Chinese named entity recognition is usually modeled as a character-level sequence labeling problem [10, 22], since Chinese sentence is a string of characters and there is no explicit delimiter like whitespace to separate characters into words. Statistical sequence modeling methods such as CRF [15] are widely used in Chinese NER [24, 27]. A core step in these methods is building feature representation for each character in sentence. Traditionally, these character features are manually designed [1, 32]. For example, character unigrams, bigrams and clusters are used as character features in [1]. Zhang et al. [33] proposed to build character features using surrounding characters and whether target character is in external dictionaries. Yu et al. [32] proposed to combine character-level features, word-level features, POS tagging features and dictionary features for CNER. These handcrafted features require a large amount of domain knowledge to design and many of them rely on external resources such as gazetteers, which may not exist in many domains. Moreover, handcrafted features such as character n-grams usually cannot capture global context information. Different from above methods, our approach can learn character feature representations from data without feature engineering, and can incorporate both local and long-distance context information.

In recent years, neural network methods have been applied to English NER [14, 16]. Most of these methods are based on LSTM-CRF architecture. For example, Lample et al. [16] used Bi-LSTM to learn hidden representations of words and used CRF to do label decoding. These methods for English NER are usually based on word-level input, and cannot be directly applied to Chinese NER which is a character-level sequence labeling task. CNN is exploited in [3] and [25] to learn word representations from characters for English NER. These word representations are combined with word embeddings and/or other features to build word features. However, there is no explicit word boundaries in Chinese texts. Thus, these CNN incorporated methods for English NER are not suitable for Chinese NER. Different from these methods, in our approach CNN is used to learn representations of characters rather than words.

Recently, neural network methods are also applied to Chinese NER [6, 7, 12]. These methods are based on LSTM-CRF framework, where LSTM is used to learn hidden representations of characters and CRF is used for joint labeling decoding. Many of these methods also incorporate handcrafted features, such as radical features [7] and position features [12], to build character representations. Different from these methods, our approach can train CNER model in an end-to-end manner and does not need any manual feature engineering. In addition, our approach is based on the CNN-LSTM-CRF architecture to fully capture both local and long-distance contexts.

Jointly training NER model with related tasks has the potential to improve the performance of NER [23, 28]. For example, Luo et al. [23] proposed to jointly train NER and entity linking models, and achieved state-of-the-art performance on English NER. Since Chinese texts lack word delimiters and identifying entity boundaries is very challenging in CNER, we propose to jointly train CNER model with word segmentation to improve the ability of CNER model in identifying entity boundaries. Similar with our approach, Peng et al. [28] proposed to jointly train CNER and CWS models in domain adaptation scenario. In their method, CNER and CWS share the same character representation model and have different label decoding models. In our approach we regard word segmentation as an auxiliary task and use it to learn word boundary aware character representations for CNER. Experiments show that our approach is more effective. In addition, we propose to automatically generate pseudo labeled samples from labeled data, which to our best knowledge has not been explored in existing CNER methods.

3 OUR APPROACH

In this section we introduce our approach for CNER in detail. First, we present the CNN-LSTM-CRF neural architecture for CNER. Next, we introduce a unified framework to jointly train CNER and word segmentation models. Finally, we introduce an automatic method to generate pseudo labeled samples from existing labeled data.

3.1 CNN-LSTM-CRF Architecture for CNER

Our proposed CNN-LSTM-CRF neural architecture for Chinese named entity recognition is illustrated in Fig. 1. Next we introduce each layer from bottom to top in detail.

The first layer is character embedding, which aims to convert a sentence from a sequence of characters into a sequence of dense vectors. In this layer, an embedding matrix $\mathbf{E} \in \mathcal{R}^{D \times V}$ is used to map each character into a dense vector, where D is embedding dimension and V is vocabulary size. Denote an input sentence as $s = [w_1, w_2, ..., w_N]$, where N is sentence length and $w_i \in \mathcal{R}^V$ is the

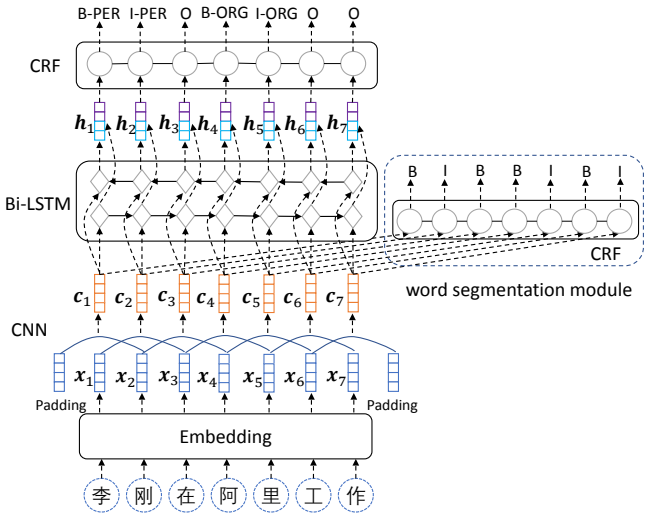

Figure 1: The framework of our approach.

one-hot representation of the i_{th} character. The output of this layer is a sequence of vectors $[\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N]$, where $\mathbf{x}_i = \mathbf{E}w_i \in \mathcal{R}^D$.

The second layer is a CNN network. CNN has been widely used in computer vision field to extract local information of images [17]. The local context of sentences is also very important for Chinese named entity recognition. For example, the word "阿里" is a location entity in "西藏阿里", while is a organization entity in "杭州阿里". Motivated by these observations, we propose to use CNN to capture the local context information for CNER. Denote $\mathbf{w} \in \mathcal{R}^{KD}$ as a filter in CNN where K is the window size, then the contextual representation of the i_{th} character learned by this filter is:

$$c_i = f(\mathbf{w}^T \times \mathbf{x}_{\lfloor i-\frac{K-1}{2} \rfloor : \lfloor i+\frac{K-1}{2} \rfloor}), \tag{1}$$

where $\mathbf{x}_{\lfloor i-\frac{K-1}{2} \rfloor : \lfloor i+\frac{K-1}{2} \rfloor}$ represents the concatenation of the embeddings of characters from $\lfloor i-\frac{K-1}{2} \rfloor$ to $\lfloor i+\frac{K-1}{2} \rfloor$, and f is the activation function. Here we select ReLU [17] as the activation function. In this layer, we use multiple filters with different window sizes (ranging from 2 to 5) to learn contextual character representations. Denote the filter number as M. The contextual representation of the i_{th} character (denoted as $\mathbf{c}_i$) is the concatenation of the outputs of all filters at this position. The output of the CNN layer is $\mathbf{c} = [\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_N]$, where $\mathbf{c}_i \in \mathcal{R}^M$.

The third layer is a Bi-LSTM network. LSTM is a special type of recurrent neural networks (RNN) which can capture long-distance sequence information and is powerful in modeling sequential data. LSTM can generate hidden states for tokens in a sequence using all previous contexts, which is beneficial for Chinese named entity recognition. For example, in sentence "阿里是中国非常著名的IT企业" (Alibaba is a famous Chinese IT company), although "IT企业" has a long distance with "阿里", it is very important for inferring that "阿里" is an organization entity. In addition, both left and right contexts can be useful for recognizing named entities. Thus, we use bidirectional LSTM (Bi-LSTM) to learn hidden representations of characters from global contexts. Denote $\overrightarrow{lstm}$ as the LSTM scanning text from left to right, and $\overleftarrow{lstm}$ as the LSTM scanning text from right to left, then the hidden representations learned by these LSTMs can be represented as $[\overrightarrow{\mathbf{h}_1}, \overrightarrow{\mathbf{h}_2}, ..., \overrightarrow{\mathbf{h}_N}] = \overrightarrow{lstm}([\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_N])$ and $[\overleftarrow{\mathbf{h}_1}, \overleftarrow{\mathbf{h}_2}, ..., \overleftarrow{\mathbf{h}_N}] = \overleftarrow{lstm}([\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_N])$. The hidden representation of the i_{th} character is a concatenation of $\overrightarrow{\mathbf{h}_i}$ and $\overleftarrow{\mathbf{h}_i}$, i.e., $\mathbf{h}_i = [\overrightarrow{\mathbf{h}_i}, \overleftarrow{\mathbf{h}_i}]$. The output of the Bi-LSTM layer is $\mathbf{h} = [\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N]$, where $\mathbf{h}_i \in \mathcal{R}^{2S}$ and S is the dimension of hidden states in LSTM.

The fourth layer in our model is conditional random field (CRF). In NER, neighboring labels usually have strong dependencies [25]. For example, *I-PER* label usually follows *B-PER* and *I-PER*, but it cannot follow *B-ORG* or *I-ORG*. Thus, it is beneficial to jointly decode the labels of characters in a sequence rather than decode them independently [4]. In this paper, we use first-order linear chain CRF [15] to jointly decode the labels of characters.

Denote $\mathbf{y} = [y_1, y_2, ..., y_N]$ as the label sequence of sentence s, where $y_i \in \mathcal{R}^L$ is the one-hot representation of the i_{th} character's label, and L is the number of labels. The input of the CRF layer is the hidden representations of characters generated by the Bi-LSTM layer, i.e., $\mathbf{h} = [\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N]$, and the output of the CRF layer is the label sequence $\mathbf{y}$. CRF is a probabilistic model. The conditional probability of label sequence $\mathbf{y}$ given input $\mathbf{h}$ is computed as follows:

$$p(\mathbf{y}|\mathbf{h};\theta) = \frac{\prod_{i=1}^{N} \psi(\mathbf{h}_i, y_i, y_{i-1})}{\sum_{\mathbf{y}' \in \mathcal{Y}(s)} \prod_{i=1}^{N} \psi(\mathbf{h}_i, y'_i, y'_{i-1})}, \tag{2}$$

where $\mathcal{Y}(s)$ is the set of all possible label sequences of sentence s, θ is the parameter set, and $\psi(\mathbf{h}_i, y_i, y_{i-1})$ is the potential function. In our approach, the potential function is:

$$\psi(\mathbf{h}_i, y_i, y_{i-1}) = \exp(y_i^T \mathbf{W}^T \mathbf{h}_i + y_{i-1}^T \mathbf{T} y_i), \tag{3}$$

where $\mathbf{W} \in \mathcal{R}^{2S \times L}$ and $\mathbf{T} \in \mathcal{R}^{L \times L}$ are parameters of the CRF layer, and $\theta = \{\mathbf{W}, \mathbf{T}\}$ in Eq. (2).

The loss function of our approach is the negative log-likelihood over all training samples, which can be formulated as follows:

$$\mathcal{L}_{NER} = -\sum_{s \in \mathcal{S}} \log(p(\mathbf{y}_s|\mathbf{h}_s;\theta)), \tag{4}$$

where $\mathcal{S}$ is the set of sentences in training data, $\mathbf{h}_s$ and $\mathbf{y}_s$ are the hidden representations and label sequence of sentence s.

3.2 Joint Training with Word Segmentation

The NER task can be regarded as a combination of two sub-tasks: extracting entity names from texts (i.e., identifying the boundaries of entity names) and classifying their types. Identifying the boundaries of Chinese entity names is quite challenging, since there is no explicit word delimiters in Chinese texts. For example, many existing Chinese NLP tools such as LTP predict that "特朗" is an entity name in the sentence "习近平常与特朗普通电话", while the correct entity name is "特朗普".

In Chinese natural language processing field, the goal of Chinese word segmentation (CWS) is segmenting Chinese texts into words (in other words, predicting the boundaries of words in texts). Thus, CWS is highly related to CNER and has the potential to help CNER predict entity boundaries more accurately. Motivated

by this observation, we propose to enhance the ability of CNER model in identifying entity boundaries by jointly training CNER and CWS models. Similar with CNER, CWS is also usually modeled as a character-level sequence labeling problem [2, 10, 21], and CRF is widely used in CWS methods. Our unified framework for jointly training CNER with CWS is shown in Fig. 1. In our framework the CNER and CWS models share the same character embeddings and CNN network. In this way, the useful information in word segmentation can be encoded to learn word boundary aware contextual character representations, which is useful for predicting entity boundaries. The loss function of the CWS module is:

$$\mathcal{L}_{CWS} = -\sum_{s \in \mathcal{S}} \log(p(\mathbf{y}_s^{seg} | \mathbf{c}_s; \theta^{seg})), \tag{5}$$

where $\mathbf{y}_s^{seg}$ is the label sequence of sentence s for word segmentation, and θ^{seg} is the parameter set of CWS model. $\mathbf{c}_s$ is the hidden character representations of sentence s output by the CNN network.

The final objective function of our approach is the combination of the CNER loss and the CWS loss as follows:

$$\mathcal{L} = (1 - \lambda)\mathcal{L}_{NER} + \lambda \mathcal{L}_{CWS}, \tag{6}$$

where $\lambda \in [0, 1)$ is a coefficient to control the relative importance of the CWS loss in the overall loss.

3.3 Pseudo Labeled Data Generation

The labeled data for Chinese named entity recognition is usually scarce in many domains. Manually annotating sufficient samples for CNER is time-consuming and expensive. Thus, an automatic method to generate labeled samples for CNER will be very useful. In this paper we propose to automatically generate pseudo labeled samples based on existing labeled data. Our method is motivated by the observation that if an entity name in a sentence is replaced by another entity name with the same concept, then the new sentence is usually correct in grammar and semantics. For example, a Chinese sentence may be "李刚在阿里工作", where "李刚" is a person entity and "阿里" is a company entity. If "王小超" is another person name and "谷歌" is another company name, then we can obtain a new sentence by replacing "李刚" with "王小超" and "阿里" with "谷歌", i.e., "王小超在谷歌工作". If we have the NER labels of the original sentence, then we can easily infer the NER labels of the pseudo sentence. For instance, if the NER labels of the original sentence in aforementioned example are "B-PER/I-PER/O/B-ORG/I-ORG/O/O", then the NER labels of the pseudo sentence are "B-PER/I-PER/I-PER/O/B-ORG/I-ORG/O/O". In addition, if we have CWS labels of the original sentence, then we can also automatically obtain CWS labels of the pseudo sentence, since entity names are usually regarded as independent words. For instance, in aforementioned example, if the CWS labels of the original sentence are "B/I/B/B/I/B/B/I", then the CWS labels of the pseudo sentence are "B/I/I/B/B/I/B/B/I".

In our method, given a set of labeled samples for CNER, we first extract all the entity names (denoted as *EN*) from them. Then we randomly select a labeled sentence, and replace each entity in this sentence with an entity randomly sampled from *EN* which has the same concept. In this way a pseudo sentence is generated and its NER labels (as well as CWS labels) can be automatically inferred. This step is repeated multiple times until a predefined number of pseudo labeled samples are generated.

4 EXPERIMENTS

4.1 Datasets and Experimental Settings

Two benchmark datasets for Chinese named entity recognition are used in our experiments. The first one is the MSRA corpus released by the third SIGHAN Chinese language processing bakeoff[1] (denoted as *Bakeoff-3*). It contains 46,364 sentences for training and 4,365 sentences for test. The second dataset is the MSRA corpus released by the fourth SIGHAN Chinese language processing bakeoff[2] (denoted as *Bakeoff-4*). This dataset contains 23,181 training sentences and 4,636 test sentences. Both datasets contain three types of named entities, i.e., *person* (denoted as *PER*), *location* (denoted as *LOC*) and *organization* (denoted as *ORG*). The statistics of these datasets are summarized in Table 1.

Table 1: The statistics of datasets. *#Sen* and *#Ent* represent the numbers of sentences and entities.

Dataset	*Training*		*Test*		
	#Sen	*#Ent*	*#Sen*	*#Ent*	*OOV Rate*
Bakeoff-3	46,364	74,528	4,365	6,190	28.16%
Bakeoff-4	23,181	37,811	4,636	7,707	21.42%

Following [31], we use *BIO* tagging scheme for CNER, where *B*, *I* and *O* respectively represent the beginning, inside and outside of entity name. The labels *B* and *I* are further combined with entity types, such as "B-PER" and "I-LOC". As for CWS, we use the *BI* tagging scheme. In the *Bakeoff-3* dataset the annotation of word segmentation in training set is provided, while in the *Bakeoff-4* dataset it is not provided. Thus, we used LTP[3] tool to segment the sentences in the training set of the *Bakeoff-4* dataset. Note that the word segmentation information is not involved in the test data.

In our experiments, the embeddings of characters are pretrained on the Sogou News Corpus[4] using the word2vec tool[5]. The dimension of character embedding is 200. These embeddings are tuned during model training. Since dropout method [30] is an effective way to mitigate overfitting, we apply it to the outputs of embedding, CNN and LSTM layers. Our approach is implemented using Tensorflow library, and RMSProp [5] is used as the optimization algorithm to learn model parameters. Hyperparameters are selected according to cross-validation on training data. In detail, the number of filters in CNN network is 400, the hidden state size of LSTM is 200, the dropout rate is 0.2, and the λ in Eq. (6) is 0.4. In each experiment, we randomly sample 10% of the training data for validation and the remaining for model training. Each experiment is repeated 10 times, and the average results are reported.

4.2 Performance Evaluation

First we compare the performance of our approach with different neural network based CNER methods, including: 1) *LSTM+CRF*, using Bi-LSTM to learn character representations and CRF to decode labels [28]; 2) *LSTM+Softmax*, using Bi-LSTM to learn character representations and softmax for label decoding; 3) *MDA*, multi-task domain adaptation method proposed by Peng et al. [28], which jointly trains CNER and CWS models via multi-task learning; 4) *LSTM+CRF+Pseudo*, *LSTM+CRF* trained on both original and pseudo labeled samples; 5) *CLC*, our CNN-LSTM-CRF architecture for CNER; 6) *CNN+LSTM+Softmax*, replacing the CRF layer in *CLC* with a softmax layer; 7) *CLC+Joint*, our unified framework for jointly training CNER and CWS models; 8) *CLC+Pseudo*, *CLC* trained on both original and pseudo labeled samples; 9) *CLC+Joint+Pseudo*, *CLC* with both joint training and pseudo labeled data.

We conducted experiments on different ratios (i.e., 5%, 25% and 100%) of training data to test the performance of different methods with insufficient and sufficient labeled samples. For those methods which involve pseudo labeled samples, the number of pseudo samples is the same with the real labeled samples. The experimental results on the *Bakeoff-3* and *Bakeoff-4* datasets are shown in Tables 2 and 3 respectively. We have several findings from the results.

First, our CNN-LSTM-CRF architecture (*CLC*) performs better than the popular *LSTM-CRF* architecture [28] on Chinese NER. For example, on the *Bakeoff-3* dataset, the improvement of *CLC* over *LSTM-CRF* in terms of Fscore is 6.08% on 5% training data and 3.31% on 100% training data. These results validate that our CNN-LSTM-CRF architecture is more suitable for Chinese NER than LSTM-CRF. This is because our model can capture both local and long-distance contexts of sentences to learn contextual character representations, which is useful for Chinese NER.

Second, joint label decoding via CRF is better than independent label decoding for Chinese NER . For instance, *CLC* performs much better than *CNN+LSTM+Softmax*, and *LSTM+CRF* can consistently outperform *LSTM+Softmax*. This is because there are strong dependencies between neighboring NER labels, and CRF can effectively capture these dependencies. In addition, *CNN+LSTM+Softmax* consistently outperforms *LSTM+Softmax*, although they both use independent label decoding. It further validates better character representations can be learned by combing CNN and LSTM to capture both local and long-distance contexts.

Third, by jointly training CNER and CWS models using our unified framework, our approach (i.e., *CLC+Joint*) can achieve better performance, especially when training data is insufficient. This is because there is inherent relatedness between CNER and CWS, since CNER model needs to identify entity boundaries and the goal of CWS is to identify word boundaries. Experimental results show that our unified framework is effective in exploiting the inherent

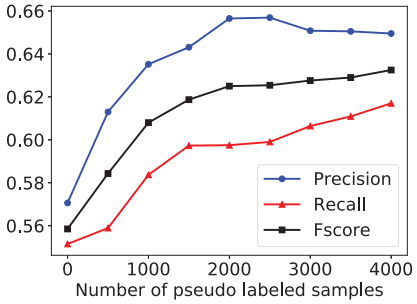

Figure 2: The influence of pseudo labeled data size.

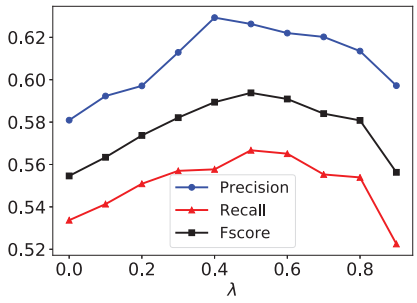

Figure 3: The influence of λ value.

relatedness between CNER and CWS, and can improve the ability of CNER model in identifying entity boundaries via jointly training CNER and CWS models. *MDA* method [28] also combines CNER and CWS. Our *CLC+Joint* approach can consistently outperform *MDA*. There are two major differences between our approach and *MDA*. First, our approach is based on the CNN-LSTM-CRF architecture while *MDA* is based on LSTM-CRF. Second, in *MDA* method CNER and CWS are regarded as equally important and share the same character representations, while in our approach CWS is regarded as an axillary task and used to learn word boundary aware character representations from local contexts. These results indicate our approach is more suitable to exploit the useful information in word segmentation for CNER.

Fourth, the automatically generated pseudo labeled samples can effectively improve the performance of our approach and baseline methods. For example, *CLC+Pseudo* significantly outperforms *CLC*, and *LSTM+CRF+Pseudo* consistently outperforms *LSTM+CRF*, especially in terms of OOV recall. Besides, the performance improvement becomes bigger when training data is insufficient. These results validate that the pseudo labeled samples automatically generated from labeled data can provide useful information for training CNER model. They can improve the generalization ability of CNER model by encouraging it to capture the contextual patterns of entity names, which is important for recognizing OOV entities. Moreover, accoding to Tables 2 and 3, after incorporating both pseudo labeled samples and joint training with CWS, the performance of our approach (*CLC+Joint+Pseudo*) can be further improved.

4.3 Influence of Pseudo Labeled Samples

Next we explore the influence of the number of automatically generated pseudo labeled samples on the performance of our approach. We conducted experiments on both datasets and the results on the *Bakeoff-4* dataset with 5% training data are shown in Figure 2. The results on the *Bakeoff-3* dataset show similar patterns.

According to Figure 2, as the number of pseudo labeled samples increases, the recall and Fscore of our approach consistently improve, while the precision first increases and slightly declines afterwards. These results show that the pseudo labeled samples automatically generated from labeled data can provide useful information for training CNER model and can improve its ability in capturing contextual patterns of entity names, which is beneficial for identifying OOV entities. Thus, the recall of our approach continuously improves when more pseudo labeled samples are incorporated. However, when too many pseudo labeled samples are used, the CNER model may overfit these patterns, resulting in the slight decline of precision.

4.4 Influence of Hyperparameters

In this section we conduct experiments to explore the influence of hyperparameters on the performance of our approach. Due to space limit, here we only show the influence of the most important hyperparameter on our approach, i.e., λ in Eq. (6). The results are summarized in Figure 3. This experiment was conducted on the *Bakeoff-4* dataset with 5% training data. λ is used to control the relative importance of CWS loss in the overall loss of our joint training framework (Eq. (6)). According to Figure 3, the performance of our approach improves when λ increases from 0, and declines when λ becomes too large. This is because when λ is too small, the useful information in word segmentation is not fully exploited. Thus, the performance is not optimal. When λ becomes too large, the auxiliary CWS task is over-emphasized and the loss of NER is not fully respected. Thus, the performance is also not optimal. A moderate value of λ is most suitable for our approach.

5 CONCLUSION

In this paper we propose a neural approach for Chinese named entity recognition. First, we propose a CNN-LSTM-CRF neural architecture for Chinese NER, where CNN and Bi-LSTM networks are used to learn character representations from both local and long-distance contexts, and CRF is used for joint label decoding. Second, we propose a unified framework to jointly train Chinese named entity recognition and word segmentation models to exploit the inherent relatedness between these two tasks and enhance the ability of Chinese NER model in identifying entity boundaries. In addition, we propose an automatic method to generate pseudo labeled samples from existing labeled data to enrich the training data. Extensive experiments on two benchmark datasets validate that our approach can effectively improve the performance of Chinese named entity recognition especially when training data is insufficient, and can consistently outperform many baseline methods.

ABSTRACT

Semi-supervised multi-view feature learning (SMFL) is a feasible solution for webpage classification. However, how to fully extract the complementarity and correlation information effectively under semi-supervised setting has not been well studied. In this paper, we propose a semi-supervised multi-view individual and sharable feature learning (SMISFL) approach, which jointly learns multiple view-individual transformations and one sharable transformation to explore the view-specific property for each view and the common property across views. We design a semi-supervised multi-view similarity preserving term, which fully utilizes the label information of labeled samples and similarity information of unlabeled samples from both intra-view and inter-view aspects. To promote learning of diversity, we impose a constraint on view-individual transformation to make the learned view-specific features to be statistically uncorrelated. Furthermore, we train a linear classifier, such that view-specific and shared features can be effectively combined for classification. Experiments on widely used webpage datasets demonstrate that SMISFL can significantly outperform state-of-the-art SMFL and webpage classification methods.

1 INTRODUCTION

In World Wide Web, there exists a huge repository of data in the form of webpages, and the size of the web is growing day-by-day. This makes it challenging for users to search relevant contents accurately. Classification of webpages, that is allocating a webpage to one category that can describe its contents [14], is regarded to be able to help improve the quality of search results [7]. Webpage usually contains multiple types of information, such as images, hyperlinks, URLs, HTML tags, etc. Different types of information is combined to describe the same webpage. Thus, webpage classification is a typical kind of multi-view data-based classification task [20, 25, 29, 37, 38]. In webpage classification task, we can only make use of a limited number of labeled webpages with a large number of unlabeled pages, since manually labeling a large repository of webpages is time and labor consuming and is infeasible. Hence, webpage classification is a semi-supervised learning problem [39, 40]. Besides, since a page usually contains rich information, the webpage data is high-dimensional [16]. Due to these characteristics, semi-supervised multi-view feature learning (SMFL) is a feasible solution for webpage classification.

In recent years, some SMFL methods have been presented. Chen et al. [1] developed a semi-paired and semi-supervised generalized correlation analysis (S^2GCA) algorithm. Volpi et al. [23] addressed manifold-regularized semi-supervised kernel canonical correlation analysis (MR-skCCA) for hyperspectral data classification. Jing

et al. presented the uncorrelated semi-supervised intra-view and inter-view manifold discriminant (USI^{2}MD) [5] method and further designed the semi-supervised multi-view correlation feature learning (SMCFL) [6] method for webpage classification. Wan et al. [24] addressed the cost sensitive semi-supervised canonical correlation analysis (CS^{3}CCA) algorithm. Zhang et al. [36] presented generalized semi-supervised structured subspace learning (GSS-SL) for cross-modal retrieval. To our knowledge, three SMFL methods, i.e., S^{2}GCA, USI^{2}MD and SMCFL, have been successfully used for webpage classification.

1.1 Motivation and Contribution

Most of existing SMFL methods generally map data of multiple views into a holistically latent space either through pursuing one projective transformation for each view, e.g., S^{2}GCA, USI^{2}MD, GSS-SL, etc., or by searching for a common transformation, e.g., SMCFL. As discussed in [6], correlation information exploration is important for webpage data. However, the first type of SMFL methods cannot make full use of the correlation information across multiple views. For the second type of SMFL methods, they cannot well preserve specific characteristic of each view. Therefore, how to effectively explore and utilize both the complementary information (particularity) and the correlation information (commonality) of different views is a significant research topic.

A few supervised/unsupervised multi-view learning methods have tried to preserve the specific characteristic of each view and uncover the shared component simultaneously [3, 12, 30]. Inspired by these works, we propose a novel SMFL approach for webpage classification. The contributions of our study can be summarized as following four points:

(1) We design a semi-supervised multi-view similarity preserving term. It jointly learns multiple view-individual transformations and one sharable transformation for exploring the particularity and the commonality of different views in the semi-supervised scenario. With this term, label information of labeled samples and the similarity information of unlabeled samples can be well utilized from both intra-view and inter-view aspects.

(2) To reduce the redundancy information across views, we design a multi-view statistical uncorrelation term, which makes the learned view-specific features to be statistically uncorrelated.

(3) We train a linear classifier based on view-specific and shared features, which further improves the discriminability of view-specific and shared features.

(4) By combining these designed terms, we propose a novel SMFL approach, named semi-supervised multi-view individual and sharable feature learning (SMISFL). Experiments on the widely used WebKB [1] and Internet Advertisements [8] datasets demonstrate the proposed approach can bring significant performance improvement for webpage classification.

2 RELATED WORK

2.1 Webpage Classification Methods

A number of webpage classification methods have been developed over the past decade, and most of these methods adopt machine learning-based techniques for performing the task [11, 28, 32]. Li et al. [10] presented the two-view transductive SVM (TTSVM) algorithm, which improves transductive SVM by employing a multi-view learning paradigm, and evaluated the effectiveness of the algorithm with webpage data. Wang et al. [26] studied large-scale cross-language webpage classification via dual knowledge transfer by using the nonnegative matrix trifactorization technique. Shivashankar et al. [19] built a positive and unlabeled learning model to determine whether two endpoint URLs refer to the same entity with the distant supervision. Saleh et al. [15] introduced a strategy called classification using multilayered domain ontology (CMDO) for vertical web page classification. These webpage classification works do not take all three characteristics of webpage classification into consideration.

In recent years, three SMFL methods, i.e., S^{2}GCA [1], USI^{2}MD [5], and SMCFL [6], have been applied to the webpage classification task. S^{2}GCA performs canonical correlation analysis on paired data, and learns features with the aim of preserving global structure of unlabeled data and achieving separability of different classes. USI^{2}MD learns a projective transformation for each view, and employs the semi-supervised intra-view and inter-view manifold discriminant learning schema and the semi-supervised uncorrelation constraint for discriminant features learning. SMCFL only learns a multi-view shared transformation that projects samples of multiple views to a common space, by considering the discriminant correlation of labeled and unlabeled samples. These three methods do not consider to explore both the particularity and the commonality across views for helping classification. In addition, they do not consider classifier design when training the classification models.

2.2 SMFL Methods

Multi-view learning in semi-supervised scenario is a hot research topic [2, 4, 13, 17, 31, 34, 35]. In recent years, some SMFL methods have been presented. MR-skCCA [23] performs kernel canonical correlation analysis between views on labeled and unlabeled data with the graph Laplacian-based manifold regularization. CS^{3}CCA [24] first uses the L2-norm manner to obtain the soft label for unlabeled data, and then embeds the misclassification cost into canonical correlation analysis. GSS-SL [36] designs the label graph constraint to help predict relevant class labels for unlabeled data, and takes the label space as a linkage to model the correlation among different modalities. Existing SMFL methods do not fully take exploration and utilization of both the view-specific and shared information into consideration.

Recently, a few supervised/unsupervised multi-view learning methods have tried to make use of the view-specific and shared information [3, 12, 30]. Xue et al. [30] presented a multi-view correlated feature learning with shared component algorithm, which learns individual information in each view and tries to capture feature correlation among multiple views by learning a shared component. Hu et al. [3] presented a sharable and individual multi-view deep metric learning (MvDML) algorithm, which learns an individual distance metric for each view to retain its specific property and learns a shared representation for different views to preserve their common properties based on deep neural network. These works are supervised/unsupervised methods without considering the joint use of labeled and unlabeled data. And these works do not well

study either the aspect of how to effectively extract discriminant features with low redundancy or the aspect of how to learn classifier with the aim of effectively using both the view-specific and shared features jointly.

3 PROPOSED APPROACH

3.1 Semi-supervised Multi-view Similarity Preserving

Let $X_m \in \mathbb{R}^{d\times N}$ be the training webpage sample set of the m^{th} $(m=1,\cdots,M)$ view, where M denotes the number of views and N is the number of samples in each view. Suppose that X_m consists of two parts of samples, i.e., $X_m = \{x_m^i\}_{i=1}^N = \left[\bar{X}_m, \widehat{X}_m\right]$, where $\bar{X}_m \in \mathbb{R}^{d\times N_l}$ denotes the labeled data set in the m^{th} view and $\widehat{X}_m \in \mathbb{R}^{d\times N_u}$ contains unlabeled data in the m^{th} view. Here, N_l and N_u separately denote the number of samples in $\bar{X}_m$ and $\widehat{X}_m$. We aim to learn the transformation $V_m = \begin{pmatrix} V_m^s \\ V^c \end{pmatrix} \in \mathbb{R}^{(d_v+d_c)\times d},\ m=1,\cdots,M$, such that sample x_m^i can be mapped into a discriminant subspace through $V_m x_m^i$. Here, $V_m^s \in \mathbb{R}^{d_v\times d}$ is the view-specific transformation, which embodies the intrinsic characteristic of the m^{th} view, and $V^c \in \mathbb{R}^{d_c\times d}$ is the view-sharable transformation, which reflects the correlation information of M views. For simplicity, d_c is considered to be equal to d_v in this paper.

For samples x_m^i and x_l^j, we define the following weight to characterize their similarity

$$w_{m,l}^{i,j} = \begin{cases} 1, \text{if } x_m^i \text{ and } x_l^j \text{ are from the same class} \\ -1, \text{if } x_m^i \text{ and } x_l^j \text{ are from different classes} \\ \exp(-\left\|x_m^i - x_l^j\right\|_2^2 / (2\sigma^2)), \text{if } x_m^i \text{ or } x_l^j \text{ is unlabeled} \end{cases}$$

where σ is calculated as the standard variation of samples in the m^{th} and the l^{th} views. $W_{m,l}\ (m=1,\cdots,M;\ l=1,\cdots,M)$ is the similarity matrix between the m^{th} and l^{th} views. And the overall similarity matrix can be defined as $W = \begin{bmatrix} W_{1,1} & W_{1,2} & \cdots & W_{1,M} \\ W_{2,1} & W_{2,2} & \cdots & W_{2,M} \\ \vdots & \vdots & \ddots & \vdots \\ W_{M,1} & W_{M,2} & \cdots & W_{M,M} \end{bmatrix}$.

In order to learn discriminant transformations, such that in the projected space, limited number of labeled samples from the same class cluster together, the labeled samples with different class labels can be well separable, and unlabeled samples can preserve the global structure, we define the following semi-supervised multi-view similarity preserving term

$$\begin{aligned} J_1(V_m|_{m=1}^M) &= \frac{1}{2M^2N^2}\sum_{m=1}^{M}\sum_{i=1}^{N}\sum_{l=1}^{M}\sum_{j=1}^{N} w_{m,l}^{i,j}\left\|\begin{pmatrix} V_m^s \\ V^c \end{pmatrix}x_m^i - \begin{pmatrix} V_l^s \\ V^c \end{pmatrix}x_l^j\right\|_F^2 \\ &= \frac{1}{M^2N^2}\sum_{m=1}^{M}\sum_{l=1}^{M} tr\left(V_m X_m L_{m,l} X_l^T V_l^T\right) \end{aligned} \tag{1}$$

where L is the Laplacian matrix containing the sub-matrices $L_{m,l}$ $(m=1,\cdots,M;\ l=1,\cdots,M)$, and L is defined as $L = D - W$. Here, D is a diagonal matrix with the i^{th} diagonal element being calculated as the sum of the i^{th} row of the overall similarity matrix W. We should minimize J_1.

This term can fully utilize the label information of labeled samples and similarity information of unlabeled samples from both intra-view and inter-view aspects.

3.2 Multi-view Statistical Uncorrelation

In order to reduce the redundancy information across views and learn pure view-specific features with view-individual transformations, we design the following multi-view statistical uncorrelation term

$$J_2(V_m^s|_{m=1}^M) = \frac{1}{M(M-1)}\sum_{m=1}^{M}\sum_{l=1,m\neq l}^{M}\left\|V_m^s Cov_{m,l} V_l^{sT}\right\|_F^2 \tag{2}$$

where $Cov_{m,l} = \frac{1}{N}\sum_{i=1}^{N}\left(x_m^i - \mu_m\right)\left(x_l^i - \mu_l\right)^T$ is the cross-covariance matrix between the m^{th} and the l^{th} views. Here, μ_m and μ_l are separately the mean samples of X_m and X_l. We should also minimize this term to enhance the complementarity of features extracted from different views.

3.3 View-specific and Shared Features-based Classification Loss

We also design a linear classifier, such that the learned view-specific and view-shared features can be effectively combined for classification. The designed view-specific and shared features-based classification loss term is given as

$$J_3(P,b) = \left\|P\left(\left(V_1\bar{X}_1\right)^T,\cdots,\left(V_M\bar{X}_M\right)^T\right)^T + b\mathrm{I}^T - Y\right\|_F^2 \tag{3}$$

where $Y \in \mathbb{R}^{C\times N_l}$ is a label matrix with each column being a one-hot label vector, $P = [P_1, P_2, \cdots, P_{2m-1}, P_{2m}, \cdots, P_{2M-1}, P_{2M}] \in \mathbb{R}^{C\times(2Md_v)}$ is the projective matrix, $b \in \mathbb{R}^C$ is a bias term, and $\mathrm{I} \in \mathbb{R}^{N_l}$ is a vector full of 1. Here, C denotes the number of classes, and each $P_{2m-1} \in \mathbb{R}^{C\times d_v}$ and $P_{2m} \in \mathbb{R}^{C\times d_v}$ are sub-matrices of P. With this term, the discriminant ability of learned features can be further improved.

3.4 Total Objective of SMISFL

By combining the terms of semi-supervised multi-view similarity preserving, multi-view statistical uncorrelation, and the classification loss, we formulate the overall objective as

$$\begin{aligned} \min_{V_1,\cdots,V_M,P,b} J = &\frac{1}{2M^2N^2}\sum_{m=1}^{M}\sum_{i=1}^{N}\sum_{l=1}^{M}\sum_{j=1}^{N} w_{m,l}^{i,j}\left\|\begin{pmatrix} V_m^s \\ V^c \end{pmatrix}x_m^i - \begin{pmatrix} V_l^s \\ V^c \end{pmatrix}x_l^j\right\|_F^2 \\ &+\alpha\frac{1}{M(M-1)}\sum_{m=1}^{M}\sum_{l=1,m\neq l}^{M}\left\|V_m^s Cov_{m,l} V_l^{sT}\right\|_F^2 \\ &+\beta\left\|P\left(\left(V_1\bar{X}_1\right)^T,\cdots,\left(V_M\bar{X}_M\right)^T\right)^T + b\mathrm{I}^T - Y\right\|_F^2 \\ &+\gamma\left(\frac{1}{M}\sum_{m=1}^{M}\left\|V_m^s\right\|_{2,1} + \|V^c\|_F^2\right) \end{aligned} \tag{4}$$

where α, β and γ are balance factors. $\frac{1}{M}\sum_{m=1}^{M}\left\|V_m^s\right\|_{2,1} + \|V^c\|_F^2$ is a regularization term to avoid the overfitting problem. We employ the $\ell_{2,1}$-norm based regularizer, which makes $V_m^s,\ m=1,\cdots,M$ to be sparse in rows, such that discriminant features can be selected for each view.

3.5 Optimization

The objective (4) is not jointly convex with regard to variables $\left\{V_m^s|_{m=1}^M, V^c, P, b\right\}$ simultaneously. We thus employ an alternating optimization strategy to optimize these variables.

