment r_i to r_j. The edge's weight is assigned using the traffic flow value, i.e., number of trajectories traversing through the edge.

To differentiate mobility behaviors and traffic patterns in different sources of trajectories, two spatiotemporal graphs are constructed respectively using the dense trajectories Δ^D and recovered Δ^{I+} from incomplete trajectories.

4.3 Multi-view Graph Embedding

The objective of citywide traffic volume inference is to estimate the unknown traffic volume values from the observed ones. This problem is challenging due to multiple interwoven factors such as the road network, vehicles' physical condition, road condition, time, etc. Our solution relies on the spatiotemporal graphs constructed from the macro trajectories, effectively factoring out those individual factors and allowing us to conduct the inference on the graphs instead.

We first embed the time-enhanced road segments (nodes of the graph) to real-valued vectors using the two spatiotemporal graphs obtained above. The embedding captures multi-hop correlations [28] between road segments at different times. Moreover, joint embeddings from the two graphs naturally account for both the GPS-tracked taxi and other vehicles monitored in the incomplete trajectories. We first introduce the embedding process on a single graph, followed by the joint embedding algorithm from the two graphs by a multi-view graph embedding method [25].

We adopt the Skip-gram model [18] to learn the embedding vector $\mathbf{u}_i^t$ for each node v_i^t in a spatiotemporal graph $G = \langle \mathcal{V}, \mathcal{E} \rangle$. Given a node in the graph, the skip-gram model aims to predict the probability of the node's context. We first define a path in G as $P_i = v_{i_1} v_{i_2} \dots v_{i_\sigma}$, where v_{i_j} in P_i is corresponding to a

node in G. We omit the time superscript here, which can be easily acquired from each layer. Given a specific node v_i^t, the set of all paths containing v_i^t formulates a set $\mathcal{P}(v_i^t)$. We define set $\mathcal{N}(v_i^t) = \{v_c | \exists P_i \in \mathcal{P}(v_i^t), v_c \in P_i\} \backslash \{v_i^t\}$ as the context of node v_i^t, which refers to all multi-hop neighbors of v_i^t (i.e., nodes closely surround v_i^t in space and time) [29]. Specifically, the following log-probability is maximized:

$$O = \sum_{v_i^t \in G} \log Pr(\mathcal{N}(v_i^t) | v_i^t)) = \sum_{v_i^t \in G} \log \prod_{v_c \in \mathcal{N}(v_i^t)} P(v_c | v_i^t)$$
$$= \sum_{v_i^t \in G} \sum_{v_c \in \mathcal{N}(v_i^t)} \log P(v_c | v_i^t).$$

and $P(v_c|v_i^t)$ is further estimated by $P(v_c|v_i^t) = \sigma(\mathbf{u}_i^{t\mathrm{T}} \mathbf{u}_c')$ where $\sigma(\cdot)$ is the sigmoid function, and $\mathbf{u}_c'$ denotes the auxiliary vector of v_c when it is treated as "context" of other nodes.

To achieve better performance and reduce computational costs, negative sampling technique [19] is applied. For each node v_i^t and a neighbor node v_c, we sample negative nodes $NG(v_i^t) = \{z | z \notin \mathcal{N}(v_i^t)\}$ which denotes unrelated road segments. The objective function for network embedding with negative sampling is:

$$O = \sum_{v_i^t \in G} \sum_{v_c \in \mathcal{N}(v_i^t)} \left\{ \log P(v_c|v_i^t) + \sum_{z \in NG(v_i^t)} \log(1 - P(v_c|v_i^t)) \right\}$$
$$= \sum_{v_i^t \in G} \sum_{v_c \in \mathcal{N}(v_i^t)} \left\{ \log(\sigma(\mathbf{u}_i^{t\mathrm{T}} \mathbf{u}_c')) + \sum_{z \in NG(v_i^t)} \log(1 - \sigma(\mathbf{u}_i^{t\mathrm{T}} \mathbf{u}_z')) \right\}.$$

The objective reads that, for each node v_i^t, we aim to maximize the probability of its co-occurrence with nodes in $\mathcal{N}(v_i^t)$, while minimize the probability of it being neighbor with nodes from $NG(v_i^t)$.

Since we have two spatiotemporal graphs of the same set of road segments, we may learn the embedding by a trade-off between the objective functions above over the two graphs. Namely,

$$O = \alpha O_{G^{\mathrm{D}}} + (1 - \alpha) O_{G^{\mathrm{I+}}}, \tag{6}$$

where G^{D} and $G^{\mathrm{I+}}$ are the graphs constructed from dense and recovered trajectories, respectively, and α balances the two terms.

4.4 Citywide Traffic Volume Inference

After learning representations for road segments that preserve spatiotemporal dynamics, we borrow a semi-supervised learning formulation [47] to propagate the traffic volume values to the unknown road segments. At first glance, one may train a regression model taking as input the road segment's embedding to predict the missing traffic volume data. However, such methods fail when only a small portion of the entire road network is monitored. We instead employ a formulation which is popular in semi-supervised learning for the inference.

We first define pairwise similarities between any two road segments. The similarity of r_i at time interval t and r_j at time interval t' is measured by:

$$sim(r_i^t, r_j^{t'}) := \omega_{i,j}^{t,t'} = \langle \mathbf{u}_i^t \cdot \mathbf{u}_j^{t'} \rangle, \tag{7}$$

where $\langle \cdot \rangle$ denotes the inner product of two vectors.

We then prune out irrelevant pairs of road segments by constructing 0-1 masks based on geospatial features (i.e., absolute distance between road segments) as well as temporal distance. The intuition behind such pruning is that traffic volume values of faraway locations usually do not have similarities, and the temporal dependencies of traffic pattern at the same location will decrease as the time lag becomes longer [39]. The "masked" pairwise similarities between road segments are defined as:

$$\omega^{\star\, t,t'}_{i,j} = \begin{cases} \omega_{i,j}^{t,t'}, & \text{if } adj(r_i, r_j) \wedge |t - t'| \leq 1, \\ 0, & \text{otherwise.} \end{cases} \tag{8}$$

Here $adj(r_i, r_j)$ is *true* if and only if r_i and r_j are adjacent on the road network. The above mask ensures only the correlations between road segments that are close enough in time and space are considered. The citywide traffic volume values $\{x_{it}\}$ are inferred by minimize the following with respect to (w.r.t.) the unknown values:

$$\mathcal{L}^\star = \sum_{1 \leq i,j \leq m, 1 \leq t,t' \leq n} \omega^{\star\, t,t'}_{i,j} (x_{it} - x_{jt'})^2. \tag{9}$$

Since the objective function is convex w.r.t. the unknown traffic volume values, gradient descent is applied to find the global solutions.

5 EXPERIMENTS

In this section, we conduct extensive experiments to answer the following research questions.

- How does the proposed JMDI perform compared with the baseline methods?
- How do each component of JMDI affect the overall performance?
- How accurate is the trajectory recovery via the deep RL architecture?
- How to balance different types of trajectories through the hyper-parameter α?
- How is the inference error distributed over space (i.e., different road segments) and time (i.e., different time periods of a day)?

5.1 Datasets

We compile a traffic volume dataset using the vehicle counting reported by the city surveillance system from a large provincial capital city in China. The incomplete trajectories are acquired using plate numbers identified by surveillance cameras (with an average F1-score of 90%). Dense trajectories are collected from GPS sensors equipped by public taxicabs. The average reporting frequency of the taxicab-carried GPS devices is 5 seconds. All those datasets are collected over the period of Aug. 2016. The road network is extracted from *Openstreetmap.org* [22]. We split roads into segments using intersections as natural cut-points and set the length of the time interval to 5 minutes. Moreover, geospatial features such as starting/ending locations, road segment length, road width, number of lanes, road type, speed limit, etc., are constructed for each road segment. We select two regions in the city. The detailed data descriptions are shown in Table 2.

5.2 Experiment Settings

We cut trajectories recursively at any $p_{i,j} \rightarrow p_{i,j+1}$ if the time interval between $p_{i,j}$ and $p_{i,j+1}$ is larger than 30 minutes. Because

Table 2: Dataset statistics.

	Region 1	Region 2
Time period	Aug. 1 - Aug 4	Aug. 14 - Aug. 20
Time interval	5 minutes	5 minute
Longitude range	116.8988 - 116.9457	117.0635 - 117.1053
Latitude range	36.6507 - 36.6926	36.6624 - 36.7052
# of all road seg.	322	143
# of monitored seg.	45	32
# of incomplete traj.	366,645	1,798,782
# of dense taxi traj.	12,562	97,315

vehicles may stop and park during such long duration, their behaviors are different from the constantly moving vehicles.

We randomly split the road segments with traffic information into training (80%) and testing (20%), respectively. We further select 20% of the training randomly as validation. The same split is used for all experiments. We run each baseline and ablation 10 times to report the average results.

We set the memory buffer size to $10,000$ and the discount factor γ to 0.8 for the deep RL framework. A feed-forward neural network with two 256-dimension hidden layers is trained using the Adam optimizer [10]. The size of a mini-batch is 128 and the learning rate is 0.0001. Parameters of the network are updated at every step of the simulator. The probability ϵ in the deep RL training is reduced linearly from 0.5 to 0.01 over $2,000$ epochs. The speed limits for every type of vehicle are restricted between $1m/s$ and $40m/s$ in the simulating environment. We set the dimension size for embedding vectors to 50. The window size for sampling in Skip-gram is 10.

5.3 Metrics

We use Root Mean Square Error (RMSE) and Mean Absolute Percentage Error (MAPE) to evaluate the performance of all methods.The detailed definitions of the two metrics are stated as below:

$$RMSE = \sqrt{\frac{1}{s}\sum_{l=1}^{s}(x_l - \hat{x}_l)^2}, \quad MAPE = \frac{1}{s}\sum_{l=1}^{s}\frac{|x_l - \hat{x}_l|}{\hat{x}_l},$$

where $x_l \in \{x_{it}\}$ is a test sample, $\hat{x}_l$ is the ground truth of x_l, and s denotes the total number of test samples.

While RMSE receives more penalties from larger values, MAPE focuses on the error of smaller values. Therefore, combining these two metrics can lead to more comprehensive conclusions. Similar to [38, 39], to evaluate relative error using MAPE, we filter out samples whose traffic volume is lower than 5 in testing, since road segments with very low traffic volume are of little interest for our problem.

5.4 Baselines

Our solution is compared with the following baselines: (1) two geospatial-based methods, (2) two supervised learning methods, and (3) two semi-supervised learning methods.

- **Spatial *k*NN** selects top k nearest road segments with traffic data and uses the average of their volume values at each time interval as the traffic volume prediction for unmonitored road segments.
- **Contextual Average** (CA) uses the averaged volume values from same-type road segments (e.g., primary, expressway, etc.) as the prediction.
- **Linear Regression** (LR) is trained on all road segments with traffic volume using geospatial features. We train regression models for each time interval.
- **XGBoost** [5] is a boosting-tree-based method which is popular in data mining community. We train XGBoost separately on each time interval.
- **Graph SSL** Classic graph-based semi-supervised learning method with loss function $\mathcal{L} = \sum_t \sum_{i,j} a_{i,j}(x_{it} - x_{jt})^2$, which is implemented following Zhu et al.. The similarity weight $a_{i,j}$ is defined using the Euclidean distance between the geospatial feature vectors r_i and r_j.
- **ST-SSL** [17] is the state-of-the-art method for inferring citywide traffic volume using dense trajectories. ST-SSL utilizes static features and estimated speed patterns from taxi trajectories to model the correlations between road segments. The citywide traffic volume is then inferred by a semi-supervised learning method.

5.5 Result Analysis of Different Methods

The comparison of JMDI with other methods in two regions is shown in Table 3. As we can see, JMDI achieves best performances in both regions. In particular, JMDI significantly outperforms geospatial-based methods due to its capability of well modeling the dynamism of traffic volume. In addition, JMDI achieves tremendous improvement compared with supervised methods. This is because supervised methods are trained on road segments with traffic data, they ignore correlations between other road segments. Moreover, both geospatial and regression-based methods fail to model spatiotemporal patterns in multi-sources trajectories, and do not well utilize information from unmonitored road segments.

JMDI significantly outperforms both Graph SSL and ST-SSL. There are two potential reasons. First, JMDI utilizes vast incomplete trajectory data to recover spatiotemporal similarities among road segments. The proposed deep reinforcement learning recovery method successfully transforms partial observations to complete route samples. Second, the joint embedding algorithm enhances the representation of road segments. Both multi-hop correlations and multi-view graph information are preserved in learned embedding vector, resulting in better performance. Furthermore, Graph SSL achieves lower errors compared with ST-SSL, a possible explanation is that the strong assumption of speed similarity does not hold in those regions. For example, most drivers will drive close to the speed limit unless the road capacity reaches the upper limit. In such condition, speeds are almost stationary while traffic volume could change depending on the number of vehicles. Moreover, it suffers from the spatial sparsity of taxi trajectories since the coverage of taxi trajectory in the city is limited.

5.6 Ablation Study

To validate each component of JMDI, the following variations of JMDI are further studied. Despite the changed part(s), all variations

Table 3: Comparison of baseline methods.

Methods	Region 1		Region 2	
	RMSE	MAPE	RMSE	MAPE
Spatial kNN	7.1404	0.6348	8.5259	0.6053
CA	8.0866	0.5251	8.1317	0.5423
LR	13.2857	1.0911	11.5781	1.0219
XGBoost	9.2157	0.6711	9.2847	0.6954
Graph SSL	6.1743	0.4457	6.3640	0.4643
ST-SSL	6.5603	0.5631	7.1528	0.5975
JMDI (Ours)	**5.5877**	**0.3675**	**5.6680**	**0.3915**

have the same framework structure and parameter settings. The results of all variations are listed in Table 4.

- **JMDI-Reg** trains XGBoost models using representation of road segments. It can be considered as appending embedding vectors to the geospatial features in previous XGBoost.
- **JMDI-Tr** replaces the trajectory recovery part using algorithm in [4]. The method infers uncertain trajectories from network-constrained partial observations by summarizing all probable routes in a holistic manner.
- **JMDI-Df** recovers trajectories using default simulator, i.e., we directly collect results from *SUMO* without training the deep reinforcement learning component.
- **JMDI-Semi** directly applies graph-based semi-supervised learning [47] on the spatiotemporal graphs to propagate known traffic volume without the embedding process. The similarity between any time-enhanced road segments (nodes of the graph) is assigned according to the edge weights (i.e., traffic flow value from trajectory data).
- **JMDI-Um** proceeds semi-supervised learning without pruning out irrelevant pairs of road segments. Namely, the raw similarity in Equation (7) is used.

JMDI-Reg performs the worst among all variations. However, it still outperforms the original XGBoost. In addition, the performance gap between JMDI-Reg and JMDI reflects the advantage of the semi-supervised method, which successfully leverages large amounts of unmonitored road segments.

The comparison between JMDI-Tr and JMDI highlights the effectiveness of the proposed trajectory recovery method. Sampling-based methods are unable to handle complex road network constraints, vehicle interactions, and other factors, thus fail to recovery highly accurate trajectories. Moreover, JMDI-Df performs worse compared with JMDI. A possible explanation is that default stationery (time independent) parameters do not describe real-world vehicle movements correctly. Furthermore, since there are fewer vehicles in the simulator, some parameters should still be altered even if the ground truth is known. For example, vehicles traverse faster and arrive earlier in a simulated environment, resulting in a higher error of trajectory recovery. In such condition, speed limits could be explicitly reduced to adjust vehicles' movement.

The performance of JMDI-Semi is obviously overtaken by JMDI. This is because the joint embedding enhances the representation capacity from multi-hop spatiotemporal correlations and multi-view graph information.

Table 4: Comparison of variations.

Methods	Region 1		Region 2	
	RMSE	MAPE	RMSE	MAPE
JMDI-Reg	7.0851	0.5182	6.9187	0.5155
JMDI-Tr	6.5091	0.5127	6.8262	0.5390
JMDI-Df	6.1445	0.4104	6.4006	0.4378
JMDI-Semi	7.9121	0.5673	7.5165	0.5366
JMDI-Um	6.0357	0.3781	6.2272	0.4057
JMDI	**5.5877**	**0.3675**	**5.6680**	**0.3915**

Table 5: Averaged arrival time error (s) of simulated vehicles.

Region	Region 1	Region 2
Default Parameters	27.2356	29.2141
Deep RL	**22.2554**	**25.2231**

The comparison of JMDI-Um and JMDI indicates the effectiveness of proposed 0-1 masks that explicitly remove unrelated road segment pairs. The propagation of traffic volume focuses on relevant pairs of road segments, improving the overall performance of JMDI distinctly.

5.7 Accuracy of Trajectory Recovery

We evaluate the trajectory recovery algorithm. Since the spatial ground truth for incomplete trajectories is unavailable, we construct validation from arrival times at monitor points. First, we manually tune speed limit parameters using greedy search approach over each hour of the simulating procedure to minimize the arrival time error. Those speed parameters are used as the default setting of the compared method. Note that we do not use the default speed limit parameters in *SUMO* (i.e., $22.4m/s$). Following Equation (1), the averaged arrival time error (in second) of the default simulator and that of the optimized simulator are compared. The results are demonstrated in Table 5. The proposed deep reinforcement learning method reduces averaged arrival error significantly, which is relatively lower by 18.29% in Region 1 and 13.61% in Region 2. Moreover, the improvement in Region 1 is relatively higher than in Region 2. A possible reason is that Region 1 has a relatively simpler environment with less traffic. Therefore, modeling the state-action relationship could be easier for the DQN.

5.8 Hyper-Parameter

We further study the hyperparameter α which balances weights between different spatiotemporal graphs. More emphasis is put to recovered trajectories when α is closer to 0, and vise versa when α is closer to 1. The performance of JMDI w.r.t different α is shown in Figure 4. As we can observe, the inference error first drops and then rises in both regions. Moreover, JMDI achieves relatively low inference errors when α falls into a certain range. However, the performance is worse when α is closer to 0 or 1. In addition, the performance of JMDI is significantly improved in both regions by leveraging incomplete trajectories. Compared with the ablation that only uses taxi data (i.e., $\alpha = 1$), JMDI reduces the RMSE value by 8.84%, 5.47%, and the MAPE value by 9.76%, 7.41% in region 1 and

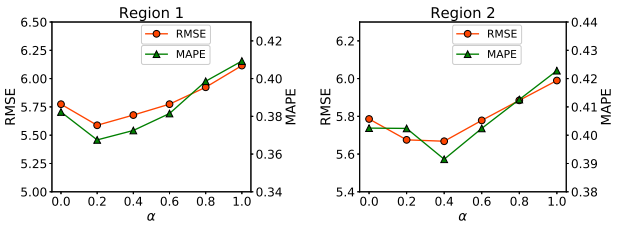

Figure 4: Performance w.r.t different α.

Table 6: Error distribution over different groups of road segments.

Group	Region 1		Region 2	
	RMSE	MAPE	RMSE	MAPE
Group 1	6.5151	0.4102	6.6741	0.4170
Group 2	3.5488	0.3368	3.4101	0.3274

region 2, respectively. This suggests the importance of modeling multi-source trajectories jointly. Besides, the relative improvement from recovered trajectories in Region 1 is larger compared with Region 2. A potential explanation is that the taxi trajectories in Region 1 are very sparse, thus brings biased spatiotemporal correlation and results in larger inference error. Moreover, recovered trajectories also contain noises and uncertainties, and that's why JMDI achieves the best performance by combining them together.

5.9 Error Distribution Interpretation

We also explore the spatiotemporal performance of JMDI, i.e., error distribution over different types of roads, and over different time periods of a day. Without loss of generality, Region 2 is selected for the interpretation.

5.9.1 Error distribution over the space. To study the performance of JMDI over different road segments, we first split road segments from testing set into two categories using road type information extracted from the map. Namely, Group 1 (i.e., major roads such as highway and primary way) and Group 2 (secondary roads like tertiary route). Generally, road segments from Group 1 have more lanes and higher average traffic volume values.

Table 6 provides a detailed illustration of the spatial performance of JMDI. As we can see, the RMSE values are higher for road segments from Group 1, as they have higher traffic volume values. RMSE values are positively correlated to the original variables themselves. Meanwhile, we also observe that the MAPE values of road segments from Group 2 is relatively lower than those of road segments from Group 1. One potential reason is that traffic volume of road segments from Group 1 has higher uncertainty. For example, traffic jams occur when the traffic volume exceeds road capacity, and this usually happens on major roads. Moreover, local events have a higher probability to happen near major roads. Those factors increase the uncertainty of traffic volume on road segments from Group 1, resulting in a high relative error (i.e., MAPE) of the framework.

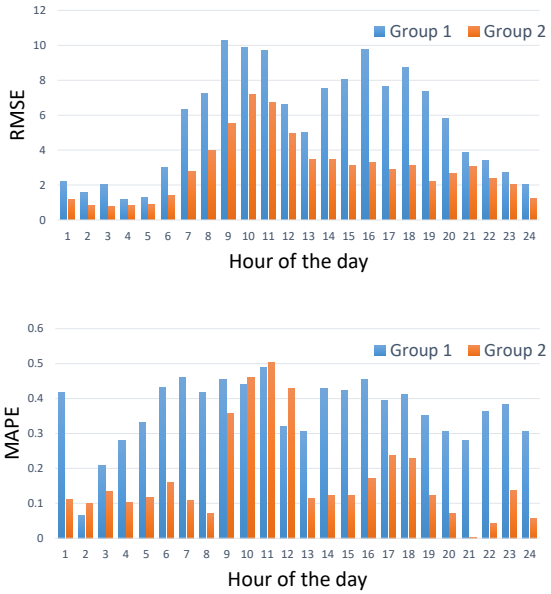

Figure 5: Error distribution over different hours of a day. Number i on x-axis indicates the i-th hour of a day. For example, 7 means the 7th hour, i.e., 6:00 to 7:00.

5.9.2 Error distribution over different time periods of the day. Since traffic volume value series are closely related to different times of a day, and peak hours are more interesting, we further explore the performance of JMDI at different hours. The averaged RMSE and MAPE values are calculated over each hour of a day in the testing set. Detailed values are illustrated in Figure 5. To better interpret those errors, we still use the same group category in Section 5.9.1.

As it reads from the figure, the RMSE values for both groups of road segments have clear patterns. The values are higher during the busy time, such as rush hours in the morning and in the afternoon. This is reasonable since common practice tells us that peak hours would have more traffic. And RMSE values are positively correlated to the ground truth values.

On the other hand, the relative error of JMDI (i.e., the MAPE values) are pretty stable for Group 1 road segments, where the values of MAPE in rush hours are slightly higher than other ones. This is again due to traffic patterns during rush hours are more uncertain, and more accidental events could change the traffic volume dramatically. Those are reasons why inference difficulty is increased, leading to higher percentage error. At the same time, JMDI achieve very low MAPE values for Group 2 road segments at around 0.1 during off-peak hours. And its MAPE values during rush hours in the morning is reasonable. This is explainable since accidental events or traffic jams are less likely to happen near roads from Group 2, because of their less traffic volume.

6 CONCLUSION

In this paper, we propose a novel framework JMDI to citywide traffic volume inference using dense and incomplete trajectories.

JMDI combines high-fidelity traffic simulator with deep reinforcement learning to recover full vehicle movements from incomplete trajectories. The masked semi-supervised approach enhanced by multi-view graph embedding is introduced for citywide traffic volume inference. We evaluate JMDI in two regions in a provincial capital city in China to demonstrate its effectiveness.

ABSTRACT

Open-domain dialogue agents must be able to converse about many topics while incorporating knowledge about the user into the conversation. In this work we address the acquisition of such knowledge, for personalization in downstream Web applications, by extracting personal attributes from conversations. This problem is more challenging than the established task of information extraction from scientific publications or Wikipedia articles, because dialogues often give merely implicit cues about the speaker. We propose methods for inferring personal attributes, such as profession, age or family status, from conversations using deep learning. Specifically, we propose several *Hidden Attribute Models*, which are neural networks leveraging attention mechanisms and embeddings. Our methods are trained on a per-predicate basis to output rankings of object values for a given subject-predicate combination (e.g., ranking the doctor and nurse professions high when speakers talk about patients, emergency rooms, etc). Experiments with various conversational texts including Reddit discussions, movie scripts and a collection of crowdsourced personal dialogues demonstrate the viability of our methods and their superior performance compared to state-of-the-art baselines.

1 INTRODUCTION

Motivation and Problem: While interest in dialogue agents has grown rapidly in recent years, creating agents capable of holding personalized conversations remains a challenge. For meaningful and diverse dialogues with a real person, a system should be able to infer knowledge about the person's background from her utterances. Consider the following example where *H* stands for a human and *A* for an agent:

H: *What's the best place for having brekky?*
A: *The porridge at Bread and Cocoa is great.*
H: *Any suggestions for us and the kids later? We already visited the zoo.*
A: *There's the San Fransisco Dungeon, an amusement ride with scary city history.*

From the word 'brekky' in the first *H* utterance, the system understands that the user is Australian and may thus like porridge for breakfast. However, the cue is missed that the user is with pre-teen children (talking about kids and the zoo), and the resulting suggestion is inappropriate for young children. Instead, with awareness of this knowledge, a better reply could have been:

A: *I bet the kids loved the sea lions, so you should see the dolphins at Aquarium of the Bay.*

A possible remedy to improve this situation is to include user information into an end-to-end learning system for the dialogue agent. However, any user information would be bound to latent representations rather than explicit attributes. Instead, we propose to capture such attributes and construct a *personal knowledge base (PKB)* with this information, which will then be a distant source of background knowledge for personalization in downstream applications such as Web-based chatbots and agents in online forums.

The advantages of an explicit PKB are twofold: it is an easily re-usable asset that benefits all kinds of applications (rather than merely fixing the current discourse), and it provides a convenient way of explaining the agent's statements to the human whenever requested. Constructing a PKB involves several key issues:

- What is personalized knowledge about users?
- How can this knowledge be inferred from the users' utterances in conversations?
- How should such background knowledge be incorporated into a dialogue system?

As for the first issue, interesting facts about a user could be attributes (age, gender, occupation, etc), interests and hobbies, relationships to other people (family status, names of friends, etc) or sentiments towards certain topics or people. In this paper's experiments, we focus on crisp attributes like profession and gender.

The second issue is concerned with information extraction from text. However, prior works have mostly focused on well comprehensible text genres such as Wikipedia articles or news stories. These methods do not work as well when conversations are the input. Compared to formal documents, dialogues are noisy, utterances are short, the language used is colloquial, topics are diverse (including smalltalk), and information is often implicit ("between the lines"). This paper addresses these problems by proposing methods that identify the terms that are informative for an attribute and leverage these terms to infer the attribute's value.

A detailed exploration of the third issue is beyond the scope of this paper, which focuses on inferring personal attributes. However, we do partially address the issue of integrating background knowledge by arguing that such information should be captured in an explicit PKB. In addition to being independent of downstream applications, an explicit PKB can provide transparency by allowing users to see what is known about them as well as giving users the opportunity to consent to this data being stored.

State of the Art and its Limitations: Currently the most successful dialogue agents are task-oriented, for instance, supporting users with car navigation or delivery orders (e.g., [23, 25]). General-purpose chatbot-like agents show decent performance in benchmarks (e.g., [13, 20, 37]), but critically rely on sufficient training data and tend to lack robustness when users behave in highly varying ways. Very few approaches have considered incorporating explicit knowledge on individual users, and these approaches have assumed that personal attributes are explicitly mentioned in the text [15, 21, 47].

To illustrate that identifying explicit mentions of attributes is insufficient, we developed an oracle to obtain an upper bound on the performance of pattern-based approaches, such as [21]. This oracle, which is described in Section 5.2, assumes that we have perfect pattern matching that correctly extracts an attribute value every time it is mentioned. (When multiple attribute values are mentioned, we assume the oracle picks the correct one.) This oracle routinely performs substantially worse than our proposed methods, demonstrating that extracting information from utterances requires *listening between the lines* (i.e., inferring the presence of attribute values that are never explicitly stated).

On the other hand, many efforts have considered the problem of profiling social media users in order to predict latent attributes such as age, gender, or regional origin (e.g., [3, 4, 8, 9, 17, 34–36, 41]). While social media posts and utterances are similar in that both are informal, the former can be associated with many non-textual features that are unavailable outside of the social media domain (e.g., social-network friends, likes, etc. and explicit self-portraits of users). We consider several user profiling baselines that rely on only textual features and find that they do not perform well on our task of inferring attributes from conversational utterances.

Approach and Contributions: We devise a neural architecture, called *Hidden Attribute Model (HAM)*, trained with subject-predicate-object triples to predict objects on a per-predicate basis, e.g., for a subject's profession or family status. The underlying neural network learns to predict a scoring of different objects (e.g., different professions) for a given subject-predicate pair by using attention within and across utterances to infer object values. For example, as illustrated later in Table 7, our approach infers that a subject who often uses terms like *theory*, *mathematical*, and *species* is likely to be a *scientist*, while a subject who uses terms like *senate*, *reporters*, and *president* may be a *politician*.

Our salient contributions are the following:

- a viable method for learning personal attributes from conversations, based on neural networks with novel ways of leveraging attention mechanisms and embeddings,
- a data resource of dialogues from movie scripts, with ground truth for professions, genders, and ages of movie characters,
- a data resource of dialogue-like Reddit posts, with ground truth for the authors' professions, genders, ages, and family statuses
- an extensive experimental evaluation of various methods on Reddit, movie script dialogues, and crowdsourced personalized conversations (PersonaChat),
- an experimental evaluation on the transfer learning approach: leveraging ample data from user-generated social media text (Reddit) for inferring users' latent attributes from data-scarce speech-based dialogues (movie scripts and PersonaChat).

2 RELATED WORK

Personal Knowledge from Dialogues: Awareness of background knowledge about users is important in both goal-oriented dialogues [6, 16] and chitchat settings [20, 47]. Such personal knowledge may range from users' intents and goals [6, 42] to users' profiles, with attributes such as home location, gender, age, etc. [16, 20, 22], as well as users' preferences [25, 47].

Prior works on incorporating background knowledge model *personas* and enhance dialogues by injecting personas into the agent's response-generating model [20, 22, 47] or by adapting the agent's speech style [16]. These approaches typically use latent representations of user information. In contrast, there is not much work on capturing explicit knowledge based on user utterances. Li et al. encode implicit speaker-specific information via distributed embeddings that can be used to cluster users along some traits (e.g., age or country) [20]. Zhang et al. describe a preliminary study on predicting simple speaker profiles from a set of dialogue utterances [47]. The most related prior work by Garera and Yarowsky captures latent biographic attributes via SVM models from conversation transcripts and email communication, taking into account *contextual features* such as partner effect and sociolinguistic features (e.g., % of "yeah" occurences), in addition to n-grams [12].

Several works explore information extraction from conversational text to build a personal knowledge base of speakers given their utterances, such as extracting *profession*: *software engineer* and *employment_history*: *Microsoft* from *"I work for Microsoft as a software engineer"*, using maximum-entropy classifiers [15] and sequence-tagging CRFs [21]. However, this approach relies on user attributes being *explicitly mentioned* in the utterances. In contrast,

our method can infer attribute values from implicit cues, e.g., *"I write product code in Redmond."*

Social Media User Profiling: The rapid growth of social media has led to a massive volume of user-generated informal text, which sometimes mimics conversational utterances. A great deal of work has been dedicated to automatically identify latent demographic features of online users, including age and gender [3, 4, 8, 9, 17, 34–36, 41], political orientation and ethnicity [26, 32–34, 41], regional origin [8, 34], personality [14, 36], as well as occupational class that can be mapped to income [10, 31]. Most of these works focus on user-generated content from Twitter, with a few exceptions that explore Facebook [35, 36] or Reddit [8, 14] posts.

Most existing studies on social media to capture users' latent attributes rely on classification over hand-crafted features such as word/character n-grams [2, 4, 34], Linguistic Inquiry and Word Count (LIWC) [27] categories [14, 32, 33], topic distributions [9, 26, 31] and sentiment/emotion labels of words derived from existing emotion lexicon [14, 26, 32, 33]. The best performing system [2] in the shared task on author profiling organized by the CLEF PAN lab [11, 30] utilizes a linear SVM and word/character n-gram features.

There have been only limited efforts to identify attributes of social media users using neural network approaches. Bayot and Gonçalves explore the use of Convolutional Neural Networks (CNNs) together with word2vec embeddings to perform user profiling (age and gender) of English and Spanish tweets [3]. Kim et al. employ Graph Recursive Neural Networks (GRNNs) to infer demographic characteristics of users [17]. Vijayaraghavan et al. exploit attention-based models to identify demographic attributes of Twitter users given multi-modal features extracted from users' profiles (e.g., name, profile picture, and description), social network, and tweets [41].

The vast majority of these works rely on features specific to social media such as hashtags, users' profile descriptions and social network structure, with only [2, 3, 31] inferring users' latent attributes based solely on user-generated text. In our evaluation we consider these three methods as baselines.

Neural Models with Attention: Recently, neural models enhanced with *attention* mechanisms have boosted the results of various NLP tasks [38, 44, 48], particularly in neural conversation models for generating responses [43, 45] and in predicting user intents [6]. While our attention approach bears some similarity to [43] in that both consider attention on utterances, both our approach's architecture and our use case differ substantially. The role of attention weights has been studied for various neural models, including feed-forward networks [40], CNNs, [46] and RNNs [1].

3 METHODOLOGY

In this section we propose Hidden Attribute Models (HAMs) for ranking object values given a predicate and a sequence of utterances made by a subject. For example, given the movie script excerpt shown in Figure 1, the *profession* predicate, and the subject *Edwards*, *policeman* should be ranked as the subject's most likely profession.

More formally, given a subject S and a predicate P, our goal is to predict a probability distribution over object values O for the predicate based on the subject's utterances from a dialogue corpus (e.g., a movie script). Each subject S is associated with a sequence of N utterances $[U_1, U_2, ..., U_N]$ containing M terms each, $U_1 = [U_{1,1}, U_{1,2}, ..., U_{1,M}]$. Each term $U_{n,m}$ is represented as a d-dimensional word embedding.

Figure 1: An excerpt from *Men in Black* (1997).

HAMs can be described in terms of three functions and their outputs:

(1) f_{utter} creates a representation R_n^{utter} of the nth utterance given the terms in the utterance:

$$R_n^{utter} = f_{utter}(U_{n,1}, U_{n,2}, ..., U_{n,M}) \tag{1}$$

(2) f_{subj} creates a subject representation R^{subj} given the sequence of utterance representations:

$$R^{subj} = f_{subj}(R_1^{utter}, R_2^{utter}, ..., R_N^{utter}) \tag{2}$$

(3) f_{obj} outputs a probability distribution over object values O given the subject representation:

$$O = f_{obj}(R^{subj}) \tag{3}$$

In the following sections we describe our proposed HAMs by instantiating these functions.

3.1 Hidden Attribute Models

HAM_{avg} illustrates the most straightforward way to combine embeddings and utterances. In this model,

$$avg(X) = \sum_{i=1}^{|X|} X_i \tag{4}$$

serves as both f_{utter} and f_{subj}; the nth utterance representation R_n^{utter} is created by averaging the terms in the nth utterance and the subject representation R^{subj} is created by averaging the N utterance representations together. Two stacked fully connected layers serve as the function f_{obj},

$$FC(x) = \sigma(Wx + b) \tag{5}$$

where σ is an activation function and W and b are learned weights. The full HAM_{avg} model is then

$$R_n^{utter} = avg(U_n) \tag{6}$$

$$R^{subj} = avg(R^{utter}) \tag{7}$$

$$O = FC_1(FC_2(R^{subj})) \tag{8}$$

where FC_2 uses a sigmoid activation and FC_1 uses a softmax activation function in order to predict a probability distribution over object values.

HAM$_{2attn}$ extends HAM$_{avg}$ with two attention mechanisms allowing the model to learn which terms and utterances to focus on for the given predicate. In this model the utterance representations and subject representations are computed using attention-weighted averages,

$$attn\text{-}avg(X, \alpha) = \sum_{i=1}^{|X|} X_i \alpha_i \tag{9}$$

with the attention weights calculated over utterance terms and utterance representations, respectively. That is, $f_{utter}(X) = attn\text{-}avg(X, \alpha^{term})$ and $f_{subj}(X) = attn\text{-}avg(X, \alpha^{utter})$, where the attention weights for each term in an utterance U_i are calculated as

$$w_i^{term} = \sigma(W^{term} U_i + b^{term}) \tag{10}$$

$$\alpha_{i,j}^{term} = \frac{exp(w_{i,j}^{term})}{\sum_j exp(w_{i,j}^{term})} \tag{11}$$

and the utterance representation weights α^{utter} are calculated analogously over R^{utter}. Given these attention weights, the HAM$_{2attn}$ model is

$$R_n^{utter} = attn\text{-}avg(U_n, \alpha^{term}) \tag{12}$$

$$R^{subj} = attn\text{-}avg(R^{utter}, \alpha^{utter}) \tag{13}$$

$$O = FC(R^{subj}) \tag{14}$$

where f_{obj} function FC uses a softmax activation function as in the previous model.

HAM$_{CNN}$ considers n-grams when building utterance representations, unlike both previous models that treat each utterance as a bag of words. In this model f_{utter} is implemented with a text classification CNN [18] with a ReLU activation function and k-max pooling across utterance terms (i.e., each filter's top k values are kept). A second k-max pooling operation across utterance representations serves as f_{subj}. As in the previous model, a single fully connected layer with a softmax activation function serves as f_{obj}.

HAM$_{CNN\text{-}attn}$ extends HAM$_{CNN}$ by using attention to combine utterance representations into the subject representation. This mirrors the approach used by HAM$_{2attn}$, with $f_{subj} = attn\text{-}avg(X, \alpha^{utter})$ and α^{utter} computed using equations 10 and 11 as before. This model uses the same f_{utter} and f_{obj} as HAM$_{CNN}$. That is, utterance representations are produced using a CNN with k-max pooling, and a single fully connected layer produces the model's output.

3.2 Training

All HAMs were trained with gradient descent to minimize a categorical cross-entropy loss. We use the Adam optimizer [19] with its default values and apply an L2 weight decay (2e-7) to the loss.

4 DATA ACQUISITION AND PROCESSING

MovieChAtt dataset. Following prior work on personalized dialogue systems, we explore the applicability of fictional dialogues from TV or movie scripts to approximate real-life conversations [20, 22]. Specifically, we compile a Movie Character Attributes (MovieChAtt) dataset consisting of characters' utterances and the characters' attributes (e.g., profession).

To create MovieChAtt, we labeled a subset of characters in the Cornell Movie-Dialogs Corpus[1] [7] of 617 movie scripts. From each movie, we derive a sequence of utterances for each character, excluding characters who have less than 20 lines in the movie. Each utterance is represented as a sequence of words, excluding stop words, the 1,000 most common first names[2], and words that occur in fewer than four different movies. The latter two types of words are excluded in order to prevent the model from relying on movie-specific or character-specific signals that will not generalize.

We extracted characters' *gender* and *age* attributes by associating characters with their entries in the Internet Movie Database (IMDb) and extracting the corresponding actor or actress' attributes at the time the movie was filmed. This yielded 1,963 characters labeled with their genders and 4,548 characters labeled with their ages. We discretized the age attribute into the following ranges: (i) 0–13: *child*, (ii) 14–23: *teenager*, (iii) 24–45: *adult*, (iv) 46–65: *middle-aged* and (v) 66–100: *senior*. In our data the distribution of age categories is highly imbalanced, with *adult* characters dominating the dataset (58.7%) and *child* being the smallest category (1.7%).

To obtain the ground-truth labels of characters' *profession* attributes, we conducted a Mechanical Turk (MTurk) crowdsourcing task to annotate 517 of the movies in our corpus. Workers were asked to indicate the professions of characters in a movie given the movie's Wikipedia article. Workers were instructed to select professions from a general predefined list if possible (e.g., doctor, engineer, military personnel), and to enter a new profession label when necessary. We manually defined and refined the list of professions based on several iterations of MTurk studies to ensure high coverage and to reduce ambiguity in the options (e.g., *journalist* vs *reporter*). We also included non-occupational "professions" that often occur in movies, such as *child* and *criminal*.

Fleiss' kappa for the crowdworkers' inter-annotator agreement is 0.47. Disagreement was oftentimes caused by one character having multiple professions (Batman is both a *superhero* and a *businessman*), or a change of professions in the storyline (from *banker* to *unemployed*). We kept only characters for which at least 2 out of 3 workers agreed on their profession, which yielded 1405 characters labeled with 43 distinct professions. The highly imbalanced distribution of professions reflects the bias in our movie dataset, which features more *criminals* and *detectives* than *waiters* or *engineers*.

PersonaChat dataset. We also explore the robustness of our models using the PersonaChat corpus[3] [47], which consists of conversations collected via Mechanical Turk. Workers were given persona descriptions consisting of 5-sentence-long descriptions (e.g., "I am an artist", "I like to build model spaceships") and asked to incorporate these facts into a short conversation (up to 8 turns) with another worker. We split these conversations by persona, yielding a sequence of 3 or 4 utterances for each persona in a conversation.

We automatically labeled personas with *profession* and *gender* attributes by looking in the persona description for patterns "I am/I'm a(n) ⟨*term*⟩", where ⟨*term*⟩ is either a profession label or a gender-indicating noun (woman, uncle, mother, etc). We manually labeled

attribute	pattern
profession	"(I|i) (am|'m)"+[one of the profession names]
gender	"(I|i) (am|'m)"+[words, indicating gender (*lady*, *father*, etc.)]
age	"(I|i) (am|'m)"+number (5-100)+"years old" "(I|i) (am|'m|was) born in"+number (1920-2013)
family status	"(I|i) (am|'m)"+[*married*, *divorced*, *single*, ...] "(M|m)y"|"(I|i) have a"+[*wife*, *boyfriend*, ...]

Table 1: Patterns for extracting ground truth labels from Reddit posts.

persons with *family status* by identifying persona descriptions containing related words (single, married, lover, etc) and labeling the corresponding persona as single or not single. Overall, we collected 1,147 personas labeled with profession, 1,316 with gender, and 2,302 labeled with family status.

Reddit dataset. As a proxy for dialogues we used discussions from Reddit online forums. We used a publicly available crawl[4] spanning the years from 2006 to 2017. Specifically, we tapped into two subforums on Reddit: "iama" where anyone can ask questions to a particular person, and "askreddit" with more general conversations. In selecting these subforums we followed two criteria: 1) they are not concerned with fictional topics (e.g. computer games) and 2) they are not too topic-specific, as this could heavily bias the classification of user attributes.

To create ground-truth labels for users, we searched for posts that matched specific patterns. The list of patterns for all four attributes is given in Table 1. For the case of *profession*, we created a list of synonyms and subprofessions for better coverage. For example, the list for *businessperson* includes *entrepreneur*, *merchant*, *trader*, etc.

We selected only posts of length between 10 and 100 words by users who have between 20 and 100 posts. Also, we removed users who claim multiple values for the same attribute, as we allow only for single-label classification. To further increase data quality, we rated users by language style, to give preference to those whose posts sound more like the utterances in a dialogue. This rating was computed by the fraction of a user's posts that contain personal pronouns, as pronouns are known to be abundant in dialogue data.

The test set, disjoint from training data and created in the same manner, was further checked by manual annotators, because the above mentioned patterns may also produce false positives, for example, the wrong profession from utterances such as "they think I am a doctor" or "I dreamed I am an astronout", or the wrong age and family status from "I am 10 years old boy's mother" or "I am a single child". The final Reddit test set consists of approximately 400 users per predicate.

Limitations. The predicates we consider are limited by the nature of our datasets. We do not consider the *family status* predicate for MovieChAtt, because the necessary information is often not easily available from Wikipedia articles. Similarly, we do not consider the *age* predicate on the PersonaChat dataset, because this attribute is not easily found in the persona descriptions. More generally, all users in our datasets are labeled with exactly one attribute value for each predicate. In a real setting it may be impossible to infer any attribute value for some users, whereas other users may have multiple correct values. We leave such scenarios for future work.

Our code and dataset annotations are available online.[5][6]

5 EXPERIMENTAL SETUP

5.1 Data

We randomly split the MovieChAtt and PersonaChat datasets into training (90%) and testing (10%) sets. The Reddit test set consists of approximately 400 users per predicate whose label extractions were manually verified by annotators. We tuned models' hyperparameters by performing a grid search with 10-fold cross validation on the training set.

For the binary predicates family status and gender, we balanced the number of subjects in each class. For the multi-valued profession and age predicates, which have very skewed distributions, we did not balance the number of subjects in the test set. During training we performed downsampling to reduce the imbalance; each batch consisted of an equal amount (set to 3) of training samples per class, and these samples were drawn randomly for each batch. This both removes the class imbalance in training data and ensures that ultimately the model sees all instances during training, regardless of the class size.

Note that all three datasets are somewhat biased regarding the attribute values and not representative for real-life applications. For example, the professions in MovieChAtt are dominated by the themes of entertaining fiction, and gender distributions are not realistic either. The data simply provides a diverse range of inputs for fair comparison across different extraction methods.

5.2 Baselines

We consider the following baselines to compare our approach against.

Pattern matching oracle. Assuming that we have a perfect sequence tagging model (e.g., [21]) that extracts a correct attribute value every time one appears in an utterance, we can determine the upper-bound performance of such sequence tagging approaches. Note that, as mentioned in the introduction, this type of model assumes attribute values explicitly appear in the text. In order to avoid vocabulary mismatches between our attribute value lists and the attribute values explicitly mentioned in the data, we augment our attribute values with synonyms identified in the data (e.g., we add terms like 'soldier' and 'sergeant' as synonyms of the the *profession* attribute's value 'military personnel'). For both MRR and accuracy, a subject receives a score of 1 if the correct attribute value appears in any one of a subject's utterances. If the correct attribute value never appears, we assume the model returns a random ordering of attribute values and use the expectation over this list (i.e., given $|V|$ attribute values, the subject receives a score of $\frac{1}{0.5|V|}$ for MRR and $\frac{1}{|V|}$ for accuracy). This oracle method does not provide class confidence scores, so we do not report AUROC with this method.

[5] https://github.com/Anna146/HiddenAttributeModels

[6] https://mpi-inf.mpg.de/departments/databases-and-information-systems/research/personal-knowledge-base

Embedding similarity. Given an utterance representation created by averaging the embeddings of the words within the utterance, we compute the cosine similarity between this representation and the embeddings of each attribute value.

Logistic regression. Given an averaged utterance representation (as used with embedding similarity), we apply a multinomial logistic regression model to classify the representation as one of the possible attribute values. This model obtains a ranking by ordering on the per-class probabilities of its output.

Multilayer Perceptron (MLP). Given an averaged utterance representation (as used with embedding similarity), we apply an MLP with one hidden layer of size 100 to classify the utterance representation as one of the possible attribute values. This model can be used to obtain a ranking by considering the per-class probabilities.

The embedding similarity, logistic regression, and MLP baselines are distantly supervised, because the subject's labels are applied to each of the subject's utterances. While this is necessary because the baselines do not incorporate the notion of a subject with multiple utterances, it results in noisy labels because it is unlikely that every utterance will contain information about the subject's attributes. We address this issue by using a window of $k = 4$ (determined by a grid search) concatenated utterances as input to each of these methods. With these distantly supervised models, the label prediction scores are summed across all utterances for a single subject and then ranked.

CNN [3]. We consider the Convolutional Neural Network (CNN) architecture proposed by Bayot and Gonçalves for the task of predititng the age and gender of Twitter users. This approach is a simpler variant of HAM_{CNN} in which f_{utter} is implemented with a *tanh* activation function and max pooling (i.e., $k = 1$) and f_{obj} is a fully connected layer with dropout ($p = 0.5$) and a softmax activation function. The CNN is applied to individual utterances and the majority classification label is used for the user, which differs from the in-model aggregation performed by HAM_{CNN}.

New Groningen Author-profiling Model (N-GrAM) [2]. Following the best performing system at CLEF 2017's PAN shared task on *author profiling* [11], we implemented a classification model using a linear Support Vector Machine (SVM) that utilizes the following features: character n-grams with $n = 3, 4, 5$, and term unigrams and bigrams with sublinear tf-idf weighting.

Neural Clusters (W2V-C) [31]. We consider the best classification model reported by Preoţiuc-Pietro et al. for predicting the occupational class of Twitter users, which is a Gaussian Process (GP) classifier with *neural clusters* (W2V-C) as features. Neural clusters were obtained by applying spectral clustering on a word similarity matrix (via cosine similarity of pre-trained word embeddings) to obtain $n = 200$ word clusters. Each post's feature vector is then represented as the ratio of words from each cluster.

For both N-GrAM and W2V-C baselines, flattened representations of the subject's utterances are used. That is, the model's input is a concatenation of all of a given user's utterances.

5.3 Hyperparameters

Hyperparameters were chosen by grid search using ten-fold cross validation on the training set. Due to the limited amount of data, we found a minibatch size of 4 users performed best on MovieChAtt and PersonaChat. All models were trained with a minibatch size of 32 on Reddit. We used 300-dimensional word2vec embeddings pretrained on the Google News corpus [24] to represent the terms in utterances. We set the number of utterances per character $N = 40$ and the number of terms per utterance $M = 40$, and truncated or zero padded the sequences as needed.

- $\textbf{HAM}_{\textbf{avg}}$ uses a hidden layer of size 100 with the sigmoid activation function. The model was trained for 30 epochs.
- $\textbf{HAM}_{\textbf{CNN}}$ uses 178 kernels of size 2 and k-max pooling with $k = 5$. The model was trained for 40 epochs.
- $\textbf{HAM}_{\textbf{2attn}}$ uses a sigmoid activation with both attention layers and with the prediction layer. The model was trained for 150 epochs.
- $\textbf{HAM}_{\textbf{CNN-attn}}$ uses 128 kernels of size 2. The model was trained for 50 epochs.

5.4 Evaluation metrics

For binary predicates (*gender* and *family status*), we report models' performance in terms of accuracy. Due to the difficulty of performing classification over many attribute values, a ranking metric is more informative for the multi-valued predicates (*profession* and *age category*). We report Mean Reciprocal Rank for these predicates.

Mean Reciprocal Rank (MRR) measures the position of the correct answer in a ranked list of attribute values provided by the model. We obtain a ranking of attribute values for a movie character or a persona by considering the attribute value probabilities output by a model. Given one ranked list of attribute values per character, MRR is computed by determining the reciprocal rank of the correct attribute value in each list, and then taking the average of these reciprocal ranks. We report both *macro MRR*, in which we calculate a reciprocal rank for each attribute value before averaging, and *micro MRR*, which averages across each subject's reciprocal rank.

Area under the ROC Curve (AUROC) measures the performance of a model as a function of its true positive rate and false positive rate at varying score thresholds. We report micro AUROC for all predicates. For multi-valued predicates, we binarize the labels in a one-vs-all fashion.

6 RESULTS AND DISCUSSION

6.1 Main Findings

In Table 2, 3 and 4 we report results for the HAMs and the baselines on all datasets (MovieChAtt, PersonaChat and Reddit) for all considered attributes (*profession*, *gender*, *age* and *family status*). We do not report results for the *pattern oracle* baseline in the tables as we evaluated the baseline solely on the MovieChAtt dataset, because the oracle essentially replicates the way we labeled persona descriptions and posts in the PersonaChat and Reddit datasets, respectively. The pattern oracle baseline yields 0.21/0.20 micro/macro MRR for *profession*, 0.67 accuracy for *gender*, and 0.41/0.40 micro/macro MRR for *age*. HAMs significantly outperform this baseline, indicating

Table 2: Comparison of models on all datasets for *profession* and *gender* attributes. Results marked with * significantly differ from the best method (in bold face) with $p < 0.05$ as measured by a paired t-test (MRR) or McNemar's test (Acc and AUROC).

that identifying explicit mentions of attribute values is insufficient in our dialogue setting.

HAMs outperform the distantly supervised models (i.e., *embedding similarity*, *logistic regression* and *Multilayer Perceptron (MLP)*) in the vast majority of cases. MLP and logistic regression perform best in several occasions for *profession* and *age* attributes when micro MRR is considered. However, their macro MRR scores fall behind HAMs, showing that HAMs are better at dealing with multi-valued attributes having skewed distribution. The low performance of these distantly supervised methods may be related to their strong assumption that every sequence of four utterances contains information about the attribute being predicted.

Comparing with baselines from prior work, HAMs significantly outperform N-GrAM [2] in many cases, suggesting that representing utterances using word embeddings, instead of merely character and word n-grams, is important for this task. Using neural clusters (W2V-C) as features for the classification task [31] works quite well for the *age* attribute, where different 'topics' may correlate with different age categories (e.g. 'video game' for *teenager* and 'office' for *adult*). However, W2V-C is often significantly worse for the *profession*, *gender*, and *family status* attributes, which may be caused by similar discriminative words (e.g., 'husband'/'wife' for *gender*) being clustered together in the same topic. The CNN baseline [3] is significantly worse than the best method in the majority of cases. Furthermore, it generally performs substantially worse than HAM_{CNN}, further illustrating the advantage of aggregating utterances within the model.

In general, HAM_{avg} performs worse than the other HAMs[7], demonstrating that simple averaging is insufficient for representing utterances and subjects. In most cases HAM_{CNN} performs slightly worse than $HAM_{CNN\text{-}attn}$, demonstrating the value of exploiting an attention mechanism to combine subject's utterances. $HAM_{CNN\text{-}attn}$ and HAM_{2attn} achieve the strongest performance across predicates, with $HAM_{CNN\text{-}attn}$ generally performing better. $HAM_{CNN\text{-}attn}$ performs particularly well on the *gender* and *family status* attributes, where detecting bigrams may yield an advantage. For example, HAM_{2attn} places high attention weights on terms like 'family' and 'girlfriend' where the previous term may be a useful signal (e.g., 'my family' vs. 'that family').

The gap between the baselines and HAMs is often smaller on PersonaChat compared with on the other two datasets, illustrating the simplicity of crowdsourced-dialogue as compared to movie scripts or Reddit discussions. This is also supported by the fact that the maximum metrics on PersonaChat are much higher. There are several factors that may be responsible for this: *(1)* the dialogue in PersonaChat was created by crowdworkers with the goal of stating facts that were given to them, which often leads to the facts being stated in a straightforward manner (e.g., "I am an author"); *(2)* PersonaChat utterances are much shorter and there are far fewer utterances per character (i.e., a maximum of 4 in PersonaChat vs. a minimum of 20 in MovieChAtt), leading to a higher density of information related to attributes; and *(3)* the persona descriptions in PersonaChat are used for many dialogues, giving models an opportunity to learn specific personas.

6.2 Study on word embeddings

In the previous experiments, we represented terms using embeddings from a word2vec skip-gram model trained on Google News. [24] In this study we compare the Google News embeddings with word2vec embeddings trained on Reddit posts, GloVe [28] embeddings trained on Common Crawl, and GloVe embeddings trained on Twitter. We also consider *ELMo* [29], a contextualized embedding model. To capture semantic variations, this model creates a contextualized character-based representation of words using a bidirectional language model. We use AllenNLP's small ELMo model[8] trained on the 1 Billion Word Benchmark of news crawl data from WMT 2011 [5].

[7] For the sake of brevity we neither instantiate nor report results for LSTM-based HAMs, such as $f_{utter} = LSTM$ and $f_{subj} = attn\text{-}avg$ or $f_{subj} = LSTM$. These models were unable to outperform HAM_{avg}, with the best variant obtaining a micro MRR of only 0.31 after grid search (profession predicate on MovieChAtt; Table 2). This is in line with recent results suggesting that RNNs are not ideal for identifying semantic features [39].

Given space limitations and the higher model variance on the *profession* attribute on MovieChAtt, we restrict the study to this predicate and corpus. We evaluated the two best performing HAMs, i.e., $HAM_{CNN\text{-}attn}$ and HAM_{2attn}. Table 5 shows the results obtained with the various embedding methods trained on different datasets. The difference in performance does not greatly vary across embedding models and datasets, with Google News embeddings performing best in terms of macro MRR and Reddit embeddings performing best in terms of micro MRR. Despite their strong performance on some NLP tasks, the ELMo contextualized embeddings do not yield a performance boost for any method or metric. We view this observation as an indicator that the choice of term embedding method is not very significant for this task compared to the method used to combine terms into an utterance representation.

Model	Corpus	$HAM_{CNN\text{-}attn}$		HAM_{2attn}	
		MRR micro / macro	AU-ROC	MRR micro / macro	AU-ROC

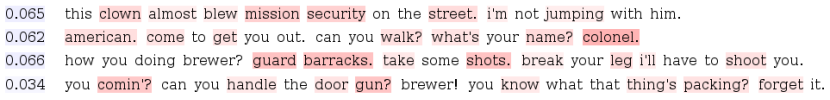
– attention on terms	0.49 / 0.40	0.81
– attention on R^{utter}	0.48 / 0.34	0.82

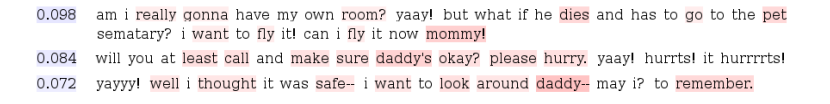
Table 6: Ablation study for the *profession* attribute.

6.3 Ablation study



We performed an ablation study in order to determine the performance impact of the HAMs' components. Given space limitations and the higher model variance on the *profession* attribute on MovieChAtt, we restrict the study to this predicate and dataset. Ablation results for HAM_{2attn} using cross validation on the training set are shown in Table 6. Replacing either representation function (i.e., f_{utter} or f_{subj}) with an averaging operation reduces performance, as shown in the last two lines. Attention on utterance representations (R^{utter}) is slightly more important in terms of MRR, but both types of attention contribute to HAM_{2attn}'s performance. Similarly, removing both types of attention corresponds to HAM_{avg}, which consistently underperforms HAM_{2attn} in Table 2, 3 and 4.

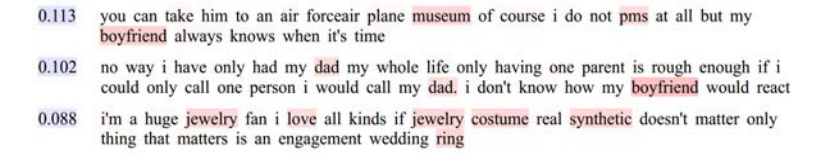
Removing attention from $HAM_{CNN\text{-}attn}$ yields HAM_{CNN}, which consistently performs worse than $HAM_{CNN\text{-}attn}$ in Table 2, 3 and 4, supporting the observation that attention is important for performance on our task. Intuitively, attention provides a useful signal because it allows the model to focus on only those terms that provide information about an attribute.



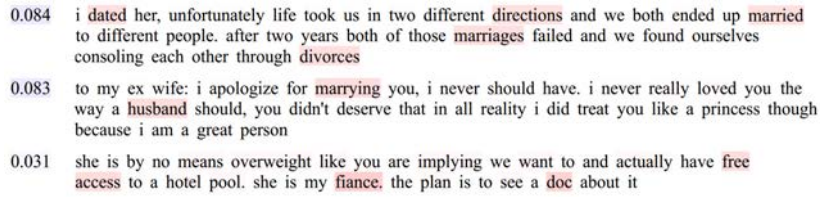
6.4 Case study on attention weights

In order to illustrate the types of terms the model is looking for, we display HAM_{2attn}'s term and utterance weights for *profession* and *age* attributes (on MovieChAtt) in Figure 2, as well as *gender* and *family status* attributes (on Reddit) in Figure 3. While HAM_{2attn} is sometimes outperformed by $HAM_{CNN\text{-}attn}$, this model is more interpretable because individual terms are considered in isolation. Note that all these dialogue snippets come from the specific datasets in our experiments, partly from fictional conversations. Some are skewed and biased, and not representative for the envisioned downstream applications.

When predicting *military personnel* as the *profession* (Figure 2a), the model focuses on military terms such as *mission*, *guard*, *barracks*,



(a) *profession*: military personnel



(b) *age* (category): child

Figure 2: Attention visualization for *profession* and *age* predicates on MovieChAtt.

(a) *gender*: female

(b) *family status*: married

Figure 3: Attention visualization for *gender* and *family status* predicates on Reddit.

and *colonel*. When predicting *child* as the *age category* (Figure 2b), on the other hand, the model focuses on terms a child is likely to use, such as *pet*, *mommy*, and *daddy*. According to Reddit posts, *female* gender is suggested by terms such as *boyfriend*, *pms* and *jewelry* (Figure 3a). Meanwhile, *married* users were identified through terms such as *dated*, *fiance* and *divorces*, along with obvious terms like *marrying* and *marriages* (Figure 3b). These examples illustrate how the model is able to infer a subject's attribute by aggregating signals across utterances.

In addition to looking at specific utterances, we investigated which terms the model is strongly associating with a specific attribute. To do so, we computed attribute value probabilities for each term in the corpus, and kept the top terms for each attribute value. The results using HAM_{2attn} are shown in Table 7, which is divided into words that appear informative (top section) and words that do not (bottom section). In the case of informative words, there is a clear relationship between the words and the corresponding profession. Many of the uninformative words appear to be movie-specific, such as names (e.g., xavier, leonard) and terms related to a *waiter's* role in a specific movie (e.g., rape, stalkers). Reducing the impact of setting-specific signals like this is one direction for future work.

profession	**significant words**
scientist	characteristics, theory, mathematical, species, changes
politician	governors, senate, secretary, reporters, president
detective	motel, spotted, van, suitcase, parked
military personnel	captured, firepower, guard, soldiers, attack
student	playing, really, emotional, definitely, unbelievable
photographer	xavier, leonard, collins, cockatoo, burke
waiter	rape, stalkers, murdered, overheard, bothering

Table 7: Top-5 words from HAM_{2attn} characterizing each profession.

Models	**profession**		**gender**		**age**	
	MRR micro / macro	AU-ROC	Acc	AU-ROC	MRR micro / macro	AU-ROC
$HAM_{CNN-attn}$	0.19 / 0.18	0.58	0.56	0.58	**0.57** / **0.54**	**0.69**
HAM_{2attn}	**0.21** / **0.21**	**0.67**	**0.61**	**0.64**	0.45 / 0.41	0.45

Table 8: Transfer learning performance of pre-trained Reddit models on MovieChAtt.

6.5 Insights on transfer learning

To investigate the robustness of our trained HAMs, we tested the best performing models (i.e., HAM_{2attn} and $HAM_{CNN-attn}$) on a transfer learning task between our datasets. Specifically, we leveraged user-generated social media text (Reddit) available in abundance for inferring personal attributes of subjects in speech-based

Models	profession		gender		family status	
	MRR micro / macro	AU-ROC	Acc	AU-ROC	Acc	AU-ROC
$HAM_{CNN\text{-}attn}$	0.20 / 0.16	0.58	**0.52**	0.50	**0.74**	**0.74**
HAM_{2attn}	**0.21** / **0.18**	**0.71**	0.51	**0.54**	0.62	0.64

Table 9: Transfer learning performance of pre-trained Reddit models on PersonaChat.

dialogues (MovieChAtt and PersonaChat). We report the results in Table 8 and 9 respectively.

While the scores on PersonaChat are low compared to those in Table 2 and 4, the HAMs' performance on MovieChAtt is often comparable with the baselines' performance in Table 2, 3 and 4. This difference may be caused by the fact that PersonaChat is a smaller, more synthetic dataset as discussed in Section 6.1. On MovieChAtt with the *profession* predicate, both HAMs match the performance of all six baselines in terms of macro MRR. Similarly, HAM_{2attn} matches the performance of five of the six baselines on the *gender* predicate (accuracy), and $HAM_{CNN\text{-}attn}$ matches the performance of four of the six baselines on the *age* predicate (macro MRR). Particularly for the *profession* attribute, missing training subjects in the Reddit dataset for certain professions such as *astronaut* or *monarch* contribute to the decreasing performance, although the models still make a reasonable prediction of *scientist* for *astronaut*. The methods do not perform as well in terms of micro MRR, which may be due to the substantially different attribute value distributions between datasets (i.e., the professions common in movies are uncommon in Reddit). Improving the HAMs' transfer learning performance is a direction for future work.

6.6 Profession misclassification study

In this section we investigate common misclassifications on the MovieChAtt dataset for the *profession* predicate, which is both the most challenging predicate and the predicate with the most possible object values (i.e., 43 on MovieChAtt). A confusion matrix for HAM_{2attn} is shown in Figure 4. Dotted lines indicate several interesting misclassifications: *policemen* are often confused with *detectives* and *special agents* (red line); *scientists* are confused with *astronauts* (yellow line), because sci-fi films often feature characters who arguably serve in both roles; and a *child* is often labeled as a *student* or a *housewife* (green line) because they sometimes use similar terms (e.g., 'school' is used by both children and students, and 'mommy' is used by both children and housewives). Finally, many occupations are confused with *criminal*, which is the most common profession in MovieChAtt.

To further compare the performance of the model on direct and transfer learning tasks we computed the confusion matrix for HAM_{2attn} trained on the Reddit dataset and using MovieChAtt as the test corpus. Interesting misclassifications include the following: artistic professions (*actor*, *painter*, *musician*, *director*) are often mixed up (red lines); *banker* is confused with *manager* (green lines); *policeman* and *airplane pilot* are confused with *military personnel* (purple lines); and *stewardess* is often confused with *nurse* as they both are related to caring and serving tasks (yellow line).

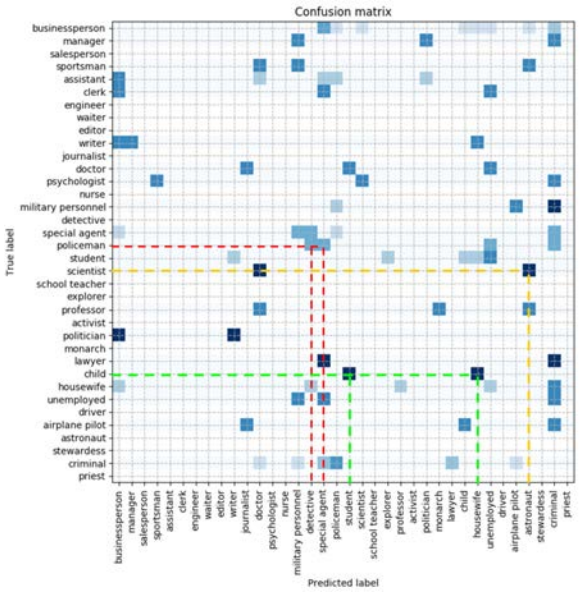


Figure 4: Confusion matrix computed with HAM_{2attn}. True positives are not shown. Darker squares indicate more misclassifications.

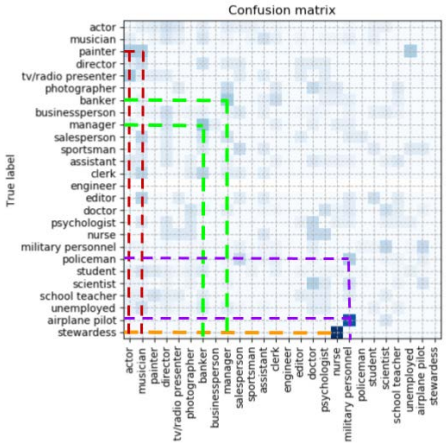

Figure 5: Confusion matrix of $Reddit_{train} \rightarrow MovieChAtt_{test}$ computed with HAM_{2attn}. True positives are not shown. Darker squares indicate more misclassifications.

7 CONCLUSION

We proposed Hidden Attribute Models (HAMs) for inferring personal attributes from conversations, such as a person's profession. We demonstrated the viability of our approach in extensive experiments considering several attributes on three datasets with diverse characteristics: Reddit discussions, movie script dialogues and crowdsourced conversations. We compared HAMs against a variety of state-of-the-art baselines, and achieved substantial improvements over all of them, most notably by the $HAM_{CNN\text{-}attn}$ and HAM_{2attn} variants. We also demonstrated that the attention weights assigned by our methods provide informative explanations of the computed output labels.

As a stress test for our methods, we investigated transfer learning by training HAMs on one dataset and applying the learned models to other datasets. Although we observed degradation in output quality, compared to training on in-domain data, it is noteworthy that the transferred HAMs matched the MovieChAtt performance of the baselines when trained on in-domain data. We plan to further investigate this theme of transfer learning in our future work on construction personal knowledge bases and leveraging them for personalized Web agents.

ABSTRACT

With millions of images that are shared online on social networking sites, effective methods for image privacy prediction are highly needed. In this paper, we propose an approach for fusing object, scene context, and image tags modalities derived from convolutional neural networks for accurately predicting the privacy of images shared online. Specifically, our approach identifies the set of most competent modalities on the fly, according to each new target image whose privacy has to be predicted. The approach considers three stages to predict the privacy of a target image, wherein we first identify the neighborhood images that are visually similar and/or have similar sensitive content as the target image. Then, we estimate the competence of the modalities based on the neighborhood images. Finally, we fuse the decisions of the most competent modalities and predict the privacy label for the target image. Experimental results show that our approach predicts the sensitive (or private) content more accurately than the models trained on individual modalities (object, scene, and tags) and prior privacy prediction works. Also, our approach outperforms strong baselines, that train meta-classifiers to obtain an optimal combination of modalities.

CCS CONCEPTS

• **Security and privacy → Social network security and privacy**.

KEYWORDS

Image privacy prediction; fusion of modalities; decision-level fusion

1 INTRODUCTION

Technology today offers innovative ways to share photos with people all around the world, making online photo sharing an incredibly popular activity for Internet users. These users document daily details about their whereabouts through images and also post pictures of their significant milestones and private events, e.g., family photos and cocktail parties [28]. Furthermore, smartphones and other mobile devices facilitate the exchange of information in content sharing sites virtually at any time, in any place. Although current social networking sites allow users to change their privacy preferences, this is often a cumbersome task for the vast majority of users on the Web, who face difficulties in assigning and managing privacy settings [30]. Even though users change their privacy settings to comply with their personal privacy preference, they often misjudge the private information in images, which fails to enforce their own privacy preferences [35]. Thus, new privacy concerns [13] are on the rise and mostly emerge due to users' lack of understanding that semantically rich images may reveal sensitive information [1, 35, 47, 57]. For example, a seemingly harmless photo of a birthday party may unintentionally reveal sensitive information about a person's location, personal habits, and friends. Along these lines, Gross and Acquisti [17] analyzed more than 4,000 Carnegie Mellon University students' Facebook profiles and outlined potential threats to privacy. The authors found that users often provide personal information generously on social networking sites, but they rarely change default privacy settings, which could jeopardize their privacy. Employers often perform background checks for their future employees using social networking sites and about 8% of companies have already fired employees due to their inappropriate social media content [54]. A study carried out by the Pew Research center reported that 11% of the users of social networking sites regret the content they posted [33].

Motivated by the fact that increasingly online users' privacy is routinely compromised by using social and content sharing applications [58], recently, researchers started to explore machine learning and deep learning models to automatically identify private or sensitive content in images [35, 45, 49–52, 57]. Starting from the premise that the objects and scene contexts present in images impact images' privacy, many of these studies used objects, scenes, and user tags, or their combination (i.e., feature-level or decision-level fusion) to infer adequate privacy classification for online images.

However, we conjecture that simply combining objects, scenes and user tags modalities using feature-level fusion (i.e., concatenation of all object, scene and user tag features) or decision-level fusion (i.e., aggregation of decisions from classifiers trained on objects, scenes and tags) may not always help to identify the sensitive content of images. Figure 1 illustrates this phenomenon through several images. For example, let us consider image (a) in the figure. Both feature-level and decision-level fusion models yield very low private class probabilities (Feature-level fusion: 0.21 and decision-level fusion: 0.33). Interestingly, a model based on the scene context (bedroom) of the image outputs a high probability of 0.62, showing that the scene based model is competent to capture the sensitive content of the image on its own. Similarly, for the image (b) (self-portrait) in Figure 1, where scene context is seldom in the visual content, the objects in the image (the "persons," "cocktail dress") are more useful (0.78) to predict appropriate image's privacy. Moreover, for images such as "personal documents" (image (c)), user-annotated

Figure 1: Anecdotal evidence of private images and their tags. The feature-level fusion is given as the concatenation of all the features (object, scene, tag) and the decision-level fusion is obtained by averaging the predictions.

tags provide broader context (such as type and purpose of the document), capturing the sensitive content (0.86), that objects and scene obtained through images' content failed to capture. On the other hand, in some cases, we can find more than one competent model for an image (e.g., for image (d)). To this end, we propose a novel approach that dynamically fuses multi-modal information of online images, derived through Convolutional Neural Networks (CNNs), to adequately identify the sensitive image content. In summary, we make the following contributions:

- Our significant contribution is to estimate the competence of object, scene and tag modalities for privacy prediction and dynamically identify the most competent modalities for a target image whose privacy has to be predicted.
- We derive "competence" features from the neighborhood regions of a target image and learn classifiers on them to identify whether a modality is competent to accurately predict the privacy of the target image. To derive these features, we consider privacy and visual neighborhoods of the target image to bring both sensitive and visually similar image content closer.
- We provide an in-depth analysis of our algorithm in an ablation setting, where we record the performance of the proposed approach by removing its various components. The analysis outline the crucial components of our approach.
- Our results show that we identify images' sensitive content more accurately than single modality models (object, scene, and tag), multi-modality baselines and prior approaches of privacy prediction, depicting that the approach optimally combines the multi-modality for privacy prediction.

2 RELATED WORK

We briefly review the related work as follows.

Ensemble models and Multi-Modality. Several works used ensemble classifiers (or bagging) to improve image classifications [11, 31, 39]. Bagging is an ensemble technique that builds a set of diverse classifiers, each trained on a random sample of the training data to improve the final (aggregated) classifier confidence [4, 43]. Dynamic ensembles that extend bagging have also been proposed [7, 9, 10] wherein a pool of classifiers are trained on a single feature set (single modality) using the bagging technique [4, 43], and the competence of the base classifiers is determined dynamically.

Ensemble classifiers are also used in the multi-modal setting [18, 38], where different modalities have been coupled, e.g., images and text for image retrieval [23] and image classification [18], and audio and visual signals for speech classification [34]. Zahavy et al. [56] highlighted that classifiers trained on different modalities can vary in their discriminative ability and urged the development of optimal unification methods to combine different classifiers. Besides, merging the Convolutional Neural Network (CNN) architectures corresponding to various modalities, that can vary in depth, width, and the optimization algorithm can become very complex. However, there is a potential to improve the performance through multi-modal information fusion, which intrigued various researchers [16, 22, 23, 32]. For example, Frome et al. [14] merged an image network [25] with a Skip-gram Language Model to improve classification on ImageNet. Zahavy et al. [56] proposed a policy network for multi-modal product classification in e-commerce using text and visual content, which learns to choose between the input signals. Feichtenhofer et al. [12] fused CNNs both spatially and temporally for activity recognition in videos to take advantage of the spatio-temporal information present in videos. Wang et al. [53] designed an architecture to combine object networks and scene networks, which extract useful information such as objects and scene contexts for event understanding. Co-training approaches [3] use multiple views (or modalities) to "guide" different classifiers in the learning process. However, co-training methods are semi-supervised and assume that all views are "sufficient" for learning. In contrast with the above approaches, we aim to capture different aspects of images, obtained from multiple modalities (object, scene, and tags), with each modality having a different competence power, and perform dynamic multi-modal fusion for image privacy prediction.

Online Image Privacy. Several works are carried out to study users' privacy concerns in social networks, privacy decisions about sharing resources, and the risk associated with them [15, 19, 24, 36, 37, 42]. Ahern et al. [1] examined privacy decisions and considerations in mobile and online photo sharing. They explored critical aspects of privacy such as users' consideration for privacy decisions, content and context based patterns of privacy decisions, how

different users adjust their privacy decisions and user behavior towards personal information disclosure. The authors concluded that applications, which could support and influence user's privacy decision-making process should be developed. Jones and O'Neill [21] reinforced the role of privacy-relevant image concepts. For instance, they determined that people are more reluctant to share photos capturing social relationships than photos taken for functional purposes; certain settings such as work, bars, concerts cause users to share less. Besmer and Lipford [2] mentioned that users want to regain control over their shared content, but meanwhile, they feel that configuring proper privacy settings for each image is a burden. Buschek et al. [6] presented an approach to assign privacy to shared images using metadata (location, time, shot details) and visual features (faces, colors, edges). Zerr et al. [57] developed the PicAlert dataset, containing Flickr photos, to help detect private images and also proposed a privacy-aware image classification approach to learn classifiers on these Flickr photos. Authors considered image tags and visual features such as color histograms, faces, edge-direction coherence, and SIFT for the privacy classification task. Squicciarini et al. [45, 46] found that SIFT and image tags work best for predicting sensitivity of user's images. Given the recent success of CNNs, Tran et al. [52], and Tonge and Caragea [49, 50] showed promising privacy predictions compared with visual features such as SIFT and GIST. Yu et al. [55] adopted CNNs to achieve semantic image segmentation and also learned object-privacy relatedness to identify privacy-sensitive objects.

Spyromitros-Xioufis et al. [44] used features extracted from CNNs to provide personalized image privacy classification, whereas Zhong et al. [59] proposed a Group-Based Personalized Model for image privacy classification in online social media sites. Despite that an individual's sharing behavior is unique, Zhong et al. [59] argued that personalized models generally require large amounts of user data to learn reliable models, and are time and space consuming to train and to store models for each user, while taking into account possible deviations due to sudden changes of users' sharing activities and privacy preferences. Orekondy et al. [35] defined a set of privacy attributes, which were first predicted from the image content and then used these attributes in combination with users preferences to estimate personalized privacy risk. The authors used official online social network rules to define the set of attributes, instead of collecting real user's opinions about sensitive content and hence, the definition of sensitive content may not meet a user's actual needs [29]. Additionally, for privacy attribute prediction, the authors fine-tuned a CNN pre-trained on object dataset. In contrast, we proposed a dynamic multi-modal fusion approach to determine which aspects of images (objects, scenes or tags) are more competent to predict images' privacy.

3 MULTI-MODALITY

The sensitive content of an image can be perceived by the presence of one or more objects, the scenes described by the visual content and the description associated with it in the form of tags [45, 49–51]. We derive features (object, scene, tags) corresponding to the multi-modal information of online images as follows.

Object (F^o): Detecting objects from images is clearly fundamental to assessing whether an image is of private nature. For example, a single element such as a firearm, political signs, may be a strong indicator of a private image. Hence, we explore the image descriptions extracted from VGG-16 [41], a CNN pre-trained on the ImageNet dataset [40] that has 1.2M+ images labeled with 1,000 object categories. The VGG-16 network implements a 16 layer deep network; a stack of convolutional layers with a very small receptive field: 3×3 followed by fully-connected layers. The architecture contains 13 convolutional layers and 3 fully-connected layers. The input to the network is a fixed-size 224×224 RGB image. The activation of the fully connected layers capture the complete object contained in the region of interest. Hence, we use the activation of the last fully-connected layer of VGG-16, i.e., fc_8 as a feature vector. The dimension of object features F^o is 1000.

Scene (F^s): As consistently shown in various user-centered studies [1], the context of an image is a potentially strong indicator of what type of message or event users are trying to share online. These scenes, e.g., some nudity, home, fashion events, concerts are also often linked with certain privacy preferences. Similar to object features, we obtain the scene descriptors derived from the last fully-connected layer of the pre-trained VGG-16 [25] on the Places2 dataset which contains 365 scene classes within 2.5 million images [60]. The dimension of scene features F^s is 365.

Image Tags (F^t): For image tags, we employ the CNN architecture of Collobert et al. [8]. The network contains one convolution layer on top of word vectors obtained from an unsupervised neural language model. The first layer embeds words into the word vectors pre-trained by Le and Mikolov [27] on 100 billion words of Google News, and are publicly available. The next layer performs convolutions on the embedded word vectors using multiple filter sizes of 3, 4 and 5, where we use 128 filters from each size and produce a tag feature representation. A max-pooling operation over the feature map is applied to capture the most important feature of length 256 for each feature map. To derive these features, we consider two types of tags: (1) user tags, and (2) deep tags. Because not all images on social networking sites have user tags or the set of user tags is very sparse [48], we predict the top d object categories (or deep tags) from the probability distribution extracted from CNN.

Object + Scene + Tag (F^{ost}): We use the combination of the object, scene, and tag features to identify the neighborhood of a target image. We explore various ways given in [12] to combine the features. For example, we use fc_7 layer of VGG to extract features of equal length of 4096 from both object-net and scene-net and consider the max-pooling of these vectors to combine these features. Note that, in this work, we only describe the combination of features that worked best for the approach. We obtain high-level object "F^o" and scene "F^s" features from fc_8 layer of object-net and scene-net respectively and concatenate them with the tag features as follows: $F^{ost} = f^{cat}(F^o, F^s, F^t)$. $F^{ost} = F^o(i), 1 \leq i \leq 1000, F^{ost}(i + 1000) = F^s(i), 1 \leq i \leq 365, F^{ost}(i + 1365) = F^t(i), 1 \leq i \leq 256$.

4 PROPOSED APPROACH

We seek to classify a given image into one of the two classes: *private* or *public*, based on users' general privacy preferences. To achieve this, we depart from previous works that use the same model on all image types (e.g., portraits, bedrooms, and legal documents), and

propose an approach called "Dynamic Multi-Modal Fusion for Privacy Prediction" (or DMFP), that effectively fuses multi-modalities (object, scene, and tags) and dynamically captures different aspects or particularities from image. Specifically, the proposed approach aims to estimate the competence of models trained on these individual modalities for each target image (whose privacy has to be predicted) and dynamically identifies the subset of the most "competent" models for that image. The rationale for the proposed method is that for a particular type of sensitive content, some modalities may be important, whereas others may be irrelevant and may simply introduce noise. Instead, a smaller subset of modalities may be significant in capturing a particular type of sensitive content (e.g., objects for portraits, scenes for interior home or bedroom, and tags for legal documents, as shown in Figure 1).

The proposed approach considers three stages to predict the privacy of a target image, wherein we first identify the neighborhood images that are visually similar and/or have similar sensitive content as the target image (Section 4.1). Then, using a set of base classifiers, each trained on an individual modality, we estimate the competence of the modalities by determining which modalities classify the neighborhood images correctly (Section 4.2). The goal here is to select the most competent modalities for a particular type of images (e.g., scene for home images). Finally, we fuse the decisions of the most competent base classifiers (corresponding to the most competent modalities) and predict the privacy label for the target image (Section 4.3).

Our approach considers two datasets, denoted as $\mathcal{D}^T$ and $\mathcal{D}^E$, that contain images labeled as *private* or *public*. We use the dataset $\mathcal{D}^T$ to train a base classifier for each modality to predict whether an image is public or private. Particularly, we train 3 base classifiers $\mathcal{B} = \{B^o, B^s, B^t\}$ on the corresponding modality feature sets from $\mathcal{F}$. Note that we use the combination of feature sets F^{ost} only for visual content similarity and do not train a base classifier on it. The competences of these base classifiers are estimated on the $\mathcal{D}^E$ dataset. We explain the stages of the proposed approach as follows. The notation used is shown in Table 1.

4.1 Identification of Neighborhoods

The competence of a base classifier is estimated based on a local region where the target image is located. Thus, given a target image T, we first estimate two neighborhoods for T: (1) visual similarity based (N_V^T) and (2) privacy profile based (N_P^T) neighborhoods.

The neighborhood N_V^T of target image T consists of the k_v most similar images from $\mathcal{D}^E$ using visual content similarity. Specifically, using the F^{ost} features obtained by concatenating object, scene, and tag features (as explained in Section 3), we determine the k_v most visually similar images to T by applying the K-Nearest Neighbors algorithm on the $\mathcal{D}^E$ dataset.

The neighborhood N_P^T of target image T consists of k_p most similar images to T by calculating the cosine similarity between the privacy profile of T and images from the dataset $\mathcal{D}^E$. We define privacy profile (denoted by $\overline{T}$) of image T as a vector of posterior privacy probabilities obtained by the base classifiers $\mathcal{B}$ i.e., $\overline{T} = \bigcup_{B_i \in \mathcal{B}} \{P(Y_T = private|T, B_i), P(Y_T = public|T, B_i)\}$. For image (a) in Figure 1, $\overline{T} = [0.62, 0.38, 0.5, 0.5, 0.29, 0.71]$. We consider the privacy profile of images because images of particular image content (bedroom images or legal documents) tend to possess similar privacy probabilities with respect to the set of base classifiers $\mathcal{B}$. For instance, irrespective of various kinds of bedroom images, the probabilities for a private class obtained by base classifiers $\mathcal{B}$, would be similar. This enables us to bring sensitive content closer irrespective of their disparate visual content. Moreover, we consider two different numbers of nearest neighbors k_v and k_p to find the neighborhoods since the competence of a base classifier is dependent on the neighborhood and estimating an appropriate number of neighbors for the respective neighborhoods reduces the noise.

Table 1: Mathematical notations.

Notation	Description
$\mathcal{D}^T$	$= \{(I_1, Y_1), \cdots, (I_m, Y_m)\}$ a dataset of labeled images for base classifier training.
$\mathcal{D}^E$	$= \{(X_1, Y_1), \cdots, (X_n, Y_n)\}$ a dataset of labeled images for competence estimation.
T	A target image with an unknown privacy label.
$\mathcal{F}$	$= \{F^o, F^s, F^t, F^{ost}\}$ a collection of modality feature sets of object, scene, tag, and object+scene+tag, respectively.
$\mathcal{B}$	$= \{B^o, B^s, B^t\}$ a set of base classifiers trained on corresponding modality feature sets from $\mathcal{F}$ (e.g., B^o is trained on F^o).
N_V^T	The visual similarity based neighborhood of image T estimated using visual content features F^{ost}, i.e., the set of most similar images to T based on visual content.
k_v	The size of N_V^T, where $1 \leq k_v < n$.
N_P^T	The privacy profile based neighborhood of target T, i.e., the set of most similar images to T based on images' privacy profiles.
k_p	The size of N_P^T, where $1 \leq k_p < n$.
C	$= \{C^o, C^s, C^t\}$ a set of "competence" classifiers corresponding to the base classifiers from $\mathcal{B}$ (e.g., C^o for B^o).
Φ	$= \{\phi^o, \phi^s, \phi^t\}$ a set of "competence" feature vectors for training the "competence" classifiers.

4.2 "Competence" Estimation

We now describe how we estimate the "competence" of a base classifier. For instance, for the image (a) in Figure 1, scene model has a higher competence than the others, and here, we capture this competence through "competence" features and "competence" classifiers. Specifically, we train a competence classifier for each base classifier that predicts if the base classifier is competent or not for a target image T. The features for learning the competence classifiers and the competence learning are described below.

4.2.1 Derivation of "Competence" Features. We define three different sets of "competence" features wherein each set of these features captures a different criterion to estimate the level of competence of base classifiers dynamically. The first competence feature ϕ_1, for image T, is derived from the neighborhood N_V^T (based on visual similarity) whereas the second competence feature ϕ_2 is obtained from the neighborhood N_P^T (based on privacy profile). The third competence feature ϕ_3 captures the level of confidence of base classifiers for predicting the privacy of the image (T) itself. We create a "competence" feature vector by concatenating all these competence features $\phi = \{\phi_1 \cup \phi_2 \cup \phi_3\}$ into a vector of length $|\phi| = k_v + k_p + 1$. We extract such competence vectors corresponding to each base

Algorithm 1 The "Competence" Learning

1: **Input**: A dataset $\mathcal{D}^E = \{(X_1, Y_1), \cdots, (X_n, Y_n)\}$ of labeled images; $F^{ost}_{X_j}$ combination of modality feature sets for X_j; a set of base classifiers $\mathcal{B} = \{B^o, B^s, B^t\}$.
2: **Output**: A set of "competence" classifiers $C = \{C^o, C^s, C^t\}$.
3: $\mathcal{D} = \{D^o, D^s, D^t\} \leftarrow \varnothing$; // Datasets for training competence classifiers, initially empty.
4: $C \leftarrow \varnothing$; // A set of competence classifiers, initially empty.
5: **for all** $X_j \in \mathcal{D}^E$ **do**
6: $N_V^{X_j} \leftarrow IdentifyVisualNeighborhood(k_v, X_j, F^{ost}_{X_j}, \mathcal{D}^E)$; // k_v nearest neighbors of X_j obtained using visual content similarity.
7: $\overline{X_j} \leftarrow ComputePrivacyProfile(X_j, \mathcal{B})$; //Privacy profile.
8: $N_P^{X_j} = IdentifyPrivacyNeighborhood(k_p, \overline{X_j}, \overline{\mathcal{D}^E})$; // k_p most similar images of $\overline{X_j}$ obtained using privacy profile similarity.
9: **for all** $B_i \in \mathcal{B}$ **do** // Iterate through the set of base classifiers.
10: $\phi_{i,j} \leftarrow CompetenceFeatures(X_j, N_V^{X_j}, N_P^{X_j}, B_i)$;
11: **if** $Predict(B_i, X_j) = Y_j$ **then** // predicted correctly.
12: $L_{i,j} \leftarrow 1$; // B_i is competent for X_j.
13: **else**
14: $L_{i,j} \leftarrow 0$; // B_i is not competent for X_j.
15: **end if**
16: $D^i \leftarrow D^i \cup \{(\phi_{i,j}, L_{i,j})\}$
17: **end for**
18: **end for**
19: **for all** $D^i \in \mathcal{D}$ **do** // Train competence classifiers.
20: $C_i \leftarrow TrainCompetenceClassifier(D^i)$;
21: $C \leftarrow C \cup C_i$
22: **end for**
23: **return** C;

Algorithm 2 Dynamic Fusion of Multi-Modality

1: **Input**: A target image T; $\mathcal{D}^E = \{(X_1, Y_1), \cdots, (X_n, Y_n)\}$ a dataset of labeled images; F^{ost}_T combination of modality feature sets for T; a set of base classifiers $\mathcal{B} = \{B^o, B^s, B^t\}$; and a set of competence classifiers $C = \{C^o, C^s, C^t\}$.
2: **Output**: Privacy label Y_T.
3: $B' \leftarrow \varnothing$; // the subset of most competent base classifiers.
4: $CS \leftarrow \varnothing$; // the set of competence scores.
5: $T_{ba} \leftarrow Agreement(\mathcal{B}, T)$; // Base classifiers' agreement on T's label.
6: **if** $T_{ba} \leq |\mathcal{B}|$ **then**
7: $N_V^T \leftarrow IdentifyVisualNeighborhood(k_v, T, F^{ost}_T, \mathcal{D}^E)$; // k_v nearest neighbors of T obtained using visual content similarity.
8: $\overline{T} \leftarrow ComputePrivacyProfile(T, \mathcal{B})$; //Privacy profile of T.
9: $N_P^T = IdentifyPrivacyNeighborhood(k_p, \overline{T}, \overline{\mathcal{D}^E})$; // k_p most similar images of $\overline{T}$ obtained using privacy profile similarity.
10: **for all** $B_i \in \mathcal{B}$ & $C_i \in C$ **do** // Iterate through the set of base and competence classifiers.
11: $\phi_i \leftarrow CompetenceFeatures(T, N_V^T, N_P^T, B_i)$;
12: $CS_i \leftarrow PredictCompetence(F_i, C_i)$; // Predict competence score for base classifier B_i.
13: **if** $CS_i > 0.5$ **then** // If the predicted competence score is greater than 0.5 then the base classifier B_i is competent.
14: $B' \leftarrow B' \cup \{B_i\}$
15: $CS \leftarrow CS \cup \{CS_i\}$
16: **end if**
17: **end for**
18: $Y_T = WeightedMajorityVote(T, B', CS)$ // Votes are first weighted by the competence score and then majority vote is taken.
19: **end if**
20: **return** Y_T

classifier in $\mathcal{B}$ (e.g., ϕ^o for B^o, refer to Figure 2). We extract these "competence" features as follows.

ϕ_1: A vector of k_v entries that captures the correctness of a base classifier in the visual neighborhood region N_V^T. An entry j in ϕ_1 is 1 if a base classifier $B_i \in \mathcal{B}$ accurately predicts privacy of image $X_j \in N_V^T$, and is 0 otherwise, where $j = 1, \cdots, k_v$. For the target image in Figure 2, $\phi_1 = \{1, 1, 0, 1, 0, 1, 1\}$, obtained by B^o.

ϕ_2: A vector of k_p entries that captures the correctness of a base classifier in the privacy profile neighborhood region N_P^T. An entry j in ϕ_2 is 1 if a base classifier $B_i \in \mathcal{B}$ accurately predicts privacy of image $X_j \in N_P^T$, and is 0 otherwise, where $j = 1, \cdots, k_p$. For the target image in Figure 2, $\phi_2 = \{1, 1, 1, 1, 1\}$, obtained using B^o.

ϕ_3: We capture a degree of confidence of base classifiers for target image T. Particularly, we consider the maximum posterior probability obtained for target image T using base classifier B_i i.e. $Max(P(Y_T = Private|T, B_i), P(Y_T = Public|T, B_i))$, where $B_i \in \mathcal{B}$. For the target image in Figure 2, $\phi_3 = 0.67$, obtained using B^o.

4.2.2 "Competence" Learning. We learn the "competence" of a base classifier by training a binary "competence" classifier on the dataset $\mathcal{D}^E$ in a Training Phase. A competence classifier predicts whether a base classifier is competent or not for a target image. Algorithm 1 describes the "competence" learning process in details. Mainly, we consider images from $\mathcal{D}^E$ as target images (for the training purpose only) and identify both the neighborhoods (N_V, N_P) from the dataset $\mathcal{D}^E$ itself (Alg. 1, lines 6–8). Then, we extract "competence" features for each base classifier in $\mathcal{B}$ based on the images from these neighborhoods (Alg. 1, line 10). To reduce noise, we extract "competence" features by considering only the images belonging to both the neighborhoods. On these "competence" features, we train a collection of "competence" classifiers C corresponding to each base classifier in $\mathcal{B}$ (Alg. 1, lines 19–22). Precisely, we train 3 competence classifiers $C = \{C^o, C^s, C^t\}$. To train "competence" classifier $C_i \in C$, we consider label $L_i = 1$ if base classifier $B_i \in \mathcal{B}$ predicts the correct privacy of a target image (here, $X_j \in \mathcal{D}^E$), otherwise 0 (Alg. 1, lines 11–16).

4.3 Dynamic Fusion of Multi-Modality

In this stage, for given target image T, we dynamically determine the subset of most competent base classifiers. We formalize the process of base classifier selection in Algorithm 2. The algorithm first checks the agreement on the privacy label between all the base classifiers in $\mathcal{B}$ (Alg. 2, line 5). If not all the base classifiers agree, then we estimate the competence of all the base classifiers and identify the subset of most competent base classifiers for the target image as follows. Given target image T, Algorithm 2 first identifies both the neighborhoods (N_V^T, N_P^T) using the visual features F^{ost}

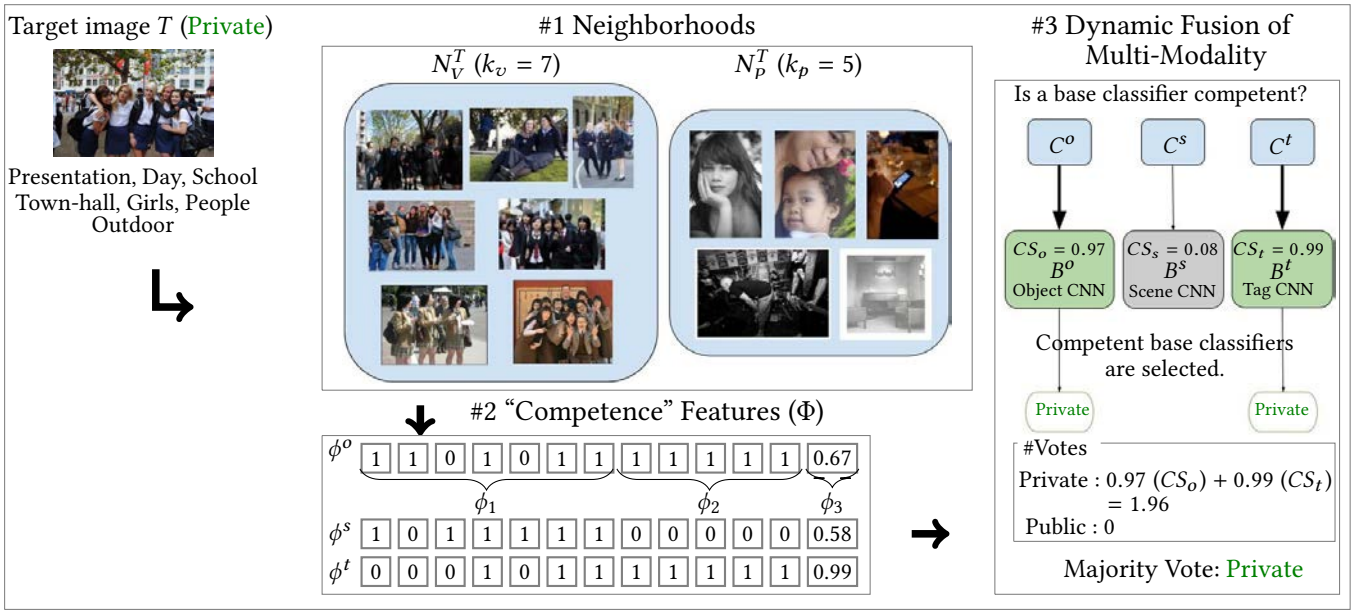

Figure 2: Illustration of the proposed approach using an example.

and privacy profile from $\mathcal{D}^E$ dataset (Alg. 2, lines 7–9). Using these neighborhoods, we extract "competence" feature vectors (explained in Section 4.2) and provide them to the respective "competence" classifiers in C (learned in the Training Phase) to predict competence score of base classifier B_i. If the competence score is greater than 0.5, then base classifier B_i is identified as competent to predict the privacy of target image T (Alg. 2, lines 10–17). Finally, we weight votes of the privacy labels predicted by the subset of most competent base classifiers by their respective "competence" score and take a majority vote to obtain the final privacy label for target image T (Alg. 2, line 18). A "competence" score CS_i is given as a probability of base classifier B_i being competent. We consider the majority vote of the most competent base classifiers because certain images (e.g., vacation) might require more than one base classifiers (object and scene) to predict the appropriate privacy. If both the privacy classes (private and public) get the same number of votes, then the class of a highest posterior probability is selected.

Illustration of the Proposed Approach . Figure 2 shows the illustration of the proposed approach through an anecdotal example. We consider a target image T whose privacy has to be predicted. For T, we first identify two neighborhoods: (1) visual content (N_V^T), 2. privacy profile (N_P^T). For N_V^T, we use visual content features F^{ost} to compute the similarity between target image T and the images from the dataset $\mathcal{D}^E$. The top $k_v = 7$ similar images for N_V^T are shown in the figure (left blue rectangle). Likewise, for N_P^T, we compute the similarity between privacy profile of the target image $\overline{T}$ and privacy profiles of images in $\mathcal{D}^E$. We show the top $k_p = 5$ similar images for N_P^T in the right blue rectangle of Figure 2. From these neighborhoods, we derive a "competence" feature vector ϕ for each base classifier in $\mathcal{B}$ (e.g., ϕ^o for B^o). We show these "competence" features in the figure as a matrix of feature values. We input these features to the respective "competence" classifiers from C (e.g., ϕ^o to C^o), that predict whether a base classifier $B_i \in B$ is competent to predict correct privacy label of the target image (T). The "competence" classifiers (C^o, C^s, C^t) are shown as blue rectangles on the right side of Figure 2. The base classifiers B^o and B^t are predicted as competent and hence are selected to obtain the final privacy label for the target image. The competent base classifiers are shown in green rectangles on the right side of Figure 2. Once we select the competent base classifiers, we take a weighted majority vote on the privacy labels, predicted by these base classifiers. For example, in this case, the competent base classifiers B^o and B^t predict the privacy of T as "private," and hence, the final privacy label of T is selected as "private." It is interesting to note that the target image (T) contains "outdoor" scene context that is not useful to predict the correct privacy label and hence, the scene model B^s is not selected by the proposed approach for the target image.

5 DATASET

We evaluate our approach on a subset of 32,000 Flickr images sampled from the PicAlert dataset, made available by Zerr et al. [57]. PicAlert consists of Flickr images on various subjects, which are manually labeled as *public* or *private* by external viewers. The guideline to select the label is given as: private images belong to the private sphere (like self-portraits, family, friends, someone's home) or contain information that one would not share with everyone else (such as private documents). The remaining images are labeled as public. The dataset of 32,000 images is split in $\mathcal{D}^T$, $\mathcal{D}^E$ and *Test* sets of 15,000, 10,000 and 7,000 images, respectively. Each experiment is repeated 5 times with a different split of the three subsets (obtained using 5 different random seeds) and the results are averaged across the five runs. The public and private images are in the ratio of 3:1 in all subsets.

Table 2: Exploratory analysis.

Test	Pr(%)	Pu(%)	O(%)
Object is correct	49	95.7	84.8
Scene is correct	51	94.7	84.4
Tag is correct	57	91.1	83
All are correct	30	87.3	73.9
All are wrong	27	1.5	7.4
Atleast one modality is correct	**73**	**98.5**	**92.6**

6 EXPERIMENTS AND RESULTS

We evaluate the privacy prediction performance obtained using the proposed approach DMFP, where we train a set of base classifiers $\mathcal{B}$ on images in the dataset $\mathcal{D}^T$, and dynamically estimate the "competence" of these base classifiers for target images in *Test* by identifying neighborhoods (N_V, N_P) using images in $\mathcal{D}^E$. We first consider various values of neighborhood parameters k_v and k_p and show their impact on the performance of the proposed approach. Then, we compare the performance of the proposed approach with the performance obtained using three types of mechanisms: (1) components of the proposed approach, that are used to fuse the multi–modal characteristics of online images, (2) the state-of-the-art approaches for privacy prediction, and (3) strong baselines that select models based on their competence (e.g., Zahavy et al. [56]) and that attempt to yield the optimal combination of base classifiers (for instance, using stacked ensemble classifiers).

Evaluation Setting. We train base classifiers ($\mathcal{B}$) using the Calibrated linear Support Vector Machine (SVM) implemented in Scikit-learn library to predict more accurate probabilities. We use 3-fold cross-validation on the dataset $\mathcal{D}^T$ to fit the linear SVM on the 2–folds, and the remaining fold is used for calibration. The probabilities for each of the folds are then averaged for prediction. We train "competence" classifiers (C) on the dataset $\mathcal{D}^E$ using logistic regression to predict "competence" scores between $0-1$ for base classifiers. If base classifier B_i gets a "competence" score greater than 0.5 then the base classifier is considered competent. To derive features from CNN, we use pre-trained models presented by the VGG-16 team in the ILSVRC-2014 competition [41] and the CAFFE framework [20]. For deep tags, we consider top $d = 10$ object labels as $d = 10$ worked best.

Exploratory Analysis. We provide exploratory analysis in Table 2 to highlight the potential of merging object, scene and tag modality for privacy prediction. We predict privacy for images in the *Test* set using base classifiers in $\mathcal{B}$ and obtain "private" (Pr), "public" (Pu) and "overall" (O) accuracy for: (a) a modality is correct (e.g., object), (b) all modalities are correct, (c) all modalities are wrong, and (d) at least one modality is correct. Table 2 shows that out of the three base classifiers (top 3 rows), the tag model yields the best accuracy for the private class (57%). Interestingly, the results for "at least one modality is correct" (73%) show that using multi-modality, there is a huge potential (16%) to improve the performance of the private class. This large gap is a promising result for developing multi-modality approaches for privacy prediction. Next, we evaluate DMFP that achieved the best boost in the performance for the private class using these modalities.

6.1 Impact of Parameters k_v and k_p on DMFP

We show the impact of neighborhood parameters, i.e., k_v and k_p on the privacy prediction performance obtained by the proposed approach DMFP. k_v and k_p are used to identify visual (N_V) and privacy profile (N_P) neighborhoods of a target image, respectively (Alg. 2 lines 7–8). We experiment with a range of values for both the parameters $k_v, k_p = \{10, 20, \cdots, 100, 200, \cdots, 1000\}$, in steps of 10 upto 100 and then in steps of 100. We also experiment with larger k_v and k_p values, but for better visualization, we only show the values with significant results. Figure 3 shows the F1-measure obtained (using 3-fold cross-validation on the $\mathcal{D}^E$ dataset) for the private class for various k_v and k_p values. We notice that when we increase the k_v parameter the performance increase whereas when we increase k_p parameter, the performance increases upto $k_p = 200$, then the performance decreases gradually. The results show that the performance is quite sensitive to changes in the privacy neighborhood (N_P) parameter k_p, but relatively insensitive to changes in the visual neighborhood (N_V) parameter k_v. We get the best performance for $k_v = 900$ and $k_p = 100$. We use these parameter values in the next experiments.

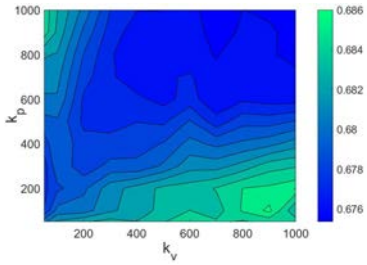

Figure 3: F1-measure obtained for various k_v and k_p values.

6.2 Evaluation of the Proposed Approach

We evaluate the proposed approach DMFP for privacy prediction in an ablation experiment setting. Specifically, we remove a particular component of the proposed approach DMFP and compare the performance of DMFP before and after the removal of that component. We consider excluding several components from DMFP: (1) the visual neighborhood N_V (DMFP$-N_V$), (2) the privacy profile neighborhood N_P (DMFP$-N_P$), (3) "competence" features (e.g., DMFP$-\phi_1$), and (4) base classifier selection without "competence" learning (e.g., $N_V - CL$). For option (4), we consider a simpler version of the proposed algorithm, in which we do not learn a competence classifier for a base classifier; instead, we rely solely on the number of accurate predictions of the samples from a neighborhood. We evaluate it using images from three regions: (a) neighborhood N_V only ($N_V - CL$), (b) neighborhood N_P only ($N_P - CL$), and (c) both the neighborhoods N_P and N_V ($\{N_P + N_V\} - CL$).

Table 3 shows the class-specific (private and public) and overall performance obtained by the proposed approach (DMFP) and after removal of its various components detailed above. Primarily, we wish to identify whether the proposed approach characterizes the private class effectively as sharing private images on the Web with everyone is not desirable. We observe that the proposed approach achieves the highest recall of 0.627 and F1-score of 0.684 (private class), which is better than the performance obtained by eliminating the essential components (e.g., neighborhoods) of the proposed approach. We notice that if we remove either of the neighborhood

Table 3: Evaluation of dynamic multi-modal fusion for privacy prediction (DMFP).

N_V or N_P, the recall and F1-score drop by 5% and 4%. This suggests that both the neighborhoods (N_V, N_P) are required to identify an appropriate local region surrounding a target image. It is also interesting to note that the performance of DMFP−N_P (removal of N_P) is slightly lower than the performance of DMFP−N_V (removal of N_V), depicting that neighborhood N_P is helping more to identify the competent base classifier(s) for a target image. The N_P neighborhood brings images closer based on their privacy probabilities and hence, is useful to identify the competent base classifier(s) (this is evident in Figure 2). We also show that when we remove competence learning (CL) i.e., $N_V - CL$, $N_P - CL$, and $\{NV + NP\} - CL$, the precision improves by 4% (private class), but the recall and F1-score (private class) drops by 9% and 5% respectively, showing that competence learning is necessary to achieve the best performance.

We also remove the "competence" features one by one and record the performance of DMFP to understand which competence features are essential. Table 3 shows that when we remove feature ϕ_1 corresponding to the neighborhood N_V, the performance drops significantly ($\approx$ 4%). Likewise, when we remove ϕ_2 (feature corresponding the N_P region), we notice a similar decrease of 4% in the F1-score of private class. Note that, when we remove the "competence" features corresponding to their neighborhoods (such as ϕ_1 for N_V and ϕ_2 for N_P), we get nearly similar performance as we remove the respective neighborhoods from the proposed approach (DMFP−N_V and DMFP−N_P); implying that removing "competence" features (e.g., ϕ_1) is as good as removing the corresponding neighborhood (N_V). However, a close look at the performance suggests that the performance obtained using DMFP−ϕ_1 (recall of 0.553) is slightly worse than the performance of DMFP−N_V (recall of 0.57). Similarly, for DMFP−ϕ_2, the performance (recall) decrease from 0.572 obtained using DMFP−N_P to 0.565. The performance decrease can be explained as when we remove the neighborhood N_V or N_P, the respective "competence" features are empty, and that might be helpful for some cases (as zero-valued ϕ_2 feature of ϕ^s was helpful in Figure 2). Additionally, the recall of DMFP−N_V and DMFP−N_P are similar whereas the recall of DMFP−ϕ_1 (0.553) is slightly worse than the recall of DMFP−ϕ_2 (0.565). The results suggests that the neighborhood N_V is more dependent on the "competence" features as compared to the neighborhood N_P. We experimented with the probability based "competence" features (instead of boolean features), but did not yield improvements in the performance.

6.3 Proposed Approach vs. Base Classifiers

We compare privacy prediction performance obtained by the proposed approach DMFP with the set of base classifiers $\mathcal{B}$: 1. object (B^o), 2. scene (B^s), and 3. image tags (B^t).

Table 4 compares the performance obtained by the proposed approach (DMFP) and base classifiers. We achieve the highest performance as compared to the base classifiers and show a maximum improvement of $\approx$ 10% in the F1-score of private class. We notice that our approach based on multi-modality yields an improvement of 11% over the recall of object and scene models and an improvement of $\approx$ 6% over the recall of the tag model, that is the best-performing single modality model obtained for the private class from the exploratory analysis (refer to Table 2). Still, our approach makes some errors (See Table 2 and 3, 73% vs. 62%). A close look at the errors discovered that a slight subjectivity of annotators could obtain different labels for similar image subjects (e.g., food images are very subjective).

Error Analysis. We perform error analysis to further analyze the results of the proposed approach. We first determine the errors generated by all the base classifiers in $\mathcal{B}$ and corrected by the proposed approach DMFP. We calculate the percentage of corrected errors for private class, public class and overall (considering both the classes) and show them in Table 6. We compute the percentage of corrected errors as the number of corrected errors of private (or public) class over the total number of private (or public) class errors. We calculate the fraction of overall corrected errors by considering both public and private classes. The table shows that we correct 14% − 27% of private class errors, 18% − 58% of public class errors and overall we eliminate 16% − 37% errors. Note that errors generated for the private class are much larger than the public class

(See Table 4) and hence, even a comparatively smaller percentage of corrected errors constitute to a significant improvement. We also analyze results by showing predictions of samples in Figure 4, for which at least one base classifier fails to predict the correct privacy of an image. For instance, for example (b), scene model failed to predict the correct privacy of the image; however, DMFP identifies the competent base classifiers, i.e., object, and tag and predict the correct privacy label. We also show an example (image (d)) for which all the base classifiers fail to predict the correct privacy class and hence, the proposed approach also fails to predict the correct label. The image of a food is very subjective and hence, generic base classifiers will not be sufficient to predict the correct labels of such images. In the future, these generic models can be extended to develop hybrid approaches, that consider both generic and subjective privacy notions to predict personalized privacy labels.

6.4 Proposed Approach vs. Baselines

We compare the performance of the proposed approach DMFP with multi-modality based baselines described below.

1. Model Selection by Zahavy et al. [56]: The authors proposed a deep multi-modal architecture for product classification in e-commerce, wherein they learn a decision-level fusion policy to choose between image and text CNN for an input product. Specifically, the authors provide class probabilities of a product as input to the policy trained on a validation dataset and use it to predict whether image CNN (or text CNN) should be selected for the input. In other words, policy determines the competence of the CNNs for its input and thus, we consider it as our baseline. For a fair comparison, we learn 3 policies (corresponding to the competence classifiers C), wherein each policy (say object policy) predicts whether the respective base classifier (object) should be selected for a target image. Note that we learn these policies on the $\mathcal{D}^E$ dataset. Finally, we take a majority vote of the privacy label predicted by the selected base classifiers (identified by the policies) for a target image.

2. Majority Vote: We consider a majority vote as another baseline, as we use it for final selection of privacy label for a target image. Unlike our approach, a vote is taken without any pre-selection of base classifiers. We predict privacy of a target image using base classifiers in $\mathcal{B}$ and select a label having highest number of votes.

3. Decision-level Fusion: Fixed rules, that average the predictions of the different CNNs [25] or select the CNN with the highest confidence [38]. The first rule is equivalent to the majority vote baseline, and hence, we show the results for the second rule only. The second rule is given as: $Y_T = argmax_i([{P_i}^o + {P_i}^s + {P_i}^t]/3)$, where $i = 0$ (public), 1 (private). P^o, P^s, and P^t denotes the posterior probabilities (private or public) obtained using object (B^o), scene (B^s) and tag (B^t) modality respectively.

4. Stacked Ensemble (Stacked–en): Stacking learns a meta-classifier to find an optimal combination of the base learners [5, 26]. Unlike bagging and boosting, stacking ensembles robust and diverse set of base classifiers together, and hence, we consider it as one of the baselines. We use the same set of base classifiers $\mathcal{B}$ to encode images in $\mathcal{D}^T$ using posterior probabilities $P(Y_I = private|I, B_i)$ and $P(Y_I = public|I, B_i)$ where $B_i \in \mathcal{B}$. We train a meta-classifier on this encoded $\mathcal{D}^T$ dataset using calibrated SVM classifier. We use this meta-classifier to predict privacy class of an encoded target image T (using the posterior probabilities obtained by the base classifiers $P(Y_T = private|T, B_i)$ and $P(Y_T = public|T, B_i)$). As we use $\mathcal{D}^E$ only to learn "competence" classifiers, we do not consider it for training a meta-classifier for a fair comparison.

5. Clusters-based Models (Cluster–en): We create 5 clusters of $\mathcal{D}^T$ dataset using hierarchical clustering mechanism and the combination of object, scene and tag features (F^{ost}). We train a calibrated SVM model on each cluster using the combination of

features F^{ost}. For target image T, the most relevant cluster is identified using $k = 15$ nearest neighbors, and the model trained on that cluster is used to predict the privacy of the target image. We consider this as another baseline, because clustering images that are shared online, brings similar image types (e.g., portraits) together and models trained on these clusters can be competent to predict privacy of target images of respective image types. The number of clusters and neighbors are estimated based on the $\mathcal{D}^E$ dataset.

Table 5 compares the performance obtained by the proposed approach DMFP with the performance obtained using the baseline models. We observe that DMFP learns better privacy characteristics than baselines with respect to private class by providing improvements of 4.5%−14% and 4%−20% in the F1-score and recall of private class. When we learn the "competence" of the base classifiers ($\mathcal{B}$) on the $\mathcal{D}^E$ dataset without identifying the neighborhoods (the first baseline, Zahavy et al. [56]), the precision, recall and F1-score drop by 9%, ≈ 6%, ≈ 7%. It is interesting to note that the precision of DMFP−CL (Refer Table 3, $N_V - CL$, $N_P - CL$, $\{N_V + N_P\} - CL$), i.e., 0.79 is better than the first baseline (Zahavy et al. [56]), i.e., 0.662 whereas the recall of the first baseline (0.568) is better than DMFP−CL (0.534). However, when we combine the neighborhoods ($\{N_V + N_P\}$) and the first baseline (competence learning), i.e., the proposed approach DMFP, we get better performance than each of these methods. Another detail to note that the performance of the first baseline (Zahavy et al. [56]) is very close to the image tags model (see Table 5, 4) and even though the baseline uses multi-modality, the performance does not exceed significantly over the individual base classifiers (object, scene, image). Zahavy et al. [56] performed well for product classification, but it failed to yield improved results for privacy prediction because unlike product images or ImageNet images (that contains single object in the image), images that are shared online are much more complex (containing multiple objects, and scene) and diverse (having different image subjects such as self-portraits, personal events). The results suggest that it is hard to generalize the competency of base classifiers on all types of image subjects and hence, the competence of the base classifiers needs to be determined dynamically based on the neighborhoods of a target image.

Table 5 also shows that F1-measure of private class improves from 0.637 achieved by majority vote (the second baseline), 0.65 obtained by decision-level fusion (the third baseline), 0.636 obtained by stacked−en (the fourth baseline), and 0.545 obtained by cluster−en (the fifth baseline) to 0.684 obtained by DMFP. Additionally, we notice that the proposed approach is able to achieve a performance higher than 85% in terms of all compared measures. Note that a naive baseline which classifies every image as "public" obtains an accuracy of 75%. With a paired T-test, the improvements over the baseline approaches for F1-measure of a private class are statistically significant for p-values < 0.05.

6.5 Proposed Approach vs. Prior Image Privacy Prediction Works

We compare the privacy prediction performance obtained by the proposed approach DMFP with the state-of-the-art works of privacy prediction: **1. object** [49, 50] (B^o), **2. scene** [51] (B^s), **3. image tags** [45, 49, 50] (B^t), 4. PCNH privacy framework [52], and 5. Concatenation of all features [51]. Note that the first three works are the feature sets of DMFP and are evaluated in the Experiment 6.3. We describe the remaining prior works (i.e., 4 and 5) in what follows. **4. PCNH privacy framework** [52]: The framework combines features obtained from two architectures: one that extracts convolutional features (size = 24), and another that extracts object features (size = 24). The object CNN is a very deep network of 11 layers obtained by appending three fully-connected layers of size 512, 512, 24 at the end of the fully-connected layer of AlexNet [25]. The PCNH framework is first trained on the ImageNet dataset [40] and then fine-tuned on a privacy dataset. **5. Combination of Object, Scene and User Tags (Concat)** [51]: Tonge et al. [51] combined object and scene tags with user tags and achieved an improved performance over the individual sets of tags. Thus, we compare the proposed approach with the SVM models trained on the combination of all feature sets (F^{ost}) to show that it will not be adequate to predict the privacy of an image accurately. In our case, we consider object and scene visual features instead of tags and combine them with user tags to study multi-modality with the concatenation of visual and tag features.

Table 7 compares the performance obtained by the proposed approach (DMFP) and prior works. We achieve the highest performance as compared to the prior works and show a maximum improvement of ≈ 10% in the F1-score of private class. We notice that our approach based on multi-modality yields an improvement of 11% over the recall of almost all the prior works (Refer Table 4 and 7). Particularly, we show improvements in terms of all measures over the PCNH framework, that uses two kinds of features object and convolutional. We found that adding high-level descriptive features such as scene context and image tags to the object features help improve the performance. In addition to the individual feature sets, we also outperform the concatenation of these feature sets (denoted as "Concat"), showing that "Concat" could not yield an optimal combination of multi-modality. We notice that the performance of "Concat" is slightly lower than the performance of base classifiers (Refer Tables 4 and 7). We find this is consistent with Zahavy et al. [56] results, that concatenated various layers of image and tag CNN and trained the fused CNN end-to-end but did not yield a better performance than the individual CNN (image or tag).

7 CONCLUSIONS AND FUTURE WORK

In this work, we estimate the competence of object, scene and image tag modalities, derived through convolutional neural networks and dynamically identify the set of most competent modalities for a target image to adequately predict the class of the image as *private* or *public*. The proposed approach contains three stages wherein we first identify neighborhoods for a target image based on visual content similarity and privacy profile similarity. Then, we derive "competence" features from these neighborhoods and provide them to the "competence" classifiers to predict whether a modality is competent for the target image. Lastly, we select the subset of the most competent modalities and take a majority vote to predict privacy class of the target image. Experimental results show that our approach predicts the sensitive (or private) content more accurately than the models trained on an individual modality (object, scene, and tags), multi-modality baselines and prior privacy prediction

Table 7: Dynamic multi-modal fusion for privacy prediction (DMFP) vs. prior image privacy prediction works.

approaches. Also, our approach could aid other applications such as event understanding, image classification, to on the fly decide which CNN (object, scene or tag) to use based on a target image.

In the future, it will be interesting to study dynamic multi-modal fusion in personalized privacy setting. Also, other types of competence learning approaches and competence features can be developed for estimating the competence of base classifiers.

ABSTRACT

Personalized recommendation algorithms learn a user's preference for an item by measuring a distance/similarity between them. However, some of the existing recommendation models (e.g., matrix factorization) assume a linear relationship between the user and item. This approach limits the capacity of recommender systems, since the interactions between users and items in real-world applications are much more complex than the linear relationship. To overcome this limitation, in this paper, we design and propose a deep learning framework called *Signed Distance-based Deep Memory Recommender*, which captures non-linear relationships between users and items *explicitly* and *implicitly*, and work well in both general recommendation task and shopping basket-based recommendation task. Through an extensive empirical study on six real-world datasets in the two recommendation tasks, our proposed approach achieved significant improvement over ten state-of-the-art recommendation models.

KEYWORDS

Memory recommender; signed distance; metric-based attention.

1 INTRODUCTION

Recommender systems [1] have been deployed in many online applications such as e-commerce, music/video streaming services, social media, *etc.* They have played a vital role for users to explore new items and for companies to increase their revenues. Most of recommendation algorithms model user preferences and item properties based on observed interactions (*e.g.,* clicks, reviews, ratings) between users and items [20, 21, 30]. In a perspective, we can view most of the recommendation models as a measurement of similarity or distance between a user and an item. For instance, the well known latent factor (i.e., matrix factorization) models [19] usually employ an inner product function to approximate the similarity between the user and the item. Although the latent factor models achieved competitive performance in some datasets, they did not correctly capture complex (i.e., non-linear) relationships between users and items because the inner product function follows limited linear nature.

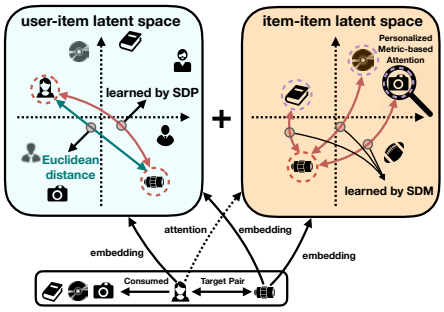

Figure 1: We consider a recommender as a signed distance approximator, and decompose the signed distance between a user and an item into two parts: the left box learns an explicitly signed distance between the user and item (i.e., the *camera lens*), the right box learns an implicitly signed distance between the user and the item via the user's recently consumed items (i.e., the *book*, *CD* and *camera*). Our novel personalized metric-based soft attention is applied to the consumed items to optimize their contributions to the output signed distance score. Then the two parts are combined to obtain a final score. Most of linear latent factor models are equivalent to simply measuring the linear Euclidean distance in the user-item latent space (shown as the green line).

Existing recommendation algorithms faced difficulties in finding good kernels for different data patterns [30], only focused on user-item latent space without considering the item-item latent space together [12, 24, 25, 43, 57], or required additional auxiliary information (e.g., item description, music content, reviews) [4, 17, 29, 31, 53]. To overcome the drawbacks, in this paper we aim to propose and build a deep learning framework to learn a non-linear relationship

between a user and a target item by measuring a distance from the observed data. In particular, we propose *Signed Distance-based Deep Memory Recommender* (SDMR), which captures non-linear relationship of the user and item *explicitly* and *implicitly*, combines *explicitly* and *implicitly* measured relationship to produce a final distance score for the recommendation, and performs well in both general recommendation task and shopping basket-based recommendation task.

SDMR internally combines two signed distances, each of which is measured by our proposed *Signed Distance-based Perceptron* (SDP) and *Signed Distance-based Memory Network* (SDM). On one hand, SDP explicitly measures a non-linear signed distance between the user and the item. Many existing models [13, 16] rely on a pre-defined metric such as Euclidean distance (the green line in Figure 1) which is much more limited than the customized non-linear signed distance learned from the data (the red curves in Figure 1). On the other hand, SDM implicitly measures a non-linear signed distance between the user and the item via the user's recently consumed items. SDM is similar to the item neighborhood-based recommender [36, 42] in nature. However, it is more advanced in several aspects, as shown in the right side of Figure 1. First, SDM only focuses on a set of recently consumed items of the target user (*e.g.,* the *book*, *CD* and *camera* in Figure 1) as context items. Second, it employs additional memories to learn a novel personalized metric-based attention on the consumed items. The goal of our proposed attention is to compute weights of each consumed item *w.r.t.* the target item (i.e., the *camera lens*). In the example, the attention module assigns higher weights on the *camera* and lower weights on the *book* and *CD*. Unlike our approach, most of the existing neighborhood-based models consider contribution of consumed items to the target item equally, leading to suboptimal results. Last but not the least, we update the attention weights via a gated multi-hop to build a long-term memory within SDM. This multi-hop design helps refine our attention module and produces more accurate attentive scores.

The contributions of this work are summarized as follows:

- We design a deep learning framework which can tackle both general recommendation task and shopping basket-based recommendation task.
- We propose SDMR that combines two signed distance scores internally measured by SDP and SDM, which capture non-linear relationship between a user and an item explicitly and implicitly.
- To better balance the weights among consumed items of the user, we propose a novel multi-hop memory network with a personalized metric-based attention mechanism in SDM.
- Extensive experiments on six datasets in two different recommendation tasks demonstrate the effectiveness of our proposed methods against ten baselines.

2 RELATED WORK

Latent Factor Models (LFM) have been extensively studied in the literature, which include Matrix Factorization [16], Bayesian Personalized Ranking [39], fast matrix factorization for implicit feedbacks (eALS) [13], *etc.* Despite their success, LFM suffer from several limitations. First, LFM overlook associations between the user's previously consumed items and the target item (e.g. mobile phones and phone cases). Second, LFM usually rely on inner product function, whose linearity limits the capability of modeling complex user-item interactions. To address the second issue, several non-linear latent factor models have been proposed, with the help of Gaussian process [23] or kernels [30, 62]. However, they either require expensive hyper-parameter tuning or face difficulties in finding good kernels for different data patterns.

Neighborhood-based models [36, 42] are usually based on the principle that similar users prefer similar items. The problem turns into finding the neighbors of a user or an item based on a pre-defined distance/similarity metric, such as *cosine vector similarity* [3, 22], *Person Correlation similarity* [6], *etc.* The recommendation quality highly depends on a chosen metric, but finding a good pre-defined metric is usually very challenging. Furthermore, these models are also sensitive to the selection of neighbors. Our proposed SDM is similar to neighborhood-based models in nature, but it exploits a novel personalized metric-based attention for assigning attentive weights to context items. Therefore, our approach is more robust and less sensitive than conventional neighborhood-based models.

NeuMF [12] is a neural network that generalizes matrix factorization via Multi Layer Perceptron (MLP) for learning non-linear interaction functions. Similarly, some other works [24, 25, 43, 57] substitute MLP with auto-encoder architecture. It is worth noting that all these approaches are limited by only considering the user-item latent space, and overlook the correlations in the item-item latent space. Besides, some deep learning based works [32, 34, 45, 51] employ auxiliary information such as item description [17], music content [53], item visual features [4, 29], reviews [31] to address the cold-start problem. However, this auxiliary information is not always available, and it limits their applicability in many real-world systems. Another line of works use deep neural networks to model temporal effects of consumed items [14, 37, 49, 56]. Although our proposed methods do not explicitly consider the temporal effects, SDM utilizes the time information to select a set of recently consumed items as the context items of the target item.

The most closely related work to our work is recently proposed (*Collaborative Memory Network* (CMN) [7]). In this work, Memory Network [48] is adapted to measure similarities between users and user neighbors. Key differences between our work and CMN are as follows: (i) First, we follow an item neighborhood based design, whereas CMN follows a user neighborhood based design. The prior work showed that item neighborhood based models slightly outperformed user neighbor based models [27, 42]; (ii) Second, our proposed SDM model uses our proposed personalized metric-based attention mechanism and produces signed distance scores as output, whereas CMN exploited a traditional inner product based attention; (iii) Third, we use a gated multi-hop architecture [28], which was shown to perform better than the original multi-hop design [48].

3 PROBLEM STATEMENT

In this section, we describe two recommendation problems: (i) general recommendation task; and (ii) shopping basket-based recommendation task. In following sections, we focus on solving them.

General recommendation task: Given a whole item set $V = \{v_1, v_2, ..., v_{|V|}\}$, and a whole user set $U = \{u_1, u_2, ..., u_{|U|}\}$. Each user $u_i \in U$ may consume several items $\{v_{i1}, v_{i2}, ..., v_{ik}\}$ in V,

denoted as a set of context items c. In this task, given previously consumed items of a user u_i, a recommendation model predicts a next target item v_j that u_i may prefer, denoting this task as estimating $P(u_i, v_j|c)$. Note that some existing works assume independent relationships between v_j and context items in the set $\boldsymbol{c}$, leading to $P(u_i, v_j|c) = P(u_i, v_j)$ [12, 13]. In our work, we model the u_i's preference on v_j in two steps: (i) an explicit preference of u_i on v_j in a signed distance based perceptron, and (ii) an implicit preference of u_i on v_j via summing attentive effects of context items toward target item v_j in a signed distance based memory network.

Shopping Basket-based recommendation task: This problem is based on the fact that users go shopping offline/online and add some items into a basket/cart together. Each shopping basket/cart is seen as a transaction, and each user may shop once or multiple times, leading to one or multiple transactions. Let $T^{(u)} = \{t_1, t_2, ..., t_{|T^{(u)}|}\}$ as a set of the user u's transactions, where $|T^{(u)}|$ denotes the number of user u's transactions. Each transaction $t_i = \{v_1, v_2, ..., v_{|t_i|}\}$ consists of several items in the whole item set V. In this problem, it is assumed that all the items in t_i are inserted into the same basket at the same time, ignoring the actual order of the items being inserted and considering t_i's transaction time as each item's insertion time. Given a target item $v_j \in t_i$, the rest of the items in t_i will be seen as the context items of v_j, denoted as c (i.e. $c = t_i \backslash \{v_j\}$). Then, given the set of context items c, a recommendation model predicts a conditional probability $P(u, v_j|c)$, which is interpreted as the conditional probability that u will add the item v_j into the same basket with the other items c.

Both of the recommendation tasks above are popular in the literature [8, 12, 37, 40]. The *general recommendation task* differs from the *shopping basket-based recommendation task* because there is no specific context items of the target item in the *general recommendation task*. Note that the two tasks are *personalized* recommendation problems. In fact, there are *non-personalized* recommendation problems such as *session-based recommendation* [14], where users (i.e. user IDs) are not available in transactions. However, in this paper, we focus on *personalized* recommendation tasks because they are more preferred in the literature [8, 37, 40].

4 PROPOSED METHODS

Our proposed *Signed Distance-based Deep Memory Recommender* (SDMR) consists of two major components: *Signed Distance-based Perceptron* (SDP) and *Signed Distance-based Memory network* (SDM). We first describe an overview of our models as follows:

- Given a target user i and a target item j as two one-hot vectors, we pass the two vectors through the user and item embedding spaces to get user embedding u_i and item embedding v_j.
- On one hand, our proposed *Signed Distance-based Perceptron* (SDP) will measure a signed distance score between u_i and v_j by a multi-layer perceptron network.
- On the other hand, given target user i, target item j, and the user i's recently consumed context items s as the input, our *Signed Distance-based Memory network* (SDM) will measure a signed distance score between user i and item j via attentive distances between context items s and target item j.

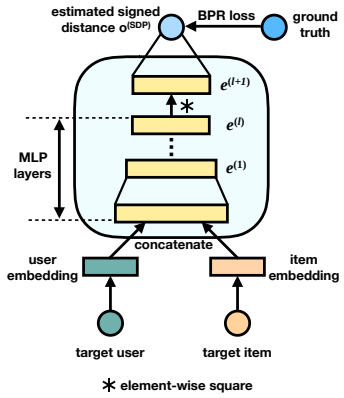

Figure 2: The illustration of our SDP model.

- Then, the *Signed Distance-based Deep Memory Recommender* (SDMR) model will measure a total distance between user i and item j by learning a combination of SDP and SDM. The smaller the total distance is, the more likely user i will consume item j.

Next, we describe SDP, SDM, and SDMR in detail.

4.1 Signed Distance-based Perceptron (SDP)

We first propose *Signed Distance-based Perceptron* (SDP) that *explicitly* learns a signed distance between a target user i and a target item j. An illustration of SDP is shown in Figure 2. Let the embedding of a target user i be $\boldsymbol{u}_i \in \mathbb{R}^d$, and the embedding of a target item j be $\boldsymbol{v}_j \in \mathbb{R}^d$, where d is the number of dimensions in each embedding. First, SDP takes a concatenation of these two embeddings as the input and proceeds as follows:

$$\boldsymbol{e}^{(1)} = f_1(\mathbf{W}^{(1)} \begin{bmatrix} \boldsymbol{u}_i \\ \boldsymbol{v}_j \end{bmatrix} + \boldsymbol{b}^{(1)}) \tag{1}$$

$$\boldsymbol{e}^{(2)} = f_2(\mathbf{W}^{(2)} \boldsymbol{e}^{(1)} + \boldsymbol{b}^{(2)}) \tag{2}$$

$$\dots \tag{3}$$

$$\boldsymbol{e}^{(\ell)} = f_\ell(\mathbf{W}^{(\ell)} \boldsymbol{e}^{(\ell-1)} + \boldsymbol{b}^{(\ell)}) \tag{4}$$

$$\boldsymbol{e}^{(\ell+1)} = square(\boldsymbol{e}^{(\boldsymbol{\ell})}) \tag{5}$$

$$o^{(SDP)} = \boldsymbol{w}^{(o)\top} \boldsymbol{e}^{(\ell+1)} + \boldsymbol{b}^{(o)} \tag{6}$$

where $f_l(\cdot)$ refers to a non-linear activation function at the layer l^{th} (e.g. `sigmoid`, `ReLu` or `tanh`), and $square(\cdot)$ denotes an element-wise square function (e.g $square([2, 3]) = [6, 9]$). Through experimental results, we choose `tanh` as the activation function because it yields slightly better results than `ReLu`. From now on, we will use $f(\cdot)$ to denote the `tanh` function. It can be easily observed that Eq. (1) – (4) form a trivial Multi-Layer Perceptron (MLP) network, which is a popular design [12, 60] to learn a complex and non-linear interaction between user embedding $\boldsymbol{u}_i$ and item embedding $\boldsymbol{v}_j$. Our new design starts at Eq. (5) – Eq. (6). In Eq. (5), we apply the element-wise squared function $square(\cdot)$ to the output vector $\boldsymbol{e}^{(l)}$ of the MLP and obtain a new output vector $\boldsymbol{e}^{(l+1)}$. Next, in Eq. (6), we use a fully connected layer $\boldsymbol{w}^{(o)}$ to combine different dimensions in $\boldsymbol{e}^{(l+1)}$ and yields a final distance value $o^{(SDP)}$. Our idea of using $\boldsymbol{w}^{(o)}$ in here is that after applying the element-wise square function $square(\cdot)$ in Eq. (5), all the dimensions in $\boldsymbol{e}^{(l+1)}$ will be

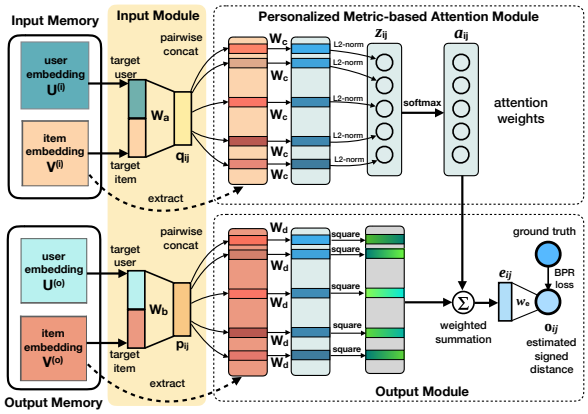

Figure 3: The illustration of a single-hop SDM, which consists of a memory module, an input module, an attention module, and an output module.

non-negative. Thus, we consider each dimension of $\boldsymbol{e}^{(l+1)}$ as a distance value. The edge weights $\boldsymbol{w}^{(o)}$ will then be used to combine those distant dimensions to provide a more fine-grained distance.

We note that SDP can be reduced to a squared Euclidean distance with the following setting: at Eq. (1), $\mathbf{W}^{(1)} = [\mathbb{1}, -\mathbb{1}]$ with $\mathbb{1}$ denotes an identity matrix and so $\mathbf{W}^{(1)} \begin{bmatrix} \boldsymbol{u}_i \\ \boldsymbol{v}_j \end{bmatrix} = \boldsymbol{u}_i - \boldsymbol{v}_j$; the activation $f(\cdot)$ is an identity function; the number of MLP layers $\ell = 1$; the edge-weights layer at Eq. (6): $\boldsymbol{w}^{(o)} = \mathbf{1}$ (e.g. the all-ones matrix), bias $\boldsymbol{b}^{(o)} = \mathbf{0}$. Note that if $\boldsymbol{w}^{(o)}$ in Eq. (6) is an all-negative layer, it will yield a negative value, which we name as a signed distance[1] score. If we see each user $\boldsymbol{i}$ as a point in multi dimensional space, and the user's preference space is defined by a boundary Ω, we can interpret this signed distance score as follows: When the item $\boldsymbol{j}$ is out of the user $\boldsymbol{i}$'s preference boundary Ω, the distance $d(\boldsymbol{i}, \boldsymbol{j})$ between them is positive (i.e. $d(\boldsymbol{i}, \boldsymbol{j}) > 0$) and it reflects that user $\boldsymbol{i}$ does not prefer item $\boldsymbol{j}$. When the distance between user $\boldsymbol{i}$ and item $\boldsymbol{j}$ is shortened and $\boldsymbol{j}$ is right on the boundary Ω, the distance between them is zero and it indicates user $\boldsymbol{i}$ likes item $\boldsymbol{j}$. As $\boldsymbol{j}$ is coming inside Ω, the distance between them becomes negative and reflects a higher preference of user $\boldsymbol{i}$ on item $\boldsymbol{j}$. In short, we can see SDP as a signed distance function, which could learn a complex signed distance between a user and an item via a MLP architecture with non-linear activations and an element-wise square function $square(\cdot)$. In the recommendation domain, the signed distances will provide more fine-grained distance values, thus, reflecting users' preferences on items more accurately.

4.2 Signed Distance-based Memory Network (SDM)

We propose a multi-hop memory network, *Signed Distance-based Memory network* (SDM), to model *implicit* preference of a user on the target item via the user's previously consumed items (i.e., context items). The implicit preference is represented as a signed distance. First, we describe a single-hop SDM, and then describe how to extend it into a multi-hop design. Following the traditional architecture of a memory network [28, 48, 58], our proposed single-hop SDM has four main components: a memory module, an input module, an attention module, and an output module. The overview of SDM's architecture is presented in Figure 3. We will go into details of each SDM's module as follows:

4.2.1 Memory Module: We maintain two memories called input memory and output memory. The input memory contains two embedding matrices $\mathbf{U}^{(i)} \in \mathbb{R}^{M \times d}$ and $\mathbf{V}^{(i)} \in \mathbb{R}^{N \times d}$, where M and N are the number of users and the number of items in the system, respectively. d denotes the embedding size of each user and each item. Similarly, the output memory also contains two embedding matrices $\mathbf{U}^{(o)} \in \mathbb{R}^{M \times d}$ and $\mathbf{V}^{(o)} \in \mathbb{R}^{N \times d}$. As shown in Figure 3, the input memory will be used to calculate attention weights of a user's consumed items (i.e., context items), whereas the output memory will be used to measure a final signed distance between the target user and the target item via the user's context items.

Given a target user i, a target item j and a set of user i's consumed items as context items $\mathcal{T}_j^{\,i}$, the output of this module is the embeddings of user i, item j, and all context items $k \in \mathcal{T}_j^{\,i}$: $(\boldsymbol{u}_i, \boldsymbol{v}_j, <\boldsymbol{v}_1, \boldsymbol{v}_2, ..., \boldsymbol{v}_k>)$. Since this module has a separated input memory and output memory, we obtain $(\boldsymbol{u}_i^{(i)}, \boldsymbol{v}_j^{(i)}, <\boldsymbol{v}_1^{(i)}, \boldsymbol{v}_2^{(i)}, ..., \boldsymbol{v}_k^{(i)}>)$ as the output of the input memory, and $(\boldsymbol{u}_i^{(o)}, \boldsymbol{v}_j^{(o)}, <\boldsymbol{v}_1^{(o)}, \boldsymbol{v}_2^{(o)}, ..., \boldsymbol{v}_k^{(o)}>)$ as the output of the output memory. It is obvious that $\boldsymbol{u}_i^{(i)}$ is the i-th row of $\mathbf{U}^{(i)}$, $\boldsymbol{v}_j^{(i)}$ and $\boldsymbol{v}_k^{(i)}$ are the corresponding j-th and k-th row of $\mathbf{V}^{(i)}$. A similar explanation is applied to $\boldsymbol{u}_i^{(o)}$ $\boldsymbol{v}_j^{(o)}$, and $\boldsymbol{v}_k^{(o)}$.

4.2.2 Input Module: The goal of the input module is to form a non-linear combination between the target user embedding and the target item embedding. Given the target user embedding $\boldsymbol{u}_i^{(i)}$ and the target item embedding $\boldsymbol{v}_j^{(i)}$ from the input memory in the memory module, following the widely adopted design in multimodal deep learning work [47, 61], the input module simply concatenates the two embeddings, and then applies a fully connected layer with a non-linear activation $f(\cdot)$ (i.e. `tanh` function) to obtain a coherent hidden feature vector as follows:

$$\boldsymbol{q}_{ij} = f\left(\mathbf{W}_a \begin{bmatrix} \boldsymbol{u}_i^{(i)} \\ \boldsymbol{v}_j^{(i)} \end{bmatrix} + \boldsymbol{b}_a\right) \tag{7}$$

where $\mathbf{W}_a \in \mathbb{R}^{d \times 2d}$ is the weights of input module. Note that $q_{ij} \in \mathbb{R}^d$ can be seen as a query embedding in Memory Network [48].

Similarly, if the inputs of the input module are the target user embeddings $\boldsymbol{u}_i^{(o)}$ and the target item embeddings $\boldsymbol{v}_j^{(o)}$ from the output memory, we can form a non-linear combination between $\boldsymbol{u}_i^{(o)}$ and $\boldsymbol{v}_j^{(o)}$ (i.e. an output query), denoted as $\boldsymbol{p}_{ij}$, as follows:

$$\boldsymbol{p}_{ij} = f\left(\mathbf{W}_b \begin{bmatrix} \boldsymbol{u}_i^{(o)} \\ \boldsymbol{v}_j^{(o)} \end{bmatrix} + \boldsymbol{b}_b\right) \tag{8}$$

4.2.3 Attention Module: The goal of the attention module is to assign attentive scores to different context items (or candidates) given the combined vector (or a query) $\boldsymbol{q}_{ij}$ of the target user i and target item j obtained in Eq. (7). First, we calculate the squared $\mathcal{L}2$ distance between $\boldsymbol{q}_{ij}$ and each candidate item $\boldsymbol{v}_k^{(i)}$ as follows:

[1] https://en.wikipedia.org/wiki/Signed_distance_function

$$z_{ijk} = \left\| f\left(\mathbf{W}_c \begin{bmatrix} \boldsymbol{q}_{ij} \\ \boldsymbol{v}_k^{(i)} \end{bmatrix} + \boldsymbol{b}_c\right)\right\|_2^2 \quad (9)$$

where $||\cdot||_2$ refers to the $\mathcal{L}2$ distance (or Euclidean distance), which is widely used in previous works to measure similarity among items [8] or between users and items [15]. To better understand our intuition in Eq. (9), we will break it into smaller parts and explain them. First, similar to the intuition of Eq. (7), we have $f\left(\mathbf{W}_c \begin{bmatrix} \boldsymbol{q}_{ij} \\ \boldsymbol{v}_k^{(i)} \end{bmatrix} + \boldsymbol{b}_c\right)$ component to define a non-linear combination between the input query $\boldsymbol{q}_{ij}$ and each context item embeddings $\boldsymbol{v_k}^{(i)}$. Then, $||\cdot||_2^2$ will measure the squared $\mathcal{L}2$ distance of the combined vector. It is worth to note that with a following setting: $\boldsymbol{W}_a = [\mathbf{0}, \mathbb{I}]$ where $\mathbb{I}$ refers to an identity matrix and $\mathbf{0}$ is an all-zeros matrix; $f(\cdot)$ is an identity function; $\boldsymbol{W}_c = [\mathbb{I}, -\mathbb{I}]$; bias terms $\boldsymbol{b}_a = \boldsymbol{b}_c = 0$. Then, in Eq. (7), $\boldsymbol{q}_{ij} = f\left(\mathbf{W}_a \begin{bmatrix} \boldsymbol{u}_i^{(i)} \\ \boldsymbol{v}_j^{(i)} \end{bmatrix} + \boldsymbol{b}_a\right) = \boldsymbol{v}_j^{(i)}$; in Eq. (9), $f\left(\mathbf{W}_c \begin{bmatrix} \boldsymbol{q}_{ij} \\ \boldsymbol{v}_k^{(i)} \end{bmatrix} + \boldsymbol{b}_c\right) = \boldsymbol{v}_j^{(i)} - \boldsymbol{v}_k^{(i)}$, and $z_{ijk} = ||(\boldsymbol{v}_j^{(i)} - \boldsymbol{v}_k^{(i)})||_2^2$, which simply generalizes a squared $\mathcal{L}2$ distance between the target item j and the context item k. Additionally, with another setting: $\boldsymbol{W}_a = [\mathbb{I}, -\mathbb{I}]$; $f(\cdot)$ is an identity function; $\boldsymbol{W}_c = [\mathbb{I}, \mathbb{I}]$; bias terms $\boldsymbol{b}_a = \boldsymbol{b}_c = 0$. Then, in Eq. (7), $\boldsymbol{q}_{ij} = f\left(\mathbf{W}_a \begin{bmatrix} \boldsymbol{u}_i^{(i)} \\ \boldsymbol{v}_j^{(i)} \end{bmatrix} + \boldsymbol{b}_a\right) = \boldsymbol{u}_i^{(i)} - \boldsymbol{v}_j^{(i)}$, in Eq. (9), $f\left(\mathbf{W}_c \begin{bmatrix} \boldsymbol{q}_{ij} \\ \boldsymbol{v}_k^{(i)} \end{bmatrix} + \boldsymbol{b}_c\right) = \boldsymbol{u}_i^{(i)} - \boldsymbol{v}_j^{(i)} + \boldsymbol{v}_k^{(i)}$, and $z_{ijk} = ||(\boldsymbol{v}_k^{(i)} + \boldsymbol{u}_i^{(i)} - \boldsymbol{v}_j^{(i)})||_2^2$, which simply generalizes a squared $\mathcal{L}2$ distance between the target item j and the context item k where the user i plays as a translator [9]. The two examples above show that our proposed design can learn a more generalized distance between target and context items.

The output squared $\mathcal{L}2$ distance in Eq. (9) will show how similar the target item j and the context item k are. The lower the distance score is, the more similar two items j and k are. Next, we use the Softmax function to normalize and obtain attentive score between j and k as follows:

$$a_{ijk} = \frac{exp(-z_{ijk})}{\sum_{p \in \mathcal{T}_j^i} exp(-z_{ijp})} \quad (10)$$

where $\mathcal{T}_j^i$ is the set of user $\boldsymbol{i}$'s neighborhood items. The **minus** sign in Eq. (10) is used to assign a higher attention score for a lower distance between two items (j, k).

We note that the $\mathcal{L}2$ distance (or Euclidean distance) satisfies four conditions of a metric [2]. While the crucial triangle inequality property of a metric was shown to provide a better performance compared to the inner product [15, 38, 46] in recommendation domains, to our best of knowledge, most of existing attention designs [2, 5, 26, 33, 44, 54, 59] adopted the inner product for measuring attentive scores. Hence, this proposed attention design is the **first attempt** to bring metric properties into the attention mechanism.

Similar to [50], we limit the number of considering context items by choosing the user $\boldsymbol{i}$'s $\boldsymbol{s}$ most recently consumed items before target item $\boldsymbol{j}$ as the context items of target item $\boldsymbol{j}$. Here, $\boldsymbol{s}$ can be selected via tuning with a development dataset. The soft attention vector containing attentive contribution scores of $\boldsymbol{s}$ context items toward the target item $\boldsymbol{j}$ of a user $\boldsymbol{i}$ is given as follows:

$$\boldsymbol{a}_{ij} = \left[a_{ij1}, \cdots, a_{ijs}\right]^T \quad (11)$$

4.2.4 Output Module: Given the attentive scores $\boldsymbol{a}_{ij}$ in Eq.(11) and the combined vector $\boldsymbol{p}_{ij} \in \mathbb{R}^d$ of the user embedding $\boldsymbol{u}_i^{(o)}$ and item embedding $\boldsymbol{v}_j^{(o)}$ from the output memory $\boldsymbol{U}^{(o)}$ and $\boldsymbol{V}^{(o)}$, the goal of this output module is to measure a total output distance $\boldsymbol{o}_{ij}^{(SDM)}$ between the output target item embeddings $\boldsymbol{v}_j^{(o)}$ and all the user $\boldsymbol{i}$'s output context item embeddings $\boldsymbol{v}_k^{(o)} (k \in T_j^i)$ using attention weights $\boldsymbol{a}_{ij}$ and the output query $\boldsymbol{p}_{ij}$ as follows:

$$o_{ij}^{(SDM)} = \boldsymbol{w}_e^\top \boldsymbol{e}_{ij} + b_e \quad (12)$$

where $\boldsymbol{e}_{ij} \in \mathbb{R}^d$ is calculated as follows:

$$\boldsymbol{e}_{ij} = \sum_{k \in \mathcal{T}_j^i} \boldsymbol{a}_{ijk} \times square\left(f\left(\mathbf{W}_d \begin{bmatrix} \boldsymbol{p}_{ij} \\ \boldsymbol{v}_k^{(o)} \end{bmatrix} + \boldsymbol{b}_d\right)\right) \quad (13)$$

In here, let $\boldsymbol{r}_{ijk} = f\left(\mathbf{W}_d \begin{bmatrix} \boldsymbol{p}_{ij} \\ \boldsymbol{v}_k^{(o)} \end{bmatrix} + \boldsymbol{b}_d\right)$. Similar to the previously discussed intuition in Eq (9), $\boldsymbol{r}_{ijk}$ is a flexible combination between $\boldsymbol{p}_{ij}$ and each output context item embeddings $\boldsymbol{v}_k^{(o)}$; $square(\cdot)$ is an element-wise squared function. Our idea in Eq. (12), (13) is similar to the idea in Eq. (5), (6) of the SDP model. First, in Eq. (13), each context item k will attentively contribute to the target item j via a squared Euclidean measure. Second, in Eq. (12), each non-negative dimension in e_{ij} will be considered as a distance dimension and we use an edge-weights layer $\boldsymbol{w}_e$ to combine them flexibly. When there is only one context item in $\mathcal{T}_j^i$, then in Eq. (13), the attention score $\boldsymbol{a}_{ijk}$=1.0, leading to $\boldsymbol{e}_{ij} = square(\boldsymbol{r}_{ijk})$, which is similar to Eq. (5). In this case, SDM will measure the distance between target item j and context item k in the same way as SDP model does. Note that Eq. (13) is similar to Eq. (6) so SDM can also learn a signed distance value, which also provides a more fine-grained distance compared to a general distance value.

4.2.5 Multi-hop SDM:. Inspired by previous work [48] where the multi-hop design helped to refine the attention module in Memory Network, we also integrate multiple hops to further extend our SDM model to build a deeper network (Figure 4). As the gated multi-hop

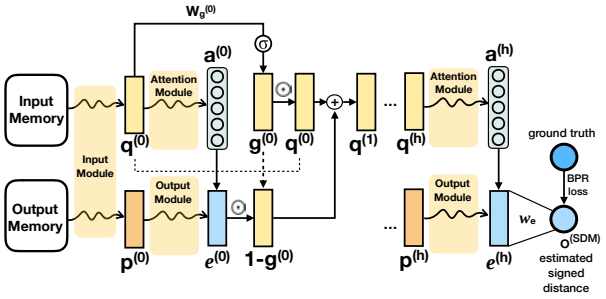

Figure 4: The illustration of our multi-hop SDM.

[2] https://en.wikipedia.org/wiki/Metric_(mathematics)

design [28] was shown to perform better than the original multi-hop design with a simple residual connection in [48], we employ this gated memory update from hop to hop as follows:

$$\boldsymbol{g}^{(h-1)} = \sigma(\mathbf{W}_g^{(h-1)}\boldsymbol{q}^{(h-1)} + \boldsymbol{b}_g^{(h-1)}) \tag{14}$$

$$\boldsymbol{q}^{(h)} = (1 - \boldsymbol{g}^{(h-1)}) \odot \boldsymbol{e}^{(h-1)} + \boldsymbol{g}^{(h-1)} \odot \boldsymbol{q}^{(h-1)} \tag{15}$$

where $\boldsymbol{q}^{(h-1)}$ is the input query embedding as shown in Eq. (7) at hop $h-1$, $\mathbf{W}_g^{(h-1)}$ and bias $\boldsymbol{b}_g^{(h-1)}$ are hop-specific parameters, σ is the sigmoid function, $e^{(h-1)}$ is the output of Eq. (13) at hop $h-1$, $\boldsymbol{q}^{(h)}$ is the input query embedding at the next hop h. So the attention could be updated at hop h accordingly using $\boldsymbol{q}^{(t)}$ as follows:

$$\alpha_{ijk}^{(h)} = \frac{exp(-z_{ijk}^{(h)})}{\sum_{p \in \mathcal{T}_j{}^i} exp(-z_{ijp}^{(h)})}, \text{ where } z_{ijk}^{(h)} = \left\| f\left(\mathbf{W}_c^{(h)} \begin{bmatrix} \boldsymbol{q}_{ij}^{(h)} \\ \boldsymbol{v}_k^{(i)} \end{bmatrix} + \boldsymbol{b}_c\right)\right\|_2^2 \tag{16}$$

The multi-hop architecture with gated design further refines the attention for different users based on the previous output from hop to hop. Hence, if the final hop is h then the SDM model with h hops, denoted as *SDM-h*, will use $\boldsymbol{a}_{ij}^{(h)}$ to yield a final signed distance score as follows:

$$o_{ij}^{(SDM-h)} = \boldsymbol{w}_e^\top \boldsymbol{e}_{ij}^{(h)} + b_e^{(h)} \tag{17}$$

where $\boldsymbol{e}_{ij}$ is calculated as:

$$\boldsymbol{e}_{ij}^{(h)} = \sum_{k \in \mathcal{T}_j{}^i} \boldsymbol{a}_{ijk}^{(h)} \times square\left(f\left(\mathbf{W}_d^{(h)} \begin{bmatrix} \boldsymbol{p}_{ij}^{(h)} \\ \boldsymbol{v}_k^{(o)} \end{bmatrix} + \boldsymbol{b}_d^{(h)}\right)\right) \tag{18}$$

Weight constraints in multi-hop SDM model: To save memory, we use the global weight constraint in multi-hop SDM. Particularly, input memory $\boldsymbol{U^{(i)}}, \boldsymbol{V^{(i)}}$ and output memory $\boldsymbol{U^{(o)}}, \boldsymbol{V^{(o)}}$ are shared among different hops. All the weights are shared from hop to hop $\boldsymbol{W}_a^{(1)} = \boldsymbol{W}_a^{(2)} = ... = \boldsymbol{W}_a^{(h)}; \boldsymbol{W}_b^{(1)} = \boldsymbol{W}_b^{(2)} = ... = \boldsymbol{W}_b^{(h)}; \boldsymbol{W}_c^{(1)} = \boldsymbol{W}_c^{(2)} = ... = \boldsymbol{W}_c^{(h)}; \boldsymbol{W}_d^{(1)} = \boldsymbol{W}_d^{(2)} = ... = \boldsymbol{W}_d^{(h)}$; and so do all bias terms. The gate weights are also global weights: $\boldsymbol{W}_g^{(1)} = \boldsymbol{W}_g^{(2)} = ... = \boldsymbol{W}_g^{(h)}$.

4.3 Signed Distance-based Deep Memory Recommender (SDMR)

Now we propose Signed Distance-based Deep Memory Recommender (SDMR), a hybrid network that combines SDP and SDM. The first approach to combine them is to employ a weighted summation of the output scores from SDP and SDM as follows:

$$o = \beta o^{(\text{SDP})} + (1 - \beta) o^{(\text{SDM})} \tag{19}$$

where $o^{(\text{SDP})}$ is the signed distance score obtained at Eq. (6), $o^{(\text{SDM})}$ is the signed distance score obtained at Eq. (17), and $\beta \in [0, 1]$ is a hyper-parameter to control the contribution of SDP and SDM. When β=0, SDMR becomes SDM. When β=1, SDMR becomes SDP.

However, to avoid tuning an additional hyper-parameter β, we do not use Eq. (19) for SDMR. Instead, we let SDMR self-learns the combination of SDM and SDM as follows:

$$o = ReLU\left(\boldsymbol{w}_u^\top \begin{bmatrix} \boldsymbol{e}^{(\ell+1)} \\ \boldsymbol{e}^{(h)} \end{bmatrix} + b_u\right) \tag{20}$$

where $\boldsymbol{e}^{(\ell+1)}$ is the final layer embedding from SDP and is obtained at Eq. (5), $\boldsymbol{e}^{(h)}$ is the final hop output from the multi-hop SDM obtained at Eq. (18). We note that SDP and SDM are first pre-trained separately using the BPR loss function (see the next section). Then, we obtain $\boldsymbol{e}^{(\ell+1)}$ from SDP, and $\boldsymbol{e}^{(h)}$ from SDM, and keep them fixed in Eq. (20) to learn $\boldsymbol{w}_u$ and b_u. We use ReLU in Eq. (20) because ReLU encourages sparse activations and helps to reduce over-fitting when combining the two components SDP and SDM.

4.4 Loss Functions

We adopt the Bayesian Personalized Ranking (BPR) as our loss function, which is similar to the idea of AUC (area under the curve):

$$\mathcal{L} = \underset{\theta}{\text{argmin}} \left(- \sum_{(u, i^+, i^-)} \log \sigma(o_{ui^-} - o_{ui^+}) + \lambda \|\theta\|^2 \right) \tag{21}$$

where we uniformly sample tuples in a form of (u, i^+, i^-) for user u with positive item (consumed) i^+ and negative item (unconsumed) i^-. λ is a hyper-parameter to control the regularization term, and $\sigma(\cdot)$ is the sigmoid function. Note that other pairwise probability functions could be plugged in Eq. (21) to replace $\sigma(\cdot)$. Both SDP and SDM are end-to-end differentiable since we uses soft attention over the output memory. Hence, we can utilize back-propagation to learn our models with stochastic gradient descent or Adam [18].

5 EMPIRICAL STUDY

We evaluate our SDP, SDM, SDMR models against ten state-of-the-art baselines in two recommendation tasks: (i) *general recommendation task*, and (ii) *shopping basket-based recommendation task*. We mainly aim to answer the following research questions (RQs):

- **RQ1:** How do SDP, SDM, and SDMR perform compared to other state-of-the-art models in both general recommendation task and shopping basket-based recommendation task?
- **RQ2:** Why/How does the multi-hop design help to improve the proposed models' performance?

5.1 Datasets

General recommendation task: In this task, we evaluate our proposed models and state-of-the-art methods using different datasets with various density levels as follows:

- **Movielens** [41]: It is a widely adopted benchmark dataset for collaborative filtering evaluation. We use two versions of this benchmark dataset, namely MovieLens100k (or ML-100k) and MovieLens1M (or ML-1M).
- **Netflix Prize** [3]: It is a real-world dataset collected by Netflix. This dataset was collected from 1999 to 2005, and consists of 463,435 users and 17,769 items with 56.9M of interactions. Since the dataset is extremely large, we subsample the Netflix dataset by randomly picking one-month data for evaluation.
- **Epinions** [35] [4]: It is an online rating dataset where users can share product feedback by giving explicit ratings and reviews.

In preprocessing preparation, we adopted a popular k-core preprocessing step [11, 25, 52] (with *k-core* = 5) to filter out inactive users with less than five ratings and items which are consumed

[3] https://www.netflixprize.com/
[4] http://www.trustlet.org/downloaded_epinions.html

Table 1: Statistics of the four datasets in the general recommendation task.

Statistics	ML-100k	ML-1M	Netflix	Epinions
# of users	943	6,040	1,888	23,137
# of items	1,682	3,706	3,724	23,585
# of interactions	100,000	1,000,209	103,254	461,982
Density (%)	6.3%	4.5%	1.5%	0.08%

Table 2: Statistics of the two real-world transactional datasets in the shopping basket-based recommendation task.

Statistics	IJCAI-15	Tafeng
# of users	2,433	22,851
# of items	4,534	22,291
avg # of items in a transaction	6.28	9.28
# of generated instances	15,422	523,653
Density (%)	0.14%	0.10%

by less than five users. Since ML-100k and ML-1M are already preprocessed, we only apply 5-core preprocessing step on the Netflix and Epinions datasets. We also binarize the rating scores as implicit feedback by converting all observed rating scores as positive interactions and the remaining as negative interactions. The statistics of the four datasets are summarized in Table 1.

Shopping basket-based recommendation task: We use two real-world transaction datasets as follows:

- **IJCAI-15** [5]: It consists of shopping logs of users from Tmall [6]. Since the original dataset is extremely large scale. We subsample IJCAI-15 by randomly picking 20k transactions for evaluation.
- **Tafeng** [7]: It is a grocery store transaction data. It contains four month transaction data from November 2000 to February 2001 by T-Feng supermarket.

Users in both IJCAI-15 and Tafeng datasets are logged under four types of actions: *click*, *add-to-cart*, *purchase*, and *add-to-favourite*. We consider all the four types as the *click* action. We only keep transactions with at least five items. This is because we will take one item out for testing, another item for development. In the remaining three items, one will be taken out as a target item and the two items will be used as the context items. Attentive scores will be assigned to the context items. In each of original transactions, we generate data instances of the format $< \mathbf{c}, v_c >$ where v_c is the target/predicting item and $\mathbf{c}$ is a set of all other items in the same transaction with v_c. In particular, in each transaction t, each time we pick one item out as a target item and leave the rest of items in t as corresponding context items. Subsequently, for each transaction t containing $|t|$ items, we can generate $|t|$ data instances. The statistics of the two transactional datasets are summarized in Table 2.

For an easy reference, we call (ML-100k, ML-1M, Netflix, Epinions) as *Group-1 dataset* and (IJCAI-15, Ta-Feng) as *Group-2 datasets*.

5.2 Baselines and State-of-the-art Methods

We compared our proposed models against several strong baselines in the general recommendation task as follows:

- **Item**KNN [42]: It is an item neighborhood-based collaborative filtering method. It exploited cosine item-item similarities to produce recommendation results.
- **Bayesian Personalized Ranking (MF-BPR)** [39]: It is a state-of-the-art pairwise matrix factorization method for implicit feedback datasets. It minimizes $\sum_i \sum_{j^+,j^-} -log\sigma(u_i^T v_{j^+} - u_i^T v_{j^-}) + \lambda(||u_i||^2 + ||v_{j^+}||^2)$ where (u_i, v_{j^+}) is a positive interaction and (u_i, v_{j^-}) is a negative sample.
- **Sparse LInear Method (**SLIM**)** [36]: It learns a sparse item-item similarity matrix by minimizing the squared loss $||A - AW||^2 + \lambda_1||W|| + \lambda_2||W||^2$, where A is a $m \times n$ user-item interaction matrix and W is a $n \times n$ sparse matrix of aggregation coefficients of context items.
- **Collaborative Metric Learning (CML)** [15]: It is a state-of-the-art collaborative metric-based model that utilizes Euclidean distance to measure similarities between users and items. For fair comparison, we learn CML with BPR loss by minimizing $-\sum_{i,j^+,j^-} log(\sigma(||u_i - v_{j^-}||_2^2 - ||u_i - v_{j^+}||_2^2))$, where $||\cdot||_2^2$ is a squared Euclidean distance, (u_i, v_{j^+}) is a positive interaction and (u_i, v_{j^-}) is a negative sample.
- **Neural Collaborative Filtering (NeuMF++)** [12]: It is a state-of-the-art matrix factorization method using deep learning architecture. We use a pre-trained NeuMF to achieve its best performance, and denote it as NeuMF++.
- **Collaborative Memory Network (CMN++)** [7]: It is a state-of-the-art memory network based recommender. Its architecture follows traditional user neighborhood based collaborative filtering approaches. It adopts a memory network to assign attentive weights for other similar users.

Even though our approaches do not model the order of consumed items in the user's purchase history (e.g. rigid orders of items), since we consider latest s items as the context items to predict the next item, we still compare our models with some key sequential models to further show our models' effectiveness as follows:

- **Personalized Ranking Metric Embedding (PRME)** [8]: Given a user u, a target item j, and a previous consumed item k, it models a personalized first-order Markov behavior with two components: $d_{ujk} = \alpha||v_u - v_j||^2 + (1-\alpha)||v_k - v_j||^2$, where $||\cdot||_2^2$ is a squared $\mathcal{L}2$ distance. Then PRME is learned by minimizing BPR loss.
- **PRME_s:** It is our extension of PRME, where the distance between the target item j and the previous consumed item k is replaced by the average distance between j and each of previous s items: $d_{ujs} = \alpha||v_u - v_j||^2 + (1-\alpha)\frac{1}{|s|}\sum_{k \in s}||v_k - v_j||^2$. We use BPR loss to learn PRME_s.
- **Translation-based Recommendation (TransRec)** [9]: It uses first-order Markov and considers a user u as a translator of his/her previous consumed item k to a next item j. In another word, $prob(j|u,k) \propto \beta_j - d(u + v_k - v_j)$ where β_j is an item bias term, d is a distance function (e.g. $\mathcal{L}1$ or $\mathcal{L}2$ distance). We use $\mathcal{L}2$ distance because it was shown to

perform better than $\mathcal{L}1$ [9]. TransRec is then learned with BPR loss.

- **Convolutional Sequence Embedding Recommendation (Caser)** [49]: It is a state-of-the-art sequential model. It uses convolution neural network with many horizontal and vertical kernels to capture the complex relationships among items.

The strong sequential baselines above surpassed many other sequential models such as: TransRec outperformed FMC[40], FPMC [40], HRM [55]; Caser surpassed GRU4Rec [14] and Fossil [10], so we exclude them in our evaluation.

Comparison: In the general recommendation task, we compare our proposed models with all **ten** strong baselines listed above. In the shopping basket-based recommendation task, since the sequential models often work better than general recommendation-based models (see Table 3), we only compared our proposed models with sequential baselines. We name general recommendation baselines (i.e. ItemKNN, BPR, SLIM, CML, NeuMF++, CMN++) as *Group-1 baselines*, and call sequential baselines (i.e. PRME, PRME_s, TransRec, Caser) as *Group-2 baselines* for an easy reference.

5.3 Experimental Settings

Protocol: We adopt the widely used *leave-one-out* setting [12, 60], in which for each user, we reserve her last interaction as the test sample. If there are no timestamps available in the dataset, then the test sample is randomly drawn. Among the remaining data, we randomly hold one interaction for each user to form the development set, while all others are utilized as the training set. Since it is very time-consuming and unnecessary to rank all the unobserved items for each user, we follow the standard strategy to randomly sample 100 unobserved items for each user. Then, we rank them together with the test item [12, 19].

Assigning item orders: Sequential models need rigid orders of consumed items but consumed items in the same transaction (in IJCAI-15 and TaFeng datasets) are assigned the same timestamp of the transaction containing these items. Hence, we assigned the item timestamps where the orders of items are kept as in the original dataset. This may give credits to sequential models but not our methods (because our methods will use all consumed items in the same transaction as context items and do not model the item orders).

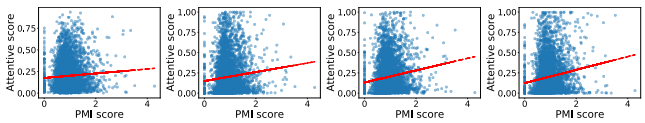
Hyper-parameters selection: We perform a grid search for the embedding size d from $\{8, 16, 32, 64, 128\}$ and regularization terms from $\{0.1, 0.01, 0.001, 0.0001, 0.00001\}$ in all the models. We select the best number of hops for CMN++ and our SDM from $\{1, 2, 3, 4\}$. In NeuMF++, we select the best number of MLP layers from $\{1, 2, 3\}$. In our models, we fix the batch size to 256. We adopt Adam optimizer [18] with a fixed learning rate of 0.001. Similar to CMN++ and NeuMF++, the number of negative samples is set to 4. We use one layer perceptron for SDP (more complex datasets may need more than one layer to get better results). In the four datasets used in general recommendation task (e.g ML-100k, ML-1M, Netflix, Epinions), to avoid too many *zero paddings* for users with a smaller number of consumed items or too many context items are kept in the memory, which unnecessarily slow down the model's execution, we follow [50] to limit the number of context items using latest s consumed items. We search s in {5, 10, 20}. In the two shopping basket-based recommendation datasets (i.e. IJCAI-15 and TaFeng), since the maximum number of items in a transaction is small (e.g. 13 in IJCAI-15, and 18 in TaFeng), we consider all the other items in the same transaction with the target item as its context items. All the hyper-parameters are tuned using the development dataset. Our source code is available at: *https://github.com/thanhdtran/SDMR*.

Evaluation Metrics: We evaluate all models' performance by two widely used metrics: Hit Ratio (*hit@k*), and Normalized Discounted Cumulative Gain (NDCG@k), where k is a truncated number or *top-k* item recommendation. Intuitively, *hit@k* shows whether the test item is in the *top-k* list or not, while *NDCG@k* accounts for the position of the hits by assigning higher scores to the hits at top ranks and downgrading the scores to hits by log_2 at lower ranks.

5.4 Experimental Results

RQ1: Overall results in general recommendation task: The performance of our proposed models and the baselines are shown in Table 3. First, we observe that SDP significantly outperformed BPR in all four datasets in *Group-1 datasets*, improving *hit*@10 from 8.33~41.19%, and NDCG@10 from 10.44~44.56%. Although SDP and BPR shared the same loss function, the difference between them is SDP measured a signed distance score between a target user and a target item via a MLP which modeled a non-linear interaction between them, while BPR used Matrix Factorization with inner product. This result confirms the effectiveness of using signed distance based similarity over inner product in the general recommendation task. Second, we compare SDP with CML. CML worked by trying to minimize the squared Euclidean distance scores between target users and target items. Our SDP, in another hand, works by minimizing signed distance scores of non-linear interactions (via non-linear activation functions) between target users and target items. We observe that SDP performed better than CML in all *Group-1 datasets*, improving *hit*@10 from 8.33~11.19%, and NDCG@10 from 7.06~12.24%. On average, SDP improved *hit*@10 by 7.5% and *NDCG*@10 by 9.5% compared to CML. Our SDP even gain competitive results compared to NeuMF++ and CMN++. On average, SDP is just slightly worse than NeuMF++ and CMN++ by -2.67% for *hit*@10, and -1.68% for *NDCG*@10. All of these results show the effectiveness of using signed distance in our SDP model.

Next, we compare SDM with neighborhood-based baselines. Both SLIM and item-KNN used previously consumed items of a user to make the prediction for the next item. SDM significantly outperformed both baselines, improving *hit*@10 from 20.53~130.92% and NDCG@10 from 39.05~106.35% compared with SLIM. It is an obvious result because the neighborhood-based baselines barely measured linear similarities between the target item and the user's consumed items. In contrast, our SDM produced signed distance scores and assigned personalized metric-based attention weights to each of consumed items that contribute to the target item.



We then compare SDM with CMN++ and NeuMF++. SDM outperformed CMN++ in all *Group-1 datasets*, improving *hit*@10 from 11.71~35.93% and NDCG@10 from 26.51~43.38%. On average, it improves *hit*@10 by 18.63% and *NDCG@10* by 32.84% compared to CMN++. This result shows the effectiveness of our personalized metric-based attention with signed distance and item-based neighborhood design over the traditional inner product-based attention

Table 3: General Recommendation Task: Overall performance of the baselines, and our proposed SDP, SDM, and SDMR on four datasets. The last four lines show the relative improvement of the SDM and SDMR over the best baseline method in General Recommenders (Group 1) and Sequential Recommenders (Group 2), respectively.

Method type	Method	ML-100k		ML-1M		Netflix		Epinions	
		hit@10	NDCG@10	*hit*@10	NDCG@10	*hit*@10	NDCG@10	*hit*@10	NDCG@10
General Recommenders (Group 1)	Item-KNN	0.166	0.073	0.235	0.110	0.039	0.019	0.121	0.096

(a) Hop 1. **(b) Hop 2.** **(c) Hop 3.** **(d) Hop 4.**

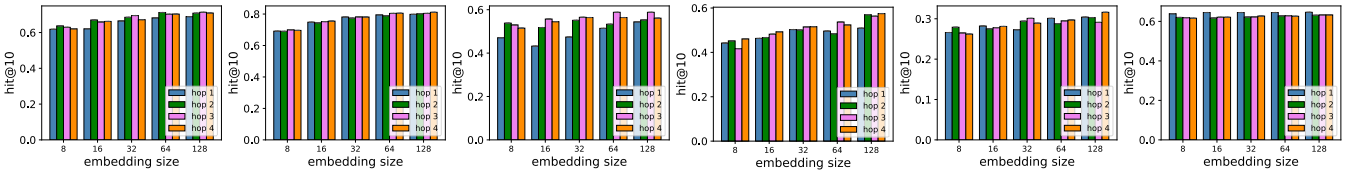

Figure 5: ML-100K: Scatter plots of PMI scores and attentive scores generated by SDM with h hops (h={1, 2, 3, 4} from left to right). The red lines are the linear trend lines. The Pearson correlation between two scores increases when h increased.

in a user-based neighborhood design in CMN++. SDM also outperformed NeuMF++, improving *hit*@10 from 13.97~34.35%, and NDCG@10 from 27.42~42.34%. On average, in all *Group-1 datasets*, SDM outperformed all the baselines in "General Recommenders" (Group 1), improved *hit*@10 by 18.13% and *NDCG*@10 by 32.58% compared to the best baseline in *Group 1*.

Finally, we look at the performance of SDMR model, which is the proposed fusion of SDP and SDM. Compared to SDM, our SDMR insignificantly downgrades SDM on *hit*@10 measurement with a very small amount, but it does help a lot in refining the ranking of items and boosting *NDCG*@10 results. As shown in Table 3, SDMR improved from 8.46~29.20% for *NDCG*@10, and by 17.37% for *NDCG*@10 on average compared to SDM in *Group-1 datasets*. SDMR also surpassed all the methods in *Group 1*. On average, SDMR improved *hit*@10 by 17.18% and NDCG@10 by 55.20% compared to the best model in *Group 1*.

We also compared our models with some strong sequential models in Table 3. Sequential models exploited consuming time of items and model their rigid orders, which often lead to a much improved performance compared to general recommendation models in *Group-1 baselines*. As such, compared to the best sequential baseline model, on average, SDM improves *hit*@10 by 3.94% and *NDCG*@10 by 5.68% , and SDMR improves *hit*@10 by 3.15% and *NDCG*@10 by 24.14% compared to the best sequential model reported in Table 3.

Overall results in shopping basket-based recommendation task: Table 4 shows the performance of our models and sequential baselines in *Group-2 datasets*. Again, our models outperformed all the sequential baselines. On average, SDM improved *hit*@10 by 9.2% and *NDCG*@10 by 8.1%, SDMR improved *hit*@10 by 11.3% and *NDCG*@10 by 32.4% compared to the best reported baseline.

5.5 RQ2: Understanding our multi-hop personalized metric-based attention design?

In the previous section, we see that our models outperformed many strong baselines in **six** different datasets of the **two** different recommendation problems. In this part, we explore why did we achieve those better results? As "attention is all you need" [54], the core reason brought us an surpassed performance accredit to the metric-based attention which are further refined via multi-hop design. Therefore, we want to explore quantitatively and qualitatively how our attention with multi-hop design worked by answering two smaller research questions: (i) what did our metric-based attention with multi-hop design learn?, (ii) did the metric-based attention with multi-hop design improve recommendation results? Without a special mention, since our SDMR model just learned a combination between SDP and SDM without re-learning the learned-already parameters in SDP and SDM, we explore SDM in this section to understand how attention with multi-hop design works. Note that we conduct this analysis for ML-100k only due to space limitation and the availability of movies genre in ML-100k (for visualization in Figure 7).

What did our metric-based attention with multi-hop design learn? To answer this question, we first measure the *point-wise mutual information* (PMI) between two certain items j and k as:

$$PMI(j,k) = log\frac{P(j,k)}{P(j) \times P(k)} \tag{22}$$

where $P(j,k)$ is the joint probability between two items j and k, which shows how likely j and k are co-preferred ($P(j,k) = \frac{\#(j,k)}{|D|}$, where D denotes a collection of all item-item pairs, and $|D|$ is the total number of item-item co-occurrence pairs in D). Similarly, $P(j)$ and $P(k)$ are the probabilities of the item j and k in D, respectively (e.g. $P(j) = \frac{\#(j)}{|D|}$, $P(k) = \frac{\#(k)}{|D|}$). Intuitively, a PMI score between two items shows how likely the two items are co-purchased/co-preferred. The higher the PMI score between j and k is, the more likely the user will purchase j if k was purchased before.

We denote SDM-h is the SDM model with h hops. Now, given a target item j and the user's context items k, *SDM-h* will assign attentive scores for all (j,k) pairs. We also get PMI scores (from Eq. (22)) of (j,k) pairs. Next, we plot a scatter plot of PMI scores and attentive scores for all (j,k) pairs to see the relationship between the two scores. Our results for ML-100k dataset is shown in Figure 5.

In Figure 5, the Pearson correlation between PMI scores and attentive scores are 0.059, 0.097, 0.143, and 0.146 for SDM-1, SDM-2, SDM-3 SDM-4, respectively. It indicates that as we increase the number of hops in SDM model, PMI scores and attentive scores are more positively correlated. In another word, as we increase the number of hops, our metric-based attention with multi-hop design will assign higher weights for co-purchased items, which is what we desire. Furthermore, scatter plots in Figure 5a presents that there is a high density of points with small attentive scores. This indicates that attention in SDM-1 is distributed to several items (which is somewhat close to equally focusing on context items). However, when we increase the number of hops h, the density spreads up to the top, indicating that the model tends to give a higher attention to some context items, which can be more relevant than others. This observation is consistent with "learning to attend" in [2, 59].

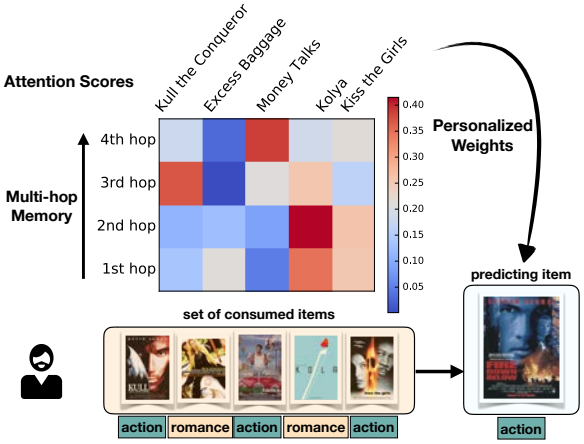

Figure 7: Multi-hop Attention visualization.

Did the metric-based attention with multi-hop design improve recommendation results? We answer this research question by showing the results of SDM model when varying number of hops h from {1, 2, 3, 4} with different embedding sizes and visualize attention scores of SDM-h with a random observation as follows:

Varying number of hops with different embedding sizes: The performance of SDM-h regarding *hit*@10 with h from {1, 2, 3, 4} and embedding size from {8, 16, 32, 64, 128} is presented in Figure 6. We see that more hops tend to give additional improvement in all 6 datasets, except in Tafeng dataset where SDM with more hops over-fitted. In ML-100k and ML-1M, the optimal number of hops are 3 or 4. In Netflix, SDM with 3 hops performed well. In Epinions and IJCAI-15, SDM-4 tends to achieve better results. Overall, the selection of the number of hops depends on the dataset complexity, and it varies from datasets to datasets.

Attention Visualization: Lastly, to visualize how the personalized metric-based attention with multi-hop design works, we chose one user from ML-100K data. The learned weights at each hop of SDM is shown in Figure 7. The target item in this example is an action movie called *Fire Down Below* (1997). The first two hops of SDM

assigned high weights to two romance movies, and the lowest score to the action movie *Money Talks* (1997). The 3rd-hop and 4th-hop attention refined the weights of movies to better reflect the correlations and similarities *w.r.t* the target movie. At last, *Money Talks* (1997) was assigned with the highest weight 0.386, and the total weights of two romance movies decreased to less than 0.2. This result shows the effectiveness of our multi-hop SDM model.

6 CONCLUSION

In this paper, we have studied the top-k recommendation problem in a signed distance learning perspective. Different from previous works, we have considered two independent signed distance models for measuring user-item and item-item similarities respectively via deep neural networks. Extensive experiments have been performed on six real-world datasets in general recommendation and shopping basket-based recommendation task. We presented that our proposed SDMR outperformed **ten** baselines in all two recommendation tasks. To an extension, future works can integrate position embeddings [54] in our models, which give our models a sense of which position they are dealing with, which can further improve our model's performance when rigid orders of items are available.

ABSTRACT

Collaborative crowd computing, e.g., human computation and crowdsourcing, involves a team of workers jointly solving tasks of varying difficulties. In such settings, the ability to manage the workflow based on workers' skills and task strains can improve output quality. However, many practical systems employ a simple additive scoring scheme to measure worker performance, and do not consider the task difficulty or worker interaction. Some prior works have looked at ways of measuring worker performance or task difficulty in collaborative settings, but usually assume sophisticated models. In our work, we address this question by taking a competitive perspective and leveraging the vast prior work on competitive games. We adapt TrueSkill's standard competitive model by treating the task as a fictitious worker that the team of humans jointly plays against. We explore two fast online approaches to estimate the worker and task ratings: (1) an ELO rating system, and (2) approximate inference with the Expectation Propagation algorithm. To assess the strengths and weaknesses of the various rating methods, we conduct a human study on Amazon's Mechanical Turk with a simulated ESP game. Our experimental design has the novel element of pairing a carefully designed bot with human workers; these encounters can be used, in turn, to generate a larger set of simulated encounters, yielding more data. Our analysis confirms that our ranking scheme performs consistently and robustly, and outperforms the traditional additive scheme in terms of predicted accuracy.

1 INTRODUCTION

Human computation [38] and crowdsourcing [14] leverage the human processing power of online crowds to solve tasks that are beyond the capabilities of computer algorithms. Even though most of these tasks involve independent human workers, a significant portion of them requires the collaborative effort of two or more workers. One representative example is multi-player human computation games [40], originally proposed by Luis von Ahn as a money-free alternative to incentivize humans to perform such diverse tasks as image annotation [39], music tagging [27], collecting common sense facts [41], or locating objects in images [42]. These games usually require the agreement of the players[1] for data verification. Collaboration thus serves as a quality control mechanism. For example, in the ESP game [39], two randomly paired-up players simultaneously provide labels for a given image without communicating one with another. Collaboration also occurs in highly complex crowdsourcing tasks such as multilingual translation, to exploit complementary knowledge from different workers to generate high quality results [23, 32].

The performance of a joint task mainly depends on three factors. The first is task difficulty, which intuitively measures how hard it is for workers to generate outcomes intended by requesters. For example, in the ESP Game, a picture of a lion would be easy to name, since the majority of players are able to give specific labels, e.g., "lion". In contrast, an image of a tapir is more challenging, given that most people can only identify it as an "animal". The second factor is the skill of individual workers, which can be affected by their education, personal experience, etc. Normally, skilled workers are able to generate outputs of a higher quality compared to the low-skilled ones. The third, also the most distinctive factor of collaborative crowd computing, concerns the inter-worker interaction, i.e., the mechanism to determine the collective output given individual contributions. For instance, several human computation games rely on the agreement between two or more players as a verification mechanism. As a result, low-skilled players may have a greater impact on the game outcome. In the tapir image example, a knowledgeable player may key in the exact name of the tropical mammal, which, however, will not be accepted by the game if the partner fails to recognize it. Such crowd computing tasks can be best characterized as weak-link games [13]. The dual type, strong-link interactions in which more skilled workers may have a greater impact on the group outcome, also occurs in collaborative crowd computing. Crowd translation for instance only takes the

[1] Whenever there is no ambiguity, we use the terms worker and human interchangeably. In game contexts, we additionally use all three terms worker, player, and human interchangeably.

best translation derived from various answers generated by a team of workers [23].

To achieve the desired output quality and maintain worker engagement in collaborative crowd computing, one approach is to rate human participants based on their skill and tasks based on their difficulty. First, a rating system gives workers the incentive to devote more efforts to the tasks for potentially higher monetary rewards. This can, in turn, lead to better outcomes. Second, it allows for balanced collaborations, teaming up workers of similar skill levels. Third, it enables more proper task assignments, i.e., workers receive tasks that match their skills. Existing crowd computing projects often use an additive scoring scheme to assess worker performance [27, 39, 41]. Upon the completion of a collaborative task, each member of the group receives a score according to the joint performance. A project can rank all its workers based on their total scores summed over all the tasks they have performed, possibly in different groups. This scoring scheme is not an accurate indicator of personal skills, as a low-skilled worker that finishes significantly more tasks than a more skillful counterpart may probably end up with a higher score. Taking the average score can avoid this issue, but it still suffers from two significant shortcomings as a performance measure. First, it does not take into account the task difficulty, only the outcome. Intuitively, a high-quality output of a challenging task should be valued more than that of an easy one. Second, it ignores worker interaction, which can be a critical factor. Motivated by its pivotal role and the aforementioned shortcomings, some prior work has looked at ways of jointly rating workers and tasks in collaborative crowd computing [4, 7, 11, 20, 21, 33, 34, 36, 43–45]. These works typically assume fairly sophisticated models; the ratings of workers and/or tasks are subsequently inferred by maximizing a proper log-likelihood function.

In this work, we adopt an alternative perspective: instead of coming up with new schemes, we seek to leverage the state-of-the-art work on competitive games. Our model is the standard Bayesian rating scheme of TrueSkill for competitive games [12], which additionally treats the task as a fictitious worker that the team of humans plays against. We further discuss two online methods to estimate the ratings under this model: (1) an ELO rating scheme [9] that iteratively updates the ratings based on the expected and the actual outcome; and (2) Expectation Propagation (EP) [30, 31], a message-passing algorithm that performs approximate Bayesian inference. We evaluate the efficacy of the proposed rating framework using data from a simulated ESP Game with 100 participants conducted on Amazon Mechanical Turk (MTurk). We empirically show that our framework is more robust than the average scoring scheme, with the ELO scheme having the most consistent performance. We further assess the strengths and weaknesses of all methods. Our contributions can be summarized as follows:

- We show how to leverage TrueSkill's standard rating model in competitive games for the purpose of rating participants and tasks in collaborative projects. In this direction, we derive, for the first time, the update equations for the online schemes of ELO and EP in the collaborative scenario.
- We perform a human study on MTurk by properly adjusting the ESP game. Our study allows us to empirically assess the strengths and weaknesses of our proposed methods to the average scoring scheme, commonly employed in several human computation projects.
- We propose a novel experimental design, where we pair a human player with a carefully designed bot instead of a human player. This allows us, in turn, to generate a large set of encounters from a smaller dataset at a low cost.

The rest of the paper is structured as follows. We first survey related work. We then introduce our Bayesian TrueSkill-based rating model, and explore worker and task rating estimation via (1) a simple ELO rating scheme, and (2) an Expectation Propagation message passing algorithm. Following that, we present our human study on MTurk and the experimental results. Finally, we conclude the paper with discussions and future work.

2 RELATED WORK

We review existing scoring schemes in collaborative crowd computing, as well as rating and ranking in competitive games.

2.1 Scoring in Collaborative Crowd Computing

Additive scoring is the most common way to assess worker performance in existing crowd computing projects. In the ESP game for instance, a match results in a score varying from 50 to 150, with more specific labels rewarding a higher score. Similarly, in TagATune for tagging music clips [27] and Verbosity for collecting commonsense facts [41], both players earn 1 point if they reach an agreement or 0 points otherwise. These games order players according to their total scores across all the tasks they have performed, and thus the number of jobs completed may outweigh individual skill in the ranking. Computing the average score per task can avoid this issue, but still fails to consider the influence of task difficulty and intra-group dynamics. In contrast, although under a different setting, the more complicated schemes for ranking or rating players proposed for conventional competitive games may provide useful insights for collaborative crowd computing.

2.2 Ranking and Rating in Competitive Games

Assume a game with a finite set of players. A ranking is defined as a total preorder $\preceq$ on the set of players. For two players i, j, the relationship $i \preceq j$ denotes that player i ranks at most as high as player j. A rating, on the other hand, is a quantitative assessment index that denotes the skill level of a player. Higher-skilled players are associated with higher ratings in contrast to those with lower skills. Compared to rating, ranking merely shows that one player is better than another, but how much better remains unknown.

For ranking, there are three main approaches [3]. (1) The model-based approach determines the player ratings and subsequently calculates the induced ranking by sorting the computed ratings. (2) The score-based approach measures player performance with a scoring scheme (e.g., total or average score), and ranks players based on their score. (3) The axiomatic approach is inspired by axiomatic economic theory [35]. The idea is to determine a ranking scheme based on a set of axioms that must be satisfied.

Model-based rating methods usually view skill as a latent variable that characterizes the players. They assume that a fixed probability distribution (model) governs the outcome of an encounter between two players of given skills [3]. In particular, $F(r_i, r_j)$ denotes the

probability that player i with skill r_i beats player j with skill r_j; note that $F(r_i, r_j) = 1 - F(r_j, r_i)$. The probability distribution is computed a priori based on historical data. It primarily follows two models: the Thurstone Case V model [37] assumes the Gaussian distribution $F(r_i, r_j) = \Phi(r_i - r_j)$, where $\Phi(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{-\frac{x^2}{2}} dx$, whereas the Bradley-Terry model [2] assumes the logistic variant $F(r_i, r_j) = \frac{1}{1+e^{-(r_i - r_j)}}$. Subsequently, one can use a maximum likelihood approach to estimate the players' skills based on paired-comparison data, and rank them accordingly. In practice, the skill parameters are called ratings, and the function F is the rating function. Under the linear paired comparison model [6], we assume that the result of an encounter between any two players depends only on their rating difference.

Given that maximum likelihood estimation is complex and requires the complete paired-comparison data, an alternative is the ELO rating system [9]. Under this online scheme, every player is associated with an ELO rating. Whenever an encounter between two players occurs, the scheme computes the probability that each of the two players wins. It subsequently rewards or punishes players, depending on whether they performed better or worse than expected. The ELO rating system has been widely deployed for player ranking in real-world competitive games such as chess, association football, American football, basketball, Major League Baseball, Scrabble, and snooker.

The above rating methods do not directly handle the uncertainties over the ratings. Hence, prior research has proposed Bayesian rating schemes to tackle this [10]. The idea is to model the belief about a player's skill as a Gaussian belief distribution characterized by a mean μ and a standard deviation σ. Recently, TrueSkill has been introduced as a more general online Bayesian rating system which can further handle (1) teams of players rather than just individual players, and (2) settings where more than two teams compete simultaneously [12].

Of course, the topic of ranking and rating from pairwise comparisons with items of various difficulties has attracted considerable attention in the machine learning community, see e.g., [4, 7, 11, 20, 21, 33, 34, 36, 43–45]. In particular, several sophisticated studies within the machine learning community investigate the problem from a theoretical perspective. In this work, we take a different approach by looking into fast online schemes inspired by competitive games that are relatively simple to implement and deploy. Our interest in TrueSkill is due to its enormous success in both identifying and tracking the skills of gamers in Xbox Live by Microsoft, and its ability to properly match gamers into competitive matches. Our goal is thus to examine how the most popular and successful rating schemes in competitive games can be adapted to ameliorate ranking in collaborative crowd computing in a fast online manner and empirically assess them, rather than investigate new theory and propose novel sophisticated ranking schemes.

Finally, note that there has been extensive research within the crowdsourcing community aimed at improving worker performance, including different filtering mechanisms, the use of golden standards, explicitly verifiable questions as well as gamification with scoring mechanisms aimed at improving data quality [1, 8, 15, 24, 25, 29]. Such work is complementary to ours, since our sole focus in on schemes for jointly rating the workers' skills and task strains.

3 BAYESIAN RATING MODEL

In this section, we introduce a TrueSkill-based Bayesian rating model and two online rating estimation methods for assessing works and tasks in collaborative crowd computing. Our model takes into account both the worker interaction and the task difficulty.

3.1 High-level Overview

Before examining our model in detail, we first provide a high-level overview. Since both the worker skills and the task strains are unknown, we represent them as random variables, which are characterized by two important parameters, the mean and the variance. Higher values for the former are associated with a belief for a higher worker skill (or task strain) compared to lower values. On the other hand, the variance describes the degree of certainty in our belief, with lower values corresponding to higher certainty.

Given the random variables, a model describes how the various variables are related to each other. In collaborative tasks, the model has in general two parts: (1) the first part describes how the performance of the team of workers depends on their individual skills; (2) the second part describes when the team of workers solves a task of a given strain successfully or not.

Since the random variables are unknown, our goal is to then infer their values given the model from a set of encounters, where teams of workers try to solve a task. There are two general families of methods. Online methods update the random variables after each encounter, whereas offline methods do the update based on the entire dataset. Offline methods can in principle lead to optimal estimates, but online methods have the advantage of being faster and simpler. Practical rating schemes for competitive games have traditionally relied on online methods (see section 2.2), and we take a similar approach in our work.

3.2 Model

Our scheme is inspired by TrueSkill [12] and by prior work on question difficulty estimation in community question answering services [28].

Let i and j be the two workers[2] with ratings r_i and r_j, respectively, that collaboratively try to solve human computation task t. We denote the encounter between i and j when they perform task t as $< i, j, t >$. TrueSkill assumes that the belief about the rating r_i of player i follows a normal distribution $\mathcal{N}(r_i; \mu_i, \sigma_i^2)$ with mean μ_i and variance σ_i^2. When i performs a task t, its performance p_i will follow a normal distribution $\mathcal{N}(p_i; r_i, \delta^2)$. The variance δ^2 is due to the fact that the performance of a player may vary due to assorted factors that we cannot directly model. When players i and j collaboratively perform task t, their joint performance p will depend on the type of interaction between them. As we argued in the Introduction, in some human computation games, the inter-group interaction is asymmetric and takes the form of a weak-link game, whereas certain crowdsourcing tasks such as collaborative design can be modeled as the dual strong-link game. In the former

[2]For teams consisting of just two workers, we use the terms team and pair interchangeably.

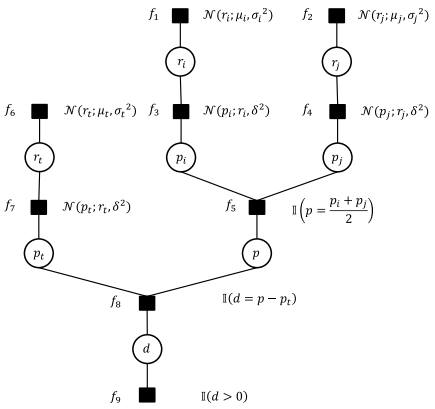

Figure 1: Factor graph for an encounter $< i, j, t >$ where the pair of workers (i, j) correctly solves task t.

(latter) case, workers of higher (lower) skill have a higher impact on the task output. In our work, we adopt a simpler symmetric approach where the interaction dynamics is simply modeled as the average of the player performances. This is similar to the model that TrueSkill considers to measure the performance of teams consisting of several players. Despite being less accurate, this model has the advantage of being linear (as opposed to the non-linear minimum or maximum operators), and allows for tractable inference.

In order to take into account the second feature of collaborative human computation, i.e., the task difficulty, we properly adapt the approach proposed in [28]. The idea is to model each task as an additional player, whose rating and performance also follow normal distributions. After encounter $< i, j, t >$ has taken place, we review the task output that the players jointly produced. If the pair of workers produced high quality output (e.g., informative or specific labels in the ESP game), we assume that the pair beat the fictitious worker that represents task t. In the opposite case, the pair loses to the fictitious worker. We do not consider the case of a draw. This approach actually turns the collaborative task into a competitive game. Note that we use the same variance δ^2 for the performance of the human players and the task for simplicity, but we could in principle also adopt different variances depending on the collaborative project at hand.

Figure 1 schematically depicts an example factor graph in the case where the pair of workers answers the question correctly, or "beats" the question. It has the form of a factor graph [26], which is basically a bipartite graph that consists of variables (circles) and nine factor nodes $f_1, \ldots, f_9$ (squares). The structure of the factor graph gives information about the dependencies of the factors.

Note that we can extend the model of Figure 1 in three ways. First, we can model the fact that ratings vary over time by assuming a Gaussian drift of skill between time steps given by $Pr(r_i^t | r_i^{t-1}) = \mathcal{N}(r_i^t; r_i^{t-1}, \tau^2)$ [5, 12]. Second, we can handle the case of more players by just adding one rating node r_k and one performance node p_k for each additional player k, and then defining the joint performance to be equal to the average of the individual player performances, i.e., $p = \frac{p_i+p_j+p_k+\cdots}{n}$, where n the number of players. Third, we can handle situations where the task output is not binary (correct versus incorrect or specific versus generic), but may take on one of $L > 2$ possible values (e.g., low, medium, or high specificity). To accommodate this, we can extend Figure 1 by considering $L-1$ tasks rather than just one, where each task also consists of a rating node r_t^l and one performance node p_t^l, where $2 \leq l \leq L$. Furthermore, we add $L-1$ difference nodes d^l that correspond to the difference between the team performance p and task performance p_t^l, where $2 \leq l \leq L$. Whenever an encounter occurs, we determine the level l^o of the outcome that the team of workers produced. Subsequently, we assume that the team beats all the tasks that correspond to level equal to or less than l^o, and loses to all task nodes that correspond to levels greater than l^o, i.e., $d_l > 0$ if and only if $l \leq l^o$. The natural interpretation for this is that if a team of workers generates an outcome of level l^o, where $1 \leq l^o \leq L$, this is equivalent to assuming that the team has (1) beaten all task levels lower than or equal to level l^o, and (2) has lost to all task levels greater than l^o. Note also that we do not need a node for the lowest level, since the team of workers is always guaranteed to beat that level; for instance, in a correct versus incorrect scenario, the team of workers can do no worse than giving an incorrect answer.