(1) Fix $\{V_1^s, V_2^s, \cdots, V_M^s\}$ and V^c, and update P, b

The objective function (4) is reduced to

$$\min_{P,b} J_3 = \left\| P\left(\left(V_1\bar{X}_1\right)^T, \cdots, \left(V_M\bar{X}_M\right)^T\right)^T + b\mathrm{I}^T - Y\right\|_F^2 \tag{5}$$

When updating $P(b)$, $b(P)$ is fixed. By setting the derivative of J_3 w.r.t. P, b to zero, we have

$$P = -BA^T\left(AA^T\right)^{-1}, b = -\frac{1}{N_l}D\mathrm{I} \tag{6}$$

where $A = \left(\left(V_1\bar{X}_1\right)^T, \cdots, \left(V_M\bar{X}_M\right)^T\right)^T$, $B = b\mathrm{I}^T - Y$, and $D = P\left(\left(V_1\bar{X}_1\right)^T, \cdots, \left(V_M\bar{X}_M\right)^T\right)^T - Y$.

(2) Fix P and b, and update $\{V_1^s, V_2^s, \cdots, V_M^s\}$ and V^c

We update V_m^s view by view. When updating V_m^s, V^c and $\left\{V_l^s\right\}_{l\neq m}$ are fixed. The objective function (4) is reduced to

$$\begin{aligned}\min_{V_m^s} \tfrac{1}{M^2N^2}&\left(\begin{array}{l} tr\left(V_m^s X_m L_{m,m} X_m^T V_m^{sT}\right) \\ +2\sum_{l\neq m}^{M} tr\left(V_m^s X_m L_{m,l} X_l^T V_l^{sT}\right)\end{array}\right) \\ &+\alpha\tfrac{2}{M(M-1)}\sum_{l\neq m}^{M}\left\|V_m^s Cov_{m,l} V_l^{sT}\right\|_F^2 \\ &+\beta\left\|P_{2m-1}V_m^s\bar{X}_m + E_1\right\|_F^2 + \gamma\tfrac{1}{M}\left\|V_m^s\right\|_{2,1}\end{aligned} \tag{7}$$

where $E_1 = \sum_{l\neq m}^{M} P_{2l-1}V_l^s\bar{X}_l + \sum_{m=1}^{M} P_{2m}V^c\bar{X}_m + \left(b\mathrm{I}^T - Y\right)$.

Differentiating (7) with respect to V_m^s and setting it to zero, we have

$$\begin{aligned}&\tfrac{1}{M^2N^2}\left(V_m^s\left(X_m L_{m,m} X_m^T\right) + \sum_{l\neq m}^{M}\left(V_l^s X_l L_{m,l}^T X_m^T\right)\right) \\ &+\alpha\tfrac{2}{M(M-1)}\sum_{l\neq m}^{M}\left(V_m^s Cov_{m,l} V_l^{sT} V_l^s Cov_{m,l}^T\right) \\ &+\beta\left(P_{2m-1}^T P_{2m-1} V_m^s\bar{X}_m\bar{X}_m^T + P_{2m-1}^T E_1\bar{X}_m^T\right) + \gamma\tfrac{1}{M}G_m^s V_m^s = 0\end{aligned} \tag{8}$$

where G_m^s is a diagonal matrix with its i^{th} diagonal element as $G_m^s(i,i) = 1/\left(2\left\|V_m^s(i,:)\right\|\right)$. Here $V_m^s(i,:)$ represents the i^{th} row of V_m^s. According to [33], the element in G_m^s is usually calculated as $G_m^s(i,i) = \frac{1}{2\sqrt{\|V_m^s(i,:)\|^2+\varepsilon}}$, where ε is set as a small positive value.

Then, we can obtain V_m^s by solving the following problem

$$V_m^s H_m^s + Q_m^s V_m^s + K_m^s V_m^s O_m^s = R_m^s \tag{9}$$

where $H_m^s = \frac{1}{M^2N^2}X_m L_{m,m} X_m^T + \frac{2\alpha}{M(M-1)}\sum_{l\neq m}^{M} Cov_{m,l} V_l^{sT} V_l^s Cov_{m,l}^T Q_m^s = \gamma\frac{1}{M}G_m^s$, $K_m^s = \beta P_{2m-1}^T P_{2m-1}$, $O_m^s = \bar{X}_m\bar{X}_m^T$, and $R_m^s = -\left(\frac{1}{M^2N^2}\sum_{l\neq m}^{M}\left(V_l^s X_l L_{m,l}^T X_m^T\right) + \beta P_{2m-1}^T E_1\bar{X}_m^T\right)$. The optimization problem in (9) can be solved by using the algorithm in the literatures [9, 22].

Algorithm 1 SMISFL

(1) **Input**: Multi-view training samples X_m, $m = 1, \cdots, M$, test sample $y = \{y_m\}|_{m=1}^M$.
(2) **Output**: The class label of y.
(a) Randomly initialize $V_m^s|_{m=1}^M$, V^c, P and b.
(b) **Repeat**:
(c) Update P and b with Eq. (6).
(d) Update $V_m^s|_{m=1}^M$ and V^c by solving (9) and (11).
(e) **Until Convergence**
(f) Map $\{y_m\}|_{m=1}^M$ with the learned transformations $V_m^s|_{m=1}^M$ and V^c by $\begin{Bmatrix} V_m^s \\ V^c \end{Bmatrix} y_m$, and then utilize the classifier parameters P and b for classification.

When updating V^c, $\left\{V_1^s, V_2^s, \cdots, V_M^s\right\}$ is fixed. The objective function (4) can be reduced to

$$\begin{aligned}\min_{V^c} \tfrac{1}{M^2N^2}&\sum_{m=1}^{M}\sum_{l=1}^{M} tr\left(V^c X_m L_{m,l} X_l^T V^{cT}\right) \\ &+\beta\left\|\sum_{m=1}^{M} P_{2m}V^c\bar{X}_m + E_2\right\|_F^2 + \gamma\left\|V^c\right\|_F^2\end{aligned} \tag{10}$$

where $E_2 = \sum_{m=1}^{M} P_{2m-1}V_m^s\bar{X}_m + \left(b\mathrm{I}^T - Y\right)$.

By firstly differentiating (10) with respect to V^c and setting it to zero, we can obtain V^c by solving the following problem

$$V^c H^c + Q^c V^c + \sum_{m=1}^{M}\sum_{l=1}^{M} K_{ml}^c V^c O_{ml}^c = R^c \tag{11}$$

where $H^c = \frac{1}{M^2N^2}\sum_{m=1}^{M}\sum_{l=1}^{M} X_m L_{m,l} X_l^T$, $Q^c = \gamma\mathrm{I}$, $K_{ml}^c = \beta P_{2m}^T P_{2l}$, $O_{ml}^c = \bar{X}_l\bar{X}_m^T$, and $R^c = -\beta\sum_{m=1}^{M} P_{2m}^T E_2\bar{X}_m^T$. The problem (11) can also be solved by using the algorithm in the literatures [9, 22]. Algorithm 1 summarizes the proposed SMISFL approach.

4 EXPERIMENTS

4.1 Dataset

We validate the effectiveness of our approach on two widely used datasets, i.e., WebKB [1] and Internet Advertisements [8] (AD). WebKB contains 1051 webpages, described by two views, i.e., the page view that includes the textual content on the page and link view that includes the hyperlinks pointing to the page. 1051 pages can be categorized into two classes: the course class including 230 pages and the non-course class including 821 pages. We use the preprocessed version of this dataset provided by [18], where 3000-dimensional and 1840-dimensional feature vectors are separately extracted from the page and link documents. The AD dataset includes 3279 samples that can be categorized into two classes: 458 advertisement and 2821 non-advertisement samples. A preprocessed version of this dataset [8] is used, where each sample is regarded as a binary vector with quite large sparsity. As in [5, 6], three views, i.e., 495 base URL features, 472 destination URL features and 457 image URL features, are selected.

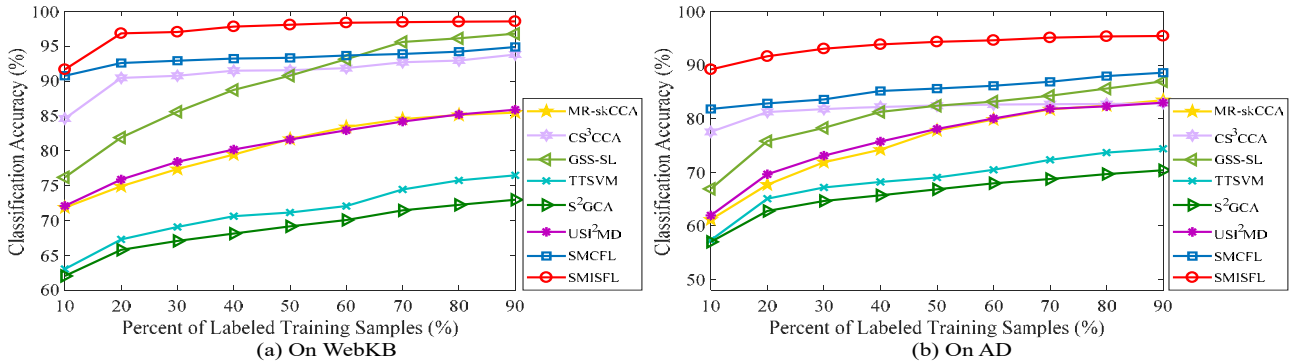

Figure 1: Average classification accuracies of compared methods on WebKB and AD datasets.

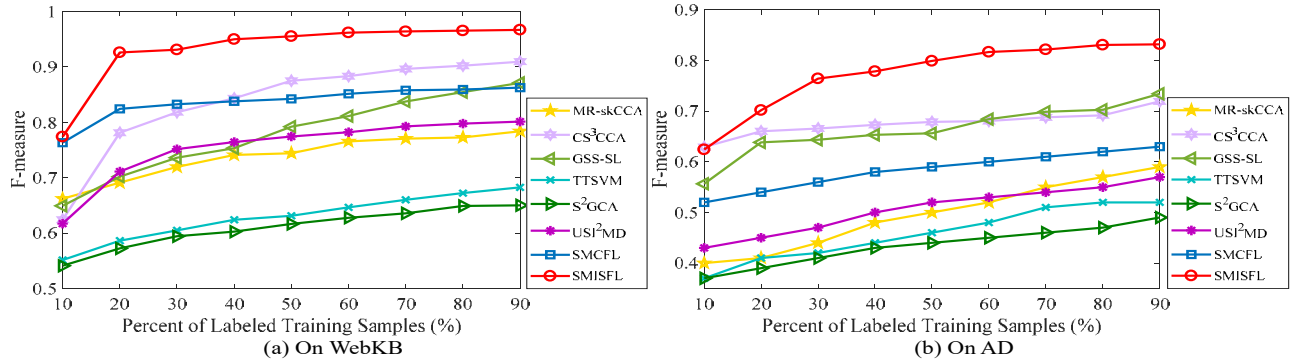

Figure 2: Average F-measure values of compared methods on WebKB and AD datasets.

Table 1: Average classification results (% for CA) and running time (seconds) of compared methods.

Method	WebKB				AD			
	CA	F1	TR	TE	CA	F1	TR	TE
CS^{3}CCA	91.13	0.84	0.56	0.13	81.80	0.68	5.80	1.37
GSS-SL	89.42	0.78	0.61	0.15	80.53	0.66	3.57	1.21
TTSVM	71.09	0.63	-	0.35	68.62	0.46	-	0.95
S^{2}GCA	68.75	0.61	2.84	0.34	65.96	0.43	7.78	1.12
USI^{2}MD	80.80	0.76	2.76	0.18	76.25	0.51	18.65	1.21
SMCFL	93.27	0.84	0.44	0.09	85.40	0.58	5.08	0.28
SMISFL	**97.25**	**0.93**	**0.21**	**0.05**	**93.63**	**0.77**	**0.45**	**0.08**

4.2 Experimental Settings

In experiments, we compare our SMISFL approach with two categories of state-of-the-art related methods including: (1) Webpage classification methods: **TTSVM** [10], **S^{2}GCA** [1], **USI^{2}MD** [5], and **SMCFL** [6]; (2) SMFL methods: **MR-skCCA** [23], **CS^{3}CCA** [24], and **GSS-SL** [36].

Like in [5, 6], PCA [21] is performed to reduce the dimensionalities of samples in different views to 1050 for WebKB and 456 for AD. On each dataset, we randomly select half of each class for training and use the remaining samples for testing. The training samples are further split into the labeled training sample set and the unlabeled training set according to a certain percentage (e.g., 20% of training samples used as labeled samples) for semi-supervised learning. TTSVM, S^{2}GCA and CS^{3}CCA were originally designed for two views-based problems. Following [5, 6], on AD dataset, two views that yield the best classification results are used for these three methods. For compared methods, we report their results with the listed results in [6] or with the codes provided by the authors. In experiments, the tuning parameters (α, β and γ in Eq. (4), and the dimensionality of V_m, i.e., d_v) of SMISFL are set as $\alpha = 1$, $\beta = 10^2$, $\gamma = 10^2$, and $d_v = 10$ on WebKB, and $\alpha = 1$, $\beta = 10^{-1}$, $\gamma = 10^2$, and $d_v = 10$ on AD.

4.3 Results and Analysis

In this paper, we adopt the measures of classification accuracy (CA) and F-measure (F1) [27] to evaluate the classification effects

of our approach and compared methods. We perform webpage classification experiments with the ratio of the number of labeled training samples to the total number of training samples increasing from 10% to 90%. Figs. 1 and 2 show the results measured by CA and F1 on two datasets, respectively. In these figures, each result is the average result across 20 random running. To statistically observe the results in the figures, we also calculate the mean result of each method across different percentages of labeled training samples, and we list these mean results in Table 1.

In Figs. 1 and 2, and Table 1, our SMISFL approach can always obtain better classification results with respect to the CA and F1 measures than compared webpage classification methods and state-of-the-art SMFL methods. From Table 1, SMISFL can improve the classification results by **3.98%**=(97.25%-93.27%) for CA and **0.09**=(0.93-0.84) for F1 on WebKB, and improve the classification results by **8.23%**=(93.63%-85.40%) for CA and **0.09**=(0.77-0.68) for F1 on AD. Better F1 results also mean that SMISFL can well classify the samples of the minority class, since samples used for training the model are class-imbalanced. The reason for the classification result improvement against all compared methods mainly lies in that the complementary information and the correlation information of different views of webpage data is effectively explored and leveraged under semi-supervised setting for classification.

Table 1 also reports the average training (TR) and testing (TE) time (for the total test set) of compared methods in the semi-supervised learning case that 20 percent of training samples are used as labeled samples. Our hardware configuration comprises i7-8700K CPU and 32 GB memory. From the table, SMISFL needs significantly less training and testing time than compared webpage classification and SMFL methods.

4.4 Discussion

In this subsection, we evaluate the important components of SMISFL. We separately call the version of SMISFL without the semi-supervised multi-view similarity preserving term as **SMISFL-s**, the version of SMISFL without the multi-view statistical uncorrelation term as **SMISFL-u**, the version of SMISFL without the view-specific and shared features-based classification loss term as **SMISFL-c**. For SMISFL-c, we concatenate feature representations of multiple views and employ the nearest neighbor classifier for classification. Furthermore, we conduct SMISFL without learning the view-individual transformation or the view-sharable transformation, and separately call these versions as **SMSFL** and **SMIFL**. Table 2 shows the result comparison.

From the table, the classification results of SMISFL-s, SMISFL-u and SMISFL-c are obviously inferior to that of SMISFL, and when only one of view-specific and shared transformations is used, SMISFL experiences an obvious performance degradation. This result means that the learned complementary and correlation features from multi-view data are useful for webpage classification, and the joint utilization of view-specific and shared features helps improve the performance. In addition, the designed three terms can help learn features with favorable discriminative capability.

Table 2: Classification results of variants of SMISFL.

Method	WebKB		AD	
	CA(%)	F1	CA(%)	F1
SMISFL-s	83.36	0.69	89.72	0.66
SMISFL-u	96.86	0.89	92.64	0.73
SMISFL-c	90.87	0.78	89.49	0.70
SMSFL	95.43	0.89	90.96	0.65
SMIFL	94.93	0.90	90.12	0.72
SMISFL	**97.25**	**0.93**	**93.63**	**0.77**

5 CONCLUSION

In this paper, we propose a novel SMFL approach SMISFL for webpage classification. It jointly learns the view-individual and sharable transformations by fully using of the labeled and unlabeled webpage data. Discriminant features with complementarity and correlation are well explored and effectively combined for classification. Experimental results on two widely used datasets demonstrate that SMISFL outperforms state-of-the-art SMFL and webpage classification methods. Results also validate the effectiveness of the semi-supervised view-individual and sharable feature learning scheme.

ABSTRACT

In this paper, we study the fairness-aware classification problem by formulating it as a constrained optimization problem. Several limitations exist in previous works due to the lack of a theoretical framework for guiding the formulation. We propose a general fairness-aware framework to address previous limitations. Our framework provides: (1) various fairness metrics that can be incorporated into classic classification models as constraints; (2) the convex constrained optimization problem that can be solved efficiently; and (3) the lower and upper bounds of real-world fairness measures that are established using surrogate functions, providing a fairness guarantee for constrained classifiers. Within the framework, we propose a constraint-free criterion under which any learned classifier is guaranteed to be fair in terms of the specified fairness metric. If the constraint-free criterion fails to satisfy, we further develop the method based on the bounds for constructing fair classifiers. The experiments using real-world datasets demonstrate our theoretical results and show the effectiveness of the proposed framework.

1 INTRODUCTION

Fairness-aware classification is receiving increasing attention in the machine learning fields. Since the classification models seek to maximize the predictive accuracy, individuals may get unwanted digital bias when the models are deployed for making predictions. As fairness becomes a more and more important requirement in machine learning, it is imperative to ensure that the learned classification models can strike a balance between accurate and fair predictions. Previous works on this topic can be mainly categorized into two groups: the in-processing methods which incorporate the fairness constraints into the classic classification models (e.g., [5, 7, 8, 17, 18]), and the pre/post-processing methods which modify the training data and/or derive fair predictions based on the potentially unfair predictions made by the classifier (e.g., [4, 6, 20–22]). In this work, we focus on the in-processing methods.

Very recently, several works have been proposed for formulating the fairness-aware classification as constrained optimization problems [5, 7, 8, 10, 16–18]. Generally, they aim to minimize a loss function subject to certain fairness constraints, e.g., demographic parity (i.e., the difference of the positive predictions between the sensitive group and non-sensitive group) is less than some threshold. However, most quantitative fairness metrics such as demographic parity [13], mistreatment parity [17], etc., are non-convex due to the use of the indicator function, thus making the optimization problem intractable. A widely-used strategy to achieve convexity in optimization is to adopt surrogate functions for both loss function and constraints. In [18], the authors applied the linear surrogate functions to non-convex risk difference as the decision boundary fairness for margin-based classifiers. Similarly in [5], a convex constraint is derived from the risk difference. One challenge is that, when surrogate functions are used to convert non-convex functions to convex functions, estimation errors must exist due to the difference between the surrogate function and the original non-convex function. Thus, achieving the fairness constraints represented by surrogate functions does not necessarily guarantee achieving the real fairness criterion. Hence, how to achieve fairness-aware classification via constrained optimization still remains an open problem.

In this paper, we propose a general framework for fairness-aware classification which addresses the gap incurred by the estimation errors due to the surrogate function. The framework can formulate various commonly-used fairness metrics (risk difference [12], risk ratio [12], equal odds [6], etc.) as convex constraints that are then directly incorporated into classic classification models. Within the framework, we first present a constraint-free criterion (derived from the training data) which ensures that any classifier learned from the data will guarantee to be fair in terms of the specified fairness metric. Thus, when the criterion is satisfied, there is no need to add any fairness constraint into optimization for learning fair classifiers. When the criterion is not satisfied, we need to learn fair classifiers by solving the constrained optimization problems. To connect the surrogated fairness constraints to the original non-convex fairness metric, we further derive the lower and upper bounds of the real fairness measure based on the surrogate function, and develop the refined fairness constraints. This means that, if the refined constraints are satisfied, then it is guaranteed that the real fairness measure is also bounded within the given interval. The bounds work for any surrogate function that is convex and differentiable at zero with the derivative larger than zero. In the experiments, we evaluate our method and compare with existing works using the real-world datasets. The results demonstrate the correctness of the

constraint-free criterion and the superiority of our method over existing ones in terms of achieving fairness and retaining prediction accuracy.

2 FAIRNESS-AWARE CLASSIFICATION

In this section we present our fairness-aware classification framework. We first introduce the unconstrained optimization formulation for the classic classification models as proposed in [2], and then present our constrained optimization formulation for fairness-aware classification. Throughout the paper, we use the vector $\mathbf{X} \in \mathcal{X}$ to denote the features used in classification, and $Y \in \mathcal{Y} = \{-1, 1\}$ to denote the binary label. We denote the sensitive attribute by S, assuming that it is associated with two values: sensitive group s^- and non-sensitive group s^+. The training data $\mathbb{D} = \{(\mathbf{x}_i, s_i, y_i)\}_{i=1}^N$ is a sample drawn from a unknown but fixed distribution.

2.1 Classification Problem

The learning goal of classification is to find a classifier: $f : \mathcal{X} \mapsto \mathcal{Y}$ that minimizes the average of the classification loss (a.k.a the empirical loss), given by

$$\mathbb{L}(f) = \mathbb{E}_{\mathbf{X},Y}[\mathbb{1}_{f(\mathbf{x})\neq y}], \tag{1}$$

where $\mathbb{1}_{[\cdot]}$ is an indicator function. The classification problem can then be formulated as an optimization problem:

$$\min_{f\in\mathcal{F}} \mathbb{L}(f) = \min_{f\in\mathcal{F}} \mathbb{E}_{\mathbf{X},Y}[\mathbb{1}_{f(\mathbf{x})\neq y}].$$

Directly solving this optimization problem is intractable since the objective function is non-convex [2]. For efficient computation, another predictive function h is adopted which is performed in real number domain $\mathcal{R}$, i.e., $h : \mathcal{X} \mapsto \mathcal{R}$. By letting $f = \text{sign}(h)$, the empirical loss can be reformulated as

$$\begin{aligned}\mathbb{L}(f) = \mathbb{L}(h) &= \mathbb{E}_{\mathbf{X},Y}\Big[\mathbb{1}_{\text{sign}\left(h(\mathbf{x})\right)\neq y}\Big] \\ &= \mathbb{E}_{\mathbf{X}}\Big[Pr(Y=1|\mathbf{x})\mathbb{1}_{h(\mathbf{x})<0} + Pr(Y=-1|\mathbf{x})\mathbb{1}_{h(\mathbf{x})>0}\Big].\end{aligned} \tag{2}$$

If we replace the indicator function (a.k.a 0-1 loss function) with a convex surrogate function ϕ, the empirical loss can be rewritten as

$$\mathbb{L}_\phi(h) = \mathbb{E}_{\mathbf{X}}\Big[Pr(Y=1|\mathbf{x})\phi\big(h(\mathbf{x})\big) + \big(1 - Pr(Y=1|\mathbf{x})\big)\phi\big(-h(\mathbf{x})\big)\Big],$$

which is known as the ϕ-loss, and the optimization problem is reformulated as $\min_{h\in\mathcal{H}} \mathbb{L}_\phi(h)$. In the past decades, a number of surrogate loss functions have been proposed and well studied, such as the hinges loss, the square loss, the logistic loss, the exponential loss, etc..

2.2 Fairness-aware Classification Problem

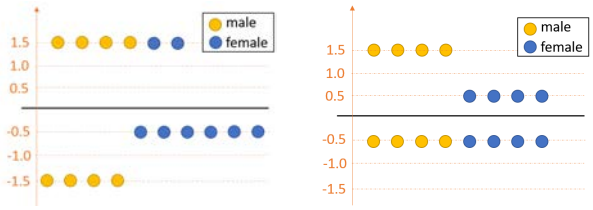
The fairness-aware classification aims to find a classifier that minimizes the empirical loss while satisfying certain fairness constraints. Several fairness notions or definitions are proposed in the literature, such as demographic parity [13], mistreatment parity [17], etc..

Demographic parity is the most widely-used fairness notion in the fairness-aware learning field. It requires the decision made by the classifier is independent to the sensitive attribute, such as sex or race. Usually, demographic parity is quantified with regard to risk difference [12], i.e., the difference of the positive predictions between the sensitive group and non-sensitive group. For example, in the context of hiring, risk difference can be given by the probability difference of being predicted to be hired between male applicants and female applicants. Using the same language as that in the previous subsection, the risk difference produced by a classifier f is expressed as

$$\mathbb{RD}(f) = \mathbb{E}_{\mathbf{X}|S=s^+}[\mathbb{1}_{f(\mathbf{x})=1}] - \mathbb{E}_{\mathbf{X}|S=s^-}[\mathbb{1}_{f(\mathbf{x})=1}]. \tag{3}$$

As a quantitative metric, we say that classifier f is considered as fair if $|\mathbb{RD}(f)| \leq \tau$, where τ is the user-defined threshold. For instance, the 1975 British legislation for sex discrimination sets $\tau = 0.05$. By directly incorporating the risk difference into the optimization problem, we formulate the fair classification problem as follows.

Problem Formulation 1. *The goal of the fairness-aware classification is to find a classifier f that minimizes the loss $\mathbb{L}(f)$ while satisfying fairness constraint $|\mathbb{RD}(f)| \leq \tau$. It can be approached by solving the following constrained optimization problem*



$$\begin{aligned}\min_{f\in\mathcal{F}} \quad & \mathbb{L}(f) \\ \textit{subject to} \quad & \mathbb{RD}(f) \leq \tau, \quad -\mathbb{RD}(f) \leq \tau,\end{aligned} \tag{4}$$

where $\mathbb{L}(f)$ and $\mathbb{RD}(f)$ are defined in Eq. (1) *and Eq.* (3).

Obviously, solving the above problem is computationally intractable, since both $\mathbb{L}(f)$ and $\mathbb{RD}(f)$ contain indicator functions.

The real-value function $h(\mathbf{x})$ and the surrogate functions have been proposed in the recent works [1, 8, 18, 19]. For example, Zafar et al. [19] have proposed the decision boundary covariance to quantify the fairness and serve as constraints, which is equivalent to applying the linear surrogate functions to Problem Formulation 1. They have set the constraint thresholds as c and $-c$, which specify the threshold for the covariance. However, solving the optimization problem with surrogated constraints does not necessarily result in a fair classifier in terms of the original non-convex fairness requirements, e.g., $-\tau \leq \mathbb{RD}(f) \leq \tau$. In fact, there is no any fairness guarantee on the produced classifier. We use an example to show this. Consider two margin-based classifiers where the surrogate functions are linear functions of the distance from the data point to the decision boundary. Therefore, the risk difference is computed by counting the number of data points above and below the decision boundary, and the surrogated risk difference (a.k.a the decision boundary covariance) is computed by measuring the average signed distance from the data points to the decision boundary. In the dataset shown in Figure 1a, we obtain that the surrogated risk difference is 0 but the real risk difference is 0.25. This means that a classier obtained by solving the constrained optimization problem actually can be very unfair. In the dataset shown in Figure 1b, the risk difference is 0 but the surrogated risk difference is 0.5, meaning that some fair classifiers cannot be obtained by solving the optimization problem with surrogated constraints.

The use of the surrogate function inevitably produces estimation errors and leads to the mismatch between the surrogated constraints and the original non-convex fairness constraints. Some intuitive techniques have been introduced to tune the threshold of the surrogated constraints for learning fair classifiers. For example, Zafar et al. [19] have proposed to build an unconstrained classifier and

(a) A classifier that meets the surrogated RD constraint makes unfair predictions.

(b) A classifier that doesn't meet the surrogated RD constraint makes fair predictions.

Figure 1: Two classifiers and their predictions.

consider its risk difference as the initial threshold, say c^*, then they heuristically select a factor $m \in [0, 1]$ and let the threshold $c = m \times c^*$. However, the relationship between the threshold c of the surrogated constraints and the hard threshold τ of the original metrics is unclear hence users have to repeatedly conduct experiments on the datasets.

3 CONVEX FAIRNESS CLASSIFICATION FRAMEWORK

In this section, we propose a general framework for fairness-aware classification which addresses the gap incurred by the estimation error due to the use of the surrogate function. Our framework can formulate various fairness metrics (e.g., risk difference, risk ration, equal odds, etc.) as convex constraints and incorporate them into classic classification model. In the following sections, we present our framework based on the risk difference. In the appendix, we show how our framework can be easily extended to other fairness metrics, e.g., risk ratio, equalized odds.

We first present a constraint-free criterion that is derived from the data. This criterion ensures that any classifier learned from the data are fair in terms of the specified fairness metric. Then when this criterion is satisfied, there is no need to incorporate any fairness constraints for learning fair classification. When this criterion is not met, we formulate the fairness-aware classification task as a convex optimization problem. To fill the gap between the surrogated constraints and the real fairness metrics, we derive the upper and lower bounds for the real fairness metrics and further develop refined convex constraints. If the refined constraints are satisfied, it is guaranteed that the original non-convex fairness requirements are satisfied, e.g., $-\tau \leq \mathbb{RD}(f) \leq \tau$.

3.1 Constraint-free Criterion

We propose a constraint-free criterion to determine whether the fairness constraints are necessary. As discussed in Section 2.1, the unconstrained classification problem is well studied and users can safely apply the classic methods for building a fair classifier.

We first define two special classifiers f_{max} and f_{min} which obtain the maximal and the minimal risk differences respectively.

Definition 1. *The maximal risk difference classifier $f_{\max}$ and the minimal risk difference classifier $f_{\min}$ are defined as:*

$$f_{\max}(\mathbf{x}) = \begin{cases} 1 & \text{if } \eta(\mathbf{x}) \geq p, \\ -1 & \text{otherwise,} \end{cases} \qquad f_{\min}(\mathbf{x}) = \begin{cases} -1 & \text{if } \eta(\mathbf{x}) \geq p, \\ 1 & \text{otherwise,} \end{cases}$$

where we denote $P(S = s^+|\mathbf{x})$ by $\eta(\mathbf{x})$ and $P(S = s^+)$ by p.

These two classifiers provide the maximum and minimum of risk difference among all classifiers f out of the model space $\mathcal{F}$:

Theorem 1. *For any classifier f, it always holds that $\mathbb{RD}^- \leq \mathbb{RD}(f) \leq \mathbb{RD}^+$, where $\mathbb{RD}^- = \mathbb{RD}(f_{\min})$ and $\mathbb{RD}^+ = \mathbb{RD}(f_{\max})$.*

The proof of Theorem 1 is included in the manuscript[1] on the arXiv. From Theorem 1, we directly obtain Corollary 2.

Corollary 2. *Given the threshold τ, for a training data if we have $\mathbb{RD}^+ \leq \tau$ and $\mathbb{RD}^- \geq -\tau$, then any classifier learned from this dataset is fair in terms of risk difference.*

Given a dataset, we can always build two classifiers f_{max} and f_{min}, then compute $\mathbb{RD}^+$ and $\mathbb{RD}^-$. If Corollary 2 is satisfied, users can safely apply any classification models to build classifiers without any fairness concern.

3.2 Convex Fairness-aware Classification

When the constraint-free criterion is not satisfied, it is required to incorporate fairness constraints when learning classifiers, e.g., solving Problem Formulation 1. To this end, we adopt two different surrogate functions for converting the original problem into a convex optimization. We firstly adopt a real-value predictive function h and let $f = \text{sign}(h)$, then rewrite the risk difference as

$$\begin{aligned} &\mathbb{RD}(f) = \mathbb{RD}(h) \\ &= \mathbb{E}_{\mathbf{X}|S=s^+}\left[\mathbb{1}\left[\text{sign}\left(h(\mathbf{x})\right) = 1\right]\right] - \mathbb{E}_{\mathbf{X}|S=s^-}\left[\mathbb{1}\left[\text{sign}\left(h(\mathbf{x})\right) = 1\right]\right] \\ &= \mathbb{E}_{\mathbf{X}|S=s^+}[\mathbb{1}_{h(\mathbf{x})>0}] + \mathbb{E}_{\mathbf{X}|S=s^-}[\mathbb{1}_{h(\mathbf{x})<0}] - 1. \end{aligned}$$

It follows that

$$\begin{aligned} \mathbb{RD}(f) &= \mathbb{E}_{\mathbf{X}}\left[\frac{P(S=s^+|\mathbf{x})}{P(S=s^+)}\mathbb{1}_{h(\mathbf{x})>0} + \frac{P(S=s^-|\mathbf{x})}{P(S=s^-)}\mathbb{1}_{h(\mathbf{x})<0} - 1\right] \\ &= \mathbb{E}_{\mathbf{X}}\left[\frac{\eta(\mathbf{x})}{p}\mathbb{1}_{h(\mathbf{x})>0} + \frac{1-\eta(\mathbf{x})}{1-p}\mathbb{1}_{h(\mathbf{x})<0} - 1\right], \end{aligned} \tag{5}$$

where we denote $P(S = s^+|\mathbf{x})$ by $\eta(\mathbf{x})$ and $P(S = s^+)$ by p for simplicity, thus $P(S = s^-|\mathbf{x}) = 1 - \eta(\mathbf{x})$ and $P(S = s^-) = 1 - p$.

It is intuitive that the indicator function in above formula can be replaced with the surrogate function. The challenge here is, two constraints $\mathbb{RD}(f) \leq \tau$ and $-\mathbb{RD}(f) \leq \tau$ are opposite to each other. Thus, replacing all indicator functions with a single surrogate function will result in a convex-concave problem, where only heuristic solutions for finding the local optima are known to exist. Therefore, we adopt two surrogate functions, a convex one $\kappa(\cdot)$ and a concave one $\delta(\cdot)$, each of which replaces the indicator function for one constraint. As a result, the formulated constrained optimization problem is convex and can be efficiently solved. We call the risk difference represented by $\kappa(\cdot)$ and $\delta(\cdot)$ as the κ, δ-risk difference, denoted by $\mathbb{RD}_\kappa(h)$ and $\mathbb{RD}_\delta(h)$. Almost all commonly-used surrogate functions can be adopted for $\kappa(\cdot)$ and $\delta(\cdot)$, by performing some shift or flip. Curves of some examples for $\kappa(\cdot)$ and $\delta(\cdot)$ are shown in Figure 2.

As a result, we obtain the following convex optimization formulation for learning fair classifiers.

[1] https://arxiv.org/abs/1809.04737

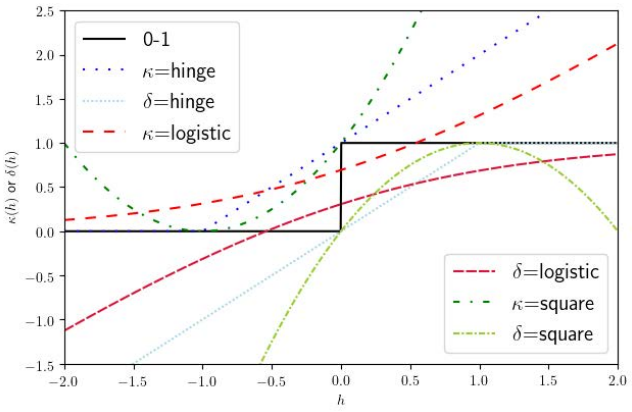


Figure 2: Curves of examples for $\kappa(\cdot)$ and $\delta(\cdot)$.

Problem Formulation 2. *The fairness-aware classification is converted into a convex optimization problem. The optimal solution h^* can be obtained by solving*

$$\begin{aligned} \min_{h\in\mathcal{H}} \quad & \mathbb{L}_\phi(h) \\ \textit{subject to} \quad & \mathbb{RD}_\kappa(h) \le c_1, \quad -\mathbb{RD}_\delta(h) \le c_2, \end{aligned}$$

where $\kappa(\cdot)$ is a convex surrogate function, $\delta(\cdot)$ is a concave surrogate function, c_1, c_2 are the thresholds of the κ, δ-risk difference, and

$$\mathbb{L}_\phi(h) = \mathbb{E}_{\mathbf{X}}\Big[Pr(Y=1|\mathbf{x})\phi\Big(h(\mathbf{x})\Big) + \Big(1-Pr(Y=1|\mathbf{x})\Big)\phi\Big(-h(\mathbf{x})\Big)\Big],$$

$$\mathbb{RD}_\kappa(h) = \mathbb{E}_{\mathbf{X}}\Big[\frac{\eta(\mathbf{x})}{p}\kappa\Big(h(\mathbf{x})\Big) + \frac{1-\eta(\mathbf{x})}{1-p}\kappa\Big(-h(\mathbf{x})\Big) - 1\Big],$$

$$\mathbb{RD}_\delta(h) = \mathbb{E}_{\mathbf{X}}\Big[\frac{\eta(\mathbf{x})}{p}\delta\Big(h(\mathbf{x})\Big) + \frac{1-\eta(\mathbf{x})}{1-p}\delta\Big(-h(\mathbf{x})\Big) - 1\Big].$$

After obtaining h^*, we build the fair classifier by letting $f^* = \text{sign}(h^*)$ and f^* is the final fair classifier. We emphasize that in Problem Formulation 2, the constraint thresholds are rewritten as c_1 and c_2 due to the difference between the surrogated constraints and the original non-convex constraints.

3.3 Refined Fairness-aware Classification

In this section, we develop the upper and lower bounds of the risk difference $\mathbb{RD}(h)$ with the κ, δ-risk difference $\mathbb{RD}_\kappa(h)$ and $\mathbb{RD}_\kappa(h)$. Based on the bounds, we present the method to derive c_1, c_2 for $\mathbb{RD}_\kappa(h), \mathbb{RD}_\delta(h)$, which provides a fairness guarantee that the solution $f^* = \text{sign}(h^*)$ to Problem Formulation 2 satisfies the fairness requirements, e.g., $-\tau \le \mathbb{RD}(f^*) \le \tau$. The method works for various types of surrogate functions (e.g., hinge, square, logistic, exponential, etc.).

We begin with defining the conditional risk difference $C^\eta\Big(h(\mathbf{x})\Big)$ for a specific subpopulation $\mathbf{x}$:

$$C^\eta\Big(h(\mathbf{x})\Big) = \frac{\eta(\mathbf{x})}{p}\mathbb{1}_{h(\mathbf{x})>0} + \frac{1-\eta(\mathbf{x})}{1-p}\mathbb{1}_{h(\mathbf{x})<0} - 1,$$

where η is the abbreviation of $\eta(\mathbf{x})$.

Then, according to Eq. (5), we have $\mathbb{RD}(f) = \mathbb{E}_{\mathbf{X}}[C^\eta\Big(h(\mathbf{x})\Big)]$. When surrogate function $\kappa(\cdot)$ (resp. $\delta(\cdot)$) is adopted, we similarly define the conditional κ-risk difference

$$C^\eta_\kappa\Big(h(\mathbf{x})\Big) = \frac{\eta(\mathbf{x})}{p}\kappa\Big(h(\mathbf{x})\Big) + \frac{1-\eta(\mathbf{x})}{1-p}\kappa\Big(-h(\mathbf{x})\Big) - 1,$$

and we have $\mathbb{RD}_\kappa(h) = \mathbb{E}_{\mathbf{X}}\Big[C^\eta_\kappa\Big(h(\mathbf{x})\Big)\Big]$.