As a final remark, our model assumes that each worker is characterized by a single rating $\mathcal{N}(r_i; \mu_i, \sigma_i^2)$. In reality, a worker may have different skills for different tasks; for instance, they may be very knowledgeable about sports but know little about books. It is possible to consider multiple ratings per worker, one per task. In the remainder of the paper, as a proof of concept, we use a single rating per worker, which can be viewed as an indicator of the worker's average ability to provide high quality output on any task.

3.3 ELO Rating Scheme

Let $< i, j, t >$ be the encounter between i and j when they jointly perform task t. The task serves as a fictitious participant that plays against the human pair as shown in the graph model of Figure 1. Before the encounter takes place, assume the ratings of the workers are r_i and r_j, and the rating of the task node is r_t. The combined rating for the pair of workers will be according to our model $r = \frac{r_i+r_j}{2}$. The task node exhibits a performance p_t that is normally distributed around r_t with a fixed variance δ^2, while the performance p of the human pair node is normally distributed around r with a fixed variance $\frac{\delta^2+\delta^2}{4} = \frac{\delta^2}{2}$. But then the random variable $p - p_t$ will be normally distributed around $r - r_t$ with a variance $\delta^2 + \frac{\delta^2}{2} = \frac{3\delta^2}{2}$. The probability that the pair of workers beats the task will then be equal to $Pr(p > p_t | r, r_t) = \Phi(\frac{\sqrt{2}(r-r_t)}{\sqrt{3}\delta})$.

Our online ELO rating scheme will update the pair rating and the task rating after the encounter to reflect the game outcome, based on the premise that an entity should be "punished" if it did worse than expected, or boosted if it exceeded expectations. The expected outcome (in terms of the pair of workers beating the task node) will be $expected^{<i,j,t>} = \Phi(\frac{\sqrt{2}(r-r_t)}{\sqrt{3}\delta})$. The actual outcome $actual^{<i,j,t>}$ will be 1 if the pair of humans beats the task, and 0 otherwise. The resulting ELO update is:

$$r' = r + K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$
$$r'_t = r_t - K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$

Parameter $K > 0$ is a positive real number called the K-factor fixed in advance that is related to the maximum adjustment from a single encounter. Note that we increase the rating of an entity if it does better than expected, or we decrease it in the opposite case; the adjustment is proportional to (1) the K-factor, and (2) the difference between the actual and the expected outcome.

The update rule for the human pair can be rewritten as:

$$\frac{r_i' + r_j'}{2} = \frac{r_i + r_j}{2} + K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>}) \Leftrightarrow$$
$$r_i' + r_j' = r_i + r_j + 2 \cdot K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$

But then we can split the $2 \cdot K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$ update amount equally to the two workers, so that we have:

$$r_i' = r_i + K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$
$$r_j' = r_j + K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$

Regarding convergence, in the presence of balanced matches, the ELO ratings converge exponentially fast to the actual player ratings [16]. If, on the other hand, the schedule is unbalanced, convergence can be very slow and a plethora of equilibria can emerge, depending on the exact initial distribution of initial ratings. Note that despite these theoretical concerns, ELO is a very robust scheme and widely used in several popular competitive games (see section 2.2). Algorithm 1 describes the update rules for ELO rating.

ALGORITHM 1: ELO Rating for Bayesian Factor Graph of Figure 1.

Input: An encounter $< i, j, t >$, prior ratings r_i, r_j, r_t, performance variance δ^2, and K-factor K.

Output: Updated ratings r_i', r_j', r_t' after encounter $< i, j, t >$.

Compute:

$$expected^{<i,j,t>} = \Phi(\frac{\sqrt{2}(r - r_t)}{\sqrt{3}\delta})$$
$$actual^{<i,j,t>} = \begin{cases} 1, & \text{if pair } (i, j) \text{ beats task } t \\ 0, & \text{otherwise} \end{cases}$$

Update:

$$r_i' = r_i + K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$
$$r_j' = r_j + K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$
$$r_t' = r_t - K \cdot (actual^{<i,j,t>} - expected^{<i,j,t>})$$

3.4 Bayesian Rating Scheme

We can estimate the unknown ratings with Expectation Propagation (EP), a deterministic approximate inference technique [30, 31]. Our goal is to determine the posterior distributions over the variables r_i and r_j, after encounter $< i, j, t >$ has occurred. EP is essentially an online message-passing algorithm for the factor graph of Figure 1.

Before going into the details, we briefly examine inference algorithms on factor graphs, i.e., graphs where the global function can be factorized into a product of local functions (factors) that depend on the node variables. The main algorithm for this class of graphs is the sum-product algorithm [26], which operates on the factor graph and attempts to compute various marginal functions. The basic idea is that if the graph is acyclic (as in our case), then it is possible to execute a message-passing algorithm where messages are passed from factor nodes to variable nodes, and vice versa. The algorithm terminates once two messages have passed over every edge, one in each direction. The message passing procedure for continuous variables is described by the following equations:

$$\textit{marginal distribution: } p(v) = \prod_{f \in n(v)} m_{f \to v}(v)$$
$$\textit{variable to factor: } m_{v \to f}(v) = \prod_{h \in n(v) - f} m_{h \to v}(v)$$
$$\textit{factor to variable: } m_{f \to v}(v) = \int \cdots \int f(V) \prod_{u \in n(f) - v} m_{u \to f}(u) dV_{-v}$$

where $m_{v \to f}(v)$ the message sent from variable v to factor f, $m_{f \to v}(v)$ the message sent from factor f to variable v, $n(x)$ is the set of neighbors of node x, V the set of variables connected to factor f, and V_{-v} the components of vector V except for variable v.

Of particular importance in our framework are the sum and difference of normal distributions. Assume two normal distributions $\mathcal{N}(x_1; \mu_1, \sigma_1^2)$ and $\mathcal{N}(x_2; \mu_2, \sigma_2^2)$. Their sum will be distributed according to $\mathcal{N}(x_1 + x_2; \mu_1 + \mu_2, \sigma_1^2 + \sigma_2^2)$, and their difference according to $\mathcal{N}(x_1 - x_2; \mu_1 - \mu_2, \sigma_1^2 + \sigma_2^2)$. Moreover, in the message-passing algorithm, we often need to compute the product of two edge messages, or the ratio of a node message to an edge message. Since the messages in our framework are normal densities, given two normal densities $m_1 = (\mu_1, \sigma_1^2)$ and $m_2 = (\mu_2, \sigma_2^2)$, their product will be $m_1 \cdot m_2 = (\frac{\sigma_2^2 \cdot \mu_1 + \sigma_1^2 \cdot \mu_2}{\sigma_1^2 + \sigma_2^2}, \frac{\sigma_1 \cdot \sigma_2}{\sqrt{\sigma_1^2 + \sigma_2^2}})$ and their ratio $m_1 \div m_2 = (\frac{\sigma_2^2 \cdot \mu_1 - \sigma_1^2 \cdot \mu_2}{\sigma_2^2 - \sigma_1^2}, \frac{\sigma_1 \cdot \sigma_2}{\sqrt{|\sigma_2^2 - \sigma_1^2|}})$.

The only complication is created by factor f_9, which is non-Gaussian. To tackle this, we approximate the non-Gaussian posterior marginal $p(d)$ of node d with a normal distribution, using the technique of moment matching [31]. This technique consists in computing the mean and variance of the non-Gaussian message, and subsequently approximating it with a Gaussian distribution with the same first two moments. Moment matching provably minimizes the Kullback-Leibler divergence for Gaussian distributions. Assuming a message $m_{f_8 \to d} = (\mu_{f_8 \to d}, \sigma_{f_8 \to d}^2)$, the approximate posterior marginal $\hat{p}(d)$ will have mean and variance [19]:

$$\hat{\mu}_d = \mu_{f_8 \to d} + \sigma_{f_8 \to d} \cdot u\Big(-\frac{\mu_{f_8 \to d}}{\sigma_{f_8 \to d}}\Big) \quad (1)$$
$$\hat{\sigma}_d^2 = \sigma_{f_8 \to d}^2 \cdot \Big(1 - w\Big(-\frac{\mu_{f_8 \to d}}{\sigma_{f_8 \to d}}\Big)\Big) \quad (2)$$

where

$$u(x) = \begin{cases} \frac{\phi(x)}{1 - \Phi(x)}, & \text{if } x < 0 \\ -\frac{\phi(x)}{\Phi(x)}, & \text{if } x > 0 \end{cases}, w(x) = u(x) \cdot (u(x) - x).$$

Note that ϕ and Φ denote the probability density function and the cumulative distribution function of the standard normal distribution $\mathcal{N}(0, 1)$, respectively. Algorithm 2 presents the message-passing inference process.

Finally, note that even though Figure 1 and Algorithm 2 assume a single encounter, it is possible to assume multiple encounters, as long as the underlying factor graph does not have cycles [30, 31].

ALGORITHM 2: Approximate Inference for Bayesian Factor Graph of Figure 1.

Input: An encounter $< i, j, t >$, the prior ratings (μ_i, σ_i^2), (μ_j, σ_j^2), (μ_t, σ_t^2), and the performance variance δ^2.
Output: The posteriors $p(r_i \mid < i, j, t >)$, $p(r_j \mid < i, j, t >)$, and $p(r_t \mid < i, j, t >)$.

8. $m_{d \to f_8} = \frac{\hat{p}(d)}{m_{f_8 \to d}}$
9. $m_{f_8 \to p} = m_{p_t \to f_8} + m_{d \to f_8}$, $m_{f_8 \to p_t} = m_{p \to f_8} - m_{d \to f_8}$
10. $m_{p \to f_5} = m_{f_8 \to p}$, $m_{p_t \to f_7} = m_{f_8 \to p_t}$
11. $m_{f_5 \to p_i} = 2 \cdot m_{p \to f_5} - m_{p_j \to f_5}$, $m_{f_5 \to p_j} = 2 \cdot m_{p \to f_5} - m_{p_i \to f_5}$
12. $m_{p_i \to f_3} = m_{f_5 \to p_i}$, $m_{p_j \to f_4} = m_{f_5 \to p_j}$
13. $m_{f_3 \to r_i} = (\mu_{p_i \to f_3}, \sigma^2_{p_i \to f_3} + \delta^2)$, $m_{f_4 \to r_j} = (\mu_{p_j \to f_4}, \sigma^2_{p_j \to f_4} + \delta^2)$, $m_{f_7 \to r_t} = (\mu_{p_t \to f_7}, \sigma^2_{p_t \to f_7} + \delta^2)$

//Posterior rating marginals
14. $p(r_i \mid < i, j, t >) = m_{f_3 \to r_i} \cdot m_{f_1 \to r_i}$, $p(r_j \mid < i, j, t >) = m_{f_4 \to r_j} \cdot m_{f_2 \to r_j}$, $p(r_t \mid < i, j, t >) = m_{f_7 \to r_t} \cdot m_{f_6 \to r_t}$

However, in practice the player encounters can form cycles, for instance when every player is paired with every other player. For this reason, we favor our simpler model in Figure 1, which considers a single encounter and avoids cycles in the underlying factor graph.

4 EXPERIMENT

We test our framework using the ESP game as a case study, as it is typically viewed as the most influential human computation game.

4.1 System and Task Design

Figure 2 depicts the graphical user interface of the game used in our experiment. It closely resembles the original Google Image Labeler, the commercially licensed version of the ESP game [17]. Our implementation is web-based and written in JavaScript and PHP, and also uses an Apache HTTP web server.

The rules in our implementation have both similarities and differences, compared to the original version. First, players have 40 seconds to match on a label for any image, while in the original game players were given 120 seconds to try to match as many pictures as possible. This is related to the fact that we do not include a passing mechanism, as we discuss later. Second, if a pair of players match on a label, they both earn a score ranging from 10 to 100 depending on the label specificity, which they can immediately see upon agreement. Third, if time is out, players win 0 points each (no agreement reached), and they move on to the next image. Fourth, for every picture we additionally include a short list of 0 to 2 taboo (off-limits) labels that players are not allowed to provide. As opposed to the original game, our version does not allow players to skip an image and move on to the next one, because we need to know their performances in all tasks to be able to rate them better.

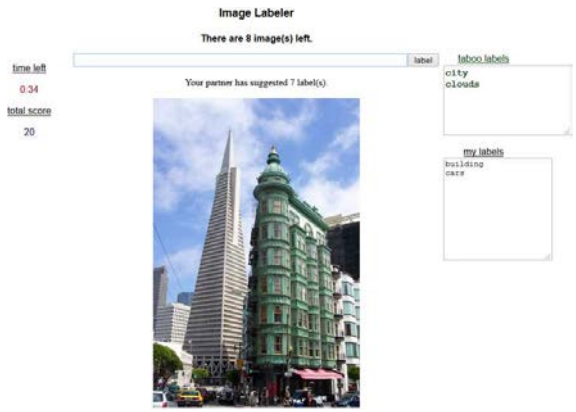

Figure 2: The interface of our simulated ESP game.

Regarding the actual tasks, we select 10 pictures from the Internet (Figures 3a-3j). Our tasks satisfy two properties: (1) they cover various common themes in the original ESP game such as animals, food, Hollywood, architecture, and science, and (2) they have both a generic and a specific component. For instance, Tapir accepts generic labels such as "animal" or "large" as well as the specific animal name. Transamerica can be labeled with the generic label "skyscraper" or the specific label "San Francisco".

Figure 3: Pictures from our MTurk experimental evaluation.

4.2 Experiment Design

An interesting design of our experiment is that we do not directly ask two humans to play with each other. Instead, we develop a bot that simulates a high-skilled player; a human worker is then paired with our bot. The motivation behind this decision is threefold. First,

a bot allows us to control the label scores. It is practically impossible to know in advance all possible labels that two human players may agree on and assign scores to them. A bot with a predefined set of labels with associated scores can tackle this issue. Of course, this requires that the label set is large enough and carefully selected; we discuss this point in more detail later. Second, it is easier to infer human players' true skill as the baseline, since the bot does not act as the weak link in the collaboration. Third, as we discuss below it is possible to simulate a very large number of human encounters based on the bot responses, which would be very difficult and costly to do directly. Interestingly, our design novelty is appropriate for any collaborative task where the goal is to generate many encounters at a lower cost. This method can be applied to real collaborative crowd computing tasks in cold-start situations to generate an initial assessment of task difficulty and worker skill.

We did not mention to the players they are playing against a bot; instead, we instructed them that they would be paired with another human player. In addition, we generate the time period between two consecutive labels randomly from 1 to 5 seconds to give the human workers the impression that they are playing with a real human instead of a bot, especially given that they only play together for 10 images. The bot provides 12-14 representative labels per image that we carefully select so that: (1) they range from very specific to very generic in decreasing order to prioritize high-quality labels, and (2) they cover the main objects or semantic aspects of the image. This ensures that both high-skilled and low-skilled players can reach an agreement with the bot. In addition, we created variations of these representative labels, such as singular and plural form, capitalized first letter for names etc. For each image, the bot generates the labels in decreasing order of specificity, because in game-theoretical terms it is a dominant strategy for a rational player to output the labels in that order [18]; otherwise, the pair of players might first match on a label with lower specificity (and thus lower score). The label selection was based on a preliminary pilot study on MTurk, where we asked 20 workers to provide both generic and specific labels for each picture. Following that, we asked two researchers to rank the labels of each image from the most generic to the most specific independently. The Spearman's coefficient of 0.82 (p-value < 0.05) suggests strong inter-rater reliability. We invited a third researcher into the group discussion to resolve disagreement and come up with the final assessment. The top six or seven labels from the generic and specific categories then form the label set for each image. We subsequently assigned scores using even intervals between consecutive terms, so that the most generic picture gets a score of 10 and the most specific a score of 100, and we rounded the remaining scores to the nearest multiple of 10.

Finally, we upload our game as a human intelligence task (HIT) on Amazon Mechanical Turk (MTurk). Upon successful completion of the HIT, i.e., reaching an agreement in at least eight out of the ten images presented in a randomized order, workers earn \$0.25, for an average hourly rate per worker of about \$3.0. To motivate workers to put more effort into the game, we include a bonus of \$5 to the 5 workers with the highest total scores. For quality control purposes, we only allowed MTurk workers with acceptance rates for submitted tasks of at least 80%, and with at least 10 submitted tasks in their history. Note that a worker may be truthful but still have low skill, the two notions are not contradictory. Given that our study involves specific labels, we restrict our tasks to MTurk workers in the US.

4.3 Data Collection

In total, we accepted data from 100 workers. For each worker, we recorded the set of labels provided for each image until either a match or a timeout occurred, as well as the corresponding timestamp. From these results, we were able to generate two datasets. (1) The first dataset, which we call BOT-PARTNER, contains the 10×100=1,000 encounters between the population of the 100 players and the bot. (2) The second dataset, which we name HUMAN-PARTNER, contains the (hypothetical) encounters between any two players from the 100 workers. It is indeed possible to simulate these encounters, based on the (label, timestamp) recorded information. One problem is that not all encounters are valid. For instance, assume that one player reaches an agreement with the bot in the first 5 seconds, whereas it takes 35 seconds for another player to reach an agreement for the same image. In the simulated encounter where these two players are paired together, there may be no match because the first player only played for a limited time. To account for this, we ignore (invalid) encounters that result in no match, when at least one of the two players played the corresponding image for less than 40 seconds (this happens when the player did not manage to match on any label). By construction, HUMAN-PARTNER is not an unbiased dataset: encounters involving players who match with the bot in BOT-PARTNER may be ignored; on the other hand, encounters where both players did not match with the bot can never be ignored (they either match on a new label or they do not match yielding a score of 0). Given this bias, we expect any given method will not produce identical rankings on the two datasets.

In particular, HUMAN-PARTNER contains 17,357 (valid) encounters in total (instead of $10 \times \binom{100}{2} = 49,500$); furthermore, by construction it has a bias toward low-skilled workers, as it takes these workers longer to come to a match with the bot and as a result their encounters are more likely to be kept. This is an inherent limitation of this design scheme that we also discuss in Section 5.4. Note that in BOT-PARTNER a player can only generate a match on the predetermined 10-12 labels that the bot is programmed to provide; in contrast, in HUMAN-PARTNER matches occur on labels that both human workers provided, which may be different from the predetermined labels of the bot. The total number of matched labels over all 17,357 encounters that were different from the bot's labels were 129: 22 for "Pumpernickel", 10 for "Tapir", 13 for "Hunger Games", 7 for "Captcha", 31 for "Declaration", 10 for "Soba Noodles", 14 for "Transamerica", 8 for "Albert Einstein", 1 for "Cheetah", and 13 for "Phi-beta-sigma". Note that intuitively easier tasks such as "Cheetah" or "Albert Einstein" resulted in fewer new matches than harder tasks such as "Pumpernickel", or tasks that are associated with a plethora of objects and/or concepts such as "Declaration". In order to assign a score to matched labels not in the predetermined set, we asked the previous three raters that we used to select labels for the bot to score these new labels from 10 to 100 in multiples of 10 according to how specific they were. The value of 60 was used as a cutoff: labels with specificity 10-50 were classified as generic, whereas labels with specificity 60-100 were classified as specific. The average of the three values was then selected as the label's

score. For labels where the three values differed significantly, we invited a fourth rater to confirm and finalize the score.

Table 1 provides descriptive statistics about the matched labels (specific, generic, or no match) in BOT-PARTNER for each of the ten tasks. Note that the first three columns sum up to 100, i.e. the number of workers since in BOT-PARTNER each worker is involved in one encounter per task. Images where fewer players managed to match on a specific label are usually associated with a higher average matching time (the Pearson's correlation coefficient is -70.65%). These images naturally correspond to harder tasks; for instance, "Transamerica" or "Pumpernickel" are harder than "Albert Einstein" or "Cheetah". Alternatively, the Specific:Generic ratio can serve as an indicator of the image's difficulty. Easier tasks tend to have high values for that ratio; for instance, for "Cheetah" this ratio stands at 24. Difficult tasks, on the other hand, are associated with a lower ratio; for example, for "Transamerica" it stands at 0.59.

Table 1: Statistics for the ten tasks in BOT-PARTNER

	Specific	Generic	No match	Matching time (sec)
Pumpernickel	45	40	15	12.71 ± 7.34
Tapir	76	22	2	11.44 ± 6.95
Hunger Games	90	3	7	8.93 ± 7.68
Captcha	61	36	3	9.69 ± 8.06
Declaration	69	20	11	14.82 ± 8.58
Soba Noodles	71	23	6	9.15 ± 6.00
Transamerica	35	59	6	13.33 ± 12.08
Albert Einstein	93	6	1	8.07 ± 7.93
Cheetah	96	4	0	7.15 ± 8.37
Phi-beta-sigma	76	20	4	11.78 ± 8.79

Table 2 summarizes the descriptive statistics of matched labels for HUMAN-PARTNER. We have added a column "Invalid" that contains the number of invalid encounters. Note that there are totally $\binom{100}{2} = 4,950$ encounters for every image; hence, the first four columns sum up to 4,950. It is not surprising that most encounters are invalid, given that the majority of encounters in BOT-PARTNER result in a match and thus last less than 40 seconds. A higher Specific:Generic ratio is again associated with easier tasks, which are in turn associated with lower matching times. However, we notice in Tables 1 and 2 that for any image the ratios between the specific and generic matches are not necessarily the same in BOT-PARTNER and HUMAN-PARTNER. The percentage of generic matches over all 10 tasks is 24.5% in the former but 28.23% in the latter dataset. The reason for this discrepancy is that in the first dataset the bot simulates a highly skilled player, so encounters are more likely to occur on specific labels. Thus, even though the two datasets are based on the same 10 tasks and the same set of 100 workers, they may result in different workers' skills and task strains.

Note that the above tables do not contain information about how individual workers did across the 10 tasks. Intuitively, we expect that high-skilled workers tend to produce more specific tasks. To test for this, we considered the ELO rating (see Section 5) for the 100 workers based on BOT-PARTNER. We then isolate the top-25 workers as well as the bottom-25 ones, and subsequently simulate encounters among the top 25 workers only; or, among the top 25 and the bottom 25 workers; or, among the bottom 25 workers only.

Table 2: Statistics for the ten tasks in HUMAN-PARTNER

	Specific	Generic	No match	Invalid	Matching time
Pumpernickel	413	451	41	4045	14.65±8.16
Tapir	819	978	6	3147	11.66±7.63
Hunger Games	1405	33	20	3492	10.02±5.28
Captcha	1043	400	20	3487	11.84±7.25
Declaration	806	199	83	3862	18.19±9.30
Soba Noodles	1163	922	5	2860	11.45±7.37
Transamerica	437	1497	51	2965	15.12±9.30
Albert Einstein	2580	61	4	2305	8.73±6.56
Cheetah	1771	66	0	3113	8.42±5.68
Phi-beta-sigma	1816	213	54	2867	13.08±9.13

We only keep the valid encounters. The percentage of encounters resulting in specific matches stands at 88.31%, 61.20%, and 31.44%, respectively, which is in full accordance with our intuition. We also observe that the percentage of valid encounters that result in no match is 0.57%, 3.44%, and 9.44%, respectively. This suggests that encounters involving low-skilled workers are significantly more likely to result in a generic match or no match at all.

5 RATING RESULTS AND ANALYSIS

For each encounter in either dataset, we asked three raters from our research group who were blind to the conditions to vote whether the quality of the matched label (if a match occurred) is high (e.g., informative and specific) or low; we combine the answers with majority voting. We then rate the workers with the following three methods: (1) AVERAGE score, where a specific match yields 1 point and a generic match or a no match yields 0 points, (2) ELO rating of Algorithm 1 with $K = 24.0$, and (3) EP of Algorithm 2 with $\mu_0 = 25, \sigma_0 = \frac{25}{3}, \delta = \frac{\sigma_0}{2}$ (based on [12]). In BOT-PARTNER, we consider that each team consists of a single human player, whereas in HUMAN-PARTNER each team consists of a pair of workers. We compare our proposed rating framework with the baseline average scoring scheme in terms of consistency, accuracy, and robustness.

5.1 Output Similarity across Rating Schemes

First, we investigate how similar the three methods perform on each dataset. To compare the methods, we consider the rankings that the worker ratings and task strains induce, and subsequently calculate the similarities between them using Spearman's rank correlation coefficient[3] [22]. The correlation metric in this context makes sense as a way of capturing the degree to which the different methods agree on the generated rankings; intuitively, they should be positively correlated since they rank based on the same data.

Table 3 contains our results. In general, HUMAN-PARTNER is more challenging for AVERAGE, because (1) not all encounters are valid, and (2) it has a bias toward low-skilled workers. As a result, the task schedules are unbalanced, and the number and type of encounters for each worker varies. In comparison, rankings produced by the three methods have stronger correlations in BOT-PARTNER, where the schedule is balanced, i.e., each player plays with the bot in all 10 tasks for a total number of 10 encounters as

[3]The p-values of all reported correlation coefficients are very low due to the high sample size and we do not report them here.

Table 3: Spearman's correlation coefficient between worker rankings and task rankings from different methods

	BOT-PARTNER		HUMAN-PARTNER	
	WORKER	TASK	WORKER	TASK
AVERAGE-ELO	95.66%	89.09%	73.89%	67.27%
AVERAGE-EP	75.90%	53.94%	50.85%	30.91%
ELO-EP	85.94%	76.97%	85.63%	74.55%

opposed to the less regular second dataset. ELO and EP are generally strongly correlated, since they both rely on the same Bayesian factor graph of Figure 1. One possible reason for the weaker correlation between AVERAGE and EP is that we perform EP after each individual encounter instead of simultaneously optimizing over multiple encounters. This may make EP less accurate, as it needs both the mean and variance. In contrast, the simpler update rules of ELO using only the mean can produce results closer to those of AVERAGE. We also note that the rankings that different methods produce are less correlated for the images than for the workers, possibly due to the very low number of tasks (10) compared to the higher number of workers (100). This is more pronounced for EP.

Next, we investigate whether the same method yields consistent rankings when applied to BOT-PARTNER and HUMAN-PARTNER based on Spearman's correlation coefficient. Using the rank correlation coefficient to compare rankings in different datasets is tricky, because a higher correlation coefficient does not necessarily imply a better ranking. For example, using a random but fixed ranking across different datasets yields a correlation coefficient of 1, even though the underlying random ranking may be totally unrelated to the ground truth. Despite this, Spearman's correlation coefficient can serve as a necessary condition for consistency: given the two datasets refer to the same set of workers and tasks, we intuitively expect similar rankings in the two datasets.

Table 4 shows the correlation coefficients for worker and task rankings for all methods. We observe that worker rankings are positively correlated at around 65%-70%, while task rankings are very strongly correlated at above 90%, with AVERAGE being the least consistent. Task rankings are probably more consistent because a task participates in many more encounters than a worker, so its strain can be estimated more accurately. The positive correlations suggest that dataset HUMAN-PARTNER that we generated by emulation is consistent with the original dataset BOT-PARTNER and can be used in conjunction with it.

Table 4: Spearman's correlation coefficient between worker rankings and task rankings in two datasets

	WORKER RANKINGS	TASK RANKINGS
AVERAGE	65.61%	90.30%
ELO	67.60%	95.15%
EP	71.65%	92.73%

To gain insight into the different rankings, we consider the image "Phi-beta-sigma" in HUMAN-PARTNER. AVERAGE ranks it as the 5th easiest, whereas ELO ranks it as the 3rd easiest. The reason for this discrepancy is that AVERAGE only considers the specificity of the outputs, whereas ELO additionally considers information about the workers involved. We manually verified that there were five players who did not perform well in other tasks, yet managed to score high in "Phi-beta-sigma". This is because these workers provided specific labels such as "fraternity", "frat", or "sorority". Furthermore, three players that did well in other tasks did not perform well in that image, possibly because they were unaware of both the exact Greek characters or their connection to fraternities and sororities. Given that low-rating workers provided specific answers, ELO and EP adjust the image rating to be lower (easier).

The above example additionally demonstrates that the various methods can coexist and play a complementary role. When they are in agreement, this suggests very small uncertainty over the ranking. Disagreement, on the other hand, may be indicative of some interesting fact about the task or the workers.

5.2 Prediction Accuracy

Ratings can be used for balanced task assignment. To confirm this, we investigate whether the worker and task ratings of the three methods can accurately predict output quality. In particular, we predict that a worker (pair of workers) in BOT-PARTNER (HUMAN-PARTNER) will match on an informative label, if its rating (their average rating) is greater than the task rating. Otherwise, we predict that the worker (pair of workers) will agree on a generic label. Table 5 contains the accuracy for each method on each dataset.

Table 5: Prediction accuracy of task output

	BOT-PARTNER	HUMAN-PARTNER
AVERAGE	60.83%	64.56%
ELO	75.63%	70.08%
EP	62.29%	58.13%

Overall, ELO performs significantly better than EP in both datasets. This may be because (1) the EP update occurs after each individual encounter instead of optimizing over all encounters simultaneously, and (2) EP considers both the mean and the variance while ELO only needs the mean. Furthermore, we note that ELO achieves consistently higher accuracy than AVERAGE. It is telling that even in HUMAN-PARTNER with the 17,357 encounters, AVERAGE does not manage to outperform ELO. This demonstrates our original claim that even in large datasets AVERAGE does not capture the complex dynamics of the worker interaction and the task strain, which can hurt performance.

5.3 Effect of Worker Interaction

We next investigate the effect of worker interaction. For this purpose, we consider a modified Bayesian rating scheme, where a player's performance is only determined by itself and not the joint effort (this only affects ELO and EP). In other words, even though the team of players jointly produces the output, we assume in this experiment that each player's performance in an encounter depends only on their individual skill. In BOT-PARTNER, this was already the case since we considered teams consisting of a single worker. We now assume this to also be the case in HUMAN-PARTNER, and we investigate how the correlation coefficients for worker and task rankings between AVERAGE, ELO, and EP change. We show our

results in Table 6. We make two observations. First, the correlation of both ELO and EP compared to AVERAGE decreases substantially. This is because we assume a less accurate model that ignores worker interaction. Second, ELO and EP are still highly correlated, since they both estimate the ratings for the same (wrong) model.

Table 6: Correlation coefficient between worker rankings and task strains in HUMAN-PARTNER without interaction

	WORKER RANKINGS	TASK STRAINS
AVERAGE-ELO	44.44%	58.79%
AVERAGE-EP	30.27%	39.39%
ELO-EP	88.46%	92.73%

Finally, we study the robustness of the various schemes by looking at the effect of unbalanced task schedules. For this purpose, we consider the dataset BOT-PARTNER, but this time we assume that each encounter occurs with a fixed probability p. Trivially, the case of p=1 corresponds to the full dataset where all encounters are considered. In Figure 4, we calculate Spearman's coefficient between the ranking that each method produces when p=1 and the ranking it generates as p decreases from 0.1 to 0.9. For each value of p, we randomly sample 20 subsets of encounters, and report the average. We observe that AVERAGE has consistently the worst performance, in the sense that the ranking it produces changes more significantly as p decreases. ELO is the most robust, followed by EP. This confirms our claim that the average score is very good as long as the task schedules are balanced, whereas ELO and EP are more robust and superior for unbalanced schedules.

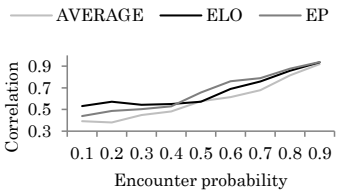

Figure 4: Spearman's correlation coefficient for worker rankings in terms of encounter probability in BOT-PARTNER.

5.4 Discussion

Our proposed experimental design based on simulated encounters has the potential to generate very large datasets from a small initial dataset that acts as a seed in cold-start situations. It is thus a cost-efficient solution, tailored for costly human studies involving large numbers of participants. Furthermore, it has the advantage that we can control how large the generated dataset will be by adjusting the encounter probability p. In principle, we can even generate a larger number of smaller datasets by doing many simulations with small values of p. A downside is that the generated dataset can contain a large number of invalid encounters. Furthermore, our scheme is not necessarily unbiased, since it is more likely to keep encounters with low-skilled workers as it takes these workers longer to match with the bot. Note that this is not a general property of our proposed scheme but related to the specifics of the ESP game where players immediately move on to the next task as soon as a match is reached.

All three methods are online and thus fast to implement in any collaborative crowd computing scenario. Relaxing the original model without considering the worker interaction leads to very inconsistent rankings and discrepancy between ELO and AVERAGE. This suggests that worker interaction is indeed an important ingredient of our model and leads to better rankings. ELO has the highest prediction accuracy of over 70% out of the three methods, followed by AVERAGE. Furthermore, ELO leads to the most consistent worker ranking even as the encounter probability decreases, followed by EP. This suggests that ELO is a very robust algorithm that generally outperforms AVERAGE. Its strengths lie in the facts that (1) it takes into account the worker dynamics and the task strains, and (2) it has a simple update rule that only relies on the mean. Compared to ELO, EP converges much faster [12]. It also leads to consistent rankings, and in some cases beats AVERAGE. EP tries to optimize over both the first two moments, i.e., the mean and the variance information. ELO, on the other hand, is based on the same model but uses a simpler update rule with only the mean, making it generally more robust when we do not simultaneously optimize over multiple encounters. The fact that our Bayesian graph model is approximate and does not capture the true dynamics may also contribute to the robustness of the simpler ELO scheme.

In general, all three methods are valuable and can convey important information about the worker ratings and task strains. Of particular interest are cases of disagreement, where the models produce very different ratings. This may indicate that low-skilled workers have produced high-quality output for a task that workers of higher rating have failed, or that a task has been surprisingly hard for high-skilled workers. The service requester can utilize this information to generate better assignments and improve the output quality. Even though AVERAGE is generally a resilient method, especially as the number of encounters grows, our empirical evaluation demonstrates that a collaborative ELO rating system can outperform it in terms of consistency, accuracy, and robustness. This implies that ELO could serve as the primary rating system.

6 CONCLUSION

Collaborative human computation and crowdsourcing are characterized by tasks of varying difficulties and involve interactions among human workers. In this work, we show how to leverage the standard rating schemes in competitive games for rating participants and tasks in collaborative crowd computing. Experimental results demonstrate that collaborative ranking using our TrueSkill-inspired rating framework can lead to better results than the traditional additive scoring scheme. In the future, we would like to explore how the specific type of interaction (e.g., weak-link, strong-link, linear) affects the rating process in our model. We will also consider the uncertainty over the output that the workers jointly produce. This is especially true for human computation games, where the game service provider relies on the player agreement to accept the output, but has no other way to know for sure whether it is correct or specific, etc. It would thus be valuable to extend our frameworks so that they can handle cases where there is additional uncertainty over the worker output.

ABSTRACT

Key to recommender systems is learning user preferences, which are expressed through various modalities. In online reviews, for instance, this manifests in numerical rating, textual content, as well as visual images. In this work, we hypothesize that modelling these modalities jointly would result in a more holistic representation of a review towards more accurate recommendations. Therefore, we propose Multimodal Review Generation (MRG), a neural approach that simultaneously models a rating prediction component and a review text generation component. We hypothesize that the shared user and item representations would augment the rating prediction with richer information from review text, while sensitizing the generated review text to sentiment features based on user and item of interest. Moreover, when review photos are available, visual features could inform the review text generation further. Comprehensive experiments on real-life datasets from several major US cities show that the proposed model outperforms comparable multimodal baselines, while an ablation analysis establishes the relative contributions of the respective components of the joint model.

1 INTRODUCTION

One classic formulation for recommender system is rating prediction [13]. Increasingly ratings are no longer the sole modality for expressing one's preference. The most common scenario now is when rating is but a component of an online review, which also contains a textual description of one's experiences with a product or a place. Figure 1 illustrates a review from Yelp.com for *Antica Ristorante*, a popular Italian restaurant in the Financial District of NYC. The writer *Adam W.* assigned it the highest rating of 5 stars, and articulated his impression through sentences stating supporting factors such as amazing and flavorful clam linguini, attentive servers, and homemade grappa. Evident from the example is how vividly the textual description embodies multi-faceted user's preferences, with the rating being a culminating assessment.

We start off with the premise that the textual content of a review would be useful to rating prediction. Upon perusing the existing literature on content-based recommender systems (see Section 2),

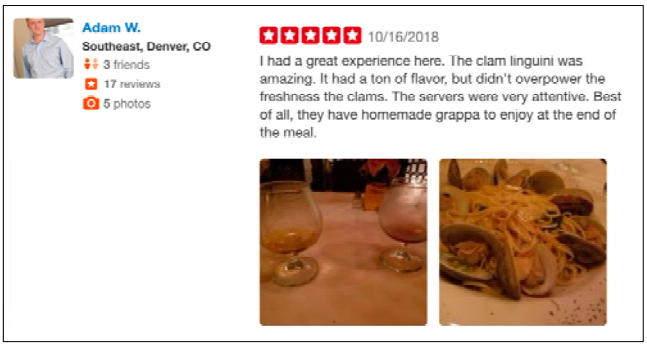

Figure 1: Example of *Yelp* review for Antica Ristorante

we observe a couple of distinctions in our intended setting here. First, when textual content was used for recommendation, in most cases it was in association with the item (e.g., product description, paper abstract), rather than with the user-item tuple (i.e., a review). Even in those cases that relied on review texts, the approach was usually to aggregate all the reviews belonging to an item into a document [19, 20]. Second, textual content was commonly seen as observations or features, rather than as a generative output.

Problem We express the problem as *multimodal review generation*. Given a user and an item, we seek to generate both the rating and the review text. Prior works tend to address one given the other. For instance, several content-based recommendations [10, 33] generate ratings based on observed text. On the other hand, product review generation [5] seeks to generate the review text based on user, item, and the observed rating. To showcase the benefits of joint modeling, we will compare to these classes of baselines. For an additional benefit, the generated text could also potentially serve as explanations [7, 37] to the rating-based recommendation.

Moreover, multimodality for a review goes beyond numerical rating and textual content. Given the proliferation of multimedia smartphones, arming virtually everyone with a camera on hand, online reviews frequently also contain photos. When such photos are available, they often provide an illustrative backdrop to the various facets mentioned in the text, as attested to by Figure 1. Hence, we hypothesize that photos could be helpful to review generation, and consider review photos as another input to the problem.

Approach We propose a model called *Multimodal Review Generation* or *MRG*, which joins rating prediction with non-linearity and review text generation with LSTM. The joint modeling implies that the users and items' representations would be sensitive to the text generation process, and the generated text would be personalized and item-sensitive. Another novel aspect to *MRG* is incorporating visual features in the text generation. The selection of words to describe an item is challenging given the large variance among items.

To supplement the sentiment features encoded in users and items' representations, we will use visual features extracted from photos to provide additional clues. Intuitively, words that could describe a photo in a review would be suitable to describe some facet of the item of interest. However, we make the deliberate design decision to use image features to help generate review text, rather than to also attempt generating the images themselves. This is because our primary intention is to model user's subjective preferences, which would be expressed much more evidently in the rating and the text.

Contributions We design the *MRG* model (see Section 3), which jointly models rating prediction and text generation at the review level by incorporating LSTM cells with a novel fusion gate as a kind of soft attention to weigh the relative contributions of sentiment features and visual features that provide context to the text generation. We also describe the learning and inference algorithms respectively. In Section 4 we conduct comprehensive experiments against baselines for both rating prediction and review generation that showcase the benefits of their joint modeling and incorporation of visual features, as well as an ablation analysis that establishes the contributions of the various components of our model.

2 RELATED WORK

In this section, we review the two groups of literature most related to our problem, namely: content-based recommendation and text generation (particularly relating to online reviews).

Content-Based Recommendation. The vast majority of recommendation works are based on modeling ratings [31], and most rely on matrix factorization [13]. These include the popular methods such as Probabilistic Matrix Factorization or PMF[22], Non-negative Matrix Factorization or NMF [15], and Singular Value Decomposition with neighborhood information or SVD++ [12], which we will use as baselines to validate the benefits of content modeling. Note that we focus on models that fit rating values, rather than pairwise rankings [8, 29] that are generally seen as a different formulation.

Later approaches seek to model textual content to supplement ratings. One direction is to apply topic modeling to item content, and relate an item's topic distribution to its latent factors for use in matrix factorization-like rating prediction. Such approaches [19, 20, 32] outperform rating-only methods. The more recent direction is to rely on neural approaches. For instance, [33] improves upon [32] by replacing the topic model with a Stacked Denoising AutoEncoder (SDAE) to learn item latent factors. ConvMF [10] learns a Convolutional Neural Network to extract latent features for an item from its text reviews. DeepCoNN [38] models user and item's review texts separately using siamese CNN and joins the two sets of features in the manner of Factorization Machine [28]. The latter three are state-of-the-art, having been compared favorably to the prior ones based on topic models, and will be used as baselines.

There are two key distinctions between ours and the approaches in this category. First, we model review-level textual content, i.e., the text is associated with the user-item tuple, rather than with the item or the user alone. Second, we seek to generate a piece of natural language text as an output, as opposed to feature vectors.

Review Text Generation. Learning to generate text is intensively investigated in natural language processing, where it can be applied to language modeling, machine translation, or speech recognition. The idea is to learn a model which can generate a sequence of text based on sequential dependencies and contexts. Long Short-Term Memory (LSTM) [9], a gated version of recurrent neural networks, is capable of capturing long-term dependencies and is demonstrably an effective approach [3, 6, 31].

The review text generation technique closest to ours is Att2Seq [5]. The work models user, item, and rating as given attributes, and learns to generate a review text through an attention mechanism. Note that we do not take the rating as a given; instead we seek to generate the rating concurrently. In Section 4, we will compare to Att2Seq as one of the review generation baselines, assessing their performance in both scenarios when the test rating is unknown (our setting) and when it is given (their original setting). Other review generation methods are not directly comparable. For instance, some expect extraneous inputs not applicable to our setting, such as generating tips based on a review [16], generating review based on pre-defined phrases [25], or considering the neighborhood reviews of a user [34]. In turn, [24] is based on pairwise ranking, which is usually seen as a different formulation from rating prediction. None makes use of visual features from images.

By incorporating visual features in the text generation, our problem is related to image captioning [35, 36]. The key distinction is our incorporation of user and item latent factors, which implies that in our case the "captioning" is effectively item-sensitive and personalized. In Section 4 we will compare to [35] as a image-based text generation representative not affected by either user or item.

Table 1: List of notations

Symbols	Description
$\mathcal{X}^r$	set of rating observations
$\mathcal{X}^s$	set of review text with images
$\mathcal{U}$	set of users
$\mathcal{I}$	set of items
$\mathcal{A}$	set of image annotations
$\mathbf{P}$	user embedding matrix
$\mathbf{Q}$	item embedding matrix
$\mathbf{E}$	word embedding matrix
$\mathbf{W}$	weight projection matrix
b	bias term
Θ	set of neural parameters

3 MULTIMODAL REVIEW GENERATION

We now describe our proposed *Multimodal Review Generation* or *MRG*, first the model architecture, then the learning and inference. Table 1 reproduces the notations for ease of reference.

Problem. The universal sets of users and items are denoted $\mathcal{U}$ and $\mathcal{I}$. We are given $\mathcal{X}^r$ and $\mathcal{X}^s$ for learning. $\mathcal{X}^r$ is the set of rating observations, whereby each observation is a triple (u, i, r) indicating that a user $u \in \mathcal{U}$ assigns to an item $i \in \mathcal{I}$ a rating score of $r \in \mathbb{R}$. In turn, $\mathcal{X}^s$ is the set of review content observations, whereby each observation is a quadruple (u, i, d, m) with d being a review text document and m is a corresponding image. We further assume that for each observation in $\mathcal{X}^r$, there is at least one corresponding observation in $\mathcal{X}^s$ for the same user and item, i.e., each rating is accompanied by at least a review text and an image.

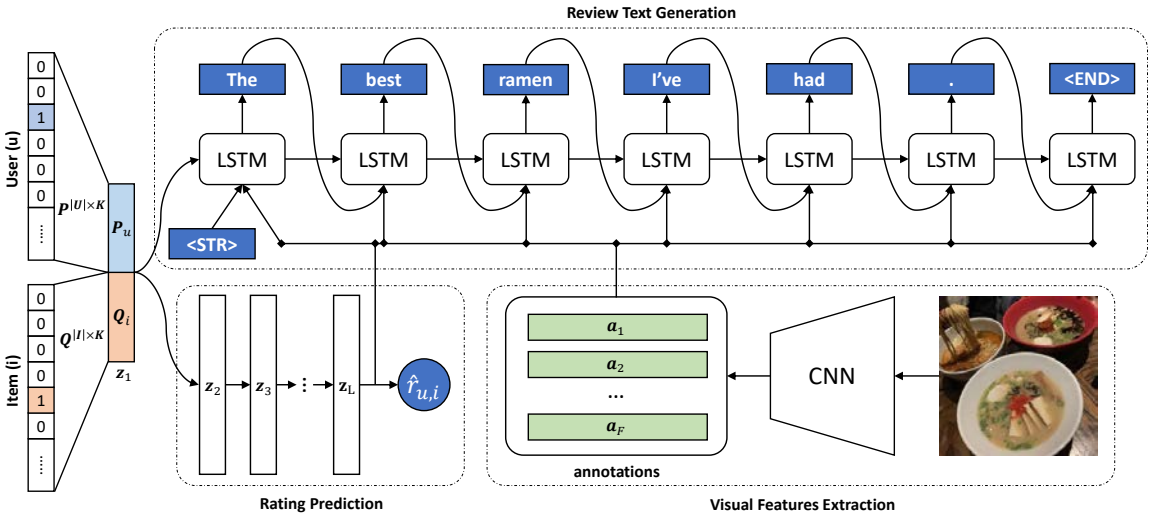

Figure 2: Overall Architecture of Multimodal Review Generation (MRG) model

The problem of multimodal review generation can thus be stated as follows. From $\mathcal{X}^r$ and $\mathcal{X}^s$, we seek to learn a model, which could output a predicted rating score $\hat{r}$ and a synthesized review document $\hat{d}$ given a user u, an item i, and an image m. The image is not a must, but could be useful. One use case is when a user is observed to have an image of an item (such as an Instagram posting), and we seek to assess the likely rating and review text. Alternatively, we could maintain a set of images reflecting different facets of an item, which could then be sampled for a given user. As we will see shortly, even when image is unavailable, the model is still capable of producing both a rating prediction and a synthesized review text.

3.1 Model Architecture

Fig. 2 shows the neural model architecture, with several components including rating prediction and review text generation, as well as visual features extraction. We describe each component in turn.

Rating Prediction with Non-Linearity. Traditionally, matrix factorization [13] models rating via a *bilinear* function, such as:

$$\hat{r}_{u,i} = \mathbf{p}_u^T \mathbf{q}_i + b_u + b_i + \mu \tag{1}$$

where $\mathbf{p}_u, \mathbf{q}_i$ are user and item latent factors, b_u, b_i are user and item biases, and μ is the global bias (average rating).

An emerging idea is to use *non-linearity* to capture the interactions between users and items. Non-linear transformations promise to learn better representations as shown for various tasks [6, 14, 21]. We propose to utilize Multilayer Perceptron or MLP as the rating prediction component. In a different formulation, MLP was combined with matrix factorization to learn pairwise ranking scores [8].

User u and item i are encoded as one-hot vectors. With the help of user embedding matrix $\mathbf{P}^{|\mathcal{U}|xK}$ and item embedding matrix $\mathbf{Q}^{|\mathcal{I}|xK}$, we project the one-hot vectors onto the user embedding vector $\mathbf{P}_u$ and item embedding vector $\mathbf{Q}_i$. These are concatenated and projected through a number L of neural layers followed by non-linear transformations, as shown below. The model outputs a rating $\hat{r}_{u,i}$ based on the representation learned from the last layer.

$$\mathbf{z}_1 = \begin{pmatrix} \mathbf{P}_u \\ \mathbf{Q}_i \end{pmatrix} \tag{2}$$

$$\mathbf{z}_2 = \phi(\mathbf{W}_2 \mathbf{z}_1 + b_2) \tag{3}$$

$$\ldots \tag{4}$$

$$\mathbf{z}_L = \phi(\mathbf{W}_L \mathbf{z}_{L-1} + b_L) \tag{5}$$

$$\hat{r}_{u,i} = \mathbf{W}_r \mathbf{z}_L + b_r \tag{6}$$

Above, $\mathbf{W}_l$ is learned projection matrix, b_l is bias of the neural layer l. In turn, ϕ is hyperbolic tangent ($tanh$) function, and $\mathbf{W}_r, b_r$ are projection matrix and bias of the output layer.

Review Text Generation with Sensitivity to User and Item. The text generation component (upper part of Fig. 2) is built on LSTM. First, we describe how we generate text as a language model with only textual contexts. Then, we introduce the notion of user and item with sentiment information from the rating prediction component. Later on, we extend it further with visual information.

Let $d = \{w_1, \ldots, w_T\}$ be a review text document, where w_t is the word at position t. We encode each word w_t as an one-hot vector $\mathbf{y}_t \in \mathbb{R}^V$, where V is the vocabulary size. Thus, document d becomes a sequence of one-hot vectors $\mathbf{y} = \{\mathbf{y}_1, \ldots, \mathbf{y}_T\}$. We implement our LSTM (see Fig. 3) according to following equations:

$$\mathbf{x}_t = \mathbf{E}\mathbf{y}_{t-1} \tag{7}$$

$$\mathbf{f}_t = \sigma(\mathbf{W}_{fx}\mathbf{x}_t + \mathbf{W}_{fh}\mathbf{h}_{t-1} + b_f) \tag{8}$$

$$\mathbf{i}_t = \sigma(\mathbf{W}_{ix}\mathbf{x}_t + \mathbf{W}_{ih}\mathbf{h}_{t-1} + b_i) \tag{9}$$

$$\mathbf{o}_t = \sigma(\mathbf{W}_{ox}\mathbf{x}_t + \mathbf{W}_{oh}\mathbf{h}_{t-1} + b_o) \tag{10}$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \phi(\mathbf{W}_{cx}\mathbf{x}_t + \mathbf{W}_{ch}\mathbf{h}_{t-1} + b_c) \tag{11}$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \phi(\mathbf{c}_t) \tag{12}$$

where $\mathbf{E} \in \mathbb{R}^{mxV}$ is the learned word embedding matrix initialized randomly or from pre-trained word embeddings [21, 27], $\mathbf{W}_*, b_*$ are learned projection matrices and biases initialized randomly, and σ, ϕ are *sigmoid* and *tanh* activation functions respectively.

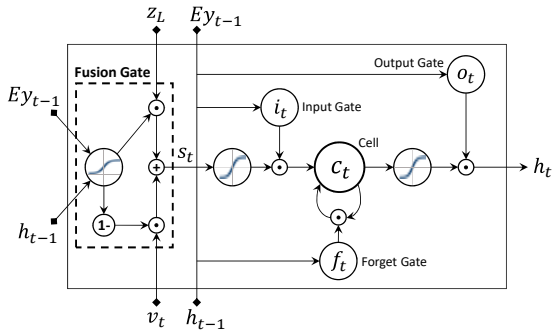

Figure 3: LSTM Cell with Fusion Gate

Because we seek to generate a document that would be relevant to the item at hand yet sensitive to user preferences, we initialize the LSTM with user embedding $\mathbf{P}_u$ and item embedding $\mathbf{Q}_i$.

$$\mathbf{c}_0 = \phi(\mathbf{W}_{c0}\mathbf{z}_1 + b_{c0}) \tag{13}$$

$$\mathbf{h}_0 = \phi(\mathbf{W}_{h0}\mathbf{z}_1 + b_{h0}) \tag{14}$$

Above, $\mathbf{z}_1$ is the concatenated vector of $\mathbf{P}_u$ and $\mathbf{Q}_i$ (Eq. 2). $\mathbf{W}_{c0}, \mathbf{W}_{h0} \in \mathbb{R}^{n\times 2K}$ and b_{c0}, b_{h0} are learned projection matrices and biases. n is the number of hidden dimensions of the LSTM state.

By sharing the user and item embeddings between the rating prediction and review text generation components, we seek shared representations that will be beneficial to both components [2, 23]. Moreover, in addition to sequential dependencies, we supply the LSTM with sentiment information. In other words, at each time step t, in addition to the generated word from $t-1$, we use $\mathbf{z}_L$ (Eq. 5) as another input source of the LSTM by simply concatenating it with previous generated word embedding:

$$\mathbf{x}_t = \begin{pmatrix} \mathbf{E}\mathbf{y}_{t-1} \\ \mathbf{z}_L \end{pmatrix} \tag{15}$$

The intuition to use $\mathbf{z}_L$ is because the final representation of the rating prediction component is hypothesized to be the most representative features of the sentiment of the review.

Review Text Generation with Visual Features. Based on the previously described components, we would already meet the dual objectives of rating prediction and review text generation. In some cases, additional information in the form of photo(s) may be available. For instance, a user may not have reviewed an item, but she may have an Instagram posting about the item. In such cases, we hypothesize that visual features would provide additional clues that could improve the review text generation further.

To extract feature vectors, also referred to as *annotations*, from images, we use convolutional neural network or CNN. For each image m, we get a set of annotation vectors $\mathcal{A} = \{\mathbf{a}_1, \ldots, \mathbf{a}_F\}, a_j \in \mathbb{R}^D$, where F is the number of annotations.

$$\mathcal{A} = \text{CNN}(m) \tag{16}$$

Our *MRG* architecture employs 19-layer Oxford VGGNet [30] as the visual feature extractor. We use the pre-trained model of VGGNet on ImageNet [4] without finetuning, and treat the $14 \times 14 \times 512$ feature map output from the fifth convolutional layer (conv5_3) as our image annotations. In consequence, each image will be transformed into 196 annotation vectors $\mathbf{a}_j$ with $D = 512$.

At each time step t, we want to supply our LSTM a context vector as a visual clue for generating the next word which is relevant to the image. Each annotation $\mathbf{a}_j$ is a compression of a small region of the image. Not all annotations are contributing visual information equally. Therefore, we apply soft attention mechanism [3, 35] to allow the model to weigh on the more relevant annotations. Thus, the visual context vector $\mathbf{v}_t$ is obtained by the following equations:

$$\mathbf{e}_{tj} = \phi(\mathbf{W}_{ea}\mathbf{a}_j + \mathbf{W}_{eh}\mathbf{h}_{t-1} + b_e) \tag{17}$$

$$\alpha_{tj} = \frac{\exp(\mathbf{W}_\alpha \mathbf{e}_{tj})}{\sum_{k=1}^{F}\exp(\mathbf{W}_\alpha \mathbf{e}_{tk})} \tag{18}$$

$$\mathbf{v}_t = \sum_{j=1}^{F} \alpha_{tj}\mathbf{a}_j \tag{19}$$

where $\mathbf{W}_{ea} \in \mathbb{R}^{D\times D}, \mathbf{W}_{eh} \in \mathbb{R}^{D\times n}, \mathbf{W}_\alpha \in \mathbb{R}^{1\times D}$, and b_e are learned projection matrices and bias randomly initialized.

Fusion Gate as Soft Attention between Sentiment and Visual Information. In addition to $\mathbf{z}_L$, the visual context vector $\mathbf{v}_t$ is treated as another source of input for our LSTM. Although we hypothesize that each generated word is either based on sentiment or visual information, we relax that constraint by allowing the model to make soft decisions. We introduce a fusion gate (Fig. 3), which can be seen as an attention mechanism for the LSTM. The fusion gate will learn to give the importance weights for sentiment features $\mathbf{z}_L$ and visual features $\mathbf{v}_t$ and combine them into a final context vector $\mathbf{s}_t$. More information from visual features means less information from sentiment features going through the gate.

$$\gamma_t = \sigma(\mathbf{W}_{\gamma y}\mathbf{E}\mathbf{y}_{t-1} + \mathbf{W}_{\gamma h}\mathbf{h}_{t-1} + b_\gamma) \tag{20}$$

$$\mathbf{s}_t = \gamma_t \mathbf{z}_L + (1-\gamma_t)\mathbf{v}_t \tag{21}$$

$$\mathbf{x}_t = \begin{pmatrix} \mathbf{E}\mathbf{y}_{t-1} \\ \mathbf{s}_t \end{pmatrix} \tag{22}$$

$\mathbf{W}_{\gamma y} \in \mathbb{R}^{1\times m}, \mathbf{W}_{\gamma h} \in \mathbb{R}^{1\times n}$, and b_γ are learned projection matrices and bias randomly initialized. Constructing the fusion gate requires the number of dimensions of $\mathbf{z}_L$ and $\mathbf{v}_t$ to be equal. Thus, we make sure the rating prediction component outputs $\mathbf{z}_L \in \mathbb{R}^D$.

The output probabilities are computed based on previous word, the LSTM state, and the context vector from fusion gate:

$$\mathbf{g}_t = \mathbf{W}_g\phi(\mathbf{W}_{gy}\mathbf{E}\mathbf{y}_{t-1} + \mathbf{W}_{gh}\mathbf{h}_t + \mathbf{W}_{gs}\mathbf{s}_t) \tag{23}$$

$$p(\mathbf{y}_{tj}|\mathbf{x}_t) = \frac{\exp(\mathbf{g}_{tj})}{\sum_{k=1}^{V}\exp(\mathbf{g}_{tk})} \tag{24}$$

$\mathbf{W}_g \in \mathbb{R}^{V\times m}, \mathbf{W}_{gy} \in \mathbb{R}^{m\times m}, \mathbf{W}_{gh} \in \mathbb{R}^{m\times n}, \mathbf{W}_{gs} \in \mathbb{R}^{m\times D}$ are learned projection matrices randomly initialized. The word with the highest output probability will be chosen as the generated one.

$$\mathbf{y}_t^* = \underset{\mathbf{y}_j, j\in V}{\text{argmax}}\, p(\mathbf{y}_{tj}|\mathbf{x}_t) \tag{25}$$

Discussion. The relative generality of *MRG* can be seen from how the full-fledged model could be reduced into simplified models that work with less information. As earlier stated, the model is still capable of generating rating prediction and synthesizing review text without visual features. Without rating prediction, the model is effectively solving a personalized image captioning problem where the generated text will describe the image based on the user's experience of the item. If both visual features and rating prediction

Algorithm 1 Parameter Learning with Stochastic Gradient Descent

      $\mathbf{Q}_k = \mathbf{Q}_k - \eta \cdot \frac{\partial}{\partial \mathbf{Q}_k} \mathcal{L}^s(j, k, d, m)$
      $\Theta_s = \Theta_s - \eta \cdot \frac{\partial}{\partial \Theta_s} \mathcal{L}^s(j, k, d, m)$
      $\mathbf{E}_{w \in d} = \mathbf{E}_{w \in d} - \eta \cdot \frac{\partial}{\partial \mathbf{E}_{w \in d}} \mathcal{L}^s(j, k, d, m)$
    end for
  end for
end while
return $\{\mathbf{P}, \mathbf{Q}, \mathbf{E}, \Theta_r, \Theta_s\}$

are removed, the model is solving the problem of personalized review text generation without any further information. If the goal is solely to predict ratings, both visual features and review text can be removed, leaving the model with only rating prediction. In Section 4, we will investigate the respective contributions of various components towards the final model as well as the performance of different architectural variants in an ablation analysis.

3.2 Model Learning and Inference

Learning. Our model consists of two supervised learnable components. To learn the parameters based on rating information, the model minimizes the regularized square error on the set $\mathcal{X}^r$:

$$\mathcal{L}^r = \frac{1}{2} \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} \mathbb{1}_{u,i} (r_{u,i} - \hat{r}_{u,i})^2 + \frac{\lambda_{wr}}{2} \sum_{\theta \in \Theta_r} \|\theta\|_2^2 \|\theta\|_2^2 + \frac{\lambda_{ur}}{2} \sum_{u \in \mathcal{U}} \|\mathbf{P}_u\|_F^2 + \frac{\lambda_{ir}}{2} \sum_{i \in \mathcal{I}} \|\mathbf{Q}_i\|_F^2$$

$\mathbb{1}_{u,i}$ is the indicator function which is equal to 1 if user u rated item i and equal to 0 otherwise, $\|.\|$ denotes the Frobenius norm of matrix, Θ_r is the set of parameters of rating prediction component, and $\lambda_{wr}, \lambda_{ur}, \lambda_{ir}$ are hyper-paramenters for regularization.

To learn the review text generator, we update the parameters by minimizing the regularized negative log-likehood on the set $\mathcal{X}^s$:

$$\mathcal{L}^s = \sum_{(u,i,d,m) \in \mathcal{X}^s} \sum_{w \in d} -\log p(\mathbf{y}_w | \mathbf{x}) + \frac{\lambda_{ws}}{2} \sum_{\theta \in \Theta_s} \|\theta\|_2^2 + \frac{\lambda_{us}}{2} \sum_{u \in \mathcal{U}} \|\mathbf{P}_u\|_F^2 + \frac{\lambda_{is}}{2} \sum_{i \in \mathcal{I}} \|\mathbf{Q}_i\|_F^2$$

where Θ_s is the set of parameters of rating prediction component, and $\lambda_{ws}, \lambda_{us}, \lambda_{is}$ are hyper-paramenters for regularization.

Algorithm 2 Multimodal Review Generation with Greedy Search

Input: user (u), item (i), image (m)
Output: estimated rating ($\hat{r}$), generated review text ($\hat{d}$)

initialization
  $\mathbf{P}_u, \mathbf{Q}_i \leftarrow$ user and item embeddings
  $t = 0$, $\mathbf{T} \leftarrow$ maximum review length
  $\Pi = [] \leftarrow$ generated word array
  $w_0 =$ "<start>", $\mathbf{y}_0 = \mathbf{y}_{w_0} \leftarrow$ starting word
  $\mathbf{c}_0, \mathbf{h}_0 \leftarrow$ LSTM initialized states from $[\mathbf{P}_u; \mathbf{Q}_i]$
  $\mathcal{A}_m = \text{CNN}(m) \leftarrow$ generated annotations from image m
$\mathbf{z}_L \leftarrow$ generated sentiment features from $[\mathbf{P}_u; \mathbf{Q}_i]$
$\hat{r} = \mathbf{W}_r \mathbf{z}_L + b_r$
while $t < T$ **do**
  $t = t + 1$
  $\mathbf{E}\mathbf{y}_{t-1} \leftarrow$ input word embedding
  $\mathbf{v}_t \leftarrow$ generated visual context from $\mathcal{A}_m$
  $\mathbf{s}_t \leftarrow$ generated fusion context from $\mathbf{z}_L$ and $\mathbf{v}_t$
  $\mathbf{x}_t = [\mathbf{E}\mathbf{y}_{t-1}; \mathbf{s}_t] \leftarrow$ input of the LSTM
  $\mathbf{y}_t = \underset{\mathbf{y}_j, j \in V}{\text{argmax}}\, p(\mathbf{y}_{tj} | \mathbf{x}_t) \leftarrow$ greedy selection
  $w_t = \text{map_to_word}(\mathbf{y}_t)$
  if $w_t ==$ "<end>" **then**
    break
  end if
  Π.append(w_t)
end while
$\hat{d} = \text{join}(\Pi)$
return $\{\hat{r}, \hat{d}\}$

The final objective of the model is the weighted combination of $\mathcal{L}^r$ and $\mathcal{L}^s$:

$$\mathcal{J} = \underset{\mathbf{P}, \mathbf{Q}, \mathbf{E}, \Theta_r, \Theta_s}{\text{minimize}} \Big(\frac{\lambda_r}{2} \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} \mathbb{1}_{u,i} (r_{u,i} - \hat{r}_{u,i})^2 + \lambda_s \sum_{(u,i,d,m) \in \mathcal{X}^s} \sum_{w \in d} -\log p(\mathbf{y}_w | \mathbf{x}) + \frac{\lambda_{wr}}{2} \sum_{\theta \in \Theta_r} \|\theta\|_2^2 + \frac{\lambda_{ws}}{2} \sum_{\theta \in \Theta_s} \|\theta\|_2^2 + \frac{\lambda_u}{2} \sum_{u \in \mathcal{U}} \|\mathbf{P}_u\|_F^2 + \frac{\lambda_i}{2} \sum_{i \in \mathcal{I}} \|\mathbf{Q}_i\|_F^2 \Big)$$

λ_r, λ_s are hyper-parameters to balance the importance between two components, $\lambda_{wr}, \lambda_{ws}, \lambda_u, \lambda_i$ are hyper-parameters for regularization of Θ_r, Θ_s, user embeddings, item embeddings respectively.

We derive a learning algorithm based on stochastic gradient descent using backpropagation (Alg. 1). Each triple (u, i, r) in $\mathcal{X}^r$ may be associated with quadruples (u, i, d, m) in $\mathcal{X}^s$. For each observation in $\mathcal{X}^r$, we update user, item embeddings and parameters in Θ_r by minimizing $\mathcal{L}^r$. With each $(u, i, r) \in \mathcal{X}^r$, we find corresponding $(u, i, d, m) \in \mathcal{X}^s$, and update user, item embeddings, parameters in Θ_s, word embeddings by minimizing $\mathcal{L}^s$. One might argue that the model can be updated based on observations from $\mathcal{X}^s$ before $\mathcal{X}^r$. We update rating prediction first because review text generation requires features from the rating, supplying the LSTM with more accurate sentiment signals. We can speed up the training with mini-batch gradient descent yielding a faster rate of convergence.

Table 2: Data Statistics

Data	#users	#items	#ratings	#docs	#images
CH	2,908	2,725	19,453	82,283	38,978
LA	36,918	23,601	355,553	1,539,355	680,892
NY	21,474	15,160	199,723	818,682	382,368
SF	7,999	3,375	65,228	320,165	139,014

Inference. To generate a review given a user u, an item i and an image m, we derive an inference algorithm for our *MRG* model (see Alg. 2). The rating $\hat{r}_{u,i}$ is first estimated using rating prediction component that also outputs the sentiment features $\mathbf{z}_L$. The review text generation is based on greedy strategy, where at each time step t, the word with the highest probability is chosen for the review.

4 EXPERIMENTS

Our experimental objective is to investigate the following research questions with respect to the proposed model *MRG*.

- **RQ#1:** Does factoring content via the review generation task improve the performance of *MRG* in rating prediction compared to rating-only matrix factorization approaches?
- **RQ#2:** Does coupling rating prediction and text generation at the review level help *MRG* to outperform comparable content-based recommender systems in rating prediction?
- **RQ#3:** Does factoring sentiment and visual features help *MRG* to generate review texts closer to the ground truth?
- **RQ#4:** How do the different components of *MRG* contribute to its performance? How do different architecture variants perform in rating prediction and review text generation?

4.1 Experimental Setup

Datasets. We use datasets of online reviews crawled from *Yelp* covering 4 US cities, namely: Chicago (CH), Los Angeles (LA), New York (NY), and San Francisco (SF). Table 2 shows some statistics about these datasets. Within each online review, there is a rating, a review text, and one or more images taken by the user. The set $\mathcal{X}^r$ consists of all rating observations. The set $\mathcal{X}^s$ is constructed as follows. First, we split the review text into shorter passages; in this case, each sentence is considered a review document d. A review image m could be paired with multiple documents. To identify the best-matching documents to an image, we rank sentences within the same review based on the cosine similarity of their TF-IDF scores to that of the user-provided image description, and consider up to 5 highest-ranked documents above a threshold (0.1) to be relevant. These would then form the (u, i, d, m) quadruples in $\mathcal{X}^s$.

Task #1: Rating Prediction. One evaluation task is rating prediction. Since *Yelp* uses rating scores $r_{u,i}$ from 1 to 5, our model learns to estimate ratings within that range. We rely on two standard metrics for rating prediction, namely: Mean Absolute Error (*MAE*) and Root Mean Square Error (*RMSE*) as shown below.

$$MAE = \frac{1}{N} \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} \mathbb{1}_{u,i} |r_{u,i} - \hat{r}_{u,i}|$$

$$RMSE = \sqrt{\frac{1}{N} \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} \mathbb{1}_{u,i} (r_{u,i} - \hat{r}_{u,i})^2}$$

Table 3: Hyper-parameter settings

Method	Hyper-parameters
PMF	latent factors = 10, $\lambda_U = \lambda_V = 0.1$
NMF	latent factors = 30
SVD++	latent factors = 10, $\lambda = 0.01$
CDL	$K = 50, \lambda_v = 10, \lambda_n = 1000, \lambda_u = \lambda_w = 0.1$
ConvMF	$k = 50, p = 200, \lambda_u = 1, \lambda_v = 100$
DeepCoNN	$\lvert x_u \rvert = \lvert y_i \rvert = 50, c = 200, t = 3$
Att2Seq	$m = 200, r = 200, n = 256, L = 2$
SAT	$m = 200, n = 256, \lambda = 1$
MRG	$K = 200, m = 200, n = 256, L = 2, \lambda_r = \lambda_s = 1.0, \lambda_{wr} = \lambda_{ws} = \lambda_u = \lambda_i = 0.0001$

$\mathbb{1}_{u,i}$ is the indicator function which is equal to 1 if user u rated item i in the testing set and equal to 0 otherwise, N indicates the total number of rating observations in the testing set.

For RQ#1 to validate the use of content, we compare *MRG* with the following rating-based matrix factorization methods.

- **PMF**: Probabilistic Matrix Factorization [22] models matrix factorization under probabilistic framework with the assumptions of Gaussian distribution for rating values.
- **NMF**: Non-negative Matrix Factorization [15] ensures that the factorized user and item matrices are non-negative.
- **SVD++**: Singular Value Decomposition [12] learns from ratings as well as considers neighborhood information.

For RQ#2 to validate the modeling of content at review level, we compare *MRG* with the following content-based recommendation methods that incorporate textual content at the item level.

- **CDL**: Collaborative Deep Learning [33] uses Stacked Denoising AutoEncoder (SDAE) to learn item features.
- **ConvMF**: Convolutional Matrix Factorization [10] replaces the SDAE with a convolutional neural network (CNN).
- **DeepCoNN**: [38] models both user and item features from aggregated review texts using siamese CNN.

Task #2: Review Text Generation. The other evaluation task is generating review text. BLEU [26] is a well-known metric for evaluating the quality of generated text, which has been widely used for machine translation and image captioning. We use smoothed BLEU [18] and report the results of BLEU scores from 1 to 4. Another metric is ROUGE [17] which has been extensively used for text summarization. We report the F-measure, which is the geometric mean of the precision and recall of ROUGE-1 (covering 1-grams) and ROUGE-L (covering the longest subsequences) respectively.

A review may be associated with multiple photos. We therefore evaluate the generated text under two scenarios: photo level and rating level. Photo level means the generated text for each photo is evaluated individually, and we report the average results over all the photos. Rating level will first aggregate (i.e., average) the results associated with all the photos of the same review, and then we report the average results across all the ratings. For the latter scenario, the ground-truth references corresponding to the photos of the same rating are merged. The purpose is to make the comparison fair for the baselines not using visual information.

Table 4: Review text generation performance evaluated @ photo level (*higher is better*)

	ROUGE-L	16.76	16.85	16.62	**18.55**

For RQ#3, to validate review text generation, we compare with two text generation methods constructing three baselines.

- **Att2Seq**: Attribute-to-Sequence [5] treats user, item, and rating as three attributes and generates review text with the attention-based multilayer LSTMs. We compare with two versions of Att2Seq which are: without observing rating (*-Rating*) that is similar to our setting and with observed rating (*+Rating*) that is the authors' original setting (which confers it an advantage since the ground-truth rating is given).
- **SAT**: Show, Attend, and Tell [35] is the state-of-the-art method for image captioning, which exploits visual features using attention mechanism and generates the captions using LSTM.

Experimental Settings. For each dataset in Table 2, we reserve 10% of the data for model validation. The remaining 90% is split into training and testing sets. For evaluating rating prediction, we report results for different training percentages (80%, 60%, 40%, and 20%). This is to examine the effects of sparsity on rating prediction, which is a crucial issue for recommender systems. For evaluating review text generation, we use the same split, yet we report the results for 80% training and 20% testing due to space limitations.

We tune all the comparative models for their respective best performance. Table 3 indicates the discovered hyper-parameter settings used for different methods. For PMF, NMF, and SVD++, we use grid search to find the number of latent factors from $\{10, \ldots, 100\}$ where we end up with 10 for PMF, 30 for NMF, and 10 for SVD++. The regularization hyper-parameters are searched from $\{0.001, 0.01, 0.1, 1.0\}$.

For CDL, ConvMF, and DeepCoNN, the number of item features is grid-searched from $\{10, 50, 100, 200\}$ and 50 gives the best performance and fair comparison between three methods, whereas $\{100, 200\}$ cause overfitting. Regularization hyper-parameters of the models are tuned using the validation set.

For LSTM-based models Att2Seq, SAT, and *MRG*, we use the same number of dimensions of the LSTM cells (256). SAT and *MRG* use one-layer LSTM whereas Att2Seq uses two layers of LSTMs as we respect the original design of the authors. In practice, we observe negligible improvements of using more than one layer for *MRG* so we keep using one layer for the gain in efficiency. Att2Seq and *MRG* use the same number of dimensions for user and item embeddings as well as rating embeddings for the former. Other hyper-parameters are tuned using the validation set. In testing, the maximum length of generated text is set at $T = 20$ for all the methods. *MRG* [1] is implemented using Tensorflow [1] and trained with batch size of 64. We update the parameters using Adam [11] rule with learning rate $\eta = 0.0003$, $\beta_1 = 0.9$, $\beta_2 = 0.99$, and $\epsilon = 10^{-8}$.

The vocabulary is built from words appearing at least 3 times in training and validation sets. Infrequent words are replaced with special <UNK> token. All models using word embeddings are initialized from Glove [27] pre-trained word embeddings of 200 dimensions.

[1] https://code.preferred.ai/mrg

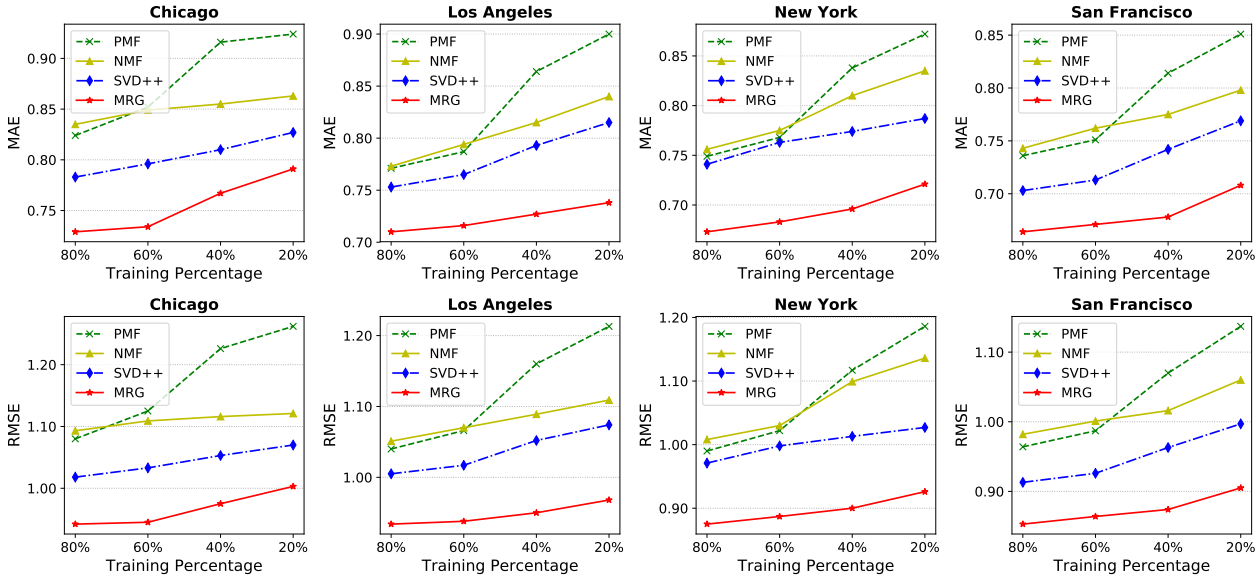

Figure 4: Rating prediction comparision with content-based approaches (*lower is better*) (The results are statistically significant with $p < 0.01$ based on the paired sample t-test)

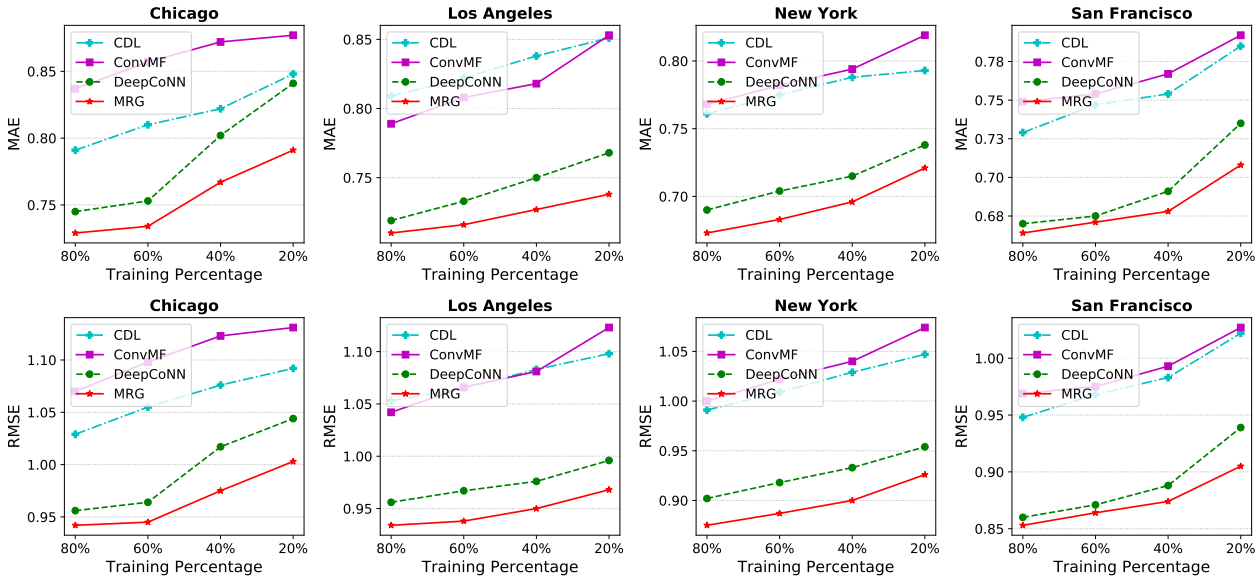

Figure 5: Rating prediction comparision with content-based approaches (*lower is better*) (The results are statistically significant with $p < 0.01$ based on the paired sample t-test)

4.2 Comparison to Baselines (RQ#1 to RQ#3)

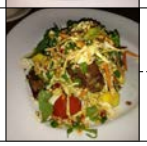
We now compare the relative performance of *MRG* with respect to the baselines, corresponding to the first three research questions.

RQ#1. First, we consider the effects of using content for rating prediction. Figure 4 shows the performance of *MRG* in rating prediction compared to matrix factorization approaches as we vary the degree of sparsity. Lower MAE or RMSE implies higher accuracy. Expectedly, with less training data, the performance generally worsens because greater sparsity may cause overfitting.

In relative terms, the clear consensus across four datasets and two metrics is that *MRG* outperforms the baselines. This validates the advantage of modeling content in addition to ratings.

Among the three baselines, SVD++ with the advantage of modeling neighborhood information tends to perform better than PMF and NMF. In turn, PMF performs slightly better than NMF with 80% data in training, but deteriorates quickly with more sparsity.

RQ#2. We now compare *MRG* with content-based recommendation methods, namely: CDL, ConvMF, and DeepCoNN. Figure 5 illustrates the performance of these models. Here, it is also evident that *MRG* outperforms the baselines, which we attribute to its modeling content at the review level. In contrast, CDL and ConvMF that model content at item level (aggregating the reviews of an item into one document) tend to perform similarly across the datasets, with the exception of Chicago where CDL seems to have an edge. In turn, DeepCoNN performs better than both CDL and ConvMF, because DeepCoNN exploits review texts for both item and user.



RQ#3. Table 4 and Table 5 show the results of review text generation at photo level and rating level respectively with 80% training. The baselines are text generation methods Att2Seq that relies on user, item, rating, and SAT that relies on image. For all the datasets, *MRG* consistently has higher BLEU and ROUGE scores than the baselines, indicating that it synthesizes review texts that are closer to the ground-truth references. This helps to validate the joint modeling of rating prediction and review text generation.

Examining the baselines, we see that for Chicago, Los Angeles, and San Francisco, Att2Seq with rating (*+Rating*) performs slightly better than without rating (*-Rating*). That indicates that sentiment information encoded in the rating does contribute to review text generation. In some cases, SAT that uses image information is slightly better than Att2Seq (no image). However, this is an imperfect comparison as Att2Seq factors in user and item, whereas SAT does not. For a clearer sense, we conduct an ablation analysis.

4.3 Ablation Analysis (RQ#4)

To investigate the respective contribution of our architecture components to the overall performance of *MRG*, we conduct an ablation analysis. Table 6 shows the rating prediction performance of our model when we systematically remove different components as discussed at the end of Section 3.1. The ticks indicate which information is included. The model with rating prediction alone (*User + Item*) is the worst, performing at similar levels as the matrix factorization baselines. The review text generation component (*Text*) sharply boosts the results because of the strongly evident preference information from text. When the visual features (*Photo*) are introduced, the sentiment features are aligned more accurately with the sentiment words during the text generation process, which in turn benefits the learned representations of the rating prediction. The improvements are even clearer as the data becomes sparser.

Table 7 and Table 8 show the review text generation quality at the photo level and the rating level respectively. The model with only (*User + Item*) performs the worst, as the generated text becomes generic because of the loss of the guiding information during generation process. Adding either the sentiment signal (*Rating*) or the visual signal (*Photo*) individually improves the results, indicating that these components are useful. The gain of adding *Rating* is relatively higher than adding *Photo*. The final model that combines both signals consistently outperforms the rest, demonstrating the utility of joining these components in the overall architecture. Due to space limitation, we omit BLEU-2 and BLEU-3 measurements as both of them show the same trend as discussed.

		3.0	the boston clam chowder was pretty salty and i 've had lots of clam chowder before .

(b) Case Study #2: An item (Tadich Grill) is reviewed by two users with different sentiments.

	Photo	Rating	Review
Philz Coffee		**4.6**	**i 've had a few times for the best breakfast sandwich .**
		4.0	the avocado toast was surprisingly good .
A16		**4.2**	**i was n't sure to try the pizza .**
		3.0	i think i might want to try their other pizzas which might be better tasting than their funghi .

(c) Case Study #3: A user (Rodney "Hungry Trikker" H.) reviews two different items.

Figure 6: Multimodal review generation. The first line next to each photo (bold) is generated rating & text, and the second line is the ground truth. Photos are best seen in color.

4.4 Case Studies

To gain an intuitive sense of the workings of the *MRG* model, we illustrate several examples of the rating prediction as well as the synthesized text generated by *MRG*. The first case study in Fig. 6a examines the text generated for two photos by the same user for an item. The predicted rating (bold) is close to the ground-truth and is the same for both photos since it is for the same item. The predicted texts (bold) also have some similarity to the ground-truth. Interestingly, the texts corresponding to the photos are different

Table 6: Ablation analysis: rating prediction performance (*lower is better*)
(The results are statistically significant with $p < 0.01$ based on the paired sample t-test)

in their objects ("steak" vs. "beef") rather than in their sentiment, signalling the utility of images in differentiating content in the text generation. The second case study in Fig. 6b examines two users with different sentiments for an item, as reflected by their ratings. Here, both photos depict clam chowder, but the generated texts are different: "good" for the more positive user, and "salty" for the more negative user. Finally, the third case study in Fig. 6c depicts how the same user may review two items. In one case, the object of interest is a toast or sandwich. In the other, it is pizza. These are examples of how rating prediction interacts with review text generation sharing some sentiment signals, and how the visual features help to align with aspect words allowing the sentiment features to align with the sentiment words.

5 CONCLUSION

We propose *MRG*, a neural model for multimodal review generation that joins a rating prediction component and a review text generation component informed by visual features. Through comprehensive experiments and ablation analysis, we establish its utility for recommendation tasks, outperforming both content-based recommender systems and review text generation baselines. We attribute the outperformance to a more holistic representation of various signals within a review, yielding more accurate recommendations.

Revisiting Wedge Sampling for Triangle Counting

ABSTRACT

Triangle counts of massive graphs can provide important information regarding the structure of the networks these graphs model. Exact triangle counting can be expensive and thus researchers have proposed a number of approximation approaches. The state-of-the-art triangle count approximation techniques depend on wedge (two-path) sampling. In this paper we offer a mechanism to significantly improve wedge sampling for triangle counting. We shrink the sampling space by eliminating wedges that are less likely to participate in triangles. Experiments over large-scale real-world graphs show that proposed mechanism provides five- to a few hundred-folds sampling space reduction. When compared against the state-of-the-art approaches, it requires as low as ∼100× less sampling to provide the same accuracy, or makes as low as ∼8× less error when used with the same sampling ratio.

1 INTRODUCTION

The number of triangles in a graph is an important metric that represents the transitivity of the relations and the degree of clustering of the entities modeled by the graph. This metric has use in applications such as social network analysis [40], gene expression microarray data analysis [18], or text summarization [2].

Currently, practically used exact triangle counting and listing algorithms have a complexity of $O(m^{3/2})$ [30], where m is the number of edges. However, target graphs of interest for triangle counting can have billions of edges and hundreds of billions of triangles, which render exact algorithms costly. Furthermore, for many settings the exact triangle count is not necessary and approximations are sufficient as the graphs are dynamic. Thus, a number of approximation solutions for estimating the triangle count have been proposed [6, 7, 9, 10, 14, 16, 21, 22, 24, 28, 31–33, 36–38].

The state-of-the-art approximation approaches utilize wedge sampling. Wedge-sampling-based solutions have shown to be fast and accurate in estimating triadic measures [32, 38]. These approaches sample wedges from a graph, check whether sampled wedges are "closed" (form a triangle in the original graph) or not, and based on the ratio of closed and open wedges, estimate the triangle count in the original graph. Unfortunately, in large-scale power-law graphs there are too many wedges compared to the number of triangles. The number of wedges in such graphs can easily be in the order of trillions and the chances of finding a "closed" wedge can be as low as one in ten thousand. Estimating the number of triangles available with confidence while sampling from such a large wedge-space requires a significant number of samplings.

In this paper we revisit the wedge-sampling approaches for estimating triangle counts in large graphs. We first show that during sampling it is not necessary to consider all of the wedges in a graph and it is possible to reduce the sampling space significantly. In a preprocessing step, we first define a partial ordering of vertices, and then use that ordering to categorize wedges into three groups. We show that sampling from any one of these groups is sufficient for triangle counting. We use this finding to restrict the sampling-space for triangle counting, which leads to more accurate estimations with far fewer sampled wedges when compared to existing aproaches.

We theoretically prove that our mechanism guarantees at least a three-fold reduction in the sampling space, thus guaranteeing an accuracy no worse than standard wedge sampling, and we show via experimental analysis that we achieve one to two orders of magnitude reduction in practice for real-world graphs. Note that such reduction can pave the way for more accurate analysis and estimations over larger graphs (e.g. in some cases, the number of candidate wedges for sampling decrease so much that running exact algorithms become feasible).

Our contributions can be listed as follows:

- We show that any total order on the vertices of a graph can be used to divide the wedges in a graph into three categories, all of which can be separately and accurately used for triangle count estimation.
- We provide a greedy total ordering heuristic that divides the wedges in a graph such that the number of wedges in a pre-specified category is guaranteed to be at most one third of the total number of wedges.
- We prove that the number of wedges sampled using our greedy heuristic is a 2-approximation, i.e., it is at worst twice as much as that of an optimal ordering for the considered category.

- We provide a wedge-sampling based algorithm that utilizes our categorization for improved triangle count estimation.
- We provide closed form expressions for the Relative Standard Error of our algorithm to allow for comparison against previously proposed algorithms over known graphs.
- We evaluate the triangle counting performance of the proposed algorithm against the state-of-the-art over real-world large-scale graphs. Results indicate that proposed sampling algorithm outperforms the state-of-the-art significantly, requiring between two to hundred-fold less sampling to provide the same estimation accuracy.

In the remainder of the paper, we first provide a brief background and the related work (Section 2), then explain our improved wedge sampling approach (Section 3), and then we evaluate our approach (Section 4) and conclude (Section 5).

2 RELATED WORK

Given an undirected graph $G = (V, E)$, where V is a set of n vertices, and E is a set of m edges, we would like to find out T, the number of triangles (three edge cycles) in G. The triangle counting problem can be considered a special case of the subgraph counting [20] or specific length cycle counting [3] problems.

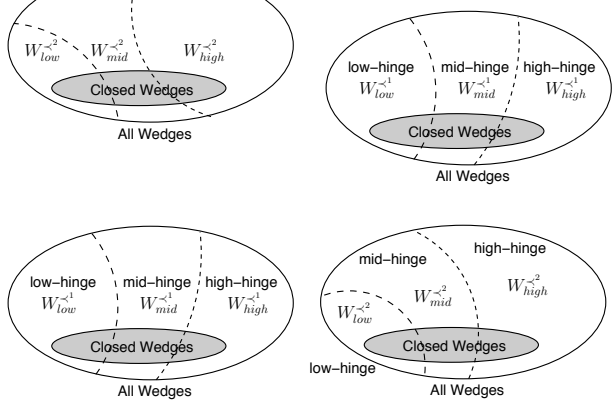
The most efficient algorithm for exact triangle counting uses the fact that if A is the adjacency matrix of G, then the diagonal elements of A^3 contain (two times) the number of triangles of the corresponding vertex. The complexity of this algorithm is $O\left(m^{2\gamma/(\gamma+1)}\right)$ [3], where m is the number of edges in the graph and γ is the exponent of the used matrix multiplication algorithm. Considering a low known $\gamma < 2.38$ for matrix multiplication [25], this complexity can be listed as $\approx O(m^{1.407})$.

Practically efficient exact triangle counting algorithms generally have a complexity of $O(m^{3/2})$ and we refer [30] for a thorough practical comparison of efficient in-memory sequential counting and listing implementations. As most graphs of interest do not fit in memory, some triangle counting studies focus on reducing the number of disk I/Os performed [12, 19] during counting, while others focus on parallelizing the counting process [4, 11, 39].

In cases where the exact count is not needed and an "accurate enough" approximation to the actual count is sufficient, significantly faster triangle-count approximation approaches can be utilized. These approaches can be further divided into the streaming settings where graph components arrive as a data stream [1, 6, 9, 14, 16, 17, 27, 35], and the static settings where the entire graph is available for analysis [32, 33, 37, 38]. Our focus on this work is on the static scenario, where the sampling approaches randomly sample edges [10, 37] or adjacent edge pairs (wedges) [33, 38] to estimate the number of triangles in G based on the statistics obtained from the sampled graph.

State-of-the-art approximation solutions to triangle counting for static settings are based on wedge sampling [33, 38]. The wedge sampling solution proposed in [33] uniformly samples wedges and multiplies one third of the ratio of closed-wedges among the sampled wedges with the total number of wedges in the graph to approximate the total number of triangles in the graph. The solution proposed in [38] note that in graphs with power-law degree distribution, the triangles are not uniformly distributed across wedges and uniform sampling leads to bias necessitating more sampling. They suggest starting with uniform edge sampling and then converting the sampled edges to wedges via further sampling another edge from the connected edges of the first sampled edge.

In this work we also focus on wedge-sampling based triangle count approximation. Our contribution is in proving that for the problem of triangle counting the space of wedges can be significantly reduced (at least three times provably and one to two orders of magnitude in experimented real-world graphs). This reduction in turn leads to more accurate estimation with less sampling. Our space reduction approach has the additional benefit of eliminating the bias in wedges for power law-graphs. Once the space is reduced, we use the uniform wedge sampling approach described in [33] to estimate the triangle count.



In addition to triangle counting, sampling techniques have been used for estimating counts of other important patterns in graphs such as 4-paths [15], diamonds [5], butterfly patterns in bipartite graphs [29], and cliques of any size [13]. Among these works, 4-path sampling work presented in [15] is of most interest to this work. It utilizes a similar approach to what we propose to first order vertices and use this ordering to reduce the set of 4-paths investigated as an implementation improvement. Unfortunately they only provide empirical analysis of this approach without providing detailed theoretical proofs of its search space reduction implications. In this work we provide a better ordering approach for better search space reduction than their approach, and provide theoretical proofs regarding the quality of the proposed approach. We believe this work sheds further light into why they observe significant improvements in their empirical tests when they use an ordering.

3 REVISITING WEDGE SAMPLING

In this section we first show that given a total ordering of vertices in a graph, it is possible to categorize the wedges in the graph into three groups such that sampling wedges only from one group is sufficient for accurate triangle count estimation. We then offer a simple greedy mechanism to obtain a total ordering such that the number of wedges in one of the categories is significantly smaller than the total number of wedges in the graph. We prove that via the proposed ordering, the number of wedges in the category we choose is at least three times less than the total number of wedges in the graph. We also prove that proposed ordering leads to at most two times more wedges in the target group compared to an optimal ordering for that group.

3.1 Categorizing Wedges and Using One Category for Triangle Sampling and Counting

Let $\prec$ define a total ordering on the vertices of a graph $G = (V, E)$. Using this total ordering, we can categorize wedges (two-paths) in G into three groups based on the hinge vertex of the wedge as defined below. We say that the *hinge vertex*, or *hinge* for short, of any given wedge w_{ijk} formed using the edges $\{v_i, v_j\}$ and $\{v_j, v_k\}$ is the vertex common to both edges, i.e., v_j. Then, we categorize the wedge w_{ijk} as a *high-hinge*, *mid-hinge*, or *low-hinge* wedge if the hinge vertex v_j is the highest, middle, or the lowest respectively

(a) Categorization due to $\prec^1$ (b) Categorization due to $\prec^2$

Figure 1: Orderings $\prec^1$ and $\prec^2$ divide the wedges into low-, mid-, and high-hinge categories. For both orderings, any category can be used for sampling triangles since the number of closed wedges in each category is equal to the number of triangles (closed wedges), i.e., $\overline{W}^{\prec^1}_{low}$=$\overline{W}^{\prec^1}_{mid}$=$\overline{W}^{\prec^1}_{high}$=$\overline{W}^{\prec^2}_{low}$=$\overline{W}^{\prec^2}_{mid}$=$\overline{W}^{\prec^2}_{high}$=$T$. Even though the number of triangles in each category is the same, the ratio of triangles to wedges ($\overline{W}/W$) is different for each category. Using the low-hinge category due to $\prec^2$ would be the best among these six options as that option has the highest triangle-to-wedge ratio.

when compared to the other two vertices of the wedge with respect to the total ordering $\prec$.

To estimate the triangle count of a graph G, it is sufficient to sample wedges only from any one of the wedge categories described above. For a given ordering $\prec$ of V, any triangle in G contains exactly one low-hinge, one mid-hinge, and one high-hinge wedge. To observe this, assume a triangle composed of the edges $\{v_i, v_j\}$, $\{v_i, v_k\}$, and $\{v_j, v_k\}$. Without loss of generality, let $v_i \prec v_j \prec v_k$. Clearly, the wedges w_{jik}, w_{ijk}, and w_{ikj} that have hinge vertices v_i, v_j, and v_k are low-hinge, mid-hinge, and high-hinge wedges respectively.

No matter which category of wedges one samples from, all triangles in G can be found during sampling. Thus, wedge-based sampling algorithms proposed in [33] for triangle count estimation can be applied using only one category of wedges for sampling. Intuitively, the smaller the number of wedges in the target category that will be used for sampling, the higher the improvement achieved over sampling wedges from all categories. This is due to the fact that the number of wedges in a category is equal to the number of triangles plus the number of so-called *open* wedges, which do not form triangles, in that category. This intuition is supported by our theoretical analysis as we show that the sampling error reduces as the ratio of open wedges reduces in a category.

As the number of wedges in each category depend on the ordering, we try to find an ordering that reduces the number of wedges in one category. In our approach, we focus on reducing the number of wedges in the low-hinge category. Note that we could have easily selected the high-hinge category as well since the number of low-hinge wedges in an ordering and the number of high-hinge wedges in the reverse ordering are the same.

For a given total order $\prec$, and any given vertex $v \in V$, let $d^{\prec}_{+}(v)$ be the number of vertices adjacent to v that are ordered after v, i.e., $d^{\prec}_{+}(v) = |\{u \in V \mid \{v,u\} \in E, v \prec u\}|$. Similarly, let $d^{\prec}_{-}(v)$ be the number of vertices adjacent to v that are ordered before v, i.e., $d^{\prec}_{-}(v) = |\{u \in V \mid \{v,u\} \in E, u \prec v\}|$. Clearly, the degree of v is $d(v) = d^{\prec}_{+}(v) + d^{\prec}_{-}(v)$. Given this notation, we define the number of low-hinge wedges in the graph G as $W^{\prec}_{low} = \sum_{v \in V} \binom{d^{\prec}_{+}(v)}{2}$. Similarly, we define the number of high-hinge wedges as $W^{\prec}_{high} = \sum_{v \in V} \binom{d^{\prec}_{-}(v)}{2}$, and the number of mid-hinge wedges as $W^{\prec}_{mid} = \sum_{v \in V} (d^{\prec}_{+}(v) \times d^{\prec}_{-}(v))$. Summing up, the total number of wedges is $W = \sum_{v \in V} \binom{d(v)}{2} = W^{\prec}_{low} + W^{\prec}_{mid} + W^{\prec}_{high}$. Also note that for any total ordering $\prec$, there is exactly one low-hinge, one mid-hinge, and one high-hinge wedge in any triangle. Therefore, the number of *closed* low-hinge wedges ($\overline{W}^{\prec}_{low}$), the number of *closed* mid-hinge wedges ($\overline{W}^{\prec}_{mid}$), and the number of *closed* high-hinge wedges ($\overline{W}^{\prec}_{high}$) are all equal to the number of triangles, i.e., $\overline{W}^{\prec}_{low} = \overline{W}^{\prec}_{mid} = \overline{W}^{\prec}_{high} = T$.

3.2 A Greedy Ordering Heuristic for Small Low-Hinge Wedge Count

As shown in Fig. 1 different orderings lead to different number of wedges in low-, mid-, high-hinge categories. For better estimation via smaller number of samplings, it is ideal to use an ordering that provides the smallest number of wedges in one category. However, ordering itself should not be more expensive than the sampling algorithm. In this section we describe a greedy ordering heuristic that provides a categorization where the number of wedges in the low-hinge category is at most one third of the total number of wedges. Furthermore, we prove that the number of low-hinge wedges produced by our greedy ordering is at most twice as much as the minimum number of low-hinge wedges any ordering can produce.