Note that the values of $C^\eta\Big(h(\mathbf{x})\Big)$ and $C^\eta_\kappa\Big(h(\mathbf{x})\Big)$ depend on $\eta(\mathbf{x})$ and $h(\mathbf{x})$, which are determined by the subpopulation of the data specified by $\mathbf{x}$, as well as predictive function h. In order to study the general situations for any specific subpopulation and any possible predictive function, we denote $h(\mathbf{x})$ as α and define the generic conditional risk difference $C^\eta(\alpha)$ and the generic conditional κ-risk difference $C^\eta_\kappa(\alpha)$:

$$C^\eta(\alpha) = \frac{\eta}{p}\mathbb{1}_{\alpha>0} + \frac{1-\eta}{1-p}\mathbb{1}_{\alpha<0} - 1, \quad C^\eta_\kappa(\alpha) = \frac{\eta}{p}\kappa(\alpha) + \frac{1-\eta}{1-p}\kappa(-\alpha) - 1,$$

for any $\eta \in [0,1]$ and $\alpha \in \mathcal{R}$. Then, the minimal conditional risk difference $H^-(\eta)$ and the minimal conditional κ-risk difference $H^-_\kappa(\eta)$ for any arbitrary subpopulation and any possible predictive function are given by

$$H^-(\eta) = \min_{\alpha\in R} C^\eta(\alpha) = \min_{\alpha\in R}\Big[\frac{\eta}{p}\mathbb{1}_{\alpha>0} + \frac{1-\eta}{1-p}\mathbb{1}_{\alpha<0} - 1\Big],$$

$$H^-_\kappa(\eta) = \min_{\alpha\in R} C^\eta_\kappa(\alpha) = \min_{\alpha\in R}\Big[\frac{\eta}{p}\kappa(\alpha) + \frac{1-\eta}{1-p}\kappa(-\alpha) - 1\Big]. \quad (6)$$

It is straightforward that the minimal risk difference $\mathbb{RD}^-$ is equivalent to the expectation of $H^-(\eta(\mathbf{x}))$ since for any possible $\mathbf{x}$, $H^-(\eta(\mathbf{x}))$ provides the minimal conditional risk difference. Similarly, the minimal κ-risk difference achieved by any predictive function (denoted by $\mathbb{RD}^-_\kappa$) is the expectation of $H^-_\kappa(\eta(\mathbf{x}))$, as given by

$$\mathbb{RD}^-_\kappa = \mathbb{E}_{\mathbf{X}}\Big[H^-_\kappa(\eta(\mathbf{x}))\Big].$$

Finally, we define the minimal conditional κ-risk difference within interval α s.t. $\alpha(\eta - p) \ge 0$:

$$H^\circ_\kappa(\eta) = \min_{\alpha:\alpha(\eta-p)\ge 0} C^\eta_\kappa(\alpha). \quad (7)$$

We similarly define $H^+(\eta)$ the maximal conditional risk difference, $H^+_\delta(\eta)$ the maximal conditional δ-risk difference, $\mathbb{RD}^+_\delta$ the maximal δ-risk difference, as well as $H^\circ_\delta(\eta)$ the minimal conditional δ-risk difference within interval α s.t. $\alpha(\eta - p) \ge 0$.

Now, we are able to present our results, which are given in Theorem 3 and Corollary 4. The proof can be found in the manuscript[2] on the arXiv.

Theorem 3. *If $\kappa(\cdot)$ is convex and differentiable at zero with $\kappa'(0) > 0$, $\delta(\cdot)$ is concave and differentiable at zero with $\delta'(0) > 0$, then for any predictive function h, we have*

$$\begin{aligned} \psi_\kappa(\mathbb{RD}(h) - \mathbb{RD}^-) &\le \mathbb{RD}_\kappa(h) - \mathbb{RD}^-_\kappa, \\ \psi_\delta(\mathbb{RD}^+ - \mathbb{RD}(h)) &\le \mathbb{RD}^+_\delta - \mathbb{RD}_\delta(h), \end{aligned} \quad (8)$$

where

$$\psi_\kappa(\mu) = H^\circ_\kappa\Big(p(1-p)\mu + p\Big) - H^-_\kappa\Big(p(1-p)\mu + p\Big),$$

$$\psi_\delta(\mu) = H^+_\delta\Big(p(1-p)\mu + p\Big) - H^\circ_\delta\Big(p(1-p)\mu + p\Big).$$

[2] https://arxiv.org/abs/1809.04737

In Theorem 3, $\psi_\kappa(\mu)$ and $\psi_\delta(\mu)$ are directly derived from the surrogate function κ and δ. Some commonly-used surrogate functions κ, δ and their corresponding ψ_κ, ψ_δ functions are listed in Table 1. The inequalities in Theorem 3 bound the difference between $\mathbb{RD}(h)$ and $\mathbb{RD}^+, \mathbb{RD}^-$ by the differences $\mathbb{RD}_\kappa(h) - \mathbb{RD}_\kappa^-$ and $\mathbb{RD}_\delta^+ - \mathbb{RD}_\delta(h)$. Since $\mathbb{RD}^-, \mathbb{RD}^+, \mathbb{RD}_\kappa^-, \mathbb{RD}_\delta^+$ can be computed from the dataset, we connect the original non-convex constraints and the surrogated convex constraints.

We reformulate Theorem 3 and explicitly give the upper and lower bounds of $\mathbb{RD}(h)$ in Corollary 4.

Corollary 4. *For any predictive function h, let classifier $f = sign(h)$, if $\kappa(\cdot)$ is convex and differentiable at zero with $\kappa'(0) > 0$, $\delta(\cdot)$ is concave and differentiable at zero with $\delta'(0) > 0$, then risk difference $\mathbb{RD}(f)$ is bounded by following inequalities:*

$$\mathbb{RD}(f) \le \mathbb{RD}^- + {\psi_\kappa}^{-1}\Big(\mathbb{RD}_\kappa(h) - \mathbb{RD}_\kappa^-\Big),$$
$$\mathbb{RD}(f) \ge \mathbb{RD}^+ - {\psi_\delta}^{-1}\Big(\mathbb{RD}_\delta^+ - \mathbb{RD}_\delta(h)\Big).$$

Based on the upper and lower bounds of $\mathbb{RD}(f)$, we can derive the thresholds c_1, c_2 for the surrogated constraints in Problem Formulation 2. For example, if we aim to obtain a classifier f such that $-\tau \le \mathbb{RD}(f) \le \tau$, we only require the upper bound of $\mathbb{RD}(f)$ is smaller than τ and the lower bound is larger than $-\tau$. That is:

$$\mathbb{RD}^- + {\psi_\kappa}^{-1}\Big(\mathbb{RD}_\kappa(h) - \mathbb{RD}_\kappa^-\Big) \le \tau,$$
$$\mathbb{RD}^+ - {\psi_\delta}^{-1}\Big(\mathbb{RD}_\delta^+ - \mathbb{RD}_\delta(h) \ge -\tau.$$

Thus, we obtain the refined constraints and if the refined constraints are satisfied, the original risk difference requirements are guaranteed to be satisfied.

We modify Problem Formulation 2 to obtain Problem Formulation 3 with refined fairness constraints which guarantee the real non-convex fairness requirement.

Problem Formulation 3. *A classifier $f^* = sign(h^*)$ that achieves fairness guarantee $-\tau \le \mathbb{RD}(f) \le \tau$ can be obtained by solving the following constrained optimization*

$$\min_{h \in \mathcal{H}} \quad \mathbb{L}_\phi(h) \tag{9}$$
$$\textit{subject to} \quad \mathbb{RD}_\kappa(h) \le \psi_\kappa(\tau - \mathbb{RD}^-) + \mathbb{RD}_\kappa^-,$$
$$-\mathbb{RD}_\delta(h) \le \psi_\delta(-\tau + \mathbb{RD}^+) + \mathbb{RD}_\delta^+.$$

Note that the right-hand sides of above two inequalities are constants for a given dataset. Therefore, the constrained optimization problem is still convex. We can optimally solve this problem and the solution $f^* = sign(h^*)$ is guaranteed to satisfy $-\tau \le \mathbb{RD}(f^*) \le \tau$.

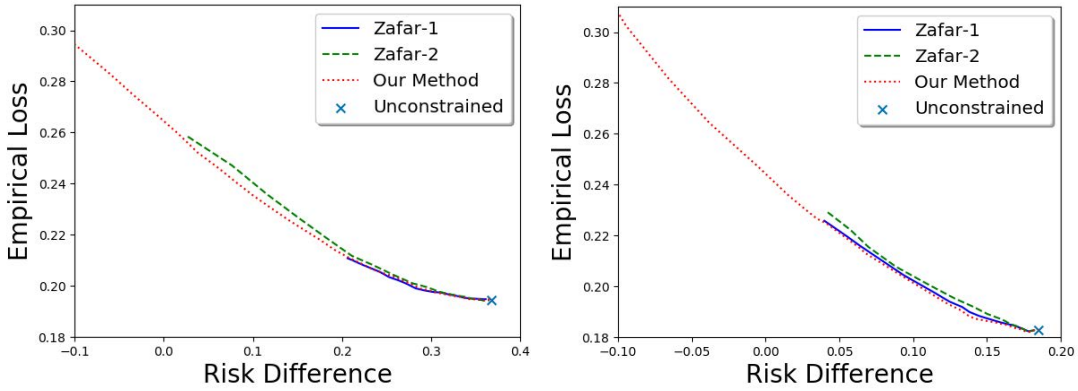
Table 1: Some common surrogate functions for κ-δ and the corresponding $\psi_\kappa(\mu)$ and $\psi_\delta(\mu)$.

Name of κ-δ	$\kappa(\alpha)$ for $\alpha \in \mathbf{R}$	$\delta(\alpha)$ for $\alpha \in \mathbf{R}$	$\psi_\kappa(\mu)$ or $\psi_\delta(\mu)$ for $\mu \in (0, 1/p]$
Hinge	$\max\{\alpha+1, 0\}$	$\min\{\alpha, 1\}$	μ
Square	$(\alpha+1)^2$	$1-(1-\alpha)^2$	μ^2
Exponential	$\exp(\alpha)$	$1-\exp(-\alpha)$	$(\sqrt{(1-p)\mu+1} - \sqrt{1-p\mu})^2$

4 EXPERIMENTS

4.1 Experimental Setup

Dataset. In the experiments we use two datasets: Adult and Dutch. The Adult dataset [9] contains a total of 48,842 instances, each of which is characterized by 14 attributes (e.g., `sex`, `age`, `work_class`, `education`, `income`, etc.). We consider `sex` as the sensitive attribute with two values, `male` and `female`. Then, we consider `income` as the class label. The Dutch dataset [23] contains a total of 60,420 instances, each of which is characterized by 12 attributes. Similarly, we use `sex` as the sensitive attribute, and `occupation` as the class label.



Baseline. We compare our method with two related works, referred to as Zafar-1 [18] and Zafar-2 [17], both of which formulate the fairness-aware classification problem as constrained optimization problems. In [18], the authors quantify fairness using the covariance between the users' sensitive attribute and the signed distance from the feature vectors to the decision boundary. The fairness constraint is formulated as covariance $\le m \times c^*$, where c^* is the measured fairness of the unconstrained optimal classifier and m is a multiplication factor $\in [0, 1]$. In [17], the fairness is quantified similarly with the distance function being replaced with a convex non-linear function. As a result, the obtained problem is a convex-concave optimization problem. In the experiments, we adopt the Disciplined Convex-Concave Programming (DCCP) [15] as proposed in [17] for solving the convex-concave optimization problem. For our method and Zafar-1, the convex optimization problem is solved using CVXPY [3]. The datasets and implementation are available at http://tiny.cc/fair-classification.

4.2 Constraint-free Criterion of Ensuring Fairness

To demonstrate the sufficiency criterion of learning fair classifiers, we build the maximal/minimal risk difference classifiers $f_{\min}, f_{\max}$ for both Adult and Dutch datasets, and measure the risk differences they produce, i.e., $\mathbb{RD}^-$ and $\mathbb{RD}^+$. The results are shown in the first two rows in Table 2. As can be seen, in both datasets we have large maximal and minimal risk differences. In order to evaluate a situation with small a risk difference, we also create a variant of Adult, referred to as Adult*, where all attributes are binarized and the sensitive attribute `sex` is shuffled to incur a small risk difference. Then, we build a number of classifiers including Linear Regression (LR), Support Vector Machine (SVM) with linear kernel, Decision Tree (DT), and Naive Bayes (NB), using the three datasets as the training data with with 5-fold cross-validation. After that, their risk differences are quantified on the testing data, as shown in the last four rows in Table 2. We can see that all values are within $\mathbb{RD}^-, \mathbb{RD}^+$ which are consistent with our constraint-free criterion.

4.3 Learning Fair Classifiers

We build our fair classifiers on both Adult and Dutch datasets by solving the optimization problem defined in Problem Formulation 2. For surrogate functions, we use the logistic function for $\phi(\cdot)$, and the hinge function for $\kappa(\cdot)$ and $\delta(\cdot)$. We also compare our methods with Zafar-1 and Zafar-2. The results are shown in Figure 3, which

(a) Adult **(b) Dutch**

Figure 3: Comparison of fair classifiers.

Table 2: $\mathbb{RD}^+$, $\mathbb{RD}^-$ and risk differences of Linear Regression (LR), Support Vector Machine (SVM), Decision Tree (DT), and Naive Bayes (NB).

$\mathbb{RD}(\cdot)$	Adult	Dutch	Adult*
$\mathbb{RD}^+$	0.967	0.516	0.046
$\mathbb{RD}^-$	-0.967	-0.516	-0.046
LR	0.371	0.185	0.000
SVM	0.434	0.156	0.001
DT	0.316	0.184	0.001
NB	0.447	0.144	0.001

depict the relationship between the obtained risk difference and empirical loss. For our method, different risk differences are obtained by adjusting relax terms c_1 and c_2, while for Zafar-1 and Zafar-2 different risk differences are obtained by adjusting the multiplication factor m. As can be seen, our method can achieve much smaller risk difference than Zafar-1 and Zafar-2. This may be because Zafar-1 linear functions to formulate the fairness constraints, which may incur large estimation errors; while Zafar-2 formulates a convex-concave optimization problem, where only the local optima can be reached. For the same reason, we can observe that our method produces better empirical loss than Zafar-2 given any same risk difference.

5 CONCLUSIONS

In this paper, we studied the fairness-aware classification problem and formulated it as the constrained optimization problem. We proposed a general framework which addresses all limitations of previous works in terms of: (1) various fairness metrics can be incorporated into classic classification models as constraints; (2) the formulated constrained optimization problem is convex and can be solved efficiently; and (3) the lower and upper bounds of real fairness measures are established using surrogate functions, which provide a fairness guarantee for our framework. Within the framework, we proposed a constraint-free criterion under which the learned classifier is guaranteed to be fair in terms of the specified fairness metric, as well as developed the method for learning fair classifiers if the constraint-free criterion fails to satisfy. The results demonstrate the correctness of the constraint-free criterion and the superiority of our method over existing ones in terms of achieving fairness and retaining prediction accuracy.

A OTHER FAIRNESS NOTIONS

Risk ratio is a common fairness notion [11, 14]. It also requires the decision is independent with the protected attribute. Different with the risk difference, the unfairness is quantified by the ratio of the positive decisions between the non-protected group and the protected group. Let's formalize the risk ratio $\mathbb{RR}(h)$ of classifier h:

$$\mathbb{RR}(h) = \frac{\mathbb{E}_{\mathbf{X}|S=s^+}\left[\mathbb{1}_{h(\mathbf{x})>0}\right]}{\mathbb{E}_{\mathbf{X}|S=s^-}\left[\mathbb{1}_{h(\mathbf{x})>0}\right]}.$$

The fairness constraints with regards to risk ratio could be expressed as

$$\mathbb{RR}(h) = \frac{\mathbb{E}_{\mathbf{X}|S=s^+}\left[\mathbb{1}_{h(\mathbf{x})>0}\right]}{\mathbb{E}_{\mathbf{X}|S=s^-}\left[\mathbb{1}_{h(\mathbf{x})>0}\right]} \leq \tau.$$

Similar to Eq. (5), we express the constraints as

$$\mathbb{E}_{\mathbf{X}}\left[\frac{\eta}{p}\mathbb{1}_{h(\mathbf{x})>0} + \tau\frac{1-\eta(\mathbf{x})}{1-p}\mathbb{1}_{h(\mathbf{x})>0}\right] - \tau \leq 0. \tag{10}$$

Equalized odds and equalized opportunity are proposed by Hardt et al. [6]. Equalized odds requires the protected attribute and the predicted label are independent conditional on the truth label. To quantify the strength of equalized odds, we simply propose the prediction difference between two groups conditional on the truth label. So, the equalized odds is

$$\mathbb{EO}(h) = \mathbb{E}_{\mathbf{X}|S=s^+,Y}[\mathbb{1}_{h(\mathbf{x})>0}] - \mathbb{E}_{\mathbf{X}|S=s^-,Y}[\mathbb{1}_{h(\mathbf{x})>0}].$$

Similarly, a classifier h is considered as fair with regard to equalized odds if $\mathbb{EO}(h) \leq \tau$.

Let's reformulate the equalized odds constraints:

$$\begin{aligned}\mathbb{EO}(h) &= \mathbb{E}_{\mathbf{X}|S=s^+,Y}[\mathbb{1}_{h(\mathbf{x})>0}] + \mathbb{E}_{\mathbf{X}|S=s^-,Y}[\mathbb{1}_{h(\mathbf{x})<0}] - 1 \\ &= \mathbb{E}_{\mathbf{X}|Y}\left[\frac{P(S=s^+|\mathbf{x},y)}{P(S=s^+|y)}\mathbb{1}_{h(\mathbf{x})>0} + \frac{1-P(S=s^+|\mathbf{x},y)}{1-P(S=s^+|y)}\mathbb{1}_{h(\mathbf{x})<0}\right] - 1 \leq \tau.\end{aligned} \tag{11}$$

Equalized opportunity is a relaxation of equalized odds where only the positive group ($Y = 1$) is taken into account:

$$\mathbb{EOP}(h) = \mathbb{E}_{\mathbf{X}|Y=1}\Big[\frac{P(S = s^+|\mathbf{x}, Y = 1)}{P(S = s^+|Y = 1)}\mathbb{1}_{h(\mathbf{x})>0} + \frac{1 - P(S = s^+|\mathbf{x}, Y = 1)}{1 - P(S = s^+|Y = 1)}\mathbb{1}_{h(\mathbf{x})<0}\Big] - 1 \leq \tau. \quad (12)$$

By simply replacing the indicator functions with surrogate functions, we can readily extend our framework to the constraints (10), (11), (12) with regard to the three notions. Our criterion and bounds are also extensible to the three notions.

ABSTRACT

Modeling people's activities in the urban space is a crucial socio-economic task but extremely challenging due to the deficiency of suitable methods. To model the temporal dynamics of human activities concisely and specifically, we present State-sharing Hidden Markov Model (SSHMM). First, it extracts the urban states from the whole city, which captures the volume of population flows as well as the frequency of each type of Point of Interests (PoIs) visited. Second, it characterizes the urban dynamics of each urban region as the state transition on the shared-states, which reveals distinct daily rhythms of urban activities. We evaluate our method via a large-scale real-life mobility dataset and results demonstrate that SSHMM learns semantics-rich urban dynamics, which are highly correlated with the functions of the region. Besides, it recovers the urban dynamics in different time slots with an error of 0.0793, which outperforms the general HMM by 54.2%.

1 INTRODUCTION

The rapid urbanization process makes the topic of understanding urban dynamics, i.e. the temporal patterns of urban activities becomes increasingly important. However, traditional approaches rely on expensive manual surveys, yet the understanding is still coarse-grained and limited in geographical scope [1]. Fortunately, the advent of the mobile Internet and Location-Based Social Networks (LBSNs) makes it possible to collect population-scale urban mobility data, which sheds new light on this open problem. Previous works demonstrated that the movements of citizens can be utilized to infer the functions of urban regions [20, 22], and urban activities (e.g., working, resting, etc.) are closely correlated with urban mobility patterns [19, 23], which indicates the feasibility of leveraging urban mobility data to model urban dynamics.

In this paper, we aim to harness the power of massive urban mobility data to deepen the understanding of urban dynamics. The research problem is non-trivial mainly for three reasons: (1) Urban mobility behaviour is a *noisy* representation of urban activities. Therefore, it is difficult to robustly and accurately infer the underlying urban activities from the empirical observation of urban mobility behaviour. (2) The semantic-rich mobility data, i.e., check-in data on LBSNs, is sparse in urban space, especially in sparsely populated areas which poses challenges to extract reliable patterns of urban dynamics for different regions in urban systems. (3) Modern cities are complicated socio-economic systems, where each urban region possesses different urban dynamics due to its unique activities. Therefore, it is challenging to interpret the identified urban dynamics and reveal the underlying mechanisms.

Motivated by these challenges, we propose a novel State-sharing Hidden Markov Model (SSHMM), which considers the mobility behavior of an urban region to reveal the urban dynamics. Specifically, the model learns the urban dynamics of a region as transitions between hidden states, where each state maps to a certain urban activity. The corresponding mobility behavior is generated from the hidden state, which allows the same urban activities to be mapped to slightly different mobility behavior and effectively addresses the problem of data noisy. More importantly, SSHMM facilitates different urban regions to share the same set of hidden states. Therefore, it addresses the challenge of data sparsity , which fully exploits the correlation between different regions. Finally, as a generative model, SSHMM can also characterize the urban dynamics as hidden state sequences. Based on the identified state sequences, we further design an clustering analysis technique to reveal their correlation with urban functions (i.e., land use) and provides a meaningful interpretation of the urban dynamics.

The contributions of our research are three-fold:

(1) We propose a novel urban dynamics revealing model SSHMM. It can robustly and accurately infer the underlying urban activities from noisy and sparse urban mobility data by sharing model parameters across different regions. In addition, it achieves qualitative representations of urban dynamics as the transition patterns between urban activities.

(2) We propose an effective and efficient algorithm to infer the parameters of our model. By splitting the long observations into shorter ones and updating the parameters in parallel, we reduce the training time of learning R groups of parameters to that of only one group, where R is the number of regions.
(3) We evaluate our method using population-scale mobility dataset, which demonstrate that our SSHMM model learns meaningful and explainable urban dynamics.

2 RELATED WORK

Urban dynamics modeling. Urban dynamics, generally defined as how sociological indicators change over time [5] which focuses on characterizing human daily activity rhythms in the city [1, 14]. Time is an important dimension to understand the city. Abbar et al. [1] built activity time series in cities to identify different dynamic patterns via the geo-tagged data from Twitter. Zhang et al. [23] utilized the geo-tagged social media to model people's activities in the urban space via representative learning. Zong et al. [27] investigated to generate dynamic population distributions from static PoIs. Lin et al. [12] considered the impact of PoIs in different time of one day to achieve better crowd flow prediction. Besides, Yuan et al. [22] proposed an LDA model to detect the existence of different functional regions in a city through the GPS trajectory and PoI datasets, and Yao et al. [20] presented a city zone embedding framework using human mobility patterns to infer urban functions. Different from the existing works based on statistical analysis [1] and data visualization [14], we propose a specific model to learn hidden state from human mobility and check-ins to represent urban dynamics.

Hidden Markov Model and its application. Hidden Markov Model (HMM) is a statistical Markov model in which the system being modeled is assumed to be a Markov process with unobserved (i.e., hidden) states [16]. In HMM, model mixture and parameter sharing are very helpful to deal with increasingly complex tasks [6]. One of the well-known mixture methods is the Gaussian mixture model based HMM (GMM-HMM). The second example is shared-distribution HMM, where clustering is carried out for parameters sharing and output distributions are shared with each other if they exhibit acoustic similarity [8]. Another model tied-mixture HMM uses both mixture and parameter sharing, which belongs to semi-continuous HMM [2, 7, 11].

Our proposed SSHMM is also a kind of parameter sharing HMM. While different from previous works, we design it to automatically learn a set of states for the continuous observations and no following clustering is conducted to force the parameters shared. Both based on the Gaussian emission function, we use multi-dimentional Gaussian instead of GMM. In addition, though HMM has been successfully applied into the topic of mobility modeling, most of the work concentrated on individual mobility prediction [13, 24, 26], and we are the first to apply it in urban dynamics modeling.

3 OVERVIEW

3.1 Problem Description

Before formally define our investigated problem, we give the definition of mobility behaviour observation as follows,

Definition 1 (Mobility Behaviour Observation). *The mobility behaviour sequences of region r is a time-ordered sequence $O_r = [O_{r,1}, O_{r,2}, ..., O_{r,N}]$, where $O_{r,n}$ is a tuple of length L, standing for the observation in n-th time slot. It contains two parts: (1) $\{o_{r,n,1}, o_{r,n,2}, o_{r,n,3}\}$ denotes the number of people who arrive at, leave from and stay in this region in this time slot. (2) $\{o_{r,n,4}, o_{r,n,5}, ..., o_{r,n,L}\}$ denotes the check-in frequency of different categories of PoIs.*

Now, we formulate the urban dynamics understanding problem. Given the mobility behaviour observations of a group of regions in the city, we aim to (1) discover hidden states represented by the volume of population and the visited frequency of different PoIs to understand the intrinsic life modes in the city; (2) reveal urban dynamics represented by hidden state sequences to understand the daily life rhythms and their correlation with urban functions; (3) characterize dynamic regularity by learning state transition probability to achieve dynamic prediction.

3.2 Model Description

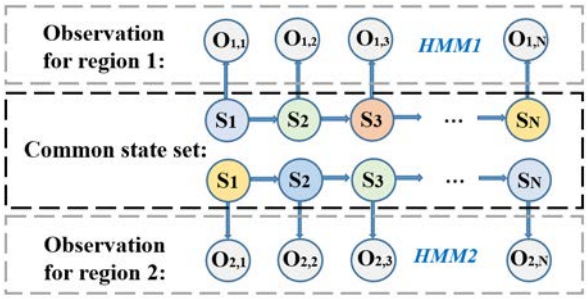

Figure 1: An illustration of the SSHMM, where two kinds of dynamics for region 1 and 2 are generated from the same set of states and each state is presented by a unique color.

Definition 2 (SSHMM). *HMM is parameterized by two parts, one is the state transition parameter characterizing how the states transit and the other is the state emission parameter characterizing how the observation generated by the state. SSHMM contains R groups of HMMs for R groups of observation sequences. However, these HMMs share the same parameters, which means all the observations are generated by the same set of hidden states.*

Our model is based on the general assumptions of HMM, where each observation $O_{r,n}$ is generated from one hidden state s_n, which has L dimensional features, and the n-th hidden state s_n merely depends on the previous state s_{n-1}. We use one HMM denoted by θ_r to model the dynamics of r-th region, therefore we need to learn R groups of transition parameters for R regions in the city. Figure 1 gives the illustration of our model. There are two observation sequences for region 1 and 2, so we learn two HMMs for them respectively. These observations are generated by the same set of states, since life modes (i.e., sleeping, working, etc.) in a city are limited and there exists some similarities between different regions with similar functions. Moreover, the massive mobility data is often sparse and mobility behaviour is a noisy representation of urban activities, which indicates that we can achieve more robust and accurate models by sharing states. These states appear in different time slots, which reveals different dynamics of these two regions.

4 METHODOLOGY

4.1 Data Pre-processing

We first adopt the map segment method [22] to obtain the geographical boundaries of each region formed by the road network. In view of the urban mobility patterns and life-styles, those regions are used as an unit to reveal the dynamics instead of simply dividing the city into grids. To share the states in the city, we normalize mobility behaviour observations to eliminate the problem regarding the difference of population between regions. For mobility, i.e., the number of arriving, leaving and staying, we directly conduct min-max normalization for each region over different time slots respectively. For check-ins, i.e., the visit frequency of PoIs, we first compute the TF-IDF [15] weights based on the region-PoI matrix in each time slot to indicate how popular a PoI category is in a certain time slot. Then, for each region we conduct the min-max normalization on the TF-IDF weights over different time slots to re-scale the mobility behaviour observations to $0-1$. After pre-processing, we regard the aggregated activities in the city as normalized time series, which is denoted by $O = \{O_1, O_2, ..., O_r, ..., O_R\}$ as **Definition 1**.

4.2 Model Definition

When generating $o_{r,n}$ from state s_n, we assume that the emission probability is Gaussian distribution, i.e., $p(o_{r,n,l}|s_n) = N(o_{r,n,l}|\mu_n, \sigma_n)$. The reason to chose the Gaussian is intuitive: μ_n describes the fundamental feature of s_n, while the corresponding observations generated by s_n is slightly different from the mean μ_n with the difference controlled by the variance σ_n. Therefore, we build the SSHMM parameterized by R groups of parameters $\theta = \{\theta_1, \theta_2, ..., \theta_r, ..., \theta_R\}$ with $\theta_r = \{\pi_r, A_r, \mu, \sigma\}$ denoted for r-th region, where
(1) $\pi_r \in \mathbb{R}^{K\times 1}$ denotes the initial distribution over K hidden states, i.e., $\pi_{r,k} = p(s_1 = k)(1 \le k \le K)$;
(2) $A_r \in \mathbb{R}^{K\times K}$ denotes the transition probabilities among the K hidden states. If $(n-1)$-th state is $s_{n-1} = j$, then the probability for n-th state s_n to be k is given by $A_{r,j,k}$, i.e.,$p(s_n = k|s_{n-1} = j) = A_{r,j,k}$;
(3) $\mu, \sigma \in \mathbb{R}^{K\times L}$ denotes the mean and variance of observation probability, i.e., $p(O_{r,n}|s_n = k) = \prod_{l=1}^{L} \frac{1}{\sqrt{2\pi\sigma_{k,l}}} \exp\left(-\frac{(o_{r,n,l}-\mu_{k,l})^2}{2\sigma_{k,l}}\right)$.

It is worth noting that we do not use the subscript r to distinguish μ, σ of different HMMs, because in SSHMM they are determined by the common state set.

4.3 Model learning

4.3.1 Parameter Inference. To infer the parameters, we use Expectation-Maximization method (EM) [4] as the solution. Since SSHMM shares the same set of hidden states, the existing famous Baum-Welch algorithm [18] cannot be applied directly. The insight of EM method is to maximize log likelihood, parameters can be updated by maximizing $Q(\theta_r, \theta_r^t)$ step by step. Therefore, we derive the Q-function for all regions as Eq.1, and we can maximize it to enable the log likelihood converge to its maximum.

$$\begin{aligned} Q(\theta, \theta^t) = &\sum_{r=1}^{R}\sum_{S} p(S|O_r, \theta_r^t) \ln \pi_{r,k} + \sum_{r=1}^{R}\sum_{S}\sum_{n=1}^{N-1} p(S|O_r, \theta_r^t) \ln p(s_{n+1}|s_n) \\ &+ \sum_{r=1}^{R}\sum_{S}\sum_{n=1}^{N} p(S|O_r, \theta_r^t) \ln p(O_{r,n}|s_{r,n}), \end{aligned} \tag{1}$$

where $p(O_r|S, \theta_r^t)$ can be calculated as follows,

$$\begin{aligned} p(O_r|S, \theta_r^t) = &\pi_{r,k} p(O_{r,1}|s_{r,1}) \cdot p(s_{r,2}|s_{r,1}) p(O_{r,2}|s_{r,2}) \\ &\cdots (s_{r,N}|s_{r,N-1}) p(O_{r,N}|s_{r,N}). \end{aligned} \tag{2}$$

From Eq. 1, we observe that optimization parameters π, A (i.e., $p(s_{n+1}|s_n)$) and $\{\mu, \sigma\}$ (i.e., $p(O_{r,n}|s_{r,n})$) appear independently, so we maximize each item separately. Consequently, the forward distribution $\alpha(s_{r,n})$ and backward distribution $\beta(s_{r,n})$ are defined as

$$\begin{aligned} \alpha(s_{r,n}) &= p(O_{r,n}|s_{r,n}) \sum_{s_{r,n-1}} \alpha(s_{r,n-1}) p(s_{r,n}|s_{r,n-1}), \\ \beta(s_{r,n}) &= \sum_{s_{r,n+1}} \beta(s_{r,n+1}) p(O_{r,n+1}|s_{r,n+1}) p(s_{r,n+1}|s_{r,n}), \end{aligned} \tag{3}$$

where $\alpha(s_{r,1}) = \pi_{r,k} p(O_{r,1}|s_{r,1} = k)$ and $\beta(s_{r,N} = k) = 1$. Then, two probability can be derived from α and β as follows,

$$\begin{aligned} \gamma(s_{r,n}) &= p(s_{r,n}|O_r) = \alpha(s_{r,n})\beta(s_{r,n})/p(O_r), \\ \xi(s_{r,n}, s_{r,n+1}) &= p(s_{r,n_1}, s_{r,n}|O_r) \\ &= \alpha(s_{r,n-1}) p(s_{r,n}|s_{r,n-1}) P(O_{r,n}|s_{r,n}) \beta(s_{r,n})/p(O_r), \end{aligned} \tag{4}$$

where $p(O_r) = \sum_{s_{r,N}} \alpha(s_{r,n})$. Based on Eq. 3 and 4, we can thus optimize the parameters π, A and $\{\mu, \sigma\}$ separately as follows.

$$\begin{aligned} \pi_{r,k}^{(t+1)} &= \gamma(s_{r,1}^k), \\ A_{r,j,k}^{(t+1)} &= \frac{1}{\Xi_j} \sum_{n=2}^{N} \xi(s_{r,n-1}^j, s_{r,n}^k), \\ \mu_{k,l}^{(t+1)} &= \frac{1}{\Gamma_K} \sum_{r=1}^{R}\sum_{n=1}^{N} \gamma(s_{r,n}^k) o_{r,n,l}, \\ \sigma_{k,l}^{(t+1)} &= \frac{1}{\Gamma_K} \sum_{r=1}^{R}\sum_{n=1}^{N} \gamma(s_{r,n}^k)(o_{r,n,l} - \mu_{k,l}^{(t+1)})^2, \end{aligned} \tag{5}$$

where $\Gamma_K = \sum_{r=1}^{R}\sum_{n=1}^{N} \gamma(s_{r,n}^k)$, $\Xi_j = \sum_{n=2}^{N}\sum_{i=1}^{K} \xi(s_{r,n-1}^j, s_{r,n}^i)$.

4.3.2 Learning algorithm. Another difficulty is that the process could be inefficient when applied into large-scale datasets due to two aspects. First, the large dataset with a long period N leads the computation of α and β complicated as Eq. 3, and the result may even cause the float number exceeding. Second, the time complexity of parameter inference is $O(RNLK^2)$. which is mainly costed by the calculation of ξ as Eq. 4. The computational complexity of which is quadratic in K, rendering it inefficient for large K. However, if the time period is short or K is not large enough, the model is unable to capture all the dynamic patterns in the city.

To overcome these problems, we first split the long observation sequences into several shorter sub-sequences for each round. By doing this, we not only utilize all the data for parameter learning but also avoid float-point number exceeding. Second, from Eq. 5, we can observe that the updating of $\pi_{r,k}$ and $A_{r,j,k}$ for region r is independent. Thus, we update them in parallel and cuts down the time complexity to $O(NLK^2)$ approximately. The detailed procedure is shown in Algorithm 1. In each iteration, we run EM-steps for W rounds, and in each round, we fed the subsequences of length N into the model. After calculating the $\alpha(s_{r,n})^{(t+1)}$, $\beta(s_{r,n})^{(t+1)}$, $\gamma(s_{r,n})^{(t+1)}$, $\xi(s_{r,n})^{(t+1)}$, $\pi_{r,k}^{(t+1)}$ and $A_{r,j,k}^{(t+1)}$ **in parallel** for all the regions in each round, we update the state parameters $\mu_{k,l}^{(t+1)}$, $\sigma_{k,l}^{(t+1)}$

until the convergence is realized. The code is made publicly available [1].

Algorithm 1: SSHMM parameter learning.

Input: Observations $O = \{O_1, O_2, \ldots, O_R\}$, Maximum Iterations $MaxIter$;
Output: $\theta_r = \{\pi_r, A_r, \mu, \sigma\}$ $\forall 1 \le r \le R$;
Procedure:
  Initialization: $t = 0$, initial $\pi^{(0)}_{r,k} = 1/K$, $A^{(0)}_{r,j,k} = 1/K$, $\mu^{(0)}_{k,l} = random(0, 1)$, $\sigma^{(0)}_{k,l} = random(0, 0.1)$, $\forall 1 \le j, k \le K, 1 \le l \le L$.
  while $t < MaxIter$ **do**
    for $w = 1, 2, \ldots, W$ **do**
      E-step: $\forall 1 \le r \le R$, calculate $\alpha(s_{r,n})^{(t+1)}$, $\beta(s_{r,n})^{(t+1)}$, $\gamma(s_{r,n})^{(t+1)}$, $\xi(s_{r,n})^{(t+1)}$ **in parallel** based on old parameters $\theta^{(t)}_r$ utilizing the $w\text{-}th$ subsequence of O_r.
      M-step: $\forall 1 \le r \le R$, update $\pi^{(t+1)}_{r,k}$, $A^{(t+1)}_{r,j,k}$ **in parallel**. Update $\mu^{(t+1)}_{k,l}$, $\sigma^{(t+1)}_{k,l}$ utilizing $\gamma(s_{r,n})^{(t+1)}$, $\xi(s_{r,n})^{(t+1)}$ $\forall 1 \le r \le R$.
    Update t: $t = t + 1$

4.4 Dynamics Revealing and Functions Inferring

With the model $\theta_r = \{\pi_r, A_r, \mu, \sigma\}$ obtained from Algorithm 1, the state sequences can be decoded by Viterbi algorithm [17], which can represent the dynamics of that state. Recall that regions with similar dynamic patterns could have similar functions, we match the dynamics with the functions by clustering the state sequence of different regions via k-medoids algorithm [9]. In k-medoids algorithm, we define the distance of two sequences as the sum of the Euclidean distance of the mean of the two corresponding states. Then, the distance between states is defined as the Euclidean distance between the mean value vector of Gaussian distribution of these two states. Finally, the distance between state sequences S_i, S_j is the average distance of all the corresponding state sequences.

We adopt *Davies-Bouldin index* (DBI) [3] to determine the number of clusters, which reflects the ratio between inter-cluster distance and inter-cluster distance. A smaller DBI usually indicates a more effective division. Finally, similar dynamics in each cluster would present the same kind of function in the city.

4.5 Dynamics Prediction

SSHMM also has the ability of prediction. Through Viterbi algorithm, we can identify the last state of the region based on the observation. With the advantage of a probabilistic model, we can firstly obtain the current state of the region according to the current observation, then predict the next state according to the latest state by maximizing the transition probability. Formally, given the current observation sequence of $r\text{-}th$ region denoted by $O_{r,1}O_{r,2}, ..., O_{r,n}$, we decode its corresponding hidden state sequence as $s_{r,1}s_{r,2}, ..., s_{r,n}$. If the latest state $s_{r,n}$ is $i\text{-}th$ state, then the state in the next time slot can be predicted as $s_{r,n+1} = \arg\max_{1 \le j \le K} A_{r,i,j}$. This is to say, we can predict the volume of population flows and the percentage of PoIs visited in the next time slot by utilizing the mean value μ, σ of the identified next state.