The intuition of our ordering mechanism stems from the observation that the earlier the order of a vertex, the higher the chances of that vertex to be the hinge of a low-hinge wedge, as a low-hinge wedge can only be formed with vertices ordered after that vertex. Thus, it stands to reason to place vertices that have low degrees early on in the ordering to reduce the number of wedges in the low-hinge category. Intuitively, ordering the vertices in G based on their vertex degrees reduces the number of wedges in the low-hinge category significantly. This is exemplified in Fig. 2, where the total number of low-hinge wedges are an order of magnitude (14× precisely) less than the total number of wedges.

In Fig. 2, we compare the cumulative distribution of wedges, closed wedges, low-hinge wedges, and closed low-hinge wedges for the real world Citeseer citation graph [23] in a log-log graph. Note that the cumulative closed low-hinge wedge figure (shown with lower triangles) saturates very fast and after the vertices of degrees up to 30 are considered, reaches very close to the total number of triangles T, which is its final value. This suggests that most triangles have a low degree vertex (e.g. a vertex with a degree smaller or equal to 30), which is a common pattern observed in real-world power-law graphs. Furthermore, the number of wedges (shown with capital W) starts to deviate from the number of low-hinge wedges significantly when we consider vertices of degree 20 and higher. This confirms our intuition explained in the above paragraph that placing vertices that have low degrees early on in the ordering reduces the number of low-hinge wedges. The number of wedges, as expected, increase quadratically as the degree increases.

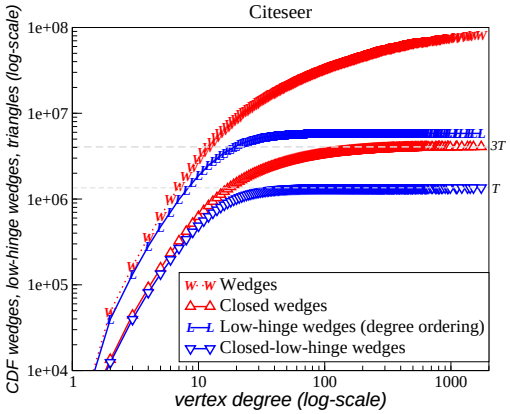


Figure 2: Cumulative distribution function for wedges, closed wedges, low-hinge wedges based on the degree ordering, and closed low-hinge wedges for the Citeseer dataset.

Note the mismatch between the wedge and triangle distributions. As the degree of vertices increase, the number of wedges increase much faster than the number of triangles. Thus a uniform sampling across wedges will be biased towards high-degree vertices. On the other hand, note the similarity between the distributions of the number of low-hinge wedges and the number of closed low-hinge wedges. A uniform low-hinge wedge sampling approach would not have the bias that the uniform wedge-sampling approach has.

The ordering based on the degrees alone can be further improved by taking into account the following observation: the only vertices that matter for a given vertex are those that appear after that given vertex. In this regard, if the vertices are ordered incrementally, placing a vertex into the total order increases the probability of its unordered neighbors becoming the hinge of low-hinge wedges, because their remaining degrees decreases by one. Taking advantage of this observation, we provide a *GreedyOrder* method to describe a total order (Algorithm 1). In *GreedyOrder*, we maintain a min heap priority queue over the degrees of vertices (lines 2-3). In a loop we remove the next smallest degree vertex from the queue (line 5) and reduce the degrees of the all the vertices incident to the removed vertex (lines 7-10). This loop continues till the queue gets empty. Vertices are ordered based on the removal order.

Complexity of *GreedyOrder* is $O(m \log n)$ as all edges are traversed only once by the algorithm and the complexity of the an update (*DecreaseKey*) is $O(\log n)$. Note that the complexity of the simple vertex degree ordering is $O(n \log n)$.

3.2.1 GreedyOrder Reduces Search Space Threefold. Here we prove that for a graph ordered by *GreedyOrder* the number of low-hinge wedges is at most one third of the total number of wedges.

Theorem 1. *Given a graph G and any ordering $\prec_{gr}$ obtained via GreedyOrder(G), the number of low-hinge wedges is at most one third of the total number of wedges, i.e., $W_{low}^{\prec_{gr}} \leq \frac{1}{3}W$.*

Proof. To count W, we will count the total number of wedges in which a given vertex v is the lowest order vertex, and then we will sum these counts for each vertex. Thus, every wedge will be counted exactly once and this sum will be equal to W. When counting, we will also rely on the following invariant that *GreedyOrder* guarantees: any vertex u appearing after another vertex v in the order $\prec_{gr}$ has a remaining degree of at least $d_+^{\prec_{gr}}(v)$ when v is removed from the priority queue. Note that, $d_+^{\prec_{gr}}(v)$ is the degree of v when v is removed from the priority queue in *GreedyOrder*(G).

Let us consider a vertex v when it is removed from the priority queue, i.e., when the order of v is determined. Also, let us consider another vertex u among the $d_+^{\prec_{gr}}(v)$ adjacent vertices of v still in the queue. Using the invariant above, the remaining degree of u is at least $d_+^{\prec_{gr}}(v)$ at the time v is removed from the priority queue. Thus, there are at least $d_+^{\prec_{gr}}(v) - 1$ wedges for which u is the hinge vertex and v is the lowest order vertex. Since there are $d_+^{\prec_{gr}}(v)$ vertices in the priority queue that are adjacent to v, the total number of mid-hinge and high-hinge wedges whose lowest order vertex is v is at least $d_+^{\prec_{gr}}(v) \times (d_+^{\prec_{gr}}(v) - 1)$. Also, recall that $W_{low}^{\prec_{gr}} = \sum_{v \in V} \binom{d_+^{\prec_{gr}}(v)}{2}$. Therefore, we have $W \geq \sum_{v \in V} \binom{d_+^{\prec_{gr}}(v)}{2} + d_+^{\prec_{gr}}(v)(d_+^{\prec_{gr}}(v)-1)$, which implies $W \geq 3W_{low}^{\prec_{gr}}$ proving the theorem. □

Algorithm 1 *GreedyOrder*$(G = (V, E))$

```
1:  L ← ∅                                   ▷ Empty list that will contain the ordering
2:  D ← ComputeVertexDegrees(V, E)          ▷ O(m)
3:  Q ← BuildMinHeap(D)
4:  while Q ≠ ∅ do                          ▷ O(m log n)
5:      x ← VertexID(Q.ExtractMin())
6:      L.Append(v_x)
7:      for all v_y ∈ Adjacency(v_x) do
8:          d_y ← d_y − 1                   ▷ reduce degree of v_x's neighbors
9:          Adjacency(v_y) ← Adjacency(v_y) − {v_x}
10:         Q.DecreaseKey(v_y, d_y)
11: return L                                ▷ return ordered vertex list
```

We note that a three-fold space reduction is very important as in normal wedge sampling the number of closed wedges is three times the number of triangles, i.e. 3T, whereas when sampling low-hinge wedges, the number of closed low-hinge wedges is equal to the number of traingles, i.e. T. If $W < 3W_{low}^{\prec_{gr}}$ was possible, then this would have meant that for some graphs it is more likely to find closed wedges when sampling from W compared to sampling from $W_{low}^{\prec_{gr}}$. With the above proof, we show that sampling from $W_{low}^{\prec_{gr}}$ is always as good as or better than sampling from W. We also note that for certain families of graphs, such as complete graphs, the above theorem is tight, i.e., $W_{low}^{\prec_{gr}} = \frac{1}{3}W$, the number of wedges in the low-hinge category is exactly 1/3 of the total number wedges in the graph.

3.2.2 GreedyOrder is 2−Approximate. Even though Theorem 1 proves that the improvement obtained using Alg. 1 to reduce $W_{low}^{\prec_{gr}}$ is at least threefold, as we will discuss in the evaluation of our algorithms, in practice we observe one to two order of magnitude reduction in the wedge space when we apply this algorithm on various graphs.

Regardless of the reduction ratio, we also prove that our algorithm produces a total ordering of the vertices that is provably very close to the best ordering that minimizes the number of low-hinge wedges. More precisely, we prove that if the best ordering $\prec_{opt}$ has $W_{low}^{\prec_{opt}}$ low-hinge wedges, then the low-hinge wedge count, $W_{low}^{\prec_{gr}}$, of the ordering $\prec_{gr}$ generated by Alg. 1 is at most twice that of the optimal ordering.

To prove our approximation bound we first show that any ordering produced by *GreedyOrder* will satisfy another important invariant. To define this invariant we first expand the ordering notation $\prec$ for a set of vertices as follows. We say that the vertex set X is ordered before vertex set Y if all vertices in X are ordered before all vertices in Y. That is, $X \prec Y$ if $\forall x \in X$ and $\forall y \in Y$, we have $x \prec y$. Using this definition, we show that there exists a paritition of the vertex set V independent of the ordering $\prec_{gr}$ that *GreedyOrder* generates and yet the sets of the partition are ordered with respect to $\prec_{gr}$:

Lemma 1. *Let $V_0, V_1, \ldots, V_k$ be the partition of the set of vertices V where V_i is the smallest subset that ensures that the minimum modified degree in the subgraph obtained by the removal of the vertices $\cup_{j=0}^{i} V_j$ is greater than i. Then, for any total ordering $\prec_{gr}$ generated by GreedyOrder, we have $V_0 \prec_{gr} V_1 \ldots \prec_{gr} V_k$.*

Proof. We prove the following statement on ℓ by induction: Letting $U_\ell = \cup_{j=0}^{\ell} V_j$, for any two vertices $v \in U_\ell$ and $v' \in V \setminus U_\ell$, we have $v \prec v'$ in the ordering provided by *GreedyOrder*. Proving this statement for all $\ell = 0, \ldots, k$ proves our lemma statement.

For the case of $\ell = 0$, the statement holds trivially since all vertices in V_0 have degree 0 and will be processed the earliest by *GreedyOrder* before any other vertex with positive degree.

Assuming the statement true for ℓ, we prove the statement for $\ell + 1$. Using the statement for ℓ, for any two vertices $v \in U_\ell$ and $v' \in V \setminus U_{\ell+1} \subset V \setminus U_\ell$, we have $v \prec v'$ in our ordering. Therefore, all we need to prove is that for any two vertices $v \in V_{\ell+1}$ and $v' \in V \setminus U_{\ell+1}$, we have $v \prec v'$ in our ordering. Assume towards a contradiction that we have $v' \prec v$ instead. Then, consider the earliest vertex $y \in V \setminus U_{\ell+1}$ with respect to the ordering $\prec$. From above, we have $y \prec v$. Furthermore, by definition of V_i, we know that $d_+^{\prec_{gr}}(y)$, the modified degree of y, must be at least $\ell + 1$ when y is ordered by *GreedyOrder*. However, this means that every vertex u satisfying $y \prec u$ must have a remaining degree of at least $\ell + 1$ at the time of ordering y. This contradicts the definition of V_ℓ in that it was the smallest such set. This is because there exists a proper subset of V_ℓ whose removal still guarantees that all other vertices have degree larger than ℓ. The contradiction proves the statement and therefore the lemma. □

Using the partitioning from the above lemma, we can now show that the number of low-hinge wedges of any total order $\prec_{gr}$ generated by *GreedyOrder* is at most twice that of any other ordering, and in particular at most twice that of the optimal ordering.

Theorem 2. *$W_{low}^{\prec_{gr}} \leq 2W_{low}^{\prec}$ for any total ordering $\prec_{gr}$ generated by GreedyOrder, and any total ordering $\prec$.*

Proof. Let $V_0, V_1, \ldots, V_k$ be the partitioning of the set of vertices V as defined in Lemma 1. Then, the statement of the lemma can be written as:

$$2W_{low}^{\prec} - W_{low}^{\prec_{gr}} = \sum_{i=0}^{k} \sum_{v \in V_i} 2\binom{d_+^{\prec}(v)}{2} - \binom{d_+^{\prec_{gr}}(v)}{2} \geq 0 \quad (1)$$

To prove this, for $i = 0, \ldots, k$, let $n_i = |V_i|$ and let $\mu_i(\prec)$ be the average low-degree of the vertices in V_i in the ordering $\prec$; i.e., $\mu_i(\prec) = \sum_{v \in V_i} d_+^{\prec}(v)/n_i$. Using the inequality between root-mean square and arithmetic mean, we get:

$$\begin{aligned}
\sum_{v \in V_i} 2\binom{d_+^{\prec}(v)}{2} &= \sum_{v \in V_i} (d_+^{\prec}(v))^2 - \sum_{v \in V_i} d_+^{\prec}(v) \\
&\geq n_i \left(\sum_{v \in V_i} d_+^{\prec}(v)/n_i \right)^2 - n_i \mu_i(\prec) \\
\sum_{v \in V_i} 2\binom{d_+^{\prec}(v)}{2} &\geq n_i \mu_i(\prec)(\mu_i(\prec) - 1) \quad (2)
\end{aligned}$$

Note that $\mu_i(\prec_{gr}) = \sum_{v \in V_i} d_+^{\prec_{gr}}(v)/n_i$. Also note that in (1), the term $\sum_{v \in V_i} \binom{d_+^{\prec_{gr}}(v)}{2}$ is maximized if we let $d_+^{\prec_{gr}}(v)$ to take the extreme values, the highest value can be i and for simplicity of the proof, we will assume the lowest value to be 1 (a longer proof follows if we allow 0 low-degree vertices). Since the average of $d_+^{\prec_{gr}}(v)$ is $\mu_i(\prec_{gr})$, we can assume a ratio of $i - \mu_i(\prec_{gr})$ vertices with $d_+^{\prec_{gr}}(v) = 1$ and $\mu_i(\prec_{gr}) - 1$ vertices with $d_+^{\prec_{gr}}(v) = i$ in the worst case. Then, we can state:

$$\begin{aligned}
\sum_{v \in V_i} \binom{d_+^{\prec_{gr}}(v)}{2} &\leq \frac{n_i}{i-1}(i - \mu_i(\prec_{gr}))\binom{1}{2} \\
&\quad + \frac{n_i}{i-1}(\mu_i(\prec_{gr}) - 1)\binom{i}{2} \\
\sum_{v \in V_i} \binom{d_+^{\prec_{gr}}(v)}{2} &\leq n_i(\mu_i(\prec_{gr}) - 1)\frac{i}{2} \quad (3)
\end{aligned}$$

Substituting in (1) the bounds we obtain in (2) and (3), we get $2W_{low}^{\prec} - W_{low}^{\prec_{gr}} \geq \sigma = \sum_{i=1}^{k} \sigma_i$, where σ_i is defined below, and we note that it suffices to show $\sigma \geq 0$ to prove the theorem:

$$\sigma_i = n_i \left(\mu_i(\prec)(\mu_i(\prec) - 1) - (\mu_i(\prec_{gr}) - 1)\frac{i}{2} \right)$$

Letting $\mu_i(\prec) = \mu_i(\prec_{gr}) + \phi_i/n_i$, we rewrite σ_i to obtain:

$$\sigma_i = \phi_i(\mu_i(\prec) + \mu_i(\prec_{gr}) - 1) + n_i(\mu_i(\prec_{gr}) - 1)\left(\mu_i(\prec_{gr}) - \frac{i}{2}\right) \quad (4)$$

To prove that $\sigma \geq 0$, we make the following observations:
(i) $\mu_i(\prec_{gr}) \geq \frac{i}{2}$,
(ii) for any $\ell = 1, \ldots, k$, $\sum_{i=1}^{\ell} \phi_i \leq 0$, and
(iii) $\sum_{i=1}^{k} \phi_i = 0$.

The first observation can be shown by the fact that every vertex $v \in V_i$ has degree at least i in the graph restricted to the vertices $\cup_{j=i}^{k} V_j$, which shows that there are at least $\frac{in_i}{2}$ edges incident to the vertices in V_i, and hence $\mu_i(\prec_{gr}) \geq \frac{i}{2}$. For the second observation, the definition of V_1 maximizes $\sum_{v \in V_1} d_+^{\prec_{gr}}(v)$, and in general, the definition of V_i maximizes $\sum_{v \in \cup_{j=1}^{i} V_j} d_+^{\prec_{gr}}(v)$. Therefore, for

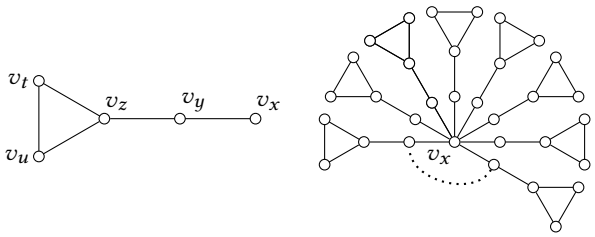

Figure 3: Illustration of proof of Lemma 2.

any ordering $\prec$, and for any $\ell = 1, \ldots, k$, we obtain $\sum_{i=1}^{\ell} \phi_i \leq 0$. Finally, the third observation is correct because each edge in the entire graph is counted exactly once, hence the sum of the modified degrees must be the same regardless of the ordering $\prec$.

First, we simplify the terms σ_j for those indices j with non-negative ϕ_j values. Using the first observation that $\mu_j(\prec_{gr}) \geq \frac{j}{2}$, the property that $\mu_j(\prec) \geq \mu_j(\prec_{gr})$ (directly implied by $\phi_j \geq 0$), and using (4), we can bound σ_j by:

$$\sigma_j \geq \phi_j(j-1)$$

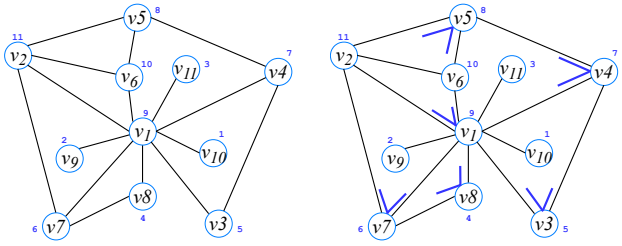
Using the second and the third observations, we know that each reduction in an earlier vertex set V_i must be corrected as an increment in a later vertex set V_j for some $j > i$. Then, we prove $\sigma \geq 0$ by showing that each of the terms σ_i for those indices i with negative ϕ_i values satisfies $\sigma_i \geq i\phi_i$, or equivalently $\hat{\sigma}_i = \sigma_i - i\phi_i \geq 0$. Using the equation (4), we simplify $\hat{\sigma}_i$ to obtain the desired result:

$$\begin{aligned}\hat{\sigma}_i =& (\mu_i(\prec) - i + \mu_i(\prec_{gr}) - 1)\phi_i \\ &+ n_i(\mu_i(\prec_{gr}) - 1)\left(\mu_i(\prec_{gr}) - \frac{i}{2}\right) \\ =& -\frac{i}{2}\phi_i + n_i(\mu_i(\prec) - 1)\left(\mu_i(\prec) - \frac{i}{2}\right)\end{aligned}$$

If $\mu_i(\prec) \geq \frac{i}{2}$, then the above immediately implies $\hat{\sigma}_i \geq 0$ proving the theorem. Otherwise, we have $\mu_i(\prec) < \frac{i}{2}$. Furthermore, since $\mu_i(\prec_{gr}) \geq \frac{i}{2}$, we have $\mu_i(\prec) - \frac{i}{2} \geq \frac{\phi_i}{n_i}$. Still, we can show

$$\hat{\sigma}_i \geq \phi_i \left(\mu_i(\prec) - \frac{i}{2} - 1\right) \geq 0$$

This shows that $\hat{\sigma}_i \geq 0$ in either case, proving the theorem. □



We also show that the 2-approximation of *GreedyOrder* is tight, that is, we can construct examples of graphs and orderings $\prec$ of its vertex set for which $W_{low}^{\prec_{gr}} / W_{low}^{\prec}$ gets arbitrarily close to 2.

Lemma 2. *For any given $\varepsilon > 0$, there exists a graph and an ordering $\prec$ of its vertices where $W_{low}^{\prec_{gr}} > (2-\varepsilon) W_{low}^{\prec}$.*

Proof. Consider a gadget of five vertices as shown in Figure 3. The gadget includes a triangle v_u, v_t, v_z and a two path v_z–v_y–v_x. Also, assume that the degree of v_x is high enough that our ordering algorithm chooses first the vertex v_y followed by v_z, v_t, v_u. For these four vertices our low wedge count is increased by two. However, the ordering $\prec$ where the vertices of this gadget are ordered v_u, v_t, v_z, and v_y would have resulted in a wedge count of one. To magnify the impact of such savings and prove Lemma 2, we consider the graph with at least $c > 1/\varepsilon$ copies of this gadget such that the vertex v_x is shared among the gadgets as shown in Figure 3. In this example graph, *GreedyOrder* can produce two low-hinge wedges for all gadgets but the last one, for which it will produce a single wedge. Therefore, we get $W_{low}^{\prec_{gr}} = 2c - 1$ in the worst case. Clearly the ordering $\prec$ would produce one wedge per gadget resulting with $W_{low}^{\prec} = c$, proving $W_{low}^{\prec_{gr}} > (2-\varepsilon) W_{low}^{\prec}$ as desired. □

(a) Example graph with 11 vertices, 16 edges, 56 wedges, and 5 triangles. Vertex ordering (shown with blue indexes) is performed by *GreedyOrder*.

(b) Low-hinge wedges based on the ordering in (a) are marked with blue wedges. There are 6 low-hinge wedges 5 of which are closed.

Figure 4: Illustration of low-hinge wedges on an example graph.

3.3 Triangle Count Estimation via Sampling Low-Hinge Wedges

In this section we describe how we estimate the number of triangles in a graph by taking advantage of the properties of the ordering $\prec_{gr}$. Proposed approach is presented in Alg. 2. As seen in the algorithm, we first assign every vertex v a probability $p(v)$ equal to $\binom{d_+^{\prec_{gr}}(v)}{2} / W_{low}^{\prec_{gr}}$ (lines 2–3). Then, we sample k random vertices from the vertex set V with repetitions according to the assigned probability distribution (line 5). For each sampled vertex v_i, we sample a wedge out of the $\binom{d_+^{\prec_{gr}}(v_i)}{2}$ wedges of v_i (lines 6-7). If the sampled wedge is closed, i.e., the third edge is in the original graph, then we increment a sum S by one (lines 8-9). Finally, we output our triangle count prediction by multiplying S/k (the ratio of discovered closed wedges to the sampled wedges) with $W_{low}^{\prec_{gr}}$, the number of low-hinge wedges (line 10).

Figure 4(a) shows a sample graph with 11 vertices, 16 edges, 56 wedges, and 5 triangles[1]. A vertex ordering using a run of the *GreedyOrder* is indicated with a blue index number placed next to each vertex. Figure 4(b) indicates the low-hinge wedges of G based on the ordering in Figure 4(a). Out of the 6 low-hinge wedges, 5 of them are closed. The wedge space reduction is ~ 9× (from 56 to 6). As an example, if we run *LowHingeWedgeSample* on the sample graph with $k = 3$, we'll find 2 or 3 closed wedges, which will lead to a prediction of 2/3*6=4 or 3/3*6=6 triangles.

3.4 Expected Value, Variance, and RSE of Low-Hinge Wedge Sampling

In this section we analyze and provide closed form expressions for the expected value, the variance, and the relative standard error of our algorithm to be able to reason about its performance on graphs whose properties are known.

Considering every wedge selection step using $i = 1$ to k, and numbering every triangle in the graph using $j = 1$ to T, we introduce the following indicator variables for our analysis: let w_{ij} be the indicator variable whose value is 1 if and only if the low-hinge wedge for the j^{th} triangle is chosen at the i^{th} wedge selection step; and 0 otherwise[2]. Using these indicator variables, the output of our algorithm, S, can be expressed as:

$$S = \sum_{i=1}^{k} \sum_{j=1}^{T} w_{ij}.$$

We express the output of our algorithm in terms of the ratio of triangles T in the graph to the number of considerable wedges $W_{low}^{\prec gr}$, i.e., $R^{gr} = T/W_{low}^{\prec gr}$. Note that intuitively, as the ratio R^{gr} gets larger, the accuracy of our algorithm should increase and the number of samples we need to pick to achieve a given error rate in estimation should decrease. We can express $\mathbb{E}(S)$, the expected value of S, and $var(S)$, the variance of S, in terms of R^{gr} and in terms of k, the number of samples:

Lemma 3. *The expected value of S is kR^{gr}.*

Proof. We know that $\mathbb{E}(w_{ij}) = 1/W_{low}^{\prec gr}$, therefore, we get

$$\mathbb{E}(S) = \sum_{i=1}^{k} \sum_{j=1}^{T} \mathbb{E}(w_{ij}) = \sum_{i=1}^{k} \sum_{j=1}^{T} 1/W_{low}^{\prec gr} = kT/W_{low}^{\prec gr} = kR^{gr}$$

as desired, proving the lemma. □

Lemma 4. *The variance of S is $kR^{gr}(1 - R^{gr})$.*

Proof. For brevity, in the following analysis we will use the notation Λ to indicate $W_{low}^{\prec gr}$. We have $var(w_{ij}) = \frac{1}{\Lambda} - \frac{1}{\Lambda^2}$. Also, for any $i \neq i'$, we have $covar(w_{ij}, w_{i'j'}) = 0$ since the two selection processes at the two steps i and i' are independent of each other. Finally, for any $j \neq j'$, we have $covar(w_{ij}, w_{ij'}) = 0 - \frac{1}{\Lambda^2}$ since only one wedge is selected at each selection step. Therefore, we have:

$$\begin{aligned}
var(S) &= \sum_{i=1}^{k} \sum_{j=1}^{T} var(w_{ij}) + \sum_{i=1}^{k} \sum_{j \neq j'} covar(w_{ij}, w_{ij'}) \\
&= \sum_{i=1}^{k} \sum_{j=1}^{T} \left(\frac{1}{\Lambda} - \frac{1}{\Lambda^2}\right) + \sum_{i=1}^{k} \sum_{j \neq j'} \left(-\frac{1}{\Lambda^2}\right) \\
&= kT\frac{1}{\Lambda} - kT\frac{1}{\Lambda^2} - kT(T-1)\frac{1}{\Lambda^2} \\
&= k\frac{T}{\Lambda}\left(1 - \frac{1}{\Lambda} - \frac{T-1}{\Lambda}\right) \\
&= kR^{gr}\left(1 - \frac{T}{\Lambda}\right) \\
&= kR^{gr}\,(1 - R^{gr})
\end{aligned}$$

proving the variance stated in the lemma. □

We compare our method to previous work using the Relative Standard Error (RSE) values of all of the methods and base our arguments on the RSE values. Applying the formula for the relative standard error $RSE(S) = \sqrt{var(S)}/\mathbb{E}(S)$, we obtain:

$$RSE(S) = \frac{\sqrt{kR^{gr}(1 - R^{gr})}}{kR^{gr}} = \sqrt{\frac{1 - R^{gr}}{kR^{gr}}} \tag{5}$$

4 EVALUATION

In this section we provide an experimental analysis of the proposed methodology.

4.1 Experimental Setup

We compare the performance of our low-hinge-based wedge sampling algorithm (LWS) with the state-of-the-art wedge sampling [33] (WS) and edge-based wedge sampling [38] (EWS) approaches using large-scale graphs modeling real-world networks. As a comparison metric (and to verify our theoretical analysis presented in Section 3.4), we observe the relative standard error (RSE) values of different algorithms. We also compare these values with the theoretical analysis we provided in Section 3.4. In the figures, in addition to the RSE estimation we provide for LHS, we draw the estimations for WS and EWS using the formulations for the expected RSE values of these algorithms presented in [38]. It is important to note that the formulation for WS (shown below) has a striking similarity to the formulation in Eq. 5, allowing us to compare WS and LHS using the clustering coefficients (C) and the R values directly:

$$RSE(WS) = \sqrt{\frac{1 - C}{kC}} \tag{6}$$

In order to provide comparable results, as was done in [10, 38], we report the corresponding RSE values of the three algorithms for a given sampling probability. We vary the sampling probability until one of the algorithms achieves RSE ≤ 0.01. Considering the randomized nature of the sampling based approximation algorithms, we calculate the experimental RSE values observed with k different runs of the algorithms using the formula:

$$RSE = \frac{\sqrt{\frac{1}{k}\sum_{i=1}^{k}(\Delta_i - \mu)}}{T},$$

[1] We used the same sample graph presented in [38].

[2] We would like to thank the anonymous reviewer who pointed out the error in our initial indicator variable defition.

where Δ_i is the estimate obtained in the i-th run and μ is the mean of all of the k runs, i.e., $\mu = \frac{1}{k}\sum_{i=1}^{k}\Delta_i$. In all of our experiments, we use $k = 1000$.

We conducted the experiments on a server with 16 CPUs and 64 GB of RAM. The implementation was done on C++. We experimented over 20 real-world datasets with varying sizes that were made available in [10]. Largest of the datasets contain more than 40 million vertices and 30 billion triangles.

Features of the datasets (the number of vertices (n), edges (m), and description) used in the experiments are listed in Table 1. Other interesting features of the datasets such as the number of triangles (T), the number of wedges (W), and the clustering coefficients (C), as well as the number of low-hinge wedges ($W_{low}^{\prec_{gr}}$) and the R values for the greedy (R^{gr}) and degree ordering (R^{dg}) schemes, which can be used to estimate the RSE values using Eq. 5 are presented in Table 2.

4.2 Empirical Analysis

As seen in Table 2, the number of low-hinge wedges $W_{low}^{\prec_{gr}}$ are in general one to two orders of magnitude lower than the total number of wedges W for all graphs, indicating a significantly reduced sampling space for LHS. Also we can see in the table that for all datasets both R^{gr} and R^{dg} are significantly larger than C indicating that our approach has a much higher chance of hitting a triangle than in WS. Furthermore, for all datasets, R^{gr} is larger than R^{dg} showing that *GreedyOrder* reduces the sampling space more than a degree ordering solution would do. We observe from Equations (5) and (6) that the higher (and closer to 1) the R or C value is, the lower the RSE is expected to be. Given that R^{gr} is larger than C and R^{dg} for all datasets, LHS using the greedy ordering is expected to lead to lower RSE compared to other approaches for all datasets.

More strikingly, in Table 2 we observe that the value of R^{gr} is very close to one for many datasets (e.g. Web-NotreDame, Web-Arabic), which indicate that our approach shrank the sampling space so much that the number of low-hinge wedges is almost equal to the number of triangles and almost all samplings lead to closed wedges. Simply, by sampling very few low-hinge wedges (e.g., approximately 34 low-hinge wedges to get an RSE of 0.05 for Web-NotreDame or for Web-Arabic) and by mutliplying the number of closed wedge ratio with the number of low-hinge wedges, we can accurately estimate the total number of triangles (e.g., Web-NotreDame and Web-Arabic has more than 8 million and 36 billion triangles respectively). Note here that, irrespective of the utilized approach, to offer a correct sampling, the sampling space cannot be reduced to a size less than the total number of triangles, which shows how effective our reduction is.

Figure 5, provides an empirical comparison of the relative standard errors of WS, EWS and LHS over the 20 datasets listed in Table 1. The figure also depicts the RSE estimations indicated by [38] for WS and EWS, and by Equation 5 for LHS. In the figure the x-axis indicates different sampling ratios experimented with (in terms of number of sampled wedges) and the y-axis indicates the corresponding RSE values obtained by the three algorithms. Both the x- and y-axis is presented in log-scale and the x-axis range is selected such that the RSE values for LHS will range between 0.20 and 0.01.

First we note that for all datasets depicted in Figure 5, the empirical RSE observations we make for LHS perfectly match the theoretical bounds we compute using Equation 5. This proves the validity of our theoretical analysis. We also observe that, as expected, the datapoints in Figure 5 for WS, EWS and LHS all exhibit parallel trends in the log-log graph irrespective of the sampling ratio. In other words, all lines in the figure have the same slope with different constants defining their difference. This is expected as WS and LHS practically run the same algorithm albeit on different sampling spaces and all of WS, EWS, and LHS depend linearly on the sampling ratio, therefore, the ratio of their RSE values remain the same across different sampling probabilities.

In all of the datasets LHS performs significantly better than the other algorithms and offers highly confidant estimations with very small number of samplings. We note that since Figure 5 is a log-log figure, the constant difference between the lines in fact indicate a multiplicative difference. i.e. for all datasets, LHS offers two to eight times lower RSE at the same sampling ratio and this multiplicative distance remains fixed per dataset at all sampling ratios.

Note that the parallel nature of the figures will continue even if more samplings are done and the RSE gets lower. For any sampling ratio LHS will provide more accurate results, and for any desired RSE value LHS will be able to achieve that value with lower number of samplings. For example, in the As-skitter dataset, to achieve an RSE of around 0.11, LHS needs to sample just 165 wedges whereas EWS needs to sample 9476 wedges (a 57× difference). This difference is more profound in Web-Arabic where LHS needs 113× less sampling. LHS offers the highest RSE improvement ($\sim$ 8×) at the same sampling ratio over the best of WS and EWS at the Web-Arabic and Web-NotreDame datasets. This is expected as on these datasets, LHS achieves close to one R^{gr}, which indicate that LHS performs close to optimal wedge-space reduction.

5 CONCLUSION

We proposed a methodology to significantly improve the performance of wedge-sampling based triangle counting approaches by reducing the size of sampling space. We achieved this by ordering

the vertices of the graph, using this ordering to categorize wedges, only using low-hinge wedges for sampling. If degrees of vertices are available, we showed that a simple degree ordering can significantly reduce the size of sampling space. We proved that the reduction achieved by a slightly more complex ordering mechanism is at least three-fold in theory, is a 2-approximation to the best achievable reduction for low-hinge wedges, and provides one to two orders of reduction in practice. Through rigorous analysis over large-scale real-world graphs, we show that our approach offers highly confident estimations always outperforming the state-of-the-art approaches two to eight times in terms of accuracy or up to 100× in terms of sampling size for the same level of accuracy.

ABSTRACT

The phenomenal growth of graph data from a wide variety of real-world applications has rendered graph querying to be a problem of paramount importance. Traditional techniques use structural as well as node similarities to find matches of a given query graph in a (large) target graph. However, almost all existing techniques have tacitly ignored the presence of *relationships* in graphs, which are usually encoded through interactions between node and edge labels. In this paper, we propose *RAQ—**R**elationship-**A**ware Graph **Q**uerying*—to mitigate this gap. Given a query graph, RAQ identifies the k best matching subgraphs of the target graph that encode similar relationships as in the query graph. To assess the utility of RAQ as a graph querying paradigm for knowledge discovery and exploration tasks, we perform a *user survey* on the Internet Movie Database (IMDb), where an overwhelming 86% of the 170 surveyed users preferred the relationship-aware match over traditional graph querying. The need to perform subgraph isomorphism renders RAQ NP-hard. The querying is made practical through *beam stack search*. Extensive experiments on multiple real-world graph datasets demonstrate RAQ to be effective, efficient, and scalable.

1 INTRODUCTION

Graphs act as a natural choice to model data from several domains. Examples include social networks [13], knowledge graphs [8, 11], and protein-protein interaction networks (*PPIs*) [27, 28]. Consequently, graph-based searching and querying have received significant interest in both academia [15,21,22,32,35,40] and industry (e.g., Facebook's Graph Search [3] and Google's Knowledge Graph [4]).

One of the most common queries in these frameworks is to find similar embeddings of a query graph q in a much larger target graph G. More formally, given a query graph q, a target graph G and a similarity function $sim(q, g)$, the goal is to identify the top-k most similar subgraphs $g \subseteq G$ to the query graph q. Traditional similarity functions consider two graphs as similar if they are structurally similar and they contain similar nodes [21, 22, 29, 48]. Two nodes are said to be similar if they are represented by similar feature vectors; the most common form being just a node label. Despite significant advancements in the field of graph querying [15, 22, 48], this commonly adopted definition of similarity is oblivious to the presence of *relationships* in the graphs. In this work, we bring the power of relationships to graph querying.

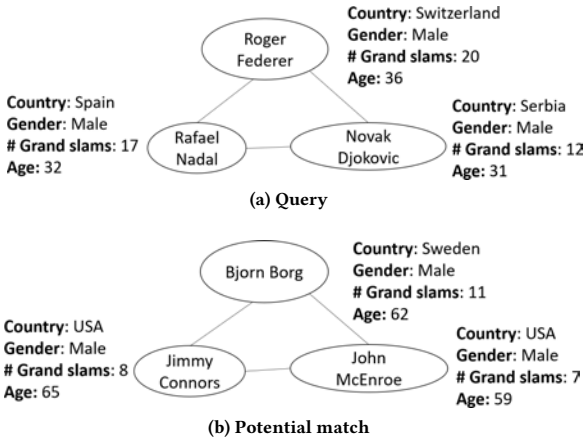

Figure 1: Two subgraphs from the Wikipedia knowledge graph. For simplicity, we drop the directionality and model them as an undirected graph.

To give an example of a relationship, consider the entity tuples ⟨Rafael Nadal, Roger Federer⟩ and ⟨John McEnroe, Bjorn Borg⟩ from the Wikipedia knowledge graph. Although the entities in these two tuples are different, both tuples encode a similar relationship; they represent players who played during the same era and won multiple grand slam tournaments between them. Annotating knowledge graphs with relationship information in the form of edge labels has been shown to expose a higher level of semantics than simple entity-to-entity matching [19, 44].

Fig. 1a presents a query subgraph from Wikipedia knowledge graph containing well-known tennis players of the current era. Wikipedia further characterizes each node with a bunch of summary features as shown in the figure. Now, consider the task of identifying a subgraph from Wikipedia similar to the query in Fig. 1a. Consider Fig. 1b, which depicts another group of well-known tennis players: Bjorn Borg, Jimmy Connors and John McEnroe. Would a tennis fan consider these two groups to be similar? There is a strong possibility that she would since both the groups respectively represent players

who played during the same era and won multiple grand slam tournaments among them.

Let g_1 and g_2 be two graphs. Most of the existing techniques [18, 22, 29, 47, 48] rely on mapping each node in g_1 to some node in g_2, and the cumulative similarity of the mapped node pairs dictate the overall similarity score between g_1 and g_2. When such a strategy is applied to the above two subgraphs (Fig. 1a and 1b), none of the possible node mappings would return a high score since their feature vectors are not similar. For example, Federer is not similar to any of the nodes in Fig. 1b, since he is from a different generation as indicated by his "Age", and belongs to a different country. The "Gender" and "# Grand slams" will fetch some similarity, however, that may not be enough to offset the dissimilarity in the other two features. More fundamentally, although a graph contains a *group/collection* of nodes, *existing techniques* treat each node as an *independent entity* while comparing two graphs. Consequently, *group-level relationships*, that can be identified only by analyzing the *group-level interactions* between node feature vectors, are not reflected in the similarity score. For example, the relationship that each group contains players from roughly the same generation, as hinted by the "Age" feature, cannot be inferred through node similarity alone, where nodes are treated independently. This observation forms the core motivation behind our work to move beyond node similarity, and match subgraphs based on the *relationships encoded through non-trivial interactions between node features*.

Several important questions arise at this juncture. *What is the precise definition of a relationship? How do we quantify the strength of a relationship? Are all relationships equally important?* In this paper, we answer these questions. In sum, we make the following key contributions:

- We propose a novel graph querying paradigm, *RAQ (Relationship-Aware Graph Querying)*, that incorporates the notion of *relationship* in its similarity function (Sec. 3). The proposed formulation automatically mines the relationships manifested in the query graph and ranks their importance based on their *statistical significance* (Sec. 4).
- We design the RAQ search algorithm, which employs *beam stack search* on an R-tree to identify good *candidates*. These candidates are further refined through *neighborhood signatures* constructed using random walks with restarts to prune the search space and compute the *optimal* answer set. (Sec. 5).
- Empirical evaluation (Sec. 6) on real datasets establishes three key properties. (1) RAQ produces results that are *useful*. This is validated by two user surveys. (2) RAQ *complements* existing graph similarity metrics by finding results that traditional techniques are unable to find. (3) RAQ is up to 5 times faster than baseline strategies and scales to million-sized networks.

  The code is available at: https://github.com/idea-iitd/RAQ.

2 RELATED WORK

Research work done in both exact and approximate (sub-)graph querying have employed a plethora of similarity functions. The most prominent of them being graph edit distance (GED) [47, 48], maximum and minimum common subgraph [12, 16], edge misses [41], structural similarity [15, 21, 22, 38, 40, 42], node-label mismatches [38, 40], and statistical significance of node-label distributions [14]. However, all these methods operate oblivious to the presence of *relationships in the query graph*.

Query-by-example Paradigm: The need to query based on relationships is touched upon by the recent line of work on Query-by-example [19, 24–26]. All these techniques take an edge or a set of edges as input, and this input is treated as an *example* of what the user wants to find. Each exemplar edge connects two entities of the knowledge graph and the edge label denotes the relationship between these entities. Typical relationships in a knowledge graph are "friendOf", "locatedIn" etc. Given the exemplar edges, the common goal in this line of work is to identify subgraphs from the target graph that are connected by the same edge labels as expressed in the exemplars. Our work is motivated by the same line of thought and revamps this paradigm through the following innovations.

(1) **Mining relationships:** While [19, 24–26] assume that relationships are explicitly provided in the form of edge labels, we *mine* these relationships from feature-value interactions observed between a pair of nodes. Thus, RAQ is not constrained by the explicit availability of edge relationships. This results in a more powerful model since it is hard to capture all possible relationships through a small set of edge labels. Furthermore, unlike existing query-by-example techniques, RAQ is not limited to edge-labeled (relationship-annotated) graphs alone, and exposes a more generic framework capable of operating on graphs with both node and edge labels.
(2) **Multiple relationships:** Existing techniques assume each edge to be associated with only one relationship. In our formulation, each edge encodes d relationships corresponding to each of the d features characterizing a node.
(3) **Relationship importance:** All relationships in the exemplar edges are assumed to be of equal importance. In the proposed paradigm, we analyze all of the identified relationships and quantify their importance through statistical significance. As we will see later in Sec. 6.3, users find this weighting relevant.
(4) **Relationship similarity:** Existing query-by-example techniques are incapable of computing similarity between relationships. This is a natural consequence of the fact that relationships are reduced to *categorical edge labels*. Thus, relationships between two pairs of nodes are either considered *identical or different*. In contrast, *RAQ is not limited to a binary matching*. For example, the relationship with respect to "# Grand slams" between Federer and Nadal is similar to that between Bjorg and McEnroe, but not identical.

Overall, the proposed paradigm is more generic, and therefore more challenging to solve algorithmically.

3 PROBLEM FORMULATION

The input to our problem is a *target graph*, a *query graph*, and the value k corresponding to the top-k matches that need to be identified.

Definition 1 (Target Graph). *The target graph $G = (V, E, \mathbb{F})$ contains a node set V, an edge set E, and a set of d-dimensional feature*

vectors $\mathbb{F}$, where each feature vector $f(v) = [f_1(v), \ldots, f_d(v)]$ characterizes a node $v \in V$. Optionally, each edge may also be annotated with an edge label.

Without loss of generality, we assume that for each feature value $f_i(v)$, $0 \leq f_i(v) \leq 1$. A query graph $q = (V_q, E_q, \mathbb{F}_q)$ follows the same notational structure as the target graph. Both the target graph and the query graph can be either directed or undirected. Our goal is to identify *isomorphic* embeddings of the query graph within the target graph, such that they encode relationships similar to that manifested in the query. Graph $g_1 = (V_1, E_1, \mathbb{F}_1)$ is *isomorphic* to $g_2 = (V_2, E_2, \mathbb{F}_2)$ if there exists a bijection ϕ such that for every vertex $v \in V_1$, $\phi(v) \in V_2$ and for every edge $e = (u, v) \in E_1$, $\phi(e) = (\phi(u), \phi(v)) \in E_2$ and the labels of e and $\phi(e)$ are the same. Among all isomorphic embeddings of the query graph q in the target graph G, we want to select the k embeddings that possess the highest *relationship-aware similarity (RAS)* to q (defined formally in Def. 3).

Problem 1 (Top-k Relationship-aware Querying). *Given a query graph q, a target graph G, and a positive integer k, identify the graphs $\mathbb{A} = \{g_1, \cdots, g_k\}$, such that (1) $\forall g_i \in \mathbb{A}$, g_i is a subgraph of G, (2) $\forall g_i \in \mathbb{A}$, g_i is isomorphic to q, and (3) $\nexists g' \subseteq G$ such that $RAS(g', q) > RAS(g_i, q)$ for some $g_i \in \mathbb{A}$.*

The main task is to design the relationship-aware similarity function $RAS(g, q)$ for any two isomorphic graphs g and q.

4 RELATIONSHIP-AWARE SIMILARITY

We first define what a relationship is. Intuitively, each feature represents the characteristics of a node and the relationship between two nodes is inferred by studying the interplay between their feature values. For example, considering Djokovic and Nadal, both entities are of the same gender, similar age, have won a large number of grand slam tournaments, but are citizens of different countries. Interactions between each corresponding feature of the connected nodes generate a relationship, and hence, a d-dimensional feature vector would produce d relationships per edge. We capture these relationships in the form of a *relationship vector* $s(e)$ corresponding to each edge $e = (u, v)$.

Definition 2 (Relationship Vector). *The relationship vector, $s(e)$, of an edge $e = (u, v)$ captures the features that are preserved in the relationship between u and v. Formally, $s(e) = [s(f_1, e), \ldots, s(f_d, e)]$ where*

$$s(f_i, e) = \begin{cases} \Gamma(f_i(u), f_i(v)), & \text{if } f_i \text{ is real valued} \\ 1, & \text{if } f_i \text{ is categorical and } f_i(u) = f_i(v) \\ 0, & \text{if } f_i \text{ is categorical and } f_i(u) \neq f_i(v) \end{cases}$$

$$\text{where } \Gamma(x, y) = \begin{cases} 1, & \text{if } x = y = 0 \\ \min\{x, y\} / \max\{x, y\}, & \text{otherwise} \end{cases} \quad (1)$$

Example 1. *The relationship vector $s(e)$ for the edge e connecting Nadal and Djokovic in Fig. 1a is $[0, 1, 0.71, 0.97]$. The second dimension is 1 since it is a categorical feature and both are males. The third dimension is non-categorical and thus, the similarity between them is $\frac{12}{17}$. Similarly, the relationship vector of the edge between Connors and McEnroe in Fig. 1b is $[1, 1, 0.88, 0.91]$.*

From its definition, each dimension in the relationship vector takes a value in the range $[0, 1]$. A value close to 1 indicates that both endpoints of the edge share similar values. Two edges e and e' are considered similar if they encode similar relationships. Thus, to quantify their similarity, we compute the similarity between their relationship vectors:

$$eSim(e, e') = \sum_{i=1}^{d} w(i) \cdot \Gamma\left(s(f_i, e), s(f_i, e')\right) \quad (2)$$

$eSim(e, e')$ is a weighted *min-max* similarity between the two relationship vectors. The *weight* $w(i)$ of the i^{th} relationship (feature) represents its relative importance with respect to the other relationships, and the function $\Gamma\left(s(f_i, e), s(f_i, e')\right)$ operates as defined in Eq. 1. We add the constraint that $\sum_{i=1}^{d} w_i = 1$.

Example 2. *Assume that each relationship is of equal importance and, therefore, $\forall i$, $w_i = \frac{1}{d}$. The similarity between the edges Nadal-Djokovic and Connors-McEnroe is, thus, $0.25 \times 0 + 0.25 \times 1 + 0.25 \times \frac{0.71}{0.88} + 0.25 \times \frac{0.91}{0.97} = 0.68$.*

Given two isomorphic subgraphs q and g, and an isomorphic mapping ϕ from the edges in q to the edges in g, the *relationship-aware similarity (RAS)* with respect to the mapping ϕ is the similarity between the mapped edges from q to g:

$$RAS_{\phi}(q, g) = \sum_{\forall e_q = (u_q, v_q) \in E_q} eSim\left(e_q, \phi(e_q)\right) \quad (3)$$

Definition 3 (Relationship-aware Similarity). *The relationship-aware similarity (RAS) between q and g is the maximum RAS under all possible isomorphic mappings:*

$$RAS(q, g) = \max_{\phi} \left\{RAS_{\phi}(q, g)\right\} \quad (4)$$

Quantifying Relationship Importance: The obvious question now is how to infer the weights in $eSim(e, e')$ (Eq 2). One option is to ask the user to provide the weights. However, such a strategy may not be practical. Specifically, each edge may encode a large number of relationships corresponding to features characterizing the participating nodes, and providing a weight with respect to each relationship is hard for general users. Also, providing a large number of input parameters is a cumbersome procedure. Hence, ideally, the weights should be automatically inferred.

The simplest approach is to assume that all relationships are of equal importance, i.e. $\forall i, w_i = \frac{1}{d}$. This assumption however, may be unrealistic. To elaborate, *is the relationship that both Nadal and Djokovic are males as important as the relationship that both of them have won a large number of grand slam tournaments?* Intuitively, such an assumption appears to be odd.

More importantly, should the importance be constant under all situations and should it ignore the feature values. For example, consider an edge between two tennis players who have won no grand slams. In such a case, both would have a similarity of 1 in the "# Grand Slams" dimension. In that case, is the importance of grand slams the same between these two players as compared to Nadal and Djokovic? From a human psychological point of view, we value events that are rare. The relationship between Nadal and Djokovic stands out since they have won so many grand slams. We capture this intuition through *statistical significance*. Higher the statistical significance of a relationship, more is its weight.

4.1 Statistical Significance of Relationships

Statistical significance tests quantify whether an event occurred due to chance alone or is a result of some additional factor. Several statistical tests exist [20], such as the chi-square test [7], p-value [31,33,34], g-test [45], Kruskal-Wallis test, Anderson-Darling test, Shapiro-Wilk test, etc., to quantify the statistical significance of an event. However, none of the techniques work directly on both categorical data (e.g., country) as well as continuous-valued data (e.g., age). Thus, we need to either map continuous data into a discrete space or convert discrete, categorical data into a continuous domain. Since converting categorical data such as gender and country into a continuous space is not feasible, we discretize continuous data into bins. We use the *chi-squared statistic* [36] to measure statistical significance since it is known to produce robust results [7,37] and is efficient to compute.

Converting continuous data into discrete bins has been extensively studied [23]. While any discretization technique can be used, we use kernel-density estimation based method [10] since it is unsupervised and non-parametric and, therefore, easy to apply on any continuous valued variable.

Let x be some event in a random experiment and S be the sample space. For all outcomes $y \in S$, let O_y represent the number of times outcome y has occurred. The chi-square statistic, X^2, measures the statistical significance of the event x through the deviation of the *observed* frequency of all possible outcomes O_y from their *expected* frequency E_y given by the *null model*:

$$X^2 = \sum_{\forall y \in S} \frac{(O_y - E_y)^2}{E_y}. \tag{5}$$

The higher the chi-square, the more statistically significant the observed event is.

In our problem, an event corresponds to a relationship. A relationship is manifested in the form of feature values assumed by the two endpoints of an edge. Thus, we should compute the observed frequency of a relationship and compare it to its expected frequency as per the chi-square protocol. Towards that end, each edge $e = (u, v)$ gives rise to a *relationship tuple* $\tau = (f_i(u), f_i(v))$ corresponding to feature f_i. Let $\mathcal{V}(f_i)$ represent the set of unique tuples assumed by feature f_i across all edges in a graph g. Then, the *observed frequency*, O_τ, for any relationship tuple $\tau \in \mathcal{V}(f_i)$ is simply the number of times τ is encountered in g.

Example 3. *Let us revisit Fig. 1a. As a pre-processing step, we would first discretize "# Grand slams" and "Age" into discrete categories. Let us assume that grand slam wins are bucketed into the following bins – Poor: 0, Good: 1-5, Very Good: 6-10, Great: 11-15, All time great (ATG):> 15. Therefore, $\mathcal{V}$("# Grand slam") contains the tuples (ATG,ATG) and (ATG,Great) with observed frequencies 1 and 2 respectively. Similarly, $\mathcal{V}$("Gender") = {(Male, Male)}, where observed frequency $O_{(Male,Male)} = 3$.*

Null Model: We assume that relationship tuples in the query graph are drawn independently and randomly from the distribution of tuples in the target graph G. If the distribution of a relationship tuple in the query graph deviates significantly from the distribution in target graph, we call the corresponding relationship statistically significant.

Let $P(f_i) = \{p_1, \ldots, p_{|\mathcal{V}(f_i)|}\}$ denote the probability distribution of relationship tuples for feature f_i in the target graph $G = (V, E, \mathbb{F})$. Here, $p_j \in P(f_i)$ represents the probability of finding tuple $\tau_j \in \mathcal{V}(f_i)$ in the target graph and is equal to the ratio $\frac{freq(\tau_j)}{|E|}$, where $freq(\tau_j)$ denotes the frequency of tuple τ_j in the target graph. Since each relationship tuple of feature f_i in the query graph is drawn randomly and independently from $P(f_i)$, the *expected frequency* E_τ of any tuple τ in the query graph $q = (V_q, E_q, \mathbb{F}_q)$ is

$$E_\tau = |E_q|.p_\tau \tag{6}$$

The chi-square value of f_i with observed frequency O_τ is, therefore,

$$X^2_{f_i} = \sum_{\forall \tau \in \mathcal{V}(f_i)} \frac{(O_\tau - E_\tau)^2}{E_\tau} \tag{7}$$

Example 4. *Let us compute the significance of the grand slam and gender relationships in Fig. 1a. Since very few of the tennis players have won a grand slam tournament, we assume that in the target graph, 5% of the edges have the relationship tuple (ATG, Great) and 1% have the tuple (ATG, ATG). Therefore, the expected frequency of (ATG, Great), (ATG, ATG) and all other tuples in Fig. 1a is $0.05 \times 3 = 0.15$, $0.01 \times 3 = 0.03$ and $0.94 \times 3 = 2.82$ respectively. Consequently,*

$$X^2_{\#Grandslam} = \frac{(2-0.15)^2}{0.15} + \frac{(1-0.03)^2}{0.03} + \frac{(0-2.82)^2}{2.82} = 57$$

In the gender relationship, let us assume that in the target graph 50% of the edges contain the tuple (Male, Male), 40% contain (Female, Female) and 10% contain (Female, Male). Therefore, the expected frequency of (Male, Male), (Female, Female) and (Female, Male) in Fig. 1a are 1.5, 1.2 and 0.3 respectively. Consequently, $X^2_{Gender} = 3$. Therefore, we conclude that the grand slam relationship is much more significant than the relationship that all players are males.

Since the importance of each relationship is proportional to its statistical significance, the weight w_i of the i^{th} feature in Eq. (2) is

$$w_i = \frac{X^2_{f_i}}{\sum_{j=1}^{d} X^2_{f_j}} \tag{8}$$

5 RELATIONSHIP-AWARE QUERYING (RAQ)

The naïve approach to solve a top-k query is to first enumerate all possible subgraphs of the target graph, identify those that are isomorphic to the query, and then rank these isomorphic subgraphs based on their relationship-aware similarity. However, this approach is prohibitively expensive since the target graph contains exponential number of subgraphs. In fact, the problem is NP-complete since finding isomorphic embeddings of a query graph within the target graph reduces to *subgraph isomorphism* [18]. We, therefore, need to design a more scalable searching algorithm.

5.1 Bottom-Up Exploration

We first analyze a bottom-up exploration strategy. First, we pick an arbitrary edge e_q from the query graph q and map it to an arbitrary edge e of the target graph. We call e_q the *seed edge*. This forms an 1-edge common subgraph of q and G. Next, we try to grow it into a 2-edge subgraph by extending both e_q and e through one of their neighboring edges such that the two extended subgraphs are isomorphic and, therefore, a common subgraph of q and G.

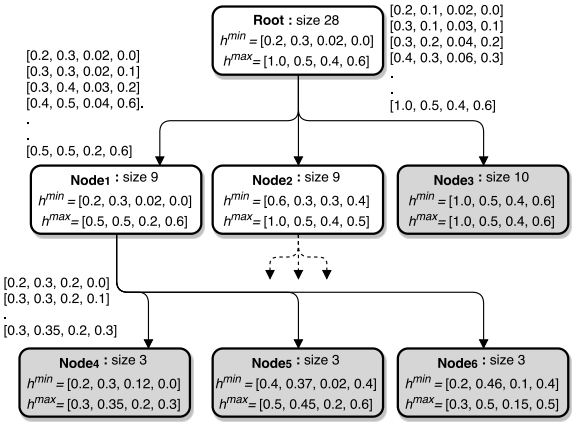

Figure 2: The structure of the R-tree. The leaf nodes are colored in grey. We do not explicitly show the relationship vectors in the leaf nodes due to space limitations.

This procedure of growing using a neighboring edge continues iteratively till either of the following two cases become true:

(1) The subgraph cannot be grown any further such that it remains a subgraph of both q and G. In this case, we fail to find an isomorphic embedding of q.
(2) The subgraph becomes isomorphic to q. We compute its similarity to q and store it as a candidate.

Once the growing procedure terminates, the search restarts by mapping the seed query edge to another edge of G.

Once all possible mappings of the seed edge are explored, we pick another query edge as the seed and repeat the procedure. Finally, the k highest scoring isomorphic embeddings are returned.

The bottom-up exploration is brute-force in nature and explores all possible combinations. However, it offers some concrete directions to improve.

(1) **Seed selection:** Can the seed edge be more strategically selected so that good candidates are found early?
(2) **Seed mapping:** Can the seed edge be mapped to an edge e in the target graph more intelligently so that with a high likelihood an isomorphic embedding is found around e, which is also highly similar to query graph q?
(3) **Pruning bad candidates:** Can a candidate subgraph be pruned early by guaranteeing that it cannot be in the top-k?

5.2 Seed Selection and Mapping

Intuitively, we should explore the mapping that has the highest chance of growing into high-scoring isomorphic match to the query. An obvious approach is to compute edge similarity (Eq. 2) between all pairs of query edges and target graph edges, and choose the most similar pair. The computation cost for this is $O(|E_q| \cdot |E|)$. Since $|E|$ is a large number, we need a more efficient algorithm for this task. The similarity between two edges is essentially a weighted min-max similarity between two high-dimensional points, since each edge is represented by a d-dimensional relationship vector. Indexing high-dimensional points have been extensively studied [9], and we choose R-tree [17] for our framework. R-tree recursively partitions the entire dataset of relationship vectors into *MBRs*.

Definition 4 (Minimum Bounding Rectangle, MBR). *Given a set of d-dimensional relationship vectors, $\mathbb{D} = \{s(e_1), \cdots, s(e_m)\}$, an MBR $\mathcal{H}$ on $\mathbb{D}$ is the smallest axis-parallel d-dimensional hyper-rectangle that encloses all vectors in $\mathbb{D}$.*

An MBR $\mathcal{H}$ can be uniquely represented by the co-ordinates of its *smallest* and *largest* diagonal points h^{min} and h^{max} respectively. More specifically, $h^{min} = [h_1^{min}, \ldots, h_d^{min}]$, where $h_i^{min} = \min_{\forall s(e) \in \mathbb{D}} \{s(f_i, e)\}$, and h^{max} is defined analogously. An example of an R-tree is shown in Fig. 2.

We use the notation $e \in \mathcal{H}$ to denote that the relationship vector $s(e)$ of e is contained within MBR $\mathcal{H}$. Mathematically, this means $\forall i,\ h_i^{min} \leq s(f_i, e) \leq h_i^{max}$. We define the similarity between a relationship vector $s(e_q)$ of an edge e_q and an MBR $\mathcal{H}$ as follows:

$$eSim(e_q, \mathcal{H}) = \max_{\forall e \in \mathcal{H}} \{eSim(e_q, e)\}$$
$$= \sum_{i=1}^{d} w(f_i, e_q) \cdot \max_{s(f_i,e) \in [h_i^{min}, h_i^{max}]} \left\{\Gamma(s(f_i, e_q), s(f_i, e))\right\}$$

Simply put, $eSim(e, \mathcal{H})$ provides the maximum similarity between e and any possible edge contained within $\mathcal{H}$. This similarity value can be used to provide the following upper bound on $\mathbb{D}$.

Theorem 1. *If $\mathcal{H}$ is an MBR on a set of d-dimensional relationship vectors $\mathbb{D}$ and e_q is a query edge then,*

$$\max_{\forall s(e) \in \mathbb{D}} \{eSim(e_q, e)\} \leq eSim(e_q, \mathcal{H}).$$

We use Theorem 1 to search for the most similar edge to the query edge e_q using the *best-first* search. Specifically, starting from the root node, we prioritize all child nodes based on the distance of their MBRs to the query edge. The best child node is then chosen to explore next and the process is recursively applied till we reach a leaf node (MBR without a child). Once a leaf node is reached, we compute the similarity to all nodes in this MBR and retain the highest scoring one. The *best-first* search procedure stops when all MBRs that remain to be explored have a maximum possible similarity smaller than the highest scoring target edge we have found till now. We discuss this more formally in Sec. 5.4.

5.3 Avoiding Local Maxima

While the above algorithm is efficient in locating a similar edge, it is prone to getting stuck in a local maxima. Specifically, searching for similar edges may lead us to a good match in a bad neighborhood (local maxima), and such leads should be avoided. A neighborhood is bad if one or both of the following are true:

(1) The structure around the mapped edges is different.
(2) The distributions of relationships around the mapped edges are different and, therefore, even if an isomorphic mapping is found, the similarity among the mapped edges (relationship vectors) is likely to be low.

Can we avoid dissimilar neighborhoods without explicitly performing isomorphism tests?

Neighborhood Signature: We answer the above question by mapping the neighborhood of an edge into a feature vector such that if two neighborhoods are similar, then their feature vectors are similar as well. This is achieved using *Random Walks with Restarts (RWR)*. RWR starts from a source node and iteratively jumps from

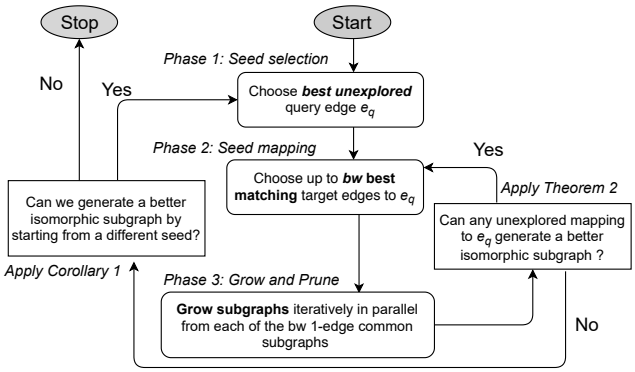

Figure 3: Flowchart of the searching algorithm in RAQ.

the current node to one of its neighbors with equal probability. To bound the walker within a δ-hop neighborhood with a high likelihood, RWR employs a restart probability of $\alpha = \frac{1}{\delta}$. At any given state, with α probability, the walker returns to the source. Otherwise, the walker jumps to a neighbor.

Let e be the edge whose neighborhood needs to be captured. We arbitrarily choose one of the endpoints of e as the source node. RWR is initiated from it and for each edge e' that is traversed, a *counter* $c(e')$ records the number of times e' have been traversed. The RWR is performed for a large number of iterations after which, we compute the *neighborhood signature* of edge e as a d-dimensional feature vector $N(e) = [n_1, \cdots, n_d]$, where

$$n_i = \sum_{\forall e' \in \mathbb{E}} \frac{c(e')}{C} \times s(f_i, e') \tag{9}$$

where $\mathbb{E}$ is the set of all edges visited in the RWR and s is as defined in Def. 2 and C is the total number of iterations.

The signature captures the distribution of relationships around the source edge e. Edges that are closer to e have a higher say. Consequently, the signature not only captures the relationship vectors in the neighborhood, but is also structure sensitive. While it is still possible for two dissimilar neighborhoods to have similar signatures, the chances that two dissimilar neighborhoods produce similar signatures across all d dimensions is small.

We construct the neighborhood signature of all edges in the target graph as part of the index construction procedure. The signatures of the edges in the query graph are computed at query time. The neighborhood hop parameter δ is typically a small value since query graphs for knowledge discovery tasks are normally small [25]. In our empirical evaluation, we set δ to 3.

5.4 RAQ Search Algorithm

Fig. 3 outlines the flowchart and Alg. 1 presents the pseudocode. There are three major phases: selecting the most promising query edge e_q for exploration (*seed selection phase*), identifying the best matching target edges (*seed mapping phase*), and growing subgraphs from these initial seeds in bottom-up manner (*growth phase*).

Before we execute any of the phases, two operations are performed. First, we compute the neighborhood signatures of each edge in the query (line 1). Second, we use a priority queue called *Ans*, which stores the k most similar subgraphs identified till now (line 2). Initially, *Ans* is empty.

5.4.1 Phase 1: Seed Selection. We select the unexplored query edge $e_q \in E_q$ that has the highest similarity to the root node of R-tree (line 5). An edge is *unexplored* if it has not already been selected in this phase in some earlier iteration.

5.4.2 Phase 2: Seed Mapping. We use *best-first search* to find the leaf node in R-tree that has the highest similarity to e_q. In this leaf node, we perform a *beam stack search* [49] with *beam width* bw (lines 13-20). Instead of mapping e_q to the most similar target edge, beam stack search selects the bw target edges that have the highest neighborhood similarity to e_q and explores them further. The *neighborhood similarity* between two edges e_q and e is the weighted L_1 distance between their neighborhood signatures.

$$\text{Neighborhood_Similarity}(e_q, e) = \sum_{i}^{d} w_i \cdot \|N(i, e_q) - N(i, e)\|$$

Recall that w_i is the importance of the i^{th} relation and more important relations have a higher say in defining the neighborhood similarity.

5.4.3 Phase 3: Grow and Prune. Each of the bw edges selected in the previous phase generates a common 1-edge subgraph of the query and the target graph. We now grow them one edge at time to larger subgraphs (line 19). On any such subgraph $g = (V_g, E_g)$ we can apply the following bound.

Theorem 2. *The maximum similarity of any isomorphic match to query graph q formed by growing g further is $\widehat{RAQ}(q, g) = RAQ(q, g) + |E_q| - |E_g|$.*

Proof. The maximum similarity between any two edges is 1 (Eq. 2). Therefore, the maximum similarity contributed from the edges yet to be added is at most $|E_q| - |E_g|$. The theorem follows. □

Corollary 1. *Let e_q be a query edge and $\mathcal{H}$ be an MBR in the R-tree. The maximum similarity of any isomorphic subgraph formed by mapping e_q to any edge contained within $\mathcal{H}$ is $\widehat{RAQ}(e_q, \mathcal{H}) = eSim(e_q, \mathcal{H}) + |E_q| - 1$.*

Equipped with the above upper bounds, we prioritize each of the initial 1-edge common subgraphs based on $\widehat{RAQ}(q, g)$ (Theorem 2). More specifically, we initialize another priority queue PQ and insert all 1-edge subgraphs in PQ (line 14). The subgraph g with the highest upper bound is popped from PQ. We check if $\widehat{RAQ}(q, g)$ is larger than the k^{th} highest similarity score in *Ans* (line 17). If yes, we explore all possible single edge extensions of g to create common subgraphs with one more edge (line 20). If g becomes isomorphic to q after extension, then we add it to *Ans*. Otherwise, we insert it back to PQ (line 20). Otherwise, if the check (at line 17) fails, then we are guaranteed that none of the unexplored subgraphs in PQ can lead to a better solution than what we already have and, hence, Phase 3 completes (lines 7-18).

5.5 Properties of RAQ Framework

Correctness Guarantee: The RAQ framework provides the *optimal answer set*. We do not prune off any possibility without applying

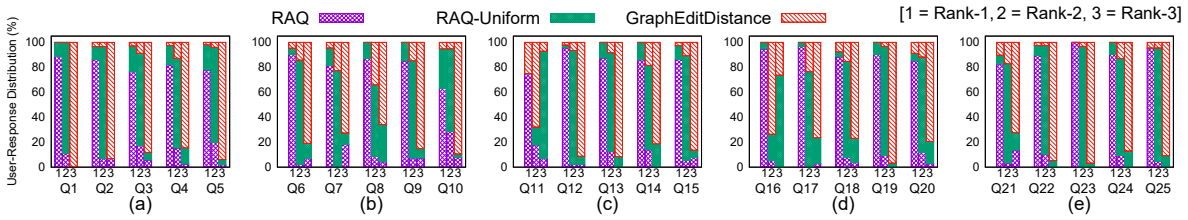

Figure 4: The distribution of the received user responses.

Algorithm 1 RAQ Search Algorithm

Input: $G = (V, E, \mathbb{F})$, $q(V_q, E_q, \mathbb{F}_q)$, k, $RAQIndex$
Output: Top-k subgraphs of G with highest relationship-aware similarity to q.

Compute neighborhood signature for each edge in q
$Ans \leftarrow \emptyset$ {Priority queue of maximum size k. Stores isomorphic matches in descending order of similarity.}
$Cands \leftarrow \emptyset$
while $\exists e \in E_q$, $\widehat{RAQ}(e, rootNode.MBR) > Ans.leastValue()$ and e has not been explored **do**
  $e_q \leftarrow$ unexplored query edge with highest similarity to MBR in root node
  Initialize $Cands$ with the root node of R-tree
  while $Cands$ is not empty **do**
    $n \leftarrow Cands.poll()$
    $max \leftarrow \widehat{RAQ}(e_q, n.MBR)$.
    if $max \leq Ans.leastValue()$ **then**
      break
    if n is a leaf node **then**
      while $\widehat{RAQ}(e_q, n.MBR) > Ans.leastValue()$ and n contains unexplored edges **do**
        $PQ \leftarrow$ Priority queue containing bw unexplored edges with similar neighborhoods to e_q
        while PQ is not empty **do**
          $g \leftarrow PQ.poll()$
          if $\widehat{RAQ}(g, q) \leq Ans.leastValue()$ **then**
            break
          $\mathbb{G} \leftarrow$ Grow g through all possible 1-edge extensions to form common subgraphs
          Add all isomorphic matches in $\mathbb{G}$ to Ans and remaining subgraphs in $\mathbb{G}$ to PQ
    else
      Add all children of n to $Cands$.
return Ans

Theorem 2 or Corollary 1. Consequently, we do not lose out on any candidate that can be in the top-k answer set.

Index construction cost: The cost of constructing the R-tree is $O(d|E|\log(|E|))$. We also compute and store the neighborhood signature of each edge through random walk with restarts. This step can be performed in $O(|V|^2)$ time for the entire graph [43, 46]. Thus, the total computation cost is $O(|V|^2 + d|E|\log(|E|))$.

Memory Footprint: R-tree consumes $O(d|E|)$ space since it stores d-dimensional relationship vectors of all edges. The neighborhood signatures are also d-dimensional feature vectors and hence the total cost is bounded by $O(d|E|)$.

Querying Time: As stated earlier, the problem is NP-complete. Hence, akin to most existing graph search algorithms [18, 22, 25], the worst case running time remains exponential. However, with the application of efficient heuristics and effective pruning bounds, we compute the top-k answer set in milliseconds as elaborated next.

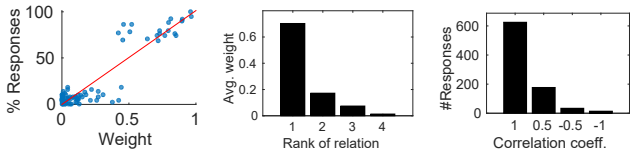
6 EXPERIMENTS

In this section, we evaluate the RAQ paradigm through user surveys, case studies, and scalability experiments.

6.1 Datasets

We consider a mix of various real (large) graphs (Table 1).

• The **IMDb** dataset [5] contains a collaboration network of movie artists, i.e., actors, directors, and producers. Each node is an artist featuring in a movie, and two artists are connected by an edge if they have featured together in at least one movie. Each node possesses 4 features: (i) year of birth, (iii) the set of all the movies the artist has featured in, (iv) the most prevalent genre among his/her movies, and (v) the median rating of the movie set.



• The **DBLP** dataset [2] represents the citation network of research papers published in computer science. Each node is a paper and a directed edge from u to v denotes paper u being cited by paper v. Each node possesses 5 features: (i) publication venue, (ii) the set of authors, (iii) year of publication, (iv) the rank of the venue, and (v) the subject area of the venue. The publication year and venue rank are numerical features while the rest are categorical in nature. The first three features are obtained from the DBLP database while the last two are added from the CORE rankings portal [1].

• The **DBLP (co-author)** dataset [2] represents the co-authorship network of the research papers. Each node is an author of a paper and edges denote collaboration between two authors. Each node possesses 5 features: (i) number of papers published by the author, (ii) the number of years for which the author has been active (calculated as the difference between the latest and the first paper), (iii) the set of venues in which the author has published, (iv) the set of subject area(s) of the venues in which the author has published, and (v) the median rank of the venue (computed as the median of the ranks of all the venues where the author has published). The number of papers published, number of years active, and the median rank are numerical features, while the rest are categorical.

• The **Pokec** dataset [6] presents data collected from an online social network in Slovakia. Each node is a user of the social network and a directed edge $e = (u, v)$ denotes that u has a friend v (but not necessarily vice versa). Each node is characterized by six features: (i) gender, (ii) age, (iii) joining date, (iv) timestamp of last login (v) public: a boolean value indicating whether the friendship information of a user is public, and (vi) profile completion

Table 1: Summary of datasets used in our experiments.

Dataset	# Nodes	# Edges	Type	Mean Degree	# Features
IMDb	88K	781K	Undirected	17.59	7
DBLP	3.2M	6.8M	Directed	2.13	5
DBLP (co-author)	1.8M	7.4M	Undirected	8.44	5
Pokec	1.6M	30.6M	Directed	19.13	6

(a) Weight Correlation (b) Relation Weights (c) Rank Correlation

Figure 5: (a) Correlation between weights and user-perceived relationship importance. Variation in (b) average weights from most to least important relationship, (c) Correlation across user responses.

percentage. While public and gender are categorical features, the rest are numerical.

6.2 Experimental Setup

All experiments are performed using codes written in Java on an Intel(R) Xeon(R) E5-2609 8-core machine with 2.5 GHz CPU and 512 GB RAM running Linux Ubuntu 14.04.

Query graph: Query graphs are generated by selecting random subgraphs from the target graph. Following convention in graph querying [22, 25], we considered queries with size up to 10 edges. All reported results were averaged over 30 random query graphs.

Baselines: To measure the quality of graphs returned by RAQ, we compare its performance to three baselines:

• **RAQ-uniform:** To answer the question whether setting the weight of a relationship in proportion to its statistical significance helps, we implement RAQ-uniform as the setting where all relationships are considered equally important.

• **Graph edit distance (GED):** The *edit distance* between graphs q and g is the minimum *cost* of *edits* required to convert q to g [18]. An edit corresponds to deleting a node or an edge, adding a node or an edge, or substituting a node. Each edit has a cost. Deletions and additions of nodes or edges have a cost of 1. The cost of substituting a node u with v is proportional to the distance between them. We use the *min-max distance* between the feature vectors of two nodes to compute the distance. The replacement cost $rep(u, v)$ is:

$$rep(u, v) = 1 - sim(u, v)$$

$$sim(u, v) = \frac{1}{d}\sum_{i=1}^{d} s_i(u, v) \qquad \text{where}$$

$$s_i(u, v) = \begin{cases} \frac{\min\{f_i(u), f_i(v)\}}{\max\{f_i(u), f_i(v)\}} & \text{if} \quad f_i \text{ is real valued} \\ 1 \quad \text{if} \quad f_i \text{ is categorical and } f_i(u) = f_i(v) \\ 0 \quad \text{if} \quad f_i \text{ is categorical and } f_i(u) \neq f_i(v) \end{cases}$$

$rep(u, v)$ is always within the range $[0, 1]$.

• **Query by example (QBE):** We choose [26] to compare against the QBE paradigm (described in Sec. 2). To make it compatible to our framework, we model the node features as edge labels. Specifically, if u and v are connected in the original network, we introduce d edges between them. The i^{th} edge between u and v corresponds to the i^{th} relationship (feature), and this relationship is captured in the form of edge label by concatenating the feature values $f_i(u)$ and $f_i(v)$. All numerical features are discretized into bins [10] since otherwise, there would be infinitely many edge labels.

Parameters: The default value of k in a top-k query is set to 10. The branching factor in R-tree is $b = 4$.

6.3 User Survey: IMDb Dataset

To assess the relevance of the results retrieved using the proposed RAQ paradigm, we conducted two surveys spanning 170 users each, using collaboration patterns (subgraph queries) from the IMDb dataset. The user-base was carefully chosen to ensure *diversity* in various aspects such as profession (engineers, researchers, homemakers, doctors, business executives etc.), educational background (from undergraduates to doctorates in science, engineering, medicine etc.), gender (approximately equal distribution between females and males), and age (from 20 to 70 years old). Each user was presented with 5 queries randomly sampled from the master query pool, which led to a total of 850 user-responses for each user survey. To enable the users in understanding the tasks better, they were briefed on the capabilities of the RAQ framework and the semantic interpretation of a graph.

Relationship Importance: The first user survey studies whether statistical significance is consistent with human intuition. For this, we constructed a query pool of 20 edges (representing collaboration between two artists) along with their node features. For each query edge, we randomly choose two relationships (features), and the users were asked to identify the relatively more important relationship. A large number, 692/850 (81.4%), of the received user-responses considered the relationship with higher statistical significance to be more important. Considering the null hypothesis that either relationship is equally probable to be chosen as important, this observed outcome possesses a p-value of 1e−74 and is, therefore, highly statistically significant.

Moving ahead, we also analyze the correlation between the weight (normalized X^2 value) of a relationship and the proportion of times the feature is chosen as the preferred one in the survey. Fig. 5a shows that the higher the weight of a relationship, the more likely it is to be chosen as important in the user-responses. This is also indicated by their significantly high Pearson's correlation coefficient [30] of 0.923. Fig. 5b presents the average weight of the k^{th} ranked feature, where k is varied in the x-axis. We observe an exponential decay in weights, with the rank-1 relationship possessing a weight of 0.72 on average. This result, in conjunction with Fig. 5a, shows that the highest ranked relationship has a much higher likelihood of being perceived as important in the user-responses. Overall, this survey provides substantive evidence to support the use of statistical significance in quantifying relationship importance.

Ranking Results based on Relevance: The second survey evaluates the relevance of the results retrieved by RAQ and the three baselines discussed above. For this task, we considered a query pool consisting of 25 query subgraphs (representing group-level artist collaborations) possessing a judicious mix of node features (artist types, prominence, genres, etc.). For each query, the users were presented with top-1 results returned by the four algorithms being studied, and were asked to rank the results based on the user-perceived relevance to the query. To eliminate bias, the mapping of which result comes from which algorithm was masked from the user, and the order of the results presented were randomized. For ensuring simplicity and brevity, each query was annotated with

Table 2: Comparing the quality of RAQ with the considered baselines using both user-level and query-level responses.

Retrieved	User-level Responses (%)			Query-level Responses (%)		
Rank	RAQ	Uniform	GED	RAQ	Uniform	GED
1	**86.0**	10.6	3.4	**100.0**	0.0	0.0
2	10.0	**75.4**	14.6	0.0	**92.0**	8.0
3	4.0	14.0	**82.0**	0.0	8.0	**92.0**

the most important relationship, which was shown to correspond well with human perceived importance in the first survey.

Interestingly, across all 25 queries, QBE returned an empty answer set since it did not find any subgraph from IMDb, other than the query itself, which had nodes connected by the same relationships as in the query. This result is not surprising. As we discussed in Sec. 2, QBE operates in a binary world where two relationships are either identical or different. This result indicates that while QBE is an intuitive and powerful framework for relationship-annotated knowledge graphs, it is not well-suited for graphs where the relationships are encoded through interactions between feature vectors characterizing each node. Owing to this result, the user survey reduced to a comparison among three techniques.

Table 2 summarizes the user responses and in Fig. 4, we plot the distribution of the received responses within each retrieved rank for each query. An overwhelming 731 (86%) of the 850 received user responses deemed RAQ results to be the most relevant (rank-1 match) to the input query. Considering the null hypothesis where any one of the three results is equally likely to be chosen as the preferred one, this observed outcome is highly statistically significant (p-value of 2e−232). Moving beyond the analysis of rank-1 responses, we observe a high rank-correlation between the user-responses and the expected outcome, i.e., RAQ, RAQ-Uniform, and GED at ranks 1, 2, and 3 respectively, indicated by the average Spearman's coefficient $\rho = 0.803$ [39]. It is evident from Fig. 5c that $\approx 74\%$ of the user-responses perfectly match the expected output ranking with $\rho = 1$.

In addition to analyzing the user-level responses, we performed a query-level analysis as well. Specifically, for each query-rank combination, we identified the algorithm preferred by the highest number of users. As is clear from Table 2, RAQ results were considered to be the most relevant (rank-1) for all 25 (100%) queries.

6.4 Case Study: DBLP Dataset

In this section, we showcase results from the DBLP co-author dataset and discuss how RAQ is able to identify relationship patterns that node-based distance measures like GED are unable to. Each node in this experiment is characterized by three features, *number of papers published*, *median venue rank*, and *subject area*. The subject area corresponds to the area of the venue where the author has published most of her works.

The query presented in Fig. 6a represents a collaboration pattern comprising prolific authors working in the field of *data mining*. Fig. 6b presents the matched subgraph by RAQ, which is a collaboration pattern among prolific authors working in the field of *databases*. As can be seen, all authors in Fig. 6b possess the median venue rank as "A*" and the subject area as "DB". It is evident that RAQ captures the relationship that each group contains prolific authors from the same community. The result presented in Fig. 6b is not even within the top-10,000 matches produced by GED. This is natural since the two groups do not contain similar nodes.

Fig. 6c demonstrates RAQ's ability to adapt with the query. More specifically, while the subject area was a preserved relationship in query 1, query 2 presents collaborations among authors with high paper counts, but from diverse backgrounds. The result, Fig 6d, is a collaboration pattern among authors from diverse backgrounds as well, but all prolific with a large number of papers.

Correspondence between RAQ and edit distance: In this section, we show that RAQ retrieves results that node-based techniques are unable to find. We perform a top-5 query on random query graphs with sizes varying from 3 to 10. For each of the top-5 RAQ results, we find its rank using GED. We plot the average rank in GED for each of the query graph sizes (Fig. 7a). Since it is hard to scale beyond top-10,000 in GED, if a RAQ result does not appear within top-10,000, we set its rank to 10,000. The GED rank of the top-5 RAQ matches is close to 10,000 on average. This behavior is not a coincidence. Node-based similarity functions match graphs by considering each node as an independent entity and remains blind to the patterns found when the nodes are considered as a group. Consequently, they miss out on similarities that RAQ is able to discover.

6.5 Efficiency and Scalability

We next compare the running time of RAQ with RAQ-uniform and QBE [26] (Fig. 7b). We omit GED since for query graphs sizes beyond 5 it is impractically slow. RAQ is up to 5 times faster than QBE which suffers due to replication of each edge d times corresponding to d relationships. RAQ is faster than RAQ-uniform, since in RAQ, the relationships weights are skewed. Hence, pruning strategies are more effective than RAQ-uniform, where all relationships are equally important.

Fig. 7c demonstrates the growth of querying time against query graph size. As expected, the growth of is exponential since the search space grows exponentially with query graph size. Nonetheless, RAQ limits the running time to a maximum of only 5 s.

Notice that RAQ is fastest in Pokec even though Pokec is the largest network containing more than 30 million edges. The variance in feature values in Pokec is low. Consequently, the chance that a randomly picked subgraph is identical to the query is larger. Owing to this property, the search for the query graph converges quickly. Overall, these results establish that RAQ is a fast and practical search mechanism.

Next, we study the impact of target graph size on the querying time. For this experiment, we extract four different subgraphs of the entire network covering 25%, 50%, 75% and 100% of the nodes (and all edges between them) of the entire network (Figs. 7d, 7e) In DBLP, the querying time increases with increase in target graph size. In Pokec, we do not observe a similar trend. Since we employ best-first search, the search procedure stops as soon as the upper bound of an unexplored candidate is smaller than the k^{th} most similar subgraph we have already found. While an increase in target graph size increases the search space, it also enhances the chance of the k^{th} subgraph being more similar and therefore an earlier termination

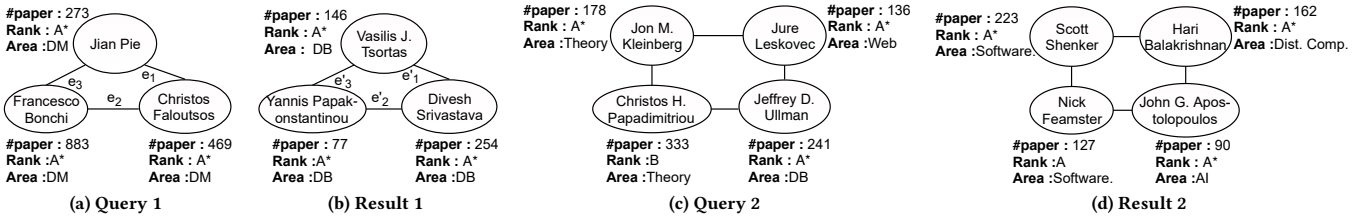


Figure 6: Matched subgraphs by RAQ.

(c) Growth of querying time against query graph size and (d-e) target graph size. (f-g) Impact of target graph size on queries of various sizes. (h) Growth of querying time against k. (i-j) Growth of index construction time against network size.

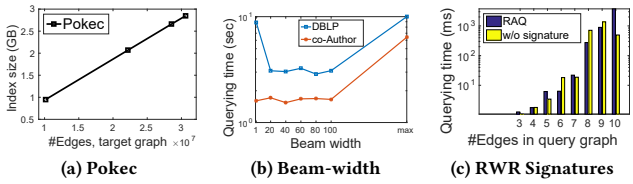

Figure 8: (a) Growth of RAQ's memory footprint against network size. Impact of (b) beam width and (c) neighborhood signatures on querying time.

of the best-first search. Due to this conflicting nature of our search operation, we do not see a consistent trend in the running time against the target graph size.

Figs. 7f and 7g study the impact of query graph size on the querying time. In general, we see any upward trend in the querying time as the size of the query graph increases.

Fig. 7h presents the variation of querying time across various values of k. We notice that the querying time flattens out very rapidly. This is due to the fact that the number of subgraphs explored till the answer set converges remains relatively same even for larger values of k.

Indexing Costs: Figs. 7i, 7j present the results of indexing costs on DBLP and Pokec. Even on Pokec, which contains more than 30 million edges, RAQ completes index construction within 33 minutes. RAQ index structures have a linear space complexity as reflected in Fig. 8a where we depict the memory footprint.

6.6 Optimization

The efficiency of the search algorithm RAQ is dependent on two major components: *neighborhood signatures* for identifying similar neighborhoods and *beam-stack search* to grow and prune initial candidates. In this section, we analyze their impact on RAQ.

Beam-width controls the number of simultaneous subgraphs we grow to form isomorphic matches to the query. We vary this parameter and plot the corresponding querying times in Fig. 8b. A beam width of 1 reduces to depth-first search, where an initial bad choice needs to be explored till the end before moving to a different one. A larger beam width allows other promising candidates explored earlier. A very large value, however, keeps switching too often among the candidates. Overall, a beam width between 40 and 60 provides the highest speed-up.

We study the importance of neighborhood signatures. We compare the time taken for top-k search using two techniques: RAQ with neighborhood prioritization through signatures and RAQ without neighborhood prioritization. Fig. 8c presents the results in the Pokec dataset. We observe that for smaller query graphs, RAQ without neighborhood optimization performs better. However, for larger query graphs neighborhood, typically, optimization helps. For smaller query graphs, the neighborhood of a query edge itself is very small and, thus, they lack much discriminative information. When the query size grows, the neighborhood of an edge is larger and the chances of getting stuck in a local maxima increases. Signatures allows us to escape these regions.

7 CONCLUSIONS

In this paper, we addressed the problem of graph querying under a novel *Relationship-Aware Querying (RAQ)* paradigm. RAQ captures the relationships present among nodes in the query graph and uses these relationships as an input to the similarity function. Majority of the existing techniques consider each node as an independent entity and, hence, remain blind to the patterns that exist among them when considered as a whole. RAQ not only mines these patterns in the form of relationships but also weighs their importance in proportion to their statistical significance. An overwhelming majority of 86% of the users surveyed preferred RAQ over existing metrics. To address the computational challenges posed by graph querying, we designed a flexible searching algorithm, which performs beam-stack search on an R-tree to prune the search space. Empirical studies on real-world graph datasets established that RAQ is scalable and fast. Overall, RAQ opens a new door in the graph querying literature by surfacing useful results that would otherwise remain hidden.

ABSTRACT

Dynamically extracting and representing continually evolving knowledge entities is an essential scaffold for grounded intelligence and decision making. Creating knowledge schemas for newly emerging, unfamiliar, domain-specific ideas or events poses the following challenges: (i) detecting relevant, often previously unknown concepts associated with the new domain; and (ii) learning ontological, semantically accurate relationships among the new concepts, despite having severely limited annotated data. To this end, we propose a novel LSTM-based framework with attentive pooling, BOLT-K, to learn an ontology for a target subject or domain. We bootstrap our ontology learning approach by adapting and transferring knowledge from an existing, functionally related source domain. We also augment the inadequate labeled data available for the target domain with various strategies to minimize human expertise during model development and training. BOLT-K first employs semantic and graphical features to recognize the entity or concept pairs likely to be related to each other, and filters out spurious concept combinations. It is then jointly trained on knowledge from the target and source domains to learn relationships among the target concepts. The target concepts and their corresponding relationships are subsequently used to construct an ontology. We extensively evaluate our framework on several, real-world bio-medical and commercial product domain ontologies. We obtain significant improvements of 5-25% F1-score points over state-of-the-art baselines. We also examine the potential of BOLT-K in detecting the presence of novel kinds of relationships that were unseen during training.

1 INTRODUCTION

Ontologies, taxonomies or knowledge graphs represent an effective way of organizing massive amounts of real world information into a structured format. In particular, domain-specific ontologies are valuable resources that formally model the conceptual vocabulary of a given domain. Building accurate ontologies from trustworthy sources [36, 51, 65, 66, 69] with sufficient coverage of concepts and relationships among them is time-consuming and labor-intensive. A number of approaches to automate this process have been proposed. For instance, building ontologies based on statistical, linguistic and graphical features [45, 68, 76]; enriching existing ontologies with domain-specific information [63]; and embedding-based methods to complete knowledge graphs [2, 23, 31, 47, 61, 62, 70, 73, 79, 80]. Nevertheless, they only utilize textual corpora and other accompanying information from the specific domain under consideration. They do not leverage the abundant, hierarchically structured knowledge that might be available in functionally and/or semantically *similar* or *related* subjects or domains. This is especially valuable in fields ranging from epidemiology to crisis response, and from bio-medicine to commercial product catalogs, where emerging knowledge can be frequent and crucial. For instance, there is no semantically coherent ontology associated with the recently surfaced human disease of *Zika fever*, knowledge of which is evolving to-date. It will therefore be highly useful to take advantage of its connections to similar vector-borne diseases like *Dengue* or *Malaria*, for which well organized and annotated information from domain experts is available. Further, there are multiple challenges associated with building comprehensive ontologies for e-commerce product platforms [11, 29]. Numerous closely related product catalogs often have incomplete or incorrectly labeled attributes. Using annotations from semantically similar product listings (such as products from the same category) can help embellish existing listings with missing attributes, as well as detect errors in the labeled attributes. In our work, we *bootstrap* the task of learning ontologies for novel domains or subjects, by adapting and *transferring* existing knowledge from related domain ontologies. This also alleviates the requirement of human expertise to obtain sufficient labeled data on the newly emergent subject.

A crucial task in constructing ontologies is learning hierarchical relationships among multiple concepts from unstructured text. This task requires large amounts of annotated training data associated with ontological concepts and their corresponding relationships. This process is time-consuming, expensive, and necessitates a significant amount of expert knowledge to categorize associations in niche domains that a layperson is unlikely to know about. To resolve this issue, Mintz et al [42] heuristically aligned texts with knowledge graphs via distant supervision to automatically generate training examples. Lin et al [32] applied distant supervision with sentence-level selective attention, while Zeng et al [79] coupled it with multi-instance learning to learn relationships. However such efforts either do not address the problem of the highly imbalanced occurrence of different relationships [53], or require a sizable number of sentences connecting related entities. Another popular strategy to address the issue of insufficient labeled data is *data augmentation*. This technique artificially expands labeled training

sets by generating new data points or transforming the existing ones, such that the class label properties are preserved [22, 35, 52].

In this paper, we propose a framework *BOLT-K* – Bootstrapping Ontology Learning via Transfer of Knowledge. It uses a long short term memory (LSTM) neural network with attentive pooling, to learn an ontology hierarchy for a given *target* domain. We first obtain all the concepts that constitute the target ontology. We subsequently devise an approach based on semantic and topological attributes to identify the concept pairs likely to be connected by a relationship, and eliminate the remaining spurious combinations. To address the issue of limited relationship-labeled training data, we utilize publicly available textual corpora and ontological information from a functionally similar *source* domain. We also employ data augmentation techniques to generate additional training examples for the target domain. We train our model jointly on the target and source hierarchy information, by sharing the hidden feature representations and appropriate model parameters among them. Finally, we predict ontological relationships between the concepts of the target domain, to construct an ontology for it. We extensively evaluate our framework on several real-world datasets, highlighting the transferability of concepts across comparable subjects. We show that BOLT-K can significantly improve the quality of learned ontologies over state-of-the-art baselines, when bootstrapped with relevant knowledge from a similar subject or domain.

To summarize, the key contributions of our work are:

- We develop a flexible and generalizable framework, BOLT-K, to automatically learn ontologies for contemporary novel or emergent sub-domains of rapidly evolving fields such as bio-medicine, epidemiology, e-commerce and crisis response.
- We propose to transfer existing knowledge from functionally similar domains, and augment the insufficient labeled target training data. This significantly lessens the need for manual expertise during model development and training.
- We extensively evaluate BOLT-K on real-world datasets for various sub-domains within bio-medicine and product graphs. We also show BOLT-K's capability in detecting novel types of relationships that were unseen during training.

2 RELATED WORK

The following lines of research are related to our work: (i) augmentation of textual training data; (ii) learning ontological relationships; and (iii) transfer learning for natural language processing tasks.

Training data augmentation: This is a common and successful technique in the image processing literature [12, 52, 55], and is slowly gaining popularity in NLP applications [22, 35, 52]. A caveat though, is that supplementing text data via transformations, interpolations or affine perturbations is not as straightforward as performing these enhancements for images. Kafle et al [24] proposed two methods of data augmentation for visual question answering: (i) using semantic segmentation annotations with labels to synthesize certain kinds of questions; and (ii) training a stacked LSTM model to generate questions about images. A common technique of augmenting text is to replace words or phrases with their synonyms from a thesaurus [82], or with appropriate n-grams from a language model [52]. Another technique is to translate sentences into a second language, and then translate them back into the original language to obtain a slight variation of the original sentence [13, 54, 71]. Progress has also been made in developing generative models based on variational autoencoders for sentence generation [7, 21, 58]. In this work, we employ a combination of text substitutions for data augmentation, as specified in Section 4.2.

Relation Extraction: Deep learning models such as convolutional neural networks (CNNs), recurrent neural networks (RNNs) and graph-RNNs have been successful in automatically learning features for extracting semantic relations between a pair of entities [49, 57, 72, 79]. A number of approaches have also employed attention mechanisms in conjunction with RNNs for relation extraction and classification [32, 84]. Another way of solving this problem is by formulating it as a link prediction problem in knowledge graphs [2, 23, 31, 47, 61, 70, 73]. Since our method addresses relation extraction at the level of a sentence or a group of sentences, we find that a bidirectional LSTM with attention-based pooling works well for our purpose. Similar to our work, there have been efforts to extract relations with an insufficient number of labeled examples per relationship type. Yuan et al [78] formulated this as a one-shot classification problem and solve it using a convolutional siamese neural network. Levy et al [30] turned it into a reading comprehension problem by associating multiple textual questions with each relation type and learning answers for them.

Transfer learning: Zhang et al [81] have surveyed various cross-dataset transfer learning techniques. This includes the kind of knowledge transfer paradigm that our work addresses, i.e. minimizing the generalization error in the target domain with the help of training instances from two disjoint source and target domains. Transfer learning has been highly useful in low-resource domains such as bio-medicine [26, 40]. Ganin et al [17] introduced a representation learning approach for domain adaptation by adding a gradient reversal layer in a feed forward neural network. They trained their model on a document sentiment classification task using labeled data from a source domain and unlabeled data from a target domain. Long et al [34] presented another approach that learns an unsupervised residual function to adapt classifiers from a source domain to a target domain. Similar to our work, prior efforts addressed the sharing of structural parameters across multiple task domains [1]. Yang et al [74] developed a framework for three different types of transfer learning paradigms in hierarchical RNNs for a sequence tagging task; namely cross-domain, cross-application and cross-lingual transfer. Knowledge transfer has also been used to inform inter-related NLP tasks such as named entity recognition, part-of-speech tagging, chunking and word segmentation [9, 48].

3 PROBLEM FORMULATION

We propose to learn an ontology for a *target* domain for which labeled information is very limited, by transferring potentially useful semantic and ontological knowledge from a distinct but related *source* domain. We refer to each element of the ontologies associated with these domains as an *entity* or a *concept*.

The inputs to our problem are:

(1) A knowledge ontology S consisting of entities, categories and labeled relationships S_R among them, for a source domain

(2) A small number of concept pairs that will be part of the ontology T for the target domain. These have been labeled with their respective relationship type from a set of target relationship types T_R. Since the target is an emergent domain with little to no labeled information available, we only require at least one labeled concept pair per relation type in T_R. Note that though S and T are from related domains, there may or may not be relationship types common to both S and T. This is not a requirement for our method.

(3) Corpora of text documents whose sentences contain occurrences of the concepts in S and concepts associated with the target domain, which are to be part of T. These documents can either be expert-authored such as research papers, or can be from public resources such as news articles or encyclopedias. We utilize the text corpora associated with the target domain to extract the set of concepts to be inserted into T, as explained in Section 4.1.

We extract the sentences containing co-occurrences of the concept pairs linked by relationship types in S_R as part of training data from the source. However, it is unlikely for a whole lot of information to be available about the emergent, target domain concepts in the corpora. Thus as part of the target training data, we restrict BOLT-K to use at least one and at most five labeled instances per relationship type in T_R. These would contain co-occurrences of a small number of target concept pairs. We employ data augmentation techniques to enhance this limited amount of training data (Section 4.2). Our BOLT-K approach thus makes use of (i) the abundant labeled relationship information from S and; (ii) the minimal amount of labeled relation information from T, to learn relationships between various pairs of concepts for the target domain.

4 THE BOLT-K FRAMEWORK

In this section we describe our proposed BOLT-K approach (Figure 1). Among the set of concepts that are to be part of the target ontology T, we first identify the pairs of concepts that are likely to be related to each other in T, and filter out the remaining spurious pairs. Next, we augment the limited number of available training instances that are labeled with the target relationships from T_R. We then use this dataset along with the annotated information from S to learn the relations between the remaining target concepts in T. The identified concept pairs for T and the relationship types between them that have been predicted by our model can be used to construct a complete ontology for the target domain T.

We now describe each step of our BOLT-K framework in detail.

4.1 Filtering Unrelated Target Concept Pairs

This is the first step of our algorithmic pipeline. We acquire the entity and category concepts from the given source ontology structure S. We assume for the purpose of simplification, that a list of the concepts that need to be a part of the target ontology T has been provided to us by a domain expert. Alternatively, we can also use emerging entity extraction algorithms [10, 14] to locate and extract concepts from the target text document corpus. This corpus can consist of news reports, laboratory records or research articles authored by domain experts, related to the target topic. It is highly inefficient (quadratic complexity) and unnecessary to consider all

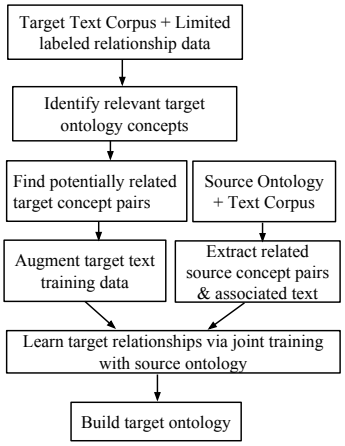

Figure 1: Pipeline of our BOLT-K framework

possible pairs of target concepts while learning relationships between them. Hence, our next step is to identify the concept pairs likely to be linked by a relationship and filter out the remaining pairs. Our empirical investigations (Figure 3) show that using only semantic information is insufficient to capture the likelihood of a relationship between pairs of target concepts. Hence, we also incorporate structural information by modeling the target concepts as a graph. We construct a weighted concept graph T_G, whose nodes consist of the concepts that are to be a part of the target ontology T. We link two nodes by an edge if they have co-occurred together at least once in a document in the target text corpus, within W words of each other. Inspecting a sample of documents in our corpora showed that related concepts often co-occur not in the same sentence, but in consecutive sentences. Since the length of an average sentence is about 10-12 words, we use $W = 25$ to indicate adjacent sentences. The weight of an edge is given by the pointwise mutual information (PMI) between the two concept nodes of the edge:

$$PMI(c_1, c_2) = log\Big(\frac{num(c_1, c_2)}{num(c_1) \cdot num(c_2)}\Big)$$

where $num(c)$ (or $num(c_1, c_2)$) is defined as the number of occurrences of a particular concept (or co-occurrences of a pair of concepts within W words of each other) in the target text corpus.

The PMI metric semantically gives us a good sense of the possibly related target concepts. Nevertheless, it yields a number of false positives which we seek to eliminate, by utilizing additional topological properties of the concept graph. We examine if the local neighborhood of a concept is a sufficient indicator of its potential relationships. However, we empirically find that local structural information is insufficient to account for concept relationships (Figure 3). Therefore, we employ a more global measure for this purpose that takes into account the overall concept graph topology, namely edge-based random walk betweenness centrality [46] (also called current-flow betweenness centrality [3]). For each edge in the weighted graph T_G, it measures approximately how often a node is traversed by a random walker going from any node in the network to another. If a concept c_1 appears often on random walks from concept c_2, then it is likely to be related to c_2. Finally, we learn a global threshold based on the betweenness centrality values, and

consider only those target concept pairs as potentially related if their edge betweenness centrality value is above the threshold.

We now have the set of source concept pairs that are related via labels in S_R to each other from the source ontology S. We have also obtained the set of target concept pairs that are likely to be related to each other and which will form the target ontology T. We now generate a training dataset for both the source and target domains, which will serve as input to the next step of BOLT-K's pipeline, i.e. learning the relationship between the pairs of target concepts. From the source and target document corpora, we extract sentences or blocks of sentences in which potentially related concepts co-occur within W words of each other. Henceforth, for ease of understanding, we call a group of W consecutive words a *sentence*, even though they may physically span more than one sentence of text. We mark the occurrences of the related concepts or entities in each sentence. As mentioned earlier, the target dataset may not have an abundant amount of labeled data available. To account for this, we limit BOLT-K to use at most 5 labeled concept pairs (and hence at most 5 sentences containing them) per target relationship type for training.

4.2 Data Augmentation for the Target Domain

A crucial requirement of building a predictive model is the availability of a sufficient amount of labeled training data for the relationship types of the target domain. Hence, to control generalization error and avoid overfitting to the limited training data available, we adopt the technique of *training data augmentation*. It artificially enhances labeled training datasets by transforming the available data items such that the class label properties are preserved. This lends a major advantage to our approach, i.e. the ability to transfer properties from one taxonomic hierarchy to another at no additional annotation cost. Some effective methods of performing text data augmentation with minimal human effort could be to create sentence paraphrases, or to substitute specific words or phrases with likely candidate words (e.g. synonyms). In our work, we augment the relationship-annotated target training sentences by replacing chosen words in them. We want to do this as diversely as possible, such that the syntactic and semantic equivalence between the original and altered sentence is maintained. Inspired by Ratner et al [52], we first identify the noun, verb and adjective terms in the target training sentences using the StanfordCoreNLP part-of-speech tagger [39]. We filter out the terms that do not occur above a learned frequency threshold. Out of these selected terms, we then iteratively sample a term occurring to the left, in between, and to the right of a pair of entities or concepts in each target sentence for substitution. We do not replace more than two terms in a single sentence at a time, to preserve the meaning and grammatical correctness of the modified sentence. We replace the chosen terms in the following three ways.

The first is by constructing an n-gram language model [52]. It is built by recording the frequencies of n-gram occurrences in the source and target corpora, filtering out the less frequent n-grams, and applying Laplace smoothing to the n-gram counts. This model samples words conditioned on the words preceding them. It identifies the n-gram n_x preceding the word or phrase x to be replaced. It then finds from the corpora a list of terms l_x, following n_x, sorted in descending order based on frequency. It finally replaces x with the term at index i in l_x. i is picked based on a geometric distribution $P[i] \sim p^i$, where a more frequent term has a higher probability of being chosen as a substitute [83]. The value of p is fixed at 0.5. The n-gram model falls back to using bigrams (or unigrams), in case the required trigram (or bigram) was filtered out.

For our second technique, we replace the chosen words in each sentence with one of their synonyms from their synset gloss in WordNet [15]. Since synonyms in a gloss are ranked according to how frequently they are observed in natural language, we use a similar geometric distribution as mentioned above to pick a synonym substitute. For our third substitution strategy, we use a pre-trained word2vec [41] word embedding model induced on texts from PubMed, PMC and the English Wikipedia [43]. After obtaining vector representations for each of the terms to be replaced, we substitute them with the terms most similar to their vector representations in the embedding space. We present a comparative evaluation of the three augmentation strategies in Table 3. Once we enhance the labeled dataset for the target domain, we use this data in combination with the labeled examples from the source domain to train the core model of BOLT-K, as described in Section 4.3.

4.3 BOLT-K Core Model

We now introduce the core model architecture of BOLT-K. It utilizes human-annotated knowledge on ontological concept relationships from a source domain, and minimally labeled and artificially augmented data from a functionally similar target domain, to learn a hierarchical ontology for the target domain. We build an LSTM-based model with attentive pooling to learn an ontology for the target concepts. We transfer ontological relationship knowledge from the source to the target domain in this model, by sharing the hidden layer representation and some of the model parameters between the two domains. We also combine the objective functions of both domains for effective training. Such models have been used in the literature for transfer learning in various applications [74, 81].

4.3.1 Base Model Components. Figure 2 presents an overview of the core model of our proposed BOLT-K framework. It consists of two parts: a *base* model architecture which is shared among both the source and target domains, followed by domain-specific neural network layers. We first describe each of the base model components in detail.

The input to our model is a set of sentences obtained from the source or target text corpora. Each sentence consists of n words $[x_1, x_2, ..., x_n]$. These words include a pair of ontology entities linked by a relation label. Recent literature (e.g. [16, 25, 64, 67, 77]) has seen immense success in transforming words into high-dimensional embeddings for diverse applications. The next layer of our model is thus an embedding layer, which represents every input word x_i as an embedding d_i. d_i is formed by concatenating the character-level representation of x_i with its word embedding from a pre-trained word2vec model [43]. This word2vec model has been trained on texts from PubMed, PMC and the English Wikipedia. Words which lack embeddings in the word2vec model are given a random representation. We obtain the character-level representation of each word using a CNN. CNNs have been shown to encode useful morphological information like word prefixes and suffixes from the characters of a word [8, 37, 56]. Our CNN model consists

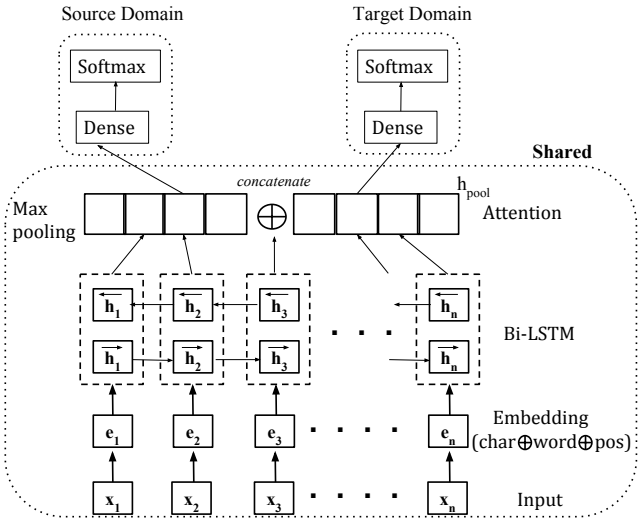

Figure 2: Proposed BOLT-K model architecture

of a convolution layer followed by dropout and max pooling. Its input is randomly initialized for each character of a given word x_i, and its output is a character-level representation of x_i. We form a final embedding e_i by appending two additional position indicators to each d_i. These are the normalized word-distances of word x_i from both the related concepts in their respective sentence. The embedding matrix $[e_1, e_2, ..., e_n]$ is updated during model training and serves as input to the next layer, i.e. the bidirectional LSTM.

Bidirectional LSTM [18] based models are used for a variety of sequence modeling tasks where it is often beneficial to utilize both the past and future context. These networks extend the traditional uni-directional LSTM [20] units that only consider past sequential information, by accounting for temporal context information from future time steps. At the core of the LSTM unit is a memory cell controlled by three sigmoidal gates: the input gate i_t deciding whether the unit retains its current input x_t or not, the forget gate f_t to enable the unit to forget its previous memory context c_{t-1}, and the output gate o_t controlling the context transferred to the hidden state h_t. The recurrences for the LSTM are defined as:

$$\begin{aligned} i_t &= \sigma(W_i x_t + U_i h_{t-1} + b_i) \\ f_t &= \sigma(W_f x_t + U_f h_{t-1} + b_f) \\ o_t &= \sigma(W_o x_t + U_o h_{t-1} + b_o) \\ c_t &= f_t * c_{t-1} + i_t * \tanh(W_c x_t + U_c h_{t-1} + b_c) \\ h_t &= o_t * \tanh(c_t) \end{aligned}$$

where σ is the sigmoid function, tanh is the hyperbolic tangent function and $*$ represents the product with the gate value. W, U and b are matrices of network parameters to be trained. As shown in Figure 2, the Bi-LSTM layer combines its forward ($\overrightarrow{h_t}$) and backward ($\overleftarrow{h_t}$) sequence contexts using the concatenation operation ($\oplus$). The output h_t of this layer at time step t is given by:

$$h_t = \overrightarrow{h_t} \oplus \overleftarrow{h_t}$$

The Bi-LSTM layer generates a sequence of word-level representations $[h_1, h_2, ..., h_n]$ utilizing past and future context, where $h_{j,t}$ denotes the j-th element of h_t. We perform one-dimensional max pooling to obtain a fixed length vector from the Bi-LSTM output.

$$m_{pool,j} = \max_{1 \le t \le n} [h_{j,t}]$$

The max pooling operation assumes that the important and relevant latent semantic features in the sentence are present at the positions [28] containing the maximum value of h_t. However, this might not always be the case. Hence, to focus on words that are crucial in predicting the relationship between entities which might lie anywhere in a sentence, and to give less importance to irrelevant information in the sentences, we utilize an *attention* mechanism. It highlights the important tokens in a given input sequence, which are responsible for performing feature selection for the model as well as for its predictions. Inspired by Yang et al [75], we introduce a word-level attention layer to capture the similarity of a word token with respect to its neighboring context tokens in an input sequence. It assigns weights to the hidden outputs h_t from the Bi-LSTM layer as follows:

$$\begin{aligned} z_{j,t} &= \tanh(W_z h_{j,t} + b_z) \\ \alpha_{j,t} &= \frac{exp(W_a^T z_{j,t})}{\sum_t exp(W_a^T z_{j,t})} \\ att_{pool,j} &= \textstyle\sum_t \alpha_{j,t} h_{j,t} \end{aligned}$$

Here, W_z and b_z are the weight matrix and bias vector respectively associated with the hidden state h_t from the Bi-LSTM layer, and $h_{j,t}$ represents the j-th sentence. Their non-linear transformation yields z_t, for which W_a is the corresponding weight matrix. $\alpha_{j,t}$ are the normalized attention weights representing token importances from a softmax function at time step t. $att_{pool,j}$ is the attention-focused hidden state representation, given by the linear combination of the Bi-LSTM output h_t and the attention weights.

The final output of the base model $h_{pool,j}$ is the concatenation ($\oplus$) of the outputs of the max pooling layer and the attention layer.

$$h_{pool,j} = m_{pool,j} \oplus att_{pool,j}$$

4.3.2 Knowledge Transfer Components. All the layers in the base model described in Section 4.3.1, namely the input, embedding, bidirectional LSTM, attention and pooling layers are shared and informed by training data from both the source and target domains. The output from the base model or the shared block in Figure 2 serves as input to two separate fully connected dense layers, followed by two softmax layers, one each for the source and target domains. The softmax function predicts the relationship type between a pair of concepts in an input sentence.

4.3.3 Training. We next outline how we transfer information from the source to the target domain by training our model jointly for both domains. We adopt a training procedure similar to that described by Yang et al. [74]. At each iteration, we sample one of the domains from the source and target based on a binomial distribution, where the binomial probability is a tuned parameter. We then optimize the objective function of the chosen domain by training on a sampled batch of labeled instances. The parameters of the shared block are thus updated due to training inputs from both domains, while the fully connected layers are only affected by their corresponding domain. We repeat this procedure until convergence, with early stopping based on the target domain performance.

We used 200-dimensional LSTM units with L2 regularization in our framework. We optimized the cross-entropy error between the true and predicted labels using Adam [27] with gradient clipping. We set the initial learning rate to 0.001 with a decay of 0.05. Dropout [60] was applied to the Bi-LSTM and pooling layers with a probability value of 0.5. Computational support for all our experiments was provided by the Ohio Supercomputer Center [5].

5 EVALUATION

5.1 Data Collection

We used the Open Biological and Biomedical Ontology (OBO) Foundry [59] and the National Center for Biomedical Ontology portal [44] which are collaborative repositories of science based ontologies, to obtain a family of ontologies related to the bio-medical domain. Each ontology has been curated with the important and relevant concepts associated with its specific sub-domain or subject, as well as the relationship types among the concepts. We also created and used commercial product ontologies from the open-source Web Data Commons project [50]. It contains structured data extracted from the web on different topics. Table 1 shows the statistics of various ontologies we have tested our BOLT-K framework on. These include for each ontology the number of concepts present in it, the number of related concept pairs, the total number of relationship types, and the median number of sentences available for a single relationship type. The first six rows are based on various human diseases and disorders. The next two rows show ontologies of flowering plants (*Angiosperms*) and non-flowering plants (*Gymnosperms*). The final three rows are based on three popular kinds of commercial products that are frequently manufactured, bought and sold, namely, *Earphones, Phones* (mobile phones) and *Television sets*. These ontologies are diverse and contain a total of less than 10K concepts, and less than 20 unique kinds of relationships.

We picked ontologies of sub-domains that are based on related subjects shown in Table 1, and used them interchangeably as both *source* and *target* ontologies to test our framework. For instance, *Dengue* and *Malaria* are both vector-borne diseases transmitted by mosquitoes and share some causes, symptoms and effects, so we use them as a source-target pair. Likewise, *Alzheimers, Multiple Sclerosis, Depression* and *Anxiety* are mental health disorders; *Gymnosperms* and *Angiosperms* are two classes of plant varieties; *Earphones* are an accessory of *Phones*; and *Phones* and *Televisions* are electronic devices sharing some common properties. Hence, we also used these as source-target ontology pairs to test BOLT-K.

As mentioned in Section 3, we require a corpus of text documents containing sentences associated with the concepts in the source and target ontologies S and T. To fulfill this requirement for the bio-medical sub-domains, we used a combination of PubMed [4], PubMed Central (PMC) and the English Wikipedia. For an ontology subject $\mathfrak{C}$, we consider all those articles from PubMed, PMC and Wikipedia as part of a text corpus associated with $\mathfrak{C}$ if they contain the term $\mathfrak{C}$ either in their title or abstract. For the last three rows of product hierarchies in Table 1, we constructed a text corpus from the product information and descriptions extracted from the Amazon Product Dataset [19]. This dataset includes information about the numerous commodities sold online on www.amazon.com.

Table 1: Statistics of various domain ontologies used

Ontology sub-domain name	No. of concepts	No. of concept pairs	No. of relations	Median no. of sentences per relation
Dengue	5035	5923	11	6010
Malaria	2643	3556	11	5070
Alzheimers	5738	5961	2	9602
Multiple sclerosis	9036	11310	2	16518
Depressive disorder	2008	4576	3	3025
Anxiety disorder	1978	4194	3	3637
Gymnosperms	539	502	9	716
Angiosperms	306	302	10	590
Earphones	115	146	11	28
Phones	189	337	16	256
Television sets	72	87	11	8

5.2 Results

5.2.1 Identifying Related Concept Pairs. We first present in Figure 3 the performance of BOLT-K as well as two other baselines on the first step of identifying potentially related concepts for the target ontology, as described in Section 4.1. We consider each ontology in Table 1 as a target ontology.

Our first baseline (yellow bars of *context similarity* in Figure 3) associates a context with each target concept. This is a set of nearby words around the mention of the concept in the target text corpus. If a target concept has multiple mentions (and hence multiple contexts) in the corpus, we pick the context associated with a randomly selected mention. We then compute an embedding for each concept using a normalized term-frequency (*tf*-) weighted sum of the embeddings of its context terms. We use a pre-trained word2vec model [43] to get the term embeddings, ignoring the context terms that do not have embeddings in this model. The *tf*- weights are obtained from the frequencies of occurrence of the chosen context terms, in the available contexts associated with every mention of the target concept. Once we generate an aggregated embedding of each concept, we compute the pairwise cosine similarity between all pairs of concept embeddings. We filter out all those concept pairs that do not have a similarity value above a learned threshold, and consider the remaining pairs as potentially related. Our second baseline (green bars of *2-hop jaccard* in Figure 3) estimates structurally similar concepts as possibly related to each other. It computes the 2-hop Jaccard index between pairs of connected concepts in the concept graph defined in Setion 4.1. For concepts c_1 and c_2, the Jaccard index is given by the number of neighbor concepts common to both c_1 and c_2 and reachable from them in 2 hops, divided by the union of the neighbors of c_1 and c_2. The pink bars of *RWBC* in Figure 3 denote the edge-based random walk betweenness centrality technique used in BOLT-K. The orange portions seen in the last three bars show an overlap between the result numbers of the context-based similarity and the 2-hop Jaccard strategies.

The RWBC measure considers a more global view of the concept graph along with semantic attributes. We find that this causes a marked improvement over merely using either semantic information (the context similarity baseline), or the local structural neighborhood of concepts in the weighted concept network (the Jaccard index baseline). Our random walk betweenness centrality measure

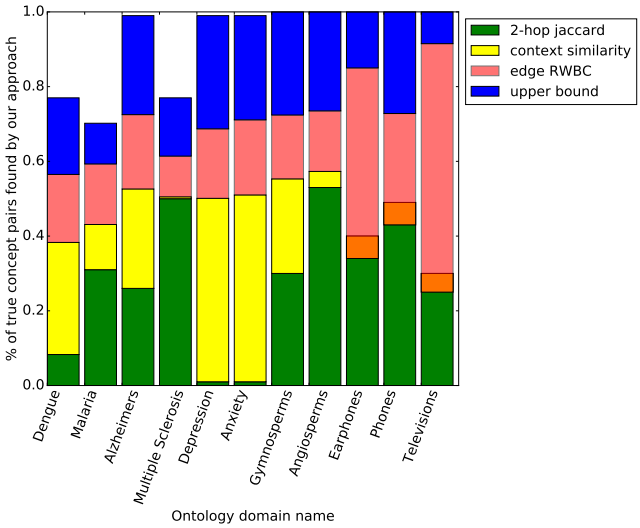

Figure 3: Performance of multiple approaches on identifying the concepts that are to constitute the target ontology

correctly identifies as *related*, about 60-75% of the linked concept pairs for the bio-medical ontologies. For the product hierarchies, it identifies more than 70% of the related concept pairs. We note here that every pair of related concepts that is present in the considered ontologies may not occur in the text corpora, i.e. may not be accompanied by textual information. There is thus a limitation on the number of potentially related concept pairs that can be found by our technique. The blue bars show this *upper bound* on the identifiable pairs of linked concepts for each ontology instance. This value is 76-80% for *Dengue*, *Malaria* and *Multiple Sclerosis*, and nearly 100% for the remaining hierarchies. Changing the scale of the result of BOLT-K's edge-based betweenness centrality strategy based on this upper bound, we observe an accuracy of more than 75% in finding potentially related concept pairs for the ontology instances.

5.2.2 Constructing Domain Ontologies via Knowledge Transfer. To the best of our knowledge, no existing work learns ontological relationships for a new target subject by levering prior knowledge from a distinct but related source subject. Thus, we compare our method with existing state-of-the-art techniques that only use information from the target domain. We evaluate all approaches on the task of ontological relationship prediction for the target ontology in Table 2. We reiterate that BOLT-K *does not* assume that the source and target ontologies have the same types of relationships. It uses at most 5 relationship-labeled concept pair training examples per target domain. We compare BOLT-K with the following baselines:

(1) PCNN-Att [79]: It employs a piecewise CNN with a sentence-level attention mechanism and distant supervision.
(2) Path-Max [80]: It considers CNNs coupled with probabilistic relation paths learnt from the sentences between entities.
(3) BLSTM-Att [84]: It uses a Bi-LSTM model without pooling, and with an attention mechanism different from ours.
(4) ComplEx [61]: It uses low-rank matrix factorization to learn complex-valued embeddings for entities and relations. We found ComplEx to outperform multiple other knowledge graph completion techniques like TransR [31], TransD [23], DistMult [73] and HolE [47], so we report only its results.
(5) BOLT-K ($t_{sr} = 0.6$) - no Att: This is a variant of our model at a target sub-domain data sampling rate $t_{sr} = 0.6$ (the probability of the model being trained on data from the target sub-domain), on using max pooling without attention.
(6) BOLT-K ($t_{sr} = t_{sr}$): The last five rows of Table 2 are variants of BOLT-K at target data sampling rates $t_{sr} = \{0, 0.4, 0.6, 0.8, 1\}$.

The first column of Table 2 shows the different approaches, and the subsequent columns show the ontology datasets. The $S \rightarrow T$ and $S \leftarrow T$ sub-columns for each column $S \leftrightarrow T$ indicate the direction of knowledge transfer, from ontology S to T and T to S respectively for our approach. The 'arrows' have no significance for the other approaches, merely indicating the ontology for which relations are being learnt (T in case of $S \rightarrow T$ and S in case of $S \leftarrow T$). These results have been computed after applying all augmentation strategies from Section 4.2 to the target training dataset.

We observe that BOLT-K obtains a 5-25% F1-score gain over the baselines in learning relationships for the different ontologies, with the best performance at a target training data sampling rate of 0.6. This reinforces our hypothesis of the utility of levering prior source knowledge in learning ontologies for a newly emergent target domain or sub-domain. BOLT-K is outperformed by ComplEx [61] by about 1% and 4% F1 score points respectively on the *Earphone* $\rightarrow$ *Phone* and the *Phone* $\rightarrow$ *Earphone* product ontology pairs. We believe this is because though these two products are somewhat related, their distinct characteristics may falsely inform our model and detract from its performance. BOLT-K performs better on the product pair of *Phones* and *Televisions* which share relatively more common attributes. It is interesting to observe the difference in performance on interchanging the source and target subject ontologies. For example, there is more value in transferring knowledge from the *Phone* to the *Television* domain, compared to the reverse.

We further note that the overall performance of all approaches on the bio-medical ontologies is significantly better than on the commercial product ontologies. A reason for this could be the quality of textual data available. The text descriptions are often quite generic and repetitive across different product relation types (e.g. *"details about apple iphone 6 16gb - at&t - gold - great condition"*). The variation and uniqueness in context and sentence structure is much lesser than the text data for the bio-medical ontology datasets that come from research, news or encyclopedia articles. Since ComplEx [61] utilizes less information from textual descriptions compared to the other methods, it performs better on the product datasets which have lower quality text input. We also analyze the topological structure of the concept graph (from Section 4.1) for the various ontology datasets. We find multiple well-separated connected components in case of the bio-medical ontologies, signifying a higher separability of their relationship categories. However, the product datasets have few (≤ 3) connected components for more than 10 relation categories. This implies that it is harder to distinguish between the product relationship types based on the current information.

5.2.3 Role of Target Training Data Size. Augmenting the limited amount of available target training data is a crucial step in our approach. Figure 4 (top) shows the change in F1-score of BOLT-K at the

Table 2: Baseline F1 scores on the ontology pairs of Dengue ↔ Malaria, Alzheimers ↔ Multiple Sclerosis, Gymnosperms ↔ Angiosperms, Earphones ↔ Phones, and Phones ↔ Televisions. We use at most 5 target training sentences per relation type with data augmentation. t_{sr} is the target sub-domain sampling probability. The first sub-column of every S ↔ T source-target ontology pair denotes knowledge transfer from S → T and the second denotes S ← T (i.e. knowledge transfer from T → S).

Approach	Deng ↔ Mal		Alz ↔ Mult Scl		Depr ↔ Anxi		Gymno ↔ Angio		Earph ↔ Phone		Phone ↔ TV	
	S→T	S←T	S→T	S←T	S→T	S←T	S→T	S←T	S→T	S←T	S→T	S←T

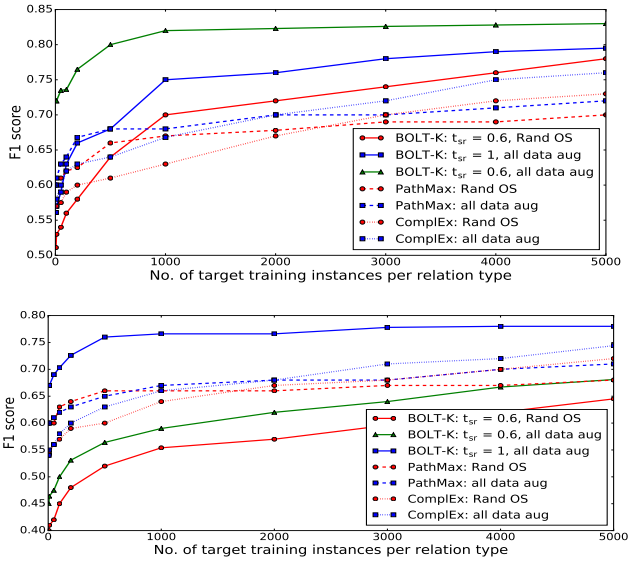

Figure 4: F1-score vs training data size for Dengue → Malaria (top) and Dengue → Angiosperms (bottom) ontology pairs.

target data sampling rates $t_{sr} = \{0.6, 1\}$ for the *Dengue → Malaria* ontology pair. We compare BOLT-K to the best performing baselines from Table 2 (*PathMax* [80] and *ComplEx* [61]), as the number of training instances per relation type are increased. We also show in Figure 4 (bottom) an attempt to learn an ontology for *Angiosperms* using information from a dissimilar and unrelated subject, *Dengue*. The solid, thick dashed and thin dashed line plots denote BOLT-K, PathMax and ComplEx respectively. The red plots use only random oversampling to augment the training data, while the blue and green plots use all strategies in Section 4.2. We observe that in case of *Dengue → Malaria* (top plot), as expected, the F1-score of each model rises with the amount of training data it receives. This gain is particularly significant at the left of the x-axis, from 5 to about 1000 training instances per relation category. Employing better data augmentation strategies than random oversampling contributes to the performance. Transferring knowledge from the source ontology lends us a consistent advantage of at least 5%, even at the maximum number of target training instances per relation type. In case of *Dengue → Angiosperms* (bottom plot), BOLT-K performs the best at $t_{sr} = 1$, i.e. without any input from the unrelated source (blue solid line plot). It obtains a 4% gain over ComplEx at the maximum number of training examples per relation class. However, training input from the dissimilar source *Dengue* causes a performance drop (red and green solid line plots).

We next examine in Table 3 the impact of different data augmentation strategies on the performance of BOLT-K, on the *Dengue → Malaria* ontology pair. We observe similar trends on the other datasets as well. The first two rows show the performance using simple random oversampling and Synthetic Minority Oversampling (SMOTE) [6] on the target training examples, followed by the three augmentation strategies described in Section 4.2. The last row of Table 3 shows that these three strategies complement one another. Employing them all together with random oversampling gives us a performance advantage of about 4-8% over any one of them.

5.2.4 Role of Attention. Table 2 indicates that attentive pooling lends BOLT-K an F1 score gain of nearly 5%. Further drilling down, Figure 5 shows a heatmap of the attention weight values learned by BOLT-K for sentences belonging to different relation types. The cells of the heatmap contain the sentence word they represent. The background color highlights the importance of a word with respect to its neighboring context, and consequently, how it affects our model's decision. The words in boldface are the concept phrases between which a relation is being predicted. For instance, the first row of the heatmap demonstrates that the words 'refers', 'to', and 'a' (dark background) are crucial in deciding the presence of an *is-a* relation between the concept phrases *virion assembly* and *process of dengue virus*. Similarly, in the fifth row, the words 'begins', 'after' and 'follows' influence the detection of the *preceded-by* relation between the concept phrases *incubation period* and *dengue disease course*. These examples show that BOLT-K has correctly learnt the relevant semantics needed to detect ontological relations between emergent concept phrases.

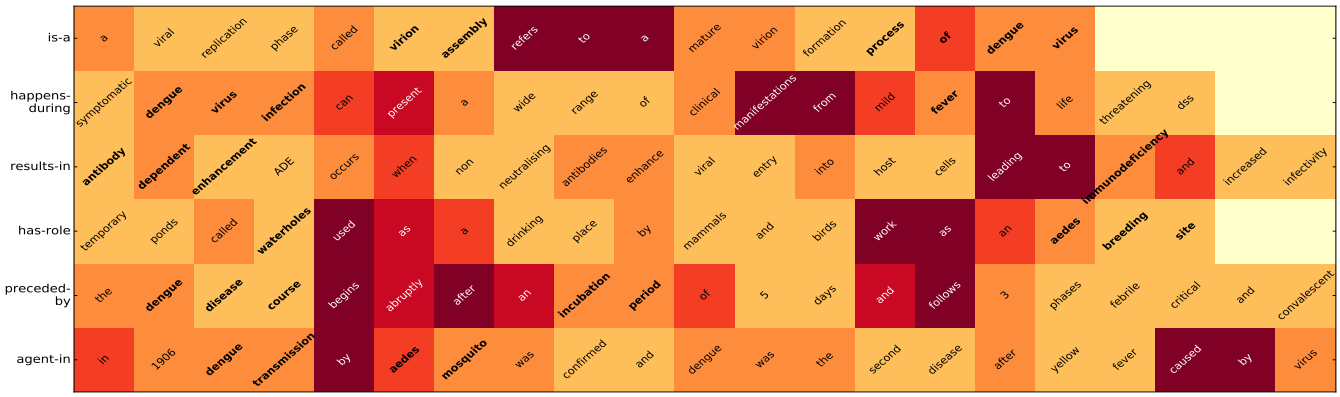

Figure 5: Visualizing word attention weights for sentences of certain relation types, for the Dengue ontology. The related concept phrase pairs in the sentence are in boldface, and a darker background corresponds to a higher attention weight.

Table 3: Assessing various training data augmentation methods for BOLT-K, on the Dengue → Malaria ontology pair

Augmentation Technique	Target F1 score
Random oversampling (Rand OS)	0.511
SMOTE oversampling	0.458
WordNet synonym based replacement + Rand OS	0.66
Word embedding based replacement + Rand OS	0.637
Trigram model based replacement + Rand OS	0.69
WordNet + Word embedding + Trigram + Rand OS	**0.713**

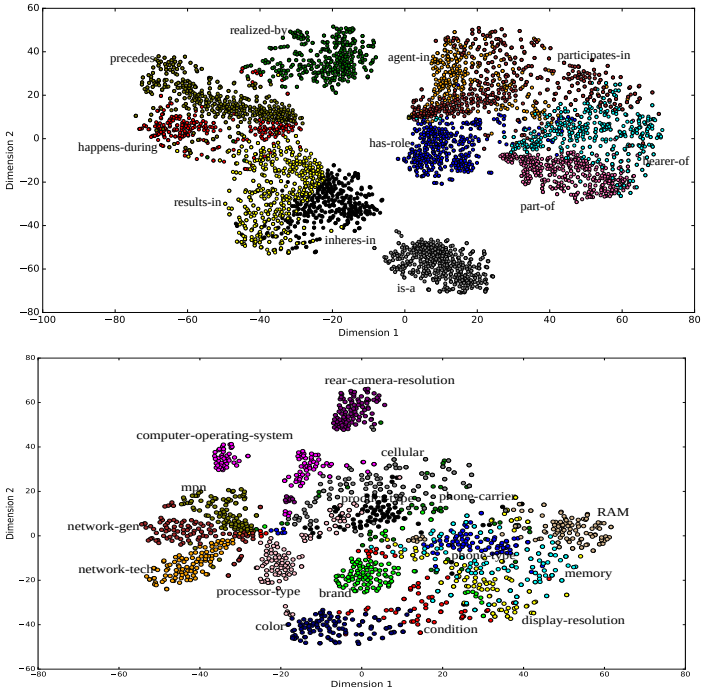

Figure 6: Visualizing learnt concept pair representations for Dengue → Malaria (top) and Televisions → Phones (bottom).

5.3 Discussion

We now dive deeper into the kind of ontological relationship information that our model can transfer across domains. Figure 6 displays the 2-dimensional t-SNE [38] visualizations of the representations learnt by BOLT-K for the sentence inputs of various relation classes. We observe that the relationships are largely well separable in case of the *Dengue → Malaria* ontology pair (Figure 6 top), with semantically similar relations co-located in their vector space. For example, the relations *participates-in, agent-in, has-role, part-of* and *bearer-of* are situated nearby, and away from the relatively dissimilar relations *results-in* and *inheres-in*. We do not see as clear a segregation between the relation categories for *Televisions → Phones* (Figure 6 bottom). But we do find some relations alike in meaning close by in the vector space too, e.g. *RAM* and *memory*, *network-gen* and *network-tech*.

Table 4 shows the relation categories dominantly mispredicted by our model and the relation type that they are frequently mispredicted as, for different ontology datasets. It also reports for each mispredicted relation category *r*, the percentage of test instances of category *r* that were mispredicted. We find that a common reason for mispredictions is the high similarity in the meaning of certain relationships, due to which they can be used interchangeably in natural language. For instance, BOLT-K is unable to distinguish between the relations *is-a* and *type-of* in case of *Depression ↔ Anxiety*, *participates-in* and *has-role* in case of *Dengue ↔ Malaria* and *preceded-by* and *develops-from* in case of *Gymnosperms ↔ Angiosperms*. We also observe this trend in some cases of the product ontology pairs (last four rows of Table 4), such as *RAM* and *memory*, *brand* and *phone-type*, and *total-size* and *viewable-size*.

As part of further analysis, we seek to understand how well our model can recognize hitherto unseen relation types. For this purpose, we remove or "leave out" one relationship class (i.e. all concept pairs and sentences associated with it) completely from the training dataset of the target sub-domain (and from the training data of the source sub-domain if present). We train our model with

Table 4: Frequently mispredicted relation types for a set of ontology pairs. For a relation type *r*, the parentheses show the percentage of mispredicted test instances of type *r*.

Source → Target	Mispred. rel type: Frequently mispred. as
Dengue → Malaria	*part-of* (35%): *is-a*; *inheres-in* (21%): *part-of*; *participates-in* (16%): *has-role*; *agent-in* (7%): *participates-in*; *bearer-of* (6%): *agent-in*
Malaria → Dengue	*part-of* (17%): *is-a*; *has-role* (17%): *part-of*; *happens-during* (8%): *part-of*; *precedes* (6%): *happens-during*
Alzheimers → Multiple Sclerosis	*type-of* (40%): *has-type*; *has-type* (38%): *type-of*
Multiple Sclerosis → Alzheimers	*type-of* (47%): *has-type*; *has-type* (41%): *type-of*
Depression → Anxiety	*is-a* (36%): *type-of*; *is-a* (12%): *has-type*
Anxiety → Depression	*is-a* (24%): *type-of*; *type-of* (18%): *has-type*
Gymnosperms → Angiosperms	*part-of* (19%): *is-a*; *adjacent-to* (20%): *part-of*; *has-part* (21%): *develops-from*; *located-in* (36%): *part-of*
Angiosperms → Gymnosperms	*preceded-by* (16%): *develops-from*; *develops-from* (11%): *part-of*; *has-participant* (11%): *part-of*; *part-of* (7%): *is-a*
Earphones → Phones	*brand* (42%): *phone-type*; *phone-type* (38%): *brand*; *display-res* (29%): color; *phone-carrier* (25%): *network-gen*; *RAM* (25%): *memory*
Phones → Earphones	*model* (44%): *product-type*; *brand* (30%): *model*; *color* (30%): *brand*; *additional-features* (22%): *compatibility*; *tagline* (20%): *brand*
Phones → Televisions	*refresh-rate* (39%): *display-type*; *model* (29%): *product-type*; *viewable-size* (29%): *total-size*; *display-res* (23%): *display-type*
Televisions → Phones	*RAM* (58%): *memory*; *cellular* (34%): *mpn*; *phone-type* (32%): *brand*; *display-res* (27%): *phone-type*; *cellular* (27%): *phone-carrier*

Table 5: Novel relation detection for Dengue → Malaria pair.

Relation type *r* left out during training	% of left out concept pairs detected as novel	Novel concept pairs missed. *s*(x%) means x% concept pairs related by *r* were mispredicted as having relation *s*.
is-a	76%	*part-of(8%), has-role(5%)*
part-of	51%	*has-role(19%), is-a(10%)*
happens-during	66%	*results-in(11%), part-of(6%)*
precedes	70%	*results-in(12%), happens-during(9%)*
results-in	61%	*precedes(14%), happens-during(9%)*
has-role	39%	*participates-in(21%), agent-in(17%)*
inheres-in	58%	*part-of(17%), bearer-of(10%)*
agent-in	41%	*participates-in(22%), bearer-of(19%)*
participates-in	46%	*has-role(23%), part-of(17%)*
bearer-of	64%	*agent-in(13%), part-of(9%)*
realized-by	67%	*results-in(9%), precedes(6%)*

the remaining training data as described in Section 4. We then use the Isolation Forest algorithm [33] with the authors' best case parameter settings to see if BOLT-K can detect concept pairs with the unseen relation type as *novel*, i.e. linked by a novel or unseen relationship. Isolation Forest takes as input the d-dimensional features obtained from BOLT-K's penultimate layer before the softmax layer. This novelty detection experiment shows our model's capability in identifying new or unseen relation categories which cannot be easily substituted by another, previously seen relation type.

The results are shown in Table 5, for the *Dengue* → *Malaria* ontology pair. The second column shows the fraction of concept pairs (whose relation class was left out while training) that have been detected as novel. For distinctive relationship types such as *is-a*, we find that more than 75% of the concept pairs which are linked by this relation in the ground truth are predicted as novel. But for left out relations which are not as semantically distinct from the other relationship types, BOLT-K is unable to satisfactorily identify that they were part of an unseen class. For instance, BOLT-K is unable to flag as novel more than 50% of the concept pairs linked by *has-role* and *participates-in*, when they were left out during training. For the concept pairs that were connected by the left-out relationship yet were not detected as novel, we investigated the relationship categories that BOLT-K was predicting them as. The third column of Table 5 shows the two dominant relation types that most concept pairs (linked by the left-out relationship) are mispredicted as belonging to. We found these predictions to be largely logical, when compared with the actual ground truth relationships. For example, 17% of the concept pairs linked by an *inheres-in* relation that was unseen during training were mispredicted as being connected by a *part-of* relation. 21% of the concept pairs connected by a *has-role* relation were mispredicted as having a *participates-in* relation. These mispredictions are semantically plausible due to the similarity in meaning of the misunderstood relationship groups.

6 CONCLUSION AND FUTURE WORK

We present BOLT-K, a Bi-LSTM framework with attentive pooling. It identifies concepts relevant to newly emerging subjects or events in various domains from their textual accounts, and automatically learns structured ontologies for them. We bootstrap this process by transferring knowledge from an existing, related sub-domain. We also leverage training data augmentation to accentuate the limited expert-labeled data available for these emergent sub-domains, at no further annotation cost. We extensively evaluate BOLT-K on real-life bio-medical and commercial product ontologies.

BOLT-K currently involves manual intervention to define functionally or logically related domains for knowledge transfer during ontology learning. In future, we plan to automate this task. Since the meaning and validity of concepts and their relationships may change over time, we seek to enrich BOLT-K by learning concept and relation representations that can effectively capture their evolving dynamics. This can enable the prediction of time instances at which concepts or relations are likely to appear, disappear or reappear with respect to an ontology snapshot. We also aim to improve BOLT-K's scalability so it can handle larger and deeper ontologies.

ABSTRACT

Finding clusters of well-connected nodes in a graph is an extensively studied problem in graph-based data analysis. Because of its many applications, a large number of distinct graph clustering objective functions and algorithms have already been proposed and analyzed. To aid practitioners in determining the best clustering approach to use in different applications, we present new techniques for automatically learning how to set clustering resolution parameters. These parameters control the size and structure of communities that are formed by optimizing a generalized objective function. We begin by formalizing the notion of a parameter fitness function, which measures how well a fixed input clustering approximately solves a generalized clustering objective for a specific resolution parameter value. Under reasonable assumptions, which suit two key graph clustering applications, such a parameter fitness function can be efficiently minimized using a bisection-like method, yielding a resolution parameter that fits well with the example clustering. We view our framework as a type of *single-shot* hyperparameter tuning, as we are able to learn a good resolution parameter with just a single example. Our general approach can be applied to learn resolution parameters for both local and global graph clustering objectives. We demonstrate its utility in several experiments on real-world data where it is helpful to learn resolution parameters from a given example clustering.

1 INTRODUCTION

Partitioning a collection of items into groups of similar items – that is, clustering – is a fundamental computational task. So commonly applied, there is a large and still-growing suite of objective functions, algorithms, and techniques for identifying *good* clusters. One powerful mathematical model for clustering is the graph, comprising nodes and (undirected) edges. For a broad overview of graph clustering, refer to any one of a number of surveys [11, 13, 28, 31]. Nearly all clustering approaches favor clusters with high internal edge density and a low external edge density. A related, but not identical, notion is that a good cluster is a set of nodes with a small cut (i.e., few edges leaving the set), and a nontrivial size (e.g., a large number of nodes, or many internal edges).

Although most clustering approaches follow these general principles, there are many different ways to formalize such goals mathematically. In practice, this array of objective functions yields a large variety of different output clusterings. Indeed, many existing (theoretical) approaches to graph clustering assume that the user knows *a priori* which objective function is appropriate for their context or job. The main design task, leading to a practical solution, is then to develop good algorithms that exactly, or approximately, optimize the objective. However, we propose that it is more natural to assume that the user starts with some a priori knowledge about the desired *structure* of clusters in a given application domain. More specifically, they can provide at least *one* example of what a *good* clustering should look like. The revised goal is to find an objective function whose optimization yields the desired type of output.

Our approach. In this article, we show how to bootstrap from this one quality clustering to learn the appropriate objective function, chosen from a parameterized family of objective functions. The efficiency of our technique relies on the clustering objective function being linear, with linear constraints, tuned by a single parameter β. Given this type of objective, we formalize the notion of a parameter fitness function, which relies on a fixed example clustering C_x of a network, and takes a parameter β as input. The fitness function computes the ratio between the objective score of C_x, when β is chosen as the input parameter, and a lower bound on the optimal clustering objective for that β. Specifically, we use a concave piecewise linear lower bound over a wide family of what we refer to as *relaxed clusterings*. Minimizing the fitness function produces a parameter (and a corresponding objective function) that C_x exactly or at least *nearly* optimizes. Thus the aim, which can be realized via a guided binary search, is to identify the parameter setting in which C_x most stands out. In the remainder of this introduction, we flesh out the context for our technique.

Parameters. There are multiple families of objective functions whose members are specified by a tunable resolution parameter. This parameter controls the size and structure of clusters that are formed by optimizing the objective. Key examples of such *generalized clustering objective functions* include the Hamiltonian objective studied by Reichardt and Bornholdt [29], the stability objective of Delvenne et al. [10], and a multi-resolution variant of the map equation [32].

In this manuscript we focus on a related clustering framework that we developed in previous work [37], based on correlation clustering [5]. This framework is named LambdaCC, after its resolution parameter λ, which implicitly controls both the internal edge density as well as the cut sparsity of nodes formed by minimizing the objective. Furthermore, LambdaCC generalizes several well-studied objectives such as modularity clustering, sparsest cut, normalized cut, and cluster deletion. All of these objectives can be viewed as special cases of the objective for appropriate settings of λ.

Global and local. The above objectives are specifically designed for global clustering, in which the goal is to find a multi-cluster partitioning of an input graph. Local clustering objectives relying on resolution parameters also exist; these focus on finding a single cluster in a localized region of a graph. Flow-based methods such as FlowImprove [4], LocalImprove [26], and SimpleLocal [35] fit into this category. These methods repeatedly solve minimum s-t cut problems for different values of a parameter α, in order to minimize a ratio-style objective related to a cluster quality measure called *conductance*. This α can be viewed as a resolution parameter that balances a trade-off between forming a cluster with a small cut, and forming a cluster with a large overlap with a seed set in the graph.

Given the unifying power and versatility of generalized clustering objective functions, the challenge of finding the right clustering technique for a specific application can often be reduced to finding an appropriate resolution parameter. However, very little work has addressed how to set these parameters in practice, in particular to capture the specific clustering structure present in a certain application domain. In the past, solving generalized objective functions for a range of resolution parameters has been used to detect hierarchical clusterings in a network [29], or as a way to identify *stable* clusterings, which consistently optimize the objective over a range of parameter values [10, 17, 32]. While both are important applications of resolution-based clustering, the ability to detect a specified type of clustering structure is important regardless of a clustering's stability or the hierarchical structure of a network. Finally, while tuning hyperparameters is a standard procedure in the broader machine learning literature, most existing approaches are not specifically designed for tuning graph clustering resolution parameters. Furthermore hyperparameter tuning techniques typically rely on performing cross validation over a large number of training examples. We are concerned with learning good resolution parameters from a *single* example clustering that represents a meaningful partitioning in a certain application domain.

Our Contributions. In this paper we develop an approach for learning how to set resolution parameters for both local and global graph clustering problems. Our results for global graph clustering rely heavily on the LambdaCC framework we developed in past work [37]. We begin by formally defining a parameter fitness function for a given clustering. We then prove that under reasonable assumptions on the input clustering and clustering objective function used, we can find the minimizer of such a fitness function to within arbitrary precision using a simple bisection-like method. Our approach can be viewed as a type of *single-shot* hyperparameter tuning, as we are able to learn an appropriate setting of a resolution parameter when given a single example clustering. We display the utility of our approach in several local and global graph clustering experiments. Our approach allows us to obtain improved community detection results on synthetic and real-world networks. We also show how our method can be used to measure the correlation between metadata attributes and community structure in social networks.

2 GRAPH CLUSTERING BACKGROUND

This section reviews the global LambdaCC [37] clustering objective and a local clustering objective that is based on regionally biased minimum cut computations [4, 26]. While there do exist many other objectives for local and global clustering, we focus on these two as they both rely crucially on resolution parameters.

Basic Notation. In this paper we consider unweighted and undirected graphs $G = (V, E)$, though many of the ideas can be extended to weighted graphs. Global graph clustering separates G into disjoint sets of nodes so that every node belongs to exactly one cluster. For local clustering, one is additionally given a set of reference or seed nodes $R \subset V$ and the objective is to find a good cluster that shares a nontrivial overlap with R. The degree of a node $i \in V$ is the number of edges incident to it; we denote this by d_i. The volume of a set $S \subseteq V$ is given by $\mathbf{vol}(S) = \sum_{i \in S} d_i$ and $\mathbf{cut}(S)$ measures how many edges cross from S to its complement set $\bar{S} = V \backslash S$. Further notation will be presented as needed in the paper.

2.1 Global Clustering with LambdaCC

The LambdaCC objective is a special case of correlation clustering (CC) [5], a framework for partitioning signed graphs. In correlation clustering, each pair of nodes (u, v) in a signed graph is associated with either a positive edge or a negative edge, as well as a nonnegative edge weight e_{uv} indicating the strength of the relationship between u and v. Given this input, the goal is to produce a clustering which minimizes the weight of *disagreements* or *mistakes*, which occur when positive edges are placed between clusters or negative edges are placed inside clusters.

The LambdaCC framework takes an unsigned graph $G = (V, E)$, a resolution parameter $\lambda \in (0, 1)$, and node weights w_u for each $u \in V$. It converts this input into a signed graph over which the correlation clustering objective can then be minimized. The signed graph $\tilde{G} = (V, E^+, E^-)$ is constructed as follows: for every $(u, v) \in E$, if $1 - \lambda w_u w_v \geq 0$, form a positive edge (u, v) in $\tilde{G}$, otherwise form a negative edge. In either case, the weight of this edge is $e_{uv} = |1 - \lambda w_u w_v|$. For every non-edge in the original graph ($(u, v) \notin E$), form a negative edge $(u, v) \in E^-$ in $\tilde{G}$ with weight $e_{uv} = \lambda w_u w_v$. The LambdaCC objective function then corresponds to the correlation clustering objective applied to $\tilde{G}$:

$$\min \sum_{(u,v) \in E^+} e_{uv}(1 - \delta_{uv}) + \sum_{(i,j) \in E^-} e_{uv}\delta_{uv}, \tag{1}$$

where δ_{uv} is a zero-one indicator function which encodes whether a clustering has placed nodes u, v together ($\delta_{uv} = 1$), or apart ($\delta_{uv} = 0$). There are two main choices for node weights: $w_u = 1$ for all $u \in V$ is the *standard* LambdaCC objective. For this simple case, we note that a node pair (u, v) which defines an edge in G will always correspond to a positive edge in G. In some applications it is useful to consider a *degree-weighted* version in which $w_u = d_u$. In this case, if $\lambda \leq 1/(d_{max}^2)$ then we can still guarantee that $E = E^+$.

However, for larger values of λ it may be possible that an edge in G gets mapped to a negative edge in $\tilde{G}$.

As a generalization of standard unweighted correlation clustering, LambdaCC is NP-hard, though many approximation algorithms and heuristics for correlation clustering have been developed in practice [2, 5, 8, 9]. In our previous work [37], we showed that a 3-approximation for standard LambdaCC can be obtained for any $\lambda \geq 1/2$ by rounding the following LP relaxation of objective (1):

$$\begin{array}{lll} \text{minimize} & \sum_{(u,v)\in E}(1-\lambda)x_{uv} + & \sum_{(u,v)\notin E}\lambda(1-x_{uv}) \\ \text{subject to} & x_{uv} \leq x_{uw} + x_{vw} & \text{for all } u,v,w \\ & 0 \leq x_{uv} \leq 1 & \text{for all } u < v. \end{array} \tag{2}$$

Furthermore, even when a priori approximations are not guaranteed, solving the LP relaxation can be a very useful way to obtain empirical lower bounds for the objective in polynomial time. In follow up work [15], we provided improved approximations for $\lambda < 1/2$ based on rounding the LP, but noted an $\Omega(\log n)$ integrality gap for some small value of λ.

Equivalence Results. LambdaCC generalizes and unifies a large number of other clustering approaches. When $\lambda = 1/(2|E|)$, the degree-weighted version is equivalent to the popular maximum modularity clustering objective [23, 24]. Standard LambdaCC interpolates between the sparsest cut objective for a graph-dependent small value of λ, and the cluster deletion problem when $\lambda > |E|/(1+|E|)$. Given its relationship to modularity, LambdaCC is known to also be related to the stochastic block model [25] and a multi-cluster normalized cut objective [42].

2.2 Local Clustering Objectives

We next consider a class of clustering objectives that share some similarities with (1), but are designed for finding a single local cluster in a specific region of a large graph. With the input graph $G = (V, E)$, we additionally identify a set of seed or *reference* nodes R around which we wish to form a good community. One common measure for the "goodness" of a cluster S is the conductance objective:

$$\phi(S) = \mathbf{cut}(S)/(\min\{\mathbf{vol}(S), \mathbf{vol}(\bar{S})\}), \tag{3}$$

which is small when S is connected very well internally but shares few edges with $\bar{S}$. A number of graph clustering algorithms have been designed to minimize local variants of (3). These substitute the denominator of (3) with a measure of the overlap between an output cluster S and the reference set R. One such objective is the following local conductance measure:

$$\phi_R(S) = \frac{\mathbf{cut}(S)}{\mathbf{vol}(R \cap S) - \varepsilon\mathbf{vol}(\bar{R} \cap S)}, \tag{4}$$

which is minimized over all sets S such that the denominator of $\phi_R(S)$ is positive. This objective includes a *locality* parameter ε that controls how much overlap there should be between the seed set and output cluster. For a general overview of this clustering paradigm and its relationship to spectral and random-walk based techniques, we refer the reader to the work of Fountoulakis et al. [14]. Specific algorithms which minimize variants of (4) include FlowImprove [4], which always uses parameter $\varepsilon = \mathbf{vol}(R)/\mathbf{vol}(\bar{R})$, and LocalImprove [26] and SimpleLocal [35], both of which choose larger values of ε in order to keep computations more local. In the extreme case where we consider $\varepsilon = \infty$, the problem reduces to finding the minimum conductance *subset* of a reference set R, which can be accomplished by the Minimum Quotient Improvement (MQI) algorithm of Lang and Rao [20].

Objective (4) can be efficiently minimized by repeatedly solving a minimum s-t cut problem on an auxiliary graph constructed from G, which introduces a sink node s attached to nodes in R, and a source node t attached to nodes in $\bar{R} = V \backslash R$. Edges are weighted with respect to the locality parameter ε and another parameter α. In order to detect whether there exists some set S with $\phi_R(S) \leq \alpha$, one can solve a local clustering objective corresponding to the minimum s-t cut objective on the auxiliary graph. We refer to this simply as the *local flow clustering objective*:

$$\min \; f_\alpha(S) = \mathbf{cut}(S) + \alpha\mathbf{vol}(R \cap \bar{S}) + \alpha\varepsilon\mathbf{vol}(\bar{R} \cap S). \tag{5}$$

If the set S minimizing f_α satisfies $f_\alpha(S) < \alpha\mathbf{vol}(R)$, then rearranging terms one can show that $\phi_R(S) < \alpha$. Thus, by performing binary search over α or repeatedly solving (5) for smaller and smaller α, one can minimize the local conductance measure (4).

Previous research has largely treated α as a temporary parameter used in one step of a larger algorithm seeking to minimize (4). Algorithms which minimize (4) do so by finding the smallest α such that the minimum of (5) is $\alpha\mathbf{vol}(R)$. We depart from this approach by instead treating α as a tunable resolution parameter for balancing two conflicting goals: finding clusters with a small cut, and finding clusters that have a large overlap with the seed set R. In the case where ε is treated as infinitely large and we are simply looking for subsets of a seed set R satisfying $\mathbf{vol}(R) \leq \mathbf{vol}(\bar{R})$, then in effect we are trying to solve the optimization problem:

$$\min \mathbf{cut}(S) - \alpha\mathbf{vol}(S) + \alpha\mathbf{vol}(R) \;\; \text{such that } S \subseteq R. \tag{6}$$

This goal is related to, but ultimately should be contrasted with, the goal of minimizing the ratio $\mathbf{cut}(S)/\mathbf{vol}(S)$. The objectives are similar in that they both tend to prefer sets with small cut and large volume. We argue that treating α as a tunable parameter is in fact more versatile than simply minimizing the ratio score. In multiple applications it may be useful to find clusters with small cut and large volume, but different applications may put a different weight on each aspect of the objective. We observe that ε also plays an important role in the size and structure of the output community when it is less than ∞. For simplicity, in this paper we can treat this as a fixed constant, and in our experimental section we simply focus on objective (6).

2.3 Parametric Linear Programs

Before moving on we provide key background on parametric linear programming which will be important in our theoretical results. A standard linear program is a problem of the form

$$\min_{\mathbf{x}} \; \mathbf{c}^T\mathbf{x} \text{ such that } \mathbf{A}\mathbf{x} \leq \mathbf{b} \tag{7}$$

where $\mathbf{c}, \mathbf{b}$ are vectors and $\mathbf{A}$ is a constraint matrix. A *parametric* linear program is a related problem of the form

$$\min_{\mathbf{x}} \; \mathbf{c}^T\mathbf{x} + \beta(\Delta\mathbf{c})^T\mathbf{x} \text{ such that } \mathbf{A}\mathbf{x} \leq \mathbf{b} \tag{8}$$

where $\Delta\mathbf{c}$ is another vector of the same length as $\mathbf{c}$ and β is a parameter controlling the difference between (7) and (8). We state a well-known result about the solutions of (8) for different β. This result is not new; it follows directly from Proposition 2.3b from [1].

Theorem 1. *Let $L(\beta)$ be the minimum of (8) for a fixed β. If we are given bounds a and b such that $L(\beta) \in \mathbb{R}$ for all $\beta \in [a, b]$, then L is a piecewise linear and concave function in β over this interval.*

Parametric LPs in Graph Clustering Applications. In our work it is significant to note that the linear programming relaxation of LambdaCC is a parametric linear program in λ. Furthermore, the local flow clustering objective can be cast as a parametric linear program in α, since this objective corresponds simply to a special case of the minimum s-t cut problem, which can be cast as an LP.

2.4 Related Work

Our work builds on previous results that introduced generalized objective functions with resolution parameters, including the Hamiltonian objective [29], clustering stability [10], a multiscale variant of the map equation [32], and the LambdaCC framework [37]. Recently Jeub et al. [17] introduced a technique for sampling values of a resolution parameter and applying hierarchical consensus clustering techniques. Our work on learning clustering resolution parameters differs from theirs in that we do not aim to provide hierarchical clusterings of a network. Instead we assume that there is a known fixed clustering, for which we wish to learn a single specific resolution parameter.

There exist many techniques for localized community detection based on seed set expansion. Among numerous others, these include spectral and random-walk based methods [3, 33], flow-based methods [4, 20, 26, 35], and other approaches which perform diffusions from a set of seed nodes and round embeddings via a sweep cut procedure [18, 39]. We build on these by interpreting hyperparameters associated with such methods as resolution parameters which can be learned to produce clusters of a certain type.

3 THEORETICAL RESULTS

The major theoretical contribution of our work is a new framework for learning clustering resolution parameters based on minimizing a parameter fitness function for a given example clustering. We present results for a generic clustering objective and fitness function, and later show how to apply our results to LambdaCC and local flow clustering.

3.1 Problem Formulation

Let $\mathcal{C}$ denote a set of valid clusterings for a graph $G = (V, E)$. We consider a generic clustering objective function $f_\beta : \mathcal{C} \to \mathbb{R}_{\geq 0}$ that depends on a resolution parameter β. The function takes as input a clustering $C \in \mathcal{C}$, and outputs a nonnegative clustering quality score for C. We assume that smaller values of f_β are better. We intentionally allow f_β to be very general in order to develop broadly applicable theory. For intuition, one can think of f_β as being the LambdaCC function (1) with $\beta = \lambda$. Alternatively, one can picture f_β to be the local flow objective (5) with $\beta = \alpha$ and with $\mathcal{C}$ representing the set of bipartitions, i.e. for any $C \in \mathcal{C}$, $C = \{S, \bar{S}\}$ for some set $S \subset V$.

Given some objective function f_β, a standard clustering paradigm is to assume that an appropriate value of β has already been chosen, and then the goal is to produce some clustering C that exactly or approximately minimizes f_β. In our work, we address an inverse question: given an example clustering C_x, how do we determine a parameter β such that C_x approximately minimizes f_β? Ideally we would like to solve the following problem:

Goal 1: Find $\beta > 0$ such that $f_\beta(C_x) \leq f_\beta(C)$ for all $C \in \mathcal{C}$. (9)

In practice, however, C_x may not exactly minimize a generic clustering objective for any choice of resolution parameter. Thus we relax this to a more general and useful goal:

Goal 2: Find the minimum $\Delta \geq 1$ such that for some $\beta > 0$
$$f_\beta(C_x) \leq \Delta f_\beta(C) \text{ for all } C \in \mathcal{C}. \quad (10)$$

This second goal is motivated by the study of approximation algorithms for clustering. In effect this asks: if we are given a certain clustering C_x, is C_x a good approximation to f_β for any choice of β? Note that this generalizes (9): if β can be chosen to satisfy Goal 1, then the same β will satisfy Goal 2 with $\Delta = 1$. Furthermore, it has the added advantage that, if solved, Goal 2 will produce a value Δ which communicates how well clusterings like C_x can be detected using variants of the objective function f_β. If Δ is near 1, it means that f_β is able to produce similar clusterings for a correct choice of β, whereas if Δ is very large this indicates that C_x will be difficult to find even for an optimal β, and thus a different approach will be necessary for detecting clusterings of this type.

Clustering Relaxations. While Goal 2 is a more reasonable target than Goal 1, it may still be a very challenging problem to solve when objective f_β is hard to optimize, e.g., if it is NP-hard. We thus consider one final relaxation that is slightly weaker than (10), but will be more feasible to work with. Let $\hat{\mathcal{C}}$ denote a superset of $\mathcal{C}$ which includes not only clusterings for G, but also some notion of a relaxed clustering, and let $g_\beta : \hat{\mathcal{C}} \to \mathbb{R}_{\geq 0}$ be an objective that assigns a score for every $C \in \hat{\mathcal{C}}$. Furthermore, assume g_β represents a lower bound function for f_β: $g_\beta(C) \leq f_\beta(C)$ for all β and all $C \in \mathcal{C}$. Our consideration of g_β is motivated by the fact that many NP-hard clustering objectives permit convex relaxations, which can be optimized in polynomial time over a larger set of relaxed clusterings that contain all valid clusterings of G as a subset. For example, the LambdaCC objective is NP-hard to optimize for every $\lambda \in (0, 1)$, but the linear programming relaxation for every λ can be solved in polynomial time, and is defined over relaxed clusterings in which pairs of nodes are assigned distances between 0 and 1. These relaxations can be rounded to produce good approximations to the original NP-hard objective [8, 9]. Since g_β is indeed easier to optimize than f_β, the following goal will be easier to approach but still provide strong guarantees for learning a good value of β:

Goal 3: Find the minimum $\Delta \geq 1$ such that for some $\beta > 0$
$$f_\beta(C_x) \leq \Delta g_\beta(C) \text{ for all } C \in \hat{\mathcal{C}}. \quad (11)$$

If we can solve (11), this still guarantees that C_x is a Δ-approximation to f_β for an appropriately chosen β. For problems where f_β is very challenging to optimize, but g_β is not, this will be a much more feasible approach. In the next section we will focus on developing theory for addressing Goal 3, though we note that in applying this theory we can still choose $g_\beta = f_\beta$ and therefore instead address the stronger Goal 2 whenever this is feasible. We will take this approach when applying our theory to the local flow objective.

3.2 Parameter Fitness Function

We now present a parameter fitness function whose minimization is equivalent to solving (11). Functions f_β and g_β take a clustering or relaxed clustering as input and output an objective score. However, we wish to view β as an input parameter and we treat an example clustering C_x as a fixed input. Thus for convenience we introduce new related functions:

$$F(\beta) = f_\beta(C_x) \tag{12}$$

$$G(\beta) = \min_{C \in \hat{C}} g_\beta(C) \tag{13}$$

The ratio of these two functions defines the *parameter fitness function* that we seek to minimize:

$$\mathcal{P}(\beta) = \frac{F(\beta)}{G(\beta)}. \tag{14}$$

Observe that this function is always greater than or equal to 1 since $G(\beta) \leq F(\beta)$ for any β. The minimizer of $\mathcal{P}$ is a resolution parameter β that minimizes the ratio between the clustering score of a fixed C_x and a lower bound on f_β. Thus, by minimizing (14) we achieve Goal 3 in (11) with $\Delta = \min_\beta \mathcal{P}(\beta)$.

In Section 2.3, we noted that the local flow clustering objective can be characterized as a parametric linear program, as can the LP relaxation of LambdaCC. Furthermore, for a fixed clustering, both objective functions can be viewed as a linear function in terms of their resolution parameter. Motivated by these facts, we present a theorem which characterizes the behavior of the parameter fitness function $\mathcal{P}$ under certain reasonable conditions on the functions F and G. In the subsequent section we will use this result to show that $\mathcal{P}$ can be minimized to within arbitrary precision using an efficient bisection-like method.

Theorem 2. *Assume $F(\beta) = a + b\beta$ for nonzero real numbers a and b. Let G be concave and piecewise linear in β, and assume $F(\beta) \geq G(\beta) \geq 0$ for all $\beta \in [\ell, r]$ where ℓ and r are nonnegative lower and upper (i.e. left and right) bounds for β. Then $\mathcal{P}$ satisfies the following two properties:*

(a) If $\beta^- < \beta < \beta^+$, then $\mathcal{P}(\beta)$ cannot be strictly greater than both $\mathcal{P}(\beta^-)$ and $\mathcal{P}(\beta^+)$.

(b) If $\mathcal{P}(\beta^-) = \mathcal{P}(\beta^+)$, then $\mathcal{P}$ achieves its minimum in $[\beta^-, \beta^+]$.

Proof. Note that for some $\gamma \in (0, 1)$, $\beta = (1-\gamma)\beta^+ + \gamma\beta^-$. By concavity of G and linearity of F, we know

$$\mathcal{P}(\beta) = \frac{F((1-\gamma)\beta^+ + \gamma\beta^-)}{G((1-\gamma)\beta^+ + \gamma\beta^-)} \leq \frac{(1-\gamma)F(\beta^+) + \gamma F(\beta^-)}{(1-\gamma)G(\beta^+) + \gamma G(\beta^-)}$$
$$\leq \max\left\{\frac{(1-\gamma)F(\beta^+)}{(1-\gamma)G(\beta^+)}, \frac{\gamma F(\beta^-)}{\gamma G(\beta^-)}\right\} = \max\left\{\mathcal{P}(\beta^+), \mathcal{P}(\beta^-)\right\},$$

which proves the first property. Now assume that $\mathcal{P}(\beta^-) = \mathcal{P}(\beta^+)$. Using property 1, we know as β increases from its lower to upper limit, $\mathcal{P}$ cannot increase and then decrease. Thus, either $\mathcal{P}$ attains its minimum on $[\beta^-, \beta^+]$, else $\mathcal{P}$ is a constant for all $\beta \in [\beta^-, \beta^+]$. If the latter is true, then for some $\beta \in [\beta^-, \beta^+]$ and some sufficiently small $\epsilon > 0$, G must be linear in the range $(\beta - \epsilon, \beta + \epsilon)$, since we know that G is piecewise linear. Therefore, $G(\beta) = c + d\beta$ and

$$\mathcal{P}(\beta) = (a + b\beta)/(c + d\beta) = constant \tag{15}$$

for $\beta \in (\beta - \epsilon, \beta + \epsilon)$ and for some $c, d \in \mathbb{R}$. This ratio of linear functions can only be a constant if $a = c = 0$, or $b = d = 0$, or if $a = c$ and $b = d$. Since we assumed a and b were nonzero, the last case must hold, and thus $\mathcal{P}(\beta) = 1$ for every $\beta \in [\beta^-, \beta^+]$, so the minimizer is obtained in this case, since $\mathcal{P}(\beta) \geq 1$ for all β. □

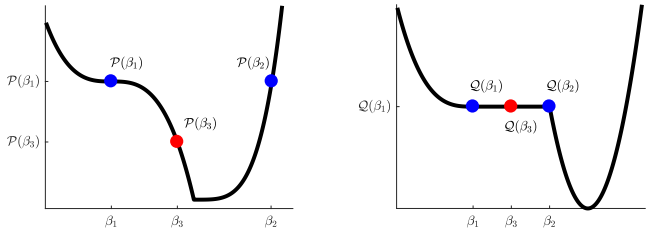

Figure 1: Function $\mathcal{P}$ satisfies both properties (a) and (b) in Theorem 2. If $\mathcal{P}(\beta_1) = \mathcal{P}(\beta_2)$, querying $\mathcal{P}$ at any point $\beta_3 \in [\beta_1, \beta_2]$ gets us closer to a minimizer. Function Q only satisfies property (a). If $Q(\beta_1) = Q(\beta_2)$, we can get stuck making queries inside a flat region of Q not near a minimizer.

In the next section we present a method for finding the minimizer of a function satisfying properties (a) and (b) in Theorem 2 to within arbitrary precision. Before doing so, we highlight the importance of ensuring that *both* properties hold. In Figure 1 we plot two toy functions, $\mathcal{P}$ and Q. Although both satisfy property (a), only $\mathcal{P}$ additionally satisfies (b). Assume we do not have explicit representations of either function, but we can query them at specific points to help find their minimizers. Consider Figure 1. If we query $\mathcal{P}$ at points β_1 and β_2 to find that $\mathcal{P}(\beta_1) = \mathcal{P}(\beta_2)$, then choosing any third point $\beta_3 \in (\beta_1, \beta_2)$ will get us closer to the minimizer. However, if $Q(\beta_1) = Q(\beta_2)$ for some β_1, β_2, we cannot be sure these points are not part of a flat region of Q somewhere far from the minimizer. It thus becomes unclear how to choose a third point β_3 at which to query Q. If we choose some $\beta_3 \in (\beta_1, \beta_2)$ and find that $Q(\beta_3) = Q(\beta_2) = Q(\beta_1)$, the minimizer may be within $[\beta_1, \beta_2]$, within $[\beta_2, \beta_3]$, or in a completely different region. Thus it is important for the denominator of a parameter fitness function to be piecewise linear in addition to being concave, since this piecewise linear assumption guarantees property (b) will hold.

3.3 Minimizing $\mathcal{P}$

We now outline an approach for finding a minimizer of $\mathcal{P}$ to within arbitrary precision when Theorem 2 holds. Our approach is closely related to the standard bisection method for finding zeros of a continuous function f. Recall that standard bisection starts with a and b such that $sign(f(a)) \neq sign(f(b))$, and then computes $f(c)$ where $c = (a + b)/2$. Checking the sign of $f(c)$ allows one to determine whether the zero of f is located within the interval $[a, c]$ or $[b, c]$. Thus each new query of the function f halves the interval in which a zero must be located.

Assume $\mathcal{P}$ satisfies properties (a) and (b) in Theorem 2 over an interval $[\ell, r]$. To satisfy Goal 3, given in (11) in Section 3.1, it suffices to find any minimizer of $\mathcal{P}$, which we do by repeatedly halving the interval in which the minimizers of $\mathcal{P}$ must lie. Our approach differs from standard bisection in that we are trying to find a *minimizer* instead of the zero of some function. The key algorithmic difference is that querying $\mathcal{P}$ at a single point between two bounds will not always be sufficient to cut the search space in

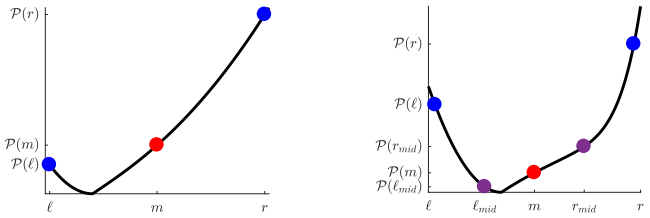

Figure 2: We evaluate $\mathcal{P}$ at left and right bounds (blue points), and at a midpoint m (red point). Left: If $\mathcal{P}(\ell) < \mathcal{P}(m) < \mathcal{P}(r)$, then we know the minimizer of $\mathcal{P}$ is in $[\ell, m]$, and we recursively call the *one-branch* phase (Algorithm 1) with new bounds ℓ and m. Right: If $\mathcal{P}(m) < \mathcal{P}(\ell) < \mathcal{P}(r)$, we don't know if the minimizer is in the left branch $[\ell, m]$ or right branch $[m, r]$. Evaluating $\mathcal{P}$ at the midpoint of each branch (purple points), we rule out branch $[m, r]$ and recursively call Algorithm 2 with new endpoints ℓ and m and midpoint ℓ_{mid}.

half. Consider Figure 2. Our method starts in a *one-branch* phase in which we know a minimizer lies between ℓ and r. If we compute $m = (\ell + r)/2$ and find that $\mathcal{P}(m)$ is between $\mathcal{P}(\ell)$ and $\mathcal{P}(r)$, this does in fact automatically cut our search space in half, as this implies that $\mathcal{P}$ is monotonic on either $[\ell, m]$ or $[m, r]$. However, if $\mathcal{P}(m) < \min\{\mathcal{P}(\ell), \mathcal{P}(r)\}$, then it is possible for the minimizer to reside within either the left branch $[\ell, m]$ or the right branch $[m, r]$. In this case, the method enters a *two-branch* phase in which it takes the midpoint of each branch ($\ell_{mid} = (\ell+m)/2$ and $r_{mid} = (m+r)/2$) and evaluates $\mathcal{P}(\ell_{mid})$ and $\mathcal{P}(r_{mid})$. If $\mathcal{P}$ returns the same value for two of the inputs (e.g., $\mathcal{P}(\ell) = \mathcal{P}(m)$), then by property (b) we have found a new interval containing the minimizer(s) of $\mathcal{P}$ that is at most half the length of $[\ell, r]$. Otherwise, we can use property (a) to deduce that the minimizer will be located within $[\ell, m]$, $[m, r]$, or $[\ell_{mid}, r_{mid}]$, and we recurse on the two-branch phase.

Algorithms 1 and 2 handle the one- and two-branch phases of the method respectively. The guarantees of our method are summarized in Theorem 3. We omit the full proof, since it follows directly from considering different simple cases and applying properties of $\mathcal{P}$ to halve the search space as outline above.

Theorem 3. *Consider a fixed clustering C_x and a corresponding parameter fitness function $\mathcal{P}_{C_x}$ satisfying the assumptions of Theorem 2. Running Algorithm 1 with input ℓ, r and a tolerance ϵ will produce a resolution parameter $\tilde{\beta}$ that is within ϵ of the minimizer of $\mathcal{P}_X$ over the interval $[\ell, r]$, in at most $\log_2((r-\ell)/\epsilon)$ recursive calls.*

4 APPLICATION TO SPECIFIC OBJECTIVES

Theorem 2 and our approach for minimizing $\mathcal{P}$ can be immediately applied to learn resolution parameters for the LambdaCC global clustering objective and the local flow clustering objective.

4.1 Local Clustering

For local clustering we consider the objective function f_α given in (5) and note that the set of valid clusterings C is the set of bipartitions. The example clustering we are given at the outset of the problem is $C_x = \{X, \bar{X}\}$ where $X \subset V$ is some nontrivial set of nodes representing a "good" cluster for a given application. We assume we

Algorithm 1 CheckOneBranch(ℓ, r, ϵ)

Base case:
if $r - \ell < \epsilon$ **then**
  return ℓ
Recursive call:
Midpoint: $m = (\ell + r)/2$
switch ℓ, m, r **do**
  case $\mathcal{P}(\ell) = \mathcal{P}(m) = \mathcal{P}(r)$
    return m
  case $\mathcal{P}(\ell) \leq \mathcal{P}(m) < \mathcal{P}(r)$
    return CheckOneBranch(ℓ, m, ϵ)
  case $\mathcal{P}(\ell) > \mathcal{P}(m) \geq \mathcal{P}(r)$
    return CheckOneBranch(m, r, ϵ)
  case $\mathcal{P}(\ell) > \mathcal{P}(m) < \mathcal{P}(r)$
    return CheckTwoBranches(ℓ, m, r, ϵ)

Algorithm 2 CheckTwoBranches(ℓ, m, r, ϵ)

Base case:
if $r - \ell < \epsilon$ **then**
  return m
Recursive call:
Left midpoint: $\ell_{mid} = (\ell + m)/2$
Right midpoint: $r_{mid} = (m + r)/2$
switch ℓ_{mid}, m, r_{mid} **do**
  case $\mathcal{P}(\ell_{mid}) = \mathcal{P}(m) = \mathcal{P}(r_{mid})$
    return m
  case $\mathcal{P}(\ell_{mid}) = \mathcal{P}(m) \neq \mathcal{P}(r_{mid})$
    return CheckOneBranch$(\ell_{mid}, m, \epsilon)$
  case $\mathcal{P}(\ell_{mid}) \neq \mathcal{P}(m) = \mathcal{P}(r_{mid})$
    return CheckOneBranch(m, r_{mid}, ϵ)
  case $\mathcal{P}(\ell_{mid}) < \mathcal{P}(m) < \mathcal{P}(r_{mid})$
    return CheckTwoBranches$(\ell, \ell_{mid}, m, \epsilon)$
  case $\mathcal{P}(\ell_{mid}) > \mathcal{P}(m) > \mathcal{P}(r_{mid})$
    return CheckTwoBranches$(m, r_{mid}, r, \epsilon)$
  case $\mathcal{P}(\ell_{mid}) > \mathcal{P}(m) < \mathcal{P}(r_{mid})$
    return CheckTwoBranches$(\ell_{mid}, m, r_{mid}, \epsilon)$

are also given a reference set R (with $\mathbf{vol}(R) \leq \mathbf{vol}(\bar{R})$) that defines a region of the graph in which we are searching for clusters. As noted previously, f_α can be viewed as a parametric linear program, and furthermore it will evaluate to a non-negative finite number for any $\alpha > 0$. Thus by Theorem 1, $G(\alpha) = \min_S f_\alpha(S)$ is concave and piecewise linear and we can apply Theorem 2. More explicitly, the local clustering parameter fitness function is

$$\mathcal{P}_X(\alpha) = \frac{\mathbf{cut}(X) + \alpha\mathbf{vol}(\bar{X} \cap R) + \alpha\varepsilon\mathbf{vol}(X \cap \bar{R})}{\min_S[\mathbf{cut}(S) + \alpha\mathbf{vol}(\bar{S} \cap R) + \alpha\varepsilon\mathbf{vol}(S \cap \bar{R})]}. \quad (16)$$

If we focus on finding clusters that are subsets of R, using objective (6), we have a simplified fitness function:

$$\mathcal{P}_X(\alpha) = \frac{\mathbf{cut}(X) - \alpha\mathbf{vol}(X) + \alpha\mathbf{vol}(R)}{\min_{S \subseteq R}[\mathbf{cut}(S) - \alpha\mathbf{vol}(S) + \alpha\mathbf{vol}(R)]}. \quad (17)$$

When we apply Algorithm 1 to minimize (16) or (17), we can query $\mathcal{P}_X$ in the time it takes to evaluate a linear function and the time it

takes to solve the s-t cut problem (5). This can be done extremely quickly using localized min-cut computations [20, 26, 35, 38].

Functions (16) and (17) should be minimized over $\alpha \in [\alpha^*, \mathbf{cut}(R)]$, where α^* is either the minimum of (4) if we are minimizing (16), or is the minimum conductance for a subset of R if we are minimizing (17). One can show that for any α outside this range, objectives (5) and (6) will be trivially minimized by $S = R$, so it is not meaningful to optimize these objectives for these α. In practice one can additionally set stricter upper and lower bounds if desired.

4.2 Global Clustering Approach

We separately consider the standard and degree-weighted versions of LambdaCC when applying Theorem 2 to global graph clustering.

Standard LambdaCC. For the standard objective, it is useful to consider the scaled version of LambdaCC obtained by dividing (1) by $1-\lambda$ and substituting for a new resolution parameter $\gamma = \lambda/(1-\lambda)$. Then the objective is

$$\min \ \sum_{(u,v)\in E}(1-\delta_{uv}) + \sum_{(u,v)\notin E}\gamma\delta_{uv}. \tag{18}$$

The denominator of the parameter fitness function for this scaled LambdaCC problem would be

$$G(\gamma) = \min_{\mathbf{x}\in\mathcal{X}} \ \sum_{(u,v)\in E} x_{uv} + \sum_{(u,v)\notin E}\gamma(1-x_{uv}) \tag{19}$$

where $\mathcal{X}$ represents the set of linear constraints for the linear program (2). Note that $G(\gamma)$ will be finite for every $\gamma \geq 0$, so Theorem 1 holds. Thus G is concave and piecewise linear as required by Theorem 2. Next, for a fixed clustering C_x, let P_x be the number of positive mistakes (pairs of nodes that are separated despite sharing an edge) and N_x be the number of negative mistakes (pairs of nodes that are clustered together but share no edge). Then objective (18) for this clustering is $P_x + \gamma N_x$, and we see that this fits the linear form given in Theorem 2 as long as the example clustering satisfies $P_x > 0$ and $N_x > 0$, which will be the case for nearly any nontrivial clustering one might consider. Finally, note that the parameter fitness function for (18) would be exactly the same as the parameter fitness function for the standard LambdaCC objective, since scaling by $(1-\lambda)$ makes no difference if we are going to minimize the ratio between the clustering objective and its LP relaxation. The parameter fitness function for standard LambdaCC is therefore

$$\mathcal{P}_{C_x}(\lambda) = \frac{(1-\lambda)P_x + \lambda N_x}{\min_{\mathbf{x}}\left[\sum_{uv\in E}(1-\lambda)x_{uv} + \sum_{uv\notin E}\lambda(1-x_{uv})\right]} \tag{20}$$

and it satisfies the assumptions of Theorem 2 as long as $P_x > 0$, $N_x > 0$, and we optimize over $\lambda \in (0,1)$.

Degree-weighted LambdaCC. Showing how Theorem 2 applies to degree-weighted LambdaCC requires slightly more work, though the same basic principles hold. The LP-relaxation of the objective is still a parametric linear program, thus is still concave and piecewise linear in λ over the interval $(0,1)$. The denominator of the parameter fitness function in this case would be:

$$\min \ \sum_{(u,v)\in E^+} e_{uv}(1-\delta_{uv}) + \sum_{(u,v)\in E^-} e_{uv}\delta_{uv}. \tag{21}$$

where e_{uv} is defined in the degree-weighted fashion (see Section 2.1). For a fixed example clustering C_x encoded by a function $\delta_x = (\delta_{uv})$, we can rearrange this into the form $a + \lambda b$ where $a = \sum_{(u,v)\in E}(1-\delta_{uv})$ and $b = \sum_{(u,v)\notin E} d_u d_v \delta_{uv} - \sum_{(u,v)\in E} d_u d_v (1-\delta_{uv})$. These values are simple to compute, and as long as they are both nonzero, the results of Theorem 2 apply. In some extreme cases it is possible that $a = 0$ or $b = 0$, but we expect this to be rare. Furthermore, our general approach may still work even when $a = 0$ or $b = 0$, Theorem 2 simply does not analyze this case. We leave it as future work to develop more refined sufficient and necessary conditions such that Algorithm 1 is guaranteed to minimize $\mathcal{P}$.

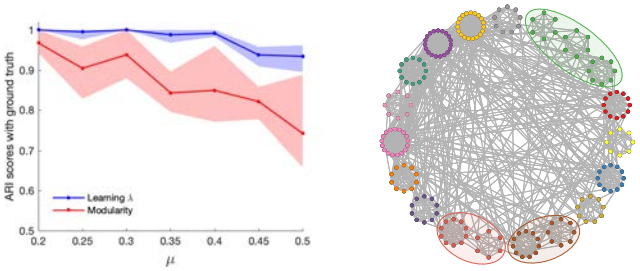

Figure 3: Left: ARI scores for detecting ground truth in LFR graphs. Solid lines indicate mean scores, and colored regions show the range of scores across 5 test graphs for each μ. Right: one of the 5 LFR test graphs for $\mu = 0.3$. Modularity ($\lambda = 1/(2|E|)$) makes mistakes by putting distinct ground truth clusters together (highlighted). For this example our approach perfectly detects the ground truth.

5 EXPERIMENTS

We consider several local and global clustering experiments in which significant benefit can be gained from learning resolution parameters rather than using previous off-the-shelf algorithms and objective functions. We implement Algorithms 1 and 2 in the Julia programming language for both local and global parameter fitness functions. Computing the LambdaCC linear programming relaxation can be challenging due to the size of the constraint set. For our smaller graphs we apply Gurobi optimization software, and for larger problems we use recently developed memory-efficient projection methods [30, 36]. For the local-flow objective we use a fast Julia implementation we developed in recent work [38]. Our experiments were run on a machine with two Intel Xeon E5-2690 v4 processors. Code for our experiments and algorithms are available at https://github/nveldt/LearnResParams.

5.1 Learning Parameters for Synthetic Datasets

Although modularity is a widely-applied objective function for community detection, Fortunato and Barthélemy [12] demonstrated that it is unable to accurately detect communities below a certain size threshold in a graph. In our first experiment we demonstrate that learning resolution parameters for LambdaCC allows us to overcome the *resolution limit* of modularity, and better detect community structure in synthetic networks. We generate a large number of synthetic LFR benchmark graphs [19], in a parameter regime that is chosen to be difficult for modularity. All graphs contain 200 nodes, average degree 10, max degree 20, and community sizes between 5 and 20 nodes. We test a range of mixing parameters μ, which controls the fraction of edges that connect nodes in different communities ($\mu = 0$ means all edges are inside the communities).

For each μ from 0.2 to 0.5, in increments of 0.05, we generate six LFR networks, one for training and five for testing. On the training graph, we minimize the degree-weighted LambdaCC parameter fitness function to learn a resolution parameter λ_{best}. This takes between roughly half an hour (for $\mu = 0.2$) to just over three hours (for $\mu = 0.5$), solving the underlying LambdaCC LP with Gurobi software. We then cluster the five test LFR examples using a generalized version of the Louvain method [7], as implemented by Jeub et al. [16]. We separately run the method with two resolution parameters: $\lambda = 1/(2|E|)$, the standard setting for modularity, and $\lambda = \lambda_{best}$. Learning λ_{best} significantly improves adjusted Rand index (ARI) scores for detecting the ground truth (see Figure 3).

5.2 Local Community Detection

Next we demonstrate that a small amount of semi-supervised information about target communities in real-world networks can allow us to learn good resolution parameters, leading to more robust community identification. Additionally, minimizing the parameter fitness function provides a way to measure the extent to which *functional* communities in a network correspond to topological notions of community structure in networks.

Data. We consider four undirected networks, DBLP, Amazon, Orkut, LiveJournal, which are all available on the SNAP repository [22], and come with sets of nodes that can be identified as "functional communities" (see Yang and Leskovec [40]). For example, members of the social network Orkut may explicitly identify as being part of a user-formed group. Such user groups can be viewed simply as metadata about the network, though these still correspond to some notion of community organization that may be desirable to detect. Following an approach taken in previous work [38], we specifically consider the ten largest communities from the 5000 best functional communities as identified by Yang and Leskovec [40].

Experimental Setup and Results. We treat each functional community as an example cluster X. We build a superset of nodes R by growing X from a breadth first search until we have a superset of size $5|X|$, breaking ties arbitrarily. The size of R is chosen so that it comprises a localized region of a large graph, but is still significantly larger than the target cluster X hidden inside of it. We compare two approaches for detecting X within R. As a baseline approach we extract the best conductance subset of R. Then as our new approach we assume we are given $\mathbf{cut}(X)$ and $\mathbf{vol}(X)$ as additional semi-supervised information. This allows us to minimize the parameter fitness function (17), without knowing what X is. This outputs a resolution parameter α_X, and we then minimize $\mathbf{cut}(S) - \alpha_X \mathbf{vol}(S) + \alpha \mathbf{vol}(R)$ over $S \subseteq R$ to output a set S_X.

Table 1 reports conductance, set size, runtimes, and F1 scores for both approaches, averaged over the ten communities in each network. Learning resolution parameters leads to significantly better F1 scores on every dataset. Additionally, learning resolution parameters for local clustering can be done much more quickly than learning λ for LambdaCC.

New Insights. In addition to improving semi-supervised community detection, minimizing $\mathcal{P}_X$ allows us to measure how well a functional community matches the topological notion of a cluster.

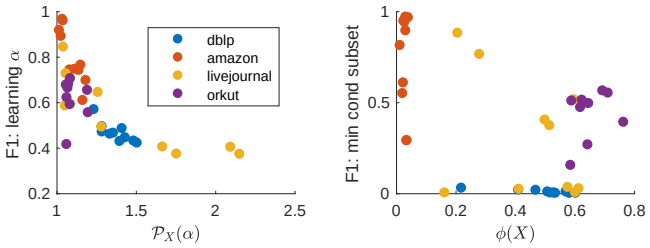

Figure 4: Left: F1 scores for detecting clusters X by learning α vs. the minimum of $\mathcal{P}_X$. Right: F1 scores obtained by finding $\min_{S \subseteq R} \phi(S)$ vs. $\phi(X)$. See the main text for discussion.

Figure 4 shows a scatter plot of F1 community recovery scores against the minimum of $\mathcal{P}_X$ for each experiment from Table 1. We note a downward sloping trend: small values of $\mathcal{P}_X$ near 1 tend to indicate that a cluster is highly "detectable," whereas a higher value of $\mathcal{P}_X$ gives some indication that the functional community may not in fact correspond to a good structural community. We also plot the F1 recovery scores for finding the minimum conductance subset of R against the conductance of functional communities. In this case we do not see any clear pattern, and we learn very little about the relationship between structural and functional communities.

5.3 Meta-Data and Global Clustering

Next we use our techniques to measure how strongly metadata attributes in a network are associated with actual community structure. In general, sets of nodes sharing metadata attributes should not be viewed as "ground truth" clusters [27], although they may still shed light on the underlying clustering structure of a network.

Email Network. We first consider the largest connected component of an email network [21, 41]. Each of the 986 nodes in the graph represents a faculty member at a European university, and edges represent email correspondence between members. We remove edge weights and directions, and consider an example clustering C_x formed by assigning faculty in the same academic department to the same cluster. We use our bisection method to approximately minimize the global parameter fitness function for the degree-weighted LambdaCC objective. We run our method until we find the best resolution parameter to within a tolerance of 10^{-8}, yielding a resolution parameter $\lambda_x = 6.5 \times 10^{-5}$ and a fitness score of $\mathcal{P}_{C_x}(\lambda_x) = 1.34$.

To assess how good or bad a score of 1.34 is for this particular application, we construct a new fake metadata attribute by performing a random permutation of the department labels, which gives a clustering C_{fake}. Approximately minimizing $\mathcal{P}_{C_{fake}}$ yields a resolution parameter $\lambda_{fake} = 3.25 \times 10^{-5}$ and a score $\mathcal{P}_{C_{fake}}(\lambda_{fake}) = 2.16$. The gap between the minima of $\mathcal{P}_{C_{fake}}$ and $\mathcal{P}_{C_x}$ indicates that although the true metadata partitioning does not perfectly map to clustering structure in the network, it nevertheless shares some meaningful correlation with the network's connectivity patterns. To further demonstrate this, we run the generalized Louvain algorithm [7, 16], using the resolution parameters λ_x and λ_{fake}. Running the clustering heuristic with λ_x outputs a clustering that has a normalized mutual information score (NMI) of 0.71 and an adjusted Rand index (ARI) score of 0.55 with C_x. Using λ_{fake}, we get NMI and ARI scores of only 0.05 and 0.003 respectively when comparing with C_{fake}.

Table 1: Output statistics on SNAP datasets for finding the minimum conductance (*mc*) subset, and learning a resolution parameter (*lr*). Runtime is given in seconds. We also provide average size ($|T|$) and conductance ($\phi(T)$) for target communities.

Graph	$\|V\|$	$\|E\|$	$\|T\|$	$\phi(T)$	F1		ϕ		run.		size	
					mc	*lr*	*mc*	*lr*	*mc*	*lr*	*mc*	*lr*
DBLP	317,080	1,049,866	3902	0.49	0.01	**0.47**	0.02	0.16	4.9	11.4	31	11680
Amazon	334,863	925,872	190	0.03	0.73	**0.80**	0.00	0.02	0.3	0.7	142	288
LiveJournal	3,997,962	34,681,189	988	0.45	0.30	**0.54**	0.06	0.10	13.7	31.3	1556	2940
Orkut	3,072,441	117,185,083	3877	0.65	0.44	**0.62**	0.42	0.46	129.8	272.6	2353	5727

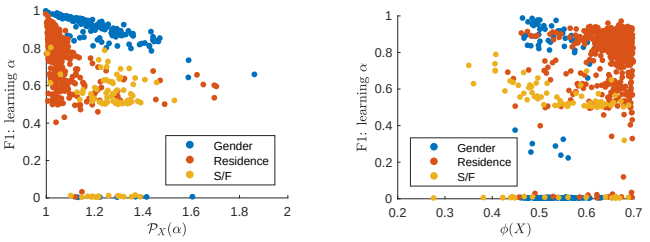
Social Networks. We repeat the above experiment on the smallest social network in the Facebook 100 datasets [34], Caltech36. This network is a subset of Facebook with $n = 769$ nodes, defined by users at the California Institute of Technology at a certain point in September 2005. Every node in the network comes with anonymized metadata attributes reporting student/faculty status, gender, major, second major, residence, graduation year, and high school. We treat each metadata attribute as an example clustering C_x. Any node with a value of 0 for an attribute we treat as its own cluster, as this indicates the node has no label for the given attribute. We do not run Algorithm 1 for each individual C_x, since this would involve redundant computations of the LambdaCC LP relaxations for many of the same values of λ. Instead, we evaluate the denominator of $\mathcal{P}$, which is the same for all example clusterings, at 20 equally spaced λ values between $1/(8|E|)$ and $2/(|E|)$. We set values of λ to be inversely proportional to the number of edges, since we expect the effect of a resolution parameter to depend on a network's size. We note for example that the resolution parameter corresponding to modularity is $\lambda = 1/(2|E|)$, which is also inversely proportional to $|E|$. Computing all of the LP bounds is the bottleneck in our computations, and takes just under 2.5 hours using a recently developed parallel solver for the correlation clustering relaxation [30].

Having evaluated the denominator of $\mathcal{P}$ at these values, we can quickly find the minimizer of $\mathcal{P}$ for each metadata attribute and a permuted fake metadata attribute to within an error of less than 10^{-5}. The smallest values of the parameter fitness function $\mathcal{P}$ for both real and permuted (fake) metadata attributes are given below:

	S/F	Gen	Maj.	Maj. 2	Res.	Yr	HS
$\min \mathcal{P}_{real}$	1.30	1.73	2.03	2.12	1.35	1.57	2.11
$\min \mathcal{P}_{fake}$	1.65	1.80	2.12	2.12	2.11	2.09	2.12

We note that the smallest values of $\mathcal{P}$, as well as the largest gap between $\mathcal{P}$ for true and fake metadata clusterings, are obtained for the student/faculty status, residence, and graduation year attributes. This indicates that these attributes share the strongest correlation with the community structure at this university, which is consistent with independent results on the Facebook 100 datasets [34, 37].

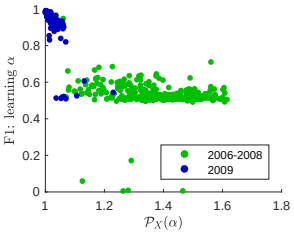
5.4 Local Clustering in Social Networks



In our final experiment we continue exploring the relationship between metadata and community structure in Facebook 100 datasets. We find that minimizing a *local* parameter fitness function $\mathcal{P}$ can be a much better way to measure the community structure of a set of nodes than simply considering the set's conductance.

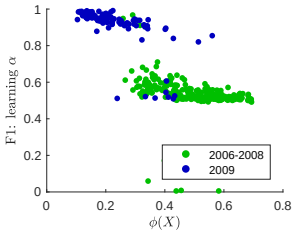
Data. We perform experiments on all Facebook 100 networks, focusing on the student/faculty status, gender, residence, and graduation year metadata attributes. For the Caltech dataset in the last experiment, these attained the lowest scores for a *global* parameter fitness function, and furthermore these are the only attributes with a significant number of sets with nontrivial conductance. For the graduation year attribute, we focus on classes between 2006 to 2009, since these correspond to the four primary classes on each campus when the networks were crawled in September of 2005 [34].

Experimental Setup. We return to an approach similar to our first experiment. For each network and metadata attribute, we consider sets of nodes identified by the same metadata label, e.g., X may represent all students in the class of 2008 at the University of Chicago. We will refer to these simply as *metadata sets*. A label of zero indicates no attribute is known, so we ignore these sets. We also discard sets that are larger than half the graph, or smaller than 20 nodes. We restrict to considering metadata sets with conductance at most 0.7, since conductance scores too close to 1 indicate that a set has little to no meaningful connectivity pattern. For each remaining metadata set X, we grow a superset R around X using a breadth first search, and stop growing when R contains half the nodes in the graph or is three times the size of X. We then minimize $\mathcal{P}_X$ as given by (17) to learn a resolution parameter α_X. This allows us to find $S_X = \operatorname{argmin}_{S \subseteq R} \mathbf{cut}(S) - \alpha_X \mathbf{vol}(S)$, and we then compute the F1 score between S_X and X. Our goal here is not to develop a new method for community detection. Rather, computing the F1 score and the minimum of $\mathcal{P}_X$ provide ways to measure how well a metadata set conforms to a topological notion of community structure, and how detectable the set is from an algorithmic perspective.



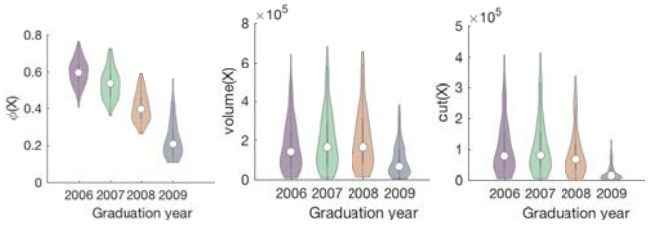
Results. While computing conductance scores provides a good first order measure of a node's community structure, we find that minimizing $\mathcal{P}$ provides more refined information for the detectability of clusters. In Figure 5 we show scatter plots of F1 detection scores against both $\min \mathcal{P}_X$ as well as $\phi(X)$ for each metadata set X. We see that especially for the gender and residence metadata sets across all networks, there is a much clearer relationship between F1 scores and $\min \mathcal{P}_X$. Values of $\mathcal{P}_X$ very close to 1 map to F1 scores near 1, and as $\mathcal{P}_X$ increases we see a downward sloping trend in F1 scores. In the conductance plot we do not see the same trend.