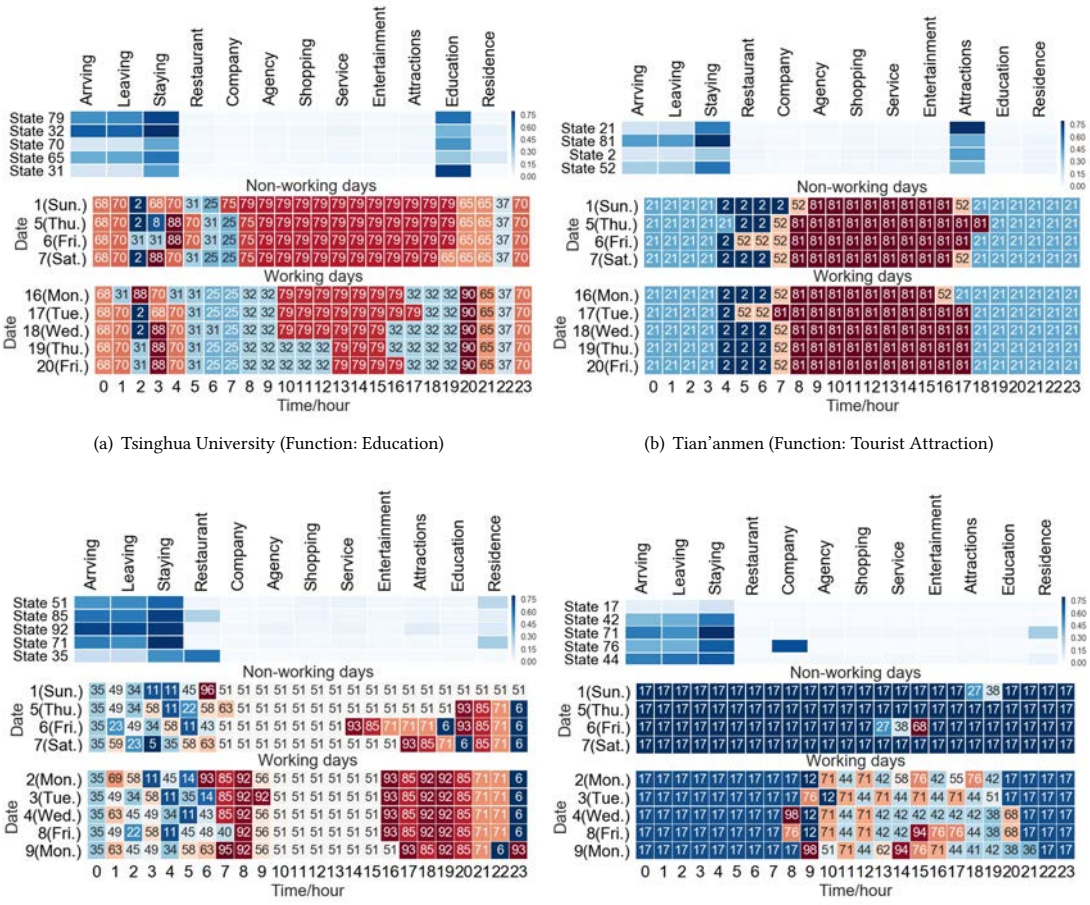
5 EXPERIMENTS

5.1 Data

The mobility dataset was collected by collaborating with *Tencent*[2], one of the largest Internet service providers in China. The collected dataset covers near 2 million users in Beijing, China from April 1st to 30th, 2018. Each trajectory record is characterized by an anonymized user ID, timestamp and the GPS location. Each check-in record consists of user ID, check-in time, check-in location and PoI, which is divided into nine categories: *Company, Agency, Shopping, Service, Entertainment, Attractions, Education* and *Residence*. We crawl the road network from Map service and divide the the downtown area in Beijing into 665 non-overlapping regions.

Ethics. To protect user privacy, all data is anonymous and stored in Tencent offline servers. We pre-process the data under their supervision and only take the aggregated results of different regions for further analysis. Our research has been reviewed and approved by both the company and Tsinghua University institutional board.

5.2 System Settings



5.2.1 Data Usage. In the experiments, we divide the dataset into two parts. We utilize 21 days of data to generate the mobility behaviour observations to train our model and use the rest for prediction evaluation. We set the length of time slot to 1 hour. The observation in each time slot is 12-dimensional, including 3-dimensional population flow volume and 9-dimensional check-in frequency.

5.2.2 Model evaluation. To evaluate the effectiveness of our model and the inferred parameters, we utilize the obtained states to recover the observations by concatenating the mean value of corresponding state in the hidden state sequence in chronological order. We adopt $\epsilon = \sqrt{\frac{\sum_{r=1}^{R}\sum_{n=1}^{N}\sum_{l=1}^{L}(\mu_{n,l} - s_{r,n,l})^2}{R \times N \times L}}$, the error between all of the observations and the activities recovered by the mean value of the corresponding hidden state as an evaluation metric.

To determine the number of hidden states and the length of time slots for training, we searched different values. From fig. 3(a), we can observe that when K increases,ϵ decreases while the training time increases rapidly. Thus, we set $K = 100$ as a trade-off between model complexity and accuracy. As Figure 3(b) show, we find the length of time window has almost no impact on the training time and ϵ. We set is as 24, i.e., train the model day by day.

5.2.3 Prediction Performance. In terms of prediction, we use the rest 9 days' data for evaluation. We compare the mean value of the predicted next state with the ground-truth observations, and the baseline is general HMM. For mobility prediction, we adopt *RMSE*, the root-mean-square error between the normalized the population flow of predicted and the ground truth [25] for measurement. For check-ins, we adopt *TopM-accuracy* to reflect the accuracy on topN frequently-visited PoI prediction of all regions [21]. A lower *RMSE* or a higher *TopM-accuracy* indicates better prediction performance.

(a) Effects of K

(b) Effects of N

Figure 3: Effects of parameters.

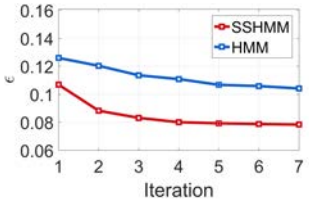

Figure 4: Model Effectiveness comparison.

5.3 Results

5.3.1 Model Effectiveness. Figure 4 shows the relationship between recovering error ϵ and the number of iterations. We compare it with the result of training independent HMM for each region with the same number of states. From Figure 4, we can observe that as the number of iterations increases, the recovering error ϵ decreases first, then tends to remain unchanged. Furthermore, our representative ability for human activities is better than HMM: When the model converges, our ϵ is 0.0793, which outperforms HMM by 54.2%.

5.3.2 Visualization of the Hidden States and Urban Dynamics. In order to demonstrate the ability of our model in discovering hidden states and revealing urban dynamics, we give a series of special examples and detailed explanations. Figure 2 visualizes the results for 6 regions. We first plot the mean value of the states with frequent occurrence, then show the state transition process in working day

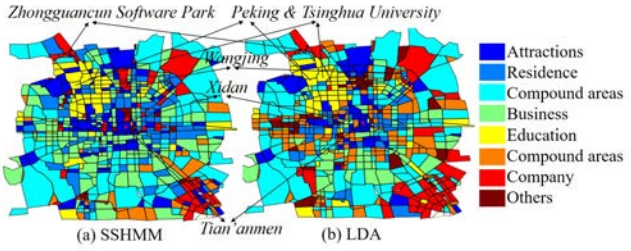
and non-working day (Apr. 5th (Thur.), 6th (Fri.) and 7th (Sat.) are the Qingming Festival), respectively.

States: Each state represents two aspects: (1) The density of the population flow. For example, **state 32** presents a large volume of flows and high density of populations, **state 21** presents a small volume of flows while a high density of populations. (2) The visit frequency of different PoIs. For example, **state 31** indicates the most frequently visited PoI is *Education*, while **state 21** indicates the most frequently visited PoI is *Attractions*. As shown in Figure 2(a), *Tsinghua University* have the **state 79** during the day, and *Tian'anmen* has **state 81**. By combining these two semantics, we can infer the activity level and lifestyle of the region. For example, **state 79** shows active school status while **state 70** shows quiet school status.

Dynamics: Dynamics are represented by the state transition processes. Take the dynamics of *Tsinghua University* as an example. As shown in Figure 2(a), during the night, there are fewer people than the day as **state 70**. Besides, in working days, there is a sudden increase in crowd flow as **state 32** appear in 8:00-9:00 and 17:00-19:00. The transition from **state 70** to **32**, from **32** to **79** in working days reveals the dynamics that only students live in the region at night and many teachers go to school in the morning, causing the population denser than night. Compared with 2(a), 2(b) shows that both in working day and non-working day, the density of population is consistently high and the PoI visited most frequently is *Attractions*, as *Tian'anmen* is one of the most famous tourist spots in China. Another interesting finding is that for residential areas as Figure 2(c), non-working days are more prosperous and lively than working days, but working areas are quiet and peaceful as Figure 2(d) shown. To conclude, Figure 2 gives the insights as follows:
(1) From the state sequence heatmap, we notice that the state sequences are aligned by day, which indicates that the dynamics in the city have a period of one day, as the states in the same time slot but with different dates are usually the same.
(2) The dynamic patterns within working days or no-working days are very similar, while the patterns between working and non-working days are determined by the function of the region.

In summary, SSHMM not only detects the urban states with different activity patterns but also reveal the rhythm of daily life.

5.3.3 Visualization of Urban Functions. To further evaluate our model to infer the functions, we cluster the state sequences by the method introduced in Section 4.4 and found that 8 types is most suitable as the minimum DBI is achieved. We compare the result with the state-of-the-art functional zones discovering method, i.e., an LDA model by utilizing the static PoIs and mobility together [22]. The geographical distribution of the regions with their function types is shown in Figure 5, where different colors present different functions. After clustering, we label their functions by the revealed semantic dynamics and manually check some regions in Figure 2 to verify their functions, which shows most of the regions with the same functions are divided into one cluster. Besides, clusters obtained by our model and LDA model have with the Normalized Mutual Information (NMI) of 0.25, which measures the similarity of two divisions with the range from -0.5 to 1 [10]. Therefore, the functions we infer from dynamic patterns are validated by the labeled regions and the state-of-the-art method.



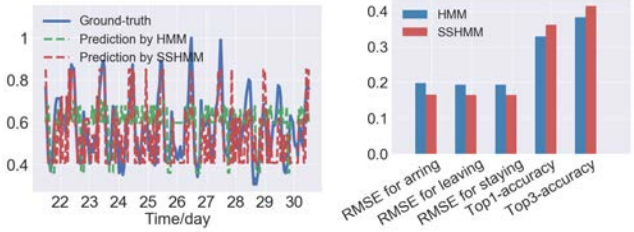


Figure 5: Visualization of the distribution of the regions with similar dynamics and functions.

(a) Prediction for the number of staying of *Tsinghua University*

(b) Evaluation metrics

Figure 6: Prediction performance compared with HMM.

5.3.4 Performance of Activity Prediction. In order to evaluate the prediction accuracy of our model, we first show the prediction of the number of staying for 9 days in *Tsinghua University* in Figure 6(a) as an example. Compared with the generate HMM, the recovered observations of our model are closer to the ground-truth in different time slots. The results for all metrics are shown in Figure 6(b), where the average *RMSE* of population flow prediction is 0.195 and the *Top3-accuracy* for PoI popularity prediction is 41.4%, outperforming the HMM by 16% and 8% respectively. These results demonstrate our SSHMM outperforms HMM in urban dynamics prediction problem.

6 CONCLUSION

In this paper, we study the problem of understanding urban dynamics. We propose a State-sharing Hidden Markov Model (SSHMM), where all the regions share a common state set, but each region has it own transition regularity. To make it practical, we not only derive the inference of the parameters but also give an efficient algorithm to update them. We evaluate our method via a real-life dataset in Beijing, which demonstrates that SSHMM learns semantics-rich urban dynamics model, recovers different activity regularities by a limited number of states and incurs low training cost. Our work also opens a new angle for dynamic urban region representation by learning the vector for both urban states (i.e, the mean of different feature dimension) and urban dynamics (i.e, the state sequence).

ABSTRACT

Hierarchical text classification has many real-world applications. However, labeling a large number of documents is costly. In practice, we can use semi-supervised learning or weakly supervised learning (e.g., dataless classification) to reduce the labeling cost. In this paper, we propose a path cost-sensitive learning algorithm to utilize the structural information and further make use of unlabeled and weakly-labeled data. We use a generative model to leverage the large amount of unlabeled data and introduce path constraints into the learning algorithm to incorporate the structural information of the class hierarchy. The posterior probabilities of both unlabeled and weakly labeled data can be incorporated with path-dependent scores. Since we put a structure-sensitive cost to the learning algorithm to constrain the classification consistent with the class hierarchy and do not need to reconstruct the feature vectors for different structures, we can significantly reduce the computational cost compared to structural output learning. Experimental results on two hierarchical text classification benchmarks show that our approach is not only effective but also efficient to handle the semi-supervised and weakly supervised hierarchical text classification.

1 INTRODUCTION

Text classification has always been an important task, particularly with the vast growth of text data on the Web needed to be classified. The applications include news classification [8], product review classification [31], spam detection [25] and so on. Hierarchical classification (HC) and structured prediction are involved since the classes are usually organized as a hierarchy. In recent decades, many approaches have been proposed for HC. For example, top-down classification [34] classifies documents at the top layer and then propagates the results to next layer until the leaves. This greedy strategy propagates the classification error along the hierarchy. Contrarily, bottom-up classification [1] backpropagates the labels from the leaves to the top layer, making the leaves with less training data but sharing some similarities with their parents and siblings may not get well considered and trained. Moreover, structural output learning, such as structural perceptron [6] and structural SVM [37], can leverage the structural information in the class hierarchy well, but they need to do Kesler construction [11, 30] where for each sub-structure, the new features are constructed based on the existing features and the class dependencies. That is why structural output learning usually takes more time to train than top-down and bottom-up approaches. All the above approaches are supervised methods. When there are more unlabeled data, it is more challenging if we consider both class dependencies and efficiency of the practical use of hierarchical text classification.

There exist several ways to use the large amount of unlabeled data, among which semi-supervised learning (SSL) [4] and weakly supervised learning such as dataless classification [3, 33] are two representative ways. An example of SSL is [29]. It uses a mixture multinomial model to estimate the posterior probabilities of unlabeled data, which share the same parameters with the naive Bayes model for the labeled data. More parameters can be introduced to model the hierarchical structure, causing the model redundant and meanwhile not accurate enough. As for weakly supervised learning, dataless classification [33] uses the semantic similarities between label descriptions and document contents to provide weak labels for documents. When applying the weak labels, current approaches simply treat each label similarity independently and do not consider the path constraints in the label hierarchy.

To tackle the above problems for semi-supervised and weakly supervised hierarchical text classification, we propose a path cost-sensitive learning algorithm based on a generative model for text. When estimating the path posterior distribution, the path-dependent scores are incorporated to make the posteriori path-sensitive. The path-dependent score evaluates how accurate the current model is in terms of classifying a document among the paths in the class hierarchy. Then during inference, classification is constrained to keep the consistency of the hierarchy. By this mechanism, we develop a simple model with fewer parameters compared with existing approaches while maintaining the consistency property for the class dependencies in the hierarchy.

The contributions of our paper are as follows:

(1) We propose **a new approach for hierarchical text classification** based on a probabilistic framework. We highlight its meanings in cost-sensitive learning and constraint learning.
(2) We show significant improvements on two widely used hierarchical text classification benchmarks and demonstrate our algorithm's **effectiveness** in **semi-supervised** and **weakly-supervised learning** settings.
(3) Our approach **reduces the complexity** of traditional methods. We achieve tens of times speedup while outperforming the state-of-the-art discriminative baseline.

The code and data used in the paper are available at https://github.com/HKUST-KnowComp/PathPredictionForTextClassification.

2 RELATED WORK

There are only a few studies on semi-supervised hierarchical (text) classification [9, 29], partially because of the difficulty to evaluate the class dependencies for unlabeled data and the time cost of using more complicated algorithms such as structural output learning [23]. Most semi-supervised hierarchical text classification works were based on EM algorithm introduced by [29]. Some are related with ours (see in Section 2.1), while others are not, e.g., [9] used EM algorithm to deal with incomplete hierarchy problem, which was not the same setting as ours. In this section, we simply start with the review of general hierarchical text classification and then explain the uniqueness and significance of our work.

Hierarchical text classification has been studied for several decades. Flat multi-label classification methods [36] ignore the hierarchy, thus poor for HC. Early works [12, 17, 22] often used "pachinko-machine models" which assigned a local classifier at each node and classified documents recursively. Top-down and bottom-up approaches utilize the local classifier ideas, but top-down is a greedy strategy so it may not find optimal solutions, while bottom-up approach does not well consider and train the classes with less training data.

To better exploit the class hierarchy, algorithms particularly designed for trees can assist. In practice, both generative and discriminative models are used. In the following, we will review the related work of these two categories.

2.1 Generative Models

[29] summarized the text generative model and provided the naive Bayes classifier and Expectation-Maximization (EM) algorithm for flat classification. As for HC, it introduced more parameters to account for the class dependencies. [24] remodeled the framework in another way. They applied shrinkage to smooth parameter estimates using the class hierarchy. [7] also used the same generative framework but proposed a clustering-based partitioning technique. These generative hierarchical methods can bring some structural information to the model, but they do not make full use of the hierarchy and have difficulties scaling to large hierarchies.

2.2 Discriminative Models

Discriminative methods are also popular for HC. Orthogonal Transfer [39] borrowed the idea of top-down classification where each node had a regularized classifier and each node's normal vector classifying hyperplane was encouraged to be orthogonal to its ancestors'. Hierarchical Bayesian Logistic Regression [16] leveraged the hierarchical dependencies by giving the children nodes a prior centered on the parameters of its parents. The idea was further developed in Hierarchically Regularized SVM and Logistic Regression [15], where the hierarchical dependencies were incorporated into the parameter regularization structure. More recently, the idea of hierarchical regularization has been applied to deep models and also showed some improvements [32]. [5] simplified the construction of classifier by building a binary classifier on each tree node and providing the cost-sensitive learning (HierCost). All the above approaches are still based on top-down or greedy classification which can result in non-optimal solutions. Another similar work with ours is [38]'s hierarchical loss for classification, which defined the hierarchical loss or win as the weighted sum of the probabilities of the nodes along the path. In contrast to their work, we use the sum of the (weakly) labeled instances along a path as score to perform path cost-sensitive learning.

To find more theoretically guaranteed solutions, some algorithms were developed based on structural output learning [6, 18, 35, 37], which can be proved to be global optimal for HC. Hierarchical SVM (HSVM) [2], one example of structural SVM, generalized SVM to structured data with a path-dependent discriminant function. In general, when performing structural output learning, Kesler construction is used to construct the feature vectors for comparing different structures [11, 30], which adds much more computation than top-down or bottom-up classification approaches.

In summary, generative and discriminative models can both be adapted to HC problems. Discriminative models achieve better performance with adequate labeled data [28], especially if a better representation for text can be found, e.g., using deep learning [32]. Whereas generative models have their advantage for handling more uncertainties [28] for limited labeled data and under noisy supervision. Our work is based on a generative model yet has the same parameter size as the flat classification. We find that it significantly boosts the performance of semi-supervised learning and weakly supervised learning as well as reduces the computational cost.

3 PATH PREDICTION FOR HIERARCHICAL CLASSIFICATION

In HC, the classes constitute a hierarchy, denoted as $\mathcal{T}$. $\mathcal{T}$ is a tree whose depth is d, with the root node in depth 0. Then the classes are distributed from depth 1 to d. We suppose that all leaf nodes are in depth d. This can always be satisfied by expanding the shallower leaf node (i.e. giving it a child) until it reaches depth d. When evaluating models, these dummy nodes from $\mathcal{T}$ can be easily removed to avoid affecting the performance measure.

Let $C_1, \ldots, C_d$ be the class sets in depth $1, \ldots,$ depth d accordingly, with sizes $M_1, \ldots, M_d$. To classify a document, we assign labels in each depth, i.e., the document gets d labels $\{c^k_{j_k} : k = 1, \ldots, d, j_k = 1, \ldots, M_k\}$. These $\{c^k_{j_k}\}$ form a path in $\mathcal{T}$ if the classification results in each depth are consistent with other depths. We want to maintain the consistency of the hierarchy, therefore we classify the documents by paths instead of by multi-label classes. After assigned a path, the document's classes are the nodes lying in the path. It is similar with structured prediction since a path can be

regarded as a structured object, which contains more information than a set of multi-label classes without path constraints.

To sum up, path prediction aims at making use of the structural information in the class hierarchy to train the classifier. Note that the classifier is for paths in the hierarchy instead of classes. The details of path prediction algorithm are given in the next section.

4 PATH COST-SENSITIVE LEARNING

In this section, we introduce our method which utilizes the structural information to learn the classifier, revealing its meanings in cost-sensitive learning and constraint learning.

4.1 Path-Generated Probabilistic Framework

We base our work on a widely-used probabilistic framework, which constructs a generative model for text. In the framework, text data are assumed to be generated from a mixture of multinomial distributions over words. Previous works [24, 29] assumed that the mixture components in the generative model have a one-to-one correspondence with the classes. However, in order to perform path prediction, we presume that the mixture components have a one-to-one correspondence with the paths.

Define $\mathcal{P}$ to be the set of all paths which start from the root node and end in some leaf node in the class hierarchy $\mathcal{T}$, so the size of $\mathcal{P}$ equals to that of the leaf nodes M_d. Let $\mathcal{V}$ be the vocabulary. Denote θ as the parameters for the mixture multinomial model. For a document x_i with length $|x_i|$, suppose x_{it} is the word frequency of word w_t in x_i, which is the document feature represented by vector space model [21]. Then the generative process runs as following.

First, select a mixture component, or equivalently a path $p_j \in \mathcal{P}$, from $P(p_j|\theta)$ (prior of p_j). Next, generate the document x_i by selecting the length $|x_i|$ and picking up $|x_i|$ words from $P(x_i|p_j;\theta)$. According to the law of total probability and the naive Bayes assumption that given the labels, the occurrence times of each word in a document are conditionally independent with its position as well as other words, the probability of generating x_i is

$$P(x_i|\theta) \propto P(|x_i|)\sum_{j=1}^{M_d} P(p_j|\theta)\prod_{w_t\in\mathcal{V}} P(w_t|p_j;\theta)^{x_{it}}. \quad (1)$$

In general, document lengths are assumed to be independent with classes, thus independent with paths. So model parameters θ include the path prior $\theta_{p_j} \equiv P(p_j|\theta)$ and the multinomial distribution over words for each path $\theta_{w_t|p_j} \equiv P(w_t|p_j;\theta)$.

4.2 Path-Dependent Scores

Given a data set $\mathcal{D} = \{(x_i, y_i) : x_i \in \mathcal{X}_l\} \cup \{x_i : x_i \in \mathcal{X}_u\}$, consisting of the labeled documents $\mathcal{X}_l$ and the unlabeled documents $\mathcal{X}_u$. We now derive the parameter estimation in a supervised manner. With only labeled data considered, we maximize $P(\theta|\mathcal{X}_l)$, which can be done by counting the corresponding occurrences of events. The event counts are usually the hard counts for flat classification. Here we use a path-dependent score to substitute it.

First we define the score of a node in $\mathcal{T}$ for a document. Suppose $x_i \in X_l$, $c^k_{j_k}$ is the k^{th} node in path p_j. The node score of $c^k_{j_k}$ for x_i, denoted as $S_i(c^k_{j_k})$, indicates the label of x_i. When x_i is labeled with the ground truth labels, $S_i(c^k_{j_k}) = 1$ if and only if $c^k_{j_k}$ is one of

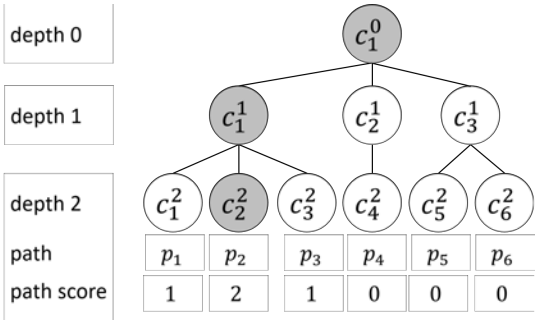

Figure 1: An example of path scores. Suppose x_i is labeled as $\{c^1_1, c^2_2\}$. S_{ij} for $j = 1, \ldots, 6$ is shown in the figure.

x_i's labels. We also consider the weakly supervised case. In [33]'s dataless text classification, for $x_i \in \mathcal{X}_l$, it is weakly labeled by the semantical similarities with classes. We assign value 1 to $S_i(c^k_{j_k})$ if x_i has the largest similarity with $c^k_{j_k}$ among all classes in depth k and 0 otherwise.

Next we introduce the path score. For $x_i \in X_l$, the score of path p_j, denoted as S_{ij}, is the sum of the nodes' scores $S_i(c^k_{j_k})$ lying in p_j except the root node since it makes no sense for classification.

$$S_{ij} \equiv S_i(p_j) = \sum_{k=1}^{d} S_i(c^k_{j_k}). \quad (2)$$

Take the hierarchy in Figure 1 as an example. x_i is labeled as $\{c^1_1, c^2_2\}$, then $S_{i2} = S_i(c^1_1) + S_i(c^2_2) = 2$, $S_{i1} = S_{i3} = 1$, while other paths score 0. If x_i is weakly labeled by the similarities, then we label it with the classes having the maximum similarity in each depth and obtain the path scores in the same way.

4.3 Path Cost-Sensitive Naive Bayes Classifier

While doing the empirical counts, the Laplace smoothing is often applied by adding one count to each event to avoid zero probability and shrink the estimator. Combining the event counts (i.e. the path scores) and the smoothing term, the parameter estimates are:

$$\hat{\theta}_{p_j} \equiv P(p_j|\hat{\theta}) = \frac{1 + \sum_{x_i\in\mathcal{X}_l} S_{ij}}{M_d + \sum_{k=1}^{M_d}\sum_{x_i\in\mathcal{X}_l} S_{ik}}, \quad (3)$$

$$\hat{\theta}_{w_t|p_j} \equiv P(w_t|p_j;\hat{\theta}) = \frac{1 + \sum_{x_i\in\mathcal{X}_l} S_{ij}x_{it}}{|\mathcal{V}| + \sum_{s=1}^{|\mathcal{V}|}\sum_{x_i\in\mathcal{X}_l} S_{ij}x_{is}}. \quad (4)$$

There are two aspects of using the path scores as event counts:

(1) Cost-sensitive performance measures are considered since different data samples are given different weights. In Figure 1, x_i is counted twice for p_2, once in c^1_1 and once in c^2_2, thus obtaining more weights. p_1 and p_3 are not right paths for x_i, but they still classify correctly in depth 1, thus get one count, less than p_2 but larger than other paths who have no correct labels at all. This path **cost-sensitive learning** behavior helps the model to maintain structural information.

(2) The path scores function as the measuring indicators of paths, capacitating the model to classify the documents by paths. The path prediction actually puts constraints on the classifier, where the prediction results must be consistent with the class

hierarchy. Furthermore, the **constraint learning** reduces the search space and improves efficiency.

After estimating θ from $\mathcal{X}_l$, for any test document x_i, the posterior probability distribution can be obtained by Bayes' rule:

$$P(y_i = p_j|x_i;\hat{\theta}) = \frac{P(p_j|\hat{\theta})P(x_i|p_j;\hat{\theta})}{P(x_i|\hat{\theta})} = \frac{\hat{\theta}_{p_j}\prod_{w_t\in\mathcal{V}}(\hat{\theta}_{w_t|p_j})^{x_{it}}}{\sum_{k=1}^{M_d}\hat{\theta}_{p_k}\prod_{w_t\in\mathcal{V}}(\hat{\theta}_{w_t|p_k})^{x_{it}}}. \quad (5)$$

Then x_i will be classified into $\arg\max_j P(y_i = p_j|x_i;\hat{\theta})$.

The path cost-sensitive naive Bayes classifier (PCNB) for the generative model are introduced above. Next we will present the semi-supervised path cost-sensitive learning algorithm.

4.4 Semi-Supervised Path Cost-Sensitive Learning

Until now, only the labeled data are used during training, but we want to make use of the unlabeled data to ameliorate the classifier. We follow [29] to apply EM technique for SSL.

When the initial parameters are given, the posterior probabilities of $\mathcal{X}_u$, computed through Eq. (5), can act as the path score S_{ij} for $x_i \in X_u$. Combining the labeled and unlabeled data together, the parameter estimates are changed into

$$\hat{\theta}_{p_j} = \frac{1+\sum_{x_i\in\mathcal{X}_l\cup\mathcal{X}_u} S_{ij}}{M_d + \sum_{k=1}^{M_d}\sum_{x_i\in\mathcal{X}_l\cup\mathcal{X}_u} S_{ik}}, \quad (6)$$

$$\hat{\theta}_{w_t|p_j} = \frac{1+\sum_{x_i\in\mathcal{X}_l\cup\mathcal{X}_u} S_{ij}x_{it}}{|\mathcal{V}| + \sum_{s=1}^{|\mathcal{V}|}\sum_{x_i\in\mathcal{X}_l\cup\mathcal{X}_u} S_{ij}x_{is}}. \quad (7)$$

Note that the numerical value of S_{ij} for $x_i \in X_u$ ranges in $[0, 1]$ since it is the posterior probability. Therefore, the unlabeled data weight less than the labeled data while estimating the parameters. It is reasonable because the labeled data are more authentic than the inference results of unlabeled data, especially in the early iterations where the model does not reach convergence.

The new θ obtained via Eqs. (6) and (7) are then used to compute the posterior probabilities of $\mathcal{X}_u$ again, which in turn update θ. The iterative process keeps maximizing the likelihood of the dataset $P(\theta|\mathcal{D})$, equivalent to maximizing the log likelihood:

$$l(\theta|X,Y) \propto log(P(\theta)P(\mathcal{D}|\theta)) = log(P(\theta)) + \sum_{x_i\in\mathcal{X}_l} log(P(y_i = p_j|\theta)P(x_i|y_i = p_j;\theta)) + \sum_{x_i\in\mathcal{X}_u} log\sum_{p_j\in\mathcal{P}} P(p_j|\theta)P(x_i|p_j;\theta). \quad (8)$$

Refer to [10], the convergence of EM can be guaranteed, but it reaches some local maxima. To enable the algorithm to find good local maxima, we initialize θ with those obtained through the naive Bayes classifier on $\mathcal{X}_l$. Algorithm 1 presents the EM algorithm for the path cost-sensitive classification (PCEM).

5 EXPERIMENTS

For empirical evaluation of effectiveness and efficiency of our approach, we design experiments on semi-supervised and weakly supervised hierarchical text classification tasks, compared to the representative and the state-of-the-art baselines.

Algorithm 1 Path Cost-Sensitive Algorithm with EM

Input: Training data $\mathcal{D} = \mathcal{X}_l \cup \mathcal{X}_u$, test data $\mathcal{D}_{test} = \mathcal{X}_{test}$, class hierarchy $\mathcal{T}$.

Training:

- Compute path scores for $\mathcal{X}_l$, using Eq. (2).
- Initialize the classifier $\hat{\theta}$ with the path-constrained naive Bayes classifier (Section 4.3).
- **while** $l(\hat{\theta})$ (Eq. (8)) not converged **do**
  E-step: use the current $\hat{\theta}$ to compute the path scores of $\mathcal{X}_u$ with Eq. (5).
  M-step: use the path scores of $\mathcal{X}_l$ and $\mathcal{X}_u$ to re-estimate $\hat{\theta}$, with Eqs. (6) and (7).
- **end while**

Testing:

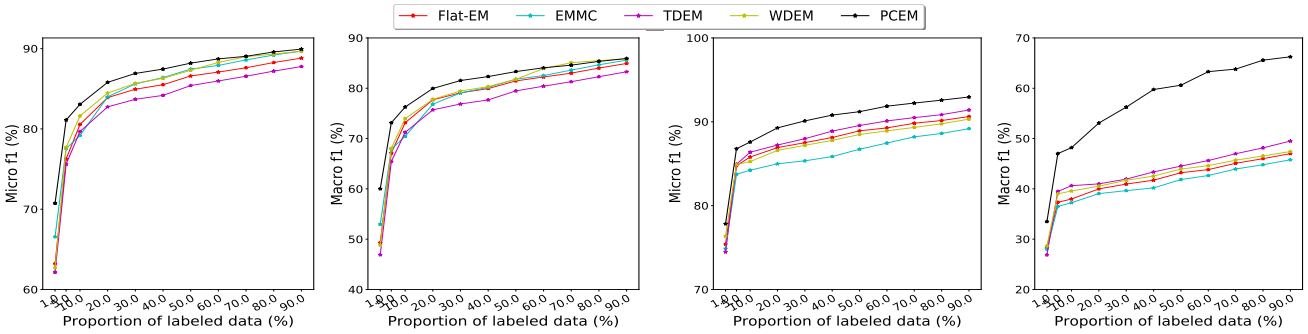
- Compute the posterior probabilities for $\mathcal{X}_{test}$ with Eq. (5). Classify $\mathcal{X}_{test}$ by selecting $\hat{j} = \arg\max_j P(y_i = p_j|x_i;\hat{\theta})$ for $x_i \in \mathcal{X}_{test}, p_j \in \mathcal{P}$. The classes of x_i are nodes in $p_{\hat{j}}$.

Output: The classifier $\hat{\theta}$ and classification results for $\mathcal{D}_{test}$.

	#Training	#Test	#Features	#Leaves	#Nodes	Depth
20NG	15,077	3,769	103,363	20	27	2
RCV1	6,395	1,733	26,888	35	56	3

Table 1: Statistics of the datasets.

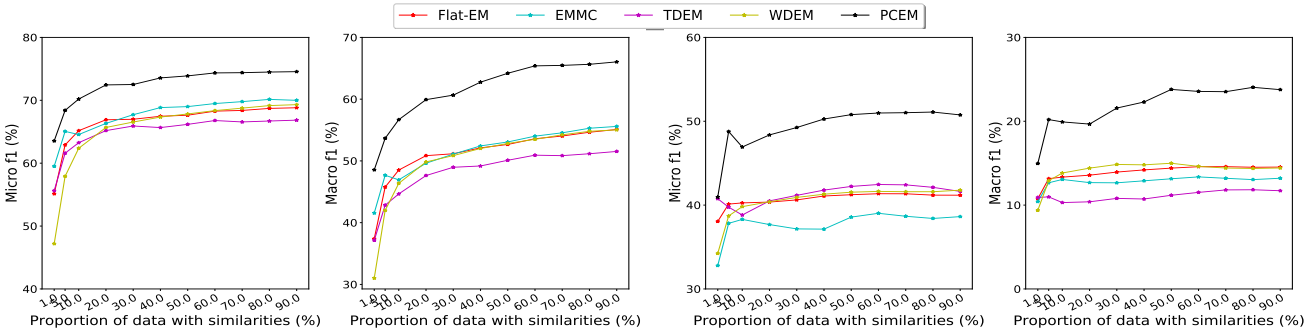
5.1 Experimental Design



5.1.1 Datasets. We use two datasets, both of which have semi-supervised and weakly-supervised version. The statistics are listed in Table 1.

- **20NG**[1] [19] 20 Newsgroups is a widely-used text classification dataset. To experiment on weakly-supervised setting and compare with semi-supervised baselines, we use dataless 20NG provided in [33].
- **RCV1** [20] RCV1 is a collection of manually labeled Reuters News from 1996-1997. We also use the subset of data provided in [33], which consists of 8,668 single-labeled news documents on the dataless setting.

5.1.2 Baselines. We compare our path cost-sensitive algorithms (**PCNB** and **PCEM**) with the following baselines:



- **Generative baselines**
  (1) Flat naive Bayes classifier (**Flat-NB**) and **Flat-EM** algorithm: the flat classifiers introduced in [29].
  (2) Naive Bayes classifier with multiple components (**NBMC**) and **EMMC**: a more expressive model proposed by [29].
  (3) Top-down naive Bayes classifier (**TDNB**) and **TDEM**: the classifiers run in the top-down way.
  (4) Win-driven naive Bayes classifier (**WDNB**) and **WDEM**: the modified hierarchical loss for classification [38].
- **Discriminative baselines**

Figure 2: Experimental results on semi-supervised classification. (a)-(d) shows the micro-F_1 score and macro-F_1 score on 20NG and RCV1. The horizontal axis is label rate (%). The vertical axis represents the F_1 scores (%).

(a) Evaluation Results on 20NG (b) Evaluation Results on RCV1

Figure 3: Experimental results on weakly-supervised classification. (a)-(d) shows the micro-F_1 scores and macro-F_1 scores on dataless 20NG and RCV1. The horizontal axis is the proportion of data with semantical similarities (%) in training set. The vertical axis represents the F_1 scores (%).

(1) Logistic regression (**LR**) and **SVM**: two classical discriminative methods. Our experiments use the LibLinear[2] [13] to train corresponding models and test. During the experiments, we found that dual solvers were much faster and even better in performance than primal solvers, so we chose dual solvers.
(2) **HierCost**[3] [5]: the state-of-the-art discriminative method for hierarchical text classification.

5.1.3 Evaluation Metrics. We use F_1 scores [40] to evaluate the performances of all methods. Denote TP_i, FP_i, FN_i as the instance numbers of true-positive, false-positive and false negative for class c_i. Let C be the set of all classes except the root node. Two conventional F_1 scores are defined as:

- **Micro**-$F_1 = \frac{2PR}{P+R}$, where $P = \frac{\sum_{c_i \in C} TP_i}{\sum_{c_i \in C}(TP_i+FP_i)}$ is the averaged precision and $R = \frac{\sum_{c_i \in C} TP_i}{\sum_{c_i \in C}(TP_i+FN_i)}$ is the averaged recall.
- **Macro**-$F_1 = \frac{1}{|C|}\sum_{c_i \in C} \frac{2P_iR_i}{P_i+R_i}$, where $P_i = \frac{TP_i}{TP_i+FP_i}$ and $R_i = \frac{TP_i}{TP_i+FN_i}$ are the precision and the recall for c_i.

For the two F_1 scores, we measure the overall performance of all classes in the hierarchy in our experiments.

5.2 Results

To evaluate our algorithms, we compare our algorithms with the baselines in semi-supervised and weakly supervised hierarchical text classification. Results on all datasets under 1% label rate are summarized in Table 2, where 1% label rate means there are 1% data in the training set are labeled or weakly-labeled, which is a common setting for semi-supervised text classification. To show that our approach (PCEM) indeed levareges unlabeled data and weakly labeled data well, we present the results under different label rates compared with other EM methods in Figure 2 and 3. For each experiment, we randomly split the training data into labeled and unlabeled according to the label rate, then run experiments using the splitted training data. The running is executed for 5 times and the mean F_1 scores are calculated. Next we will analyze the results. Time efficiency will also be discussed.

Table 2: F_1 scores (%) on 1% "labeled" data of each dataset. Under each dataset, the two columns are Micro-F_1 (left) and Macro-F_1 (right). The best results are shown in boldface. The statistical significance metrics are marked with either † if p-values < 0.05 or ‡ if p-values < 0.001.

5.2.1 Semi-Supervised Classification with True Labels. Table 2 shows that when the training data are partly labeled with the ground truth labels, PCEM has remarkable superiority over other methods all the time. The discriminative baselines do not have their advantages on the semi-supervised and weakly supervised settings. When compared with generative baselines, our approaches, either naive Bayes (PCNB) or semi-supervised (PCEM), are the best among the corresponding methods. It demonstrates that our algorithms makes good use of the structural information to improve the hierarchical classification.

As expected, EM approaches outperform the corresponding naive Bayes classifier under 1% label rate, which reveals the benefits from the unlabeled data. However, we also noticed that EM may be surpassed by NB when the label rate gets larger. That is related with whether the ratio between labeled and unlabeled data is suitable for SSL, as well as the bias of unlabeled data. This issue has been discussed in previous works [14].

To see the performance in SSL, we compare PCEM with other EM methods in Figure 2. The label rate ranges in $[1.0, 90.0](\%)$. We find that PCEM outperforms others steadily. Other hierarchical EM methods are close to Flat-EM, showing that they takes little advantage of the class hierarchy. The results reveal the effectiveness of PCEM under all label rates for semi-supervised classification.

5.2.2 Weakly-Supervised Classification on Dataless Setting. We also make a comparison with the baselines on dataless text classification. The experimental setting is the same as the semi-supervised classification, except that the training documents do not have labels. Instead, some of them are 'labeled' as classes with the maximal semantical similarities. We use the dataless 20NG and RCV1 datasets provided by [33]. Results are presented in Table 2 and Figure 3.

We find the consistent results with the semi-supervised setting. PCEM can always beat the baselines with significant improvements. PCNB is also better than other NB methods. It is worth noting that the gaps between our algorithms (PCNB and PCEM) and the baselines are bigger than those in the semi-supervised setting. We think the reason is that for this weakly-labeled dataset, the similarities can be seen as noisy labels for documents. In this noisy circumstance, our path cost-sensitive learning algorithm with the probabilistic framework is pretty good at making use of the structural information and features of unlabeled data to recover the true generative distribution.