Figures 5c and 5d show results for metadata sets associated with the 2006-2009 graduation years. For this attribute there appears to be a relationship between both conductance and the $\min \mathcal{P}$ scores. Furthermore, in both plots we see a separation of the points roughly into two clusters. A deeper exploration of these trends reveals that



(a) $\mathcal{P}_X$: Gender, S/F, Residence

(b) $\phi(X)$: Gender, S/F, Residence



(c) $\mathcal{P}_X$: Grad Year

(d) $\phi(X)$: Grad Year

Figure 5: Minimizing $\mathcal{P}_X$ gives insight into the connectivity structure of different metadata sets in Facebook 100 datasets. Plotting F1 detection scores against the minimum of $\mathcal{P}_X$ shows especially clear trends for the gender, residence, and year attributes. Plots (c) and (d) highlight an anomaly in the connectivity patterns of the 2009 graduating year classes.

(a) Conductance (b) Volume (c) Cut

Figure 6: Small conductance and cut scores in Facebook 100 datasets indicate that freshman in 2005 were largely connecting on Facebook with people in their same class.

the 2009 graduation class accounts for the majority of one of these two clusters, and there appears to be an especially clear trend between F1 detection scores and both $\phi(X)$ and $\mathcal{P}_X$ for this class.

New Insights. Figure 6 shows violin plots for $\phi(X)$, **cut**(X), and **vol**(X) for metadata sets associated with graduation years from 2006 to 2009. Overall, conductance decreases as graduation year increases. We notice that class sizes for the 2009 graduation year are much smaller on average. When these datasets were generated, Facebook users needed a .edu email address to register an account. Thus, in September 2005, the graduation class of 2009 was made up primarily of new freshman who just started college, many of whom had not registered a Facebook account yet. Interestingly, we see a slight decrease in the median cut score from 2007 to 2008, and a significant decrease from 2008 to 2009 (Figure 6c). This suggests that although there were fewer freshman on Facebook at the time, on average they had a greater tendency to establish connections on Facebook among peers in their same graduation year.

Figure 6 suggests that in the early years of Facebook, with each new year, students in the same graduating class tended to form tighter Facebook circles with members in their own class. To further explore this hypothesis, for each of the 100 Facebook datasets we consider each node from a graduating class between 2006 and 2009. In each network we compute the average *in-class connection ratio*, i.e., the number of Facebook friends each person has inside the same graduating class, divided by the total number of Facebook connections that the person has across the entire university. In 97 out of 100 datasets (all networks except Caltech36, Hamilton46, and Santa74), this ratio strictly increases as graduation year increases. For Hamilton46 and Santa74, the ratio is still significantly higher for the 2009 graduation class than any other class. If we average this ratio across all networks, as the graduation year increases from 2006 to 2009, the ratios strictly increase: 0.39 for 2006, 0.45 for 2007, 0.57 for 2008, and 0.75 for the class of 2009. Previous work on has already highlighted the influence of the graduation year attribute on the connectivity structure of Facebook 100 datasets on the whole [34]. Our exploration of these datasets has further allowed us to uncover interesting new connectivity patterns that exist between different individual graduation years.

6 DISCUSSION AND FUTURE WORK

We have introduced a new framework and theory for learning resolution parameters based on minimizing a fitness function associated with a single example clustering of interest. There are several open questions for improving our specific approach. Our bisection-like algorithm is designed to be general enough to minimize a large class of functions to within arbitrary precision. However, by making additional assumptions on either specific clustering objectives or the fixed example clustering, one may be able to develop improved algorithms for minimizing the parameter fitness function in practice. Another open question is to study which other graph clustering objectives can fit into out framework, beyond just the LambdaCC global objective and the local flow clustering objective, and whether, for example, the approach can be applied to clustering in directed graphs.

Our work can be viewed as one approach to the more general goal of learning objective functions for graph clustering applications. This general goal could involve more techniques than simply learning resolution parameters. For example, in future work we wish to explore how to learn small *motif* subgraph patterns [6] in an example clustering that may be indicative of a desirable type of clustering structure in an application of interest.

ABSTRACT

Data brokers such as Acxiom and Experian are in the business of collecting and selling data on people; the data they sell is commonly used to feed marketing as well as political campaigns. Despite the ongoing privacy debate, there is still very limited visibility into data collection by data brokers. Recently, however, online advertising services such as Facebook have begun to partner with data brokers—to add additional targeting features to their platform— providing avenues to gain insight into data broker information.

In this paper, we leverage the Facebook advertising system—and their partnership with six data brokers across seven countries—in order to gain insight into the extent and accuracy of data collection by data brokers today. We find that a surprisingly large percentage of Facebook accounts (e.g., above 90% in the U.S.) are successfully linked to data broker information. Moreover, by running controlled ads to 183 crowdsourced U.S.-based volunteers, we find that at least 40% of data broker sourced user attributes are not at all accurate, that users can have widely varying fractions of inaccurate attributes, and that even important information such as financial information can have a high degree of inaccuracy. Overall, this paper provides the first fine-grained look into the extent and accuracy of data collection by offline data brokers, helping to inform the ongoing privacy debate.

1 INTRODUCTION

Data brokers such as Acxiom [5] and Experian [23] have traditionally collected, aggregated, and linked information about people's activities, based on a variety of sources (e.g., voter records, vehicle registries, loyalty cards, and so forth). Their business model is then selling this information to third-parties such as banks, insurance companies, political campaigns, and marketers. The collection practices of data brokers have been the subject of an ongoing privacy debate. For example, data brokers typically only make data available to clients who purchase it, and not to the users who it is actually about [20]. Even worse, public-facing web sites run by data brokers [10] that purport to reveal the data only report a fraction of what they actually have [19, 47]. In fact, outside of a few niche areas (e.g., credit reports), people in the U.S. have limited if any rights to determine the provenance of, correct, or even view the data these companies have on them [38]. As a result, researchers and society at large still have a very limited understanding of the extent, accuracy, or provenance of this data collection ecosystem.

In parallel, *online services* such as Facebook and Google have been collecting information about people's online activities. Their business model is to build advertising platforms that use this data to provide advertisers with fine-grained targeting features [29, 31]. Recently, data brokers and online services have begun partnering together, allowing for the data collected about users online to be linked against data collected offline. This enables online services to provide advertisers with targeting features that concern users' offline information (e.g., advertisers can then target users based on their net worth, purchase behavior, and so forth [4, 34]). While this linking of offline and online data may seem to only further stoke the privacy debate, it does have one significant benefit: it offers a unique opportunity to gain visibility into the data broker ecosystem. Specifically, advertising platforms often provide advertisers with statistics about any audience an advertiser can target, *including those created using data broker-provided attributes.* This provides the first opportunity to gain insight into the extent of data collection by offline data brokers.

In this paper, we use the Facebook targeted advertising platform to study the *coverage* and *accuracy* of data collected by four offline data brokers (Acxiom, Epsilon, Experian, and Oracle Data Cloud - formerly Datalogix) across seven countries (U.S., U.K, Australia, Germany, France, Japan, and Brazil). [1] To examine the coverage of data brokers (i.e., the fraction of the population they have data on), we collect statistics from the Facebook advertising interface on how many Facebook users possess each of more than 600 data broker-provided attributes. Our results demonstrate that a large

[1] While Facebook reported having partnerships with six different brokers [4], we were able to find targeting attributes corresponding to only four of these brokers on Facebook's advertising platform.

percentage of Facebook accounts (e.g., ranging from over 48% of users in Japan to over 90% of users in the U.S.) are indeed linked to some data broker information, thus demonstrating for the first time the extent of offline-online data linkage, in addition to demonstrating the coverage of offline data brokers. Furthermore, we devise a methodology to study the coverage at a fine granularity based on the targeting mechanisms and statistics commonly provided by online advertising platforms in Section 3. We find that data broker coverage generally increases with the age of users, and can be significantly lower in U.S. counties with higher poverty levels. We also find that data brokers have high levels of coverage for potentially sensitive user attributes such as income (76.9% of all U.S. users), net worth (67.6%), and purchase behavior (86.7%).

Facebook provides users with an Ads Preferences Page [28] where they can see and correct what data Facebook has inferred about them; however, this page does not reveal to users *any* of the attributes sourced from data-brokers [2]. To study the accuracy of these attributes we use a recently-proposed transparency mechanism [53], which consists of running ads that reveal information about their targeting to the targeted users. Such ads, called *Transparency-enhancing advertisements* (Treads), work because advertising platforms by their very functionality only show targeted ads to users who satisfy the targeting of that ad. Thus, by running one distinct Tread targeting each individual data-broker-sourced attribute offered by the ad platform, we can reveal to users which data broker attributes they have.

To study the accuracy of attributes sourced from data brokers, we run Treads to a set of crowdworkers who installed a browser extension that collects the Treads seen by the worker, and surveys them about the accuracy of the inferred broker information. We use the results from 183 workers—corresponding to 1,432 individual inferred data broker attributes—to analyze the overall accuracy of broker and Facebook information, the per-user accuracy of broker and Facebook information, and the accuracy of broker information across various information categories. We find that the wide coverage of data broker information comes at the cost of mediocre accuracy, with around 40% of attributes being reported as "Not at all accurate" by workers. We also find that inaccuracy does not occur in an all-or-none fashion (i.e., users can have widely varying percentages of inaccurate data broker attributes). Finally, we find that even potentially sensitive attributes like financial information have mediocre accuracy, with for example 56% of attributes about investments reported as "Not at all accurate".

Taken together, our results present the first detailed look into the coverage and accuracy data broker ecosystem; our methodology could also be used to help trace the provenance of collected data, as well as to study how data collection practices change over time.

2 BACKGROUND

We begin by providing some background about offline data brokers, before explaining relevant parts of Facebook's advertising interface.

2.1 Offline data brokers

While some data brokers such as Acxiom [5], Epsilon [21], and Datalogix (now part of Oracle Data Cloud [39]) are geared towards aggregating consumer data to sell to marketers and advertisers, other companies such as Experian [23] have a greater focus on creating credit reports for businesses.

Kinds of data collected The data collected by data brokers is diverse and often very sensitive. It can include demographic information such as ethnicity and occupation, household characteristics such as age and number of children, financial information such as income and net worth, life events such as divorces, and credit-related information about property, mortgages, and investments [9, 26]. Other information collected can include sensitive health-related information such as ailments, medications, visual impairments, and health indicators [8, 26]. Publicly available detailed catalogs of data offered by data brokers are hard to find; we were only able to find the following data catalogs corresponding to Experian [26], Oracle Data Cloud [40], and Acxiom [6]. These catalogs show the diversity, sensitivity, and fine-grained nature of the information collected by these data brokers, highlighting the importance of understanding their data collection better.

Extent of data collection Data brokers reveal only high-level information about the extent of the data they collect. For example, Acxiom reveals that its data collection "now encompasses more than 62 countries, 2.5 billion addressable consumers and more than 10,000 attributes", for a "comprehensive representation of 68 percent of the world's online population" [7]. Similarly Epsilon reveals that its data covers "virtually every U.S. household" [22], and Experian reveals that it "maintains credit information on approximately 220 million U.S. consumers and 25 million active U.S. businesses", "demographic information on approximately 235 million consumers in 117 million living units across the U.S.", and "information on more than 650 million vehicles in the U.S. and Canada" [24]. However, except to their clients, these data brokers usually do not reveal detailed lists of what kinds of information they collect, and how many users are covered by different kinds of information.

Some data brokers do allow individuals to gain some insight into the data collected about them, such as Acxiom's "About the Data" site [10] and Experian's free credit reports [25]. However, these are only sanitized versions of their data and only show a fraction of the actual data collected [19, 47].

2.2 Facebook's advertising platform

Facebook's advertising platform is one of the largest and most mature online advertising platforms. It leverages Facebook's user data to allow advertisers to target *audiences* of users (i.e., sets of users with particular attributes) with ads.

Targeting parameters When specifying an audience, advertisers must specify the location (e.g., countries, states, or postal codes), age range (between 13 and 65+), and gender of users to target. In addition, advertisers can choose to include or exclude users who have certain attributes, choosing from a list containing 1,121 attributes; of these, 614 attributes come from Facebook and are present in all countries, while the others come from data brokers and can vary across countries [2]. In addition, advertisers are able to create targeting formulas of boolean expressions over attributes [11].

Size estimates Once the advertiser specifies the particular attributes of users to target, Facebook then gives the advertiser a size estimate (called the *potential reach*) that represents the number of

monthly active Facebook users who meet the targeting criteria.[2] Prior work found that the potential reach was calculated by rounding the number of matching users to two significant digits [52].

Partner categories Facebook refers to the offline information obtained by linking its profiles with data brokers (also called Facebook Marketing Partners) as *partner categories* [4]. Facebook reports that partner categories are "available to people targeting audiences located in the United States, Brazil, France, Germany, the United Kingdom, Australia, and Japan"; this includes data from Acxiom, Acxiom Japan, CCC Marketing (for Japan), Epsilon, Experian, Oracle Data Cloud, and Quantium [4]. Facebook recently announced that it would soon be terminating these partnerships and removing these categories [49] in the wake of the Cambridge Analytica scandal, and ultimately did so in October 2018.

Linking partner data One key concern with partner data is the *linking* process: essentially, identities in the partner's database need to be correctly linked with Facebook's user database to enable accurate targeting. While the exact linking methodology is not public, Facebook has stated that it is based on users' unique identifiers [34]:

> For each Facebook user, the company computes a hash code of the person's phone number, email address and other major identifiers and transmit those to Acxiom, Oracle, Epsilon and the other data brokers it works with and requests that they return all available marketing segments they offer for that user.

2.3 Related work

We next review closely related work on data brokers, linkage between offline and online identities, and online advertising platforms.

Coverage of data brokers To the best of our knowledge, there have been no studies analyzing the coverage of data brokers in a fine-grained manner; as previously mentioned, this has been due to the difficulty of conducting such a study owing to the opaque practices of data brokers. While the U.S. Federal Trade Commission (FTC) published a report in 2014 describing data brokers, their sources of data, and their clients [20], they were unable to report on the coverage of data by these data brokers at a fine-grained level.

Accuracy of data brokers There have been a number of anecdotal reports that show that data collected by data brokers can be inaccurate. For example, a journalist obtained a copy of their information held by Oracle Data Cloud [34], and examined their data as provided by Acxiom's "About the Data" site, finding that more than 70% of their attributes from either source were inaccurate. Similarly another journalist [13] found their information from Acxiom highly inaccurate, while yet another [37] found nearly 50% of their personal information purchased for a $50 fee from an undisclosed company inaccurate. While these results are intriguing, they each represent data for only a single individual.

A recent white paper [42] presented a small-scale study of 107 Deloitte U.S. employees, asking them to review their data revealed by a "leading consumer data broker" with "a publicly available, web-based portal that presents users with a variety of personal and household data." These authors restrict themselves to a small, arbitrary subset of 30 attributes, finding that nearly half of the attributes are incorrect for more than 50% of users who have them. They do not report how many of the 107 participants actually had data about them and responded to the survey. Another small-scale study [45] surveyed 8 graduate students about their information collected by Oracle BlueKai as revealed by its transparency feature, with all participants finding some inaccuracies in their profiles. These two studies focus on a non-representative sample of users, on one data broker, and (in the case of the former study) on a small set of attributes provided by the broker; in comparison, our methodology allows us to study a more general sample of users, covering multiple data brokers, avoiding the use of a sanitized version of the data, and focusing on all 507 data broker attributes that Facebook makes available through its advertising platform.

Online-offline linkage Prior work [36] has explored the potential for data brokers to link online data (Facebook profiles) and offline data (voter registration records) in target cities in the U.S., presenting one method to link such profiles. Since data brokers might potentially use more sophisticated methods to accomplish such linkage, our work makes the complementary contribution of empirically demonstrating the extent of such online-offline linkage.

Online advertising platforms A number of recent studies have looked at the privacy implications of online advertising platforms. For example, multiple projects [27, 33, 52] have discovered serious privacy leaks on Facebook's ad platform, and others [48] demonstrated the potential for abusing Facebook's ad platform to launch hard-to-detect discriminatory advertising on Facebook's ad platform. Other researchers [17, 46] have demonstrated that these weaknesses are not confined to Facebook, and are present in Google's ad platform as well. The recent inclusion of data broker-derived data—often consisting of sensitive information such as financial information—could exacerbate such ill effects.

On the other hand, recent work [2] studied Facebook's transparency mechanism that purports to show users why they were targeted with a particular ad. They found that Facebook's transparency feature does reveal information about Facebook's attributes, but *does not* reveal any information about data broker attributes that have been collected about users. Our work is therefore the first to shed light on the usage of data broker information in this ecosystem.

A number of recent studies have used Facebook's advertising platform for various demographic studies, either estimating the coverage of sensitive attributes computed internally by Facebook [16], studying the distribution of health conditions using various indirect markers [35], studying the gender divide on Facebook [30], or studying the migration of populations [55]. Our paper, on the other hand, estimates the extent of linkage between online and offline identities, and the coverage achieved by offline data brokers, using Facebook's advertising platform.

Finally, a number of recent studies have examined the accuracy of information revealed by the transparency mechanisms of online advertising platforms. While one study [50] found that participants' age and gender as revealed by Google's transparency mechanism were accurate for 65% - 74% of participants, and had missing values for 18%-29% of participants; another study [14] found that over 52% of participants reported less than half of their information as listed by the transparency mechanisms of Google, Facebook, and a

[2]Facebook previously defined potential reach as measuring the number of *daily* active users [52]; however, the definition of potential reach has always captured the notion of active users.

small broker Nielsen eXelate as "relevant". Finally, 27% of users in a recent report [1] found their information revealed by Facebook's transparency mechanism inaccurate. Our work instead chiefly focuses on the coverage and accuracy of information aggregated by offline data brokers.

3 COVERAGE

We next describe our methodology for examining the coverage of data collected by data brokers, before analyzing the results.

3.1 Methodology for studying coverage

Obtaining data broker attributes Similar to prior work [2], we use the "web inspector" feature of our web browser to identify the API call made by Facebook's ad interface to retrieve the list of targeting attributes shown to an advertiser.[3] These attributes are organized in a hierarchy, with the highest level categories being "Interests", "Demographics", and "Behaviors". These are then subdivided into sub-categories; the targeting attributes themselves are the leaf nodes of this hierarchy. For all attributes, the result of the API call contains the name of each targeting attribute, its parents in the hierarchy, and the total number of users with that attribute. For partner attributes, the result also contains the name of the partner (data broker) that the attribute was sourced from, and a brief description about the attribute.

We notice that the list of targeting attributes shown depends on the country in which the advertising account is created (and not, for example, on the country of the audience being targeted). Thus, to obtain the list of targeting attributes across different countries, we create Facebook accounts while logged in to an Amazon Web Services (AWS) instance based in that country, and then obtain the corresponding list of attributes shown. We collected these lists of targeting attributes in April 2017 for all seven countries (U.S., U.K, Australia, Germany, France, Japan, and Brazil) where Facebook reports it offers partner categories [4].

We found partner categories in all seven countries, with a varying number of data brokers in these different countries as can be seen from the first two columns of Table 1. These included all but two brokers—Quantium (for Australia) and CCC Marketing (for Japan)—reported by Facebook [4]; this may be because Facebook allows advertisers to request additional categories on a case-by-case basis from certain partners (as opposed to offering them to all advertisers via the ad interface). In addition, we collected these lists of targeting attributes for all three other countries (Canada, South Korea, and India) where we could create AWS instances; as expected, we found no partner categories corresponding to these countries.

Measuring extent of data broker coverage While it would be ideal to measure the percentage of *all* Facebook identities that have been linked to data broker information, the platform offers no way of estimating this. Instead we focus on the set of Facebook identities that are *targetable* by advertisements, since Facebook provides us estimates of the size of this set (via the *potential reach* estimates shown when creating an ad).[4]

[3]One only needs a Facebook account in order to be an advertiser and use Facebook's ad interface.

[4]These estimates could vary over longer intervals of time as they count active users [52]; thus, we ensure that all measurements corresponding to that population are made within short intervals of time. Also, these estimates are rounded to have two significant digits [52]; we verified that the magnitude of this measurement error does not affect our findings.

Country	Partner	Attribute count	Targetable		Percent
			Overall	Partner	
U.S.	**All**	507	210M	190M	90.5%
	Acxiom	128	210M	160M	76.2%
	Datalogix	350	210M	160M	76.2%
	Others[5]	10	210M	150M	71.4%
	Experian	5	210M	140M	66.7%
	Epsilon	14	210M	130M	61.9%
Australia	**All**	58	16M	13M	81.3%
	Experian	34	16M	12M	75.0%
	Acxiom	24	16M	9.1M	56.9%
U.K.	**All**	139	39M	29M	74.4%
	Acxiom	103	39M	22M	56.4%
	Datalogix	19	39M	17M	43.6%
	Experian	17	39M	15M	38.5%
Germany	Acxiom	60	31M	20M	64.5%
France	Acxiom	21	32M	18M	56.3%
Brazil	Experian	20	120M	61M	50.8%
Japan	Acxiom	17	25M	12M	48.0%

Table 1: Coverage of different data brokers across countries with partner categories. We show the total number of broker attributes, the number of Facebook identities that are targetable (Overall), the number of these identities that have at least one attribute from that broker (Partner), and the resulting coverage. Countries with more than one broker have a row indicating the coverage of all the brokers together (All).

We then estimate the coverage achieved by a broker within a particular population: *First*, we obtain the number of targetable identities corresponding to all users in that population (e.g., by obtaining the potential reach targeting that population). *Second*, we obtain the number of targetable identities within that population that have at least one attribute from that particular broker (we can do this since Facebook's ad interface allows us to target an OR of attributes, as mentioned in Section 2). While each of these numbers represents subsets of the overall population that are targetable, their ratio provides an estimate of the coverage in the overall population.

We are then able to study the coverage across different subpopulations (e.g., across genders, ages, locations, etc.), as Facebook allows us to additionally filter by those attributes (see Section 2).

Limitations Our methodology has a few limitations worth discussing. *First*, the population of targetable identities could be a biased sample of both the overall population of Facebook users, and of the overall population of that targeted country as a whole. We briefly explore this bias by focusing on the U.S., comparing the distribution of targetable identities with those of the overall population of the country (sourced from the U.S. Census Bureau's 2017 American Community Survey [ACS] 1-Year Estimates [3]). From Table 2, we see that the distribution across gender is similar for both targetable identities and for the U.S. population. However, we can see that the population of targetable identities is biased towards lower ages, with a larger percentage of people aged 44 or below than in the overall U.S. population. Nevertheless, this sample can still provide us a unique opportunity to study the coverage of data broker information across a large sample of users.

	Value	U.S. Census	Targetable	Surveyed (§4)
Age	15-24	13.3%	17.9%	22.9%
	25-34	13.8%	26.2%	37.1%
	35-44	12.6%	17.9%	22.4%
	45-54	13.0%	14.6%	8.7%
	55-64	12.9%	11.7%	7.1%
	65+	15.6%	10%	0.0%
Gender	Male	48.7%	47.8%	40.9%
	Female	51.3%	52.2%	56.8%

Table 2: Demographics of the entire U.S. population (U.S. Census), all targetable U.S. Facebook users (Targetable), and the crowdsourced users surveyed in Section 4 (Surveyed).

Second, data brokers might provide only a subset of their information to Facebook. However, Facebook has revealed that it requests "all available marketing segments they offer" from its partners [34], suggesting this is not the case. *Third*, the measured coverage of data brokers depends on the extent of linkage between Facebook profiles and offline data broker information, and thus can only provide a lower bound on the actual coverage of the data brokers. In the next section, we first demonstrate that there is a high extent of linkage between Facebook profiles and offline data broker information, thus suggesting our lower bounds are tight.

3.2 Analysis of coverage

We now examine the results on data broker coverage obtained using the methodology just described.

Extent of online-offline identity linkage We begin by examining the fraction of Facebook accounts that are linked with *any* data broker information. To do so, for each country, we measure the percentage of targetable Facebook identities that have *at least one* attribute from any of the brokers offering attributes within that country. This percentage reveals the extent of linkage of Facebook identities with offline information and serves as a lower bound.

Table 1 shows the percentage of targetable identities in different countries that have at least one data broker attribute; for countries with multiple data brokers, we include an **All** line that matches users from any of the data brokers. We make two observations: *First*, the extent of linkage is surprisingly high for the U.S., with over 90% of targetable Facebook identities having at least one data broker-provided attribute; similar high percentages of linkage are observed for Australia (81.3%), and for the U.K. (74.4%). *Second*, the extent of linkage is higher for countries where Facebook links to a larger number of data brokers (and obtains a larger number of attributes), indicating that even for the other countries, Facebook might have the ability to link a larger percentage of identities if it simply partnered with more data brokers. Taken together, these results suggest that offline and online data are being linked at massive scale. Having observed that our methodology can yield good lower bounds, we move on to further characterize the coverage.

Coverage of individual data brokers We measure the overall coverage achieved by various individual data brokers[5] in each of the seven countries we study; the results are presented in Table 1.

[5]We observed that 10 particular targeting attributes for the U.S. were labeled as coming from "data providers", indicating they are sourced from multiple brokers; in a previous crawl earlier in 2017, we observed that these were exclusively sourced from Acxiom. We mark these as "Others" when reporting results.

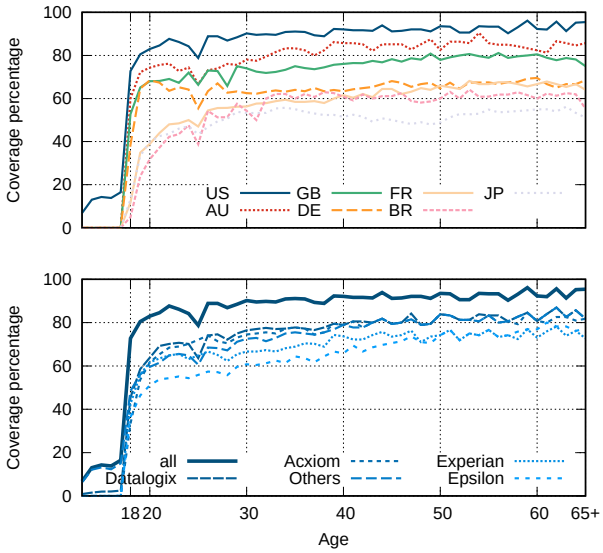

Figure 1: Breakdown of data broker coverage by age across multiple countries (top) and only within the U.S. (bottom).

We make three observations: *First*, we see that almost all the brokers achieve a coverage of at least half the targetable population in the country, irrespective of the country, showing that data brokers are successful in aggregating information about users at a global level. *Second*, we also see that the coverage can be as high as 76.2% (for Acxiom and Datalogix (now part of Oracle Data Cloud [39]) in the U.S.) and 75% (for Experian in Australia). *Third*, we see that the coverage achieved by the same broker can vary significantly (e.g., Experian covers over 66%, 75%, 38%, and 50% in the U.S, Australia, U.K., and Brazil, respectively).

Variation in coverage across ages One powerful feature of Facebook's advertising service is the ability to sub-divide any audience by additional features. As an example, we briefly study the variation of overall coverage of all data brokers in a country with users' age at the top of Figure 1. Similarly, we study the variation in coverage of individual data brokers from the U.S. at the bottom of Figure 1.

In either case, we study variation of coverage across ages taken from the set {13, 14, 15, ..., 65+}; these correspond to the ages that the interface allows us to target. We firstly observe that across countries, or across brokers in the U.S, the coverage rapidly increases between the ages of 18 and 20; this might be because these ages roughly correspond to the ages when people start acting with financial independence, and indicate that data brokers are rapidly able to cover people once they start acting as independent adults. We secondly observe that the coverage generally increases up to the age of 30, after which the rate of increase with age slows down; one exception is Epsilon in the U.S, whose coverage increases from 60.8% at age 30 to over 77.2% at age 65+. Finally, we observe that while the coverage for people below 18 years of age is zero for countries other than the U.S.; the corresponding coverage for the U.S. is non-zero, not dropping below 6.8% for the minimum studied age of 13. We observe that the data brokers in the U.S. with non-zero coverage for these users are Oracle Data Cloud (dropping from a

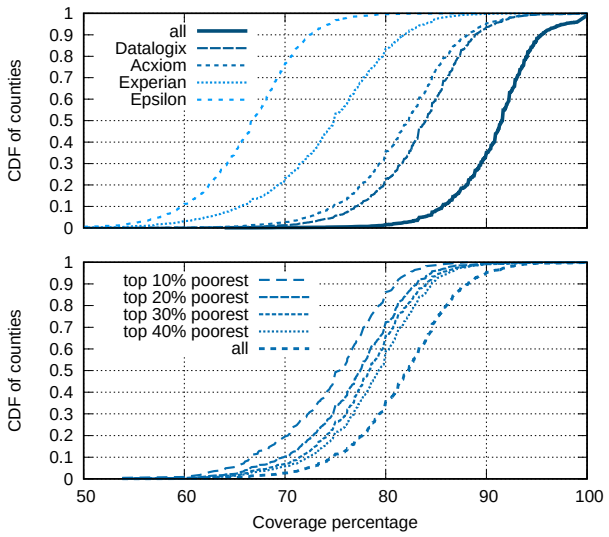

Figure 2: Cumulative distribution function (CDF) of data broker coverage across different U.S. counties (top), and of Acxiom for counties ranked by population below poverty level, as rated by the U.S. Census (bottom).

Category	Coverage
Behaviors → Purchase behavior	86.7%
Demographics → Financial → Income	76.9%
Demographics → Home → Home Ownership	72.3%
Behaviors → Automotive	68.7%
Demographics → Financial → Net Worth	67.6%
Behaviors → Financial → Spending methods	65.6%
Demographics → Home → Home Type	45.6%
Behaviors → B2B → Company size	44.1%
Demographics → Home → Home Type → Home value	43.1%
Behaviors → B2B → Industry	40.5%
Behaviors → Charitable donations	40.5%
Behaviors → Financial → Investments	40.0%
Demographics → Financial → Net Worth → Liquid assets	38.5%
Behaviors → Media → Television → Show Genre	28.7%
Behaviors → Travel	26.1%

Table 3: List of all 15 categories of data broker attributes provided on Facebook, along with the coverage (i.e., the fraction of targetable U.S. Facebook users who have at least one attribute in that category). We observe impressive coverage, with a significant variance across categories.

2.4% coverage for age 17 to a 0.8% coverage for age 13), and the brokers labeled by Facebook as "data providers", marked "Others" in the plot (dropping from 15% for age 17 to 6.3% for age 13).

Variation in coverage across U.S. counties We move on to study the variation of data broker categories across fine-grained geographic areas, plotting the CDF of the variation across different U.S. counties in Figure 2 (top). Since we cannot directly target counties on Facebook's ad platform—but we can target ZIP codes—we obtain a mapping from ZIP codes to counties [51]; we filter out military ZIP codes, P.O. box ZIP codes, and unique ZIP codes (dedicated for use by large organizations), giving us 29,916 ZIP codes in total. We further only consider ZIP codes from counties from the 50 states of the U.S. (3,110 counties in total). In the figure, we observe that the broker coverage varies widely across counties, roughly varying between 65% and 95% for Acxiom and Oracle Data Cloud, 50% and 80% for Epsilon, and 50% and 90% for Experian.

While on one hand, increased data broker coverage can have negative privacy implications, on the other hand there are a number of benefits to consumers from data broker coverage, such as better fraud prevention, improved product offerings, and more relevant (tailored) advertisements [20]. Thus, we study whether the extent of data broker coverage is correlated with the socioeconomic development of counties, specifically measured by the percentage of population in a county that is below the poverty level as per the 2012-2016 American Community Survey 5-Year Estimates [12]. In Figure 2 (bottom), we plot the CDF of coverage of one data broker (Acxiom) across the top percentiles of counties (in terms of having the highest fraction of population below poverty line), in addition to plotting the CDF of coverage across all counties. While we only show results for one data broker (owing to space constraints), we find similar results with other data brokers, and with the overall coverage of all data brokers taken together. We see that the coverage by Acxiom is indeed lower for counties with higher fractions of population below poverty line; for example, while 64.3% of all counties have at least 80% of their population covered by Acxiom, only 13.8% of those in the top 10th percentile have a similar coverage by Acxiom. This shows that data brokers indeed achieve lower coverage in counties with higher poverty rates.

Variation in coverage across attributes To understand the variation in coverage across various kinds of information, we group the 507 broker attributes available for the U.S., according to the second-to-last level of the hierarchy presented by Facebook, which we refer to as a *category*. Doing so gives us 15 categories in total where the "leaf" attributes are provided by data brokers. For example, the category Demographics → Financial → Net Worth → Liquid assets represents peoples' total liquid assets; all of the leaf attributes in this category together cover 100M people, and there are nine different leaf attributes including $1-$25K (covering 23M people), $25K-$50K (14M people), ..., up to >$3M (2.7M people). Similarly, the category Behaviors → Purchase behavior represents the kinds of purchases people make; it covers 169M people and has 175 different leaf attributes including Coupon users (100M people), Childrens' cereals (24M people), and Over-the-counter medication (43M people).

For each category, Table 3 shows the percentage of the U.S. population that is covered by at least one attribute corresponding to that category. We find that the coverage can vary significantly with the kind of targeting information, and can be as high as 86.7% for purchase behavior, and higher than 65% for sensitive categories like net worth, spending methods, home ownership, and income, but much lower 38.5% for net worth in the form of liquid assets.

4 ACCURACY

We move on to study the accuracy of data broker attributes, focusing on U.S.-based users. We first discuss the methodology we use before diving into the results.

4.1 Methodology for studying accuracy

Revealing user attributes to users While Facebook reveals Facebook-derived attributes, it has been shown to not reveal users' data broker attributes [2]. Thus, we leverage a recently-proposed mechanism that uses Facebook's advertising platform to enforce transparency on itself. Called *Transparency-enhancing advertisements* (Treads), the mechanism allows an advertiser to reveal platform-collected information about users by targeting them with ads that contain information about their targeting [53]. Specifically, we reveal to users (study participants) whether they have a particular data broker attribute by running one ad targeting all study participants, and another ad targeting only those participants who have that particular data broker attribute. If a user receives the first ad, we know they are targetable; if they receive the second as well, we know they have the data broker attribute.

To be able to target participants, we ask them to 'Like' our study's Facebook page. We then target Treads to the set of users who liked our Facebook page, with one Tread for each of the 507 data broker categories in the U.S (from Section 3.1). Since explicitly including the categories in the ad may be against Facebook's advertising policies [53], we encode each attribute by a unique numeric identifier, which we then translate into innocuous-looking text. For example, we might assign a particular attribute the identifier 852, which is then translated into "We have 8 and 52 ideas. Stay tuned."

Data collection In order to decode these Treads and to infer a user's data broker attributes, we built a browser extension for Google Chrome. The extension scans for our ads on Facebook as the user normally browses, and locally stores only the numeric identifiers in the Treads that are seen (for privacy reasons).

We then use our extension to survey users about the accuracy of their data broker attributes. As a baseline, we also survey users about the accuracy of information about them collected internally by Facebook. To do so, we gather the user's Facebook ad preferences page [28] just prior to the survey; we call these *Facebook attributes*.

When surveying participants, we randomly shuffle the data broker attributes and Facebook attributes, without revealing which is which to users. In order to avoid user fatigue, we survey them on a random sample of at most 25 data broker attributes and at most 30 attributes overall. For each user attribute, we show the user the attribute, and ask them questions about its accuracy. Specifically, we ask users whether the inferred attribute is "Not at all accurate", "Somewhat accurate", "Mostly accurate", or "Completely accurate." For data broker attributes, we also show Facebook's description of the attribute to the user.[6] For Facebook attributes, this description is not available; hence, we only show the attribute. Finally, we ask about their demographic information. Users are asked to answer only those questions they feel comfortable answering.

Changed targeting attributes Early-on during our experiments in this section (in August 2018), we found Facebook stopped supporting 120 out of the 507 original targeting attributes. [7] By freshly obtaining the set of targeting attributes from the API (in the same way as in Section 3.1), we found that each of the above 120 attributes was replaced by a similar attribute. However, the partner for all these attributes was now described as a generic "data license", perhaps indicating they were being sourced from multiple data brokers. In any case, we ran an additional 120 Treads for these attributes, and report accuracy for these under the column of "Others."

[6]For example, the attribute Behaviors → Charitable donations → Veterans , has the description, "People who are interested in donating to veteran causes."

[7]Of these 120 attributes, 96 were sourced from Acxiom (corresponding to information such as net worth, investments, spending methods, home type, charitable donations etc.), 21 were from Oracle (corresponding to information such as travel), two from Experian (corresponding to information such as home ownership) and one from Epsilon (corresponding to the length of residence).

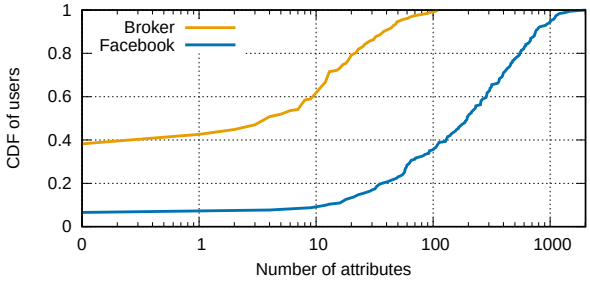

Figure 3: Distribution of inferred broker and Facebook attributes across the 183 participants who took the survey.

4.2 User recruitment

Our user study was reviewed and approved by Northeastern University's Institutional Review Board (IRB). We recruited users from Prolific [44], a crowdsourcing platform geared towards researchers; the quality of data obtained from Prolific users has been found to be comparable to that of the dominant crowdsourcing platform, Amazon Mechanical Turk [41]. We used Prolific's filters to selectively target our study at users aged 18 and above, residing in the U.S., and who use Facebook on a regular basis (at least once a month). We also followed Prolific's guidelines to selectively obtain high-quality participants [18], only considering users who had at least 10 prior submissions on Prolific, and an approval rating of at least 95 out of 100. This gave us a pool of over 4,000 potential participants, from which we recruited 300 users.

Participants were invited to participate in a research study about their reactions to their Facebook information (we did not mention data brokers until the end of the study so as not to bias participants). Participants were first asked to install our extension, for which they were paid $2. Participants were also asked to browse Facebook as they normally would in the subsequent days, and were informed how our extension works. After a period of a month, we followed up with the 231 users that still had our extension correctly installed, and requested them to take the survey (via the extension). We compensated participants $8 for completing the survey. 183 users completed the survey; this attrition rate of 39% (compared to the initial 300 users recruited) is well within the range of attrition rates observed in longitudinal studies on Prolific [18].[8]

Figure 3 shows the distribution of the number of data broker and Facebook attributes for these users who took the survey.[9] While around 61% of these users had at least one data broker attribute, 41% of the users had 10 or more data broker attributes, with the median user having four attributes. The median participant had 196

[8]The attrition was partially due to delays (of over a week) on our part in setting up the survey due to technical issues, and due to some users mistakenly assuming that the study had ended.

[9]Due to a bug in our extension in the early stages of our extension (where it failed to scan some users' Facebook home pages for our Treads, we potentially missed some users' data broker attributes. Thus, the plot potentially shows a lower bound on the actually revealed users' broker attributes.

Facebook attributes; given our limits on the number of attributes surveyed, the median number that we surveyed them on was 22.

Participant demographics To quantify the bias in the set of surveyed participants, we compare their demographics with those of the overall U.S. population [3]. For age/gender, we compare against the population of targetable Facebook identities (see Section 3).

Table 2 compares the age and gender distribution of participants. We find 56.8% of participants are female, as opposed to 52.2% of targetable Facebook identities and 51.3% of the entire U.S. population. We also find 82.4% of participants are younger than 45, as opposed to 62% of the targetable Facebook identities, and 39.7% of the offline population. Overall, this indicates a slight bias towards women, and a larger bias towards younger people, that is qualitatively similar to the bias of targetable Facebook identities.

We find that 63.4%, 8.1%, and 8.7% of our participants reported a single race of White, Black, and Asian, respectively. Thus our participant pool has a smaller percentage of White and Black participants and a larger percentage of Asian participants compared to the general U.S. population which has 72.3%, 12.7%, and 5.6% respectively of these races. 12.6% of our participants reported themselves as "Hispanic or Latino", as opposed to 18.1% of the overall population. Finally, our partipants are spread across 39 U.S. states.

Limitations Inaccuracy in data broker information revealed via Facebook's advertising platform can arise from two sources: (i) inaccuracy in the information collected by data brokers, and (ii) inaccuracy in linking data broker information to Facebook accounts. Thus, our methodology measures the cumulative effect of these two sources of inaccuracy, providing an upper bound on the inaccuracy of information collected by data brokers. However, as discussed in Section 2, Facebook only uses unique identifiers such as phone numbers and email addresses to match data broker information [34], thus indicating that the inaccuracy introduced due to the linking process is likely limited. Thus, our upper bounds are likely tight.

Additionally, the information exposed by Facebook via its advertising platform may only cover a subset of information held by data brokers. However, recent reports have stated that Facebook receives "all available marketing segments offered for [each] user" from data brokers [34]. Moreover, since our methodology relies on Treads to reveal user attributes, not all data broker attributes of each user might be successfully revealed (e.g., if some Treads that are not delivered). Finally, our methodology relies on the accuracy of attributes as reported by participants; while each participant is the best source for evaluating the accuracy of their own data, they might misunderstand what certain attributes mean, may lie, or might be subject to fatigue (which we try to limit). Besides, participants might not recall past behavior such as purchases, or imperfectly estimate information such as their financial data.

4.3 Analysis of accuracy

We next analyze the responses from participants in order to understand the accuracy of information collected by data brokers.

Overall accuracy of attributes We begin by analyzing the overall accuracy of the collected data broker attributes, shown in Table 4. We find a largely bimodal distribution: 40.6% of the 1,432 surveyed broker attributes are reported "Completely accurate", while 40.5% of them are reported "Not at all accurate." By contrast, a higher percentage (proportion test, $p < 0.001$) of Facebook attributes are reported "Completely accurate" (51.7% of the 3,464 surveyed attributes). Also, a lower percentage ($p < 0.001$) of Facebook attributes are reported "Not at all accurate" (25.3% of the 3,464 surveyed attributes). This may be due to the significantly larger amount of data that Facebook can directly observe in users' activities, when compared to data brokers. The low accuracy of data broker information has significant implications, given the widespread use of data broker information for various purposes, including for background checks.

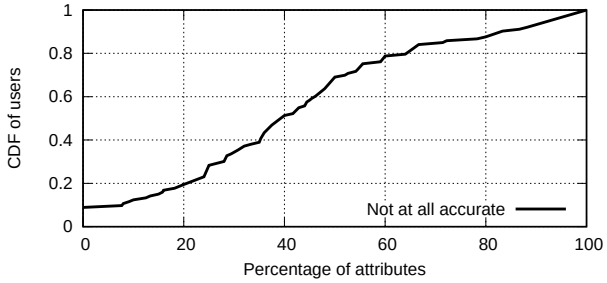

Figure 4: CDF of the fraction of users' data broker attributes rated as "Not at all accurate." We see a wide distribution.

Are inaccurate attributes stale? To study whether data broker attributes are simply inaccurate, or were previously accurate but is now out of date (*stale*), we ask users whether attributes they rated as anything other than "Completely Accurate" were accurate in the past. Specifically, we show the distribution of user responses to the question "Do you think this attribute would have accurately described you at a previous time? (For example, would it have been more accurate last year?)" in Table 5. We see that around 24% of incorrect attributes from data brokers are stale (with users responding with either "Yes" or "Probably yes"). In contrast, the percentage of incorrect attributes from Facebook that are stale is higher (32.3%). Thus, data broker attributes appear to suffer from many inaccuracies, only partially explained by out-of-date data.

User-level accuracy Inaccuracy in a user's attributes might often be because of data brokers' inability to uniquely or correctly identify users from different source databases (e.g., the user might have a very common name). Thus, it might be expected that users' attributes are inaccurate in an all-or-none fashion (i.e., that either almost all a user's attributes are incorrect, or almost all a user's attributes are correct). To study whether this is the case, we show the variation in accuracy by user in Figure 4.

Contrary to our expectation, we see that users typically have a subset of their broker attributes inaccurate, with the percentage of attributes marked "Not at all accurate" varying widely between 0% and 100%, with the median user having around 40% of their broker attributes marked "Not at all accurate." Besides, more than 90% of users who have data broker attributes have a non-zero fraction of their attributes marked "Not at all accurate." This means that inaccuracy of data broker attributes is a problem potentially affecting most people (rather than an unfortunate few).

Variation in accuracy across attributes Finally, to study how the accuracy of broker attributes varies across types or categories

	Data Brokers	Acxiom	Datalogix	Experian	Epsilon	Others	Facebook
Responses	1,432	95	728	55	18	536	3,464
Not at all accurate	40.5% ± 2.5%	27.4% ± 9.0%	42.0% ± 3.6%	21.8% ± 10.9%	55.6% ± 23.0%	42.2% ± 4.2%	25.3% ± 1.4%
Somewhat accurate	13.6% ± 1.8%	14.7% ± 7.1%	14.4% ± 2.6%	20.0% ± 10.6%	0.0% ± 0.0%	12.1% ± 2.8%	15.2% ± 1.2%
Mostly accurate	5.2% ± 1.2%	4.2% ± 4.0%	6.2% ± 1.7%	12.7% ± 8.8%	5.6% ± 10.6%	3.4% ± 1.5%	7.9% ± 0.9%
Completely accurate	40.6% ± 2.5%	53.7% ± 10.0%	37.4% ± 3.5%	45.5% ± 13.2%	38.9% ± 22.5%	42.4% ± 4.2%	51.7% ± 1.7%

Table 4: Aggregated user-reported accuracies for attributes from different data brokers and Facebook. The first column shows the accuracies for attributes from all data brokers taken together. 95% confidence intervals are shown for sample percentages.

	Data Brokers	Acxiom	Datalogix	Experian	Epsilon	Others	Facebook
Responses	833	44	445	28	11	305	1,596
Yes/Probably yes	24.0% ± 2.9%	29.5% ± 13.5%	23.8% ± 4.0%	32.1% ± 17.3%	36.4% ± 28.4%	22.3% ± 4.7%	32.3% ± 2.3%
No/Probably not	76.0% ± 2.9%	70.5% ± 13.5%	76.2% ± 4.0%	67.9% ± 17.3%	63.6% ± 28.4%	77.7% ± 4.7%	67.7% ± 2.3%

Table 5: Aggregated user-responses about the past accuracies for attributes from different data brokers and from Facebook. 95% confidence intervals are shown for sample percentages.

of information, we consider the variation of accuracy across the 15 higher-level "categories" in Facebook's hierarchy (from Section 3.2). Since we have only a relatively small number of responses for some categories, we group together categories that have fewer than 30 responses and which have a common ancestor in the hierarchy. For example, we group together Income , Net worth , and Liquid assets , which have a common ancestor (Demographics → Financial).

We show the distribution of responses in Table 6. We make multiple observations: *First*, we observe mediocre accuracy across all categories. Indeed, even categories involving important financial information such as income/net worth/liquid assets, or home ownership/home type/home value can have a high degree of inaccuracy, with 47.2% and 42.3% of respective attributes marked "Not at all accurate." This has important implications as this information might be used in important situations such as credit or background checks.

Second, we observe that some categories have higher accuracies than others. For example, the Purchase behavior category has a higher percentage of attributes marked "Completely accurate" than the Automotive category (proportion test, $p < 0.001$), and even the Income/Net worth/Liquid assets category ($p < 0.002$). While it is hard to explain why this might be the case, one potential reason is that purchase behavior is often tracked via loyalty cards provided by the data broker themselves [15], thus tracking users more directly.

Third, we find a less bimodal distribution for some categories than others. For example, the Purchase behavior , Income/Net worth/Liquid assets , and Television → Show Genre categories all have a larger percentage of intermediate accuracy levels ("Somewhat accurate" or "Mostly accurate") than the Automotive , and Spending methods categories (with $p < 0.006$ for all six pairwise comparisons). We explain why this might be the case in the following section.

Qualitative analysis of inaccuracy To better characterize how certain attributes are inaccurate, we briefly analyze participants' (free-text) responses to the question "What is incorrect about it?", asked for attributes that they did not mark "Completely accurate." Participants provided responses for 822 out of the 833 inaccurate broker attributes; however, a majority of these responses simply stated that the attribute did not correspond to the participant. We make a number of qualitative observations from the remaining responses (which are thus limited to a subset of all responses).

First, participants often reported errors of degree for categories like Purchase behavior , Income/Net worth/Liquid assets , and Television → Show Genre . For example, for attributes such as "food enthusiast" or "gadget enthusiast" that fall under the Purchase behavior category, participants responded that they might like food or occasionally purchase gadgets, but not to the extent of an enthusiast. Similarly, participants indicated that they only occasionally watched shows of a particular television show genre. For attributes under the Income/Net worth/Liquid assets category, which typically specify a range of income or net worth, participants indicated that the ranges were incorrect by different margins (ranging from "close" to "an order of magnitude below"). This explains why such categories might have less bimodal distributions compared to other categories such as Automotive , and Spending methods , which typically have attributes that are more likely to incur binary errors (e.g., make of car owned).

Second, we observed some anecdotal reasons from participants explaining how particular attributes were stale (i.e., accurate in the past but no longer so). Some responses indicated users changing their purchase behavior in response to changed life circumstances: two participants had purchased particular children's food items when they had children, or cared for children in the past. Similarly, a few participants had purchased pet products when they owned a pet. Finally, one participant had stopped buying a particular kind of frozen food in order to be more healthy. Other responses indicated reasons for changes in finance-related information such as home value (no longer accurate due to appreciation), or particular kinds of investments (participant no longer had that kind of investment).

Third, for categories like Income , Net worth , Liquid assets , or Home value , participants reported having both higher and lower values compared to their data broker attributes (which show a particular range of values for that category). While two participants reported having higher and lower incomes each, six participants reported having lower values for net worth. Nine participants reported having fewer liquid assets (of which two reported that their family

Category	Total	Not at all accurate	Somewhat accurate	Mostly accurate	Completely accurate
Purchase behavior	541	26.1% ± 3.7%	18.7% ± 3.3%	7.0% ± 2.2%	48.2% ± 4.2%
Income/Net worth/Liquid assets	53	47.2% ± 13.4%	20.8% ± 10.9%	5.7% ± 6.2%	26.4% ± 11.9%
Home Ownership/Home type/Home value	111	42.3% ± 9.2%	6.3% ± 4.5%	1.8% ± 2.5%	49.5% ± 9.3%
Automotive	252	60.7% ± 6.0%	8.7% ± 3.5%	4.0% ± 2.4%	26.6% ± 5.5%
Spending methods	141	35.5% ± 7.9%	6.4% ± 4.0%	2.1% ± 2.4%	56.0% ± 8.2%
B2B Company size/Industry	48	66.7% ± 13.3%	6.2% ± 6.8%	8.3% ± 7.8%	18.8% ± 11.0%
Charitable donations	27	40.7% ± 18.5%	18.5% ± 14.7%	3.7% ± 7.1%	37.0% ± 18.2%
Financial → Investments	50	56.0% ± 13.8%	14.0% ± 9.6%	4.0% ± 5.4%	26.0% ± 12.2%
Television → Show Genre	119	37.8% ± 8.7%	21.0% ± 7.3%	5.9% ± 4.2%	35.3% ± 8.6%
Behaviors → Travel	38	39.5% ± 15.5%	10.5% ± 9.8%	5.3% ± 7.1%	44.7% ± 15.8%

Table 6: Aggregate user-reported accuracies for attributes corresponding to different "categories" of information. The first column shows a description of the different categories of information, while the remaining columns show the aggregate distribution of user responses. 95% confidence intervals are shown for sample percentages.

might collectively have a matching amount of liquid assets), while three participants reported having more liquid assets. Finally, two participants reported having homes with higher values.

Fourth, we found some egregious errors (either in magnitude or sensitivity). For example, one unemployed student was inferred to be a C-Suite (i.e., top level) executive, while another two unemployed participants (one of whom was a student) were inferred to be corporate executives. Finally, a few participants who were non-drinkers were inferred to be likely to buy alcoholic beverages.

5 DISCUSSION

Implications of findings Recent policy is moving in the direction of requiring greater transparency and accuracy of data collection; for example, the principles of the General Data Protection Regulation (GDPR) in the European Union require organizations collecting personal data to ensure "lawfulness, fairness and transparency" and to ensure "the personal data is accurate and up-to-date, having regard to the purposes for which it's processed, and correct it if not" [43]. In this light, the findings in this paper about the coverage and lack of accuracy of information collected by data brokers calls for greater efforts from the brokers to (a) allow people to control and correct what data is collected about them, and (b) warn consumers of their data about cases where the data may not be accurate.

Future applicability of methodology Facebook removed partner categories as of October 2018 [4], meaning that it is no longer possible to study the coverage and accuracy of data brokers via Facebook's advertising platform. However, our methodology is still applicable on other platforms such as Twitter, which offers similar categories sourced from Acxiom and Oracle Data Cloud [32].

In addition, our methodology could also be used to study the coverage and accuracy of information internally gathered by online advertising platforms such as Facebook, Google, and Twitter, themselves. The existing transparency mechanisms of these platforms, revealing collected user information, have been shown to reveal an incomplete view to users [2, 17, 54]. Thus, our methodology for studying accuracy using Treads could potentially reveal the accuracy of the data that these platforms have actually collected.

Ethics All our experiments were performed as per community ethical standards. Our experiments measuring the coverage of data brokers only rely on aggregate statistics about users, and thus do not involve collection of data about individual users.

For our experiments measuring the accuracy of data broker information (approved by Northeastern University's IRB), we take multiple precautions to ensure the privacy of participants. *First*, our extension stores inferred attributes about participants locally (using their browser's local storage), and does not collect any personally identifying information from users. *Second*, participants are only required to answer questions they are comfortable answering; any attributes that participants are not comfortable answering questions about are not shared with our server. *Third*, we store the completed surveys in anonymized form. *Fourth*, users who unexpectedly see ads that explicitly state or imply their personal attributes might consider this a privacy violation. We address this concern by targeting the Treads that we run only to participants who have read our consent forms and signed up for our study, and obfuscating the targeting information in these Treads (as opposed to explicitly stating the targeting information directly).

6 CONCLUSION

The extent of data collection by online sites and offline data brokers, and the extent of linkage between online and offline identities of users are both crucial inputs to ongoing debates about user privacy. This paper used Facebook's advertising platform to (a) measure for the first time the actual extent of linkage between online (Facebook) identities and offline identities (as compiled by data brokers), (b) measure for the first time the coverage of data brokers from seven countries in a fine-grained manner, and (c) measure the accuracy of information from data brokers for U.S.-based users. Taken together, our analysis and results of the fine-grained coverage of data brokers provide new insights into the workings of data brokers, that can feed into ongoing privacy debates. We hope this paper serves as a starting point for more such analyses in the future.

ABSTRACT

The public is increasingly concerned about the practices of large technology companies with regards to privacy and many other issues. To force changes in these practices, there have been growing calls for "data strikes." These new types of collective action would seek to create leverage for the public by starving business-critical models (e.g. recommender systems, ranking algorithms) of much-needed training data. However, little is known about how data strikes would work, let alone how effective they would be. Focusing on the important commercial domain of recommender systems, we simulate data strikes under a wide variety of conditions and explore how they can augment traditional boycotts. Our results suggest that data strikes can be effective and that users have more power in their relationship with technology companies than they do with other companies. However, our results also highlight important trade-offs and challenges that must be considered by potential organizers.

1 Introduction

Large technology companies are facing a growing wave of public criticism. Just in the last year, these companies have been condemned for a wide range of practices, including those related to privacy [13, 55], harassment [20], addiction [10], effects on democracy [12], and automation [1]. The breadth and scale of the public concerns about tech companies has even led to the popularization of the term "Big Tech" [25], an adaptation of the terms "Big Oil" and "Big Tobacco" [3, 28].

However, these same companies that anger the public often are *dependent on the public* in new ways. Specifically, in addition to needing users and customers to generate revenue, *tech companies often rely on the public's "**data labor**" [44] to power mission-critical **intelligent technologies***. For example, Google requires user clicks to train its ranking algorithm [45]. Similarly, the highly-profitable recommender systems employed by companies like Amazon and Netflix require large amounts of data from users (i.e. ratings, clicks, and views) [17, 53].

Seen through the lens of the public's concerns about tech companies, these companies' dependence on user data to fuel their intelligent technologies can be understood as a potentially powerful source of new leverage for the public. To help the public action this leverage, several authors have proposed the notion of "**data strikes**" (e.g. [2, 39, 44, 52]), in which users halt their data labor [44]. The basic logic that motivates data strikes is straightforward: if users withhold their data labor from a tech company, some of the company's essential services will suffer, and this would then force the company to make concessions that are desired by the public. These concessions could range from improved privacy policies to profit sharing [2, 15].

Despite the growing discussion around data strikes, little is known about how this new type of collective action would work or about how data strikes relate to standard forms of collective action like traditional consumer **boycotts** (a type of collective action classified as political consumption [32, 42]). Additionally, as data strikes increasingly enter the realm of feasibility (see below), there is little empirical information about how effective data strikes could be, let alone the data strike configurations that would be most effective. Activists seeking to organize a data strike have no guidance regarding the number of users that would need to join them, the kinds of services most vulnerable, the types of users that would allow them to be most successful, or even whether strikes can be successful at all. Similarly, tech

companies are not aware of the potential damage that could be inflicted through data strikes.

This paper seeks to improve our basic understanding of data strikes and provide much-needed empirical information about their effectiveness. We first situate data strikes in relationship to traditional boycotts, in which a user stops patronizing a company entirely. Through the introduction of a lightweight framework that (partially) describes **collective action** in a technology company context, we highlight that most traditional boycotts against a company operating data labor-dependent intelligent technologies will implicitly also include a data strike, but that data strikes can also occur independently from boycotts. For example, a consumer who continues to purchase products from an online retailer could engage in a data strike by using private browsing windows and not providing product ratings.

Next, focusing on the domain of recommender systems, a family of intelligent technologies that are critical drivers of revenue [17, 51], we introduce a novel evaluation procedure for understanding collective action campaigns against technology companies. Our procedure uses a metric called **surfaced hits,** which can capture the effects of both a traditional boycott and a data strike. Leveraging surfaced hits, we examine how model performance changes depending on 1) the size of the participating group, 2) whether the participating group is a random group of users or a homogeneous group of users who share some characteristics (e.g. women, people interested in documentary movies), and 3) whether or not the group is conducting an independent data strike or are doing so as part of a traditional boycott.

Our results confirm that users' **data labor power** – which is mostly unique to online platforms and is manifest in a data strike – provides users with a new source of leverage in their relationships with technology companies. For small recommenders and in specific product spaces, this added leverage can be particularly substantial. A moderately-sized data strike alone – even when not part of a traditional boycott – can significantly harm the performance of a recommender system. Indeed, for moderately-sized data strikes, we observe recommender accuracy decreasing to the levels that defined the state-of-the-art in recommender algorithms in 1999. This power comes from the reduced performance for both non-striking users (who receive recommendations trained on less data) and striking users themselves (who receive recommendations that are not personalized). Additionally, our work shows that data strikes that occur as part of a traditional boycott add data labor power to the standard **consumer power** from a boycott, increasing the overall power of the collective action campaign.

Finally, our work also highlights that data strikes that are not part of a traditional boycott represent a *fundamentally new type of collective action*, one in which the *barrier to entry is much lower than in a boycott*. Most notably, we observe that data strike participants can substantially reduce the utility of a recommender system without sacrificing access to the underlying products and services. Given that it has proven difficult for people with limited financial resources to participate in political consumption activities like boycotts [32], the demonstrated effectiveness of data strikes could democratize access to these activities (e.g. users who cannot afford to use expensive alternatives to online platforms can still strike). This is analogous to an offline boycott in which a user who cannot afford expensive pizza could still participate in collective action against a local low-price pizza chain while continuing to buy their products.

Below, we adopt a standard structure to motivate, explain, and expand on our findings. We first cover related work, then discuss methods, followed by results. We close with a discussion of the issues identified in our results and by highlighting limitations.

2 Related Work

In this section, we describe how this research draws motivation from four areas in particular: the growing discussion related to data strikes, research on the relationships between tech companies and volunteer-created content, studies that generally seek to quantify the financial value of user data, and studies that looks specifically at ways to manipulate recommender system outputs.

2.1 Data Strikes

This research was most directly motivated by growing calls for collective action campaigns that force changes in technology platforms by leveraging the value of user data to these platforms [2, 11, 16, 23, 37, 44]. These growing calls use different, potentially conflicting framings of *data as capital* or *data as labor* [1]. With regard to the former (data as capital), collective action is framed in terms of a boycott, in which users stop their consumptive activities (e.g. purchasing products through a web platform, using a social media platform) which in turn prevents the flow of their capital (data, related revenue like advertising revenue) to the platform. This framing is exemplified by very recent boycotts put into practice against Facebook (e.g. [42]). The data labor view suggests that data "unions" should protect the interests of those who produce data (i.e. users) [2, 16, 44]. Just as traditional labor unions have implemented (and threatened) strikes to gain leverage when collectively bargaining, Lanier and others [16, 23] have written that data unions might similarly engage in a "strike". These authors point out that users can leverage their data in ways that resemble both traditional boycotts and strikes.

The diverse understandings of collective action campaigns that use data leverage needed to be integrated in order to make these campaigns concrete enough to simulate. Below in the Framework section, we enumerate one possible integration and use the corresponding framework to inform the design of our experiments.

Ideas about collective action campaigns that use data leverage often imagine a future in which people can "delete their data" from an online platform, and this future is becoming increasingly realistic thanks to developments and discussions in the policy domain. For instance, the European Union recently adopted the General Data Protection Regulation (GDPR) [30],

which includes a provision ensuring the right to erasure. Barring special circumstances (e.g. data critical to public health research), individuals covered by the GDPR will have the right to request that their personal data be deleted. As such, the GDPR potentially empowers activists to engage in more powerful data labor-related collective action than previously possible, in particular by erasing old data instead of just stopping the flow of new data. While it remains to be seen how often and how effectively the right to erasure will be used in practice – and how it might apply to campaigns that use data leverage specifically – the inclusion of this right highlights a large shift in regulatory practices towards data usage. The GDPR could trailblaze the way for similar or even stronger provisions by other regulatory bodies (e.g. California's State Government [6]).

In keeping with this policy trajectory and with the typical vision of collective action campaigns that use data leverage, we simulate campaigns in which people can "delete their data" when they participate. However, our approach also applies to other contexts, for instance domains in which there is *no existing data* like reviews about a new television show or location data used to predict traffic (and less directly to contexts in which participants cannot delete data, but do not execute new data labor). Furthermore, very recent research suggests that simple tools like browser extensions may help web users successfully join web-based collective action campaigns with low overhead for the user, which could help stop the flow of implicit behavioral data [39].

Finally, it is important to note that the social science literature can give some guidance as to how large one could expect the campaigns we examine to be. Data from Europe and the U.S. found that between 28% and 35% of consumers had engaged in an act of political consumption [32, 42], which includes either boycotting or "buycotting" (aligning one's purchases with a company that is perceived to align with one's political preferences).

2.2 Tech Companies and Volunteer-Created Content

A related area of research that also helped motivate this study is work that has sought to understand the dependence of technology companies on volunteer-created content like Wikipedia articles. McMahon et al. [40] showed that Google search effectiveness drops substantially when Wikipedia links are silently removed from search results, highlighting how important Wikipedia is to the success of search engines. Outside of Google's relationship to Wikipedia, Vincent et al. found that Stack Overflow and Reddit receive substantial benefits from Wikipedia in the form of impactful links and references [56]; they showed that these benefits come in the form of both increased engagement from users and advertising revenue. Although not originally intended as such, these studies can be seen as simulating a form of data-related campaign in which companies are somehow prevented from using Wikipedia content. Such campaigns would be highly unlikely given Wikipedia's content license [58] and other factors, but the design of these studies helped to inform our methodological approach outlined below.

2.3 Financial Value of Data

This work was more generally motivated by a broad body of literature seeking to understand the financial value of data and highlighting the importance of this understanding. This research includes efforts to provide individual users with transparency into the value they create, such as the Facebook Data Valuation Tool created by González Cabañas et al. [18], as well as efforts to broadly understand the value of that data at a macroeconomic scale (e.g. the value of Wikipedia to GDP statistics [4]). On the policy front, the World Economic Forum has identified data as a new "asset class" and suggests that thinking about data economics demands a new understanding of the personal data ecosystem [49].

2.4 Recommender System Manipulation

Within the recommender system literature, there has been research into various ways recommender systems might be manipulated. For instance, prior work has examined how recommender systems might be "shilled", i.e. misled so as to promote a particular product (e.g. [7, 36]). Like potential strikes, shilling attacks are an adversarial approach to manipulating the outputs of a recommender. As we explain below, our experiments specifically focus on campaigns that withhold data, so findings related to shilling are not directly applicable. However, in practice collective action participants might be able to adopt techniques from shilling, in which case this body of literature may be useful to both users and the companies against which they seek to gain leverage.

Recent research from Wen et al. explored recommender performance under conditions in which users filter some portion of their preference history to increase privacy and/or recommender accuracy [57]. Specifically, the authors found that users can filter out some of their preference history from the recommender while maintaining, or even improving, performance for implicit recommendations. This research has direct implications for data-related collective action: although users might be able to perform a "partial strike" by deleting some of their data without suffering decreased performance, these partial strikes are unlikely to be very effective, as in some cases, partial strikes by all users may improve population-level performance. In our experiments, we focus on directly simulating conditions in which users withhold *all* their data, and we also explicitly consider both data strikes and traditional boycotts. However, exploring the interplay between strikes, boycotts and data-filtering tools will be an important area of future research that is mutually beneficial to both problem contexts. In particular, the data filtering interfaces described by Wen et al. could be another outlet for users to actuate data strikes.

3 FRAMEWORK

As mentioned above, although collective action campaigns that use data leverage against technology companies have been discussed as a theoretical possibility, they have not been characterized in detail. Indeed, in the context of collective action against technology companies, the distinction between data strikes, boycotts, and combinations of the two can be unclear.

In order to simulate data strikes, we need to first concretely define data strikes and their relationship to traditional boycotts. To do so, we turned to the divergent theoretical underpinnings of the boycott and strike terms. In a boycott, participants are *consumers* who cut off the flow of an asset (e.g. money from purchases) to a firm. In a strike, participants are *laborers* who stop performing work for a firm. Users of an online platform can therefore boycott the platform by refusing to use the platform as consumers (e.g. not buying from an e-commerce site, not visiting a news site or video site, etc.) and strike against the platform by refusing to provide data (e.g. deleting data, preventing the flow of new data by using private browsing features or other privacy techniques like ad blockers or Mozilla's new Facebook Container [14]).

In most cases, *boycotts against tech companies implicitly include a data strike.* For instance, users of a video platform like YouTube who boycott (refuse to visit the website) are also implicitly conducting a data strike by cutting off the flow of behavioral data like views, likes, and comments. However, *it is often possible to participate in a data strike without boycotting the platform.* This occurs if someone continues to access a website but withholds data using privacy-preserving techniques (e.g. private browsing), leverages data management options made possible through data protection regulation, or – critically for our context – *refuses to comment on products, rate products, or review products.* The inverse, a boycott without a data strike, is less ecologically valid in the context of our work. Someone who boycotts Amazon products is unlikely to submit product reviews and ratings. While there are more nuanced situations in which this could occur, in this paper, we simulate boycotts in concert with a strike.

To put the nuanced relationship between boycotts and data strikes as defined above into better context, we consulted the literature to identify the various specific means by which these types of collective action campaigns could affect company revenue (e.g. [2, 44]). We identified four such pathways to revenue impacts:

- The **direct data labor effects** (e.g. algorithmic performance decreases leading to loss in sales)
- The **indirect data labor effects** (e.g. because algorithmic performance goes below some threshold, users quit the platform leading to loss in sales) [54].
- The **direct consumer effects** (e.g. people stop buying products or viewing ads) [32, 42].
- The **indirect consumer effects** (e.g. a large number of customers stop buying products or viewing ads, so there is a loss of economy of scale advantages) [50].

The **consumer effects** above (which make up **consumer power**) are those that exist in traditional boycotts and have been felt by targeted businesses since well before intelligent technologies came into common use. The **data labor effects** (which make up **data labor power)** are specific to collective action campaigns against companies that use data-hungry intelligent technologies. While a traditional boycott only includes direct and indirect consumer effects, a simultaneous data strike and boycott includes all four of the above components.

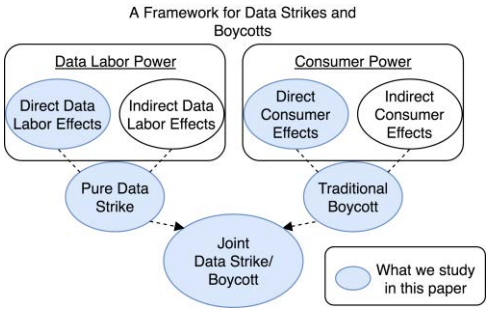

Figure 1: Graphical summary of our framework for defining data strikes and boycotts. Blue indicates aspects on which we focus.

This simple framework, depicted in Figure 1, provides a much-needed lens into the ontology of these types of collective action campaigns, but it also highlights that researchers – especially those outside a technology platform – can only simulate a portion of the effects of data strikes and boycotts. For instance, without exact sales numbers, both the direct and indirect sales effects are very difficult to study externally. Similarly, the indirect long-term effects of reduced recommender performance would be difficult to capture both for researchers external or internal to a platform (although there is at least one case of this being done internally in the search literature using an A/B test framework [54]).

Fortunately, in this paper, we show by focusing on the direct data labor effects while still considering the direct consumer effects, we can still learn a great deal about collective action campaigns that use data leverage. As we discuss below, our results support the effectiveness of data strikes, suggesting the unique relationship between users and technology companies can empower users beyond what would be the case in other contexts. We also discuss how our results can be interpreted as a *lower bound* for the effects of data strikes and boycotts against tech companies because we cannot measure indirect effects.

As discussed above, the data strikes we simulate correspond to a person "deleting their account" and using the recommender as a "guest", with no account history. Similarly, the boycotts we simulate (which include a joint strike) correspond to someone deleting their account and not using the system at all. In both cases, users not participating in a strike or boycott receive recommendations from a model that has been trained without strikers' or boycotters' data. As we discuss in Limitations, there

are many other configurations one can imagine - especially those related to strikes that do not involve the deletion of past data and play out over time - and we believe these to be important directions of future work.

4 METHODOLOGY

In this section, we first describe aspects of our methods that were consistent across all our experimental configurations. We then describe the two broad types of collective action campaigns we simulated: "general" groups comprised of randomly selected users and "homogenous groups" of users who share some characteristic (e.g. power users, fans of comedy movies).

4.1 Design of Experiments

In each experiment, we evaluate recommender systems under a variety of simulated data strike and boycott conditions. While the campaigning groups differ by experiment, the basic methods are the same.

4.1.1 Datasets. Our primary dataset was MovieLens-1M (ML-1M), which consists of 1 million "1 to 5 star" ratings for 3,706 movies provided by 6,040 users with self-reported demographic data [22]. To better understand performance against large recommenders, we additionally performed experiments with the much newer MovieLens-20M (ML-20M) dataset [22], which contains 20x more ratings but no demographic data about users. The MovieLens datasets have been hugely influential and have been central to recommender system research for decades [22].

4.1.2 Algorithm Choice and Implementation. For each experiment, we focus on the well-known and high-performing Singular Value Decomposition (SVD) recommender algorithm [41]. As validation, we also performed a smaller set of ML-1M experiments with an older and mathematically distinct algorithm: item-based K-Nearest Neighbors (k-NN) [48] adjusting for item and user baselines as described by Koren [33]. Both algorithms are implemented in the open-source Python library Surprise [27], which we extended for our experiments. All code used for our experiments and analyses is available for replication and extension on GitHub[1]. We validated the accuracy of the SVD implementation by ensuring results were comparable to published results on the ML-1M dataset [26, 34, 38, 46]. These successful comparisons are summarized in the linked GitHub repository.

4.1.3 Evaluation Procedure. We evaluated the recommender with five-fold cross-validation; for each evaluation fold, 20% of total data is available for testing and each rating is tested in exactly one fold. While data that is held out because of a simulated campaign cannot be used for training, it can be used for testing. This means we can consider results from the perspective of striking users, who will receive non-personalized recommendations which are based on each movie's average rating. This is a standard baseline for producing recommendations for users who lack personalized data and it is a widely-used way to provide preference information in a non-personalized fashion (e.g. displaying a movie's average rating instead of predicted rating for a given user).

4.1.4 Metrics for Evaluating Strikes and Boycotts. When evaluating the accuracy of explicit rating predictions for recommender systems, one common approach is to measure the error in individual predictions, e.g. through an accuracy metric such as root-mean-squared error (RMSE) which was used for the well-known Netflix Prize [41], or using information retrieval metrics such as gain (NDCG) [5] or precision. Retrieval metrics have been favored in recent years because of their ecological validity [8, 31] (e.g. "Top Ten Movies for You").

However, these standard metrics only capture performance for users who receive recommendations, and do not capture the consumer effects of users leaving due to boycotts. Therefore, this approach is not well-suited to understand boycotts from the perspective of the system owner, because the loss in revenue from boycotting users will not be visible in traditional metrics. For instance, if we simulate an 80% boycott and measure the RMSE of predicted ratings for the remaining 20% of users, the change in RMSE does not account for the users who *left the system entirely*.

To understand the relationship between data strikes and boycotts, it is critical to capture both the direct consumer effects of boycotting users and the direct data labor effects of striking users. To do so, we introduce a new metric, which we call **surfaced hits**. The metric measures the fraction of hits (defined as a rating of at least 4.0, as is common in prior work, e.g. [34]) across an entire group of users (perhaps all users, or non-boycotting users). The underlying assumption, that one hit corresponds to one unit of value for a recommender system, is supported by the widespread use of analytic metrics such as click-through-rate in online systems [17]. A perfect algorithm will surface all hits, and therefore have a surfaced hits value of 1.0. This metric can be effectively viewed as a variant of precision that sums (rather than averages) across all users and sets individual thresholds for precision equal to how many positive ratings each user has. More explicitly,

for each user $\boldsymbol{u}$:
$\boldsymbol{t_u}$ = u's test ratings
$\boldsymbol{n_u}$ = number of true ratings >= 4 in t_u
$\boldsymbol{p_u}$ = top n_u of t_u ordered by predicted rating
$\boldsymbol{h_u}$ = number of true ratings >= 4 in p_u
surfaced hits = sum($\{h_u\}$) / sum($\{n_u\}$)

As stated earlier, for both data strikes and boycotts combined with data strikes, participating users' ratings are withheld from all training data sets. Users who boycott contribute zero hits to the numerator of surfaced hits for their test ratings ($h_u = 0$). In other words, the surfaced hits value is "penalized" by marking all positive ratings for the user as a non-hit. For users in a data strike, we included the user's test ratings in the calculation of surfaced hits, but "penalize" via non-personalized recommendations (i.e. movie averages) because the user's training data is not available due to the strike.

Overall, the surfaced hits metric has three useful properties for studying data strikes and boycotts. First, when users boycott, surfaced hits is reduced proportionally to the number of positive

[1] https://github.com/nickmvincent/surprise_sandbox

ratings in the boycotting group. In other words, if enough users boycott to remove half of all the "hits" in the dataset, surfaced hits will be reduced by at least half. This allows us to understand the effects of strikes and boycotts from within a single reference frame. Second, this metric also accounts for differences in user behavior: a user with 1000 hits in their rating history has 10x the impact of a user with 100 hits in their history. This captures the potentially disproportional economic value of more active users. Third, we can calculate surfaced hits for different subsets of users (e.g. all users, non-striking users, users similar to striking users) to understand the effects of collective action from different perspectives. We verified that these metrics perform very similarly to well-established list metrics including NDCG and precision while at the same time capturing the damage that occurs when boycotting users leave a system (see Section 5.3 and the code repository).

4.2 Campaign Configurations

4.2.1 General campaigns. To get a general understanding of the relationship between campaign size and recommender system performance, we first simulated a series of "general" campaigns with random user selection. In these campaigns, the demographic make-up of the groups approximates the distribution of all users. We selected a sequence of 16 different group sizes ranging from 0.01% of users to 99% of users. For each group size, we randomly selected a group of that size to participate in the campaign. To reduce noise associated with different random configurations, we repeated each of these 16 experiments 250 times with a new random user sample for the ML-1M dataset and 40 times for the ML-20M dataset.

4.2.2 Homogeneous campaigns. We also simulated campaigns executed by "homogeneous" groups defined by shared patterns in rating behavior or shared demographic information. More specifically, we created five types of homogenous campaigns: campaigns by "fans" of specific movie genres, campaigns by three categories of demographic groups, and campaigns defined by rating behavior. We created groups of "fans" for each movie genre by identifying all users who rated at least ten movies of that genre and have an average rating for the genre of four or higher. To simulate demographically-defined campaigns, we created groups based on user-reported demographics, specifically male/female, age bracket, and occupation. For rating behavior campaigns, we created campaigns for "power users," defined as the top 10% of raters and "low frequency" users, the bottom 10% of raters.

For each of the five types of homogeneous groups, we simulated campaigns in which 50% of users within a given group participated. For example, we simulated campaigns with groups such as 50% of all women, or 50% of all comedy movie fans, and so on. Importantly, 50% participation allows us to simulate what happens to similar users who do not participate. In other words, if some women participate in a data strike, what happens to women who do not? We also viewed 50% group participation as more realistic than full participation.

Our homogenous experiments focus on the data labor effects of data strikes. The consumer effects of a homogenous boycott scale with the size of the boycott as measured by the number of positive ratings, and as we show in our general campaign experiments, this effect is substantially larger than that of strikes, but this does not negate a strike's value.

For each homogenous campaign configuration, we performed experiments with 50 sampled groups. We also compared the observed campaign effects to the expected effects for a random campaign with the same number of ratings. In order to obtain a relatively simple estimate of the "expected" effect of a data strike of some size, we computed a quadratic interpolation of our results shown in Figure 2. Our homogeneous experiments only consider the ML-1M dataset due to the lack of demographic information in ML-20M.

5 RESULTS

In this section, we first describe the relationship we observed between recommender performance and campaign size in the case of general (random users) collective action campaigns, focusing on comparing pure data strikes to strikes coupled with traditional boycotts and examining the overall effectiveness of campaigns across datasets. Next, we describe the key findings from our homogeneous group experiments, focusing on the finding that unique homogenous groups, defined demographically or behaviorally, can exert their data labor power to disproportionately affect similar users, indicating the potential for data strikes that target specific preference spaces to boost their effectiveness.

This section uses the surfaced hits metric, described above. We focus on the popular SVD algorithm because the item-based k-NN algorithm behaved similarly in our initial experiments (see GitHub repository).

5.1 General Campaign Experiments

We begin by examining the effect of general data strikes and boycotts (i.e. with random users) from the perspective of the system owner (e.g. Google, Facebook, operators of MovieLens). Next, still focusing on the perspective of system owners, we specifically zoom in on performance changes relative to un-personalized results.

Figure 2 shows the effect of data strikes (blue line) and joint data strikes and boycotts (green line) on surfaced hits (y-axis) across the system for both ML-1M (left column) and ML-20M (right column). As a reminder, a value of 1.0 would correspond to an algorithm that produces perfect ranked lists for every user.

These plots include dotted horizontal lines that provide important context: the black line shows performance of SVD with full access to the dataset (which gives 77.4% of hits), the red line shows the results of "MovieMean," which gives completely un-personalized ratings (movies are ranked in order their mean rating) and the gold line shows the results of completely randomly ranked lists (i.e. worst-case performance). Note the high number of hits associated with random lists: this is because MovieLens users tend to give movies high ratings, so when evaluating even random lists many of the items suggested for a given user will be hits. We address this phenomenon below by

focusing not only on raw changes in surfaced hits, but also on performance *relative to* un-personalized performance, i.e. we zoom in on performance change between the black and red lines.

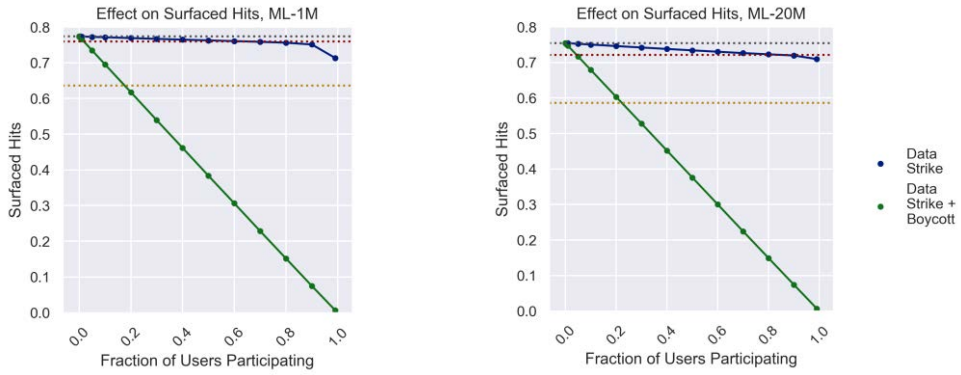

Figure 2: The relationship between campaign size and surfaced hits. Surfaced hits include all users (including strikers and boycotters), and therefore reflect the perspective of the system owner. Dotted horizontal lines provide comparisons: black (uppermost) shows fully personalized SVD, red (middle) shows un-personalized results, and gold (bottom) shows random results.

The most significant trend in Figure 2 is that boycotts are substantially more effective than data strikes. For instance, while a 30% boycott of ML-1M reduces hits to from 77.4% to 53.9%, a 30% data strike only reduces hits by 0.7% to 76.7% (ML-20M, right column, shows a similar trend). Furthermore, for both datasets a boycott of about 20% of users reduces surfaced hits to the amount expected for completely randomized recommendations. This result means that at first glance, the loss in hits caused by users who leave the system strongly outweighs the loss in hits from reduced algorithmic performance. Importantly, this finding does not fully explicate the potential of data strikes, as we will describe below.

We note that the gaps in Figure 2 between un-personalized results (red lines) and fully personalized results (black lines) appear to be small and correspond to a loss of 1.4% of surfaced hits for ML-1M and 3.3% for ML-20M. This reflects the non-linear value of recommender algorithms; the small margin between un-personalized and personalized algorithms corresponds to a large amount of value for a recommender system operator. For example, in Netflix's case, the margin between un-personalized algorithms and personalized algorithms accounts for a 2-4x increase in engagement with recommended items and $1 billion in revenue [17] (see below). Thus, we now specifically focus on the change in performance relative to un-personalized results to inspect how data strikes leverage direct data labor effects to lower recommendation performance towards un-personalized levels.

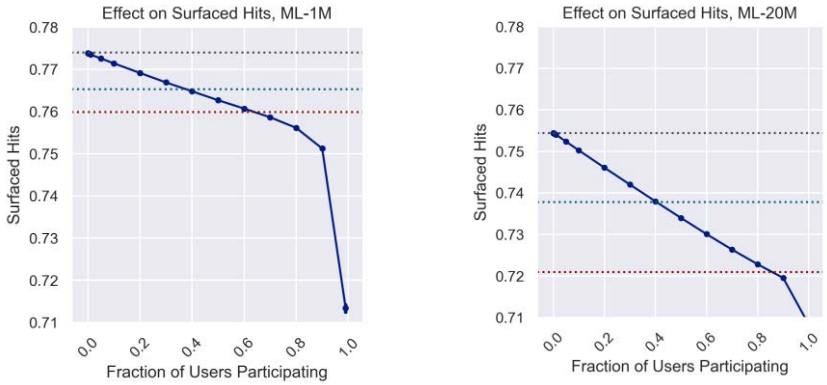

Figure 3: The relationship between data strike size and surfaced hits. Dotted horizontal lines provide comparisons: black (top) shows fully personalized SVD, cyan (middle) shows item-based k-NN (1999), and red (bottom) shows un-personalized results.

Figure 3 zooms in on surfaced hits during a data strike using the same y-axis as Figure 2. Again, the black horizontal line marks personalized performance and the red horizontal line marks un-personalized performance. Additionally, in Figure 3 the horizontal cyan line shows the performance of simple item-based k-NN (which we evaluated with full access to each

dataset), a technique that was introduced in 1999. This context shows the ability of campaigns to essentially set recommender system performance "back in time".

In Figure 3, the potential power of data strikes becomes clearer. The left side of the figure shows that campaigns had substantial effects on recommender performance for ML-1M relative to non-personalized ratings. For instance, a strike with 30% of users (which is a realistic size based on research on political consumption; see Related Work) degrades performance such that users lose roughly half the benefits of personalization. These results also illustrate the power of collective action to potentially negate decades of algorithmic advances. Looking again at MovieLens-1M, a strike by 37.5% of users can roll back hits to a level equivalent to the classic item-based k-NN algorithm introduced in 1999 [48] (cyan dotted line in Figure 3).

The ML-20M results (right column), however, suggest a somewhat more complicated story for recommenders using larger datasets. When the dataset size is increased by a factor of 20, a strike by the same percentage of users becomes somewhat less effective. If 30% of ML-1M strike (1800 users), we see a 50.2% reduction in the benefits of personalization, but if 30% of ML-20M strike (41400 users), it would only cause a 37.0% reduction.

A likely explanation of why the relationship between strike size and strike power differs between ML-1M and ML-20M lies in the two effects of a data strike, the effect on the strikers themselves and the effect on non-strikers. The first effect captures how the removal of the strikers' data lowers performance of the recommender for non-strikers (i.e. the ability of strikers to affect the experience of non-strikers). While we see similar directional relationships between ML-1M and ML-20M, this effect is more pronounced for ML-1M. For instance, at 30% strike participation, we see a 25.4% reduction in personalization for non-striking ML-1M users but just a 4.2% reduction in personalization for ML-20M (analysis in GitHub repo). ML-20M does not see an equivalent reduction in personalization for non-strikers until strike participation rates hit 77%. The explanation for this difference is likely straightforward: ML-20M has more redundant encodings of preference patterns due to its sheer size, so an equivalent percentage of strikers cannot have as much of an effect on the experience of non-strikers.

The second factor driving the strike results is the fact that, during a data strike (rather than boycott), by definition, striking users can still use the system. Because *these users must still receive a ranked list of items* (e.g. to power a Netflix-style interface), what used to be a personalized ranked list must now become a non-personalized ranked list. As noted above (Section 4.1.3), we implement this non-personalized ranked list in the most ecologically valid way possible: using the average movie rating from other users (item mean). As such, for each new user who strikes, the recommender will inch towards item mean by default, regardless of the effect on non-striking users. In other words, *even in the face of large amounts of training data, users can hurt the system by refusing to provide the input data needed to make predictions for themselves.*

Finally, we reiterate that evidence from industry suggests that in commercial systems, a change in surfaced hits has a non-linear value to recommender operators. In other words, the visually-small performance change between the red and black horizontal lines in Figures 2 and 3 may have an outsized effect on platform revenue. As mentioned before, the small surfaced hits improvement due to personalization may correspond to a 2-4x increase engagement with recommended items in other contexts [17]. Similarly, in 2010 YouTube published findings that suggest recommendations add substantial value: almost 30% of video views came from their recommender system and the recommender was the main source of views for most videos [59]. An industry report from consulting company McKinsey estimates that recommender systems account for 35% of Amazon purchases and 70% of Netflix views [24]. Taken together, this means that in many contexts, the revenue effects of data strikes seen above would be magnified relative to their appearance in the figures.

5.2 Homogeneous Campaign Group Experiments

In our homogenous campaign experiments, we examine what would occur if a demographics- or taste-defined group engaged in a data strike (e.g. women or documentary fans). Specifically, for the reasons defined above, we simulate the effects of 50% of the group striking, examining the impact on the remaining 50% in the group, as well as on the recommender overall. We use the term **Similar Users** to describe non-striking members of the striking campaign group (e.g. non-striking women in a strike by women) and **Not Similar Users** for all other non-striking users (e.g. non-women in a strike by women). Then, we define the **Similar User Effect Ratio** as the percent change in surfaced hits for Similar Users divided by the percent change in surfaced hits for Not Similar Users. One challenge with analyzing these homogenous boycotts is that the various groups are very different in size (see Table 1). Therefore, this set of analyses focuses specifically on percent change in surfaced hits, which partially mitigates the challenge in comparing data strikes by groups that are very different in size. Furthermore, when looking at the aggregate effects of homogeneous campaigns, we specifically look at the perspective of non-participating users, as both the direct consumer effects and the effects from striking users seeing un-personalized recommendations are functions of campaign size.

The results from our homogenous campaign experiments show that data strikes may be especially effective at impacting recommendations within targeted topical domains. Specifically, we observe that if homogeneous groups of people strike, non-striking users that share the same characteristic as the homogenous striking group will experience larger reductions in recommender accuracy than other users. For example, striking horror movie fans can make a large movie recommender suffer for other horror fans, potentially giving a competing movie site an opening. A secondary, related observation from these experiments, which we return to at the end of this section, is that homogenous groups' aggregate effects on non-participating users are not consistent: some groups have an outsized aggregate effect relative to their size, and vice versa.

Table 1: Examples of homogenous groups, the number of ratings in each group, percent change in surfaced hits, and the Similar User Effect Ratio.

Name	# Ratings	% change surfaced hits, Similar Users	% change surfaced hits, Not Similar Users	Similar User Effect Ratio
men	753769	-0.71	-0.64	1.11
women	246440	-0.38	-0.09	4.24
fans of horror	48464	-0.24	-0.03	7.16
under 18	27211	-0.27	-0.03	9.02
25-34	395556	-0.38	-0.3	1.28
56+	38780	-0.18	-0.03	6.97
artist	50068	0.15	-0.07	-2.26
power users	381407	-0.76	-0.45	1.71

Table 1, which includes a variety of example groups, highlights the primary finding that some groups are especially effective at lowering performance for Similar Users compared to other users. For instance, looking at Table 1, we see that when half of women strike, surfaced hits decreased for non-striking women by 0.38% while surfaced hits decreased for non-women by 0.09%. Therefore, the Similar User Effect Ratio is 0.38 / 0.09 = 4.24. This effect is exaggerated even further in the case of the "under 18" group, which has a Similar User Effect Ratio of 9.02. On the other hand, the "25-34" age group has a more or less "flat" ratio of 1.28, and the same is the case for men.

It is clear from Table 1 that some homogenous groups are able to "punch above their weight" with respect to affecting the experience of non-striking users, at least those within their homogenous group. This is particularly important with respect to large recommenders, which we saw above are more robust to this component of the data strike effect (the effect of strikers on the experience of non-strikers). Regardless of the scale of data resources available to a recommender, it appears that recommendation quality for some users may always be vulnerable to targeted data strikes by Similar Users.

One hypothesis that explains why some data strikes hurt Similar Users more than other users lies in a holistic view of the user preference space. If a group of users has substantial uniqueness– or more specifically, mathematical independence – in their preferences when compared to other groups, a campaign by that group is less likely to hurt users not in that group. At the extreme, a group whose preferences are completely orthogonal to every other group may be able to execute a campaign without substantially affecting personalization for any other group (one realistic example might be groups based on language proficiency).

To understand this relationship, we compared a group's Similar User Effect Ratios from Table 1 to a measure of preference independence based on overlap in rate/no-rate behaviors. To calculate preference independence, we first create a vector with a column for each movie (3706 columns) and value equal to the proportion of users in the group who have rated the movie (i.e. the group implicit rating vector). A group's preference independence is the cosine distance of that group's vector to the similarly calculated vector for the all groups (i.e. the centroid). We focus on groups with over 20k ratings, ignoring the six very small groups for which Similar User effects are extremely noisy.

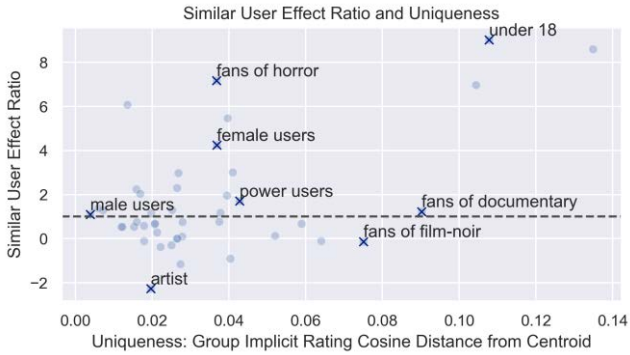

Figure 4: Scatterplot showing how homogeneous data strikes (with > 20k ratings) affect similar users differently than the general population. Along the x-axis, groups are organized by increasing uniqueness, defined by the cosine distance between the group implicit rating vector for the group and the general population. The y-axis shows the Similar User Effect Ratio. Gray dotted line shows ratio of 1. Pearson correlation is 0.55. "X" markers indicate labeled examples.

Figure 4 shows a full scatterplot of Similar User Effect Ratio for all groups with over 20k ratings. On the x-axis, we plot preference independence as defined above and on the y-axis, we plot Similar User Effect Ratio (note that negative values correspond to strikes that improve surfaced hits for Similar Users). Our experiments suggest a moderate positive relationship between a group's preference independence and the effect of a strike on non-participating Similar Users (Pearson's $r = 0.55$, $p < 0.001$), although this is likely driven by a non-trivial number of strong outliers (e.g. "under 18", "fans of horror" in Figure 4) given the Spearman correlation ($r = 0.18$, $p > 0.05$) is not statistically significant. The full interplay between preference independence and strike effectiveness is a fertile ground for research, and future work could more closely study how preference spaces might be operationalized for the purpose of data strikes.

The outsized Similar User effects for many homogenous strikes point to both strategic advantages and effects that may limit adoption. For example, if women data strike against a company to affect some lasting change (e.g. ending discriminatory practices, launching profit sharing), a homogenous strike that focuses on recruiting other women may be especially effective, with large Similar User strike effects potentially driving women away from the company to competitors and substantially reducing company revenue.

However, these effects may decrease strike adoption in some contexts. For instance, returning to a strike by women against a major tech company, imagine that the tech company provides important services to large populations (e.g. online shopping in areas with few brick-and-mortar stores, low-cost communication in areas without similarly priced options). Many potential participants may be unwilling to participate in a campaign that will disproportionately damage these services for other women, thus limiting the adoption of homogenous campaigns in certain contexts.

A related secondary observation from these experiments is that homogenous groups have varying effects on all non-strikers (rather than just Similar Users) compared to the "expected" effects based on their number of ratings (determined by a quadratic interpolation of our general results, as described above). In other words, homogenous strikes vary in their ability to "punch above their weight" with respect to their capacity to decrease performance for all non-participating users: In 34 of 50 homogeneous groups, surfaced hits for non-participating users decreased more than would be expected for a random group with an equal number of ratings. Ratios of observed to expected effect ranged from 0.52 for the group of users whose occupation was "retired" to 1.84 for "power users", with other examples including a 0.7 ratio for "fans of comedy" and a 1.35 ratio for "fans of fantasy" (see GitHub repository for more details).

Based on this secondary finding, it seems that homogenous campaigns will not always be effective at damaging the general population of users because some groups are under-performing, and even over-performing groups are limited by size in their ability to affect the general population. However, organizing campaigns with preference spaces in mind (i.e. campaigns that are homogenous in topical preferences) likely will be effective and, critically, may provide a way to challenge recommenders when the number of strikers is not sufficient to cause more general damage to performance.

5.3 Generalizing Beyond "Surfaced Hits" and SVD

In presenting our results, we have focused on our "surfaced hits" metrics. However, we also computed the more typical recommender systems evaluation metrics of RMSE, NDCG with all items, NDCG@k, Precision@k, and Recall@k for k = {5, 10}. We additionally calculated these metrics when only including "long-tail" (i.e. unpopular) movies. All these metrics produce similar results regarding the effects of various data strikes configurations, although they did not afford us the ability to analyze boycotts. The full dataset of results is available in our GitHub repository. We also note that in our early experiments using item-based k-NN, ML-1M, and traditional metrics, we observed very similar general trends, e.g. the effect of data strikes on the NDCG@10 of an item-based k-NN recommender mirrored effects on other traditional metrics for SVD.

6 DISCUSSION

In this paper, we have taken the previously hypothetical notion of data strikes, identified a wide variety of realistic campaign configurations (including when they are combined with traditional boycotts), and simulated the effect of these configurations in the recommender systems domain using best-practice evaluations. Comparing these campaign configurations and looking specifically at direct effects, we find that while the consumer power of boycotts still substantially outweighs the data labor power of data strikes, data strikes represent a potentially powerful new form of leverage. Moreover, we saw that strike organizers might specifically target preference spaces within a recommender to achieve especially effective data strikes within those spaces. Below, we discuss some of the more general implications of these results.

6.1 Barriers to Entry vs. Impact

Our results suggest that collective action organizers targeting companies that operate intelligent technologies like recommender systems have more options than is the case in traditional collective action. Specifically, these organizers have the ability to optimize for impact or for barrier to entry. Our results show that boycotts have a larger impact, but they require all participants bear the cost of not using a potentially valuable service. Strikes, on the other hand, allow users to continue to benefit from the use of technology platforms without completely losing the ability to collectively bargain. Historically, participation in political consumption has been easier for affluent groups [32] - data strikes represent an approach that may be substantially more accessible. Notably, our results suggest that new technologies focused on privacy (e.g. initiatives from Mozilla [14]) and online political consumption (e.g. recent work from Li et al. [39]) are a promising approach to empowering more individuals to participate in collective action.

This notion of low-barrier-to-entry collective action echoes early research on digital activism by Earl and Kimport, who argued that the web reduces costs for participating in protest behavior like boycotts, petitions, and email campaigns [9]. Specifically, data strikes can be seen as another tool in the toolbox of low-barrier-to-entry techniques, offering an additional avenue for people to take action against technology companies. However, we also observed that this increased accessibility is coupled with reduced power.

6.2 Towards a Holistic View of Data Strikes

Although our results give us important insight into the potential impact of data strikes and boycotts, our work likely only captures a portion of the real-world effect of a collective action against an intelligent technology. In particular, as is discussed in the Framework section, we cannot measure directly the indirect effects of traditional boycotts or data strikes. This means that our results should be interpreted as a lower bound on the effects of any data labor-related collective action campaign.

A related point that emerges from our results viewed with the lens of our framework is that collective action against

technology companies will largely be more powerful than collective action against non-technology companies. The effect of a boycott against, for instance, a clothing company, would largely not include either direct or indirect loss of data labor value (excluding edge cases like long-term sales and marketing data). Since our results suggest that these factors will be non-trivial in most tech company boycotts, a user boycotting a tech company is likely to have a greater effect on revenue than would be expected in a boycott with a more traditional type of target. We expand on these power dynamics further below.

6.3 The Power of Algorithms vs. The Power of Public Data

Outside of the context of boycotts and data strikes, our results can also be viewed as a means to better understand the power of data provided by the public relative to the power of algorithms. Namely, we observed that moderately-sized strikes can bring recommender accuracy down to the levels of early recommender systems from 1999. These results, along with the work of McMahon et al. [40] and others [18, 23], emphasize the data leverage that the public has in its relationship with data-hungry intelligent technologies and the companies that operate them. While the public perception of intelligent technologies like recommender systems is that they are largely the accomplishment of tech companies and the computer scientists they employ, these technologies are in fact a highly cooperative project between the public and companies. Without the companies and computer scientists, the intelligent technologies do not exist. But the same is also true for the public's contributions of data (i.e. data labor). This implies a much different power dynamic than is currently assumed by most people on both sides of this relationship.