5.2.3 Efficiency Comparison. Time complexity is also under consideration to evaluate our algorithms. PCNB is highly efficient, faster than all of the other methods except Flat-NB and even competitive with Flat-NB. PCEM is slightly slower than LR and SVM, but that is because EM methods leverage the unlabeled data, which cannot be used by discriminative methods. The trade-off is acceptable, especially considering the excellent performance of PCEM. Furthermore, PCEM also achieves tens of times speedup compared to HierCost.

6 CONCLUSIONS AND FUTURE WORK

We present an effective and efficient approach for hierarchical text classification. Our path cost-sensitive learning algorithm alters the traditional generative model of text with a path-generated model to constrain the classifier by the class hierarchy. We show that our algorithm outperforms other baselines on semi-supervised learning and weakly supervised learning. In addition, our model has the potential of extension to other models, not limited to the generative one, if the path-dependent scores are incorporated appropriately. For the possible future work, we will convert the current framework into a discriminative learning framework following [6] and apply deep neural models to learn a better representation for text [26, 27]. Discrimative framework will further improve the learning when there are more labeled data and deep neural models are more powerful to handle different kinds of weak supervision.

ABSTRACT

In this paper, we study the problem of recommending personalized items to users given their sequential behaviors. Most sequential recommendation models only capture a user's short-term preference in a short session, and neglect his general (unchanged over time) and long-term preferences. Besides, they are all based on deterministic neural networks, and consider users' latent preferences as point vectors in a low-dimensional continuous space. However, in real world, the evolutions of users' preferences are full of uncertainties. We address this problem by proposing a hierarchical neural variational model (HNVM). HNVM models users' three preferences: general, long-term and short-term preferences through an unified hierarchical deep generative process. HNVM is a hierarchical recurrent neural network that enables it to capture both user's long-term and short-term preferences. Experiments on two public datasets demonstrate that HNVM outperforms state-of-the-art sequential recommendation methods.

1 INTRODUCTION

Recommender Systems aim at helping users to find interesting items from rich candidates. Most traditional methods [7, 9, 18, 24, 37] are based on matrix completion where the goal is to predict the missing value. In most real scenarios, a user's actions are sequential, which can reflect the user's short-term preference and item's sequential information [25]. However, pervious methods [7, 9, 18, 24] based on matrix completion neglect sequential patterns for recommendation.

To capture users' sequential patterns, a number of methods called session-based recommendation methods [3, 10, 11, 16, 19, 34] built based on Recurrent Neural Networks (RNN) have been proposed. Session-based recommendation aims at predicting the next item that the user will interact with based on on pervious interactions with items inside the current session. Despite the appeal of these methods, they all assume that users are anonymous. However, users' profiles in many application platforms such as YouTube and Linkedin are available. In these platforms, a user's pervious session and profile can be utilized for capturing user's long-term and general preferences [15, 32] so as to personalize recommendation results. As unveiled by Jannach et al. [15, 22], both user's short-term and long-term preferences are crucial to improve recommendation performance. However, recent session-based methods [10, 11, 19] only consider user's most recent actions (short-term preference) in the current session, and neglect user's past session behavior (long-term preference) and users' profiles (general preference).

To consider both user's short-term and long-term preferences, some recent sequential models have been proposed [5, 13, 22, 26, 39]. These methods demonstrate a number of major drawbacks: (a) They do not model user's general (unchanged over time) preference corresponding to a user's profile, e.g., his id and demographics which can be leveraged to improve performance especially in job recommendation websites, e.g., Linkedin, (b) they don't model the relationship between user' past session and current session (with the exception of Quadrana et al [26]) , which is important for capturing users' long-term preferences, and (c) Recent work [26] is based on deterministic hierarchical recurrent neural networks which limit it to capture users' long-term preferences due to the restricted shallow generation process [30].

To address the aforementioned problems, we study the problem of sequential recommendation, which is to enhance personalization recommendation performances. We aim at jointly modeling users' general, long- and short-term preferences though a unified hierarchical deep generative model. Deep generative models [28, 40] have emerged as a powerful model to learn latent disentangled representations from data and improve the diversity of generative results [2, 14, 30, 41], while they have led to promising improvements in computer vision (CV) [14, 40] and neural language processing (NLP) tasks [4, 30, 41]. Specifically, we proposed a **H**ierarchical **N**eural **V**ariational **M**odel (HNVM), which models a hierarchical generative

process of three different preferences: general, long- and short-term preferences. Specifically, HNVM models user's general, long- and short-term preferences to be conditioned on user's profile, the past session and the current session, respectively. Our HNVM extends existing session-based recommendation in three directions: (a) The hierarchical generative process of HNVM makes itself to be able to effectively capture three kinds of preferences for a user, (b) It uses a two-level RNN network to model user's sequential pattern inside session and cross session, and (c) It is a hierarchical latent variables model, it is able to learn users' general and long-term preferences as latent Gaussian representations and can effectively handle the problem of restricted shallow generation process [26]. Our main contributions can be summarized as follows:

(1) We propose a novel hierarchical deep generative model which is the first model to jointly model different categories of preferences: general, long- and short- term preferences in the context of streams of sessions, such that user's profile and his past session information can be effectively captured for recommendation. (2) We propose a hierarchical stochastic gradient variational Bayes (SGVB) inference algorithm to jointly infer latent variables and estimate parameters. We derived a *conditional session − level variational lower bound* that leads to efficient Bayesian learning with back-propagation. (3) The experiment results demonstrate that our HNVM outperforms the state-of-the-art methods for sequential recommendation task.

2 PRELIMINARIES

We first introduce the task of personalized sequential recommendation, and then review the session-based recommendation with recurrent neural network (RNN) that related most to our HNVM.

2.1 Notations and Problem Formulation

Let $\mathcal{U} = \left\{u_1, u_2, ..., u_{|\mathrm{U}|}\right\}$ and $\mathcal{I} = \left\{i_1, i_2, ..., i_{|\mathrm{I}|}\right\}$ be sets of users and items, with $|\mathcal{U}|$ and $|\mathcal{I}|$ being the sizes, respectively. For each user u, let his sequential actions (sessions) sorted by time denote as a sequence of sessions $\mathbf{S}^u = \left\{\mathbf{s}_1^u, \mathbf{s}_2^u, ..., \mathbf{s}_{N_u}^u\right\}$, where N_u is the number of sessions for user u, $\mathbf{s}_n^u = \left\{i_{n,1}^u, i_{n,2}^u, ..., i_{n,|\mathbf{s}_n^u|}^u\right\}$ denotes the item sequence corresponding to the n-th session $\mathbf{s}_n^u$ of user u. Let $\mathbf{a}^u$ denote a user u's profile such as his attributes. The sequential recommendation can be formalized as a sequence prediction task: given a session sequence $\mathbf{S}^u = \left\{\mathbf{s}_1^u, \mathbf{s}_2^u, ..., \mathbf{s}_{N_u}^u\right\}$ and attribute $\mathbf{a}^u$ of user u, generate a sequence of items $\mathbf{s}_{N_u+1}^u$ that user u will interact with at session $N_u + 1$.

2.2 Session-based Recommendation with RNN

RNN has been widely used in session-based recommendation [10, 11, 19, 22, 23, 26, 32] due to it's power for modeling sequence data. However, traditional RNN suffers from vanishing gradient problem. To track this problem, two variant RNNs, namely Gated Recurrent Unit (GRU) [6] and Long Short Term Memory (LSTM) [12] networks have been proposed. Due to the simpler and less parameters, most session-based recommendation models [10, 11, 19, 22, 23, 26, 32] are built on GRU. The GRU takes as input the current item ID in the session and outputs a predicted score for next item in the session.

Given a sequence of actions (a session) $\mathbf{s}_n^u = \left\{i_{n,1}^u, i_{n,2}^u, \ldots, i_{n,|\mathbf{s}_n^u|}^u\right\}$ of user u. The session-based GRU network computes the following current hidden state vector $h_{n,t}^u$ conditional on the last hidden state vector and the current input item ID.

$$\mathbf{h}_{n,t}^u = GRU^{user}(\mathbf{h}_{n,t-1}^u, \mathbf{i}_{n,t}^u), \tag{1}$$

where the GRU^{user} represents the GRU unit [6] called user-level GRU. The $\mathbf{i}_{n,t}^u$ is a one-hot vector of current item ID $i_{n,t}^u$. The output of GRU at time t is the distributions of predicted scores for all items:

$$\hat{\mathbf{y}}_{n,t}^u = g(\mathbf{h}_{n,t}^u), \tag{2}$$

where $g(\cdot)$ is a ranking function such as softmax function. The network can be trained with several ranking loss function like cross-entropy or BPR [27] by stochastic gradient descent.

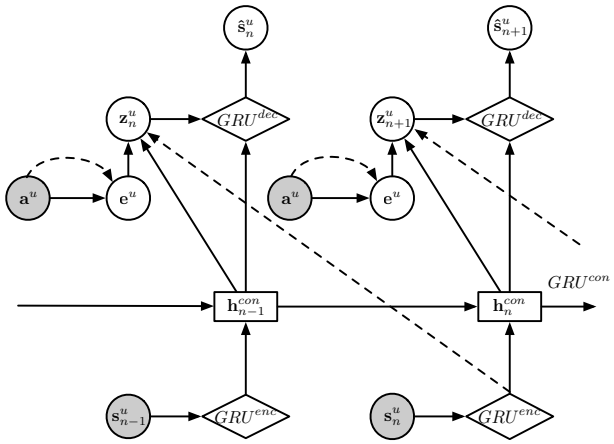

Figure 1: Graphical model of HNVM. Gray circles and white rounded boxes represent observed and latent variables, respectively. Bold solid and dashed lines represent generative and inference processes, respectively. For simplicity, we omit the latent states in encoder GRU and decoder GRU.

3 HIERARCHICAL NEURAL VARIATIONAL MODEL

We proposed a hierarchical neural variational model (HNVM) to model the session generative process for personalized recommendation. We will first introduce the hierarchical generative process, and then detail the hierarchical network in HNVM and the inference algorithm. The graphical model of HNVM is shown in Figure 1.

3.1 Generative Process

Our model HNVM can bee seen as a hierarchical generative model with a series stochastic latent variables. The goal of our model is to maximize the variational evidence lower bound [36] of the conditional log-likelihood of observed variables. For user u, the likelihood of his observed sessions is modeled as follows:

$$p(\mathbf{s}_1^u, \mathbf{s}_2^u, ..., \mathbf{s}_{N_u}^u) = \prod_{n=1}^{N_u} p(\mathbf{s}_n^u | \mathbf{s}_{<n}^u). \tag{3}$$

Due to each session $\mathbf{s}_n^u$ is a sequence of items $(i_{n,1}^u, i_{n,2}^u, ..., i_{n,3}^u)$, Eq. 3 can be further formulated as follows:

$$p(\mathbf{s}_1^u, \mathbf{s}_2^u, ..., \mathbf{s}_{N_u}^u) = \prod_{n=1}^{N_u} \prod_{t=1}^{|\mathbf{s}_n^u|} p(i_{n,t}^u | \mathbf{s}_{<n}^u, i_{n,<t}^u). \tag{4}$$

Our HNVM is a latent variable model which contains a series of latent variables $\mathbf{z}_n^u$ for each session $t = 1, ..., N_u$ in terms of user u. In order to incorporate the previous session information of user u into the next session, we first consider the prior of latent variable $\mathbf{z}_n^u$ (long-term preference) conditioned on all the past observed sessions (the session context) and the general preference $\mathbf{e}^u$:

$$\begin{aligned} p_\theta(\mathbf{z}_n^u | \mathbf{s}_{<n}^u, \mathbf{e}^u) &= \mathcal{N}(\mathbf{z}_n^u | f_{\mu_z}(\mathbf{s}_{<n}^u, \mathbf{e}^u), f_{\sigma_z^2}(\mathbf{s}_{<n}^u, \mathbf{e}^u)) \\ &= \mathcal{N}(\mathbf{z}_n^u | \mu_{z_n^u}, diag(\sigma_{z_n^u}^2)), \end{aligned} \tag{5}$$

where $\mathcal{N}(\mu, \Sigma)$ is the multivariate normal distribution with mean $\mu \in \mathbb{R}^{D_z}$ and diagonal covariance matrix $\Sigma \in \mathbb{R}^{D_z \times D_z}$. The conditional prior of the long-term preference $\mathbf{z}_n^u$ is the multivariate Gaussian distribution whose mean and diagonal covariance matrix are parameterized by neural networks $f_{\mu_z}(\cdot)$ and $f_{\delta_z^2}(\cdot)$ with input $\mathbf{s}_{<n}^u$ and $\mathbf{e}^u$. Here, $\mathbf{e}^u$ denotes the latent embedding of user u which represents his general preference and the conditional prior of $\mathbf{e}^u$ is:

$$\begin{aligned} p_\theta(\mathbf{e}^u | \mathbf{a}^u) &= \mathcal{N}(\mathbf{e}^u | f_{\mu_e}(\mathbf{a}^u), diag(f_{\sigma_e^2}(\mathbf{a}^u))) \\ &= \mathcal{N}(\mathbf{e}^u | \mu_{\mathbf{e}^u}, diag(\sigma_{\mathbf{e}^u}^2)), \end{aligned} \tag{6}$$

where the conditional prior of $\mathbf{e}^u$ is also the multivariate Gaussian distribution whose mean and diagonal covariance matrix are parameterized by neural networks $f_{\mu_e}(\cdot)$ and $f_{\delta_e^2}(\cdot)$ with input $\mathbf{a}^u$. Note that we utilize two latent variables $\mathbf{e}^u$ and $\mathbf{z}_n^u$ to represents a user's general and long-term preferences, respectively.

We model the current session $\mathbf{s}_n^u$ to be generative from the long-term preference $\mathbf{z}_n^u$ and the user's context $\mathbf{s}_{<n}^u$:

$$p_\theta(\mathbf{s}_n^u | \mathbf{z}_n^u, \mathbf{s}_{<n}^u) = \prod_{t=1}^{|\mathbf{s}_n^u|} p_\theta(i_{n,t}^u | \mathbf{z}_n^u, \mathbf{s}_{<n}^u, i_{n,<t}^u). \tag{7}$$

According the above generative process of our model, the conditional distribution can be factorized as:

$$\begin{aligned} p_\theta(\mathbf{S}, \mathbf{E}, \mathbf{Z} | \mathbf{A}) = \prod_u \prod_{n=1}^{N_u} \prod_{t=1}^{|\mathbf{s}_n^u|} p_\theta(i_{n,t}^u | \mathbf{s}_{<n}^u, i_{n,<t}^u, \mathbf{z}_n^u) \cdot \\ p_\theta(\mathbf{z}_n^u | \mathbf{s}_{<n}^u, \mathbf{e}^u) p_\theta(\mathbf{e}^u | \mathbf{a}^u), \end{aligned} \tag{8}$$

where $\mathbf{S}$ and $\mathbf{A}$ denote the observed sessions and the attributes of all users, respectively. $\mathbf{E}$ and $\mathbf{Z}$ denote the sets of latent variables of $\mathbf{e}^u$ and $\mathbf{z}_n^u$ of all users, respectively. We use θ to denote the all parameters in the generative model. In what follows, we will detail the hierarchical generative network architecture of HNVM.

3.2 The Hierarchical Network Architecture

As shown in Figure 1, our model is hierarchical, which contains three RNN networks: the *encoder* RNN, the *context* RNN [29] and the *decoder* RNN. The *encoder* RNN encodes session $\mathbf{s}_n^u$ into a fixed-size vector:

$$\mathbf{h}_{n,t}^u = GRU^{enc}(\mathbf{h}_{n,t-1}^u, \mathbf{i}_{n,t}^u), \ t = 1, 2, .., |\mathbf{s}_n^u|, \tag{9}$$

where $\mathbf{h}_{n,t}^u$ is the hidden state vector at time t, $\mathbf{i}_{n,t}^u$ is the one-hot vector of item $i_{n,t}^u$, and GRU^{enc} represents the non-linear activation GRU function [6]. The last hidden vector $\mathbf{h}_{n,|\mathbf{s}_n^u|}^u$ can be viewed as the summary of current session $\mathbf{s}_n^u$.

For the *context* RNN, it encodes the session sequence as:

$$\mathbf{h}_n^{con} = GRU^{con}(\mathbf{h}_{n-1}^{con}, \mathbf{h}_{n,|\mathbf{s}_n^u|}^u), \ n = 1, 2, .., |\mathbf{S}^u|, \tag{10}$$

where the GRU^{con} denotes the non-linear function parameterized by *context* RNN and $\mathbf{h}_n^{con}$ is the hidden state of *context* RNN. $\mathbf{h}_n^{con}$ can be viewed as the context-level representation which is the summary of all the observed previous sessions ($\mathbf{s}_{\leq n}^u$).

For the *decoder* RNN, it takes $\mathbf{h}_{n-1}^{con}$ and $\mathbf{z}_n^u$ as input to generate the next session $\mathbf{s}_n^u$:

$$\begin{aligned} \mathbf{h}_{n,0}^{dec} = \mathbf{0}, \ \mathbf{h}_{n,t}^{dec} = GRU^{dec}(\mathbf{h}_{n,t-1}^{dec}, \mathbf{i}_{n,t}^u, \mathbf{h}_{n-1}^{con}, \mathbf{z}_n^u), \\ t = 1, 2, .., |\mathbf{s}_n^u|, \end{aligned} \tag{11}$$

and the generative items are sampled according to Eq. 2. In our HNVM, the *decoder* RNN captures sequential pattern inside the current session (i.e., short-term preference).

As shown in Figure 1, the generative process (§ 3.1) of a session sequence for user u through the hierarchical network are:

(1) The *encoder* RNN encodes the $(n-1)$-th session ($\mathbf{s}_{n-1}^u$) of user u into a fix-size vector $\mathbf{h}_{n-1,|\mathbf{s}_n^u|}^{enc}$, which is taken by the *context* RNN as input to compute the context hidden state $\mathbf{h}_{n-1}^{con}$ (Eq. 10).

(2) Sample the user latent embedding $\mathbf{e}^u$ from conditional prior distribution (Eq. 6).

(3) A two-layer Multi Layer Perceptron (MLP) takes as input the concatenation of both $\mathbf{h}_{n-1}^{con}$ and the general preference $\mathbf{e}^u$. The network output is transformed to give the mean and diagonal covariance matrix of $\mathbf{z}_n^u$ in (Eq. 5) as:

$$\begin{bmatrix} \mu \\ \log(\sigma_{\mathbf{z}_n^u}) \end{bmatrix} = \text{MLP}(\mathbf{h}_{n-1}^{con}, \mathbf{e}^u). \tag{12}$$

(4) Draw latent variable $\mathbf{z}_n^u$ from the prior $p_\theta(\mathbf{z}_n^u | \mathbf{s}_{<n}^u, \mathbf{e}^u)$ whose mean and covariance matrix provided by step (3).

(5) The *decoder* RNN takes context vector $\mathbf{h}_{n-1}^{con}$ and $\mathbf{z}_n^u$ as input to generative next session $\mathbf{s}_n^u$ of user u (Eq. 7).

3.3 Inference Process

As shown in graph model Figure 1, the goal of HNVM is to infer the latent variables $\mathbf{e}^u$ and $\mathbf{z}_n^u$ for every users and all their sessions, and estimate the network parameter θ. Due to the latent variables are hierarchical and the generative process is parameterized by the neural network, it is intractable to infer these latent variables and estimate network parameters by using traditional mean-filed approximation [36]. Inspired by Deep Latent Gaussian models (DLGm) [28, 31], we propose a hierarchical conditional stochastic gradient variational Bayes (SGVB) algorithm to infer our HNVM. For our model, we consider the following type of variational distribution factorization structure:

$$q_\phi(\mathbf{E}, \mathbf{Z} | \mathbf{S}, \mathbf{A}) = \prod_u q_\phi(\mathbf{e}^u | \mathbf{a}^u) \prod_{n=1}^{N_u} q_\phi(\mathbf{z}_n^u | \mathbf{s}_{<n}^u, \mathbf{s}_n^u), \tag{13}$$

$$q_\phi(\mathbf{e}^u | \mathbf{a}^u) = \mathcal{N}(\mathbf{u} | g_{\mu_e}(\mathbf{a}^u), diag(g_{\sigma_e^2}(\mathbf{a}^u))) \tag{14}$$

$$= \mathcal{N}(\mathbf{e}^u | \tilde{\mu}_{\mathbf{e}^u}, diag(\tilde{\sigma}_{\mathbf{e}^u}^2)), \tag{15}$$

$$q_\phi(\mathbf{z}_n^u | \mathbf{s}_{<n}^u, \mathbf{s}_n^u) = \mathcal{N}(\mathbf{z}_n^u | g_{\mu_z}(\mathbf{s}_{<n}^u, \mathbf{s}_n^u), g_{\sigma_z^2}(\mathbf{s}_{<n}^u, \mathbf{s}_n^u)) \tag{16}$$

$$= \mathcal{N}(\mathbf{e}^u | \tilde{\mu}_{\mathbf{z}_n^u}, diag(\tilde{\sigma}_{\mathbf{z}_n^u}^2)). \tag{17}$$

The posteriors over $\mathbf{e}^u$ and $\mathbf{z}_n^u$ are all multivariate diagonal Gaussian distributions. Similar to the notations in generative model, we let $g_{\mu_e}(\cdot)$, $g_{\sigma_e^2}(\cdot)$, $g_{\mu_z}(\cdot)$ and $g_{\sigma_z^2}(\cdot)$ be neural networks whose parameters are denoted by ϕ. This factorization assumes the general preference $\mathbf{e}^u$ is only conditioned on u's attribute $\mathbf{a}^u$, whereas the long-term preference $\mathbf{z}_n^u$ is conditioned on $\mathbf{s}_{<n}^u$ which is the *context* RNN hidden state $\mathbf{h}_{n-1}^{con}$, and current session summary $\mathbf{h}_{n,|\mathbf{s}_n^u|}^u$. To infer latent variables and estimate network parameters, we maximize the hierarchical variational **E**vidence **L**ower **BO**und (ELBO) of the conditional log likelihood (i.e., Eq. 8):

$$\log p_\theta(\mathbf{S}|\mathbf{A}) \geq \sum_u \mathcal{L}(\theta,\phi;\mathbf{S}^u,\mathbf{a}^u) = \sum_u \sum_{n=1}^{N_u} \mathbb{E}_{q_\phi(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{s}_n^u)}\Big[\log p_\theta(\mathbf{s}_n^u|\mathbf{z}_n^u,\mathbf{s}_{<n}^u)\Big] - \mathbb{E}_{q_\phi(\mathbf{e}^u|\mathbf{a}^u)}\Big[\mathrm{KL}(q_\phi(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{s}_n^u)||p_\theta(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{e}^u)\Big] - \mathrm{KL}(q_\phi(\mathbf{e}^u|\mathbf{a}^u)||p_\theta(\mathbf{e}^u|\mathbf{a}^u)), \tag{18}$$

where $\mathrm{KL}(q||p)$ is the Kullback-Leibler (KL) divergence between distributions p and q. The derivation of the ELBO in Eq. 18 is included in Appendix A. Maximizing the ELBO (Eq. 18) is equivalent to maximize the log-likelihood of observed variables and to make the variational distributions $q_\phi(\mathbf{e}^u|\mathbf{a}^u)$ and $q_\phi(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{s}_n^u)$ of each user to be as close as possible to their intractable true posteriors $p_\theta(\mathbf{e}^u|\mathbf{S}^u,\mathbf{a}^u)$ and $p_\theta(\mathbf{z}_n^u|\mathbf{S}^u,\mathbf{a}^u)$, respectively. The last KL term in Eq. 18 has analytical form. However, for the two expectation terms, we can not compute them analytically. To solve this problem, we approximate the two terms using Monte Carlo sampling, and use suitable reparameterization trick [17, 28] with low variance.

Since the variational distribution of $\mathbf{e}^u$ does not depend on the entire session sequence $\mathbf{S}^u$, the *conditional sequence − level variational lower bound* $\mathcal{L}(\theta,\phi;\mathbf{S}^u,\mathbf{a}^u)$ can be decomposed into the sum of $\mathcal{L}(\theta,\phi;\mathbf{s}_n^u|\mathbf{a}^u)$, the *conditional session − level variational lower bound*, and the function $\mathcal{F}_{\theta,\phi}(\mathbf{a}^u)$ w.r.t θ and ϕ (see Eq. 22 in Appendix A):

$$\mathcal{L}(\theta,\phi;\mathbf{S}^u,\mathbf{a}^u) = \sum_{n=1}^{N_u} \mathcal{L}(\theta,\phi;\mathbf{s}_n^u|\mathbf{a}^u) + \mathcal{F}_{\theta,\phi}(\mathbf{a}^u). \tag{19}$$

Instead of sampling a batch at the sequence-level to maximize the ELBO, we can sample a batch at the session-level to maximize it. This method makes our model scalable when the session sequence $\mathbf{S}^u$ is extremely long, such that computing an entire sequence for a batched update is very computationally expensive.

4 EXPERIMENTAL SETUP

4.1 Research Questions

The main research questions guiding the paper are: (**RQ1**) Does HNVM outperform state-of-the-art sequential recommendation methods? (**RQ2**) How does the captured the long-term and general preferences impact recommendation accuracy? (**RQ3**) What is the impact of the number of users' past sessions for recommendation performance? (**RQ4**) Is HNVM effective on the other task like next-session recommendation?

4.2 Datasets and Data Preprocessing

In order to answer our research questions, we work with two publicly available datasets: RecSys Challenge 2015[1] (RSC) [10] and IJCAI-15 Competition datasets[2] (IJC) [26]. RSC dataset contains interactions on job posting for 770K users over a 80-days' period. IJC contains users' shopping log over six months' period in online shopping site Tmall. For RSC dataset, we first partitioned the interaction data into sessions by considering 30-minutes' idle threshold and removed interactions having type 'delete'. We hold out the last interacted item in the last session of each user as the test data, and the item before the last item as the validation set. The rest items are treated as training dataset. For the IJC dataset, we follow the the preprocessing procedure as same as that in [39]. For simplicity, we just use user's id number's one-hot vector as static profile representation $\mathbf{a}^u$ (Note that we don't use other attributes such age or gender, because there is no such information in IJC dataset). Table 1 shows the statistics of the two datasets after preprocessing.

Table 1: Statistics of datasets.

Datasets	RSC	IJC
Users	11,479	20,648
Items	59,297	25,129
Sessions	89,591	75,426
Training sessions	78,276	71,892
Test sessions	11,315	3,635
Interactions per session	6.1	2.73

4.3 Baselines and Settings

We make comparisons between the proposed HNVM model and the following state-of-the-art algorithms for sequential recommendation: (1) **POP**: This method always recommends the most-popular (the largest number of interactions in the training set) items. (2) **Item-KNN**: This method recommends items based on the cosine similarity between items. The similarity is defined by the co-occurrence number between items in sessions. (3) **BPR**: This method [27] optimizes a pair-wise ranking loss for general recommendation. (4) **NCF**: This method [9] is the state-of-the-art general recommendation method. (5) **GRU4Rec**: This model [10] utilizes the basic GRU [6] unit to the task of session-based recommendation. (6) **HRNN**: This model [26] utilizes past session information through a hierarchical RNN. We use it's HRNN-*All* version in our experiments. (7) **Caser**: This is the state-of-the-art sequential recommendation model [35] which uses convolutional filters to learn sequential patterns. It also captures user's general preference. (8) **STAMP**: This model [22] utilizes a short-term attention/memory mechanism to capture user's long- and short-term preferences.

For fair comparisons, all GRU based baselines (GRU4Rec, HRNN) including our HNVM use the BPR loss function. For all baselines, we use a grid search to find the optimal parameters using the validation set. For HNVM, we randomly initialize parameters using uniform distribution with variance 0.01 and bases equal 0. We use one-layer GRU for encoder, context and decoder RNN. The hyper-parameters are found via extensive grid search. We use AdaGrad [8] with momentum to optimize our model. The batch size is set to 256. The

[1] http://2016.recsyschallenge.com/

[2] https://ijcai-15.org/index.php/repeat-buyers-prediction-competition

hidden states of GRU are all set to 200. Since the high variance leads the gradients not stable, we multiple the diagonal covariance matrices of the prior and posterior distributions by 0.05. We use a dropout regularization [33] on the hidden states of GRU with a fixed dropout rate of 0.1. Similar to [1], we multiply the KL terms in Eq. 18 by scalar, which starts from 0 and linearly increases to 1.

4.4 Evaluation Metrics

Similar to that in [13, 26], we perform our model and the baselines on the next-item sequential recommendation task for comparisons. We use the widely used evaluation metrics: Recall@k (Recall at k), MRR@k (Mean Reciprocal Rank at k) [21] and Pre@k (Precision at k) [20, 38]. We compute the scores at depth 5, i.e., let k =5 for evaluation.

5 RESULTS AND ANALYSIS

5.1 Overall Performance (RQ1)

To start, for question **RQ1**, to evaluate the effectiveness of HNVM in personalized sequential recommendation, we examine the performance of HNVM on the next-item recommendation task. Table 2 shows the overall performance of all methods in terms of Recall@5, MRR@5 and Pre@5. From Table 2, we have the following conclusions: (1) Methods capturing users' short-term preferences like GRU4Rec, HRNN, Caser, STAMP and HNVM work better than general methods, i.e., BRP and NCF, which illustrates users' short-term preferences need to be captured for next-item recommendation task. (2) On the RSC dataset, our model HNVM and Caser outperform other sequential recommendation models, i.e., GRU4Rec and STAMP. The reason is that the user's static profile is more important in job search platform (RSC) than shopping or video platforms (IJC) and both our model HNVM and Caser can capture users' general preferences corresponding to users' profile. (3) Although our HNVM and Caser both can capture users' general and short-term preferences, our HNVM works better than Caser. The reason is that user has different purchase purpose in different sessions and Caser doesn't model this cross-session relationship (i.e., long-term preferences). (4) Our HNVM significantly outperforms HRNN, which demonstrates that the latent variable characteristic makes our model to be able to more effectively capture the users' long-term preferences. All of these findings demonstrate that HNVM can effectively capture users' different preferences and it is able to maintain significant improvements of sequential recommendation performance over the state-of-the-arts baseline methods.

5.2 Impact of the Long-term and General Preferences (RQ2)

Next, we turn to **RQ2**. For the purpose of analyzing the impact of user's long-term and general preferences on the next-item recommendation task, we spilt every sessions by the order of interaction within the sessions. We only consider sessions which have ≥ 5 interactions on RSC datasets (6736 sessions). We group interactions in these sessions as three groups: *Begin*, *Middle* and *End*. The *Begin* group contains the first 2 interactions in these sessions, the *Middle* contains 3rd -4th and the *End* contains the rest of interactions. We evaluate recommendation performance of our HNVM on these three groups, respectively. Since sessions' lengths in the IJC dataset are general very short, we only conduct this analysis on the RSC dataset. Figure 2 shows the Recall@5 and MRR@5 results with different positions of interactions on RSC datasets (the performance pattern in terms of Pre@5 is similar to that in terms of Recall@5, and thus we omit it here due to space limitations). From the results, some interesting findings can be observed: (1) For all RNN-based methods, i.e., HNVM, HRNN and GRU4Rec, the performance increases with the number of pervious items in the session, which demonstrates that these methods can both effectively capture users' short-term preference within the current session. (2) Personalized recommendation models, HNVM, HRNN and Caser significantly outperform vanilla RNN-based methods like GRU4Rec and STAMP by a large margin, and the margin is larger on the *Begin* group than that on the *Middle* group. The reason is that GRU4Rec and STAMP do not incorporate any user's past session information (i.e., long-term preferences) when user starts a new session and these models can hardly capture the user's short-term preference when she/he just clicks a few items. (3) Our HNVM significantly and consistently outperforms the best two baselines, HRNN and Caser, especially in the *Begin* and *End* groups, which illustrates that capturing both users' long-term (past session information) and general (profile information) preferences can significantly contribute to predict the first several actions and the last several actions in long sessions.

Table 2: Recommendation performance comparison on the RSC and IJC datasets in terms of Recall@5, MRR@5 and Pre@5. "Improv." denotes the improvement of HNVM relative to the best baseline.

	RSC			IJC

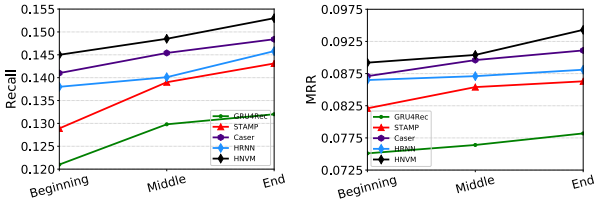

Figure 2: Performance comparison in terms of Recall@5 and MRR@5 on RSC dataset with different positions in sessions.

5.3 The Number of Past Sessions (RQ3)

We now examine the impact of the number of user's past sessions for performance. We partitioned users on RSC dataset into two groups based on the number of their past sessions: *Short* and *Long* groups. The *Short* group refers the number of user's sessions ≤ 6

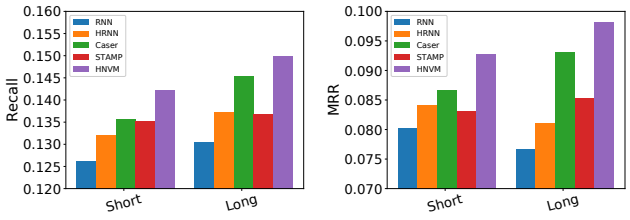

Figure 3: Performance comparison in terms of Recall@5 and MRR@5 on RSC datasets with different past session length.

Table 3: Next-session recommendation performance comparison in terms of Recall@5, MRR@5 and Pre@5.

	RSC			IJC		
	Recall	MRR	Pre	Recall	MRR	Pre
GRU4Rec	.0732	.0387	.0098	.0122	.0101	.0095
HRNN	.1054	.0607	.0149	.0213	.0198	.0157
Caser	.0987	.0531	.0128	.0187	.0177	.0139
STAMP	.0872	.0412	.0114	.0162	.0148	.0118
HNVM	**.1134**	**.0696**	**.0154**	**.0221**	**.0209**	**.0164**
Improv.	+7.6%	+14.7%	+3.4%	+3.8%	+5.6%	+4.5%

(67%), while the *Long* refers to > 6 (33%). We evaluate recommendation performance based on the two groups, respectively. As showed in Figure 3, we can observe that the performance of HRNN, Caser and HNVM on the *Long* group is better than that on the *Short* group. The reason is that HRNN, Caser and HNVM not only capture users' short-term preferences in the current session but also consider users' general (profile) or long-term (past session information) preferences , and the more the user past sessions are observed, the better the model learns the users' long-term preferences. Figure 3 shows that our model significantly outperforms the best baselines (i.e., HRNN and Caser) on next-item recommendation task.

5.4 Performance Comparison on the Next-session Recommendation Task (RQ4)

To further evaluate our model, similar to [13], we consider another sequential recommendation task: next-session recommendation. We use user's last session as test set, the session before the last as validation set and the rest of sessions as training set. Table 3 shows the next-session performance between HNVM with the best baselines. From Table 3, we can observe our HNVM and HRNN significantly outperform basic session-based methods, i.e., STAMP and GRU4Rec. The reason is that both our HNVM and HRNN effectively utilize users' past sessions and capture users' long-term preferences and these long-term preferences help models mining users' different purpose at different sessions. The finding that our HNVM outperforms HRNN indicts that the users' latent long-term preferences learnt by HNVM work better than those of HRNN.

6 CONCLUSION

In this paper, we have studied the problem of personalized sequential recommendation. To track this problem, we have proposed a hierarchical neural variational model, abbreviated as HNVM, that is the first attempt to capture users' different level preferences, i.e., general, long- and short-term preferences through a unified hierarchical generative process. HNVM can effectively model user's sequential patterns inside sessions and across sessions through it's hierarchical network structure. Our HNVM learns users' different preferences via a hierarchical Gaussian latent representations, which make it be able to capture better preferences than other deterministic model. To effectively infer our model, we have proposed hierarchical stochastic gradient variational Bayes inference algorithm. We also have derived a *conditional session − level variational lower bound*, which makes our HNVM be able to be effectively learned via sampling mini-batches at session-level. Experimental results on two publicly available datasets demonstrate the effectiveness of the proposed algorithms.

A DERIVATION OF CONDITIONAL SESSION-LEVEL VARIATIONAL LOWER BOUND

All notations below are defined in the body of the paper. The conditional variational ELBO for user u can be derived as follows:

$$\log p_\theta(\mathbf{S}^u|\mathbf{a}^u) \geq \mathcal{L}(\theta,\phi;\mathbf{S}^u,\mathbf{a}^u) =$$

$$\mathbb{E}_{q_\phi(\mathbf{e}^u,\mathbf{z}_n^u|\mathbf{S}^u)} \log \frac{p_\theta(\mathbf{e}^u|\mathbf{a}^u)\prod_{n=1}^{N_u} p_\theta(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{e}^u)p_\theta(\mathbf{s}_n^u|\mathbf{z}_n^u,\mathbf{s}_{<n}^u)}{q_\phi(\mathbf{e}^u|\mathbf{a}^u)\prod_{n=1}^{N_u} q_\phi(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{s}_n^u)}$$

$$= \sum_{n=1}^{N_u} \mathbb{E}_{q_\phi(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{s}_n^u)}\Big[\log p_\theta(\mathbf{s}_n^u|\mathbf{z}_n^u,\mathbf{s}_{<n}^u)\Big]$$

$$- \sum_{n=1}^{N_u} \mathbb{E}_{q_\phi(\mathbf{e}^u|\mathbf{a}^u)}\Big[\mathrm{KL}(q_\phi(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{s}_n^u)||p_\theta(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{e}^u)\Big] \quad (20)$$

$$- \mathrm{KL}(q_\phi(\mathbf{e}^u|\mathbf{a}^u)||p_\theta(\mathbf{e}^u|\mathbf{a}^u)), \quad (21)$$

where the expected KL terms in Eq. 20 are two Gaussian distributions, and the KL divergence $\mathrm{KL}(q_\phi(\mathbf{e}^u|\mathbf{a}^u)||p_\theta(\mathbf{e}^u|\mathbf{a}^u))$ in Eq. 21 can be computed analytically. Thus the hierarchical ELBO for a user u's sessions' sequence $\mathbf{S}^u$ as follows:

$$\mathcal{L}(\theta,\phi;\mathbf{S}^u,\mathbf{a}^u) = \sum_{n=1}^{N_u} \mathbb{E}_{q_\phi(\mathbf{z}_n^u|\mathbf{s}_{<n}^u,\mathbf{s}_n^u)}\Big[\log p_\theta(\mathbf{s}_n^u|\mathbf{z}_n^u,\mathbf{s}_{<n}^u)\Big]$$

$$+ \mathbb{E}_{q_\phi(\mathbf{e}^u|\mathbf{a}^u)}\Big[\frac{1}{2}\sum_{d=1}^{D_z} 1 + \log\frac{\tilde{\sigma}^2_{\mathbf{z}_n^u,d}}{\sigma^2_{\mathbf{z}_n^u,d}} - \frac{(\tilde{\mu}_{\mathbf{z}_n^u,d}-\mu_{\mathbf{z}_n^u,d})^2+\tilde{\sigma}^2_{\mathbf{z}_n^u,d}}{\sigma^2_{\mathbf{z}_n^u,d}}\Big]$$

$$+ \frac{1}{2}\sum_{d=1}^{D_e}(1 + \log\frac{\tilde{\sigma}^2_{\mathbf{e}^u,d}}{\sigma^2_{\mathbf{e}^u,d}} - \frac{(\tilde{\mu}_{\mathbf{e}^u,d}-\mu_{\mathbf{e}^u,d})^2+\tilde{\sigma}^2_{\mathbf{e}^u,d}}{\sigma^2_{\mathbf{e}^u,d}})$$

$$= \sum_{n=1}^{N_u} \mathcal{L}(\theta,\phi;\mathbf{s}_n^u|\mathbf{a}^u) + \mathcal{F}_{\theta,\phi}(\mathbf{a}^u), \quad (22)$$

where the two expectation terms can not be solved analytically. Therefore, we apply Monte Carlo sampling and the reparametrization trick [17] to approximate the two terms. The samples are:

$$\mathbf{e}^u = \tilde{\mu}_{\mathbf{e}^u} + \tilde{\sigma}_{\mathbf{e}^u} \odot \epsilon_{\mathbf{e}^u}, \quad \epsilon_{\mathbf{e}^u} \sim \mathcal{N}(\mathbf{0},\mathbf{I}_{D_e}), \quad (23)$$

$$\mathbf{z}_n^u = \tilde{\mu}_{\mathbf{z}_n^u} + \tilde{\sigma}_{\mathbf{z}_n^u} \odot \epsilon_{\mathbf{z}_n^u}, \quad \epsilon_{\mathbf{z}_n^u} \sim \mathcal{N}(\mathbf{0},\mathbf{I}_{D_z}), \quad (24)$$

where $\odot$ denotes an element-wise product and $\mathcal{N}(\mathbf{0},\mathbf{I})$ is the normal Gaussian distribution with mean and covariance being $\mathbf{0}$ and $\mathbf{I}$, respectively.