6.4 Limitations

This work has several limitations not yet discussed above that should be highlighted. First and foremost, this paper focused on recommender systems which, while a business-critical family of intelligent technologies, is only one family of intelligent technologies that could be vulnerable to collective action campaigns. Future work should seek to replicate our research for other intelligent technologies, for instance search ranking algorithms (e.g. [45]), "newsfeed"-style technologies (e.g. [43]), traffic prediction (e.g. [21]), and wi-fi geolocation (e.g. [19]).

As noted above, we simulate boycotts in concert with strikes owing to that being the more ecologically valid choice in the context of our study. We note that one could imagine boycotts coupled only with partial strikes: e.g. someone who boycotts a system but does not delete their past ratings. Exploring these types of configurations - and longitudinal considerations in general - is an important direction of future work.

While we used best-practice evaluation techniques in the recommender systems community [8, 22, 46], these techniques have several limitations that also affect the large literature of recommender systems research that employs them. In particular, we considered only explicit ratings and did not consider implicit preferences expressed through user behavior (which are not available in the MovieLens dataset). We also only considered our recommenders in an offline environment (as opposed to in a live experiment). Finally, to gain more insight into the nuances of recommenders, it will be valuable explore other recommender system datasets, particularly datasets from industry contexts.

Another important limitation is that in our experiments, we had to operationalize male/female as a binary variable due to the data available in the MovieLens dataset. Similarly, we were not able to test other types of demographic groups (e.g. LGBT communities, political groups). Relatedly, our use of the term "homogenous" refers to a specific demographic or topical dimension; it does not consider the diversity within our "homogenous" groups, and doing so would be a fruitful area of future work.

Finally, this paper focused on understanding the effect of collective action campaigns of various sizes and types, but it did not consider the collective action problem of organizing or actuating these campaigns. Fortunately, this problem maps to a deep body of work within social computing and related fields on sociotechnical strategies for motivating collective action online (e.g. [35, 47]). An obvious direction of future work in this research space involves building tools to organize data strikes and boycotts that leverages this body of work (either using GDPR or restricting new data collection). Recent research suggests that user-friendly tools like browser extensions may be an effective approach for making collective action campaigns easy to join and conduct [39].

6.5 Potential Negative Impacts

In response to calls for the computing community to better engage with the negative impacts of our research [29], we wish to highlight two major concerns with this work. First, we emphasize that our findings may be equally useful to organizers of campaigns as to they are to companies interested in mitigating the effectiveness of such campaigns. Relatedly, it is entirely possible that using a simulated data strike methodology, companies could identify which groups of users are and are not "useful to the algorithm", i.e. they could rank groups based on their utility to some intelligent technology and use this ranking to justify ignoring the interests of some groups. If this occurred along demographic lines, this could lead to troubling societal outcomes, e.g. if majority groups can collectively bargain with tech companies and minority groups cannot. Technologies to organize data strikes and boycotts could help mitigate this issue by recruiting users from a variety of demographic groups (perhaps, guided by future work, specifically targeting some preference space like Comedy movies or electronics products). Our results suggest that this should be a priority in the design of these technologies.

Moreover, our ability to perform simulated campaigns was predicated on the public availability of the MovieLens dataset. Substantially more accurate simulations could be run using much richer datasets available only to corporations, so in any "data strike simulation arms race", there will be a clear advantage for corporations. This means that corporations may be

able to prepare models in advance to counteract boycotts or strikes. This might be mitigated through crowdsourced data collection or other means, a ripe area for future work.

7 CONCLUSION

In this paper, we have done the work of advancing the notion of data strikes from abstract discussion point to concrete campaigns that can be simulated. Through these simulations, we provided critical early empirical information to help advance the discussion around data strikes. In doing so, we first detailed a framework that describes the key elements of collective action campaigns that action data leverage (i.e. data strikes and traditional boycotts, which respectively leverage *data labor power* and *consumer power*). We found that these campaigns can be effective, with relatively small strikes wiping away significant portions of the value of recommender systems relative to simpler techniques. However, as datasets grow larger, data strikes become less effective, and strategies that target specific groups of users or preference spaces may become necessary. We discussed the implications of our results for those seeking to organize data strikes and companies seeking to understand potential effects on their core functionality.

ABSTRACT

A semantic model of a data source is a representation of the concepts and relationships contained in the data. Building semantic models is a prerequisite to automatically publishing data to a knowledge graph. However, creating these semantic models is a complex process requiring considerable manual effort and can be error-prone. In this paper, we present a novel approach that efficiently searches over the combinatorial space of possible semantic models, and applies a probabilistic graphical model to identify the most probable semantic model for a data source. Probabilistic graphical models offer many advantages over existing methods: they are robust to noisy inputs and provide a straightforward approach for exploiting relationships within the data. Our solution uses a conditional random field (CRF) to encode structural patterns and enforce conceptual consistency within the semantic model. In an empirical evaluation, our approach outperforms state of the art systems by an average 8.4% of F_1 score, even with noisy input data.

CCS CONCEPTS

• **Information systems → Information integration**; • **Computing methodologies → Learning in probabilistic graphical models**.

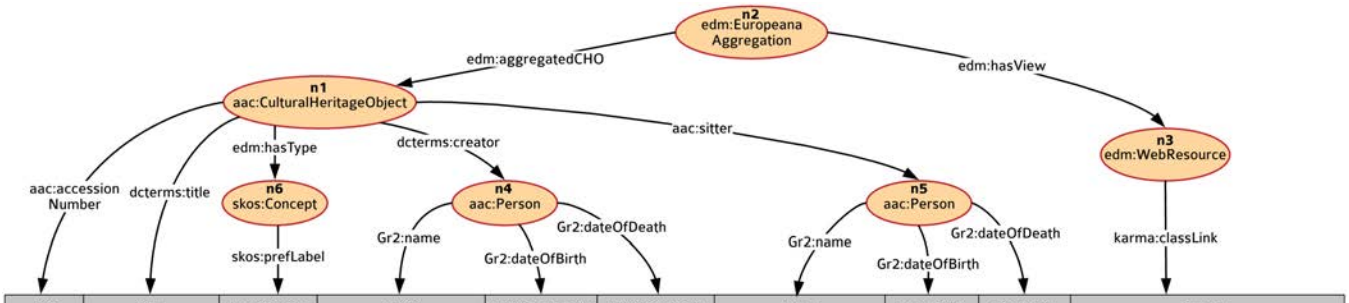
1 INTRODUCTION

There is an enormous number of data sources available on the web. Integrating information from multiple data sources enables interesting applications that can have a large social impact [27]. However, because data publishers usually publish data in different data formats and using different conventions, harvesting information can be challenging. The task of semantic modeling addresses this challenge by building a model that maps the information found in data sources to semantically meaningful structures.



A semantic model is a graph where ontology classes and source attributes are nodes and ontology properties are edges. Figure 1 depicts a semantic model for a sample data source about artworks, which contain information about paintings, their creators and sitters. By explicitly encoding the semantic type and relationship between source attributes in the graph, the model precisely describes the intended meaning of the data source. Moreover, it can be used to automatically generate R2RML rules to transform the data source to RDF triples for publishing to knowledge graphs [7, 25].

Since creating semantic models, or semantic modeling, requires significant effort and expertise, it is desirable to have an automated or semi-automated system to support users. There is previous work in predicting the semantic types of source attributes [18, 20, 22], called semantic labeling. A semantic type is a pair of ontology class and predicate. For instance, in Figure 1, the semantic type of attribute *name* is ⟨*aac:Person*, *Gr2:name*⟩. However, semantic labeling alone is insufficient for describing and publishing data as RDF because it fails to capture the relationships between attributes. Other work focuses directly on semantic modeling [29, 30]. The state-of-the-art methods use predicted semantic types of source attributes from semantic labeling systems, then build a minimum-weighted tree (Steiner Tree) that connects the attributes together. Heuristic functions and other machine learning methods, such as frequent pattern mining, are used to assign cost to edges of the tree.

Generating semantic models automatically still remains challenging for several reasons: the data of attributes may be very similar, and there is more than one possible relationship between entities. For example, it is easy to confuse a *date* attribute with created date of paintings or creators' birth date. If we simply look at one signal from the cost of the edge, it would be hard to decide which one is correct because they are similar. However, there are also multiple weak signals from its relationships with other remaining attributes that can assist our decision making. For instance, if we group values of *date* attribute by painting id and find that one painting appears to have been painted at two different points in time, then it is likely that this *date* attribute is not the created date.

To address these issues, we present a new approach for semantic modeling that uses a probabilistic graphical model (PGM). A PGM allows us to express and capture the weak signals within the data. From a set of known semantic models, we auto-generate positive and negative examples representing many possible descriptions of sources. Using this training set, the PGM is trained to distinguish between good and bad models. To predict the most probable semantic model for a data source, we use beam search to explore the

Figure 1: NPG data source and its semantic model

space of possible models and evaluate the likelihood of the model using the trained PGM as a scoring function.

The contribution of this paper is a novel way to explore relationships within data sources and semantic models using a PGM, as well as a flexible framework that can easily be extended to incorporate new features. We present experimental results on two museum datasets published in Taheriyan et al. [29]. In the experiments, we control different levels of noise by using four different semantic labeling methods. These experiments show that our approach outperforms state-of-the-art systems by an average of 8.4% F_1 score, even with noisy input data.

2 MOTIVATING EXAMPLE

In this section, we provide an example to describe the typical process of building a semantic model for a sample data source of the National Portrait Gallery (NPG[1]) museum in Figure 1. On top of the table is a semantic model of the NPG. The source attributes are data nodes or leaf nodes. The ontology classes are class nodes, and links between nodes are ontology predicates. We also say that links between two class nodes are class links. Additionally, data links are links between class nodes and data nodes. For example, *aac:Person* and *aac:CulturalHeritageObject* are class nodes, while the source attributes *title* and *classification* are data nodes. The ontology classes and predicates are from DCTerms, SKOS, ElementsGr2, AAC, EDM ontologies[2].

The first step in building a semantic model is semantic labeling. A user or an automated semantic labeling system annotates each source attribute with semantic types. For example, the attributes *title* and *image* are labeled as ⟨*aac:CulturalHeritageObject*, *dcterms:title*⟩, ⟨*edm:WebResource*, *karma:classLink*⟩, respectively. Note that we use a special predicate *karma:classLink* to indicate that the data node *image* contains URIs of *edm:WebResource*.

The second step is specifying relationships between nodes in the model. This is a complicated problem, as there are several paths to connect two nodes in the domain ontology. For instance, *aac:Person* can be *dcterms:creator* or *aac:sitter* of *aac:CulturalHeritageObject*. Another example is that *bornDate* and *artistBornDate* do not belong to same person. If we only know the scores of semantic types of attributes and how frequent a predicate is used to connect two class nodes, we may not know which path is correct.

When users model a data source, they use various information to make decisions. For example, in Figure 1, we have three people who are listed under attribute *name* and are in the "Apollo 11 Crew" painting. As a painting is usually painted by one individual, a person would conclude that these are the names of the sitters rather than the names of the creators. Attributes *artist* and *ArtistBornDate* are two columns next to each other. This is weak evidence indicating that the two columns contain the name and birth date of a person. If the *bornDate* is mislabeled as death date of *aac:Person*, we would be skeptical about having Eastman Johnson draw a painting of Chester A. Arthur when he was 5 years old. Although these signals are useful, they are not always strong and correct. Can we learn to combine and apply the signals to build a correct semantic model?

3 PROBABILISTIC GRAPHICAL MODELS FOR SEMANTIC MODELING

Our problem of learning semantic models is defined as follow: suppose we have a set of domain ontologies O, a set of sources $\{s_1, s_2, ..., s_n\}$ and their semantic models $\{sm(s_1), sm(s_2), ..., sm(s_n)\}$. Given a target source $s(a_1, a_2, ..., a_n)$, in which a_i is a source attribute, we want to automatically build its corresponding semantic model $sm(s)$.

Our approach for building semantic models is similar to the procedure humans use. We model source attributes one at a time. For every attribute, we rank its modeling options based on the likelihood of the overall semantic model. Then, we select the attribute that has the highest rank. The process ends when there is no attribute left.

As we have discussed, users can exploit multiple signals to assist their decisions. For example, in Figure 1, given two options for relation ⟨n_1_*CulturalHeritageObject*, n_4_*Person*⟩: *dcterms:creator*

[1] http://npg.si.edu/home/national-portrait-gallery
[2] These ontologies are used in the evaluation datasets

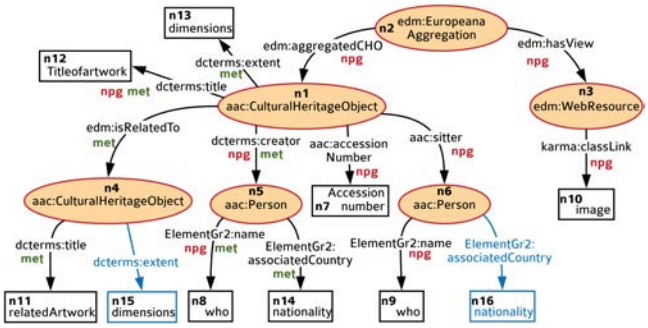

Figure 2: A example of integration graph[3]. This is built from sm(npg) and sm(met). Some nodes and properties are hidden for readability.

and *aac:sitter*, users can use the fact that name of n_4_*Person* is linked to the attribute *artist* to select predicate *dcterms:creator* over *aac:sitter*. Those signals are often collective and structural. They can be captured and represented naturally using a PGM, which is a very powerful framework that captures dependencies between relations and is robust to noise.

In Section 3.1, we describe the procedure to build a semantic model using search. We then explain how we apply and train a PGM as a ranking function in Section 3.2 and 3.3.

3.1 Searching for semantic models

Let $D_0 = sm(\{\})$ be a start state which is an empty model, $f : D_0 \rightarrow D_1$ be a transition function to move from one state to another state by adding one source attribute. Then, in general, constructing a semantic model can be solved using search algorithms by repeatedly invoking the transition function f until we reach the goal state, a tree connecting all source attributes.

Algorithm 1: TransitionFunction

Input: A search state: s_t
A set of source attributes: $A = \{a_0, ..., a_n\}$
An integration graph: G_{int}
Output: List of next search states

```
1 nextStates ← []
2 A′ ← A \ s_t.leafNodes
3 for a_i ← A′ do
4     trees ← MergeIntoTree (s_t, G_int, a_i)
5     for s_{t+1} ← trees do
6         nextStates.append(s_{t+1})
7 return nextStates
```

The transition function we use is defined in algorithm 1. We start with each unmerged attribute (line 2 - 3) and generate next states by merging them into current state (line 4). Algorithm 2 is used to combine an attribute with the current semantic model. The intuition of algorithm 2 is that we find all possible connecting paths between source attribute and leaves or root of the tree. Each path with a current tree forms a new state we want to generate.

[3]This example is based on an example from [29]

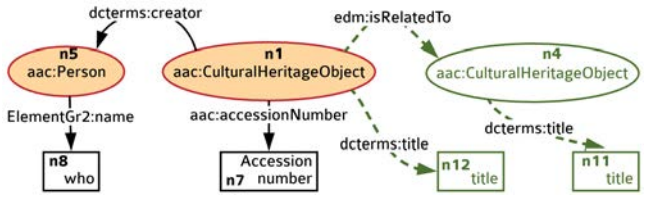

Figure 3: Two possible paths to add *title* attribute into current tree

To find the paths connecting source attribute and the existing tree, we use an integration graph from Taheriyan's work [29]. An integration graph is a directed weighted graph built from known semantic models, and represents a space of plausible semantic models we have seen in the training data. In Figure 2, we show an integration graph built from two data sources *npg* and *met*. Each link is annotated with its source name to specify where it comes from. When the graph is used in prediction, it is expanded by adding semantic types depicted in blue color. For example, in a new data source table, we have a column called *dimensions* tagged with a semantic type ⟨*aac:CulturalHeritageObject*, *dcterms:extent*⟩, we add one data node n_{15} and one link *dcterms:extent* from n_4 to n_{15}. However, we do not need to update node n_1 because we have already had link (n_1, *dcterms:extent*, n_{13}).

Now given an integration graph $G_{int} = \{V_{int}, E_{int}\}$, suppose that we are in the state s_t that we have four nodes $\{n_1, n_5, n_7, n_8\}$ as in Figure 3 and we want to merge attribute a_t = *title*. First, we need to align a_t to nodes in V_{int} that have same semantic type (line 2 in algorithm 2). The two nodes that match are n_{12} and n_{11}. For each node, we find all paths that connect the node to s_t, each path generates different tree. For example, there are two paths ($n_1 \rightarrow n_{12}$) and ($n_1 \rightarrow n_4 \rightarrow n_{11}$). Therefore, we have two next states. Each next state will be a tree that combines s_t and a merge path.

Algorithm 2: MergeIntoTree

Input: A search state: s_t
An integration graph: G_{int}
An attribute: a_t
Output: List of trees which contain the given attribute a_t

```
1 newTrees ← []
2 mntPts ← G_int.findAttribute(a_t.semanticType)
3 for mntPt ← mntPts do
4     connectedPaths ← all paths that connect leaves or root of
       s_t with mntPt
5     for path ← connectedPaths do
6         newTree ← merge mntPt to s_t using path
7         newTrees.append(newTree)
8 return newTrees
```

In addition to using the transition function in the beam search, we can also use it in interactive semantic modeling systems such as Karma [11]. In particular, from a current curated semantic model, the transition function is invoked to generate all semantic model

candidates. Then, the candidates are ranked using a scoring function to produce the top-k candidates for users to choose from. A user can also make corrections if there is no suitable option. In our approach, the scoring function directly affects the quality of our predicted semantic models. In the next section, we will describe how we use PGM to learn a scoring function.

3.2 Using Graphical Models as the score function

A probabilistic graphical model (PGM) is a well-known and effective framework to represent a probability distribution of random variables [13]. In order to apply PGMs in semantic modeling, we choose two kinds of random variables: input variables $\boldsymbol{x}$ that are links between nodes in a semantic model, and output variables $\boldsymbol{y}$ that are labels of the links. A label of a link has possible values in $\mathcal{V} = \{true, false\}$. A link with label *true* means it is correct and present in the gold semantic model. Since we are interested in predicting labels of links: $P(\boldsymbol{y}|\boldsymbol{x})$, it is natural to use a conditional random field (CRF). In particular, our standard CRF has following form:

$$P(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{Z(\boldsymbol{x}_c)} \prod_{C_p \in C'} \prod_{\Psi_c \in C_p} \Psi_c(\boldsymbol{y}_c, \boldsymbol{x}_c; \theta_p)$$

$$Z(\boldsymbol{x}_c) = \sum_{\boldsymbol{y}} \prod_{c \in C'} \prod_{\Psi_c \in C_p} \Psi_c(\boldsymbol{y}_c, \boldsymbol{x}_c; \theta_p)$$

where $\Psi_c(\boldsymbol{y}_c, \boldsymbol{x}_c; \theta_p)$ is a factor function that takes two set of variables $\boldsymbol{y}_c$ and $\boldsymbol{x}_c$ with parameters θ_p, and $Z(\boldsymbol{x}_c)$ is a partition function acted as a normalization factor to ensure the distribution $P(\boldsymbol{y}|\boldsymbol{x})$ sum to 1. The factors that have same input structure are grouped into $C' = \{C_1, C_2, ..., C_n\}$, where each C_i is a set of factors called *clique template* [26]. Factors in a clique template C_p share same parameters θ_p. A common choice of factor functions is exponential function, and each factor is log-linear with a set of feature functions f as follows:

$$\Psi_c(\boldsymbol{y}_c, \boldsymbol{x}_c, \theta_p) = \exp\left\{ \sum_k \theta_{pk} f_{pk}(\boldsymbol{y}_c, \boldsymbol{x}_c) \right\}$$

To simplify the notation, for every equation, x or y refers to one random variable, and $\boldsymbol{x}$ or $\boldsymbol{y}$ (bolded) refers to sets of random variables. Additionally, x and y symbols are used to denote input and output of a same link, respectively. For a complete guide about CRF, readers can refer to Sutton et al. [26].

Our ultimate goal is to construct a semantic model where all links are true. So the likelihood of the model being correct is $P(\forall y \in \boldsymbol{y}; y = true|\boldsymbol{x})$, and can be used as a score function for ranking. With the CRF framework above, in the following subsections, we will describe different clique templates and their features, each capture different relations between data sources and semantic models.

3.2.1 Link between nodes. These are factors over one link representing the likelihood of the link being correct or not. In particular, the factors have this form: $\Psi(y, x)$. The first feature of the factor is the confidence score of a semantic type, which is one of the outputs from the semantic labeling step. The features are defined as:

$$f_{ij}^{SS}(y, x) = \mathbf{1}_{\{y=i\}} \mathbf{1}_{\{st(x)=j\}} \text{st_score}(x); \forall i \in \mathcal{V}, j \in \mathcal{ST}$$

$$f_{ij}^{\overline{SS}}(y, x) = \mathbf{1}_{\{y=i\}} \mathbf{1}_{\{st(x)=j\}} (1 - \text{st_score}(x)); \forall i \in \mathcal{V}, j \in \mathcal{ST}$$

where $\mathbf{1}_{\{*\}}$ is an indicator function, $\mathcal{ST}$ is set of all possible semantic types, $st(x)$, $st_score(x)$ are the semantic type and confidence score of link x, respectively. These are typical features used in graphical models, where each feature has its own weight and is non-zero only when a particular condition is met.

Note that if we only use $f_{ij}^{SS}(y, x)$, then $\Psi(y = true, x) - \Psi(y = false, x) = \text{st_score}(x)(\theta_{true,j} - \theta_{false,j})$, then $\Psi(y = true, x) > \Psi(y = false, x)$ is independent of $\text{st_score}(x)$ but only weights of the features. By introducing $f_{ij}^{\overline{SS}}(y, x)$, we are able to assign higher energy to $\Psi(y = true, x)$ when confidence score is high, and higher energy $\Psi(y = false, x)$ when confidence score is low (assuming that the higher confidence score, the more chance y is true). The simple and yet efficient technique above is applied to many other signals which have continuous value in this paper.

The confidence score signal is only applied for data links. For class links, we estimate the probability of a link being correct as follows:

$$P(s, x, o) = P(s) * P(o) * P(x|s, o)$$

$$P(x|s, o) = \frac{count(s, x, o)}{count(s, o)}$$

where s, o are source node and target node of a link x in the semantic model, respectively. In the equation, the probability of nodes $P(s)$ and $P(o)$ are estimated using a logistic regression (LR) model, which is trained on the same training set of our graphical model. The intuition of two features used in the LR model is described below:

- Total confidence score of semantic types of all child data nodes of n: a class node is likely to be present in the model if it links to many data nodes.
- The merging cost of node n with another node n' that has the same label in the graph: two class nodes with disjoint sets of properties should be merged together to simplify the model.

Features of class links are defined similar to f_{ij}^{SS} as follow.

$$f_{ij}^{CL}(y, x) = \mathbf{1}_{\{y=i\}} \mathbf{1}_{\{\text{triple}(x)=j\}} P(\text{triple}(x)); \forall i \in \mathcal{V}, j \in \mathcal{T}$$

$$f_{ij}^{\overline{CL}}(y, x) = \mathbf{1}_{\{y=i\}} \mathbf{1}_{\{\text{triple}(x)=j\}} (1 - P(\text{triple}(x))); \forall i \in \mathcal{V}, j \in \mathcal{T}$$

where $\text{triple}(x) = (s, x, o)$, $\mathcal{T}$ is set of all triples.

Beyond the two features above, we also use other features which depend mostly on x. To define these features, we define a series of observation functions $o_t(x)$. The corresponding features have the form:

$$f_{it}^{LO}(y, x) = \mathbf{1}_{\{y=i\}} o_t(x); \forall i \in \mathcal{V}$$

The set of observation functions we used are listed in table 1.

3.2.2 Cardinality relationships. The cardinality constraint between two source attributes can be used to discover an incorrect model. For example, a painting should have only one primary title, i.e the id and primary title of a painting have a one-to-one relationship. If we observe that the relationship is one-to-many, then one of the properties is linked to the wrong attribute. We express the heuristic

Table 1: Observation functions used in factor of link of nodes

Features	Explanation
Delta_SS(x=j) $\forall j \in \mathcal{ST}$	Difference between score of current semantic type and the remained best semantic type
SS_rank(x)	Rank of a predicted semantic type (determined by semantic labeling method
P(x|s)	Frequency of a link x given its source node s
NoDataChild	The source node has only child class nodes
NoSiblings	The source node has only one child node
Prior	Prior probability of a link

above using factors between two outgoing links of class nodes x_1 and x_2: $\Psi(y_1, y_2, x_1, x_2)$.

Cardinality relationship between attribute a_2 and attribute a_1 is computed by averaging the number of unique values of a_2 grouped by a_1. If the average number is greater than a threshold $\alpha = 1 + |\epsilon|, \epsilon \gtrapprox 0$, we consider this to be either a one-to-many or a many-to-many relationship, otherwise, it is a one-to-one relationship. The threshold is chosen to be slightly greater than 1 in order to make this feature robust to noise in the data source (e.g., missing values). In particular, α is set to 1.05 based on experimental results. For example, in Figure 1, the cardinality of attribute *name* and attribute *ref* is $CRD(\text{ref}, \text{name})$ = 1-to-many because $\frac{1+3+1}{3} = 1.67 > \alpha$. If two attributes belong to two separate nested lists, which occurs infrequently, we do not compute its cardinality relationship and set it to NULL. The cardinality features of this clique template are defined as:

$$f^{CRD}_{ijkmn}(y_1, y_2, x_1, x_2) = \mathbf{1}_{\{y_1=i\}}\mathbf{1}_{\{y_2=j\}}\mathbf{1}_{\{st(x_1)=k\}}\mathbf{1}_{\{st(x_2)=m\}} \mathbf{1}_{\{CRD(x_1,x_2)=n\}} ; \forall i, j \in \mathcal{V}, k, m \in \mathcal{ST}, n \in \mathcal{CRD}$$

where $\mathcal{CRD}$ = {many-to-many, 1-to-many, 1-to-1, NULL}.

3.2.3 Properties co-occurrence. This clique template gives a boost to properties that are likely to occur together. For example, birth date and death date of an artist have higher co-occurrence than birth date and creation date of a painting. If we have two dates attributes, the chance of their being birth date and creation date will be lower than the chance that they are birth date and death date.

A co-occurrence frequency matrix is estimated from known semantic models and are used as features in this clique template:

$$f^{OCC}_{ijmn}(y_1, y_2, x_1, x_2) = \mathbf{1}_{\{y_1=i\}}\mathbf{1}_{\{y_2=j\}}\mathbf{1}_{\{st(x_1)=m\}}\mathbf{1}_{\{st(x_2)=n\}} \text{co_occurrence}(x_1, x_2) ; \forall i, j \in \mathcal{V}, m, n \in \mathcal{ST}$$

$$f^{\overline{OCC}}_{ijk}(y_1, y_2, x_1, x_2) = \mathbf{1}_{\{y_1=i\}}\mathbf{1}_{\{y_2=j\}}\mathbf{1}_{\{st(x_1)=m\}}\mathbf{1}_{\{st(x_2)=n\}} (1 - \text{co_occurrence}(x_1, x_2)) ; \forall i, j \in \mathcal{V}, m, n \in \mathcal{ST}$$

where x_1 and x_2 are sibling links of a class node.

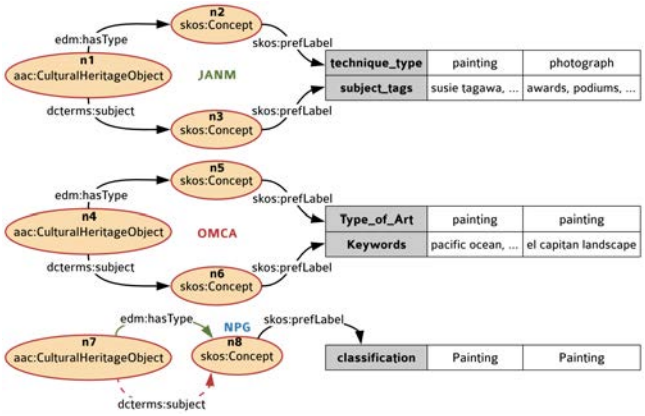

Figure 4: Excerpt from semantic models of the JANM, OMCA[4] and NPG data sources

3.2.4 Duplicated properties. An entity usually has many properties, but a few of them are duplicated. An example of a duplicated property is a class node *Person* with two links *worksFor* to two data nodes *organization1* and *organization2*. As semantic labeling systems often output the same semantic types for similar attributes, knowing which properties could be duplicated helps us identify incorrect links.

Factors in this clique template take a set of same label outgoing links of a class node and have the following features:

$$f^{DP}_{i0}(\boldsymbol{y_t}, \boldsymbol{x_t}) = \mathbf{1}_{\{|\{\forall y_i \in \boldsymbol{y_t} | y_i = true\}|=1\}}\mathbf{1}_{\{st(\boldsymbol{x_t})=i\}}; \forall i \in \mathcal{ST}$$

$$f^{DP}_{i1}(\boldsymbol{y_t}, \boldsymbol{x_t}) = \mathbf{1}_{\{|\{\forall y_i \in \boldsymbol{y_t} | y_i = true\}|>1\}}\mathbf{1}_{\{st(\boldsymbol{x_t})=i\}}; \forall i \in \mathcal{ST}$$

3.2.5 Grouping properties. In hierarchical data sources, properties of an entity are usually grouped under the same nested object. For example, birth date and name of person are properties of the *artist* object and *artist* is in a record object in a data source: {"artist": {"birth_date": "..", "name": ".."}, "title": ".."}.

Let $\text{SameScope}(x_1, x_2)$ be a function of two sibling links that output *true* if their target data nodes are under the same nested object and *false* otherwise. Then, the features of this clique template are defined as:

$$f^{GP}_{ij}(y_1, y_2, x_1, x_2) = \mathbf{1}_{\{y_1=i\}}\mathbf{1}_{\{y_2=i\}}\text{SameScope}(x_1, x_2); \forall i, j \in \mathcal{V}$$

$$f^{\overline{GP}}_{ij}(y_1, y_2, x_1, x_2) = \mathbf{1}_{\{y_1=i\}}\mathbf{1}_{\{y_2=i\}}\neg\text{SameScope}(x_1, x_2); \forall i, j \in \mathcal{V}$$

3.2.6 Structural similarity. There are many possible ways to link two class nodes. Class nodes involved in the same relationship often connect to a similar set of data nodes. For example, in Figure 4, *Concept* nodes n_2, n_5 and n_8 link with *CulturalHeritageObject* nodes via the predicate *hasType* have similar values, which are types of artworks. While *Concept* nodes n_3 and n_6 involved in different relations (*dcterms:subject*) contain values about subjects in artworks. This heuristic can be used to predict the likelihood of links between class nodes. In particular, we define factor functions taking two links x_1 and x_2, which are class link and data link, respectively. The input x_1 and x_2 form a substructure. We say two substructures are partially matched if they both have the same link x_2. For example, in Figure 4,

[4]http://www.janm.org/ and http://museumca.org/

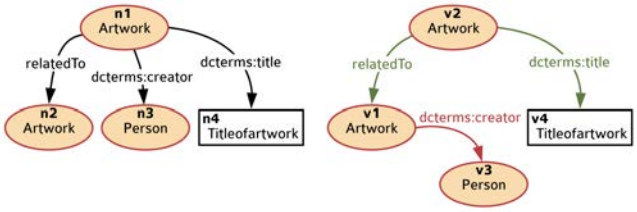

Figure 5: Example of a gold model and predicted model. The gold model is on the left side and the other is the predicted model. The green lines in the predicted model show correct links and red ones are incorrect links.

we have two substructures: $s_1 = \langle CulturalHeritageObject, hasType, Concept, prefLabel, classification\rangle$ and $s_2 = \langle CulturalHeritageObject, subject, Concept, prefLabel, classification\rangle$, in which $s2$ and $s1$ are partially matched.

The likelihood of a substructure is the maximum similarity score between its source attribute with other source attributes of other identical substructures in the training set. The reward of the substructure, Reward(x_1, x_2), is defined to be the difference between the likelihood of current substructure with the highest likelihood of other partial matched substructures. For example, in Figure 4, assuming the similarity score between attribute *classification* and attributes *technique_type*, *subject_tags*, *type_of_art*, *keywords* are 0.7, 0.5, 0.8, 0.2, respectively. Then, the likelihood of substructure $s_1 = max(0.7, 0.8) = 0.8$, and the likelihood of substructure $s_2 = 0.5$. The reward of the substructure $s_1 = 0.8 - 0.8 = 0$ while reward of $s_2 = 0.5 - 0.8 = -0.3$. Hence, our CRF will prefer s_1 to s_2.

Using Reward(x, y) function, the features of this clique template are defined as follow:

$$f_{ij}^{SrS}(y_1, y_2, x_1, x_2) = \mathbf{1}_{\{y_1=i\}}\mathbf{1}_{\{y_2=i\}}\text{Reward}(x_1, x_2); \forall i, j \in \mathcal{V}$$

$$f_{ij}^{\overline{SrS}}(y_1, y_2, x_1, x_2) = \mathbf{1}_{\{y_1=i\}}\mathbf{1}_{\{y_2=i\}} - \text{Reward}(x_1, x_2); \forall i, j \in \mathcal{V}$$

3.2.7 Error propagations. The factors of this clique template are used to remove class nodes in which all of their outgoing links are labeled *false* because they are redundant. In particular, the factors need to output high energy when all links of a class node are incorrect, and low energy when all of the outgoing links have label *false* but the incoming link is labeled *true*. Features of this clique template are defined as follow:

$$f_i^{EP}(y_0, \boldsymbol{y}_c, x_0, \boldsymbol{x}_c) = \mathbf{1}_{\{y_0=i\}}\mathbf{1}_{\{y=\text{false};\forall y\in\boldsymbol{y}_c\}}; \forall i \in \mathcal{V}$$

where x_0 is the incoming link, $\boldsymbol{x}_c$ are the outgoing links.

3.3 Training the Graphical Model

To train the graphical model, beside positive examples obtained from set of known semantic models, we also need negative examples. A typical approach to generate more training data is collecting generated semantic models from the search procedure. Then, every link in the generated models is labeled *true* or *false* using an automated labeling procedure.

3.3.1 Auto-label examples. Define rel(*sm*) is a set of triples (u, e, v) of semantic model *sm*, in which u, v is a source node and target node of a link e, respectively. The labeling procedure works as follow. First, we find the best mapping from node in the predicted model sm' to node in known model *sm* such that it maximizes the number of overlapped triples between rel(*sm*) and rel(sm'). For example, in Figure 5, if the mapping is $\{n_1 \to v_2, n_2 \to v_1, n_3 \to v_3, n4 \to v_4\}$, we have 1 overlapping triple $\langle Artwork, dcterms{:}title, Titleofartwork\rangle$. If we switch the mapping between two nodes n_1 and n_2, we have 2 overlapping triples and this is the best mapping we can have. After the alignment step, each link e in predicted model sm' is assigned a true label if its triple (u, e, v) is in rel(*sm*); otherwise, it is assigned *false*.

3.3.2 Generate training examples.

Algorithm 3: EliminateDataNodes

Input: A gold semantic model: *sm*
Output: List of new semantic models in which some data nodes have been removed

```
startStates ← []
sm_new ← remove data nodes in sm, which semantic labeling doesn't predict their semantic types correctly
for u ← sm_new.dataNodes do
    for stype ← PredictedSemanticTypes (u) do
        V_match ← all the data nodes have semantic type stype
        if |V_match | = 0 then
            state ← remove u out of sm_new
            add state to startStates
        for v ← V_match do
            if u is not v then
                state ← remove u and v out of sm_new
                add state to startStates
return startStates
```

To make the process of generating training examples efficient, instead of starting from an empty semantic model, we start from a known semantic model, remove some data nodes, then invoke the search algorithm in Section 3.1 to add back the removed attributes. The algorithm 3 describes how we remove data nodes. The goal is instead of removing random nodes, we remove the nodes that have same semantic types, so that when we add back a data node, there is always more than one possible way we can merge the data node into the model, hence generate a hard example for our graphical model to learn. For example, in Figure 1, suppose that we are removing the attribute *artist*, and *artist* is tagged with two possible semantic types: $\langle CulturalHeritageObject, title\rangle$ and $\langle Person, name\rangle$. After removing, we have two started states: the first one is the graph missing the links $\langle n_1_CulturalHeritageObject, title\rangle$ and $\langle n_4_Person, name\rangle$, the second state is omitting the links $\langle n_4_Person, name\rangle$ and $\langle n_5_Person, name\rangle$.

Note that as there are many possible examples that can be generated, each example is associated with a score computed using Taheriyan et al. [29] method, then we randomly sample the examples using the score to reduce the number of training examples. In our experiments, the number of examples is set to 300 per gold semantic model.

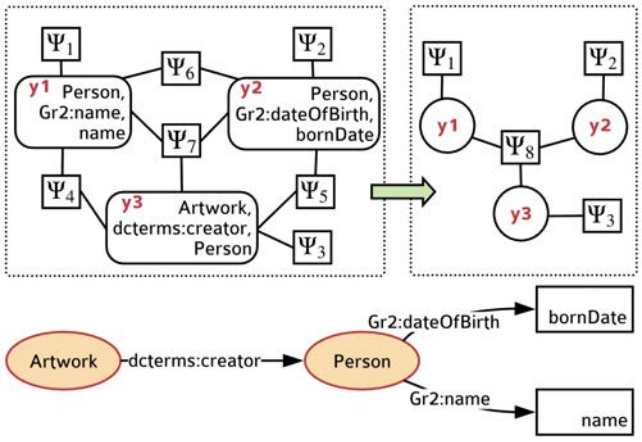

Figure 6: Factor graphs before and after eliminating cycles. In the factor graphs, we omit random variables $\boldsymbol{x}$ because their values are fixed.

3.3.3 Inference and Parameter Learning. We perform exact inference on CRF using Belief Propagation [26]. Undirected graphical models are often represented as factor graphs in which random variables and factor functions are nodes. An edge is drawn between a random variable and a factor if the variable is input of the factor function. Since we can only apply Belief Propagation to acyclic factor graphs, we eliminate cycles in our factor graphs by merging cliques which form cycles into single cliques. With the choices of factors in Section 3.2, we only need to merge factors, whose inputs are incoming links and/or outgoing links of same class nodes. For example, in the factor graph in Figure 6, the graph becomes acyclic after the four factors Ψ_4 to Ψ_7, which form cycles, are merged and replaced by a new factor:

$$\Psi_8(y_1, y_2, y_3, x_1, x_2, x_3) = \Psi_4(y_1, y_3, x_1, x_3)\Psi_5(y_2, y_3, x_2, x_3) \Psi_6(y_1, y_2, x_1, x_2)\Psi_7(y_1, y_2, y_3, x_1, x_2, x_3)$$

The problem with this approach is that the merged factors may have many variables, which results in the number of values of $\boldsymbol{y}$ we need to enumerate increasing exponentially with n: 2^n, where $n = |\boldsymbol{y}|$. Fortunately, it is not common to have a class node containing too many properties. In order to ensure the inference algorithm has reasonable runtime, we could control the number of variables in the factor by keeping top $n' < n$ most frequently used predicates. In the experiments, we set $n = 11$ so there are only maximum 2048 combinations of $\boldsymbol{y}$ values.

Our CRF is trained using the standard maximum log-likelihood and Belief Propagation. For more details about Belief Propagation and training CRF, readers can refer to the tutorial in Sutton et al. [26].

4 EXPERIMENTAL EVALUATION

4.1 Dataset and experimental setup

Our objective is to assess the ability of our method to infer correct semantic models with and without noisy data. We evaluate our approach, which is called PGM-SM, on two different datasets: ds_{edm} and ds_{crm} from Taheriyan et al. [29]. Both datasets contain data sources from different art museums in US, and in different data formats (CSV, XML, JSON, etc). However, domain experts use two different well-known data models in the museum domain: Europeana Data Model (EDM), and CIDOC Conceptual Reference Model (CIDOC-CRM) for knowledge representation. The details of two datasets are listed in Table 2. Note that we updated the semantic models in the ground-truth datasets to fix some mistakes based on the recommendation[5] from domain experts [12]. The updated datasets, experimental results and our code are available on Github[6].

Table 2: The evaluation datasets ds_{edm} and ds_{crm}

	ds_{edm}	ds_{crm}
#data sources	28	28
#classes in domain ontologies	119	147
#properties in domain ontologies	351	409
#nodes in the gold-standard models	444	970
#data nodes in the gold-standard models	310	552
#class nodes in the gold-standard models	134	418
#links in the gold-standard models	416	942

Table 3: MRR scores of three semantic labeling methods

Datasets	DSL	Serene	SemTyper
ds_{edm}	0.886	0.912	0.830
ds_{crm}	0.896	0.910	0.628

Semantic labeling methods are evaluated using standard mean reciprocal rank (MRR) [5]. We assess the quality of predicted semantic models by comparing with gold semantic models in term of precision and recall as in Taheriyan et al. [29]:

$$\text{precision} = \frac{|rel(sm) \cap rel(f^*(sm'))|}{|rel(f^*(sm'))|}$$

$$\text{recall} = \frac{|rel(sm) \cap rel(f^*(sm'))|}{|rel(sm)|}$$

$$f^* = \underset{f}{\text{argmax}}\, |rel(sm) \cap rel(f(sm'))|$$

where $rel(sm)$ is a set of triples (u, e, v) of a semantic model sm, f is a mapping function that maps nodes in sm' to nodes in sm (Section 3.3.1).

In our experiments, we use half of the dataset for training and the other half for testing. We repeat the process by three times (3-folds) and average the results. Parameters of our CRF are learned using the ADAM-AMSGRAD optimization method [21] for 60 epoches with batch size 200 and learning rate 0.05. Our experiments are run on a single machine with Intel Xeon E5-2620 v4 and 32GB RAM.

4.2 Automatic semantic modeling

In this experiment, we evaluate our method on four different semantic labelers: SemTyper [20], DSL [18], Serene [22] and Oracle.

[5]The recommendation documentation can be found at: http://review.americanartcollaborative.org/

[6]https://github.com/binh-vu/semantic-modeling

Table 4: Performances of semantic modeling systems with respect to different semantic labelers

Datasets	Labelers	Precision			Recall			F1		
		Taheriyan	Serene	PGM-SM	Taheriyan	Serene	PGM-SM	Taheriyan	Serene	PGM-SM
ds_{edm}	SemTyper	0.726	0.689	0.772	0.702	0.701	0.767	0.712	0.693	0.768
	DSL	0.656	0.708	0.812	0.618	0.734	0.820	0.635	0.719	0.815
	Serene	0.808	0.777	0.822	0.800	0.803	0.837	0.803	0.789	0.829
	Oracle	0.883	0.876	0.945	0.892	0.896	0.927	0.887	0.885	0.935
ds_{crm}	SemTyper	0.695	0.710	0.809	0.559	0.624	0.660	0.618	0.663	0.725
	DSL	0.699	0.714	0.851	0.693	0.687	0.839	0.695	0.698	0.844
	Serene	0.779	0.736	0.886	0.770	0.773	0.875	0.774	0.753	0.880
	Oracle	0.869	0.838	0.965	0.847	0.846	0.928	0.857	0.840	0.944

Table 5: Average F_1 score of PGM-SM with respect to different training size

Datasets	25% of dataset	50% of dataset
ds_{edm}	0.808	0.837
ds_{crm}	0.823	0.848

Table 6: Average running time of PGM-SM on two different datasets.

Datasets	Training time	Testing time
ds_{edm}	162.47s	9.54s
ds_{crm}	315.74s	59.37s

Each semantic labeler has different performance and characteristic, thus provides different levels of noise to our system. Of the three methods, SemTyper has the lowest MRR score indicating that its output includes many incorrect semantic types. While DSL has higher MRR score, thus provides fewer incorrect semantic types. However, the confidence score between predicted semantic types is similar since DSL predicts semantic labels based on a similarity notion. Serene has the best MRR performance, and the confidence score between correct and incorrect semantic types is very different. The Oracle semantic labeler is a labeler that always outputs the correct semantic type, thus provides no noise to the semantic modeling system. The performance of these semantic labelers is reported in Table 3.

We compare our method with two state-of-the-art semantic modeling systems: Taheriyan et al. [29] and Uña et al. [30] (Serene). The experiment results are reported in Table 4. Generally, the F_1 score increases with less noise for three systems. Among them, our approach outperforms the two baseline methods with the average increase by 6.53% and 10.92% on ds_{edm} and ds_{crm}, respectively. As both baseline methods predict semantic models by finding the minimum-weighted tree, they would be affected if the weights of edges are similar. Therefore, they are more sensitive to the noise of DSL. Our approach, however, uses the collective signals and achieves significant improvement, which indicates it is more robust to noise.

Table 5 shows the average F_1 score of PGM-SM when the number of known semantic models is 25% and 50% of the datasets. As the training size increases, the performance of PGM-SM increases. The average percentage of performance gain is 2.7%, which suggests that the model achieves reasonable performance even when the training size is small (25%). Comparing to the two baseline methods Taheriyan et al. [29] and Serene in the same scenario, PGM-SM improves the F_1 score on average 7.68% and 9.20%, respectively.

In addition, we measure the running time of our approach in terms of training and testing time listed in Table 6. The training time starts from generating training examples to finishing training PGM-SM. The testing time is total time to predict semantic models of the testing data sources. Since the size of semantic models in ds_{crm} are twice as big as the models in ds_{edm} (Table 2), we can see that the training time of ds_{crm} is nearly double ds_{edm}. The testing time does not increase correspondingly because it depends not only on the runtime of PGM but also the runtime of the search algorithm, which increases linearly with the number of attributes in the data sources.

4.3 Feature analysis

To understand the impact of each feature on the result, we perform ablation analysis by removing the factors described in Section 3.2. As the results in Table 7 have shown, dropping some factors sometimes slightly increases the F_1 score. In particular, STRUCT-SIM and ERROR-PROP are important in dataset ds_{crm}, while they are not in dataset ds_{edm}. The reason of this phenomenon is that the semantic models in ds_{crm} are very complex and structural while semantic models in ds_{edm} are not. For example, in ds_{edm}, a creation date of an artwork is modeled as a literal date time value. While in ds_{crm}, the date is represented as a class *E52_Time-Span* to capture the fact that it could take an artist many years to create an artwork. As those factors have little effect in ds_{edm}, dropping them actually makes the CRF model to learn better parameters of the remaining factors. On the other hand, CO-OCCUR and GROUPING factors

Table 7: Ablation analysis of the factors in PGM-SM. Each cell value is a difference in F_1 score upon dropping one factor.

Factor	Factor name	ds_{edm}				ds_{crm}			
		SemTyper	DSL	Serene	Oracle	SemTyper	DSL	Serene	Oracle
Structural Similarity	STRUCT-SIM	-0.009	0.004	0.020	0.008	-0.006	-0.013	-0.001	-0.015
Error Propagation	ERROR-PROP	0.005	0.005	0.004	0.000	-0.006	-0.016	-0.001	0.003
Co-occurrence	CO-OCCUR	-0.006	-0.014	-0.008	-0.005	0.024	-0.008	0.010	0.004
Grouping properties	GROUPING	0.008	-0.011	-0.003	0.008	-0.007	-0.012	0.004	0.003
Duplicated properties	DUP-PROP	-0.003	-0.009	-0.005	0.000	-0.007	-0.008	-0.003	-0.007
Cardinality relationships	CARDINALITY	-0.006	-0.020	-0.013	-0.023	-0.014	-0.049	-0.022	-0.032

show the opposite trend. DUP-PROP and CARDINALITY have positive impact on the F_1 score for all datasets and CARDINALTIY is the most important feature in our CRF model.

5 RELATED WORK

There are many studies to automatically integrate data from multiple sources. Although their goals are similar, they are different in terms of inputs and assumptions and can be clustered into three groups.

The first group focuses on problems of schema matching and mapping [3]. Schema matching generates correspondences between elements of two schemas [4, 6, 19]. For instance, Madhavan et al. [15] combine information from schema constraints (data types, foreign keys), structure and values in data sources to find one to one correspondence between elements in source schema and target schema. Schema mapping generates mapping formulas from schema matches to transform data from source schema to target schema [1, 2, 8, 9, 16, 23]. In some recent studies, Kimmig et al. [10] use probabilistic soft logic to explore information from both data examples and schema constraints to generate the mappings. The semantic modeling problem, however, is different from schema matching and mapping [29]. First, in addition to finding mappings from attributes in a data source to ontology classes and properties, we also generate relationships between the attributes. Moreover, as data sources on the Web are often lack of schema constraints and have different conventions, semantic modeling provides a straightforward approach to represent and publish the data to knowledge graph.

The second group focuses on describing semantics of web tables. Limaye et al. [14] use a probabilistic graphical model and an external knowledge base YAGO to annotate tables with entities for cells, semantic types for columns and binary relationships between columns. Mulwad et al. [17] share similar ideas with Limaye et al., in which they leverage Linked Open Data (LOD) such as DBpedia, YAGO and Wikitology to link table cells with LOD entities. After generating initial lists of candidates for cell values, they perform inference to compute the assigned types of column, cell linkage and relations between columns. Instead of using available knowledge graphs, Venetis et al. [31] build two databases of class of entities and relationships between the entities from text documents available on the Web. The column labels are assigned to maximize the probability of column values given class labels of entities. All of these approaches rely on external knowledge bases which provide possible links between cell values and known entities. Hence, performance of these approaches highly depends on the quality of the linkages. Furthermore, as not all data attributes have corresponding entities in knowledge base, e.g: birth date, phone, age; these approaches may not be applicable to a broad range of data sources and be restricted to domains where online data is widely available.

Our problem is in the final group, in which semantic models are used to precisely describe meanings of data sources and publish data to knowledge graph. The semantic models can represent a wide range of data sources and in various formats such as CSV, XML, JSON, etc. To address the semantic modeling problem, Taheriyan et al. [28, 29] build an integration graph that represents space of plausible semantic models for a new data source. Each link in the integration graph is associated with a weight representing the frequency of use of the link in previous models. First, attributes of a new data source are associated with data nodes in the integration graph. Then, the semantic model is built by finding the Steiner Tree that connects the data nodes. Uña et al. [30] also predict semantic models by finding Steiner Tree. However, to solve the Steiner Tree problem, instead of using an approximation algorithm as in Taheriyan et al. [29], they use constraint programming, an exact algorithm, which allows it to incorporate more features as additional constraints. Instead of solving the Steiner Tree problem, our approach uses a PGM to exploit collective signals from a data source. The PGM allows us to express complex dependencies between the features of good and bad semantic models. Therefore, we are able to obtain better performance than the previous state-of-the-art methods.

6 CONCLUSION AND FUTURE WORK

In this paper, we presented a novel approach for semantic modeling that uses a probabilistic graphical model to exploit relationship within data sources and semantic models. From a set of data sources and their semantic models, we train a conditional random field (CRF) to distinguish between good and bad semantic models. Then, we use the CRF to efficiently search over the combinatorial space of possible semantic models to identify the most probable model for a data source. The evaluation shows that by exploring the relationships within data, our approach generates better semantic models and is more robust to noise than previous approaches.

Because labeled data is costly to obtain, a future direction of our work is to exploit transfer learning to leverage a vast amount of available linked datasets in the Linked Open Data. For example, we can train a CRF on linked datasets, which are represented using the same domain ontologies, and reuse them as a pre-trained model. We can also enrich our training set by applying ontology matching techniques to align linked data from different ontologies to our ontologies.

Another direction for future work is to integrate semantic modeling with web data extraction. Unsupervised web data extraction methods such as Trinity [24] can extract structural data from a set of web pages. However, the output of these methods often includes many redundant data attributes. By leveraging more information from the extraction step such as the position of extracted attributes in the web pages and collective information between data attributes, we can potentially improve performance of systems that automatically extract and semantically annotate web data.

ABSTRACT

In many online platforms, people must choose how broadly to allocate their energy. Should one concentrate on a narrow area of focus, and become a specialist, or apply oneself more broadly, and become a generalist? In this work, we propose a principled measure of how generalist or specialist a user is, and study behavior in online platforms through this lens. To do this, we construct highly accurate *community embeddings* that represent communities in a high-dimensional space. We develop sets of community analogies and use them to optimize our embeddings so that they encode community relationships extremely well. Based on these embeddings, we introduce a natural measure of activity diversity, the GS-score.

Applying our embedding-based measure to online platforms, we observe a broad spectrum of user activity styles, from extreme specialists to extreme generalists, in both community membership on Reddit and programming contributions on GitHub. We find that activity diversity is related to many important phenomena of user behavior. For example, specialists are much more likely to stay in communities they contribute to, but generalists are much more likely to remain on platforms as a whole. We also find that generalists engage with significantly more diverse sets of users than specialists do. Furthermore, our methodology leads to a simple algorithm for community recommendation, matching state-of-the-art methods like collaborative filtering. Our methods and results introduce an important new dimension of online user behavior and shed light on many aspects of online platform use.

1 INTRODUCTION

In many domains of human endeavor, people must choose how broadly to allocate their energy. Should one be a *specialist*, and concentrate in depth on a narrow area of focus, or be a *generalist*, and apply oneself more broadly? In the past century, there has been a steady movement towards specialization in professional domains, including business, medicine, and academia [5, 12, 22], while in the past decade, there has been a rise of generalists, especially in entrepreneurship and in the tech industry [6, 21].

The trade-off between breadth and depth of activity is also a fundamental characteristic of user behavior in online platforms. A user can concentrate on a narrow range of activities and reap the rewards of specializing in some area of the platform, or one can maintain a more diverse set of interests at the cost of not engaging as deeply with them. Whether the choice is explicitly made or not, the scope of a user's activity ranges between being narrow and broad. There exists a continuum of possibilities between extreme specialists on one side and extreme generalists on the other, and in general users will be somewhere in the middle.

Activity Diversity in Online Platforms. The question of how diverse users' activities are illuminates a number of important issues. First, the extent to which users are generalists or specialists indicates how connected an online platform is on a global level. If most users lean towards being specialists, then the platform will tend to consist of isolated communities with little interaction between them, whereas if most users lean towards being generalists, then the platform will tend to be more cohesive and support broader engagement between members of different communities. Second, users' activity diversity styles can be indicative of the underlying incentives they face. As in medicine and academia, where the prevailing incentives once rewarded generalists but now typically steer professionals towards specialization, a preponderance of specialists or generalists in online platforms could reveal how users perceive their incentive structures. Third, the relation between breadth and depth of activity and resulting success and longevity has been the source of rich debates in other contexts [2, 18]. The study of how this plays out in online platforms could contribute to this discussion.

Despite the fundamental nature of the activity diversity problem, and its relative simplicity to state, it is difficult to study rigorously for several reasons. In the simplest form of the problem, we are given a set of activities supported by an online platform, and empirical data on what activities individual users choose to pursue. The main obstacles in measuring which users are generalists and which are specialists are twofold: first, coming up with measures of similarity between all pairs of activities, and second, ensuring that these similarities are consistent with each other. In prior work, researchers have mainly used entropy as a measure of activity diversity [7]. Entropy is very sensible in many scenarios, and is sensitive

to both the number and distribution of activities. However, it is agnostic to the similarities or differences between activities. Thus, a user whose activities are all very similar to each other would be treated the same as a user with the same distribution of engagement across activities that are very different from each other, contradicting the intuition that the former is more of a specialist.

The Present Work: Community Embeddings and the GS-Score. In this work, we present a methodology to study generalists and specialists in online platforms, and we analyze, characterize, and predict user behavior on Reddit and GitHub through this lens. On Reddit, a discussion-based content aggregation platform, we are interested in how users participate in various communities (*subreddits*) as defined by commenting on posts in those communities; and on GitHub, a social coding platform, we are interested in how users interact with (contribute, star, or watch) various code repositories.

To solve the problem of deriving high-fidelity, consistent similarities between communities, we develop and considerably extend *community embeddings*. Following previous work [11, 15], we adapt word2vec, a word embedding algorithm that assigns a vector to each word in a training corpus such that relationships between words are preserved, to assign a vector to each community in our data such that relationships between communities are preserved. In word embeddings, analogical reasoning can surprisingly be done with simple vector arithmetic. Our first contribution is developing a set of ground-truth community analogies for both Reddit and GitHub that can be used to optimize the embedding algorithm hyperparameters and vastly enhance the quality of the resulting community embeddings. In our final embeddings, analogy questions like `toronto : torontoraptors :: chicago : ___?` are answered correctly (`chicagobulls`) with extremely high accuracy.

Using our community embeddings, we are able to quantify the similarity between any two communities as the cosine similarity between their respective vector representations. Furthermore, these similarities are mutually consistent, as a result of being derived from the geometry of the same vector space. We represent a user's activities as a distribution over points in this vector space. Intuitively, a specialist's activity is concentrated in the space, and a generalist's activity is diffuse in the space (see Figure 1 for a schematic depiction). We calculate a user's *center of mass* as being the centroid of the communities they contribute to, and we define the *Generalist-Specialist score* of a user's activity to be the average cosine similarity between their communities and their center of mass, weighted by activity. The GS-score is minimized by specialists who contribute to a tight cluster of communities and maximized by generalists who contribute to communities that are far apart. We developed an online quiz to elicit human judgments about generalist and specialist users and found that they correlate very well with the GS-score. This principled measure of activity diversity in online platforms, using high-fidelity and validated community similarities calculated from community embeddings, is a key contribution of our work.

Overview of Results. Our results fall into two categories, according to our two main units of analysis: the user and the community.

We first focus on users. Applying the GS-score to Reddit and GitHub users, we observe a great diversity of user activity styles, ranging from extreme generalists to extreme specialists, at every level of activity. Compared to a random baseline, there are many more specialists than expected. On Reddit, we analyze how users' comments are voted on, and find that specialists do about 20% better in a controlled analysis. We then turn to studying user longevity, both in individual communities and on the platform as a whole. We find that specialists are much more likely than generalists to convert into long-term members of a particular community, suggesting that specialists are more selective. However, we also observe that generalists are much more likely to remain on the platform, with the effect being particularly stark on Reddit. These results have interesting implications for community managers and platform designers; on the one hand a community manager should probably seek out specialists to join their community, but on the other hand platform designers should try to be amenable to generalists and encourage exploration. Finally, we measure the diversity of the subpopulations users interact with, and find that specialists interact with significantly less diverse sets of users than generalists do.

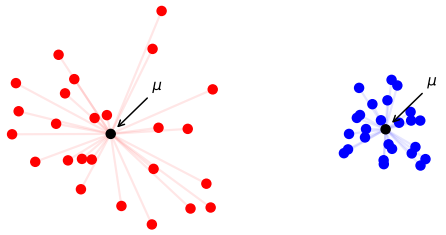

Figure 1: A schematic depicting the vector representations of communities contributed to by a generalist (left) and a specialist (right). The generalist's communities are spread out, and the specialist's communities are clustered together.

We then turn our attention to communities, and make the observation that we can define the activity diversity of a *community* to be the average activity diversity of its users. We find this *community activity diversity* score to be remarkably stable, remaining relatively constant for at least three years, even when the underlying user base turns over significantly. We also analyze which users make up the "elites" in a community and find that they skew generalist.

Finally, we apply our measure in a prediction framework and focus on two concrete, important tasks. The first is community recommendation, in which we predict which communities users will join. We develop a simple algorithm to recommend communities based on their proximity to a user's center of mass and demonstrate that it performs at least as well as state-of-the-art collaborative filtering. Furthermore, we find that specialists are much more predictable than generalists. The second problem is user retention, in which we predict if users will stay on the platform. We show that using activity diversity alone performs very well.

The rest of the paper is laid out as follows. In Section 2, we discuss the datasets, develop community embeddings, and introduce our metric of activity diversity, the GS-score; in Section 3 we analyze behavior in Reddit and GitHub through the lens of activity diversity; in Section 4 we perform our prediction tasks; in Section 5 we outline related work; and in Section 6 we discuss our work and conclude.

2 METHODOLOGY

The main goal of our work is to precisely define a measure of activity diversity that smoothly interpolates between generalists

and specialists, and apply it to the study of user behavior in online platforms. In this Section, we describe our datasets, develop our methodology to construct high-fidelity community embeddings, validate these embeddings as being accurate representations of the platforms we study, and introduce our measure of activity diversity.

2.1 Data

First we introduce the online platform datasets we use throughout the rest of the paper. We study two online platforms in depth: Reddit, a discussion-based content aggregation platform, and GitHub, a collaborative coding platform.

Reddit. Our main dataset is derived from Reddit, an online platform where users can share, view, and discuss content from around the Web. Every post is either a piece of free-standing text or a URL, and there is a discussion page where users can discuss the post. Reddit is subdivided into communities called *subreddits* that are organized around some theme; for example `r/gardening` is about gardening and `r/learnprogramming` is for people learning how to program. We are interested in user participating in these communities by *commenting* in them, i.e. by participating in discussions on discussion pages. Comments can also be voted on by other users, and each has a vote score associated with it.

Our Reddit dataset is comprised of all Reddit user comments in 2017, totalling 900M comments authored by 11.4M distinct users in 232K subreddits. We restrict our attention to the top 10,000 subreddits by activity, which account for 96.8% of all comments. The data we used is publicly available and can be downloaded from `pushshift.io` [3].

GitHub. We supplement our Reddit analyses with a dataset of GitHub activities. GitHub is an online platform where users can collaborate on coding projects that are divided into *repositories* of self-contained projects. Popular repositories frequently support a vibrant community of contributors. We treat repositories as communities, and consider adding code and bookmarking to be user contributions to these communities.

Our GitHub dataset is comprised of all GitHub commits, pull requests, forks, watches, and stars in 2017, totalling 413M actions by 8.3M distinct users in 26M repositories. Since the vast majority of repositories have very few contributors (usually 1), we restrict our attention to the top 40,000 communities by number of stars. The data we used is publicly available from the GH Archive and can be downloaded from `gharchive.org`.

2.2 Community Embeddings

As mentioned in the Introduction, a chief difficulty in formulating a measure of activity diversity is coming up with accurate similarities between all pairs of communities. Without these, it is hard to distinguish between a user who is active in two very related communities and a user who is active in two very different communities, despite the fact that intuitively the former should be treated as more specialist than the latter. The most commonly used metric for capturing user diversity among activities is entropy, which is agnostic to community similarities, and therefore treats these two users as being equally diverse in their activities.

To solve this problem, we construct high-fidelity *community embeddings*. Drawing inspiration from the major successes achieved by applying word embeddings to various natural language processing tasks, and following recent work [11, 15], we adapt the word2vec word embedding algorithm to apply to user-community interaction data to generate community embeddings. Treating communities as "words" and users who comment in them as "contexts", we embed communities into a high-dimensional vector space. Two communities are close together if users frequently comment in them both, and are far apart if they are rarely commented in by the same users. We use the skip-gram model with negative sampling and train over all pairs (c_i, u_j) of user u_j commenting in community c_i.

Using the same hyperparameters as those used in the original word2vec model, we generated an initial community embedding. It seems to work reasonably well — for example, the nearest communities to `r/Fishing` (those with highest cosine similarity with `r/Fishing`) are focused on other outdoor pursuits, e.g. `r/discgolf`. However, it is unclear how to objectively evaluate the fidelity of this embedding.

This problem of objectively measuring embedding quality also arises with word embeddings. There, researchers and practitioners solve this problem by making use of the surprising fact that embeddings preserve semantic relationships. For example, in a well-tuned word embedding, the analogy `man : king :: woman : ___`? can be correctly solved with `queen` by performing vector arithmetic on the corresponding word vectors ($\overrightarrow{\text{king}} - \overrightarrow{\text{man}} + \overrightarrow{\text{woman}} \approx \overrightarrow{\text{queen}}$). By generating a set of word analogies and then measuring how many of them a word embedding can solve by performing vector arithmetic, one can measure the quality of a word embedding.

Community analogies. To evaluate our community embeddings, we adapt this methodology to our community setting and develop large sets of ground-truth *community analogies*, which can be used to objectively evaluate the quality of a community embedding. Each analogy is a tuple (a, a', b, b') of communities such that $a : a' :: b : b'$, and it should be the case that $\overrightarrow{a'} - \overrightarrow{a} + \overrightarrow{b} \approx \overrightarrow{b'}$. We found three different classes of objective semantic relationships on Reddit communities that we can generate analogies with: university → city, sports team → city, and sports team → sport. For example, for the first class of analogies, university communities (e.g. `r/Harvard`) should all have roughly the same vector relationship with the communities of the city they are located in (e.g. `r/CambridgeMA`). Thus, it should be the case that e.g., $\overrightarrow{\texttt{r/Harvard}} - \overrightarrow{\texttt{r/CambridgeMA}} \approx \overrightarrow{\texttt{r/mcgill}} - \overrightarrow{\texttt{r/montreal}}$. Example analogies of each type are shown in Table 1. For each class of analogies, we generated a list of pairs of communities with the same semantic relationship, then took the Cartesian product of these pairs to construct all possible analogies for this class. Across our three classes, we constructed 4,392 analogies in total[1].

We can now validate our embedding. For each analogy, we rank all vector representations of communities in ascending order of distance to the point $\overrightarrow{a'} - \overrightarrow{a} + \overrightarrow{b}$. The accuracy metric Precision@k measures the fraction of analogies for which $\overrightarrow{b'}$ is among the k closest communities, and the special case Precision@1 measures what fraction of analogies are perfect, i.e. $\overrightarrow{b'}$ is the closest community to

[1]We have made our sets of ground-truth community analogies available at https://osf.io/jcz3p/.

Table 1: Example community analogies from our collection.

a	a'	b	b'	
UCSD	sandiego	georgetown	washingtondc	university to city
Harvard	CambridgeMA	mcgill	montreal

Seattle	Seahawks	oakland	oaklandraiders	
SFGiants	baseball	49ers	nfl	team to sport
lakers	nba	Dodgers	baseball	

the point $\overrightarrow{a'} - \overrightarrow{a} + \overrightarrow{b}$. Our initial embedding scores 30% Precision@1 on our set of 4,392 validation analogies.

Hyperparameter search. To optimize our embedding, we conducted a sweep over the space of word2vec parameters, generating a separate community embedding for every combination of parameter values and evaluating all of these embeddings with our analogy sets. The parameters we varied are the learning rate α, the dimensionality of the vector space, the number of negative samples, and the sampling rate. How analogy performance varies with parameters is shown in Figure 2. Optimizing the parameters in this way drastically improves the resulting community embedding. Our final embedding scores 72% Precision@1 and 96% Precision@5 on our analogy test, a massive improvement over our initial embedding scores. We show a two-dimensional projection of our final embedding in Figure 3 centered on `r/Fishing`.

Optimizing the embedding with analogies has achieved a difference in kind in the fidelity of the resulting embedding; now all of the closest communities are extremely related (e.g. `r/bassfishing`, `r/kayakfishing`, and `r/flyfishing` are the top three closest communities). We emphasize that the fact this is even possible was not a priori obvious. Community embeddings preserve semantic relationships between communities much as word embeddings do with words. Furthermore, similarly to word embeddings, optimizing community embeddings with analogies drawn from a small number of classes of semantic relationships seems to generally align the entire vector space, even for relationships we didn't train on. The vast difference in quality between the neighborhoods of `r/Fishing` in the optimized and unoptimized embeddings is typical. Also, we observe that other types of analogies suddenly work, even though they weren't explicitly trained; for example, the analogy $\overrightarrow{\text{swimming}} + \overrightarrow{\text{cycling}} + \overrightarrow{\text{running}} \approx \overrightarrow{\text{triathlon}}$ is present in our embedding, despite the fact that we didn't train any ternary relationships at all. Finally, we note that there are interesting patterns in embedding quality in the hyperparameter space — even small changes in parameters can lead to sharp drops in embedding quality, as can be seen in the ridge that cuts across the middle of Figure 2. This suggests it is important to understand where in the hyperparameter space one's embedding is.

Generating community embeddings helps us overcome two major obstacles to measuring activity diversity. First, we can now measure the similarity between any pair of communities by calculating the cosine similarity between their vector representations.

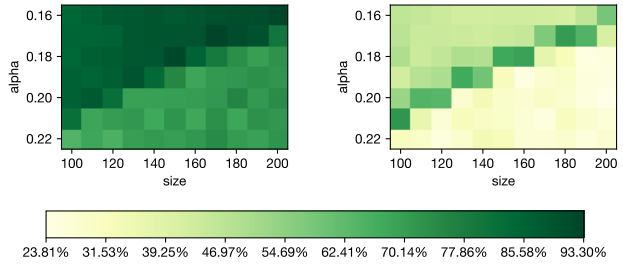

Figure 2: Heatmap of Precision@1 analogy test scores as a function of embedding algorithm hyperparameters on university to city (left) and North American sports (right).

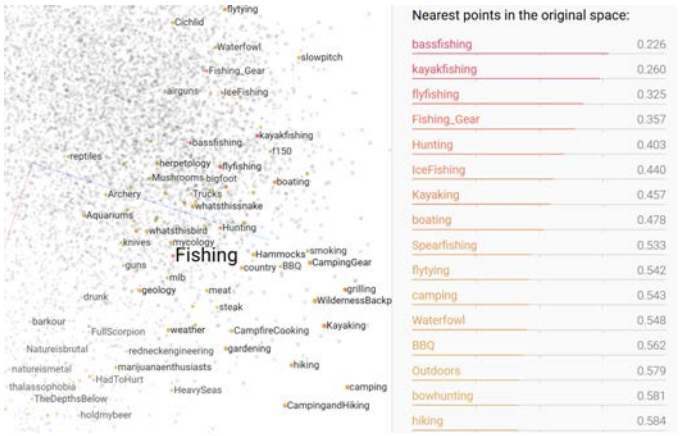

Figure 3: Two-dimensional projection of our final embedding, centered on `r/Fishing`, after performing hyperparameter search with our community analogies.

This similarity is entirely data-driven, and is in a way crowdsourced: two communities are similar if and only if many people choose to comment in them both. Other methods, such as hand-crafted taxonomies or expert classifications, are potentially biased by subjective opinions. Second, our similarities are consistent with each other, since they are derived from cosine similarities between vectors embedded in the same vector space.

2.3 Measuring Activity Diversity

We are now ready to define our measure of activity diversity. Consider a user who is active in some subset of communities. Now, if we consider their activity through the lens of our community embedding, their activity is distributed through the space according to where their communities are. Intuitively, a specialist user's activity will be concentrated in this space, as their communities are similar to each other, and a generalist user's activity will be diffuse in this space, as their communities are different from each other.

With this intuition in mind, we formulate the *Generalist-Specialist score*, or *GS-score*, as follows. Say user u_i makes w_j contributions to community c_j, and in a slight abuse of notation let $\vec{c_j}$ denote c_j's vector representation in our community embedding (note we normalize all vectors to be unit length). First we define u_i's *center of mass* to be $\vec{\mu_i} = \sum_j w_j \vec{c_j}$. Then the definition of u_i's activity diversity is very natural — it is simply the average cosine similarity between u_i's communities and his center of mass, weighted by number of contributions by community:

$$GS(u_i) = \frac{1}{J} \sum_j w_j \frac{\vec{c_j} \cdot \vec{\mu_i}}{||\mu_i||}$$

where J is the number of communities u_i is active in. When the context is clear we will refer to u_i's GS-score as GS_i. A simple interpretation of the GS-score is that it is equal to the expected cosine similarity between a user's contributions and his center of mass in the community embedding (where we say a contribution is located at the vector representation of the community it was contributed to). The GS-score ranges between -1 and 1, where -1 is an extreme generalist and 1 is an extreme specialist. In practice, the GS-score typically ranges between 0.5 and 1.

This definition fulfills a number of desiderata. First, as the communities one contributes to become more similar to each other, the measure increases and moves towards the specialist end of the spectrum. Second, as users contribute more heavily in one community, they become more specialist. Third, fixing a user's contributions and adding another contribution to a new community pushes the measure towards the generalist end.

Interestingly, the GS-score is related to another natural definition of activity diversity. Instead of comparing contributions to the center of mass, we could imagine comparing communities to each other. Consider the *all-pairs community similarity*: $\frac{1}{C} \sum_i \sum_j \vec{c_i} \cdot \vec{c_j}$, where here the sums are over contributions, $\vec{c_i}$ is the vector representing the community of the i-th contribution, and C is the total number of contributions. This quantity measures the expected similarity between two of a user's contributions. This definition is also intuitive: the closer a user's contributions are on average, the most specialist the user. After simple algebra, we derive that the all-pairs community similarity is equivalent to the square of the GS-score. This is encouraging: two different ways of defining activity diversity are rank-equivalent, which indicates that we are capturing a real property of a user's distribution over activities.

Validating the GS-score. The GS-score is natural, intuitive, and is rank-equivalent with another intuitive definition. How well does it capture human judgments of generalists and specialists? To answer this question, we developed an online quiz asking people to compare two Reddit users at a time and decide which one they think is more specialist. By eliciting human judgments in this way, we can compare human responses against our measure and measure the extent to which the two agree.

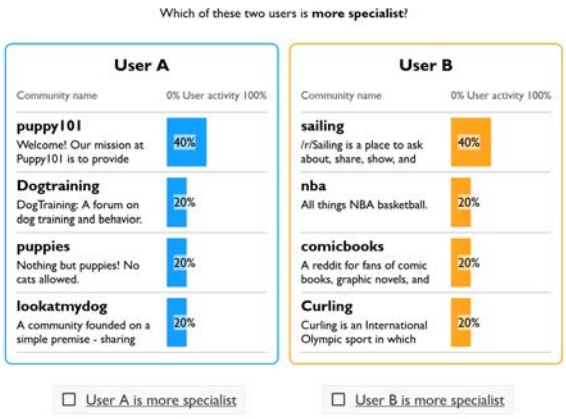

Figure 4: Screenshot of the quiz asking people to rank which user is more specialist.

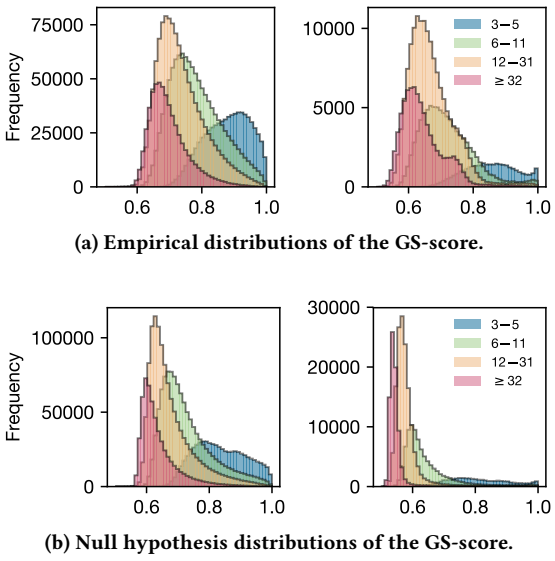
In order to elicit high-quality feedback, we developed the quiz as a game, rather than paying for responses on a crowdsourcing platform, under the assumption that people would be more inclined to answer in good faith if they were internally motivated than if they were externally motivated. When a user arrived at the quiz, they were shown an initial screen explaining, "In this quiz, you will be presented with a list of communities (subreddits) someone is a part of. The bar shows what percentage of their activity is in this community. At each step, you will be shown two users. Click the button below the user which is **more of a specialist**. A specialist is **someone whose interests focus on a particular topic**." On every subsequent screen, they were presented with one question, for example the one shown in Figure 4. Every question compares two users with exactly 4 communities each, shows the name and description of each user's communities, and the distribution of their contributions among these communities. The quiz-taker is then asked to select which user they think is more specialist.

In all, we elicited judgments on 1,807 pairs of users from 144 unique quiz-takers. Examining the relationship between how these judgments compare with the GS-score, we observe a strong correlation between the difference in GS-scores of pairs of users and the proportion of quiz-takers who agree with the GS-score (i.e. say the user with the higher GS-score is more specialist). As the difference in GS-scores grows, human judgments become more in line with the score. This is exactly what we want: as two users' activity diversity scores become closer together, it is more of a close call, and thus human judgments are less unanimous. As they become further apart, human judgments are more unanimous, and approach 90% agreement with the GS-score. Recall that even when the GS-scores of a pair of users are similar, the underlying communities they are contributing to are often very different. Thus it is reassuring that when we predict their activity diversity to be quite close, humans have a correspondingly difficult time telling them apart. The Pearson correlation between the difference in GS-scores and proportion

of quiz-takers agreeing with the GS-score is 0.94. The GS-score thus accords very well with human judgments of activity diversity.

3 ACTIVITY DIVERSITY IN ONLINE PLATFORMS

Now that we have defined and validated a measure of activity diversity in online platforms, we apply our metric and study user behavior through this lens.



3.1 User Activity Diversity

Distribution of GS-scores. First, we calculate the GS-scores of all users in our Reddit and GitHub datasets. Since we're interested in the activity diversity of those who are users of the platform itself, as opposed to "drive-by" users who may only be aware of individual communities and not the entire platform, we restrict to users who have contributed to at least three communities in their lifetime[2]. The distributions of users' GS-scores broken down by number of communities are shown in Figure 5 (top).

First and foremost, we observe a broad diversity of user types, ranging from extreme generalists to extreme specialists, on both Reddit and GitHub. For example, a Reddit user with GS = 0.96 contributed to communities `wedding`, `weddingplanning`, `JustEngaged`, whereas another user with GS = 0.63 contributed to communities `zelda`, `australia`, `bisexual`, `horror`, `AskMen`, `homeland`. We also see that the GS-score is related to the number of communities one participates in, as desired. Generally speaking, the more communities one contributes to, the more generalist one is. However, this is not always the case, also as desired. In fact, we observe a broad diversity of GS-scores even when we fix the number of communities. All of the distributions in Reddit, for example, have support that is almost as broad support as all of them together — even if you contribute to 30 communities, say, you can still be an extreme generalist or an extreme specialist, depending on how similar the communities you contribute to are. We see many examples where users with 32+ communities are more specialist than users with 5 communities.

To check that these results are meaningful, we compare against a null hypothesis. We conduct the following permutation test: for each user, we keep their number of communities the same, but draw the communities independently from the overall distribution of communities weighted by popularity. Are the empirical results we observe simply produced by the distributions of community popularity and number of communities by user?

In fact, they are not. In Figure 5 (bottom), we plot the distributions of GS-scores produced by this null hypothesis. Comparing the empirical distributions with the null hypothesis distributions, we observe several major differences. We see that there are significantly more specialists at every number of communities, especially on GitHub, in the empirical data than in the permuted data. We also observe much more overlap between the GS-scores of users with different numbers of communities in the real data. Finally, we see that the most generalist constructed users are only marginally more generalist than the most generalist real users, indicating that real

(b) Null hypothesis distributions of the GS-score.

Figure 5: Empirical (top) and null hypothesis (bottom) distributions of GS-scores over users, broken down by number of communities, in Reddit (left) and GitHub (right).

users are approaching the mathematical limit of how generalist they can be given the number of communities they are in.

Relationship with entropy. In previous work, the most popular method of measuring activity diversity is using the entropy of a user's activity distribution. We examine the relationship between the GS-score and entropy. As desired, they are related: the more specialist users have lower entropy. But there is still significant overlap in the entropy distributions of different GS-scores; the GS-score can distinguish between users with similar activity distributions but over sets of communities with different levels of coherence. The R^2 between GS-score and entropy is 0.69 in both Reddit and GitHub, meaning that a significant amount of the variance in GS-score (31%) is unexplained by entropy.

Feedback success. On Reddit, every comment can be upvoted or downvoted by other users, indicating the audience's reaction to it. We use this as a proxy for success and ask how success relates with activity diversity. The raw distribution of success as a function of user GS-score is very flat, indicating that the range of viable strategies on Reddit is broad. However, there are many potential confounding factors influencing a comment's vote score: the post it is in reply to, how long after the original post it was written, its parent comment's score, the audience that sees it, etc. Thus, we consider the following question: does a comment get a higher score than its parent? (As comments on Reddit are threaded, they have some parent they are replying to, except for top-level comments). This elegantly controls for several factors. Parent and child comments usually occur close together in time, are in direct conversation with each other and so are more likely to share topics, and if the child outscores the parent (the parent usually scores higher due to its increased exposure) it can be considered a success. We examine the probability that a comment outscores its parent as a

[2]One could use the GS-score to study the activity diversity of those who only contributed to one or two communities, but it isn't the focus of our work here.

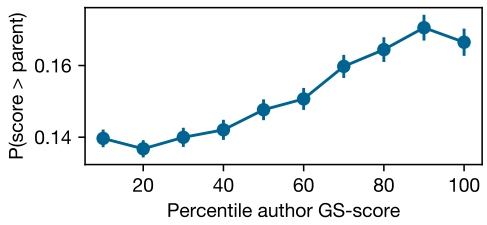

Figure 6: Comment success versus author GS-score.

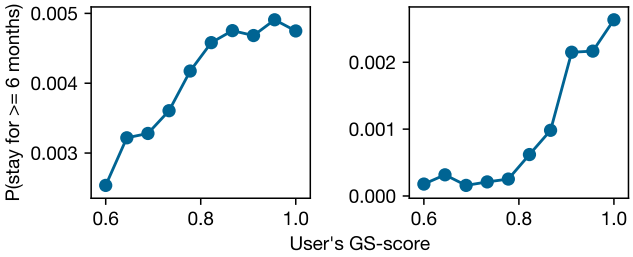

Figure 7: Likelihood of being engaged in a community for six consecutive months after first contributing, as a function of user GS-score on Reddit (left) and GitHub (right).

function of the author's GS-score in Figure 6. There is a significant, moderate effect, with specialists being 20% more likely than generalists to author a comment that outscores its parent. This is consistent with specialists being more engaged with, and more successful in, their home communities.

Longevity in communities. How long do users stay engaged in a community that they've joined? Is there a difference between how likely specialists and generalists are to stay? To answer this question, we examine all the occurrences of when Reddit and GitHub users join a new community, and calculate the likelihood that they subsequently make contributions in that community for six months in a row. Of course, this probability will be low on an absolute scale, but we are interested in whether generalist and specialists act differently. We plot this relationship in Figure 7. There is a clear, monotonically increasing relationship between the user's GS-score and the likelihood that they remain engaged for at least six months. The difference is quite large; on Reddit, specialists are about twice as likely to stay as generalists, and on GitHub the difference is even larger, with specialists about 10 times more likely than generalists to remain engaged. This reveals one way in which generalists and specialists are systematically different: generalists explore, specialists exploit. Generalists are more likely to try a new community but then leave, whereas specialists are more likely to stay in communities that they join. This has implications for community managers: given that a specialists have a much higher chance of converting into long-time members, it may be worth expending more effort or resources in recruiting specialists.

Longevity on the platform. We have just seen that specialists are more likely to stay in communities they join. What about the entire platform itself? Since activity is such a major factor in whether people will stay (as it is a sign that they are engaged), we control for activity level. Concretely, we consider users' activity in the first

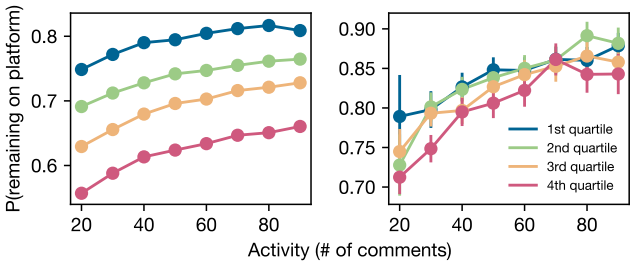

Figure 8: Likelihood of remaining on the platform versus user GS-score on Reddit (left) and GitHub (right).

half of 2015, and measure their GS-scores on this activity only. We then measure the probability that they are active two years later, in the second half of 2017, as a function of GS-score and activity.

These results are shown in Figure 8, in which there are a number of notable findings. On Reddit, there is a very large difference between generalists and specialists in the probability of leaving the platform. For any given level of activity, specialists (e.g. 4th quartile of GS-score, shown in red) are much less likely to remain on the platform than generalists (e.g. 1st quartile of GS-score, shown in blue). For example, among users with 20 contributions during the first half of 2015, generalists remain on Reddit 75% of the time while specialists remain only 55% of the time. Even more strikingly, small differences in the GS-score can trump large differences in activity. For example, users with 4th-quartile GS-scores (specialists) and 90 comments only remain 66% of the time, whereas users with 2nd-quartile GS-scores and only 20 comments remain 69% of the time. Finally, we note that the probability of remaining is monotonically increasing in activity for every quartile of GS-score. On GitHub, the differences between generalists and specialists are considerably less stark. However, specialists are still significantly less likely than generalists to remain on the platform, given activity level.

At a high level, these two groups of results suggest there is an interesting interplay between activity diversity and longevity. While specialists are more likely to stay in a given community once they've tried it, generalists are more likely to stay on the entire platform. These results have important implications for designers of online platforms. Community managers may prefer exposure to specialists to maximize the chance of acquiring new long-term members. But all else equal, generalists are more likely to be long-standing members of the platform itself. Thus, it may be in the platform's interest to expose users to a more diverse set of communities. Also, designing online platforms to attract generalists and be conducive to community exploration could be beneficial.

Diversity of exposure. Every user in a platform engages with some subset of the platform's population. Depending on the communities one contributes to, the subpopulation one is exposed to can vary dramatically, and can be quite different from the platform population as a whole. How does the diversity of the group one is exposed to vary with activity diversity? We conduct an analysis on Reddit, where for each user i we consider the set of users P_i that they replied to (comments on Reddit are threaded, and thus are often in reply to each other). We call this population of users one interacts with the "parent-universe". A key benefit of our definition of activity diversity is that it can be applied to more than a user.

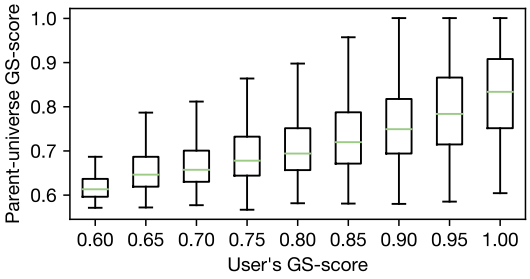

Figure 9: Distribution of the parent-universe GS-scores as a function of user GS-score.

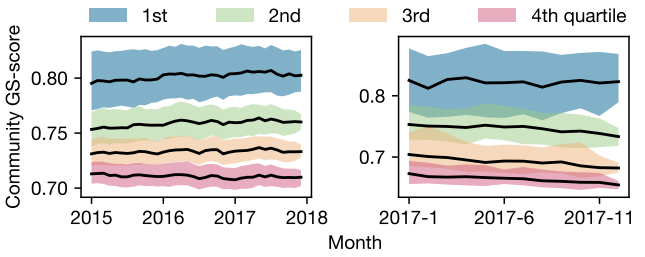

Figure 10: Stability of community GS-scores over time on Reddit (left) and GitHub (right).

Recall that the definition is an average over contributions, and so far we have been considering the set of contributions made by a user. Here we consider all contributions by users in the set P_i, and measure the activity diversity of this whole set. This is the diversity of the subpopulation user i is exposed to.

In Figure 9, we show how distributions of $GS(P_i)$ vary as a function of $GS(u_i)$ — how the diversity of the subpopulation one interacts with changes a function of one's own activity diversity. We observe a clear, strong trend: generalists are exposed to a diverse set of users, whereas specialists are exposed to more homogeneous sets of users. Users with first-decile GS-scores are exposed to a subpopulation of users with combined $GS(P_i)$ around 0.61, whereas users with tenth-decile GS-scores are exposed to a subpopulation of users with combined $GS(P_i)$ around 0.84, a huge difference. Specialists, by selecting small, coherent sets of communities to contribute to, limit themselves to relatively narrow "echo chambers", where the users they interact with are themselves very specialist in their collective interests. While this trend is intuitive, the magnitude of the effect is striking.

In this paper, we are focusing on the entire set of a user's contributions, but there are many interesting analyses to be done by concentrating on a topical subset. For example, one could straightforwardly apply the GS-score to only user contributions to overtly political subreddits. Repeating this analysis would then measure the extent to which generalists and specialists are living in political echo chambers online. We leave this and other analyses as examples of promising future work using our methodology and score.

3.2 Community Activity Diversity

We measure a user's activity diversity by considering how similar their communities are. Once we understand the activity diversity of every user in a community, we can use this to also understand the activity diversity of a *community*. Here, we define the GS-score $GS(c_i)$ of a community c_i as the weighted average over its users: $GS(c_i) = \frac{1}{N} \sum_j w_j \cdot GS(u_j)$, where u_j makes w_j contributions to c_i and there are $N = \sum_j w_j$ contributions in total. Specialist (generalist) communities are those with specialist (generalist) users on average. What kinds of communities tend to be generalist or specialist? Examining the distributions over community GS-scores, we observe a broad range of community activity diversity on both Reddit and GitHub, with most communities skewing generalist.

Community GS-score stability. Does the community GS-score capture a real property of a community? One way to test this is to measure if it is at least stable. In Figure 10, we plot how community GS-scores change over time. We separate the communities into quartiles based on their initial GS-score, then plot how the distribution of their GS-scores evolves over a 3-year period on Reddit and a 1-year period on GitHub (GitHub communities are more volatile and don't last as long on average). In both Reddit and GitHub, they are strikingly consistent. The quartiles are essentially non-overlapping in their community GS-scores for the entire period. We see strong evidence that generalist communities remain generalist and specialist communities remain specialist. Furthermore, we see evidence that communities have stable GS-scores even when the underlying user population changes dramatically. For example, the subreddit `r/gardening` has highly cyclical usage patterns over the year, being much more popular during the summer. Despite the volume of active users changing by an order of magnitude throughout the year, the community GS-score is very consistent.

Size vs. community GS-score. Finally, we observe how community size (number of users) and community GS-score relate. In Figure 11, we show a scatterplot of this relationship on Reddit (GitHub is similar). First, we observe a broad range of community GS-scores for almost every level of community size. Even communities with tens of thousands of users can have vastly different GS-scores. For example, on Reddit, `r/The_Donald` and `r/books` have exactly the same number of users during 2017 (241K), but `r/books` has a GS-score of 0.72 and `r/The_Donald` has a GS-score of 0.86, which are on opposite ends of the community activity diversity spectrum. Inspecting the communities, the GS-scores are intuitive: generalist communities are typically about very broad topics like `r/technology` or have wide appeal like `r/funny`, whereas specialist communities are typically centered around particular interests or niches like `r/FIFA` and `r/exmormon`. On GitHub, generalist communities are general-use frameworks, such as `d3` (a web-based data visualization framework), whereas specialist communities are more deeply technical, such as `grpc` (a remote procedure call system).

Elite users vs. community GS-score. Finally, we combine the user GS-score and community GS-score. Who are the top users in generalist and specialist communities? In each community, we rank users by the average comment vote score, and consider the top 5% as the "elites". Are the generalists or specialists the elites, and how does this vary with community GS-score? The relationship, shown in Figure 12, indicates that generalists are consistently more likely to be among the elites. The line $y = x$ indicates what would happen under a random baseline, and clearly the distributions are always below this line. We speculate that this is due to generalists having

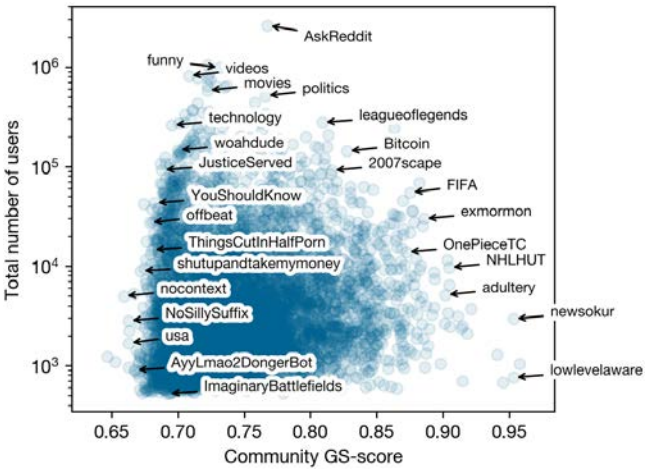

Figure 11: Community size versus community GS-score.

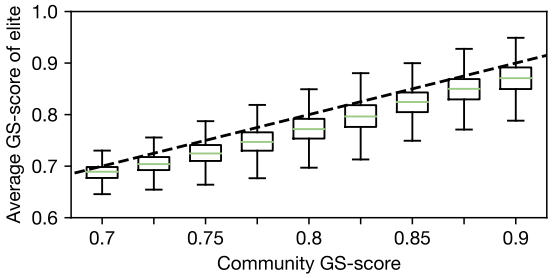

Figure 12: Elite users' GS-scores versus community GS-score.

more chances at being in the elite of a community. By our measure, a user can be in a community's elite with a small number of highly-rated comments. Since generalists are more likely to spread their activity out over more communities, they have more opportunities to be in the elite.

4 PREDICTION TASKS

In the previous Sections, we introduced our methodology for quantifying activity diversity and applied it to study user behavior in online platforms. Now we demonstrate that our insights are directly applicable to two important prediction problems in online platforms: community recommendation and user retention. We perform these tasks on our main dataset, Reddit.

4.1 Community Recommendation

Predicting which communities a user is likely to join next is a ubiquitous and important prediction task for online platforms. Our first task is to predict which new communities users will join after an initial observation period. On this task, every model outputs a ranking of communities for each user sorted by the likelihood of that user joining. We trained the models on all data from 2017 and tested them on the communities users joined for the first time during January 2018. We evaluated four models:

- **Random**: a baseline that randomly ranks communities.
- **Popularity**: communities ranked by popularity

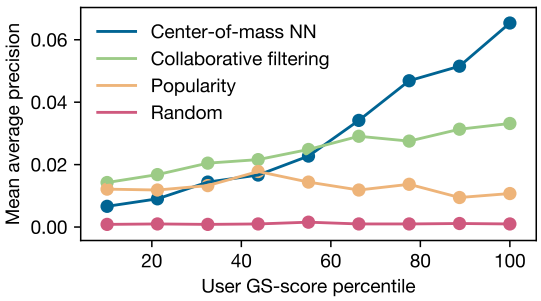

Figure 13: Performance of community recommendation models on Reddit versus user GS-score percentile.

- **Collaborative Filtering**: a state-of-the-art model (Bayesian Personalized Ranking [20]) for doing collaborative filtering with implicit data.
- **Center-of-Mass Nearest Neighbors**: a novel method using community embedding, which simply ranks communities by how cosine-similar they are to a user's center of mass during the training period (2017). Note that a community embedding trained on only 2017 data was used to ensure that the CF model and our embedding-based model had access to the exact same training data.

To assess model performance, we looked at users who were active in the training period and the test period. On Reddit, there were 20K such users with 24K total community joins. We use mean average precision (MAP) to assess the quality of community rankings produced by each model. The overall results are: 0.001 for random, 0.013 for popularity, 0.023 for CF, and 0.027 for Center-of-Mass NN. Despite being an extremely simple model, Center-of-Mass NN slightly outperforms a state-of-the-art collaborative filtering method, which demonstrates the fidelity of our community embeddings. Notice that our method doesn't even take popularity into account (which CF does).

Beyond this proof of concept, we are interested in how predictability varies with user GS-score. This relationship is shown in Figure 13, and there are two notable findings. First, it is clear that Center-of-Mass NN is competitive with CF among all users, but especially outperforms it on specialists. Second, it is remarkable that both CF and Center-of-Mass NN perform much better for specialist users. The fact that some users are so much more predictable than others, and that this correlates so well with the GS-score, is interesting and has important implications. For example, the value of recommendations could be much higher for specialists, which should inform their cost.

4.2 Platform User Retention

Predicting whether users will remain or leave the platform is another ubiquitous and important problem. Here, we demonstrate that the GS-score is valuable in solving this problem. Concretely, the task is to consider all users in an initial period and predict whether or not they will be present on the platform in a later period. We used the first half of 2015 as the initial period and the second half of 2017 as the later period, and randomly sample a balanced set

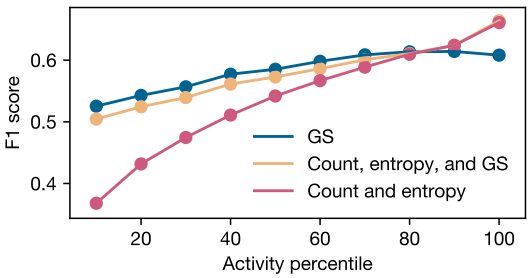

Figure 14: Performance of the Reddit longevity prediction models on users of varying activity levels.

of 464K users to consider (so that 50% stay and 50% leave). We split this into a training set and test set of equal size, and measure our models with the F1 score. We train a simple logistic regression model with comment count, entropy, and user GS-score as features. We compare against entropy since it is the main metric others have used in past work to quantify activity diversity.

We see that the GS-score alone outperforms the other models. Over most of the range of activity, but particularly for low-activity users, the improvement over entropy is quite large: for users in the lowest decile of activity, the F1 score of activity and entropy is 0.36 but the GS-score alone achieves an F1 score of 0.53 (see Figure 14). Count and entropy outperform the GS-score for the highest decile since activity is such a strong predictor of engagement.

5 RELATED WORK

Our work draws on three areas of previous research: embedding models, analyses of user behavior in social platforms, and work investigating generalists and specialists more broadly.

Embedding models. Our work draws upon the embedding methods that have precipitated revolutions in many fields, starting with natural language processing. Word embedding models like word2vec showed how to use modern model architectures to leverage large datasets and create embeddings that preserve semantic relationships [16, 17]. Subsequent work by Levy and Goldberg improved our understanding of these models, and also provided software that we used to generate our community embeddings [13, 14]. Kumar et al. applied word embedding algorithms to develop community embeddings in their study of community conflict on Reddit [11], and early steps in this direction were taken by Martin [15]. Embedding methods have also been developed for use in the context of social networks [9, 19, 24].

User behavior in social platforms. Our work is part of a large body of work investigating user behavior in social platforms. Reddit in particular has been the subject of a rich line of research. Tan and Lee study the trajectory of communities that Reddit users post in and find that users settle after an initial period of exploration [23]. They (and others) use entropy as a measure of topical concentration; as mentioned in Section 2, entropy is agnostic to the similarity or dissimilarity of different activities. Our measure and analysis builds on this work by taking community similarity into account. Hamilton et al. study community loyalty, both from the user and community perspectives [10], and Zhang et al. study community identity on Reddit, finding differences between communities with high and low churn rates [26].

Generalists and specialists. The notion of a spectrum spanning from generalists to specialists is ancient. It begins with the epigraph that opens this paper—"The fox knows many things; but the hedgehog knows one big thing."—written by 7th-century BC Greek poet Archilocus. This quote was the inspiration for the classic essay *The Hedgehog and the Fox* by philosopher Isaiah Berlin, in which he classifies writers and thinkers as either hedgehogs, those who have a single unifying idea, or foxes, those who draw on a wide array of experiences [4]. His work, in turn, brought the idea of generalists and specialists back into mainstream thought, and it has served as a useful frame ever since. As one example, Tetlock, in his studies of expert judgment and forecasters, analyzed the predictive abilities of generalists and specialists ("hedgehogs" and "foxes"), finding that specialists performed worse, especially on long-term forecasts within their specialty [25]. The problem of how broadly to allocate one's energy is ubiquitous: in biology, species are broadly categorized into generalist and specialist species [8]. Generalist species can thrive in a wide variety of environments, whereas specialist species are limited to a narrow range of environments.