ABSTRACT

Answer ranking is an important task in Community Question Answering (CQA), by which "Good" answers should be ranked in the front of "Bad" or "Potentially Useful" answers. The state of the art is the attention-based classification framework that learns the mapping between the questions and the answers. However, we observe that existing attention-based methods perform poorly on complicated question-answer pairs. One major reason is that existing methods cannot get accurate alignments between questions and answers for such pairs. We call the phenomenon "attention divergence". In this paper, we propose a new attention mechanism, called **F**ocusing **A**ttention **N**etwork(FAN), which can automatically draw back the divergent attention by adding the semantic, and metadata features. Our Model can focus on the most important part of the sentence and therefore improve the answer ranking performance. Experimental results on the CQA dataset of SemEval-2016 and SemEval-2017 demonstrate that our method respectively attains 79.38 and 88.72 on MAP and outperforms the Top-1 system in the shared task by 0.19 and 0.29.

1 INTRODUCTION

Online community forums, such as Yahoo! Answers [1] and Stack Overflow [2], have attracted many users. These users can ask or answer questions, and these archived questions and answers are very valuable. However, some of these questions have many answers, and most of these answers are low quality. Thus, *answer selection* of community question answering, which could automatically find good ones from a large number of answers, has drawn much attention in the field of natural language processing [3, 28, 34]. There are related tasks at SemEval-2016 [1] and SemEval-2017 [18].

In this paper, we focus on the task of ranking good answers ahead of bad ones, which is another form of answer selection. We illustrate an example of Qatar-Living dataset [18] from the SemEval-2017 Task 3 in Figure 1. An original question Q is shown in Figure 1(a). For convenience, we only choose three of the ten answers of question Q and show in Figure 1(b). These answers are sorted by their submitted time. They have different human labels:"Good", "Potentially Useful" and "Bad". We need to train a model, which can give the score of each answer and the answers should be sorted by the score at last, as in Figure 1(c).

Previous work on answer ranking normally used feature engineering, linguistic tools, or external resources. For example, semantic features are based on WordNet in [34]. This model pairs semantically related words based on word semantic relations. In [28], the answer ranking problem is transformed to a syntactical matching between the question/answer parse trees.

In recent years, attention based models have shown advantages in representing natural language sentences [2]. It obtains great success in many NLP tasks such as machine translation, question answering and recognizing textual entailments. When building the representation of a sentence, some attention information is added to the hidden state. For example, in attention based recurrent neural networks models each time-step hidden representation is weighted by attention.

However, so far, these traditional attention based models were shown to be successful only in modeling relatively short query and answer pairs, roughly a sentence in length [22]. One of the reasons these models under-perform for complicated longer texts, is that longer answers often contain irrelevant information and the alignments estimated by the attention model are easily corrupted due to the complexity of sentences. In other words, the attention model

A2: What they offer?
Score: 0.5

(c) The resorted answers according to their scores.

Figure 1: An example question and its answers in CQA.

cannot accurately associate each question with the corresponding target region in the answers. We call this phenomenon *attention divergence*. That is the attention regions divergence in some degree from the proper regions of target terms in the answers. This motivates us to develop some mechanism to focus attention back on the right regions of the target terms in the answers. Therefore, we propose a Focusing Attention Network (**FAN**) to accurately identify the main question and answer terms to use for the joint representation by adding the semantic and metadata features. Semantic features, which can obtain the semantic similarities between a question and an answer; metadata features, which can capture characteristics that relevant answers tend to have. Both of them are very important features to represent the sentence and we call them focusing features.

We firstly obtain the question representation with bidirectional LSTMs, next we extract semantic features, metadata features from questions and their answers, then we obtain the attentive hidden states that are weighted by the question representation and above two kinds of features as answer representation. At last, we feed the question and answer representation to the softmax classifier for classification. The experimental results on SemEval-2016 Task3 and SemEval-2017 Task3 datasets show that our method outperforms the state-of-the-art work. The main contributions of our approach are three folds:

- We propose the concept of attention divergence, which explains the poor performance of existing attention based methods on complicated long question-answer pairs.
- We develop a novel method called **FAN** to solve the attention divergence problem, where in addition to the attention component existing in most existing methods, semantic features and metadata features is introduced, which can focus deviated attention back on the target areas.
- The experimental results have verified the effectiveness of our proposed model, and also provide a promising avenue to make full use of the **FAN** model for other tasks.

In the remainder of this paper, after discussing related work in Section 2, we introduce our model in Section 3. Then, we describe our experiments in Section 4. The conclusions and discussions are presented in Section 5.

2 RELATED WORK

Question-answer selection and ranking has been an active area of research for decades, presenting many solutions. For example, Filice [8] proposes a kernel-based method which uses the ranking features, heuristics features, thread-based features and stacking features. This method obtains the best result in SemEval-2017 Task 3 subtask A. The MAP value is 88.43. Feng [5] develops a ranking system based on traditional NLP features such as tf-idf cosine, longest common subsequence, word overlap and translation probability. This method also obtains a good result in SemEval-2017 Task 3 subtask A. The MAP value is 88.24. While these methods show effectiveness, they might ignore the sentence representation in the semantic space.

Most recently, various convolution neural networks (CNNs) and recurrent neural networks (RNNs) are employed in the task of answer ranking [20, 24, 26]. Neural networks based models are proposed to represent the sentence in a semantic space and then compare the question and answer candidates in this hidden space [26]. These models will not suffer from the availability of resources, the effort of feature engineering and the systematic complexity by introducing linguistic tools, such as parse trees and dependency trees [24]. Tan [24] utilizes a simple but efficient attention mechanism in order to generate the answer representation according to the question context. Wang [26] proposes an inner attention based recurrent neural network which adds attention information before RNN hidden representation and shows the advantage in representation. These methods have the characteristics of constructing relatively valuable vector representation and they improve the results in answer ranking task. However, these methods face the issue of information loss when obtaining the last output layer.

To tackle the issue of information loss, combining feature extraction and deep neural networks has attracted many researchers [12, 23, 35]. Wu [31] combines two different methods to represent question-comment pairs, i.e., supervised model using traditional features and convolutional neural network. Takahashi [23] proposes a deep neural network with acoustic features to solve the acoustic scene classification. Zhou [35] combines human engineered feature extraction as well as those learned by the deep neural network. Koreeda [12] proposes a method that combines neural network similarities and handcrafted comment plausibility features. Combining deep neural networks and traditional features have the ability of incorporating different kinds of information.

Different from the existing approaches, in this paper we introduce the semantic features and metadata features into the attention network, which can make the attention focus on the semantic and metadata of the sentences. Other than simply combines a traditional features and the output of the last layer of CNN [30].

Though attention divergence has been observed in attention training of speech recognition [11], where the authors proposed an MTL framework that combines CTC and attention network to handle this issue, our paper is the first work that formally puts forward the concept of attention divergence. Furthermore, we design a focus-mechanism to solve this problem in the answer ranking domain.

3 OUR MODEL

Figure 2 shows the architecture of our proposed FAN model. Specifically, we adopt the BiLSTM model to obtain the preliminary representations of the question and answer. To solve the problem of attention divergence, we extract semantic futures and metadata features to enrich the question representation and then obtain a focusing attention for answer representation. Finally, we employ the softmax classifier to make the classification. We describe the details of the model in this section.

3.1 Semantic Features

Semantic and metadata are the two important components of the sentence. In order to tackle the issue of attention divergences, semantic features are introduced into the task of answer ranking. We describe our approach of extracting semantic features from questions and their answers in details. In natural language processing (NLP), word embedding maps words or phrases from the vocabulary to vectors of real numbers. It involves a mathematical embedding from a space with one dimension per word to a continuous vector space with much lower dimension. Methods to generate this mapping include neural networks [17], dimensionality reduction on the word co-occurrence matrix [13–15], probabilistic models [9], and explicit representation in terms of the context in which words appear. For each piece of a text such as answer text and question body we constructed the centroid vector from the vectors of all words in that text.

$$centroid(w_1..w_n) = \frac{\sum_{i=1}^{n} w_i}{n} \tag{1}$$

We used various feature similarities calculated using the centroid word vectors on the question body and on the answer text, as well as on parts thereof:

Question to answer similarity. We assume that a good answer should have a centroid vector that is close to that for the question. We choose the question body to answer text vector similarities.

Dependency syntax tree based word vector similarity. We obtained the dependency syntax tree with the Stanford parser [4], and calculated similarities between centroid vectors of noun phrases from the answer text and the centroid vector of the noun phrases from the question body text. The assumption is that the same parts of dependency syntax tree between the question and the answer might be closer than other parts of dependency tree.

Aligned similarity. For each word in the question body, we chose the most similar word from the answer text and took the average of all the best word pair similarities as suggested in [25]

LDA topic similarity. We performed topic clustering using Latent Dirichlet Allocation (LDA) as implemented in the gensim toolkit [21]. We built topic models with 50 topics. The assumption here is that if the question and the answer share similar topics, they are more likely to be relevant to each other.

For the similarity measures mentioned above, we measure their cosine similarity as,

$$\frac{\vec{a} \cdot \vec{b}}{\|\vec{a}\| \cdot \|\vec{b}\|} \tag{2}$$

3.2 Metadata Features

Besides semantic features described above, we also used some metadata features:

Question length. If a question is longer, it may be more clear, which may help users to give a more relevant answer [6].

Answer length. The assumption here is that longer answers could bring more useful details [33].

Question to answer length. If a question is long and the answer is short, it may be less relevant.

3.3 Focusing Attention Network

In answer ranking, given a question $Q = \{q_1, q_2, q_3, ..., q_n\}$ where q_i is i-th word ,n is the question length, we can compute its representation in bidirectional LSTM architecture as follows:

$$X = D[q_1, q_2, ..., q_n] \tag{3}$$

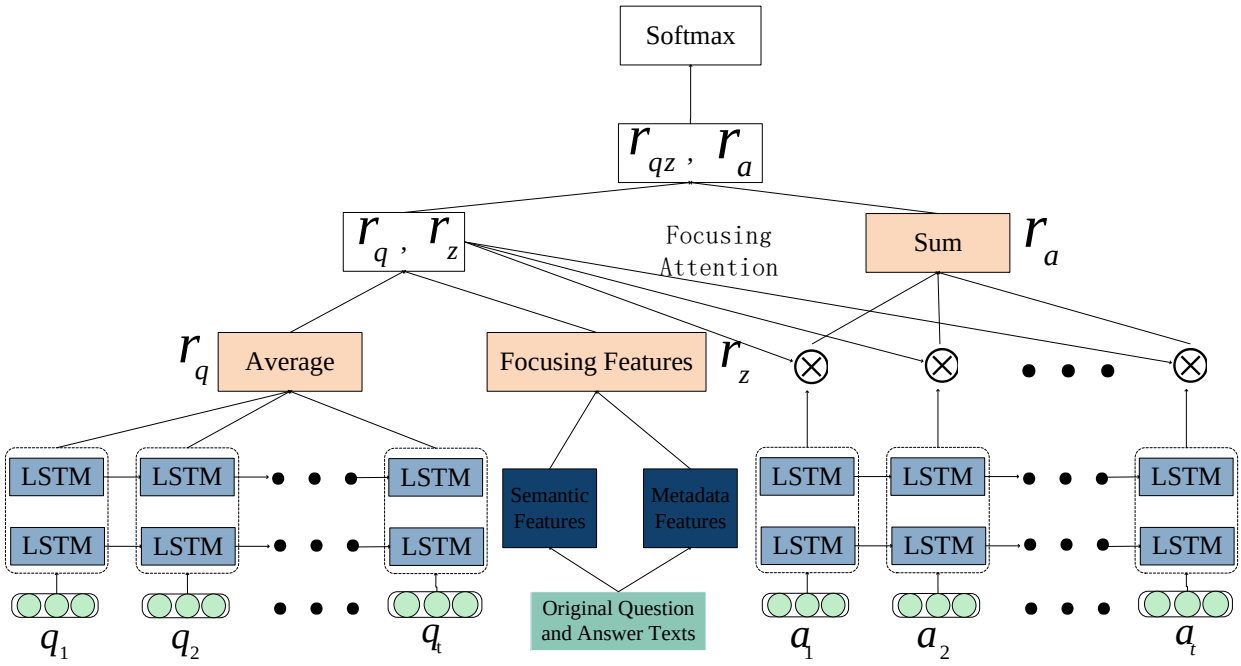

Figure 2: The architecture of our model.

$$i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i) \tag{4}$$

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f) \tag{5}$$

$$o_t = \sigma(W_o x_t + U_o h_{t-1} + b_o) \tag{6}$$

$$\tilde{c_t} = \tanh(W_c x_t + U_c h_{t-1} + b_c) \tag{7}$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c_t} \tag{8}$$

$$h_t = o_t \odot \tanh(C_t) \tag{9}$$

where D is an embedding matrix that projects word to its embedding space in R^d; W, U are weight matrices and b are bias vectors; σ is the active function such as tanh.

In the LSTM architecture, there are three gates (input i, forget f and output o) and a cell memory vector c. The input gate can determine how incoming vectors x_t alter the state of the memory cell. The output gate can allow the memory cell to have an effort on the outputs. Finally, the forget gate allows the cell to remember or forget its previous state. Single direction LSTMs suffer a weakness of not utilizing the contextual information from the future tokens. Bidirectional LSTM utilizes both the previous and future context by processing the sequence on two directions, and generates two independent sequences of LSTM output vectors. One processes the input sequence in the forward direction, while the other process the input in the reverse direction. The output at each time step is the concatenation of the two output vectors from both directions,ie. $h_t = \overrightarrow{h_t} || \overleftarrow{h_t}$.

After the bidirectional LSTM, the last hidden variable h_n or all hidden states average $\frac{1}{n}\sum_{t=1}^{n} h_t$ is adopted as the preliminary question representation r_q. We can also obtain the last hidden variable H_a for the answer sentence, where $h_a(i)$ means the last hidden output of the i-th word in the answer.

$$H_a = [h_a(1), h_a(2), ..., h_a(m)] \tag{10}$$

When modeling the candidate answer sentence with length m: $S = s_1, s_2, s_3, ..., s_m$ in multiple features based attention model, instead of using the last hidden state or average hidden states, we use multiple features based attentive hidden states that are weighted by r_q and r_z, where r_z is the merge of semantic feature vector r_s and the metadata feature vector r_m:

$$s_t \propto f_{attention}(r_q, r_z, h_a(t)) \tag{11}$$

$$\tilde{h_a}(t) = h_a(t) s_t \tag{12}$$

$$r_a = \sum_{t=1}^{m} \tilde{h_a}(t) \tag{13}$$

where $h_a(t)$ is hidden state of the answer at time t. The attention function $f_{attention}$ is computed as:

$$m(t) = \tanh(W_{hm} h_a(t) + W_{qm} r_q + W_{sm} r_z) \tag{14}$$

$$f_{attention}(r_q, r_z, h_a(t)) = \exp(w_{ms}^T m(t)) \tag{15}$$

W_{hm}, W_{qm} and W_{sm} are attentive weight matrices and w_{ms} is attentive weight vector. So we can expect that the candidate answer sentence representation r_a may be represented in a question and different kinds of features guided way: when its hidden state $h_a(t)$ is irrelevant to the question and the different kinds of features(determined by attention weight s_t), it will take less part in the final representation; but when this hidden state is relavent to the question and different kinds of features, it will contribute more in representing r_a.

Table 1: Experimental dataset on the SemEval-2016 Task 3

	train	dev	test
number of questions	2,669	244	327
number of answers	17,900	2,440	3,270

Table 2: Experimental dataset on the SemEval-2017 Task 3

	train	dev	test
number of questions	4,879	244	293
number of answers	36,198	2,440	2,930

The final question vector r_{qz} and the answer vector r_a which we obtain using multiple features based attention are both useful in the ranking task. We splice them by the row and get the high level representation of the sentence $\bar{s}$. We use it to classify the answer of the question by a softmax function

$$p = softmax(W_c\bar{s} + b_c) \tag{16}$$

$$L = -\sum_{s} \log p_{sj} \tag{17}$$

where j is the label of answer s, W_c is the weight matrices and b_c is the bias vector.

4 EXPERIMENTS EVALUATION AND ANALYSIS

In this section, we describe our experimental setting. We first introduce the dataset and the competitive methods, then present the results and analysis.

4.1 Datasets Setup

We experiment with the dataset from SemEval-2016 Task3 and SemEval-2017 Task3 on answer ranking for Community Question Answering [18, 19]. The datasets contain question-answer threads from the Qatar Living forum. Each answer in the dataset is annotated with one of the following labels, reflecting how well it answers the question: Good, PotentiallyUseful, and Bad. At SemEval-2016 and SemEval-2017 Task3, the latter two classes were merged into Bad at testing time. The statistics of the datasets are summarized in Table 1 and Table 2.

4.2 Compared with Competitive Methods

We experimentally compare our model with the other models at SemEval-2016 and SemEval-2017 Task 3. They are Kelp, ConvKN, SemanticZ in SemEval-2016 and KeLP, Beihang-MSRA and ECNU in SemEval-2017.

- KeLP: Their system learned semantic relations between questions and answers using kernels and previously-proposed features from [3]. The System is based on the KeLP machine learning platform [7].
- ConvKN: They combined convolutional tree kernels and convolutional neural networks, together with text similarity and thread-specific features [10].

Table 3: Experimental Results on the SemEval-2016 Task 3

Model	MAP	AvgRec	MRR
Random baseline [1]	52.80	66.52	58.71
Search engine [1]	59.53	72.60	67.83
KeLP [1]	79.19	88.82	86.42
ConvKN [1]	77.66	88.05	84.93
SemanticZ [1]	77.58	88.14	85.21
Attention-BiLSTMs	77.60	88.27	85.05
FAN(only semantic features)	78.10	88.30	85.65
FAN(only metadata features)	78.20	88.38	85.73
FAN(both features)	**79.38**	**88.96**	86.18

- SemanticZ: They used the semantic similarity based on word embeddings and topics [16].
- KeLP: They used tree kernels with relational links in Support Vector Machine. The questions are aligned with the answers (or with the other questions) by means of a special REL tag, directly annotated in the parse trees. It used the homonymous tree kernel software toolkit, KeLP [8].
- Beihang-MSRA: They developed a ranking system for capturing semantic relations between text pairs with little word overlap. In addition to traditional NLP features, they introduced several neural network based matching features which enable their system to measure text similarity beyond lexicons [32].
- ECNU: They explored a traditional machine learning method which used multiple types of features, e.g., Word Match Features, Topic Model-based Features, and Lexical Semantic Similarity Features. Additionally, they also built a Convolutional Neural Network (CNN) model to learn joint representation for question-comment (Q-C) pair. They combined two different methods to represent question-comment pair [29].

4.3 Experimental Settings

The questions and answers are tokenized and lemmatized using NLTK [7]. We removed the stop words and changed all the letters to lowercase. We used semantic word embeddings obtained from Word2Vec [2] models trained on different unannotated data sources including the QatarLiving and DohaNews [16]. The dimension of word embedding was 200. Tokens that did not appear in the pre-trained word embeddings were replaced with a special token, of which the embedding was initialized randomly. The number of nodes in the hidden layer of the bidirectional LSTM is 128. Therefore, the question vector r_{qz} and the answer vector r_a are 256 dimensions. We merge the features by stitching them, so we obtain the 512 dimensions feature as input. The activation we used in the bidirectional LSTM is Relu and the dropout rate is set as 0.5. To evaluate the model performance, we adopt the mean average precision(MAP), AvgRec and MRR which are the primary metrics used in QA [26, 27].

4.4 Results and Analysis

The experimental results on the SemEval-2016 and SemEval-2017 Task 3 are shown in Table 3 and Table 4.

Table 4: Experimental Results on the SemEval-2017 Task 3

Model	MAP	AvgRec	MRR
Random baseline [18]	62.30	70.56	68.74
Search engine [18]	72.61	79.32	82.37
KeLP [18]	88.43	93.79	92.82
Beihang-MSRA [18]	88.24	93.87	92.34
ECNU [18]	86.72	92.62	91.45
Attention-BiLSTMs	83.48	89.34	88.25
FAN(only semantic features)	85.10	90.56	89.85
FAN(only metadata features)	86.23	91.28	90.47
FAN(both features)	**88.72**	**93.92**	92.63

Table 5: Effectiveness of FAN Model

Question	Traditional attentive word(top 5)	FAN word(top 5)	Answer
is there any place i can find scented massage oils in qatar?	massage, oils, qatar, affordable, prices	naseem, alnadir, smartlink, chinese, prices	It's called Naseem Alnadir. Right next to the Smartlink shop. You'll find the chinese salesgirls at affordable prices there.

We can see that our MAP(with both features) respectively improvement of 19.85 and 16.11 compared with the results obtained by the search engine in SemEval-2016 and SemEval-2017. We also compare the FPN(only semantic features), the FPN(only metadata features) and the FPN(both features) models and find that both of the features are effective to solve the attention divergence problem, especially the metadata features. The model with both features obtain the best result. KeLP used various kinds of features and got the best results in SemEval-2016 and SemEval-2017 which demonstrates that feature engineering is effective in answer ranking task. ConvKN ranked second in SemEval-2016. Beihang-MSRA obtained the best AvgRec and ECNU ranked fourth in SemEval-2017. Our MAP separately improves 0.19 and 0.29 compared with the results obtained by the KeLP in SemEval-2016 and SemEval-2017. Our model also gets the best AvgRec above the other methods in SemEval-2016 and SemEval-2017. The result proves that our model can outperform the state-of-the-art systems.

We also compare our model with the traditional attention-biLSTMs model. The result shows that our MAP respectively improves 1.78 and 5.24 in SemEval-2016 and SemEval-2017. Our **FAN** model can focus attention back on the right regions of the target terms and achieve significant improvements over the other models.

4.5 Case Study

In order to better understand our proposed model, we provided an example to show why our FAN model is more effective for the answer ranking task. As shown in Table 5, for the question "*is there any place i can find scented massage oils in qatar?*", it is required to find a place, and we observe that in the traditional attention model, the top 2 attentive words associate with the question are not location names, such as *massage* and *oils*. However, in the FAN model, we observe that top 2 attentive words associate with the question are location names, such as *naseem* and *alnadir*. In particular, these two words contain the information that associate with the key word "*Naseem Alnadir*" in the good answer, which solves the issues of attention divergence for answer ranking task. Therefore, our FAN model, which enhances the question representations to rank good answers ahead of bad ones.

5 CONCLUSION

In this work, we put forward the *attention divergence* to explain the poor performance of existing attention based methods of answer ranking on complicated long question-answer pairs, and propose a novel FAN to solve this problem. Different from the existing methods, firstly, we obtain the question representation with Bidirectional LSTMs, next we extract semantic features, metadata features from questions and their answers to form the focusing features, then we use the focusing attentive network to obtain answer representation. At last, we feed the question and answer representation to the softmax classifier for classification. Experiments on SemEval-2016 and SemEval-2017 have shown the effectiveness of our proposed model, especially in terms of the Mean Average Precision and precision.

Because semantic and metadata features are the important features in the sentence and the complicated long sentences can be seen in many tasks such as text classification and reading comprehension. In future work, we plan to extend the proposed idea to text classification and other related tasks.

ABSTRACT

In recent years, with the prevalence of social media and smart devices, people causally reveal their locations such as shops, hotels, and restaurants in their tweets. Recognizing and linking such fine-grained location mentions to well-defined location profiles are beneficial for retrieval and recommendation systems. In this paper, we propose **DLocRL**, a new deep learning pipeline for fine-grained location recognition and linking in tweets, and verify its effectiveness on a real-world Twitter dataset.

1 INTRODUCTION

Twitter is a place where users can share their daily life activities by posting tweets (*i.e.,* short messages, up to 140 characters each). In many tweets, locations are implicitly or causally revealed by users at fine-grained granularity [14, 16, 17], for example, a restaurant, a shopping mall, a park or a landmark building. Here, a fine-grained location is equivalent to a point-of-interest (POI), which is a focused geographical entity [16, 26]. In this paper, we target on *recognizing* mentions of POIs and *linking* these mentions to well-defined location profiles.

The two tasks are important for several reasons. First, recognizing mentions of POIs is beneficial for information retrieval [2]. An example is that query understanding can be enhanced by exploiting POI information in location-based information retrieval systems [7, 28]. In addition, recognized POIs can be integrated into knowledge bases and support many business intelligence applications such as POI recommendation and location-aware advertising [16, 20, 22]. Second, the linked location profile can serve as side information for the tweet, and vice versa. For example, Twitter sentiment analysis can be conducted in a more precise manner by incorporating the location profile content [10].

However, recognizing POI mentions and linking these mentions to well-defined location profiles are both challenging. Due to the informal writing of tweets, POIs are usually mentioned by incomplete name, nickname, acronym or misspellings. For example, the mention *vivo* may refer to *VivoCity* which is a comprehensive shopping mall in Singapore, or a smartphone brand. Even if we have successfully recognized a POI mention, it remains challenging to link the mention to a specified location profile (*i.e.,* a specific shopping mall with address and geo-coordinates in this case).

On the other hand, existing solutions [10, 14, 16] on these two tasks require a large set of features manually designed for each task and domain, which demands task and domain expertise. For example, Li *et al.* [16] carefully designed lexical, grammatical, geographical and BILOU schema features (totally 11 features) to extract fine-grained locations from tweets. Ji *et al.* [14] proposed a joint model to recognize and link fine-grained locations from tweets with 24 hand-crafted features. Recently, Han *et al.* [10] proposed a probabilistic model with seven types of hand-crafted features to link fine-grained location in user comments. It is now generally admitted that distributed representations could better capture lexical semantics [8]. We would envision for a system that is based on

distributed representations, and that can learn informative features for location recognition and linking by itself without human effort.

In this paper, we propose DLocRL, a new **D**eep pipeline for fine-grained **Loc**ation **R**ecognition and **L**inking in tweets. DLocRL is designed to adopt effective representation learning, semantic composition, and attention and gate mechanisms to exploit the multiple semantic context features for location recognition and linking. DLocRL consists of two core modules: *recognition* module and *linking* module.

The *recognition* module aims to extract a text segment referring to a fine-grained location (*i.e.,* POI) from a given tweet. In DLocRL, we formulate the recognition task as a sequence labeling problem (*i.e.,* assigning tags to tokens in the given sequence). We adopt bi-directional long short-term memory with conditional random fields output layer (BiLSTM-CRF) to train a POI recognizer.

The *linking* module aims to link each recognized POI to a corresponding location profile. Before linking POIs to location profiles, an extensive collection of location profiles (CLP) is constructed. Given an input pair ⟨POI, Profile⟩, the *linking* module is trained to judge whether the location profile corresponds to the POI. More specifically, DLocRL utilizes two pairs of parallel LSTMs to encode the left context and right context for a POI, respectively. The location profiles are represented by their constituents with TF-IDF weights and one-hot schema. The Manhattan distance is used to measure the geographical distances between users and profiles. Finally, the representation of ⟨POI, Profile⟩ comes from three sources: tweet-level contextual information, location profile representation and geographical distance. The representation is then fed into a fully-connected layer for final linking prediction. Moreover, to take advantage of the geographical coherence information among mentioned POIs in the same tweet, we develop Geographical Pair Linking (Geo-PL), a post-processing strategy to further enhance the linking accuracy.

In summary, we make the following contributions: (1) We propose **DLocRL**, a new deep learning pipeline for fine-grained Location Recognition and Linking in tweets. To the best of our knowledge, our work is the first attempt to address location recognition and linking in the paradigm of deep learning. (2) We develop the Geographical Pair Linking (Geo-PL) approach, a post-processing strategy to further improve linking performance. (3) We conduct extensive experiments on a real-world Twitter dataset. The experimental results show the effectiveness of DLocRL on fine-grained location recognition and linking. We also conduct ablation studies to validate the effectiveness of each design choice.

2 RELATED WORK

2.1 Location Mention Recognition and Disambiguation

Recognition. Facing noisy and short tweets, traditional NER methods suffer from their unreliable linguistic features [36]. Prior solutions exploit comprehensive linguistic features like Part-of-Speech tags, capitalization [27], Brown clustering [3] to improve recognition performance. For example, Li *et al.* [16] carefully designed lexical, grammatical, geographical and BILOU schema features (totally 11 features) to extract fine-grained locations from tweets. Ji *et al.* [14] proposed a joint model to recognize and link fine-grained locations from tweets with 24 hand-crafted features. Zhang *et al.* [34] designed four types of features and trained a classifier to select the best match among gazetteer candidates. Generally, location gazetteers are widely used in location mention recognition [16, 21, 34]. For noisy text, Malmasi *et al.* [21] proposed an approach based on Noun Phrase extraction and n-gram based matching instead of the traditional methods using NER or CRF. Different from these existing works, our approach DLocRL does not require hand-crafted features.

Disambiguation. For entity disambiguation, many studies attempt to exploit the coherence among mentioned entities. Pair-wise [15] and global collective methods [11, 12, 32] have been applied to explore the coherence. Zhang *et al.* [34] and Ji *et al.* [14] observed that the geographical coherence is effective in location disambiguation task. Also, instead of tweet-level coherence, Li *et al.* [18] utilized user-level coherence to facilitate entity disambiguation. Besides, Shen *et al.* [30] introduced user interest modeling to collective disambiguation.

To form an entirely end-to-end model for joint recognition and linking, Guo *et al.* [9] and Ji *et al.* [14] adopted structural SVM and perceptron, respectively. Furthermore, the beam search algorithm [35] is also used in [14] to search the best combination of the mention recognition and linking. In this work, we devise DLocRL, a new pipeline which can be upgraded and optimized much easier than previous joint models and still achieves better performance.

2.2 Neural Networks for NER and EL

Named Entity Recognition (NER). The use of neural models for NER was pioneered by Collobert *et al.* [5], where an architecture based on temporal convolutional neural networks (CNNs) over word sequence was proposed. Chiu *et al.* [4] utilized CNN to detect character-level features and LSTM to capture the word-level context in a sentence. Yang *et al.* [33] proposed a gated recurrent unit (GRU) network to learn useful morphological representation from the character sequence of a word. Recently, Peters *et al.* [24] proposed deep contextualized word representation, which can model syntax, semantics, and polysemy. Akbik *et al.* [1] proposed contextual string embeddings, to leverage the internal states of a trained character language model to produce a novel type of word embedding.

Entity Linking (EL). Neural networks were firstly used for entity linking by Sun *et al.* [31]. They proposed a model which takes consideration of the semantic representations of mention, context, and entity. Recently, Phan *et al.* [25] proposed a neural network for entity linking with LSTM and attention mechanism. They also proposed *Pair Linking* to enhance collective linking by measuring the cosine similarity of the text embeddings between two mentioned entities.

3 MODEL DESCRIPTION

Figure 1 shows the workflow of DLocRL, which consists of recognition module and location linking module.

3.1 Location Recognition

Figure 2 shows the architecture of the location recognition module. The representation of a word consists of its pre-trained word embedding, BILOU pre-label and character-level representation.

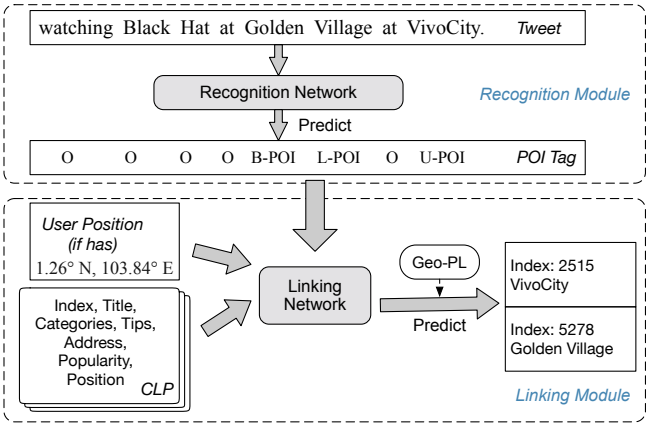

Figure 1: A running example to illustrate the workflow of DLocRL.

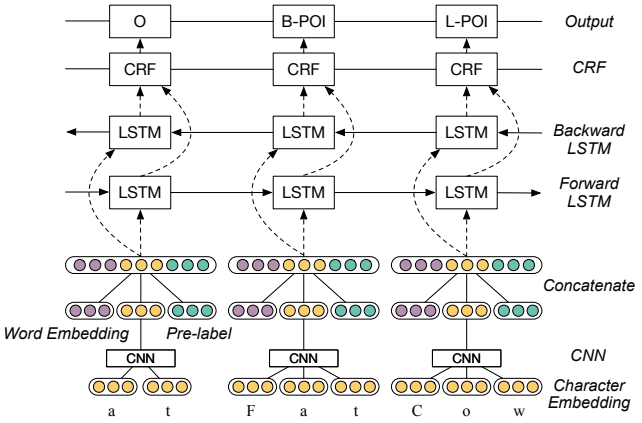

Figure 2: The architecture of location recognition module.

Finally, BiLSTM-CRF is utilized to infer tag sequence based on the representations.

Pre-trained Word Embedding. To deal with the problem of informal spellings and casual expressions, we should capture the information from tweets as accurate as possible. We use the GloVe[23] embeddings pre-trained on a large-scale Twitter corpus of two billion tweets. The vocabulary of pre-trained embeddings covers most common misspellings and aliases of most common words.

Pre-label. POI inventory, containing partial and familiar names from Foursquare, is proposed in [16] to pre-label candidate location mentions in tweets. It has been proved that pre-label is an essential resource to improve recognition performance. We use a CRF toolkit[1] to automatically assign the pre-labels with BILOU scheme[27].

Character-level Representation. Previous studies [4, 13] have shown that character-level information (*e.g.,* prefix and suffix of a word) is an effective resource for NER task. CNN and BiLSTM are commonly used in previous works to extract character-level representation. In our model, we use CNN because of its lower computational cost [4, 19].

BiLSTM-CRF. LSTM is a variant of recurrent neural network (RNN) and is designed to deal with vanishing gradients problem. BiLSTM uses two LSTMs to represent each token of the sequence based on both the past and the future context of the token. As shown in Figure 2, one LSTM processes the sequence from left to right, the other one from right to left. For a word, we concatenate its pre-trained word embedding, pre-label and character-level representation as its final representation, which is then fed into a BiLSTM layer. Then, the output sequence is fed into a CRF layer to infer the tag sequence. BiLSTM-CRF is a state-of-the-art approach to named entity recognition [6, 13].

3.2 Location Linking

Figure 3 shows the architecture of the location linking module. We use two pairs of parallel LSTMs (four in total) to encode the left-side and right-side contexts of a mention, respectively. Note that the input of the two parallel LSTMs for each side is re-weighted by two different *attentions* from the location profile. The output sequences of LSTMs are "fused" by a *fusion gate* and then fed into a max-pooling layer over all time steps as the final representation for each side context. Next, we concatenate the left-side context representation, right-side context representation, the representation of location profile together with the *Manhattan distance* between user coordinates (*i.e.,* user position attached to the tweet) and coordinates from location profile. Finally, a multilayer perceptron (MLP) with a sigmoid activated output layer is used to output a scalar ranged between zero and one as the matching score.

Location Profile Mapping Dictionary. Following [14], we use a location profile mapping dictionary to recall all possible candidates for a location mention. The *key* of the dictionary is a possible POI mention, and the *value* is the list of candidate profile indexes for the POI mention. If the mention is not in the mapping dictionary, we predict it as *un-linkable*. The dictionary is constructed with Foursquare check-in tweets.

Mention's Context. Following [25], we use LSTM networks to capture two-side contextual information of the POI mention. The difference is that we use all words in a tweet instead of specific window size. The left-side context starts from the leftmost word in a tweet and ends at the rightmost word inside the mention. Conversely, the right-side context starts from the tweet's rightmost word and ends at the leftmost word of the mention. Since the tweet does not have a long context, we use all words to understand the tweet as a whole. Note that the input of LSTM layers is re-weighted with a multi-attention mechanism, which is to be detailed shortly.

Behavioral and Semantic Information. Users often reveal their locations and describe what they are doing in tweets. For example, a user posts "Great lobster @ Red Robin!", which contains information about behavior (having lobster). Here, we name such information as ***behavioral information***. Obviously, since few restaurants serve lobster, it could be beneficial for POI disambiguation. According to our observation, tweets share the same behavioral information with the tips (*i.e.,* user comments) in the Foursquare location profile. On the other hand, some words in a tweet may be directly semantically relevant to the category or address of a location. For instance, in the tweet "Best wine at Elle's in the center", *wine* is closer to *bar* in word embedding space. Such information

[1] CRF++: https://github.com/taku910/crfpp

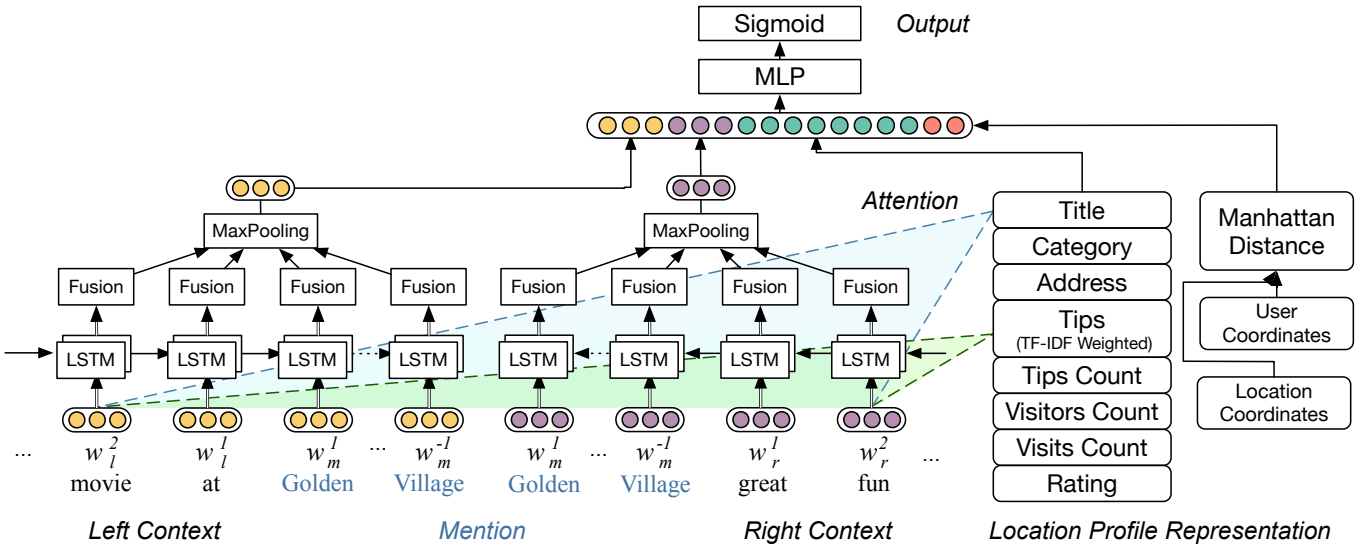

Figure 3: The architecture of location linking network. The input is a pair ⟨tweet, profile⟩, and the output is the matching score.

is beneficial for location disambiguation between *Elle's Bar* and *Elle's Salon*. Similarly, in the same example, *center* is a synonym for *Central Region*. This can be helpful for picking a location profile titled "Elle's Bar - Central Region" out of other branches of Elle's Bar. We name such information as ***semantic information***.