In the study of activity diversity in online platforms, the closest work is Adamic et al.'s research on the relationship between individual focus and contribution on Wikipedia [1]. Our work builds on theirs by introducing a higher-fidelity metric for activity similarity based on community embeddings, studying other online platforms, assigning activity diversity scores to communities, and investigating the relationship between activity diversity and additional outcome metrics. Anderson studied how skill diversity correlates with worker pay in an online crowdwork platform [2].

6 CONCLUSION

In this work, we have introduced a methodology to quantify activity diversity in online platforms, and analyzed several important phenomena around user behavior through this lens on Reddit and GitHub. We developed high-quality *community embeddings*, which encode similarities between communities as defined by their members, as well as a set of community analogies to validate them. Based on these embeddings, we introduced the *GS-score*, a principled measure of activity diversity. We found a broad spectrum of user styles, from extreme generalists to extreme specialists, and observed that specialists are more likely to produce higher-quality replies. We also observed that specialists are much more likely to stay in communities they contribute to, but generalists are much more likely to remain on the platform as a whole. We applied activity diversity to study an important question: how diverse are the subpopulations users engage with? We found that generalists engage with a significantly more diverse group of people, whereas specialists are exposed to much narrower segments of the population. We also studied the activity diversity of communities, and found that the community GS-score is remarkably stable over time, even when the underlying user base changes a lot. In our prediction tasks, we found that specialists are more predictable than generalists in which communities they will join, and that the user GS-score is much more predictive of user retention than entropy.

There are several promising directions for future work. First, the GS-score can be directly applied to answer important questions about *subsets* of user activity in online platforms. For example, it would be interesting to conduct our results on echo chambers in the subset of political activity on Reddit. The GS-score then becomes a measure of political diversity. Second, as our GS-score metric is robust and conceptually simple, it could be broadly applicable beyond the online platforms we considered in this work. It would be illuminating to apply the GS-score to other domains as well.

Acknowledgments. This work was partially supported by NSERC. We thank Josef Waller, Shunzhe Yu, and especially Will Hamilton for fruitful discussions, and we thank Jason Baumgartner and the GH Archive for providing public access to the Reddit and GitHub datasets, respectively.

ABSTRACT

Hypernymy is a semantic relation, expressing the "is-a" relation between a concept and its instances. Such relations are building blocks for large-scale taxonomies, ontologies and knowledge graphs. Recently, much progress has been made for hypernymy prediction in English using textual patterns and/or distributional representations. However, applying such techniques to other languages is challenging due to the high language dependency of these methods and the lack of large training datasets of lower-resourced languages.

In this work, we present a family of fuzzy orthogonal projection models for both monolingual and cross-lingual hypernymy prediction. For the monolingual task, we propose a Multi-Wahba Projection (MWP) model to distinguish hypernymy vs. non-hypernymy relations based on word embeddings. This model establishes distributional fuzzy mappings from embeddings of a term to those of its hypernyms and non-hypernyms, which consider the complicated linguistic regularities of these relations. For cross-lingual hypernymy prediction, a Transfer MWP (TMWP) model is proposed to transfer the semantic knowledge from the source language to target languages based on neural word translation. Additionally, an Iterative Transfer MWP (ITMWP) model is built upon TMWP, which augments the training sets of target languages when target languages are lower-resourced with limited training data. Experiments show i) MWP outperforms previous methods over two hypernymy prediction tasks for English; and ii) TMWP and ITMWP are effective to predict hypernymy over seven non-English languages.

1 INTRODUCTION

Hypernymy is a type of basic semantic relations, expressing the "is-a" relation between a concept (hypernym) and its instances (hyponyms). The automatic extraction of hypernymy relations is vital for building large-scale taxonomies, ontologies and knowledge graphs [10, 33, 51]. Such relations also benefit a variety of Web-scale applications including query understanding [48], post-search navigation [14], personalized recommendation [56], etc.

Due to its importance in NLP and real-world applications, remarkable progress has been made for hypernymy prediction. As summarized in Wang et al. [45], pattern based and distributional approaches are two major types of methods for hypernymy harvesting. Pattern based methods employ lexical patterns (e.g., Hearst patterns [13]) to extract hypernymy relations from text corpora [30]. Distributional methods can be divided as unsupervised and supervised. Unsupervised methods refer to hypernymy measures, modeling the degree of the existence of a hypernymy relation between two terms [15, 31]. Supervised algorithms classify a term pair as hypernymy or non-hypernymy based on the distributional representations of the two terms [20, 54]. While there exists some disagreement in the NLP community on which type of methods is more effective [45], Shwartz et al. [34] show that both methods can be combined via an integrated neural network, further improving the performance.

Despite the significant success, there is much room for improvement, due to the following reasons. i) The linguistic regularities of hypernymy relations are complicated to model [10, 44, 53]. For example, semantics of hypernymy relations between concept-concept pairs (subclass-of) and concept-instance pairs (instance-of) are different. Such pairs, however, are often mixed in real-world scenarios.

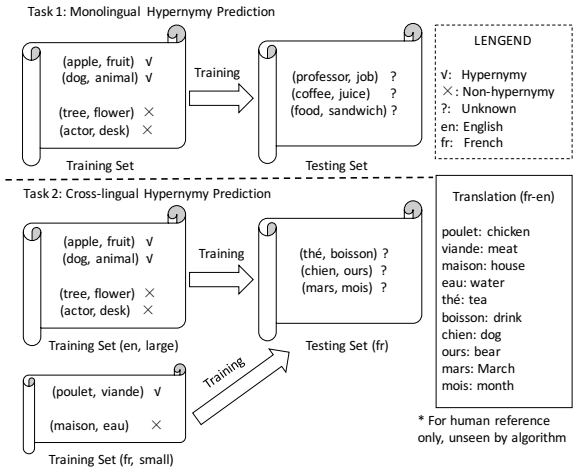

Figure 1: A toy example of monolingual and cross-lingual hypernymy prediction.

ii) Supervised distributional methods are reported to have high performance, but suffer from the "lexical memorization" problem [18]. iii) Most existing methods focus on monolingual hypernymy prediction in English only and are highly language dependent. Some analytical languages (e.g., Chinese, Vietnamese) are flexible in expressions and lack fixed patterns to extract hypernymy relations with high recall [10, 46]. Hence, most existing methods are difficult to apply to other languages. iv) Several distributional methods require additional knowledge (e.g., taxonomies and semantic hierarchies) to learning high-quality hypernymy embeddings [20, 26, 54], which are difficult to obtain for some low-resourced languages.

In this work, a family of fuzzy orthogonal projection models is presented to address the tasks of both monolingual and cross-lingual hypernymy prediction. A toy example of the two tasks is illustrated in Figure 1. For the monolingual task, we explicitly model how the embeddings of a term are mapped to those of its hypernyms or non-hypernyms, respectively, in order to avoid the "lexical memorization" problem [18]. To deal with complicated linguistic regularities, for each latent component of hypernymy and non-hypernymy relations, a fuzzy orthogonal mapping is established in the embedding space[1]. The learning process of the mappings is closely related to a generalized version of the Wahba's problem in mathematics [23], named Multi-Wahba Projection (MWP). In this work, we derive a closed-form solution to MWP and propose an MWP based neural network to distinguish hypernymy vs. non-hypernymy relations.

For cross-lingual hypernymy prediction, the goal is to predict hypernymy relations of a target language with limited training data, given a (relatively) large training set of a source language as input. Neural machine translation techniques are able to transfer knowledge across languages, but usually require a large parallel corpus, which is not feasible for some lower-resourced languages [55]. To derive a general solution for any languages, we present a Transfer MWP (TMWP) model from a source language to target languages based on neural word translation. To handle the small size of training sets of target languages, an Iterative Transfer MWP (ITMWP) model is built upon TMWP to support semi-supervised learning via training data augmentation.

In summary, we make the following major contributions:

- We propose a Multi-Wahba Projection (MWP) model to distinguish monolingual hypernymy vs. non-hypernymy relations. A closed-form solution is derived for generalized Wahba's problem.
- We propose a Transfer Multi-Wahba Projection (TMWP) model for cross-lingual hypernymy prediction. An iterative data augmentation method is introduced, named the Iterative Transfer Multi-Wahba Projection (ITMWP) model.
- We conduct extensive experiments to show that i) MWP outperforms state-of-the-art over two hypernymy prediction tasks for English, and ii) TMWP and ITMWP are effective to predict hypernymy over seven non-English languages.

The rest of this paper is organized as follows. Section 2 summarizes related work. MWP, TMWP and ITMWP models are presented in Section 3 and Section 4. Experiments are shown in Section 5 and Section 6, with the conclusion drawn in Section 7.

2 RELATED WORK

This section presents a brief overview on monolingual and cross-lingual hypernymy prediction.

2.1 Monolingual Hypernymy Prediction

In the NLP community, "hypernymy prediction" is not a standalone task, but has been evaluated under a series of tasks, e.g., unsupervised hypernymy classification [15], supervised hypernymy detection [20, 54], graded lexical entailment [41], etc. Although evaluation steps and metrics may differ, pattern based and distributional methods are two major paradigms to address these tasks [45].

Pattern based approaches use lexical patterns to extract hypernymy relations from texts. Hearst patterns [13] are the most influential patterns in English, which are employed to build a large lexical taxonomy Probase [51]. A recent study [30] reveals that using simple Hearst patterns can result in high performance for hypernymy detection. Similar Hearst pattern-like features are used in a variety of methods [28, 35]. The semantics of more generalized textual patterns can be captured by LSTM-based neural networks [34]. The reason of the success is that they are precise and have high coverage of hypernymy relations in English. For other languages, Hearst-style patterns are not necessarily effective. For example, Chinese has flexible expressions and lacks fixed patterns for hypernymy detection [10, 46]. Because we aim at providing a general solution for all languages, pattern-based approaches are difficult to apply to other languages, without language-specific modifications.

Distributional methods can be divided as supervised and unsupervised. **Unsupervised distributional approaches** are primarily based on hypernymy measures, modeling the degree of the existence of a hypernymy relation within a term pair. Typical hypernymy measures are based on distributional inclusion hypothesis [17], distributional informativeness hypothesis [31] and selective distributional inclusion hypothesis [29]. Readers can refer

[1]For hypernymy, relations related to different domains are usually treated as different components. The "subclass-of" and "instance-of" relations are treated as different components. Components of non-hypernymy relations include co-hyponymy, synonymy, meronymy, etc. Refer to [10, 49, 53] for detailed discussion.

to a comprehensive overview and evaluation on hypernymy measures in [32]. In **supervised methods**, each pair is modeled as an embedding vector as the input of a classifier to predict the relation, such as the Concat model, the Diff model, etc [29, 49]. Recently, several algorithms are proposed to learn hypernymy embeddings, which consider the taxonomic structure of concepts [6, 20, 26, 54]. For example, Yu et al. [54] learn the hypernym and hyponym embeddings for a term in a max-margin neural network based on Probase [51]. Nguyen et al. [26] propose the hierarchical embeddings trained over a text corpus and the WordNet concept hierarchy. Additionally, Drozd et al. [9] study relationships between semantic relations and word embeddings.

Projection based approaches are variants of previous methods, which learn how to map the embeddings of a term to those of its hypernyms directly. A notable model is the piecewise linear projection model [10]. It is also improved by Yamane et al. [53], which learns the number of linear projection models and the parameters of projection models jointly, and by Biemann et al. [3], Wang and He [44], which consider explicit negative samples. Wang et al. [46] learn the representations of both hypernymy and non-hypernymy in a transductive learning framework. Our work improves these approaches by multiple fuzzy orthogonal projections, and also employs a neural network for hypernymy relation classification. Hence, it takes advantages of both classification and projection approaches. Apart from the previous methods, many approaches aim at extracting hypernymy relations from various Web data sources. Gupta et al. [12], Ponzetto and Strube [27], Suchanek et al. [36] learn hypernymy from the Wikipedia category system based on lexical patterns, syntactic constraints and rule-based inference. Liu et al. [19] construct a taxonomy purely from keywords. We do not further elaborate.

2.2 Cross-lingual Hypernymy Prediction

The task of **cross-lingual hypernymy prediction** has not been sufficiently studied. Some researchers aim at building taxonomies based on multi-lingual Wikipedia [21, 47]. YAGO 3 [21] is the extension of YAGO [36], which integrates a multi-lingual taxonomy derived from Wikipedia. Wang et al. [47] propose a cross-lingual knowledge validation technique to improve the accuracy of cross-lingual hypernymy prediction from links among multi-lingual versions of Wikipedia. Wu et al. [50] introduce a bilingual topic model to align taxonomies of different languages.

In the NLP community, a few works [38, 42] determine if a word in one language is a hypernym of a word in another language. For example, these methods predict if the English word "fruit" is the hypernym of the French word "pomme" (apple). The difference between these methods and ours is that our method is capable of learning hypernymy relations where both hypernyms and hyponyms are in the target language. Hence, our method can extract culture-specific hypernymy relations where both hypernyms and hyponyms are not present in the source language.

3 MWP: THE MONOLINGUAL MODEL

In this section, we introduce the MWP model for monolinugal hypernymy prediction and give the closed-form solution of the generalized Wahba's problem.

3.1 Task Definition

Let $\vec{x}_i$ be the normalized embedding of the term x_i, pre-trained using any neural language models. Denote $y_i^{(+)}$ and $y_i^{(-)}$ as a hypernym and a non-hypernym of x_i, respectively. The task of monolingual hypernymy prediction is defined as follows:

Definition 3.1. (Monolingual Hypernymy Prediction) The goal is to train a classifier f over a hypernymy relation set $D^{(+)} = \{(x_i, y_i^{(+)})\}$ and a non-hypernymy relation set $D^{(-)} = \{(x_i, y_i^{(-)})\}$, to predict hypernymy relations $U = \{(x_i, y_i)\}$ of the same language.

3.2 Learning Hypernymy Projections

Following [10, 46, 53], hypernymy projection models assume that there exists a $d \times d$ projection matrix $\mathbf{M}^{(+)}$ such that $\mathbf{M}^{(+)}\vec{x}_i \approx \vec{y}_i^{(+)}$ where d is the dimension of word embeddings and $(x_i, y_i^{(+)}) \in D^{(+)}$. In this work, MWP further forces that the cosine similarity of the projected word embedding $\mathbf{M}\vec{x}_i$ and the true hypernym embedding $\vec{y}_i^{(+)}$ should be maximized, i.e., $\max \sum_{i=1}^{|D^{(+)}|} \cos(\mathbf{M}\vec{x}_i, \vec{y}_i^{(+)})$. Because all the word embeddings are normalized, the optimization function can be re-written as: $\max \sum_{i=1}^{|D^{(+)}|} (\mathbf{M}\vec{x}_i)^T \vec{y}_i^{(+)}$. We can see that $\mathbf{M}$ should be orthogonal to guarantee that $\mathbf{M}\vec{x}_i$ is normalized [52]. For ease of the model training process, we re-formulate the objective function as below with $\mathbf{I}$ being the $d \times d$ identity matrix:

$$\min \sum_{i=1}^{|D^{(+)}|} \|\mathbf{M}\vec{x}_i - \vec{y}_i^{(+)}\|^2 \text{ s. t. } \mathbf{M}^T\mathbf{M} = \mathbf{I}$$

However, this setting does not consider the complicated linguistic regularities of hypernymy relations. As seen in [10, 44], different types of hypernymy relations may correspond to different projection matrices. Denote K as the number of clusters, where each cluster corresponds to a hypernymy component. We apply K-means to $D^{(+)}$ using the vector offset $\vec{x}_i - \vec{y}_i^{(+)}$ as features. The cluster centroids are denoted as $\vec{c}_1^{(+)}, \cdots, \vec{c}_K^{(+)}$. We define $a_{i,j}^{(+)}$ as the weight of $(x_i, y_i^{(+)})$ over the dataset $D^{(+)}$ w.r.t. the jth cluster:[2]

$$a_{i,j}^{(+)} = \frac{\cos(\vec{x}_i - \vec{y}_i^{(+)}, \vec{c}_j^{(+)})}{\sum_{i'=1}^{|D^{(+)}|} \cos(\vec{x}_{i'} - \vec{y}_{i'}^{(+)}, \vec{c}_j^{(+)})}$$

Considering the orthogonal constraint, we minimize the weighted projection errors on the jth cluster with $\mathbf{M}_j^{(+)}$ being a $d \times d$ projection matrix w.r.t. the jth cluster:

$$\begin{aligned} \min J(\mathbf{M}_j^{(+)}) =& \frac{1}{2} \sum_{i=1}^{|D^{(+)}|} a_{i,j}^{(+)} \|\mathbf{M}_j^{(+)}\vec{x}_i - \vec{y}_i^{(+)}\|^2 \\ \text{s. t. } & \mathbf{M}_j^{(+)T}\mathbf{M}_j^{(+)} = \mathbf{I}, \sum_{i=1}^{|D^{(+)}|} a_{i,j}^{(+)} = 1 \end{aligned} \tag{1}$$

[2] We have also experimented with several fuzzy clustering algorithms, such as Gaussian Mixture Model, Fuzzy c-Means, etc. The cluster membership probabilities are related to the weights $a_{i,j}^{(+)}$. However, they perform poorly due to the high dimensionality of word embeddings. Hence, we employ K-means to generate clusters and use a heuristic approach to compute $a_{i,j}^{(+)}$.

Let $\mathcal{M}^{(+)} = \{\mathbf{M}_1^{(+)}, \mathbf{M}_2^{(+)}, \cdots, \mathbf{M}_K^{(+)}\}$ be the set of projection parameters of all the K clusters. Learning hypernymy projections is equivalent to minimizing the following objective function:

$$\begin{aligned} \min \tilde{J}(\mathcal{M}^{(+)}) =& \frac{1}{2}\sum_{j=1}^{K}\sum_{i=1}^{|D^{(+)}|} a_{i,j}^{(+)} \|\mathbf{M}_j^{(+)}\vec{x}_i - \vec{y}_i^{(+)}\|^2 \\ & \text{s. t. } {\mathbf{M}_j^{(+)}}^T\mathbf{M}_j^{(+)} = \mathbf{I}, \sum_{i=1}^{|D^{(+)}|} a_{i,j}^{(+)} = 1, j = 1, \ldots, K \end{aligned} \tag{2}$$

We refer to this model as the Multi-Wahba Projection (MWP) model. In mathematics, the Wahba's problem deals with three-dimensional vector observations between two coordinate systems, extensively applied in satellite attitude determination [23]. The MWP model is an extension to the Wahba's problem, considering d dimensional ($d > 3$) projections with K components. Because the values of different $\mathbf{M}_j^{(+)}$ ($j = 1, 2, \cdots, K$) are independent, the optimal solution to MWP is the same as the combination of minimizing K objectives $J(\mathbf{M}_j^{(+)})$. In this work, we pay attention to a closed-form solution to the Wahba's problem [22] based on Singular Value Decomposition (SVD) and extend it to d dimensions ($d > 3$):

Theorem 3.2. *The d-dimensional Wahba's problem has a closed-form solution as follows:*

(1) $\mathbf{B}_j = \sum_{i=1}^{|D^{(+)}|} a_{i,j}^{(+)} \vec{y}_i^{(+)} \vec{x}_i^T$;
(2) $SVD(\mathbf{B}_j) = \mathbf{U}_j\mathbf{\Sigma}_j\mathbf{V}_j^T$;
(3) $\mathbf{R}_j = diag(\underbrace{1, \ldots, 1}_{d-1}, det(\mathbf{U}_j)det(\mathbf{V}_j))$;
(4) $\mathbf{M}_j^{(+)} = \mathbf{U}_j\mathbf{R}_j\mathbf{V}_j^T$;

Proof. For simplicity, we omit the subscript j and the superscript (+) of all variables. Eq. (1) can be re-written as:

$$J(\mathbf{M}) = \frac{1}{2}\sum_i a_i \|\mathbf{M}\vec{x}_i - \vec{y}_i\|^2 \text{ s. t. } \mathbf{M}^T\mathbf{M} = \mathbf{I}$$

Here, each pair (x_i, y_i) has the weight a_i over the entire dataset. Because $\sum_i a_i = 1$, based on the proof of the original Wahba's problem [43], we re-write the objective function as follows:

$$J(\mathbf{M}) = 1 - \sum_i a_i \vec{y}_i^T\mathbf{M}\vec{x}_i = 1 - \text{tr}(\mathbf{M}\mathbf{B}^T) \tag{3}$$

where $\mathbf{B} = \sum_i a_i\vec{y}_i\vec{x}_i^T$. The SVD of the matrix $\mathbf{B}$ is given by: $\text{SVD}(\mathbf{B}) = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$ with the singular value matrix $\mathbf{\Sigma} = \text{diag}(\lambda_1, \ldots, \lambda_d)$.

Based on the result of SVD, we define two orthogonal matrices and one diagonal matrix:

$$\mathbf{U}_+ = \mathbf{U}\text{diag}(\underbrace{1, \ldots, 1}_{d-1}, \det(\mathbf{U})) \quad \mathbf{V}_+ = \mathbf{V}\text{diag}(\underbrace{1, \ldots, 1}_{d-1}, \det(\mathbf{V}))$$

$$\mathbf{\Sigma}' = \text{diag}(\lambda_1, \ldots, \lambda_{d-1}, \lambda_d\det(\mathbf{U})\det(\mathbf{V}))$$

Due to the orthogonality of $\mathbf{U}$ and $\mathbf{V}$, we have $\det(\mathbf{U})\det(\mathbf{V}) = \pm 1$. Hence, matrix $\mathbf{B}$ can be re-decomposed as: $\mathbf{B} = \mathbf{U}_+\mathbf{\Sigma}'\mathbf{V}_+^T$.

For simplicity, let $\mathbf{W} = \mathbf{U}_+^T\mathbf{M}\mathbf{V}_+$. Based on the cyclic invariance property of the trace, we have

$$\text{tr}(\mathbf{M}\mathbf{B}^T) = \text{tr}(\mathbf{M}\mathbf{V}_+\mathbf{\Sigma}'\mathbf{U}_+^T) = \text{tr}(\mathbf{\Sigma}'\mathbf{U}_+^T\mathbf{M}\mathbf{V}_+) = \text{tr}(\mathbf{\Sigma}'\mathbf{W})$$

Therefore, we re-write Eq. (3) as: $J(\mathbf{M}) = 1 - \text{tr}(\mathbf{\Sigma}'\mathbf{W})$.

Using the Euler axis/angle parameterization for the orthogonal matrix $\mathbf{W} = \mathcal{R}(\mathbf{e}, \phi)$, we have:

$$\begin{aligned} J(\mathbf{M}) = 1 - (\sum_{i=1}^{d-1}\lambda_i + \lambda_d\det(\mathbf{U})\det(\mathbf{V})) + (1 - \cos\phi)[\sum_{i=2}^{d-1}\lambda_i \\ + \lambda_d\det(\mathbf{U})\det(\mathbf{V}) + \sum_{i=2}^{d-1}(\lambda_1 - \lambda_i)e_i^2 + (\lambda_1 - \lambda_d\det(\mathbf{U})\det(\mathbf{V}))e_d^2] \end{aligned}$$

where $\mathbf{e} = [e_1, e_2, \cdots, e_d]$ is a unit vector and ϕ is a rotation angle. It is easy to show that $J(\mathbf{M})$ is minimized when $\cos\phi = 1$. We have:

$$\min J(\mathbf{M}) = 1 - (\sum_{i=1}^{d-1}\lambda_i + \lambda_d\det(\mathbf{U})\det(\mathbf{V})) = 1 - \text{tr}(\mathbf{\Sigma}')$$

In this condition, we have $\mathbf{W} = \mathbf{I}$. This gives the optimal solution:

$$\mathbf{M}_{opt} = \mathbf{U}_+\mathbf{V}_+^T = \mathbf{U}\text{diag}(\underbrace{1, \ldots, 1}_{d-1}, \det(\mathbf{U})\det(\mathbf{V}))\mathbf{V}^T$$

□

Complexity analysis. For simplicity, let $n = |D^{(+)}|$. The construction of the data matrix $\mathbf{B}_j$ takes $O(nd^2)$ time. Subsequent steps include the SVD, the determinant computation and the matrix multiplication of $d \times d$ matrices. The time complexity is $O(d^3)$. Hence, the total time complexity is $O(nd^2 + d^3)$. Because d is a small constant, usually around $50 \sim 300$ in practice, and n is the size of the training set, the algorithm is sufficiently efficient for the task.

3.3 Learning Non-hypernymy Projections

In the semantic relation classification task, non-hypernyms of a term can be co-hyponyms, synonyms, etc [49]. Hence, MWP is also suitable for modeling the semantics of different non-hypernymy relations. The objective is defined as follows:[3]

$$\begin{aligned} \min \tilde{J}(\mathcal{M}^{(-)}) =& \frac{1}{2}\sum_{j=1}^{K}\sum_{i=1}^{|D^{(-)}|} a_{i,j}^{(-)} \|\mathbf{M}_j^{(-)}\vec{x}_i - \vec{y}_i^{(-)}\|^2 \\ & \text{s. t. } {\mathbf{M}_j^{(-)}}^T\mathbf{M}_j^{(-)} = \mathbf{I}, \sum_{i=1}^{|D^{(-)}|} a_{i,j}^{(-)} = 1, j = 1, \ldots, K \end{aligned}$$

with $\vec{c}_1^{(-)}, \cdots, \vec{c}_K^{(-)}$ as non-hypernymy cluster centroids, and $\mathcal{M}^{(-)} = \{\mathbf{M}_1^{(-)}, \mathbf{M}_2^{(-)}, \cdots, \mathbf{M}_K^{(-)}\}$ as projection parameters. The centroids are generated by K-means over $D^{(-)}$, using $\vec{x}_i - \vec{y}_i^{(-)}$ as features.

3.4 Hypernymy Prediction Classifier

This part describes how MWP benefits hypernymy prediction by training a neural network classifier.

Due to the effectiveness of the Diff model for hypernymy classification [26], given a pair $(x_i, y_i) \in D^{(+)} \cup D^{(-)}$, we generate two groups of features:[4]

$$\mathcal{F}^{(+)}(\vec{x}_i, \vec{y}_i) = (\mathbf{M}_1^{(+)}\vec{x}_i - \vec{y}_i) \oplus \cdots \oplus (\mathbf{M}_K^{(+)}\vec{x}_i - \vec{y}_i)$$

$$\mathcal{F}^{(-)}(\vec{x}_i, \vec{y}_i) = (\mathbf{M}_1^{(-)}\vec{x}_i - \vec{y}_i) \oplus \cdots \oplus (\mathbf{M}_K^{(-)}\vec{x}_i - \vec{y}_i)$$

[3] Note that the numbers of clusters in hypernymy and non-hypernymy relations can also be different. For simplicity, we set the numbers of clusters in hypernymy and non-hypernymy relations uniformly as K.
[4] For simplicity, we omit the superscripts (+) and (−) for y_i here.

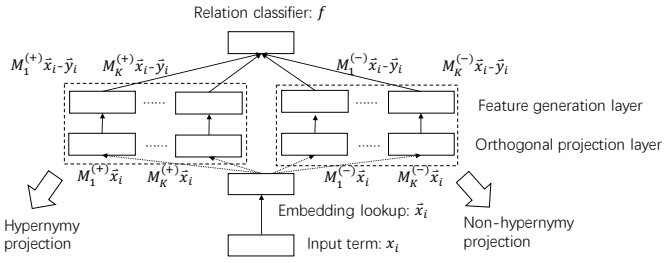

Figure 2: The MWP based neural network architecture for monolingual hypernymy prediction.

where $\oplus$ is the vector concatenation operator.

Figure 2 shows the MWP based neural network for hypernymy relation classification. For each pair $(x_i, y_i) \in D^{(+)} \cup D^{(-)}$, the model generates features $\mathcal{F}^{(+)}(\vec{x}_i, \vec{y}_i) \cup \mathcal{F}^{(-)}(\vec{x}_i, \vec{y}_i)$. A binary classifier f is trained over $D^{(+)}$ and $D^{(-)}$.[5]

The reason for designing such architecture is as follows. In distributional semantics, using embeddings $\vec{x}_i$ and $\vec{y}_i$ to predict the relation between x_i and y_i can cause the "lexical memorization" problem [18]. For example, if the classifier receives positive pairs "(dog, animal)", "(cat, animal)" and "(sheep, animal)" during training, it will "memorize" the property of the embeddings of "animal", where "animal" is regarded as a "prototypical hypernym" by [18]. In consequence, the classifier is likely to predict there is a hypernymy relation in "(rose, animal)" when seeing the term "animal".

In our approach, if there is a hypernymy relation in (x_i, y_i), the norms of the features $\mathcal{F}^{(+)}(x_i, y_i)$ are likely to be small based on Eq. (2). The norms of features $\mathcal{F}^{(-)}(x_i, y_i)$ are likely to be large. Hence the combined features $\mathcal{F}^{(+)}(x_i, y_i) \cup \mathcal{F}^{(-)}(x_i, y_i)$ are discriminative for distinguishing hypernymy vs. non-hypernymy relations. By modeling the semantics of hypernymy and non-hypernymy, this method avoids "lexical memorization". The high-level training procedure is summarized in Algorithm 1.

Algorithm 1 Monolingual Hypernymy Prediction

```
Perform K-means over D^(+), with features as x⃗_i − y⃗_i^(+);
Perform K-means over D^(−), with features as x⃗_i − y⃗_i^(−);
for j = 1 to cluster number K do
    Learn M_j^(+) and M_j^(−) by the closed-form solution;
end for
for each pair (x_i, y_i^(+)) ∈ D^(+) do
    Compute F^(+)(x⃗_i, y⃗_i^(+)) and F^(−)(x⃗_i, y⃗_i^(+));
end for
for each pair (x_i, y_i^(−)) ∈ D^(−) do
    Compute F^(+)(x⃗_i, y⃗_i^(−)) and F^(−)(x⃗_i, y⃗_i^(−));
end for
Train neural network classifier f over D^(+) and D^(−);
```

4 CROSS-LINGUAL MODELS

In this section, we introduce two projection models (i.e., TMWP and ITMWP) based on MWP for cross-lingual hypernymy prediction.

[5]We have added more hidden layers between the feature generation layer and the output layer with no improvement. Hence, an output layer is directly connected to the feature generation layer.

4.1 Transfer MWP

Let $D_S^{(+)}$, $D_S^{(-)}$, $D_T^{(+)}$ and $D_T^{(-)}$ be the training sets of hypernymy and non-hypernymy relations from the source and target languages, respectively. For low-resourced languages, the training sets are usually highly limited in size. Hence, we impose two assumptions, i.e., $|D_S^{(+)}| \gg |D_T^{(+)}|$ and $|D_S^{(-)}| \gg |D_T^{(-)}|$. We define the task of cross-lingual hypernymy prediction as follows:

Definition 4.1. (Cross-lingual Hypernymy Prediction) The goal is to train a classifier f over $D_S^{(+)}$, $D_S^{(-)}$ of the source language and $D_T^{(+)}$, $D_T^{(-)}$ of the target language, to predict hypernymy relations $U_T = \{(x_i, y_i)\}$ of the target language.

Recently, significant progress has been made in neural machine translation [39]. However, such translation technique is not sufficient to solve our task by translating training sets of the source language to the target language directly. The reasons are twofold. i) The training of neural machine translation models require a large amount of high-quality bilingual data in order to achieve high accuracy. For low-resourced languages, acquiring such data is difficult, or sometimes even infeasible [55]. ii) Cross-lingual hypernymy prediction requires the translation of words without any contexts, rather than complete sentences.

In this work, we adopt Conneau et al. [8] to learn the mappings among words across different languages. Before we train TMWP or ITMWP models, we follow the work [8] and learn a $d \times d$ projection matrix $\mathbf{S}$, which maps the embedding vector $\vec{x}$ in the source language space to $\vec{x}^*$ in the target language space such that x and x^* are terms of two languages share the same meaning.

4.1.1 Learning Hypernymy Projections. Similar to the monolingual case, the word pairs from $D_S^{(+)}$ and $D_T^{(+)}$ are grouped into K clusters. If $(x_i, y_i^{(+)}) \in D_T^{(+)}$, the features that we use for clustering are $\vec{x}_i - \vec{y}_i^{(+)}$; otherwise, we use $\mathbf{S}\vec{x}_i - \mathbf{S}\vec{y}_i^{(+)}$ as features. The objective function w.r.t. the jth cluster is as follows:

$$\begin{aligned}\min J(\mathbf{M}_j^{(+)}) =& \frac{\beta}{2} \sum_{i=1}^{|D_S^{(+)}|} a_{i,j}^{(+)} \gamma_i^{(+)} \|\mathbf{M}_j^{(+)}\mathbf{S}\vec{x}_i - \mathbf{S}\vec{y}_i^{(+)}\|^2 \\ &+ \frac{1-\beta}{2} \sum_{i=1}^{|D_T^{(+)}|} a_{i,j}^{(+)} \|\mathbf{M}_j^{(+)}\vec{x}_i - \vec{y}_i^{(+)}\|^2 \\ \text{s. t. } &\mathbf{M}_j^{(+)T}\mathbf{M}_j^{(+)} = \mathbf{I},\ \sum_{i=1}^{|D_S^{(+)}|} a_{i,j}^{(+)}\gamma_i^{(+)} = 1,\ \sum_{i=1}^{|D_T^{(+)}|} a_{i,j}^{(+)} = 1\end{aligned} \tag{4}$$

where $\gamma_i^{(+)}$ is a weight factor that imposes different scores to hypernymy relations in $D_S^{(+)}$. $\beta \in (0, 1)$ is a pre-defined balance factor that gives different importance to losses of the source and target languages. We define the unnormalized score $\tilde{\gamma}_i^{(+)}$ by:

$$\tilde{\gamma}_i^{(+)} = \cos(\mathbf{S}\vec{x}_i - \mathbf{S}\vec{y}_i^{(+)}, \frac{1}{|D_T^{(+)}|} \sum_{(x_j, y_j^{(+)}) \in D_T^{(+)}} \vec{x}_j - \vec{y}_j^{(+)})$$

which qualifies the semantic similarity between a pair $(x_i, y_i^{(+)}) \in D_S^{(+)}$ and all the hypernymy relations in $D_T^{(+)}$. Because $\sum_{i=1}^{|D_S^{(+)}|} a_{i,j}^{(+)} \gamma_i^{(+)} = 1$, $\gamma_i^{(+)}$ is computed by normalizing $\tilde{\gamma}_i^{(+)}$: $\gamma_i^{(+)} = \frac{\tilde{\gamma}_i^{(+)}}{\sum_{i'=1}^{|D_S^{(+)}|} a_{i',j}^{(+)} \gamma_{i'}^{(+)}}$.

After all the weights are computed, $\mathbf{M}_j^{(+)}$ can be learned by minimizing $J(\mathbf{M}_j^{(+)})$. We present the following theorem to compute the optimal solution of $\mathbf{M}_j^{(+)}$ in Eq. (4):

Theorem 4.2. *Eq. (4) is a variant of the d-dimensional Wahba's problem, which has a closed-form solution as follows:*

(1) $\mathbf{B}_j = \beta \sum_{i=1}^{|D_S^{(+)}|} a_{i,j}^{(+)} \gamma_i^{(+)} \mathbf{S}\vec{y}_i^{(+)} (\mathbf{S}\vec{x}_i)^T + (1-\beta) \sum_{i=1}^{|D_T^{(+)}|} a_{i,j}^{(+)} \vec{y}_i^{(+)} \vec{x}_i^T$;
(2) $SVD(\mathbf{B}_j) = \mathbf{U}_j \mathbf{\Sigma}_j \mathbf{V}_j^T$;
(3) $\mathbf{R}_j = diag(\underbrace{1, \ldots, 1}_{d-1}, det(\mathbf{U}_j) det(\mathbf{V}_j))$;
(4) $\mathbf{M}_j^{(+)} = \mathbf{U}_j \mathbf{R}_j \mathbf{V}_j^T$;

Proof. We omit the subscript j and the superscript $(+)$ of all variables in the objective function. Eq. (4) can be re-written as:

$$\min J(\mathbf{M}) = \frac{\beta}{2} \sum_{i=1}^{|D_S|} a_i \gamma_i \|\mathbf{M}\mathbf{S}\vec{x}_i - \mathbf{S}\vec{y}_i\|^2 + \frac{1-\beta}{2} \sum_{i=1}^{|D_T|} a_i \|\mathbf{M}\vec{x}_i - \vec{y}_i\|^2$$
$$\text{s. t. } \mathbf{M}^T\mathbf{M} = \mathbf{I}, \sum_{i=1}^{|D_S|} a_i \gamma_i = 1, \sum_{i=1}^{|D_T|} a_i = 1$$

Hence, $\beta \sum_{i=1}^{|D_S|} a_i \gamma_i + (1-\beta) \sum_{i=1}^{|D_T|} a_i = 1$. We can see that each pair $(x_i, y_i) \in D_S$ has the weight $\beta a_i \gamma_i$, and each pair $(x_i, y_i) \in D_T$ has the weight $(1-\beta) a_i$. Define the matrix $\mathbf{B}$ as:

$$\mathbf{B} = \beta \sum_{i=1}^{|D_S|} a_i \gamma_i \mathbf{S}\vec{y}_i (\mathbf{S}\vec{x}_i)^T + (1-\beta) \sum_{i=1}^{|D_T|} a_i \vec{y}_i \vec{x}_i^T$$

The objective $J(\mathbf{M})$ in Eq. (4) can be re-written as follows: $J(\mathbf{M}) = 1 - \text{tr}(\mathbf{M}\mathbf{B}^T)$. Therefore, we turn Eq. (4) into the d-dimensional Wahba's problem. The rest of the steps are the same as the previous proof, which are omitted here. □

Complexity analysis. For simplicity, let $n_1 = |D_S^{(+)}|$ and $n_2 = |D_T^{(+)}|$. The construction of $\mathbf{B}_j$ takes $O((n_1+n_2)d^2)$ time. The total time complexity is $O((n_1+n_2)d^2 + d^3)$.

Combining the objective functions w.r.t. all K clusters, the objective function for learning projected hypernymy embeddings in the cross-lingual case is derived as follows:

$$\min \tilde{J}(\mathcal{M}^{(+)}) = \frac{\beta}{2} \sum_{j=1}^{K} \sum_{i=1}^{|D_S^{(+)}|} a_{i,j}^{(+)} \gamma_i^{(+)} \|\mathbf{M}_j^{(+)} \mathbf{S}\vec{x}_i - \mathbf{S}\vec{y}_i^{(+)}\|^2$$
$$+ \frac{1-\beta}{2} \sum_{j=1}^{K} \sum_{i=1}^{|D_T^{(+)}|} a_{i,j}^{(+)} \|\mathbf{M}_j^{(+)} \vec{x}_i - \vec{y}_i^{(+)}\|^2$$
$$\text{s. t. } {\mathbf{M}_j^{(+)}}^T \mathbf{M}_j^{(+)} = \mathbf{I}, \sum_{i=1}^{|D_S^{(+)}|} a_{i,j}^{(+)} \gamma_i^{(+)} = 1, \sum_{i=1}^{|D_T^{(+)}|} a_{i,j}^{(+)} = 1,$$
$$j = 1, \ldots, K$$

which is referred as the Transfer Multi-Wahba Projection (TMWP) model.

4.1.2 Learning Non-hypernymy Projections. Similarly, to learn non-hypernymy projections, we group $D_S^{(-)}$ and $D_T^{(-)}$ into K clusters, using $\vec{x}_i - \vec{y}_i^{(-)}$ and $\mathbf{S}\vec{x}_i - \mathbf{S}\vec{y}_i^{(-)}$ as features, respectively. The objective function of TMWP is defined as follows:

$$\min \tilde{J}(\mathcal{M}^{(-)}) = \frac{\beta}{2} \sum_{j=1}^{K} \sum_{i=1}^{|D_S^{(-)}|} a_{i,j}^{(-)} \gamma_i^{(-)} \|\mathbf{M}_j^{(-)} \mathbf{S}\vec{x}_i - \mathbf{S}\vec{y}_i^{(-)}\|^2$$
$$+ \frac{1-\beta}{2} \sum_{j=1}^{K} \sum_{i=1}^{|D_T^{(-)}|} a_{i,j}^{(-)} \|\mathbf{M}_j^{(-)} \vec{x}_i - \vec{y}_i^{(-)}\|^2$$
$$\text{s. t. } {\mathbf{M}_j^{(-)}}^T \mathbf{M}_j^{(-)} = \mathbf{I}, \sum_{i=1}^{|D_S^{(-)}|} a_{i,j}^{(-)} \gamma_i^{(-)} = 1, \sum_{i=1}^{|D_T^{(-)}|} a_{i,j}^{(-)} = 1,$$
$$j = 1, \ldots, K$$

The learning process of the parameters $\mathcal{M}^{(-)}$ is the same as $\mathcal{M}^{(+)}$.

4.1.3 Hypernymy Prediction Classifier. After $\mathcal{M}^{(+)}$ and $\mathcal{M}^{(-)}$ are learned, we train the hypernymy relation classifier f for the cross-lingual case, with the procedure illustrated in Algorithm 2.

Algorithm 2 Cross-lingual Hypernymy Prediction (TMWP)

```
Perform K-means over D_S^(+) and D_T^(+), with features as S x_i − S y_i^(+) and x_i − y_i^(+), respectively;
Perform K-means over D_S^(−) and D_T^(−), with features as S x_i − S y_i^(−) and x_i − y_i^(−), respectively;
for j = 1 to cluster number K do
    Learn M_j^(+) and M_j^(−) by the closed-form solution;
end for
for each pair (x_i, y_i^(+)) ∈ D_S^(+) do
    Compute F^(+)(S x_i, S y_i^(+)) and F^(−)(S x_i, S y_i^(+));
end for
for each pair (x_i, y_i^(+)) ∈ D_T^(+) do
    Compute F^(+)(x_i, y_i^(+)) and F^(−)(x_i, y_i^(+));
end for
for each pair (x_i, y_i^(−)) ∈ D_S^(−) do
    Compute F^(+)(S x_i, S y_i^(−)) and F^(−)(S x_i, S y_i^(−));
end for
for each pair (x_i, y_i^(−)) ∈ D_T^(−) do
    Compute F^(+)(x_i, y_i^(−)) and F^(−)(x_i, y_i^(−));
end for
Train neural network classifier f over D_S^(+), D_S^(−), D_T^(+) and D_T^(−);
```

4.2 Iterative Transfer MWP

Because the sizes of $D_T^{(+)}$ and $D_T^{(-)}$ are highly limited, TMWP can encode very little knowledge from the target language. As different languages may have culture-specific words whose semantics can not be acquired using transfer learning, the performance is likely to suffer [7].

To further improve the performance, we introduce the Iterative Transfer Multi-Wahba Projection (ITMWP) model. Recall that $U_T = \{(x_i, y_i)\}$ is the collection of unlabeled term pairs of the target

Relation	BLESS	ENTAILMENT
Hypernymy	1,337	1,385
Other relations (Non-hypernymy)	13,210	1,385

Table 1: Statistic summarization of two general-domain hypernymy datasets.

language. The algorithmic procedure is shown in Algorithm 3. In each iteration, after $\mathcal{M}^{(+)}$ and $\mathcal{M}^{(-)}$ are learned, for each pair $(x_i, y_i) \in U_T$, we compute the confidence score as follows:

$$conf(x_i, y_i) = \frac{|\|\mathcal{F}^{(+)}(\vec{x}_i, \vec{y}_i)\|_2 - \|\mathcal{F}^{(-)}(\vec{x}_i, \vec{y}_i)\|_2|}{\max\{\|\mathcal{F}^{(+)}(\vec{x}_i, \vec{y}_i)\|_2, \|\mathcal{F}^{(-)}(\vec{x}_i, \vec{y}_i)\|_2\}}$$

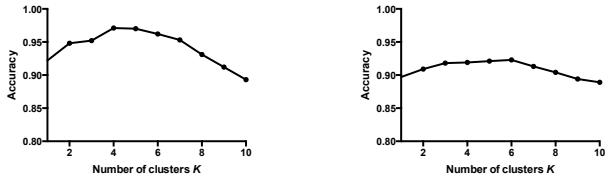
We use the confident score instead of the output of the classifier, because modern neural networks do not generate calibrated probabilistic distributions [11]. Given a threshold τ, if $conf(x_i, y_i) > \tau$, we add the pair (x_i, y_i) to the training set (either $D_T^{(+)}$ or $D_T^{(-)}$, depending on the prediction label). The TMWP models are iteratively trained over enlarged datasets until the performance does not increase over the development set. The detailed procedure of ITMWP is shown in Algorithm 3.

Algorithm 3 Cross-lingual Hypernymy Prediction (ITMWP)

```
Train TMWP over D_S^(+), D_S^(-), D_T^(+) and D_T^(-) by Algorithm 2;
while not converge do
    for each pair (x_i, y_i) ∈ U_T do
        if conf(x_i, y_i) > τ then
            if f(x_i, y_i) = HYPERNYMY then
                Update D_T^(+) = D_T^(+) ∪ {(x_i, y_i)};
            else
                Update D_T^(-) = D_T^(-) ∪ {(x_i, y_i)};
            end if
            Update U_T = U_T \ {(x_i, y_i)}
        end if
    end for
    Update TMWP over D_S^(+), D_S^(-), D_T^(+) and D_T^(-) by Algorithm 2;
end while
```

5 MONOLINGUAL EXPERIMENTS

In this section, we conduct extensive experiments to evaluate MWP over the tasks of supervised hypernymy detection and unsupervised hypernymy relation classification. We compare it with state-of-the-art approaches to make the convincing conclusion.



5.1 General-domain Supervised Hypernymy Detection

5.1.1 Task Description. We first evaluate MWP by supervised hypernymy detection in the general domain, which aims at classifying whether the hypernymy relation holds in a term pair. Experiments are conducted over two benchmark datasets that are frequently used in the NLP community: BLESS [2] and ENTAILMENT [1], consisting of 14,547 and 2,770 word pairs with labeled relations (i.e., hypernymy relations or other relations), respectively. The statistics of the two datasets are summarized in Table 1.

To obtain all the term embeddings for learning projection matrices and the hypernymy relation classifier, we use the same procedure as in Bojanowski et al. [4] to train fastText word embeddings over the entire Wikipedia corpus, with the dimensionality of word embeddings set to $d = 300$.

Method	BLESS	ENTAILMENT
Mikolov et al. [24]	0.84	0.83
Yu et al. [54]	0.90	0.87
Luu et al. [20]	0.93	0.91
Nguyen et al. [26]	0.94	0.91
MWP (Non-orthogonal)	**0.95**	0.90
MWP	**0.97**	**0.92**

Table 2: Performance comparison of general-domain supervised hypernymy detection in terms of accuracy.

(a) Dataset: BLESS (b) Dataset: ENTAILMENT

Figure 3: Parameter analysis of K over two datasets.

For evaluation, we follow exactly the same "leave-one-out" evaluation protocols that have been used in a series of NLP papers [20, 26, 54]. For the BLESS dataset [2], because the relations are related to 200 most frequent nouns in WordNet [25], we randomly select relations w.r.t. one noun for testing, and train the MWP model and the relation prediction classifier on others. For the ENTAILMENT dataset [1], one hypernymy relation is randomly selected for testing and the model is trained over others. All the experimental results are reported in averaged accuracy.

5.1.2 Baselines. To evaluate whether the learned features are useful to distinguishing hypernymy vs. non-hypernymy relations, we compare MWP against five hypernymy embedding methods:[6]

- Word2Vec [24]: It is the standard Skip-gram model, trained via the negative sampling technique.
- Yu et al. [54]: It learns hypernymy embeddings for terms based on the Probase taxonomy [51]. The algorithm is optimized by a max-margin neural network.
- Luu et al. [20]: It improves hypernymy embedding learning by a dynamic weighting neural model.
- HyperVec [26]: It combines the negative sampling based Skip-gram model [24] and the WordNet concept hierarchy [25] to learn hypernymy embeddings.
- MWP (Non-orthogonal): It is a variant of the MWP model, without orthogonal constraints on projection matrices.

5.1.3 Experimental Results. The experimental results are summarized in Table 2. In the implementation, as a default setting, we fix the number of clusters of MWP as $K = 4$. The parameter analysis of K will be presented further. From the results, we can see that MWP outperforms all previous baseline approaches. Simple models such as Word2Vec [24] do not produce satisfactory results because

[6]Based on the respective papers, the features of [20, 24, 54] are the hypernymy embeddings of two terms and the vector difference. The features of [26] are the vector difference and cosine similarity between two terms' embeddings, together with the magnitudes of the two embeddings. An SVM classifier is trained over all the features to make the prediction.

Statistics	ANIMAL	PLANT	VEHICLE
# Distinct terms	659	520	117
# Hypernymy relations	4,164	2,266	283
# Random word pairs	8,471	4,520	586

Table 3: Statistic summarization of three domain-specific hypernymy datasets.

Method	ANIMAL	PLANT	VEHICLE
Mikolov et al. [24]	0.80	0.81	0.82
Yu et al. [54]	0.67	0.65	0.70
Luu et al. [20]	0.89	0.92	0.89
Nguyen et al. [26]*	0.83	0.91	0.83
MWP (Non-orthogonal)	**0.90**	**0.92**	0.87
MWP	**0.92**	**0.94**	**0.90**

Table 4: Performance comparison of domain-specific supervised hypernymy detection in terms of accuracy. * refers to the result based on our own implementation.

the semantics of hypernymy relations are not explicitly modeled. Hence, they are probable to suffer from the "lexical memorization" problem. Compared to the strongest competitor HyperVec [26], the accuracy of MWP is higher by 3% over BLESS and higher by 1% over ENTAILMENT. The comparison between the MWP model and the variant MWP (Non-orthogonal) shows that the orthogonal constraint improves projection learning in MWP.

As there is no gold standard to determine the number of "latent components" in a hypernymy relation dataset, the choice of parameter K in MWP is mostly heuristic. Here, we investigate how the changes of K affect the performance of MWP. We set K from 1 to 10 and report the averaged accuracy over the two datasets. The results are shown in Figure 3. As seen, the performance is not very sensitive to K if the value of K is not extremely large or small. This is because we introduce the weights $a_{i,j}^{(+)}$ and $a_{i,j}^{(-)}$ in the model, resulting in the situations where all the projections are "fuzzy". Additionally, by using the clustering technique, the accuracy of MWP is boosted by over 5% and 2%, respectively.

5.2 Domain-specific Supervised Hypernymy Detection

5.2.1 Task Description. We further evaluate the effectiveness of MWP method over domain-specific datasets. In this set of experiments, we use three datasets derived from the following domain-specific taxonomies: ANIMAL, PLANT and VEHICLE [40]. The respective three evaluation datasets are constructed by extracting all possible taxonomic relations from taxonomies as possible samples and randomly pairing two terms that are not involved in any hypernymy relations as negative samples. We use the same datasets that have been generated and released by Luu et al. [20]. The statistics are summarized in Table 3.

For evaluation, we also follow the settings of Luu et al. [20]. Each time, we hold out relations w.r.t. one term for testing and train our model on the remaining terms. The results are also reported in averaged accuracy. Because a few terms in the three datasets are multi-word expressions (e.g., American tree, half track), we treat these terms as a whole to train the fastText word embeddings [4]. The default experimental settings and baselines are the same as in the general-domain experiments. Hence, we do not repeat the details again.

5.2.2 Experimental Results. From the experimental results in Table 4, it can be concluded that the proposed MWP model has high performance for hypernymy detection in specific domains. Specifically, the non-orthogonal version of MWP outperforms state-of-the-art methods over two domain-specific datasets (PLANT and ANIMAL) and is comparable to the strongest baseline Luu et al. [20] over the other one (VEHICLE). The full implementation of MWP outperforms all the baselines over the three datasets. Another interesting observation is that methods that use general corpora to training word embeddings (i.e., [20, 24] and ours) have relatively higher performance than methods that only consider the taxonomy data (i.e., Yu et al. [54]). Nguyen et al. [26] learn hypernymy embeddings using the general WordNet concept hierarchy, but still have relatively low performance in specific domains. This is because concepts in the taxonomy Probase [51] or in the WordNet concept hierarchy usually have low converge for specific domains, leading to low prediction performance.

5.3 Unsupervised Hypernymy Relation Classification

5.3.1 Task Description and Evaluation Protocols. This set of experiments involves two studies that compare MWP against various hypernymy measures. We follow the evaluation framework of Nguyen et al. [26], Roller et al. [30] over two benchmark datasets: BLESS and WBLESS, constructed by Kiela et al. [15] and Weeds et al. [49], respectively. In the first experiment, we aim at predicting the directionality of all the 1,337 hypernymy relations in BLESS. All the hypernymy relations are treated as positive samples and all the reverse-hypernymy relations are treated as negative samples. WBLESS is derived from BLESS, including a subset of 1,168 pairs. The experiment over WBLESS is more challenging, which is a binary classification task, aiming at distinguishing hypernymy relations and other relations (including a mixture of reverse-hypernymy, meronymy, co-hyponymy relations and randomly matched nouns).

The baseline hypernymy measures that we consider in this work are summarized as follows. Santus et al. [31],Weeds et al. [49], Kiela et al. [15] and Nguyen et al. [26] employ distributional methods for unsupervised hypernymy relation classification. Roller et al. [30] is the state-of-the art path-based measure by utilizing generalized Hearst patterns in a large text corpus.

In contrast to these hypernymy measures, the MWP model is a supervised relation classification model, instead of an unsupervised measure. Hence, MWP can not be directly applied to this task. Instead of using the MWP based classifier f, we design a hypernymy score based on the features:

$$\tilde{s}(x_i, y_i) = \|\mathcal{F}^{(-)}(\vec{x}_i, \vec{y}_i)\|_2 - \|\mathcal{F}^{(+)}(\vec{x}_i, \vec{y}_i)\|_2 \quad (5)$$

where the projection matrices w.r.t. $\mathcal{F}^{(+)}(x_i, y_i)$ are learned over hypernymy relations and the projection matrices w.r.t. $\mathcal{F}^{(-)}(x_i, y_i)$ are learned over others. For a term pair (x_i, y_i), if x_i is the hyponym and y_i is the hypernym, the norm of $\mathcal{F}^{(+)}(x_i, y_i)$ is likely to be smaller than that of $\mathcal{F}^{(-)}(x_i, y_i)$. Hence, we use $\tilde{s}(x_i, y_i) > \tilde{s}(y_i, x_i)$ to predict y_i is the hypernym of x_i.

Relation↓ Language →	fr	zh	ja	it	th	fi	el
# Hypernymy relations	4,035	2,962	1,448	3,034	1,156	7,157	2,612
# Non-hypernymy relations	8,947	6,382	3,203	6,081	1,977	9,433	1,454

Table 5: Statistics of hypernymy and non-hypernymy relation datasets of seven non-English languages. Language abbreviations: French (fr), Chinese (zh), Japanese (ja), Italian (it), Thai (th), Finnish (fn) and Greek (el).

Measure	BLESS	WBLESS
Santus et al. [31]	0.87	-
Weeds et al. [49]	-	0.75
Kiela et al. [15]	0.88	0.75
Nguyen et al. [26]	0.92	0.87
Roller et al. [30]	0.96	0.87
MWP (Non-orthogonal)	0.95	**0.89**
MWP	**0.97**	**0.92**

Table 6: Performance comparison of unsupervised hypernymy relation classification in terms of accuracy.

Because all the projection matrices require to be pre-trained before we can compute the features $\mathcal{F}^{(+)}(\vec{x}_i, \vec{y}_i)$ and $\mathcal{F}^{(-)}(\vec{x}_i, \vec{y}_i)$, we employ 14,135 hypernymy relations from the dataset Shwartz [34] as the training data, after removing pairs appearing in BLESS to avoid overfitting. Note that the proposed hypernymy measure in Eq. (5) is unsupervised because the Shwartz data is only employed to learn projection matrices. We do not train the hypernymy relation classifier to make the prediction over BLESS and WBLESS, nor do we use any BLESS or WBLESS data to learn projection matrices.

5.3.2 Experimental Results. The experimental results are summarized in Table 6. We can see that among all the baselines, Roller et al. [30] has the highest performance, with the accuracies as 96% and 87%, respectively. Compared to Roller et al. [30], the MWP model outperforms the method by 1% and 5% in terms of accuracy. Although the MWP model is primarily built for supervised hypernymy relation classification, by adding some slight modifications, it is also is highly effective for predicting the hypernymy relations in an unsupervised manner.

Note that we only focus on the binary classification of hypernymy relations in this work. In the future, we will extend our work to the multi-way classification of semantic relations, and evaluate it over other multi-way classification datasets (e.g., BIBLESS [26]).

6 CROSS-LINGUAL EXPERIMENTS

In this section, we evaluate two cross-lingual models (TMWP and ITMWP) over two tasks: cross-lingual hypernymy direction classification and cross-lingual hypernymy detection.

6.1 Datasets and Experimental Settings

We select English as the source language due to its wide usage and the availability of large training sets. We refer to the survey [45], and combine the five human-labeled datasets as the underlying training set of the source language: BLESS [2], Shwartz [34], Kotlerman [16], Turney [37] and ENTAILMENT [1]. After removing of duplicates and multi-word expressions, we create a large English dataset, consisting of 85,234 word pairs, containing 17,394 hypernymy relations and 67,930 non-hypernymy relations (including a mixture of other relations). All the datasets are available at https://chywang.github.io/data/www2019.zip.

For non-English languages, we utilize the Open Multilingual Wordnet project [5] to create training and testing sets[7]. We take seven non-English languages as target languages: French, Chinese, Japanese, Italian, Thai, Finnish and Greek. Versions of Wordnets are Wordnet Libre du Français (French), Chinese Open Wordnet, Japanese Wordnet, ItalWordnet (Italian), Thai Wordnet, FinnWordnet (Finnish) and Greek Wordnet. Hypernymy relations are generated by randomly sampling hypernymy relations from the Multilingual Wordnet concept hierarchies. Non-hypernymy relations consist of a mixture of holonymy, synonymy and randomly matched word pairs. The statistics of all the seven datasets are summarized in Table 5. For seven non-English languages, word embeddings are taken from pre-trained fastText word embeddings [4]. The cross-lingual mapping matrices are trained using the original code of Conneau et al. [8] over multi-lingual Wikipedia corpora with default parameter settings. The dimensions of word embeddings of all languages are set to $d = 300$.

6.2 Evaluation Protocols

We evaluate the two cross-lingual models (i.e., TMWP and ITMWP) over two cross-lingual hypernymy prediction tasks. The first is cross-lingual hypernymy direction classification. Its goal is to predict the directionality of hypernymy relations for the target language given the training sets in English and the target language. We take hypernymy relations as positive data, and reverse-hypernymy relations as negative data to train and evaluate our model. The second task is cross-lingual hypernymy detection. It aims at distinguishing hypernymy vs. non-hypernymy relations for the target language based on both datasets in English and the target language. In the experiments, we use all the data in English and 20% of the non-English language datasets for training, 20% for development and the rest 60% for testing, partitioned randomly. By rotating the 5-fold subsets of the non-English language datasets, we report the performance of all the models in terms of averaged accuracy.

Because pattern-based methods and a few distributional methods for hypernymy prediction is highly language dependent, they are not suitable for cross-lingual hypernymy prediction over arbitrary languages. Hence, we follow the evaluation protocols that used in Shwartz et al. [34]. We employ several state-of-the-art distributional approaches as baselines, introduced as follows:

- Santus et al. [31]: It is an entropy-based hypernymy measure SLQS that characterizes the semantic generality of terms.
- Kiela et al. [15]: It is a distributional generality measure that models the hierarchical property of hypernymy relations.
- Weeds et al. [49]: It is a supervised distributional model based on vector offsets of term pairs.
- Shwartz et al. [34]: It is a neural network architecture for relation classification. Because several non-English languages

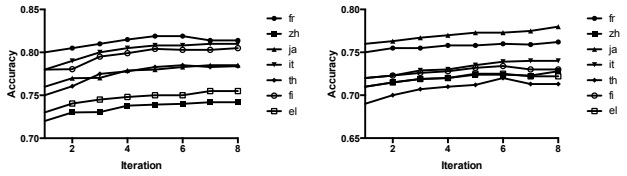
Table 7: Performance comparison of two cross-lingual hypernymy prediction tasks in terms of accuracy. TMWP (N) and ITMWP (N) are stand for TMWP (Non-orthogonal) and ITMWP (Non-orthogonal).

(e.g., Chinese, Thai) lack high-quality hypernymy patterns. The path-based sub-networks are not implemented.

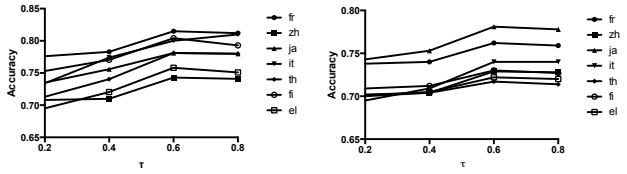
- TMWP (Non-orthogonal) and ITMWP (Non-orthogonal): They are the variants of TMWP and ITMWP without the orthogonal constraint on projection matrices, respectively.



Apart from the proposed two models and their variants, the remaining competing approaches [15, 31, 34, 49] are not designed for cross-lingual hypernymy prediction. To implement all the baselines for the two cross-lingual hypernymy prediction tasks, we employ Conneau et al. [8] to translate the embeddings of terms in the source language to those of the target languages. Next, we train all the baseline models over the English dataset after translating it to the target language and the training set of the target language. For simplicity, we set $K = 4$ and $\beta = 0.5$ for TMWP and ITMWP and their variants in all the cross-lingual experiments.

6.3 Experimental Results

The experimental results of both tasks over all the seven non-English languages are summarized in Table 7.



From the results, we can draw the following conclusions. i) For both tasks, ITMWP and TMWP outperform all the previous methods over all seven non-English languages. Overall, the proposed models boost the accuracy by 2% $\sim$ 9% for cross-lingual hypernymy direction classification, depending on different languages. The performance of our models for cross-lingual hypernymy detection is similar to that of the direction classification task. ii) By using unsupervised neural word translation and the orthogonal constraint, knowledge from the source languages can be employed to improve the performance of hypernymy prediction of the target language. iii) The performance of cross-lingual hypernymy direction classification is generally higher than cross-lingual hypernymy detection, indicating the latter task is more challenging.

We further investigate how ITMWP improves the performance. We fix $\tau = 0.7$ and run our algorithm for 8 iterations over the two tasks. The results are illustrated in Figure 4. As seen, the accuracy increases steadily during the first few iterations. The performance becomes relatively stable because there are no sufficient number of relations with high confidence that can be added to training sets.

(a) Task: cross-lingual hypernymy direction classification (b) Task: cross-lingual hypernymy detection

Figure 4: Performance of ITMWP over two cross-lingual hypernymy prediction tasks.

(a) Task: cross-lingual hypernymy direction classification (b) Task: cross-lingual hypernymy detection

Figure 5: Parameter analysis of τ over two cross-lingual hypernymy prediction tasks.

Additionally, we tune the parameter τ in ITMWP and run the algorithm in 5 iterations. The results are summarized in Table 5. It shows that the changes of performance trend are similar across different languages. The value of τ reflects the trade-off between the number of pairs to be added to the training set and the accuracies of these pairs. When τ is small, the algorithm tends to add more pairs to the training set, unavoidably introducing errors to the training set. In contrast, when τ is large, the effect of training data augmentation is reduced. We suggest that the algorithm achieves the best performance when τ is set around 0.7.

7 CONCLUSION AND FUTURE WORK

In this paper, we propose a family of fuzzy orthogonal projection models for monolingual and cross-lingual hypernymy prediction. It includes three models: MWP, TMWP and ITMWP. MWP distinguishes hypernymy vs. non-hypernymy relations based on distributional fuzzy mappings from embeddings of a term to those of its hypernyms and non-hypernyms. TMWP and ITMWP are designed to transfer the semantic knowledge from the source language to target languages for cross-lingual hypernymy prediction. Experiments illustrate the effectiveness of our models over both monolingual and cross-lingual hypernymy prediction. In the future, we plan to i) extend our method to predict multiple types of semantic relations over multiple languages, and to ii) improve cross-lingual hypernymy prediction via multi-lingual embeddings.

ABSTRACT

Repeat consumption is a common scenario in daily life, such as repurchasing items and revisiting websites, and is a critical factor to be taken into consideration for recommender systems. Temporal dynamics play important roles in modeling repeat consumption. It is noteworthy that for items with distinct lifetimes, consuming tendency for the next one fluctuates differently with time. For example, users may repurchase milk weekly, but it is possible to repurchase mobile phone after a long period of time. Therefore, how to adaptively incorporate various temporal patterns of repeat consumption into a holistic recommendation model has been a new and important problem.

In this paper, we propose a novel unified model with introducing Hawkes Process into Collaborative Filtering (CF). Different from most previous work which ignores various time-varying patterns of repeat consumption, the model explicitly addresses two item-specific temporal dynamics: (1) *short-term effect* and (2) *life-time effect*, which is named as **S**hort-Term and **L**ife-Time **R**epeat **C**onsumption (SLRC) model. SLRC learns importance of the two factors for each item dynamically by interpretable parameters. According to extensive experiments on four datasets in diverse scenarios, including two public collections, SLRC is superior to previous approaches for repeat consumption modeling. Moreover, due to the high flexibility of SLRC, various existing recommendation algorithms are shown to be easily leveraged in this model to achieve significant improvements. In addition, SLRC is good at balancing recommendation for novel items and consumed items (exploration and exploitation). We also find that the learned parameters is highly interpretable, and hence the model is able to be leveraged to discover items' lifetimes, and to distinguish different types of items such as durable and fast-moving consumer goods.

1 INTRODUCTION

Recommender system plays a crucial role in users' engagements with web-services, which makes it easier for users to explore endless items that they have not consumed (novel items) [19, 23, 36]. Meanwhile, repeat consumptions come to account for a large proportion of user-item interactions and become increasingly important in recent years. Therefore, properly recommending items user consumed before becomes a vital part of recommender systems nowadays. For example, an online shopping website can recommend the milk powder user consumed before when it is time to be used up. It is widely agreed that providing consumed items at the right time can greatly improve both users' satisfaction and sellers' profit [3, 11, 12, 40].

Temporal dynamics is an important factor to accurately model repeat consumption. Previous study about user consumption sequence presents a holistic model of sequential consumption [4]. The model takes time factor, distance factor, quality factor into consideration and the time factor turns out to be the most important one. Du et al. [16] utilize temporal point process to model recurrent user activities. That is to say, previous consumptions are likely to trigger repeat consumptions for those items (self-excitation) and such excitation decays with time.

However, existing studies about repeat consumption (e.g. [3–5, 8, 16, 32]) do not focus on modeling how the tendency of repeat consumption fluctuates with time, especially the difference between items. As a result, they fail to capture various temporal dynamics across distinct items. Actually, it is noteworthy that different items demonstrate diverse temporal patterns of repeat consumption. In particular, there are both (1) *short-term* and (2) *life-time* effects. To illustrate these two factors, Figure 1 gives an example of two items' purchase tendencies (baby diaper and feeding bottle) drifting with time. For a new mother, both baby diaper and feeding bottle are needed, so the base purchase tendencies are similar at first. After she buys both items simultaneously, their purchase tendencies increase immediately and diminish with time (*short-term effect*), which means the mother probably consumes these two items again in a short term for some reasons such as future usage. On the

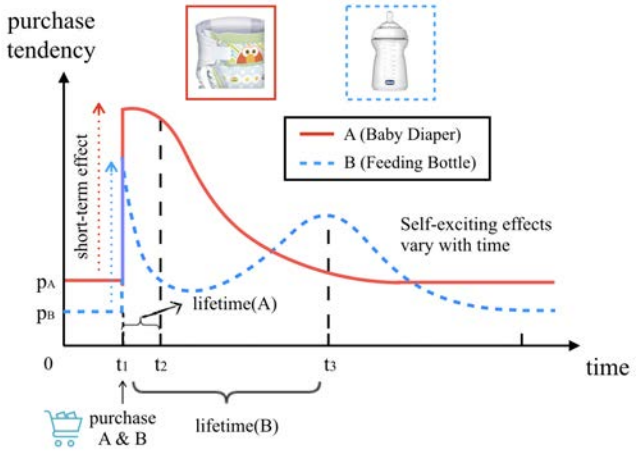

Figure 1: Illustration of two items' purchase tendencies drifting with time. There existing *short-term effect* for both baby diaper and feeding bottle after purchase, and such effect decays with time. On the other hand, *life-time effect* peaks after different periods of time, which is short for baby diaper (superposed with short-term effect) but long for feeding bottle. Both items' purchase tendencies finally decay to their basic values as time goes by.

other hand, users also tend to purchase the item again near the end of item's lifetime [20, 30]. In Figure 1, the purchase tendency of feeding bottle has another spike around t_3 (*life-time effect*), which is probably the time to change a new one. With regard to baby diaper, lifetimes of such fast-moving consumer goods are so short that the corresponding effect is superposed with short-term effect, resulting in higher tendency shortly after purchasing. As time goes by, the self-exciting effect diminishes and both items' purchase tendencies return to their basic values. Such difference between items also holds for many other cases such as snacks for A and mobiles for B.

Current methods modeling repeat consumption do not jointly model both two characteristics for different items. However, the lack of variety of temporal factors can lead to lower predictive ability. For example, when life-time effect is not considered, the dominated short-term effect will result in continuous recommendation for mobiles shortly after purchasing one, which would be annoying to users. And mobiles could not be recommended when it is the time to change to a new one.

In this paper, firstly we conduct a detailed analysis of repeat consumption and temporal dynamics on four real-world datasets spanning over 30 months. Two key factors are revealed to model the complex time-varying patterns of repeat consumption: (1) *short-term effect* and (2) *life-time effect*. We find there are many repeat consumption shortly after previous purchase even for durable goods like baby walker (short-term effect). Besides, a consumption is likely to trigger next consumptions for the same item when item's lifetime runs out (life-time effect). Moreover, the importance of short-term and life-time effect can vary wildly between distinct items.

Then, based on these findings, we propose a holistic model that can recommends both novel and consumed items simultaneously, called SLRC referring to **S**hort-Term and **L**ife-Time **R**epeat **C**onsumption model. SLRC innovatively combines collaborative filtering (CF) [24] and Hawkes Process [17], with the two temporal characteristics of repeat consumption modeled by the kernel function in Hawkes Process. The CF part of the model projects users and items to the same space, in which similar representations stand for similar properties. As a result, the CF part helps to better capture users' preferences and explore novel items. While Hawkes process utilizes patterns of repeat consumption to properly rank consumed items higher at specific time (when users need items previously consumed again), leading to a holistic model with a good balance of exploration and exploitation. Moreover, the item-specific modeling of repeat consumption makes it possible to reveal fine-grained temporal patterns and automatically discover distinct items' lifetimes, which often need to be predefined in previous work [27]. The main contributions of this work can be summarized as follows:

- Two temporal dynamics of repeat consumption: (1) short-term effect and (2) life-time effect are revealed through empirical study, which vary a lot for distinct types of items.
- A unified model, **S**hort-Term and **L**ife-Time **R**epeat **C**onsumption model (SLRC), is proposed with innovative combination of two techniques: Collaborative Filtering (CF) and Hawkes Process. The model adaptively incorporates two item-specific temporal dynamics of repeat consumption into kernel function of Hawkes Process. And the integration of CF helps SLRC to better capture users' intrinsic preference, achieving a good balance of exploration and exploitation.
- Comparative experimental results on four datasets indicate SLRC is superior to previous models of repeat consumption. SLRC is also flexible to leverage different state-of-the-art recommendation algorithms and further enhance the performance and interpretability of originals.
- With high interpretability, SLRC is able to discover distinct items' lifetimes, and hence distinguish different kinds of items such as durable goods and fast-moving consumer goods.

2 RELATED WORK

2.1 Repeat Consumption

Repeat consumption has been studied in various domains, including web revisitation [2, 9, 29, 45], repeated web search queries [40, 41], music listening [20], time-limited coupons [32], and predicting consumption rate [28]. All the work demonstrates that repeat consumption is common and important in various fields.

Early explorations of repeat consumption utilize marginal utility in economics to make prediction [42]. The *Law Of Diminishing Marginal Utility* [7] states that an item's marginal utility decreases as its quantity grows. However, this law may not always hold especially in item purchasing scenario. For example, users may buy fast-moving consumer goods again and again regularly although the accumulated quantities are growing.

There is a series of work focusing on some simplified tasks related to repeat consumption to better model intrinsic patterns. Some work predicts whether a purchase will be a repeat consumption according to item features in current time window [11]. And some other work predicts which consumed item user will prefer given the fact that current consumption is a repeat consumption [3, 5, 12]. Especially, Anderson et al. find *recency* is a key factor with a cache-based method, indicating that users tend to purchase items recently

consumed [3]. Different from these studies, we focus to build a unified and holistic model that can recommend both consumed items and novel items simultaneously, where consumed items are only properly selected at the right time.

Further, Benson et al. [4] presents a holistic model of sequential repeat consumption, which introduces time factor, distance factor (*recency*) and quality factor. Most recently, Cai et al. [8] and Du et al. [16] utilize revamped Hawkes Process to model sequential online interactive behaviors and recurrent user activities, respectively. Although these methods can make holistic recommendation, they either estimate temporal patterns over all items or move one more step to model item-specific effect of previously consumed items (self-excitation or mutual-excitation), but the degree of excitation simply decays globally with time. All these studies are lack in taking various temporal dynamics of repeat consumption into consideration. Moreover, without integrating collaborative filtering methods, they may fail to accurately capture users' personalized preference.

2.2 Collaborative Filtering and Point Process

There are other two lines of research related to our work: *Collaborative Filtering* and *Point Process*.

Collaborative Filtering analyzes relationships between users and interdependencies among products to identify new user-item associations, which is domain free and more accurate than content-based techniques [25]. Latent factor model is one of the primary methods of collaborative filtering, in which users and items are characterized on some specific number of factors inferred from the interaction patterns. A series of latent factor models have been proposed to improve performance of item recommendation [6, 10, 18, 19, 23, 35, 36]. The utilization of mutual relationships between users and items enables these methods to better capture users' preference and discover novel items users may be interested in.

Point Process is good at modeling sequential events localized in time [14]. There have been many applications of point process, including modeling user influence in social network [39, 46], predicting earthquakes [33], paper citation count [44] and user return times [38]. As a variant of temporal point process, Hawkes Process [17] explicitly models the effect of previous events (self-excitation). The triggering kernel of intensity function in Hawkes Process controls how excitation varies with time. There have been several studies leveraging recurrent neural network (RNN) to derive intensity or replace triggering kernel [15, 34, 43], but it is hard for RNN to capture very long dependencies of repeat consumption when spanning over a long period of time. The lack of interpretability is also the main weakness. Recent work utilizes temporal point process to predict high-level human actions such as eating and biking, which accounts for three time-sensitive characteristics [26]. Compared to only 8-10 actions in the work, there are millions of items in personalized recommendation task, in which case their model contains intractably numerous parameters and will fail to explore endless novel items without integrating collaborative filtering.

We further build a holistic model with combination of Collaborative Filtering and Hawkes Process to take full advantage of both techniques. The CF part of the model captures users' inherent preference and helps to explore novel items, while two temporal dynamics of repeat consumption modeled by Hawkes Process makes it possible to properly exploit consumed items, leading to a good balance of exploration and exploitation.

Table 1: Statistics of Datasets.

Dataset	#user ($\|\mathcal{U}\|$)	#item ($\|\mathcal{I}\|$)	#entry ($\sum_u \|S_u\|$)	repeat ratio	time span
Baby	25.4k	7.6k	238.7k	17.8%	2012.09 - 2014.05
Order	34.6k	86.2k	820.4k	14.0%	2016.12 - 2018.03
Recsys2017	113.8k	44.7k	1240.4k	21.2%	2016.11 - 2017.02
BrightKite	29.7k	105.2k	3591.9k	90.0%	2008.03 - 2010.10

3 EMPIRICAL STUDY ON REPEAT CONSUMPTION

In this section, we first describe the task we are tackling. Then we make several observations about repeat consumption on four real-world datasets, which serve as the foundation of our model.

3.1 Task Definition

Given a target time $\hat{t}$ and a user's consumption history before $\hat{t}$, our task is to predict top-k items the user may be interested in at target time. Note that the recommendation list here can contain both novel items and consumed items. Formally, let $\mathcal{U}$ be the set of all users. Each user $u \in \mathcal{U}$ has a consumption sequence $S_u = \{(i_1, t_1), (i_2, t_2), \cdots, (i_{N_u}, t_{N_u})\} \in \mathcal{S}$ with N_u interactions. Each interaction consists of an item $i_n \in \mathcal{I}$ and corresponding time $t_n \in \mathbb{R}^+$ $(0 \leq t_n \leq T)$, which means user u consumed item i_n at time t_n. T is the total time span observed. $\mathcal{S}$ represents all the consumption sequence in data. The sequence is sorted by time in an ascending order, i.e., $t_n \leq t_{n'}$ for any $n < n'$. For simplicity, we denote a user's consumption sequence up to time t as $S_t^u = \{(i', t') | (i', t') \in S_u \wedge t' < t\}$.

Then, we define *repeat consumption* as below:

Definition 3.1. The interaction (i, t) conducted by user u is a *repeat consumption* if and only if $\exists (i', t') \in S_t^u : \ i' = i \wedge t' < t$

3.2 Dataset Description

To illustrate critical temporal patterns of repeat consumption, we use four datasets in distinct scenarios. The datasets are described below and the consumption statistics after filtering are summarized in Table 1.

Baby. This dataset contains online purchasing information within baby category from an e-commerce retailer.

Order. This dataset contains mobile payment records in supermarkets and convenient stores. We have provided the anonymized dataset online[1].

Recsys2017. Recsys Challenge 2017[2] is a competition for job recommendation, where the item is job posting and the consumption is clicking. Then a repeat consumption is that a user clicks the same job posting again after previous click. We use click interactions in open training data (offline phase).

[1] https://github.com/THUwangcy/SLRC/tree/master/data
[2] https://www.recsyschallenge.com/2017/

BrightKite. BrightKite was a location-based social networking website, where users could check in to physical locations. The data is publicly available[3] [13].

Each record in these datasets contains user-item pair and corresponding timestamp. Users and items with less than 5 associated interactions are filtered out. Besides, we remove two types of users: (1) interactions take place within one day (likely to be attracted by promotions); (2) consumes too frequently (more likely a merchant but a normal user). These four datasets cover consumptions in different scenarios, including both online and offline consumptions, as well as different scene of shopping, job seeking and check-in. Besides the ratio of repeat consumption varies across datasets. For *BrightKite*, 90% consumptions are repeat consumption, while the repeat ratio is moderate in other datasets.

3.3 Temporal Dynamics of Repeat Consumption

To reveal the temporal dynamics of repeat consumption, we try to figure out how previous consumption triggers next purchasing for the same item and how repurchasing tendency changes with time. However, it is hard to observe actual self-exciting pattern, which is latent and we can only observe consumption behavior as a result of the latent factor. Here, we resort to study the inter-consumption gap, which means the time interval between a user's two adjacent consumptions for the same item. Inter-consumption gap is a good indicator of how the tendency for consuming an item again varies with time. For example, if there is a lot of people purchasing milk one day after previous consumption, it indicates the tendency of repurchasing milk is high after one day.

Through investigating overall and item-level distributions of inter-consumption gap, we make two important empirical observations about repeat consumption. First, consumptions for most items are likely to trigger next consumption for the same item in the short term, which we call *short-term effect*. Second, some items tend to be consumed again centrally after a period of time, which we call *life-time effect*. These two types of effects serve as the foundation of the proposed SLRC model in the next section.

3.3.1 Short-term effect. Figure 2 shows the overall distribution of inter-consumption gap in the datasets. Except for *Recsys2017*, all the distributions monotonically decrease with a heavy tail. The distribution in *Recsys2017* also diminishes quickly in the beginning, which means generally there are a lot of repeat consumptions happening shortly after previous consumption. Such short-term effect is very common in daily life. Figure 3 shows different items' inter-consumption gap distributions in *Baby* and *Order* datasets. Take milk powder in Figure 3(b) for example, one may occasionally buy a kind of milk powder online and appreciates it very much. As a result, she purchases the milk powder again recently. Even for items that are not fast-moving consumer goods, like baby care cream in Figure 3(a), it is possible to repurchase them in a short term just as a gift to others or for other reasons. As a result, the time-decaying short-term effect can be leveraged to basically model the tendency to repurchase.

3.3.2 Life-time effect. Apart from short-term effect, there is also life-time effect for repeatedly consuming items. The distribution in

[3]https://snap.stanford.edu/data/loc-brightkite.html

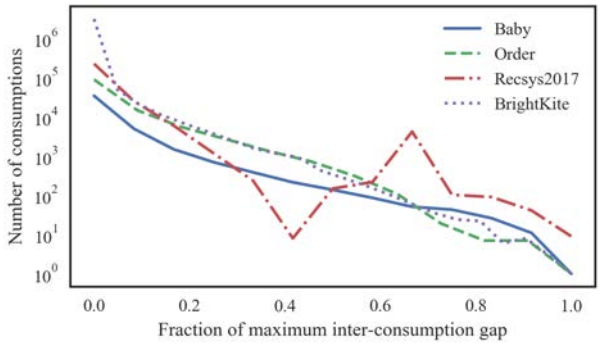

Figure 2: Distributions of inter-consumption gap. On the whole, most repeat consumptions happen shortly after the previous, while life-time effect is obvious in *Recsys2017* dataset.

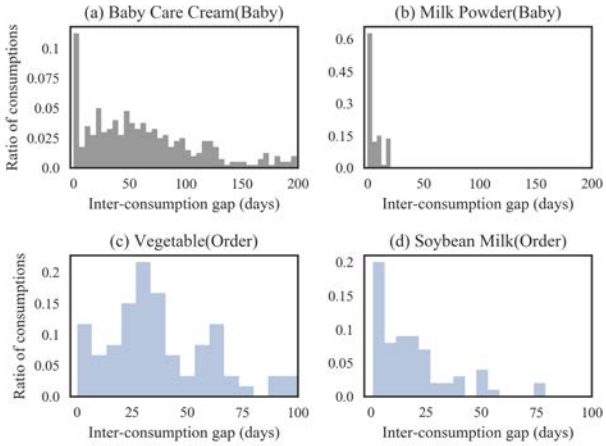

Figure 3: Inter-consumption gap distributions of different items. Various types of items inherently have distinct temporal dynamics of repeat consumption.

Recsys2017 dataset presents another spike after a long-period time, which means users may forget the information of previously clicked posts and click them again. Almost all items have their inherent lifetimes and demonstrates different time-varying patterns. For other datasets, the monotonically decreasing form on the whole can be a superimposed result of distinct distributions for various items. In Figure 3, we can see time-varying patterns differ from each other greatly. For example, in Figure 3(a)(c), baby care cream runs out in about 50 days and some families may go to supermarket monthly to resupply vegetables. When item's lifetime is going to run out, users will be more likely to purchase it again. Therefore, when taking life-time effect into consideration, we can make more accurate prediction at the right time (e.g. recommending durable goods consumed before after a long period when user tends to repurchase them).

In summary, two temporal patterns of repeat consumption: (1) *short-term effect* and (2) *life-time effect* are uncovered through investigation into inter-consumption gap distribution. More importantly, the importance of these two factors varies wildly across different items. Therefore, addressing item-specific temporal dynamics of repeat consumption will help to make more relevant recommendation.

4 SLRC MODEL

Based on the empirical observations above, we propose a holistic model with combination of collaborative filtering and Hawkes Process, which is named as **S**hort-Term and **L**ife-Time **R**epeat **C**onsumption (SLRC) model. Some preliminaries about temporal point process are introduced first. Then we detailedly describe model definition and parameter learning.

4.1 Preliminaries About Temporal Point Process

Formally, a temporal point process is a random process of which the realization consists of a list of discrete events localized in time, $\{t_n\}_{n\in\mathbb{N}}$ with the time $t_n \in \mathbb{R}^+$. In the scene of item consumption, $\{t_n\}_{n\in\mathbb{N}}$ represents a series of time that a user purchases some specific item. Given the history time of past events S_t, temporal point process introduces conditional intensity function $\lambda(t|S_t)$ representing a stochastic model for the time of the next event given all the times of previous events. For simplicity, we omit conditional sign and denote $\lambda(t)$ as conditional intensity function. Then, the probability for the occurrence of a new event given the history time S_t within a small time window $[t, t+dt)$ can be expressed as:

$$\lambda(t)dt = \mathbb{P}\{\text{event in } [t, t+dt) \mid S_t\} \,. \tag{1}$$

Besides, the conditional probability that an event does not happen since last observed time t_n is

$$U(t) = \exp\left(-\int_{t_n}^{t} \lambda(\tau)d\tau\right) \,. \tag{2}$$

Combining these two components, we have the conditional density function $f(t|S_t) = \lambda(t)U(t)$ that an event happens exactly at time t given all previous consumptions S_t [1].

The conditional intensity function $\lambda(t)$ takes various functional forms. A constant intensity leads to homogeneous Poisson Process, while non-homogeneous Poisson Process has time-varying intensity function but the events are still independent. Hawkes Process models excitations between events whose intensity function takes the form of:

$$\lambda(t) = \lambda_0 + \alpha \sum_{t_j < t} \gamma(t - t_j) \,, \tag{3}$$

where λ_0 represents the base intensity and every history event has an addictive self-exciting effect to current intensity, which varies with time and temporal characteristics are controlled by triggering kernel γ. α represents the degree of excitation.

4.2 Model Definition

Inspired by the intensity function in Hawkes Process (Eq. 3), we integrate collaborative filtering in base intensity and address both short-term and life-time effects in kernel function, leading to an intensity function in the following form:

$$\lambda^{u,i}(t) = \overbrace{\lambda_0^{u,i}}^{base} + \overbrace{\alpha_i \sum_{(t',i')\in S_t^u} I(i'=i)\gamma_i(t-t')}^{self-excitation} \,, \tag{4}$$

where the total intensity can be seen as a summation of base intensity $\lambda_0^{u,i}$ and the self-excitation[4] of all previous consumptions for item i.

4.2.1 Base intensity. Base intensity $\lambda_0^{u,i}$ models inherent personalized preference for different items. To accurately model the basic preference, we leverage collaborative filtering methods to derive the base intensity, such as Bayesian Personalized Ranking (BPRMF) and Neural Collaborative Filtering (NCF). Collaborative filtering methods model user's preference based on what she has consumed in the past and assume similar users like similar items, which helps to explore novel items. In the case of BPRMF, there is a K-dimensional latent factor for each user and item, p_u and q_i respectively. Then base intensity

$$\lambda_0^{u,i} = p_u^T q_i + b \,. \tag{5}$$

In the case of NCF, the base intensity is derived by a multi-layer neural network, which can be formulated as

$$\lambda_0^{u,i} = \phi_{out}(\phi_X(\cdots\phi_2(\phi_1(p_u^T, q_i^T))\cdots)) \,, \tag{6}$$

where ϕ_{out} and ϕ_x respectively denote the mapping function for the output layer and x-th neural collaborative filtering layer, and there are X neural CF layers in total.

We will show it is easy for SLRC model to leverage many state-of-the-art algorithms with joint parameters learning.

4.2.2 Self-excitation. In self-excitation part, $I(c)$ is an indicator function and returns 1 when c is true, otherwise 0. The triggering kernel $\gamma_i(\cdot)$ controls the temporal characteristics of self-excitation and varies with inter-consumption time interval $\Delta t = t - t'$. To explicitly address the two factors, we resolve $\gamma_i(\cdot)$ as a mixture distribution modeling short-term effect with Exponential distribution and life-time effect with Gaussian mixture distribution:

$$\gamma_i(\Delta t) = \overbrace{\pi_0^i E(\Delta t|\ 1/\beta^i)}^{short-term} + \overbrace{\sum_{z\in[1,Z]} \pi_z^i N(\Delta t|\ \mu_z^i, \sigma_z^i)}^{life-time} \,. \tag{7}$$

$E(x|\lambda)$ represents Exponential distribution with parameter λ, while $N(x|\mu,\sigma)$ is a Gaussian distribution with mean μ and standard deviation σ. The coefficient π_z^i satisfy the limit that $\sum_{z\in[0,Z]} \pi_z^i = 1$. From Eq. 7, we can see there are two factors in self-excitation:

Short-term effect. As shown in Section 3.3.1, short-term effect is really common and important for modeling repeat consumption. From Figure 2, the short-term effect diminishes quickly as time goes by, in which case an item-specific Exponential distribution is suitable for modeling it.

Life-time effect. Life-time effect also greatly influences user's repurchasing tendency, which often causes a raise of tendency after specific time intervals (e.g. 50 days after purchasing baby care cream when it is time to run out). As a result, it's natural to choose Gaussian mixture distribution to model life-time effect, for sometimes item's lifetime can be multimodal. But in our experiments,

[4]Here we only consider self-excitation (influence by the same item) because we mainly focus on repeat consumption. We leave the mutual-excitation caused by other items as future work.

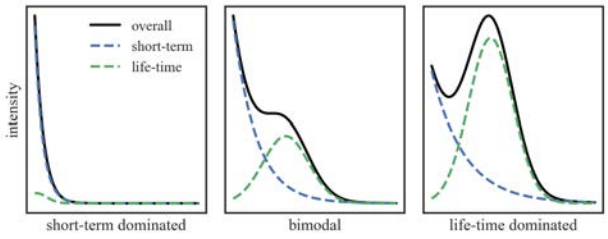

Figure 4: Illustration on the joint impact of various temporal dynamics on time-varying trends of overall intensity, characted by the triggering kernel.

we find a single Gaussian distribution is strong enough, with its mean standing for item's expected lifetime. Therefore we choose to set $Z = 1$ without loss of generality. If items' lifetimes demonstrate more complex patterns in datasets, larger Z can be chosen through cross-validation. When $Z = 1$, the triggering kernel $\gamma_i(\cdot)$ can be simplified as:

$$\gamma_i(\Delta t) = (1 - \pi^i)E(\Delta t|\ 1/\beta^i) + \pi^i N(\Delta t|\ \mu^i, \sigma^i),\ \pi^i \in [0, 1]\ . \quad (8)$$

All the parameters related to self-excitation $\Theta_s = \{\boldsymbol{\alpha}, \boldsymbol{\pi}, \boldsymbol{\beta}, \boldsymbol{\mu}, \boldsymbol{\sigma}\}$ are item-specific. We make the degree of excitation α^i a summation of global degree and item bias: $\alpha^i = \alpha + \alpha^i_b$, in which case global α can capture average degree of excitation. Figure 4 conceptually visualize how we separately model two temporal dynamics in self-excitation part, which shows different time-varying trends of overall intensity (black) can be represented as the summation of short-term effect (blue) and life-time effect (green).

As intensity $\lambda^{u,i}(t)$ indicates the tendency of consumption, the recommendation list can be derived by the followings: we calculate the intensity value of each candidate item (including novel items and consumed items) for user u at time t firstly. Then, all candidate items are ranked according to their intensity value. The top-k items in the ranked list will be recommended to users.

Different from previous work [5, 8, 31, 32, 43], we focus to build a holistic model that can recommend both novel items and consumed items. The integration of collaborative filtering methods helps to better balance recommendation of the two kinds of items. Besides, we address two temporal dynamics of repeat consumption with specifically designed item-specific triggering kernel, which is concise and powerful with high interpretability. There may be other methods to address these two factors, but what we want to do is preliminarily exploring how to incorporate item-specific temporal dynamics of repeat consumption into recommender systems. Therefore we leave other forms of intensity function as future work.

4.3 Parameter Learning

As all candidate items are ranked according to intensity value $\lambda^{u,i}(t)$, we can adopt pairwise ranking loss for optimization. For each consumption (u, i_n, t_n), a negative item i_n^- is randomly sampled from items user haven't consumed, i.e. $\mathcal{I} \backslash I_u$ (I_u is a set of unique items consumed by user u). The pairwise ranking loss is defined as follows:

$$\mathcal{L}(\Theta|\mathcal{S}) = -\sum_{n\in\mathcal{U}}\sum_{n=1}^{N_u} \log\sigma\left(\lambda^{u,i_n}(t_n) - \lambda^{u,i_n^-}(t_n)\right) + \Omega(\Theta_b)\ . \quad (9)$$

Remind that the base intensity λ_0^{u,i_n^u} can be derived by different methods. We denote Θ_b as parameters related to calculating base intensity (e.g. $\Theta_b = \{\boldsymbol{p}, \boldsymbol{q}, b\}$ for BPRMF). Θ_b may have various forms when our model leverages different algorithms. We add a $\mathcal{L}_2$ regularizer $\Omega(\Theta_b)$ to prevent the base intensity overfitting data. On the other hand, parameters related to self-excitation can be denoted as Θ_s ($\Theta = \Theta_b \cup \Theta_s$). Θ_b and Θ_s are learned together with the unified loss (Eq. 9).

Due to the success of Adam algorithm [22] in many recommendation models' parameter learning procedures, we use Adam as the learning algorithm to minimize the pairwise ranking loss. Note that such optimization method makes it easy and efficient for joint learning of parameters when leveraging different algorithms to derive base intensity.

5 EXPERIMENTS

5.1 Experimental Settings

5.1.1 Datasets and evaluation protocols. We use the same datasets described in Section 3.2, including consumptions in various scenarios. For each consumption sequence $S_u \in \mathcal{S}$, we leave the interactions at the latest time as test dataset and the interactions at the secondly latest time as validation dataset. All the remaining data are used for training. The repeat consumption ratio of each test dataset is similar with overall repeat ratio (as shown in Table 1). And for each test or validation case, we recommend top-k ($k = 5, 10$) items from a given candidate set containing ground-truth items. Considering it is too time-consuming to rank all items for some methods when dataset is large, we randomly sample a certain number of negative items besides ground-truth items to construct candidate set. The negative items are randomly sampled from all the items except for ground truth, which means the candidate set may contain both items that user has never consumed and previously consumed items (but not bought this time, which are also negative examples for this consumption). The candidate sets stay the same for all models' training and testing. As for the size of candidate set, we make it relevant to the number of unique items in the dataset (500, 5000, 2500, 5000 for *Baby*, *Order*, *Recsys2017*, *BrightKite* respectively).

To evaluate the quality of recommendation, we use Recall and *Normalized Discounted Cumulative Gain* (NDCG) as evaluation metrics. Recall measures how many ground-truth items are recommended, while NDCG concerns about whether ground-truth items are ranked higher than others by accounting for the position of hit. We calculate both metrics for each user in test or validation dataset and report the average score.

5.1.2 Baseline Methods. We compare SLRC to nine baselines in different aspects. The first three baselines are collaborative filtering models and do not take repeat consumption into consideration:

- **BPRMF**. This method apply a pairwise ranking loss to optimize Matrix Factorization (MF) model, which is competitive for item recommendation [36].

Table 2: Experimental results (higher is better). Bold face indicates the best result of each column in a particular metric. Best baseline in each metric is underlined. The relative improvement SLRC gains compared to originals is listed within parentheses. Value is significantly better than the strongest baseline ($p < 0.01$).**

- **Tensor**. Tensor factorization is widely used in context-aware recommendation [21]. Here we split the continuous time into bins and handle a three dimensional tensor (user-item-time).
- **NCF**. This is a state-of-the-art collaborative filtering method that utilizes neural networks to capture complex relationship between users and items in latent space [18].

Another three baselines incorporate repeat consumption information and can make holistic item recommendation:

- **FPMC**. This method combines MF and factorized Markov Chains with a user-specific transition matrix, which utilizes the sequence information of each user [37].
- **UtilitySVD**. This method utilizes marginal utility to model repeat consumption, where users' preference for items will change according to consumed quantity [42].
- **HCM**. It is a holistic generative model for sequential repeated consumption, which takes time, quality and distance factor into consideration. We use the last two parts of the model to conduct top-k recommendation [4].

The last three are related to Hawkes Process with similar task:

- **TSR-Hawkes**. This model aims at Time-Sensitive Recommendation with low-rank Hawkes Process, in which core parameters are assumed to have low-rank structure. The triggering kernel decays globally with time [16].
- **Neu-Hawkes**. Mei et al. [34] propose a neural Hawkes process model that uses recurrent layer to derive intensity according to events history. A novel continuous-time LSTM architecture is utilized where each memory cell exponentially decays toward some steady-state value.
- **LS-Hawkes**. The model captures long- and short-term dependency between actions with two different Hawkes Process, while both of the triggering kernels simply decay in a global way [8].

The first three baselines will further be leveraged to derive the base intensity $\lambda_0^{u,i}$ in our SLRC model. We denote the unified model as $\text{SLRC}_{\text{method}}$, such as $\text{SLRC}_{\text{BPRMF}}$.

As for other work about repeat consumption [3, 5, 11, 12] referred to in Section 2, they are used either to classify repeat consumption or to predict only items consumed before. Neither of them focuses to recommend both consumed items and novel items simultaneously. So they cannot be taken as baseline methods.

5.1.3 Implement details. We implement SLRC model in *TensorFlow* and the code has been open source[5]. We tune hyperparameters based on NDCG@10 in the validation dataset and report the results in the test dataset. All models are trained with Adam optimizer until converge with a maximum of 200 epochs. Each experiment is repeated 5 times with different random seed and the average result is reported.

For fair comparison, the batch size is fixed to 128 and the latent dimension for all models is 100. As for parameter initialization, global excitation α and parameters in mixture distribution $\boldsymbol{\beta}, \boldsymbol{\sigma}$ are initialized with 1; item bias of excitation degree α_b^i is all initialized with 0. $\boldsymbol{\pi}$ is normally initialized with 0.5 mean; $\boldsymbol{\mu}$ is also normally initialized and the mean is global average inter-consumption time interval. Other parameters are normally initialized with 0 mean. All normal initializers have 0.01 standard deviation.

5.2 Performance

Table 2 shows the performance of all baselines and the improved methods when incorporating SLRC model.

First, the performances of different baselines vary across datasets. Tensor, Neu-Hawkes, LS-Hawkes, HCM performs the best among all baselines in *Baby*, *Order*, *Recsys2017*, *BrightKite*, respectively, which shows capacities of different models in various scenarios. Tensor performs quite well in *Baby*, which may be the result of long time span and time sensitivity in this dataset. As state-of-the-art models based on Hawkes Process, Neu-Hawkes and LS-Hawkes performs robustly in all the datasets, and become the most competitive baselines in *Order* and *Recsys2017*. As for HCM, it achieves the best performance among baselines in *Brightkite* because of its high repeat consumption ratio (90%). Explicitly predicting whether current consumption will be repeat consumption in HCM greatly narrow the range of candidate items to consider. But in other datasets with