Multi-attention Mechanism. To comprehensively exploit *semantic information* and *behavioral information*, we develop a multi-attention mechanism to assign weights for the input sequence. As shown in Figure 3, we use the *title* representation and *tips* representation as two attention vectors. Specifically, given an input word embedding w_i in a tweet and an attention vector p (*i.e.,* representation of title or tips from location profile), the re-weighted input word embedding w_i' is defined by:

$$z_i = \tanh\left(V_p p + V_w w_i\right) \tag{1}$$

$$s_i = \text{softmax}(v_k z_i + v_b) \tag{2}$$

$$w_i' = w_i s_i \tag{3}$$

where V_*, v_k, and v_b are attention parameters which can be learned during training. The TF-IDF weighted tips representation (to be detailed shortly) contains the most characteristic behavioral information about a location. Thus, the attention from tips can highlight the parts which are most relevant with the tips. Similarly, the title contains rich semantic information (including *location name*, *branch name* and *business status*) which can highlight the parts relevant to the location.

Fusion Gate. To collect important information from the output of two parallel LSTMs, we borrow a simple but practical *fusion gate* from [29]. Given the output of two parallel LSTMs with different attentions (*i.e.,* x_i^1 and x_i^2), the output of fusion gate u_i is formally defined by:

$$f_i = \text{sigmoid}(W_1 x_i^1 + W_2 x_i^2 + b) \tag{4}$$

$$u_i = f_i \odot x_i^1 + (1 - f_i) \odot x_i^2 \tag{5}$$

where W_1, W_2, and b are learnable parameters. The fusion gate enables the model to learn how to weight the two input sequences, which solves the problem of the imbalanced importance of behavioral information and semantic information.

Location Profile. The properties (exclude "category") of a location profile fall into two classes: *word-based* and *numeric-based*. For *word-based* properties (*i.e.,* title, address, and tips), we represent each property by averaging all word embeddings inside it. In particular, the word embeddings of "tips" are weighted by TF-IDF schema. For *numeric-based* properties (*i.e.,* tips count, visitors count and visits count), we normalize them through the whole CLP. For *category* property, we encode it as a one-hot vector. Finally, we concatenate representations of all properties together as the location profile representation.

Manhattan Distance. To measure the distance between user coordinates and location coordinates in a city, we use the Manhattan distance (*i.e.,* taxicab distance) defined by:

$$d(p, q) = |p_x - q_x| + |p_y - q_y| \tag{6}$$

where p and q are two pairs of coordinates. Manhattan distance is better than Euclidean distance since the road network in a city or suburb is usually orthogonal. Note that not every tweet has an attached user position. For these situations, we fix the distance value to a pre-defined constant. Manhattan distance is also used in our post-processing, geographical pair linking, which will be discussed in Section 4.

Final Prediction. For all candidate location profiles in our mapping dictionary for a mention, we predict the matching score between the mention and each candidate. Formally, the final predicted location profile p_i for mention m_i is computed by:

$$p_i = \underset{p_j \in c(m_i)}{\arg\max}\, \phi(m_i, p_j) \tag{7}$$

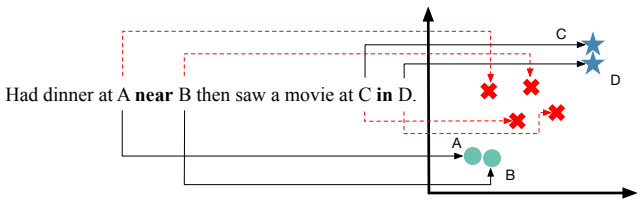

Figure 4: A wrong case of taking into account the coherence among all mentions. A, B, C and D are true POIs mentioned by a user. The incorrect predictions are marked with red dashed arrows and crosses.

where $c(m_i)$ is the candidate set for m_i and $\phi(m_i, p_j)$ is the matching score between m_i and p_j.

4 GEOGRAPHICAL PAIR LINKING

In this section, we introduce Geographical Pair Linking (Geo-PL), a post-processing strategy to enhance our linking performance.

For location linking, one of the most valuable information is the geographical coherence among mentioned locations in the same tweet. First, instead of directly calling the branch name of a chain restaurant, users are more likely to mention them with another location (usually a landmark). Second, people may describe a route by listing the locations along the way one by one, which also reveals the coherence among the mentioned locations.

For geographical coherence, prior studies often measure the distances among all mentions in a tweet. According to our observation, geographical coherence between two locations is strong enough for location disambiguation. Moreover, as illustrated in Figure 4, when a user mentions four locations with a conventional way like "Had dinner at A near B then saw a movie at C in D," the geographical coherence measurement among all mentions brings obvious error. It obtains the collective minimum but disregards the strong connection between two mentions.

To exploit pair-wise geographical coherence, we developed **Geographical Pair Linking (Geo-PL)** algorithm based on the *Pair Linking* algorithm [25]. The original algorithm measures the cosine similarity between text embeddings, while we use Manhattan distance discussed in Section 3.2 to measure the geographical coherence. Geo-PL iteratively resolves all pairs of mentions, starting from the most *confident* pair. The confidence score of a pair of links $m_i \mapsto p_i$ and $m_j \mapsto p_j$ is defined by:

$$conf(i,j) = (1-\beta)\frac{[\phi(m_i,p_i)+\phi(m_j,p_j)]}{2} + \beta\frac{1}{d(p_i,p_j)} \quad (8)$$

where β is a given coefficient representing the preference between the matching scores and the geographical coherence; d is the Manhattan distance defined by Equation 6. In the case of $p_i = p_j$, we temporarily set β to 0 when calculating. The procedure of Geo-PL (the same as Pair Linking) is detailed in Algorithm 1. Note that if there is only one POI mention in a tweet, we simply predict its location profile by Equation 7.

Algorithm 1: Geo-PL Algorithm

Input: N mentions($m_1, \ldots, m_N$). Mention m_i has candidate profiles $\{e|e_i \in C(m_i)\}$
Output: $\Gamma = (p_1, \ldots, p_N)$

$p_i \leftarrow null, \forall p_i \in \Gamma$;
foreach $pair(m_i, m_j) \wedge m_i \neq m_j$ **do**
  $Q_{m_i,m_j} \leftarrow top_pair(m_i, C(m_i), m_j, C(m_j))$;
  $Q.add(Q_{m_i,m_j})$;
end
while $\exists p_i \in \Gamma, p_i = null$ **do**
  $(m_i, e_i, m_j, e_j) \leftarrow most_confident_pair(Q)$;
  $p_i \leftarrow e_i$;
  $p_j \leftarrow e_j$;
  for $k := 1 \rightarrow N \wedge p_k = null$ **do**
    $Q_{m_k,m_i} \leftarrow top_pair(m_k, C(m_k), m_i, \{p_i\})$;
    $Q_{m_k,m_j} \leftarrow top_pair(m_k, C(m_k), m_j, \{p_j\})$;
  end
end

5 EXPERIMENT

5.1 Data Preparation

We use a Singaporean national Twitter dataset released by Ji *et al.* [14]. The dataset includes a CLP and a set of labeled tweets.

326,853 Foursquare *check-in tweets*, containing both formal auto-generated POI name and informal user mentions, are collected to build the CLP (including 22,414 valid location profiles) and the POI inventory (including 27,386 entries). Location profile mapping dictionary (see Section 3.2) is also constructed with check-in tweets. Informal mentions in check-in tweets and the indexes of crawled profiles are used as keys and values, respectively. The final location profile mapping dictionary has 24,750 keys and 63,091 *<key, value>* mappings.

The dataset consists of 3,611 labeled tweets and 1,542 POI locations, 543 of which can be linked to a profile in the CLP. 10% of tweets have an attached user position. These tweets are labeled by human annotators. All possible POI mentions are labeled with one of *NPOI* (*i.e.,* not a POI mention), *index* of linked location profile, or *NIL* (*i.e.,* cannot be linked to a profile).

We split the 3,611 labeled tweets randomly into three subsets: 2,500 tweets for training, 211 tweets for validation, and 900 tweets for testing. Same POI inventory and location profile mapping dictionary used in [14] are employed through all models in our experiments.

5.2 Parameter Setting and Evaluation Metrics

We set β, the coefficient of Geo-PL preference to 0.8 based on fine-tuning on the validation set. When concatenating the scalars to be the input of MLP, we duplicate them to the same number of dimensions as the word-based properties (*i.e.,* 200 dimensions in our experiments). This setting prevents the scalars from being "ignored" during training.

We conduct experiments on location recognition subtask, location linking subtask and the whole task, respectively. We adopt three metrics, Precision (Pr), Recall (Re) and F_1 which are widely

Table 1: Performance on Location Recognition and Location Linking.

Methods	Location Recognition			Location Linking			Recognition + Linking		
	Pr	*Re*	F_1	*Pr*	*Re*	F_1	*Pr*	*Re*	F_1
Li *et al.* [16]	**0.8962**	0.7661	0.8261	-	-	-	-	-	-
Shen *et al.* [30]	-	-	-	0.6723	0.6349	0.6531	-	-	-
Pipelined [16] [30]	-	-	-	-	-	-	0.6339	0.5635	0.5966
JoRL_L [14]	0.8926	0.7823	**0.8338**	-	-	-	0.8152	0.5952	0.6881
DLocRL	0.8575	**0.8091**	0.8326	**0.8235**	**0.7778**	**0.8000**	**0.8350**	**0.6825**	**0.7511**

used to evaluate NER and EL tasks. In particular, we use the ground-truth mentions instead of the predicted output of the recognition module, to get the metric scores for location linking.

5.3 Overall Comparison

We compare our model with state-of-the-art solutions. More specifically, we compare our model with [16] and [14] for recognition, and [30] for linking, respectively. Note that the performance of [14] on linking subtask is not provided since it is a joint model. For the whole task, we choose JoRL_L as the baseline since it is the state-of-the-art joint model in supervised learning manner. All models are fine-tuned on the validation set.

The result is shown in Table 1. We observe that DLocRL achieves the highest *recall* on location recognition. DLocRL beats Li *et al.* [16] and JoRL_L [14] with relative recall improvements of 5.61% and 3.43%, respectively. We contribute this to the fact that word/character embeddings enable our model to be more "tolerant" than prior works which depend on hand-crafted features. Although the precision score of DLocRL is not good, it does not have an impact on the whole task, because the location profile mapping dictionary can filter out most false positive (FP) prediction in the linking module.

On location linking subtask, our method outperforms the work [30] by 22.49% on precision, 22.51% on recall and 22.49% on F_1.

On the whole task, our model prominently outperforms the state-of-the-art joint solution (JoRL_L) on all three metrics (2.43% on precision, 14.67% on recall, 9.16% on F_1). Also, our model dramatically outperforms the prior state-of-the-art *pipeline* by 31.72% on precision, 21.12% on recall and 25.90% on F_1.

5.4 Effect of Multi-attention for Linking

We conduct experiments to verify the effectiveness of the multi-attention mechanism. Table 2 shows the linking performance with single attention from tips/title attentions and multi-attention. Note that the single attention approaches can only slightly improve the performance because they have "prejudice" which considers either behavioral information or semantic information. By "fusing" this two information, DLocRL eliminates the prejudice so it can effectively filter out noisy information. With the multi-attention mechanism, DLocRL improves the performance of linking module by 4.25% on precision, 4.26% on recall, and 4.26% on F_1, compared with the baseline.

5.5 Effect of Geo-PL for Linking

As discussed in Section 4, we introduce a novel post-processing strategy, named Geo-PL. Here, we conduct experiments to show the impact of Geo-PL for location linking. Table 3 shows the experimental results. Compared with no Geo-PL component, DLocRL (with Geo-PL) significantly improves precision by 13.46%, recall by 8.89% and F_1 by 11.11%.

Table 2: Effect of Multi-attention Mechanism for Linking.

Attention	Location Linking		
	Pr	*Re*	F_1
Baseline (*without attention*)	0.7899	0.7460	0.7673
Single Tips Attention	0.7983	0.7540	0.7755
Single Title Attention	0.7899	0.7460	0.7673
Tips + Title (*multi-attention*)	0.8235	0.7778	0.8000

Table 3: Effect of Geo-PL for Linking.

Strategy	Location Linking		
	Pr	*Re*	F_1
Without Geo-PL	0.7258	0.7143	0.7200
With Geo-PL	0.8235	0.7778	0.8000

6 CONCLUSIONS

In this paper, we introduce DLocRL, the first deep neural network based pipeline to recognize fine-grained location mentions in tweets and link the recognized locations to location profiles. Moreover, we develop a novel post-processing strategy which can further improve location linking performance. Through extensive experiments, we demonstrate the effectiveness of DLocRL against state-of-the-art solutions on a real-world Twitter dataset. The ablation experiments show the effectiveness of multi-attention mechanism and Geo-PL strategy on location linking.

ABSTRACT

The sequential recommendation, which models sequential behavioral patterns among users for the recommendation, plays a critical role in recommender systems. However, the state-of-the-art Recurrent Neural Networks (RNN) solutions rarely consider the non-linear feature interactions and non-monotone short-term sequential patterns, which are essential for user behavior modeling in sparse sequence data. In this paper, we propose a novel **R**ecurrent **C**onvolutional **N**eural **N**etwork model (RCNN). It not only utilizes the recurrent architecture of RNN to capture complex long-term dependencies, but also leverages the convolutional operation of Convolutional Neural Network (CNN) model to extract short-term sequential patterns among recurrent hidden states. Specifically, we first generate a hidden state at each time step with the recurrent layer. Then the recent hidden states are regarded as an "image", and RCNN searches non-linear feature interactions and non-monotone local patterns via intra-step horizontal and inter-step vertical convolutional filters, respectively. Moreover, the output of convolutional filters and the hidden state are concatenated and fed into a fully-connected layer to generate the recommendation. Finally, we evaluate the proposed model using four real-world datasets from various application scenarios. The experimental results show that our model RCNN significantly outperforms the state-of-the-art approaches on sequential recommendation.

1 INTRODUCTION

Recommender systems play a significant role in engaging and satisfying users with services provided in the age of information explosion. To build effective recommender systems, a key factor is to accurately characterize users' interests and tastes, which are intrinsically dynamic and evolving. To achieve this goal, the sequential recommendation has been proposed to recommend the successive item(s) that a user is likely to interact with based on his/her past activity sequences.

Early sequential methods like Markov chains [18] are proposed for modeling user's sequential pattern. However, these methods based on Markov chains model local sequential behaviors between every two adjacent items but have difficulties to model high-order relationships. More recently, deep neural networks have been intensively studied in related domains and made extraordinary impacts on sequential recommendation. For instance, Recurrent Neural Network (RNN) has become a popular sequential neural model. For better holding the long-term dependencies, two variants of RNN in particular, namely the Long-Short Term Memory (LSTM) [5] and the Gated Recurrent Unit (GRU) [1] have been widely used. Besides, other variants of RNN, including session-based RNN [4], hierarchical personalized RNN [10], and attention-based RNN [8] are found helpful in modeling sequences.

However, RNN holds an assumption that temporal dependency changes monotonically [9], which means that the current item or hidden state is more important than the previous one. This monotonic temporal dependency of RNN impairs the modeling of user's short-term interest. Literature work has shown that feature interactions can help capture sequential patterns especially with

sparse data [3, 11, 21]. Thus, it is crucial to consider the interactions between hidden state features in RNN when learning from sparse sequential data. In addition, CNN and RNN have been integrated for various application scenarios, such as image processing [2] and text classification [7]. However, none of them are designed for sequential recommendation.

In this paper, we propose a novel recurrent neural network model, namely **R**ecurrent **C**onvolutional **N**eural **N**etwork (RCNN), for sequential recommendation. It leverages the strengths of both the recurrent architecture of LSTM to capture complex long-term dependencies and the convolutional operation of CNN to extract local sequential patterns among hidden states. Specifically, we first generate a hidden state, *i.e*, a hidden sequential preference representation, at each time step by inputting a current item into the recurrent layer. Then, we treat recent hidden states of each time step as an "image" and search for local sequential features using horizontal and vertical convolutional filters. An intra-step horizontal filter is used to capture non-linear feature interactions, while an inter-step vertical filter is used for non-monotone local patterns. Moreover, the outputs of CNN and the hidden state vector of LSTM are concatenated together to describe user's overall interest, and then are fed into a fully-connected layer to generate a recommendation list. In summary, the main contributions of this paper are listed as follows:

- To the best of our knowledge, it is the first to propose to integrate both RNN and CNN to combine user's long- and short-term preference to generate a high-level hybrid representation for sequential recommendation.
- RCNN uses horizontal and vertical convolutional filters to learn high-order correlations among hidden state from locally to globally in a hierarchical way.
- We conduct experiments on three real datasets which demonstrate the superior performance of the proposed model with other state-of-the-art methods.

2 RELATED WORK

Different from general recommendation, sequential recommendation views the interactions as a sequence in time order and aims to predict the successive item(s) that a user is likely to interact with in the near future. Early sequential recommendation methods are based on Markov chains, which use sequential connections between users' actions to make prediction. A typical model FPMC [13] factorizes a transition matrix into item latent factors by integrating matrix factorization and Markov chains. HRM [18] further extends the idea by leveraging representations learning as latent factors. However, the above methods focus on modeling local sequential patterns between two adjacent actions while neglecting the global information of the whole sequences.

Recently, researchers have a surge of interest in applying deep learning to recommendation systems. Restricted Boltzmann Machine (RBM) [14] is one of the first neural networks applied to solve recommendation problems. Auto-encoders have also been a popular choice as the deep learning architecture of recommender systems [15, 24]. In addition, with the recent success of CNN on capturing local feature representation of images and texts [6, 7], it has shown a notable performance for top-n sequential recommendation. Caser [17] proposed to embed a sequence of recent items into "image" in the latent spaces and learn local features of the image as a sequential pattern using convolutional filters. However, CNN is capable of extracting local information while may fail to capture long-term dependencies.

On the other hand, as one of the most popular neural networks, Recurrent Neural Network (RNN) has been widely applied to model sequential data. Hidasi et al. applied RNN to model session data with a gated recurrent unit, which utilized session-parallel mini-batches and employed ranking loss functions for learning the model [4]. Tan et al. further proposed a data augmentation technique to improve the performance of RNN for session-based recommendation [16]. However, RNN holds a monotonicity assumption that the current item or hidden state is more important than the previous one, which impairs modeling of user's short-term interest. To deal with this problem, attentional mechanisms have been recently explored due to the ability of modeling user's attention. For example, NARM [8] was proposed as a hybrid encoder with an attention mechanism to emphasize user's main purpose in the current session. SHAN [22] was designed as a two-layer hierarchical attention network to take user-item and item-item interactions into account.

With the rapid development of deep neural networks, researchers further proposed to integrate CNN and RNN for various application scenarios. Lai et al. applied CNN to learn representation of texts and a bi-directional recurrent structure to capture contextual information for text classification [7]. Haque et al. designed a convolutional neural network as encoder and a multilayer LSTM network as decoder for image denoising [2]. However, none of these studies are designed for sequential recommendation and we propose to integrate RNN and CNN in an innovative way. The proposed RCNN utilizes the recurrent architecture of RNN to capture complex long-term dependencies, while employs the convolutional operation of CNN to extract short-term sequential patterns and item-specific features from the hidden states generated by RNN. With this integration method, RCNN is able to address sequential recommendation problems.

3 PROBLEM STATEMENT

In this section, we first introduce basic notations that will be used in this paper. Let $\mathcal{U} = \{u_1, u_2, ..., u_{|\mathcal{U}|}\}$ and $\mathcal{I} = \{i_1, i_2, ..., i_{|\mathcal{I}|}\}$ represent the sets of users and items respectively. Our task focuses on recommendation scenarios with implicit feedback [12, 13], which concerns whether a user $u \in \mathcal{U}$ is interacted with an item $i \in \mathcal{I}$ at time t. Each user is associated with a sequence of items from $\mathcal{I}$. By sorting interaction records in a chronological order, we can form the interaction sequence $\mathcal{I}^u = \{i_1^u, ..., i_t^u, ..., i_{|\mathcal{I}^u|}^u\}$ for user u, where $i_t^u \in \mathcal{I}$. The index t for i_t^u denotes the relative time index, instead of absolute time index in temporal recommendation like [13, 19].

With the above notations, we define the sequential recommendation task as follows. Given a user u's history sequence $\mathcal{I}^u$, we aim to infer the item(s) that user u would probably interact with in the future. Note that it is straightforward to convert the above task into *next-item* recommendation at time $t + 1$ or $next\text{-}future$ recommendation in the near future by replacing the next item with

the next item collection. For the sake of simplicity, we keep the *next-future* recommendation as the major task throughout the paper.

4 THE PROPOSED APPROACH

In this section, we introduce the proposed Recurrent Convolutional Neural Network model (RCNN), which incorporates a recurrent neural network to learn users' long-term interests and a convolutional neural network to learn users' sequential patterns and item-specific features among hidden states. As shown in Figure 1, RCNN consists of three components: a Recurrent Layer, Convolutional Layers, and a Fully-connected Layer. In the following subsections, we will introduce each part of our model and corresponding network learning strategy in detail.

4.1 Recurrent Layer

The first layer of RCNN is a long-short term memory network. LSTM [5], a variant of RNN, is able to alleviate the problem of "vanishing gradients" suffered from RNN by introducing a gate mechanism to hold long-term dependencies. Therefore, we use LSTM model in our approach for the concise and general purpose. Given the input $\mathbf{x}_t$ at the time t, the output $\mathbf{h}_t$ of the LSTM hidden layer is computed as follows.

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_i[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_i),\\
\mathbf{f}_t &= \sigma(\mathbf{W}_f[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_f),\\
\tilde{\mathbf{c}}_t &= tanh(\mathbf{W}_c[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_c),\\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t,\\
\mathbf{o}_t &= \sigma(\mathbf{W}_o[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_o),\\
\mathbf{h}_t &= \mathbf{o}_t \odot tanh(\mathbf{c}_t).
\end{aligned} \tag{1}$$

where $\mathbf{h}_0 = 0$, $\sigma(\cdot)$ is a logistic sigmoid function to do non-linear projection, and $\odot$ is the Hadamard product between two vectors. $\mathbf{i}_t, \mathbf{f}_t, \mathbf{o}_t$ and $\mathbf{c}_t$ are an input gate, a forget gate, an output gate and a cell state of the t-th object, respectively. $\mathbf{h}_t$ represents the hidden state vector to remember and store nodes of past states.

4.2 Convolutional Layers

The outputs of the recurrent layer are then fed simultaneously into a horizontal convolution layer and a vertical convolution layer. We present the previous k hidden states of user u at time t as a $k \times d$ matrix $\mathbf{E}^{(u,t)}$, where d is the hidden size and the rows of the matrix preserve the order of items. And then we regard the matrix $\mathbf{E}^{(u,t)}$ as an "image" to make the horizontal and the vertical convolution operations respectively. More details are explained below.

Horizontal Convolution on Hidden State. The convolution involves a filter vector sliding over a sequence, and picks up signals for sequential patterns at different time steps. The matrix $\mathbf{F} \in \mathbb{R}^{1\times w}$ is a filter for the horizontal convolution, where the height of a horizontal filter is 1 and the width equals to w. For each time step t in the sequence $\mathcal{I}^u$, we have a window matrix $\mathbf{E}^{(u,t)} \in \mathbb{R}^{1\times d}$ with a single hidden state (*i.e.*, $\mathbf{E}^{(u,t)} = h_t$). The result of the interaction for window matrix $\mathbf{E}^{(u,t)}$ is produced as follows:

$$v_t = \sum_{j=0}^{d-w+1} f(\mathbf{E}^{(u,t)}_{j:j+w-1} \cdot \mathbf{F} + b) \tag{2}$$

where $\cdot$ is the inner product, j is the position of $\mathbf{E}^{(u,t)}$'s row vector, $b \in \mathbb{R}$ is a bias term and f is the ReLU activation function. Moreover, we use n horizontal filters with the same size to generate multiple convolution value. The final horizontal convolution result $\mathbf{o}_t \in \mathbb{R}^n$ is

$$\mathbf{o}_t = [v_t^1\ v_t^2\ ...\ v_t^n] \tag{3}$$

where v_t^l is the convolution value generated with the l-th filter and $\mathbf{o}_t$ is a new feature representation generated from n filters for the window vector at time step t and is considered as the current item's feature interaction.

Vertical Convolution on Hidden State. We use tilde(~) for the symbols of the vertical convolution. We denote the vertical filter $\tilde{\mathbf{F}} \in \mathbb{R}^{\tilde{k}\times 1}$ for the operation of vertical convolution. For each time step t in the sequence $\mathcal{I}^u$, we have a window matrix $\tilde{\mathbf{E}}^{(u,t)} \in \mathbb{R}^{\tilde{k}\times d}$ with $\tilde{k}$ consecutive items, denoted as:

$$\tilde{\mathbf{E}}^{(u,t)} = [\mathbf{h}_{t-\tilde{k}+1}, ..., \mathbf{h}_{t-1}, \mathbf{h}_t] \tag{4}$$

where each commas represents a row vector concatenation and the full width of $\tilde{\mathbf{E}}$ equals to d. $\tilde{\mathbf{F}}$ interacts with each column of $\tilde{\mathbf{E}}^{(u,t)}$ by sliding d times from left to right for user u at time step t in a valid way, and finally yielding the vertical convolution result $\tilde{\mathbf{v}}_t \in \mathbb{R}^d$.

$$\tilde{\mathbf{v}}_t = [\tilde{v}_1\ \tilde{v}_2\ ...\ \tilde{v}_d] \tag{5}$$

$$\tilde{\mathbf{o}}_t = \tilde{\mathbf{v}}_t \odot \mathbf{h}_t. \tag{6}$$

where $\tilde{\mathbf{v}}_t$ is equal to the weights of recent items' hidden features and $\tilde{\mathbf{o}}_t$ is the final output of the vertical convolution, which denotes user u's local sequential pattern at time t. With one vertical filter we can learn to enhance the impact of the k previous items' hidden states on current interest for user u, which highlights user's short-term interest within recent $\tilde{k}$ time steps.

4.3 Fully-connected Layer

To capture the current overall preference of user u, we concatenate the outputs of the two convolutional layers and the hidden vector of LSTM together, and project them to a fully-connected layer with $\mathcal{I}$ nodes, written as

$$\mathbf{y}^{(u,t)} = \sigma(\mathbf{W}' \begin{bmatrix} \mathbf{o}_t \\ \mathbf{h}_t \\ \tilde{\mathbf{o}}_t \end{bmatrix} + \mathbf{b}') \tag{7}$$

where $\mathbf{W}' \in \mathbb{R}^{|\mathcal{I}|\times(2d+n)}$ and $\mathbf{b}' \in \mathbb{R}^{|\mathcal{I}|}$ are the weight matrix and the bias term for the output layer, respectively. $\mathbf{h}_t$ intends to capture user's long-term preferences, whereas $\mathbf{o}_t$ learns item-specific features and $\tilde{\mathbf{o}}_t$ captures short-term sequential patterns. The value $y_i^{(u,t)}$ is associated with the probability of how likely user u will interact with item i at time step t.

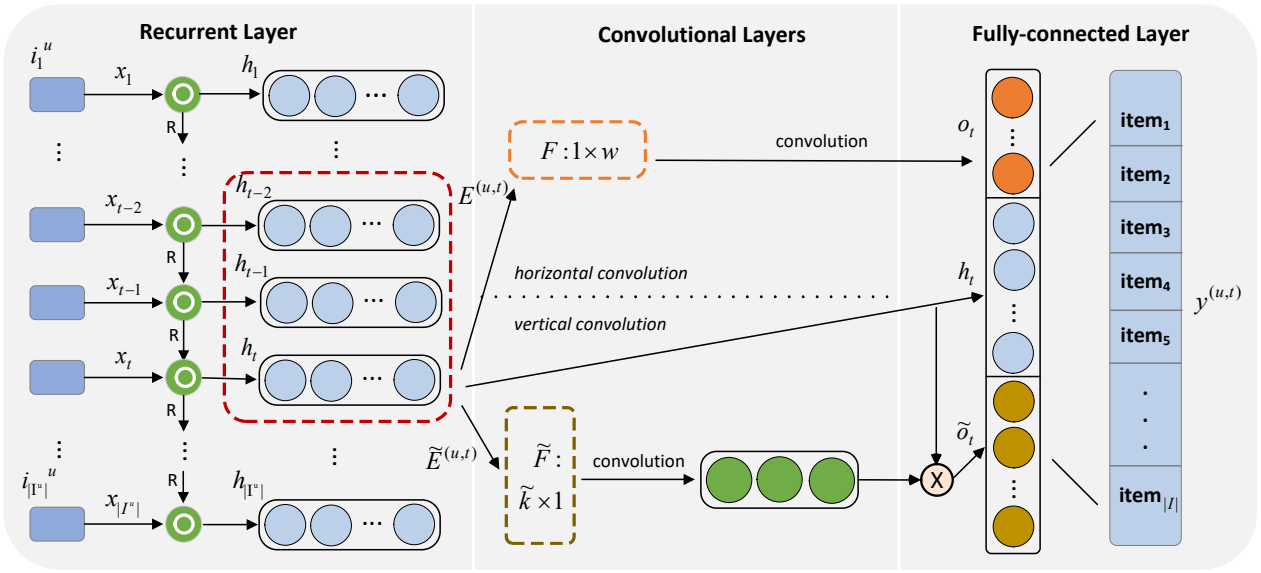

Figure 1: The overall architecture of RCNN. The red dash rectangular box represents the window matrix, while the orange and brown dash rectangular boxes are horizontal and vertical convolutional filters.

4.4 Network Learning

At last, we adapt cross-entropy as our loss function for model optimization. The objective function to be minimized in the model optimization is define as follows:

$$\mathcal{L} = -\sum_{u}^{|\mathcal{U}|}\sum_{t}^{|\mathcal{I}^u|} \hat{\mathbf{y}}^{(u,t)} log(\mathbf{y}^{(u,t)}) + (1-\hat{\mathbf{y}}^{(u,t)}) log(1-\mathbf{y}^{(u,t)}) + \lambda||\Theta||^2 \tag{8}$$

where $\mathbf{y}^{(u,t)}$ is the probability of all items interacted by user u at time $t+1$, and $\hat{\mathbf{y}}^{(u,t)}$ denotes a one-hot vector. If item i is interacted at time $t+1$, $\hat{\mathbf{y}}_i^{(u,t)} = 1$. Otherwise, $\hat{\mathbf{y}}_i^{(u,t)} = 0$. Θ represent all of the model parameters that are be learned and λ is the regularization weight .

5 EXPERIMENTS

In this section, we first introduce the experiment settings. And then we conduct experiments to answer the following research questions:

Q1: What is the performance of our model RCNN, comparing to other state-of-the-art methods?

Q2: How much do the horizontal and vertical convolutional operations help RCNN?

Q3: How do the parameters, such as the size of convolutional filters, affect the performance of RCNN?

5.1 Experimental Setup

5.1.1 Datasets. We study the effectiveness of our proposed approach on three public datasets with different kinds of items. Gowalla[1] and Foursquare[2] are two widely used check-ins datasets, which contains user-POI check-ins information in the location-based social networking sites (LBSN). Taobao is a user-purchase dataset obtained from IJCAI 2017 competition [3]. We eliminated users interacting with fewer than 15 items and items interacted by fewer than 10 users in the three datasets. After preprocessing, the basic statistics of all datasets are listed in Table 1.

Table 1: Statistics of the three datasets.

Dataset	#users	#items	#feedbacks	avg. seq. len	sparsity(%)
Gowalla	5,073	7,020	252,944	49.86	99.29
Foursquare	2,031	3,113	106,229	52.30	98.32
Taobao	2,481	1,419	72,553	29.24	97.94

5.1.2 Evaluation Metrics. For the two recommendation tasks, i.e., next-item and next-future recommendation, we divided the datasets into training/validation/test set with a 98/1/1 split and 70/10/20 split, respectively. In addition, we remove duplicate items from the test set.

To evaluate the performance of each approach, we adopt a variety of metrics widely used in previous works [4, 13], including *Hit Ratio*(HR@N), *Mean Average Precision* (MAP), *Precision*@N, and *Recall*@N. In our experiments, we choose $N = \{1, 5, 10\}$. To make results more stable, we repeated each experiment five times and used the average value of each metrics.

5.1.3 Baselines. We consider the following baselines for performance comparisons:

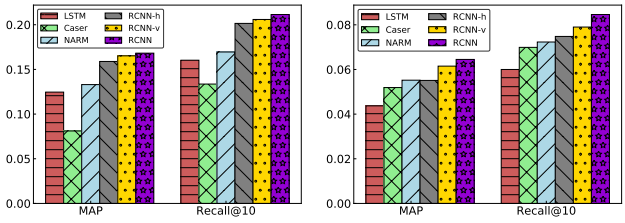
[1] http://snap.stanford.edu/data/loc-gowalla.html

[2] https://sites.google.com/site/yangdingqi

[3] https://tianchi.shuju.aliyun.com/datalab/dataSet

- **BPR-MF** [12] is a state-of-the-art method for non-sequential recommendation, which optimizes Matrix Factorization model using a pairwise ranking loss.
- **FPMC**[4][13] is a classic hybrid model combing MC and MF for next-basket recommendation. FPMC allows a basket of several items at each step. For our sequential recommendation, each basket has a single item.
- **Caser**[5] [17] is the first method of leveraging convolutional filters to learn users' sequential patterns for sequential recommendation. It incorporates the convolutional neural network with a latent factor model.
- **RUM**[6] [20] utilizes external memories to improve sequential recommendation, which contains two variants, item-level (RUM^I) and feature-level (RUM^F).
- **GRU** [1] is an extension of RNN [23], which is equipped with two gates to control the information flow for sequential recommendation.
- **LSTM** [5] is another variant of RNN, which contains a memory cell and three multiplicative gates to hold long-term dependencies.
- **NARM**[7] [8] is an RNN-based state-of-the-art model, which employs an item-level attention mechanism to capture user's main purpose from hidden states and combines it with the sequential behavior as user's final representation to generate recommendation.

5.2 Comparison of Performance



The results of different methods for both recommender tasks are illustrated in Table 2. It can be observed that:

First, among all baseline models, BPR-MF has the most unfavorable performance in nearly all the cases, since BPR-MF is an non-sequential recommendation method. The classic model FPMC performs better than BPR-MF on most cases by taking the sequential correlation between adjacent actions into account. The experimental results verify that sequential information can help improve the recommendation performance in real-world systems.

Second, both RNNs-based methods (*i.e.*, GRU, LSTM and NARM) and memory-based models (*i.e.*, Caser and RUM) improve the effectiveness by using deep neural networks. This shows the ability of neural networks on modeling users' general tastes and their sequential behaviors. On Foursquare and Gowalla datasets, both Caser and RUM achieve better performances than LSTM and GRU. But they get much worse performances on Taobao dataset. In fact, Taobao dataset have more sequential signals than Foursquare and Gowalla datasets. Therefore, both LSTM and GRU can achieve favorable performances, because of their advantages in modeling long-term dependencies. It calls us to combine a deep model with recurrent structure for improvements.

Third, in terms of memory-based methods, RUM performs better than Caser under the metric of Prec@N on Taobao dataset, yet performs worse under the metrics of Recall@N and MAP on most datasets. Overall, RUM and Caser perform well, which indicates that both KV-MN architecture and convolutional operations can capture users' preferences. Furthermore, the state-of-the-art attention-based RNN model NARM beats all the other baselines on all datasets owing to the effectiveness of the attentive mechanism. This shows the effectiveness of the attentive mechanism to capture user's evolving appetite for items.

Finally, we compare our proposed model RCNN with all the baselines. It is clear to see that RCNN consistently and significantly outperforms these baselines on all datasets. This shows that leveraging the power of convolutional neural network, RCNN can model users' sequential pattern better and capture many important features, resulting in a better recommendation. Moreover, we also observe that the performances of most models degrade as the datasets become sparser.

(a) Taobao (b) Gowalla

Figure 2: Performance with variants of RCNN in terms of Rec@10 and MAP on two datasets.

5.3 Influence of Components

To evaluate the contribution of convolutional filters to form user's final hybrid representation, we conduct experiments to analyze each component of convolution. Figure 2 shows MAP and Recall@10 on Taobao and Gowalla. (We obtained the similar results on another dataset.) RCNN-h and RCNN-v denote a downgrade version of RCNN that only uses horizontal and vertical convolution, respectively. From Figure 2, we can observe that Caser outperforms LSTM on Gowalla, while LSTM performs better than Caser on Taobao. This suggests that Caser's performance is greatly affected by the sequential signals of the data. NARM performs better than Caser and LSTM on both datasets due to the attention mechanism. However, NARM performs worse than RCNN-v, which indicates that attention mechanism of vertical convolution plays a better impact than NARM due to use of the filter and nonlinear function. RCNN-h performs better than NARM on most cases, suggesting the feature interactions of items are also important for sequential recommendation. Overall, our final model RCNN performs the best on the two datasets.

5.4 Influence of Hyper-parameters

In this subsection, we investigate the impact of the parameters w and $\tilde{k}$ in our model. Due to space limit, we only show MAP on Foursquare and Taobao datasets. We apply grid search over combinations of $w \in [8, 16, 32, 64, 128]$ and $\tilde{k} \in [2, 3, 4, 5, 6]$ for a better recommendation performance. The experiment results are shown

[4]https://github.com/khesui/FPMC
[5]https://github.com/graytowne/caser_pytorch
[6]https://github.com/ch-xu/RUM
[7]https://github.com/lijingsdu/sessionRec_NARM

Table 2: Performance comparison with baselines on all three datasets for next-item and next-future recommendation. The best performance is highlighted in boldface (higher is better).

Datasets	Methods	Next-item Recommendation				Next-future Recommendation						
		HR@1	HR@5	HR@10	MAP	Prec@1	Prec@5	Prec@10	Recall@1	Recall@5	Recall@10	MAP

Table 3: The performance of RCNN with varying w and $\tilde{k}$ in terms of MAP on Foursquare and Taobao.

Dataset	MAP: w \ $\tilde{k}$	$\tilde{k}=2$	$\tilde{k}=3$	$\tilde{k}=4$	$\tilde{k}=5$	$\tilde{k}=6$
Foursquare	w =8	0.0577	0.0566	0.0587	0.0566	0.0564
	w =16	0.0567	0.0589	0.0577	0.0580	0.0570
	w =32	0.0584	0.0577	0.0594	0.0575	0.0569
	w =64	0.0598	0.0590	**0.0602**	0.0579	0.0574
	w =128	0.0596	0.0580	0.0578	0.0574	0.0574
Taobao	w =8	0.1671	0.1673	0.1668	0.1665	0.1671
	w =16	0.1672	0.1675	0.1687	0.1692	0.1672
	w =32	0.1675	0.1674	0.1696	0.1685	0.1686
	w =64	0.1671	0.1693	0.1693	0.1684	0.1682
	w =128	**0.1698**	0.1695	0.1678	0.1672	0.1695

in Table 3. We can see that either fixing w or fixing $\tilde{k}$, the performance of our model is improved first and then deteriorated on most cases. This suggests that a proper size of filters can capture users' short-term interest and high-order feature interactions better. Consequently, the best sizes are chosen as $w = 64, \tilde{k} = 4$ on Foursquare and $w = 128, \tilde{k} = 2$ on Taobao. $\tilde{k}$ on Foursquare is larger than the value on Taobao. It may be because the average sequence length on Foursquare is longer.

6 CONCLUSIONS

In this paper, we proposed a novel **R**ecurrent **C**onvolutional **N**eural **N**etwork model (RCNN), which leverages the strengths of both RNN and CNN for sequential recommendation. RCNN utilizes the recurrent architecture of RNN to capture complex long-term dependencies, while uses the convolutional operation of CNN to extract short-term sequential patterns. Our experimental results on three real-world datasets show that RCNN significantly outperformed the state-of-the-art approaches on sequential recommendation.

ABSTRACT

With the flourishing of location based social networks, posting check-ins has become a common practice to document one's daily life. Users usually do not consider check-in records as violations of their privacy. However, through analyzing two real-world check-in datasets, our study shows that check-in records are vulnerable to linkage attacks. To address this problem, we design a *partition-and-group* framework to integrate the information of check-ins and additional mobility data to attain a novel privacy criterion — $k^{\tau,l}$*-anonymity*. It ensures adversaries with arbitrary background knowledge cannot use check-ins to re-identify users in other anonymous datasets or learning unreported mobility records. The proposed framework achieves favorable performance against state-of-art baseline in terms of improving check-in utility by 24%∼57% while providing stronger privacy guarantee at the same time. We believe this study will open a new angle in attaining both privacy-preserving and useful check-in services.

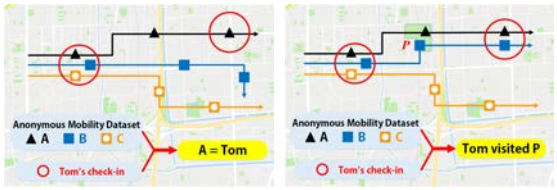
1 INTRODUCTION

Check-in service has now become a popular feature that is widely adopted by the mainstream social media platforms, such as Facebook, Twitter and Wechat. It facilitates users to document their daily activities with mobility trace and share them with public audience. Users usually do not associate the self-reported check-ins with privacy risks, since they only check-in to places they feel comfortable [4]. However, the uniqueness of human mobility often exposes their check-in records to linkage attacks, *i.e.*, revealing their identities and unreported mobility records in other anonymous mobility datasets, such as call detail records [5], transportation records [8], and credit card records [12]. Moreover, recent researches show



that most users are unaware or not able to fully anticipate the privacy risks embedded in posting check-ins [23]. Therefore, it is a paramount task for the check-in service providers to quantify the potential privacy exposures and put forward feasible solutions.

Previous efforts attempted to address the problem of linkage attacks on mobility data by ensuring user's anonymity in anonymous mobility datasets [12, 15]. That is, making sure adversary cannot achieve unique linkages based on user's check-ins through generalizing the records in anonymous mobility datasets. However, such approach often requires unacceptable data utility degeneration [35], and cannot prevent adversary from learning additional unreported mobility records [18]. It is also unrealistic for users and check-in service providers to assume all anonymous mobility datasets have been properly sanitized, since studies repeatedly demonstrated that insecure datasets had been irreversibly spread across the Internet [13, 22]. Therefore, these findings suggest it is impractical to prevent linkage attacks by sanitizing anonymous mobility datasets. In this paper, we investigate and address this problem through a novel angel — looking at the public mobility records, *i.e.*, check-ins.

In this paper, we put forward several contributions to attain both privacy-preserving and useful check-in services. First, we extend the frameworks of *k-anonymity* [26] and *l-diversity* [18] into check-in privacy preserving, and devise a novel privacy criterion $k^{\tau,l}$-anonymity. It ensures the posted check-ins cannot be exploited to distinguish user from at least other $k-1$ users in any anonymous mobility datasets, and for any time window of duration τ user's actual locations are indistinguishable from at least other $l-1$ locations. Second, we further propose a *partition-and-group* framework to optimize the check-in utility under $k^{\tau,l}$-anonymity privacy guarantee by carefully partitioning user population into small anonymity groups. Third, we conduct a thorough trace-driven evaluation on the proposed framework based on two real-world datasets. The evaluation results demonstrate that our framework significantly outperforms state-of-art baseline method in terms of achieving 24%∼57% check-in utility improvement while providing stronger privacy guarantee in the same time. In addition, 32%∼62% check-in utility boost of our framework is achieved by introducing additional mobility data, which showcases the benefits of integrating additional mobility data in privacy-preserving check-in service. Finally, our study reveals two intriguing trade-offs between the utility and privacy in check-in services: (*i*) in order to achieve modest privacy gains, users need to sacrifice significant check-in utility, *i.e.*, reducing spatio-temporal resolution of check-ins. (*ii*) users may increase the utility of their check-ins with same privacy level by letting check-in service providers to collect moderate amount of additional mobility data. Such findings may have direct implications on how to defend linkage attacks with the joint effort of check-in service providers and individual users.

2 RELATED WORKS

Linkage Attack: The linkage attacks were widely studied in multiple scenarios and had received increasing attention in recent years [17, 18, 26, 27]. The most prominent two branches are *re-identification attack* and *probabilistic attack* [7]. Specifically, the *re-identification attack* aims at recovering individuals' identities

(a) *Re-identification attack* (b) *Probabilistic attack*

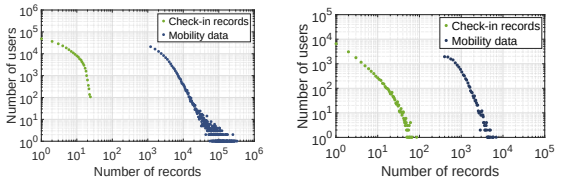


Figure 1: Illustration of linkage attacks on check-ins.

in anonymous datasets by achieving unique linkages with public datasets. For example, 87% of American population can be uniquely re-identified with the public accessible information of ZIP code, gender and date of birth [26]. Similar findings have been established in wide range of scenarios, including web browsing records [25], call detail records [35], app usage records [27, 32] and so on. One popular privacy model against such attack is *k*-anonymity, which requires to make the records of each individual indistinguishable from at least $k-1$ others [26]. On the other hand, *probabilistic attack* is a more generic linkage attack, which aims at improving some belief on individuals through correlating the datasets. Researchers demonstrated that by combining online social network data and sparse offline location data individual's locations can be predicted with high precision [19]. In addition, the salary class of individuals can be accurately inferred by correlating census data with public available information [18]. To defend such attacks, *l*-diversity and *t*-closeness have been proposed to ensure the diversity on the sensitive information within each anonymity group [17, 18, 29, 30].

We position our study in a novel scenario of defending against the linkage attacks on social media check-ins. We aim to provide strong privacy guarantee for check-in service against both *re-identification attack* and *probabilistic attack*, and design privacy solution compatible with unstructured spatio-temporal data.

Mobility Data Privacy: The literature in this area can be further broken down into two categories: aggregated mobility data privacy and individual mobility data privacy. As for the former, recent study found evidence that aggregated mobility data suffered from the risks of leaking individual trajectories [28, 33]. In addition, *differential privacy* has been applied on aggregated mobility data to provide provable privacy guarantees for individuals [1, 14]. As for individual mobility privacy, *geo-indistinguishability* model is devised to achieve practical privacy guarantee in individual mobility collecting [2, 6]. In addition, vast amount of literature were dedicated to ensure location anonymity in the context of geo-referenced queries in location based service [3, 10, 34]. On the other hand, *cloaking*, *generalization* and *suppression* techniques are leveraged to achieve *k*-anonymity in releasing anonymous individual trajectories [15, 16, 20, 21, 24]. However, recent studies showed that such approaches will be likely to result in significant data utility degeneration [11, 35].

We tackle the specific problem of designing privacy-preserving check-in service, which is closely related to prior effort in individual trajectories releasing. However, it differs from previous works that users have strong requirement for check-in utility and social desirability, which poses significant challenges on privacy solutions.

(a) WeChat dataset (b) Weibo dataset

Figure 2: The distribution of the number of user's check-ins and mobility records.

3 PROBLEM FORMULATION

We first introduce the privacy framework of k-anonymity and l-diversity, which is the basis of our model. Then, we elaborate on our novel privacy criterion — $k^{\tau,l}$-anonymity.

k-anonymity: The k-anonymity framework is originally devised to defend the re-identification attacks in relational database [26]. In check-in privacy scenario, the adversary attempts to recover user's identity in other anonymous mobility datasets by achieving a unique linkage between user's anonymous mobility data and public check-ins, which is illustrated in Figure 1(a). Therefore, it requires data sanitizing techniques that render each individual's attributes indistinguishable from at least other $k-1$ individuals', which forms an anonymity group that prevents any individuals from being uniquely re-identified.

l-diversity: It is put forward to ensure users' diversity on sensitive attributes within each anonymity group [18]. Specifically, it is designed to prevent *probabilistic attack*, where the adversary aims to learn additional mobility records the users do not report, which is illustrated in Figure 1(b). It requires each individual cannot be uniquely re-identified with the non-sensitive attributes (i.e., check-ins), while the sensitive attributes (i.e., unreported mobility records) should be of at least l different categories within each anonymity group.

$k^{\tau,l}$-anonymity: Inspired by the insights and limitations of previous models, we design a novel privacy criterion *$k^{\tau,l}$-anonymity* to address the privacy issues in check-in services. Specifically, *$k^{\tau,l}$-anonymity* requires:(i) any users on social media cannot be distinguished from at least other $k-1$ users in any other anonoymous mobility datasets based on their public check-ins; (ii) for any time window of duration τ users' unreported locations cannot be discriminated from at least $l-1$ other potential locations. Therefore, the knowledge adversary can acquire through linkage attacks, *i.e.*, users identity in other anonymous mobility datasets and unreported mobility records, is effectively bounded by user specific parameters k, τ, l. In other words, *$k^{\tau,l}$-anonymity* is able to provide strong privacy guarantee against both *re-identification attack* and *probabilistic attack*.

4 DATASETS

4.1 Data Collection

We utilize two real-world datasets collected from large scale user population in two mainstream social media platforms: WeChat and Weibo. The detailed information is discussed as follows.

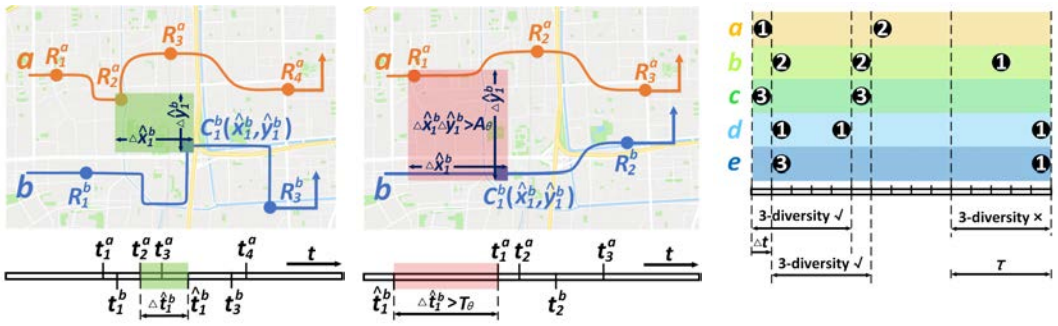
WeChat Dataset[1]: WeChat platform is currently the most popular social media platform in China. This dataset consists of 530,050 check-ins collected from 100,000 users, which are randomly selected from the general user population spread across Beijing city. It covers two and a half month of usage, *i.e.*, from Jan. 1 to Mar. 15, 2018. We also collect an additional mobility dataset including over 193 millions mobility records from same user population during same time period. The mobility records are collected when users invoke location based services in WeChat, such as posting check-ins and using map services.

Weibo Dataset[2]: This dataset is collected by a previous research [31]. It contains 11,866,425 mobility records and 78,412 check-ins on Weibo platform from 17,425 users located in Shanghai during one week, *i.e.*, from Apr.19 to Apr.26, 2016. Different from WeChat dataset, the Weibo dataset is collected by internet service provider by performing deep packet inspection on cellular traffic.

To demonstrate the basic statistics of datasets, we show the probability distribution function (PDF) of number of mobility records and check-in records of each user in Figure 2. From the results, we can observe that they all follow a fat-tailed distribution, which echos with the findings in previous researches [9]. It indicates that our datasets are representative of typical check-in behaviors.

5 SOLUTION

5.1 Definitions



Formally, we define the additional mobility data of user i as $R^i = \left\{r_m^i\right\}$, where r_m^i is the m-th record of user i. It can be expressed as a tuple $r_m^i = (x_m^i,\ y_m^i,\ t_m^i)$, with x_m^i, $y_m^i$and t_m^i denoting the longitude, latitude and time stamp, respectively. On the other hand, we denote the *check-in records* as $C^i = \left\{c_m^i\right\}$, where c_m^i is the m-th check-ins of user i. Since the check-in records after sanitization may have various spatial and temporal resolution, c_m^i is defined as $(\hat{x}_m^i,\ \Delta\hat{x}_m^i,\ \hat{y}_m^i,\ \Delta\hat{y}_m^i,\ \hat{t}_m^i,\ \Delta\hat{t}_m^i)$, with $[\hat{x}_m^i,\ \hat{x}_m^i+\Delta\hat{x}_m^i] \times [\hat{y}_m^i,\ \hat{y}_m^i+\Delta\hat{y}_m^i]$ and $[\hat{t}_m^i,\ \hat{t}_m^i + \Delta\hat{t}_m^i]$ denoting the coverage in spatial and temporal dimensions, respectively.

5.2 Basic Operations

We limit our data sanitizing techniques to *generalization* and *suppression*, i.e., addressing the privacy problem by reducing check-in's spatiotemporal resolution or leaving out check-ins. Such operations avoid adding noises to check-in records that may displace users to places they never been to or injecting fabricated check-ins, which maintains the integrity of check-ins and avoid compromising their social figures. On the other hand, to effectively defend against *probabilistic attack*, we also define a *diversity check* operation to ensure the diversity on sensitive information within anonymity groups. In addition, we also define a cost function to measure the check-in utility loss in attaining privacy criterion. The basic operations are described as follows:

Generalization: It is to reduce spatial and temporal resolution of check-ins so that they overlap with other user's check-ins or unreported mobility records. In this way, the adversary can no longer uniquely link the check-ins with anonymous mobility data, which

[1]https://weixin.qq.com/
[2]https://weibo.com/

(a) *Generalization* (b) *Suppression* (c) *Diversity check*

Figure 3: The illustrations of three basic data sanitizing operations.

effectively prevents the *re-identification attacks*. We define the *generalization* operation as $G(c^\star, r^\star)$, where $c^\star$ and $r^\star$ are check-in and other user's mobility record, respectively. This operation will output *generalized* check-ins, which is demonstrated in Figure 3(a).

Suppression: When the spatial and temporal resolution of check-in records is too low, their utility is diminished. In real-world scenario, some "outlier" check-ins may require significant *generalization* to prevent *re-identification attacks*, which renders the check-ins useless. Specifically, *suppression* operation $S(c^\star)$ will return *true* for leaving out the check-ins $c^\star$ when spatial coverage exceed A_θ or temporal coverage exceed T_θ. That is, the system will recommend users not to post such check-ins. The *suppression* operation is demonstrated in Figure 3(b). Without loss of generality, A_θ and T_θ are set to $1000km^2$ and 120 hours, respectively.

Diversity check: We define *diversity check* operation as $D(\{R^\star\}, \tau, l)$, with $\{R^\star\}$ denoting the unreported mobility records of the inspected anonymity group. The illustration of *diversity check* is presented in Figure 3(c). Specifically, the operation search the total time duration with a sliding time window of duration τ and step length of minimal time resolution Δt. Then, it computes the number of distinct locations in each time window with each individual contribute at most one distinct location. If there is a time window with less than l distinct locations then the operation returns $false$ for failing the diversity check. Otherwise, it returns *true* for passing.

Cost function: It is defined as a linear combination of the spatial and temporal coverage of the investigated check-in, which can be computed as follows,

$$U(c_m^i) = \begin{cases} \lambda_a \cdot \sqrt{A} + \lambda_t \cdot T, & if A < A_\theta \text{ and } T < T_\theta, \\ \lambda_a \cdot \sqrt{A_\theta} + \lambda_t \cdot T_\theta, & otherwise, \end{cases}$$

where $A = |\Delta\hat{x}_m^i| \times |\Delta\hat{y}_m^i|$ and $T = |\Delta\hat{t}_m^i|$ denote the spatial and temporal coverage of generalized check-in. In this study, we set both λ_a and λ_t to 0.5, which indicates 1 km diameter of spatial coverage and 1 hour temporal coverage map to similar cost. In addition, since the check-ins are *suppressed* if their spatial coverage exceed A_θ or temporal coverage exceed T_θ, we set cost function at maximum value to represent complete lost in utility.

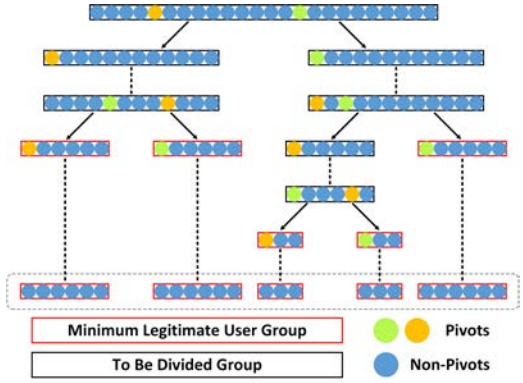


Figure 4: Illustration of *partition-and-group* framework.

5.3 Partition-and-Group Framework

One key problem in optimizing the privacy mechanism on large scale check-ins is how to partition the user population into optimal anonymity groups. The check-in utility will be significantly improved by carefully classifying the users into numerous small anonymity group that passes *diversity check* compared with putting all of them in one group. We use the word "legitimate" to refer to the anonymity groups that pass the *diversity check*. Achieving the optimal partition of user population requires to enumerate all the legitimate anonymity group, which is a NP-hard problem and cannot be readily solved in real-world scenario. We design a novel *partition-and-group* framework to efficiently optimize the check-in utility through a "divide-and-conquer" manner. The idea is to iteratively break down the user population into two small subsets until the *minimum legitimate anonymity groups* are met, which is illustrated in Figure 4. An important problem is determining whether a anonymity group is *minimum legitimate anonymity group*, i.e., the anonymity group cannot be divided into smaller subsets that all pass *diversity check*. We exploit a convenient property of *diversity check* to address this problem, which is formally described in the following proposition.

Proposition 5.1. *If an anonymity group does not pass the* diversity check*, then any subsets of this anonymity group will not pass the* diversity check.

Proof. Suppose the unreported mobility records of an anonymity group do not pass the *diversity check* of parameters (τ, l). Based

Algorithm 1: Partition-and-group algorithm.

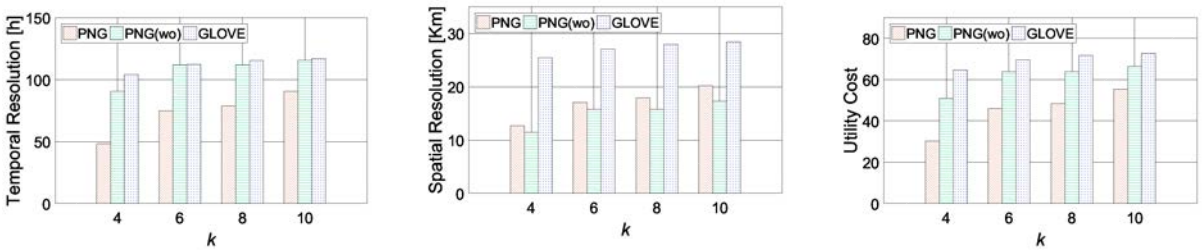
Input: Check-in data $\mathbb{C}$, mobility data $\mathbb{R}$
Input: Anonymity k, diversity l, time window τ
Output: Sanitized check-in data $\hat{\mathbb{C}}$
foreach $i,\ j\ \in\ \mathbb{C},\ j \neq i$ **do**
  $\mathbb{C}^\star \leftarrow k^{\tau,\ l}$-merge$(\mathbb{C}[\{i,j\}], \mathbb{R}[\{i,j\}], 2, 0, 0)$;
  $W[a,b] \leftarrow sum([U(c^\star)|\ \forall\ c^\star \in \mathbb{C}^\star])$;
checkin_stack.insert$(\mathbb{C})$; *mobility_stack.insert*$(\mathbb{R})$;
stop $\leftarrow$ *false*;
while *stop* $\neq$ *false* **do**
  $\mathbb{C}^\star \leftarrow$ *checkin_stack.pop*();
  $\mathbb{R}^\star \leftarrow$ *mobility_stack.pop*();
  if *! divide-2-group*$(\mathbb{C}^\star, \mathbb{R}^\star, W, k, l, \tau)$ **then**
    checkin_group.insert$(\mathbb{C}^\star)$;
    mobility_group.insert$(\mathbb{R}^\star)$;
  else
    $\mathbb{C}_1, \mathbb{C}_2, \mathbb{R}_1, \mathbb{R}_2 \leftarrow$ divide-2-group$(\mathbb{C}^\star, \mathbb{R}^\star, W, k, l, \tau)$;
    checkin_stack.insert$(\{\mathbb{C}_1, \mathbb{C}_2\})$;
    mobility_stack.insert$(\{\mathbb{R}_1, \mathbb{R}_2\})$;
  if *checkin_stack* $== \emptyset$ **then**
    stop $\leftarrow$ *true*;
while *checkin_group* $\neq \emptyset$ **do**
  $\mathbb{C}^\star \leftarrow$ *checkin_stack.pop*();
  $\mathbb{R}^\star \leftarrow$ *mobility_stack.pop*();
  $\mathbb{C}^\star \leftarrow k^{\tau,\ l}$-merge$(\mathbb{C}^\star, \mathbb{R}^\star, k, l, \tau)$;
  $\hat{\mathbb{C}}$*.insert*$(\mathbb{C}^\star)$;
Return $\hat{\mathbb{C}}$;

on the definition of *diversity check*, there exist at least one time window $[t, t+\tau]$ that the number of distinct locations is less than l. Since the number of distinct locations increases with number of users monotonically, any subsets of inspected anonymity group will have less than l distinct locations in $[t, t+\tau]$. Therefore, any subsets of inspected anonymity group will not pass the *diversity check*. □

The above proposition guarantees that an anonymity group is *minimum legitimate anonymity group* if it cannot be further divided into two legitimate subsets, since any subsets of anonymity groups that cannot pass *diversity check* will not pass the *diversity check*. Build upon this proposition, we design the *partition-and-group* algorithm with the pseudocode presented in Algorithm 1. The elementary building block is $k^{\tau,\ l}$*-merge* function, which first performs *diversity check* on the given user group and then enumerates through all the users within the group to find optimal mobility records from each user for the check-in to *generalize* with. The *partition-and-group* algorithm first computes the cost matrix W, with $W[i,j]$ filled with the cost of achieving 2-anonymity on the check-ins of user i and j with $k^{\tau,\ l}$*-merge* algorithm. Then, it iteratively partition each anonymity group into two subsets with *divide-2-group* algorithm, and when an anonymity group cannot be divided further it is considered as a final anonymity group. The *divide-2-group* algorithm equally divides the user group into 2 anonymity groups based on their distance to two pivot users that have maximum overall distance to other users. If both groups fail the *diversity check*, the input anonymity group is deemed unable to be further divided. On the other hand, the failed group keeps borrowing one most distant user from the succeed group, until they both pass or fail the *diversity check*. Finally, we apply $k^{\tau,\ l}$*-merge* function on each final anonymity group to ensure all users are protected by $k^{\tau,\ l}$*-anonymity*.

6 EVALUATION

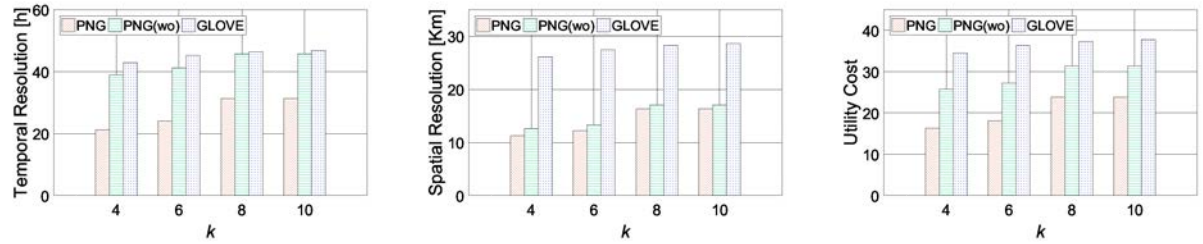
6.1 Performance Comparison



Our solution, denoted by *PNG*, aims to achieve $k^{\tau,\ l}$*-anonymity* to prevent both *re-identification attack* and *probabilistic attack*. In order to show its superiority, we consider two baselines, *i.e.*, *PNG(wo)* and *GLOVE*. *PNG(wo)* is a degraded version of *PNG*, in the condition that only *k-anonymity* is guaranteed to defend *re-identification attack*. On the other hand, *GLOVE* [15] is a state-of-art solution to achieve same privacy guarantee as *PNG(wo)*. To compare the performance of these three solutions, we utilize three metrics of average temporal resolution, average spatial resolution and average utility cost of the sanitized check-ins. Note that *GLOVE* cannot be scalable to large populations due to the high computation complexity. In order to ensure fair comparison, we measure the performance of these three solutions based on two subsets with 5,000 users that are randomly sampled from our two datasets for one-month duration.

We show the performance comparison of these three solutions with different values of k and l(=k/2) in Figure 5 and Figure 6. We can observe that our *PNG* solution outperforms the other two baselines in all privacy settings. With 4-anonymity and 2-diversity on Weibo and WeChat datasets, the average temporal resolutions of sanitized check-ins are 23h and 48h, while the spatial resolutions are 11km and 12km, respectively. Such spatial and temporal resolution is sufficient to accomodate user's need in documenting their daily life. However, the average spatial and temporal resolutions for *PNG(wo)* are much higher, and most of sanitized check-ins from *GLOVE* are too coarse-grained to use with the average temporal resolution reaches as much as 104h. Similar results are observed in average spatial resolution. Furthermore, when it comes to the average utility loss, *PNG* has 24% and 53% improvements in the comparison with *PNG(wo)* and *GLOVE* on WeChat dataset. In addition, *PNG* has 27% and 57% improvements in the comparison with *PNG(wo)* and *GLOVE* on Weibo dataset. In summary, all these results have demonstrated that our proposed *PNG* solution can significantly reduce check-in utility loss even when a stricter privacy criterion $k^{\tau,\ l}$*-anonymity* is met.

6.2 Impact of System Parameters



Now we analyze the impact of three key system parameters, *i.e.*, k, l and the amount of available additional mobility records, on the performance of our *PNG* solution.

First, based on both WeChat and Weibo datasets, we measure the performance of *PNG* with different settings of k and l, and show the results in Figure 7 and Figure 8. Take WeChat dataset for example, with a fixed 2-*diversity*, the average temporal resolution, spatial resolution and utility cost increase monotonously as k grows from 2 to 14. However, further increase of k does not result in a significant check-in utility degeneration, suggesting that achieving a stricter privacy guarantee will only cause limited margin check-in utility

loss. In other words, it indicates our solution can achieve favorable check-in utility when strong privacy protection is needed. As for *probabilistic attack*, a lager l indicates stronger privacy protection. For both WeChat and Weibo datasets, a larger l will also cause additional check-in utility loss. However, the additional utility cost for preventing *probabilistic attack* is much smaller when k is of higher value. It indicates the *PNG* framework provides efficient solution to defend both *re-identification attack* and *probabilistic attack*.

Second, we evaluate the impact of the amount of additional mobility data. Generally speaking, with more complete knowledge about user's mobility behavior, the system is able to better measure the privacy sensitive of each check-in record and derive better privacy solutions. The results of different percentages of additional mobility data are shown in Figure 9. In Figure 9(a), we can observe

(a) WeChat Dataset (b) Weibo Dataset

Figure 9: Impact of the amount of additional mobility data.

that only 20% additional mobility data in WeChat dataset grants the system a 28.6% performance boost in check-in utility. In addition, when more than 60% additional mobility data is provided the performance of system gradually reaches a relative high point, with 30.9% utility improvement compares with no additional mobility data. Similar results are observed on Weibo dataset, which is shown in Figure 9(b). To conclude, the above evaluation verifies our intuition that moderate amount of additional mobility data can lead to significant check-in utility improvement, which showcases the feasibility of our system in real-world scenario.

7 CONCLUSION

In this paper, we investigate the problem of understanding and defending the linkage attacks on check-in services. We design a novel *partition-and-group* framework that integrates the information of check-ins and additional mobility data to provide privacy-preserving and useful check-in service. Evaluation results show that the proposed framework significantly outperforms state-of-art baseline in terms of improving the check-in utility by 24%∼57% and providing stronger privacy guarantee in the same time. We believe our study opens a new angle on measuring and preserving user privacy on check-in services.

ABSTRACT

Classic supervised learning makes the *closed-world assumption* that the classes seen in testing must have appeared in training. However, this assumption is often violated in real-world applications. For example, in a social media site, new topics emerge constantly and in e-commerce, new categories of products appear daily. A model that cannot detect new/unseen topics or products is hard to function well in such open environments. A desirable model working in such environments must be able to (1) reject examples from unseen classes (not appeared in training) and (2) incrementally learn the new/unseen classes to expand the existing model. This is called *open-world learning* (OWL). This paper proposes a new OWL method based on meta-learning. The key novelty is that the model maintains only a dynamic set of seen classes that allows new classes to be added or deleted with no need for model re-training. Each class is represented by a small set of training examples. In testing, the meta-classifier only uses the examples of the maintained seen classes (including the newly added classes) on-the-fly for classification and rejection. Experimental results with e-commerce product classification show that the proposed method is highly effective[1].

1 INTRODUCTION

An AI agent working in the real world must be able to recognize the classes of things that it has seen/learned before and detect new things that it has not seen and learn to accommodate the new things. This learning paradigm is called *open-world learning* (OWL) [2, 7, 9]. This is in contrast with the classic supervised learning paradigm which makes the *closed-world assumption* that the classes seen in testing must have appeared in training. With the ever-changing Web, the popularity of AI agents such as intelligent assistants and self-driving cars that need to face the real-world open environment with unknowns, OWL capability is crucial.

For example, with the growing number of products sold on Amazon from various sellers, it is necessary to have an open-world model that can automatically classify a product based on a set S of product categories. An emerging product not belonging to any existing category in S should be classified as "unseen" rather than one from S. Further, this unseen set may keep growing. When the number of products belonging to a new category is large enough, it should be added to S. An open-world model should easily accommodate this addition with a low cost of training since it is impractical to retrain the model from scratch every time a new class is added. As another example, the very first interface for many intelligent personal assistants (IPA) (such as Amazon Alexa, Google Assistant, and Microsoft Cortana) is to classify user utterances into existing known domain/intent classes (e.g., Alexa's skills) and also reject/detect utterances from unknown domain/intent classes (that are currently not supported). But, with the support to allow the 3rd-party to develop new skills (Apps), such IPAs must recognize new/unseen domain or intent classes and include them in the classification model. These real-life examples present a major challenge to the maintenance of the deployed model.

Most existing solutions to OWL are built on top of closed-world models [2, 3, 9, 30], e.g., by setting thresholds on the logits (before the softmax/sigmoid functions) to reject unseen classes which tend to mix with existing seen classes. One major weakness of these models is that they cannot easily add new/unseen classes to the existing model without re-training or incremental training (e.g., OSDN [3] and DOC [30]). There are incremental learning techniques (e.g., iCaRL [24] and DEN [21]) that can incrementally learn to classify new classes. However, they miss the capability of rejecting examples from unseen classes. This paper proposes to solve OWL with both capabilities in a very different way via meta-learning.

Problem Statement: At any point in time, the learning system is aware of a set of seen classes $S = \{c_1, \ldots, c_m\}$ and has an OWL model/classifier for S but is unaware of a set of unseen classes

$U = \{c_{m+1}, \dots\}$ (any class not in S can be in U) that the model may encounter. The goal of an OWL model is two-fold: (1) classifying examples from classes in S and reject examples from classes in U, and (2) when a new class c_{m+1} (without loss of generality) is removed from U (now $U = \{c_{m+2}, \dots\}$) and added to S (now $S = \{c_1, \dots, c_m, c_{m+1}\}$, still being able to perform (1) without re-training the model.

Two main challenges for solving this problem are: (1) how to enable the model to classify examples of seen classes into their respective classes and also detect/reject examples of unseen classes, and (2) how to incrementally include the new/unseen classes when they have enough data without re-training the model.

As discussed above, existing methods either focus on the challenge (1) or (2), but not both. To tackle both challenges in an unified approach, this paper proposes an entirely new OWL method based on meta-learning [1, 10–12, 32]. The method is called *Learning to Accept Classes* (L2AC). The key novelty of L2AC is that the model maintains a dynamic set S of seen classes that allow new classes to be added or deleted with no model re-training needed. Each class is represented by a small set of training examples. In testing, the meta-classifier only uses the examples of the maintained seen classes (including the newly added classes) on-the-fly for classification and rejection. That is, the learned meta-classifier classifies or rejects a test example by comparing it with its nearest examples from each seen class in S. Based on the comparison results, it determines whether the test example belongs to a seen class or not. If the test example is not classified as any seen class in S, it is rejected as unseen. Unlike existing OWL models, the parameters of the meta-classifier are not trained on the set of seen classes but on a large number of other classes which can share a large number of features with seen and unseen classes, and thus can work with any seen classification and unseen class rejection without re-training.

We can see that the proposed method works like a nearest neighbor classifier (e.g., kNN). However, the key difference is that we train a meta-classifier to perform both classification and rejection based on a learned metric and a learned voting mechanism. Also, kNN cannot do rejection on unseen classes.

The main contributions of this paper are as follows.

(1) It proposes a novel approach (called L2AC) to OWL based on meta-learning, which is very different from existing approaches.

(2) The key advantage of L2AC is that with the meta-classifier, OWL becomes simply maintaining the seen class set S because both seen class example classification and unseen class example rejection/detection are based on comparing the test example with the examples of each class in S. To be able to accept/classify any new class, we only need to put the class and its examples in S.

The proposed approach has been evaluated on product classification and the results show its competitive performance.

2 L2AC FRAMEWORK

As an overview, Fig. 1 depicts how L2AC classifies a test example into an existing seen class or rejects it as from an unseen class. The training process for the meta-classifier is not shown, which is detailed in Sec. 2.2. The L2AC framework has two major components: a ranker and a meta-classifier. The ranker is used to retrieve some examples from a seen class that are similar/near to the test example. The meta-classifier performs classification after it reads the retrieved examples from the seen classes. The two components work together as follows.

Assume we have a set of seen classes S. Given a test example x_t that may come from either a seen class or an unseen class, the ranker finds a list of top-k nearest examples to x_t from each seen class $c \in S$, denoted as $x_{a_{1:k}|c}$. The meta-classifier produces the probability $p(c = 1|x_t, x_{a_{1:k}|x_t,c})$ that the test x_t belongs to the seen class c based on c's top-k examples (most similar to x_t). If none of these probabilities from the seen classes in S exceeds a threshold (e.g., 0.5 for the sigmoid function), L2AC decides that x_t is from an unseen class (rejection); otherwise, it predicts x_t as from the seen class with the highest probability (for classification). We denote $p(c = 1|x_t, x_{a_{1:k}|x_t,c})$ as $p(c|x_t, x_{a_{1:k}})$ for brevity when necessary. Note that although we use a threshold, this is a general threshold that is not for any specific classes as in other OWL approaches but only for the meta-classifier. More practically, this threshold is pre-determined (not empirically tuned via experiments on hyper-parameter search) and the meta-classifier is trained based on this fixed threshold.

As we can see, the proposed framework works like a supervised lazy learning model, such as the k-nearest neighbor (kNN) classifier. Such a lazy learning mechanism allows the dynamic maintenance of a set of seen classes, where an unseen class can be easily added to the seen class set S. However, the key differences are that all the metric space, voting and rejection are learned by the meta-classifier.

Retrieving the top-k nearest examples $x_{a_{1:k}}$ for a given test example x_t needs a ranking model (the ranker). We will detail a sample implementation of the ranker in Sec. 3 and discuss the details of the meta-classifier in the next section.

2.1 Meta-Classifier

Meta-classifier serves as the core component of the L2AC framework. It is essentially a binary classifier on a given seen class. It takes the top-k nearest examples (to the test example x_t) of the seen class as the input and determines whether x_t belongs to that seen class or not. In this section, we first describe how to represent examples of a seen class. Then we describe how the meta-classifier processes these examples together with the test example into an overall probability score (via a voting mechanism) for deciding whether the test example should belong to any seen class (classification) or not (rejection). Along with that we also describe how a joint decision is made for open-world classification over a set of seen classes. Finally, we describe how to train the meta-classifier via another set of meta-training classes and their examples.

2.1.1 Example Representation and Memory. Representation learning lives at the heart of neural networks. Following the success of using pre-trained weights from large-scale image datasets (such as ImageNet [25]) as feature encoders, we assume there is an encoder that captures almost all features for text classification.

Given an example x representing a text document (a sequence of tokens), we obtain its continuous representation (a vector) via an encoder $h = g(x)$, where the encoder $g(\cdot)$ is typically a neural network (e.g., CNN or LSTM). We will detail a simple encoder implementation in Sec. 3.

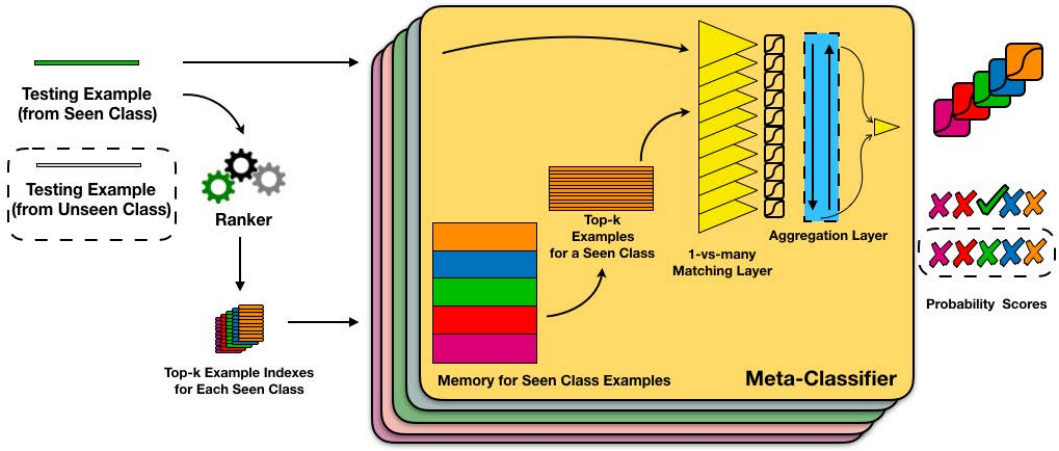

Figure 1: Overview of the L2AC framework (best viewed in colors). Assume the seen class set S has 5 classes and their examples are indicated by 5 different colors. L2AC has two components: a ranker and a meta-classifier. Given a (green) testing example from a seen class, the ranker first retrieves the top-k nearest examples (memory indexes) from each seen class. Then the meta-classifier takes both the test example and the top-k nearest examples for a seen class to produce a probability score for that class. The meta-classifier is applied 5 times (indicated by 5 rounded rectangles) over these 5 seen classes and yields 5 probability scores, where the 3rd (green) class attends the maximum score as the final class (green) prediction. However, if the test example (grey) is from an unseen class (as indicated by the dashed box), none of those probability scores from the seen classes will predict positive, which leads rejection.

Further, we save the continuous representations of the examples into the memory of the meta-classifier. So later, the top-k examples can be efficiently retrieved via the index (address) in the memory. The memory is essentially a matrix $E \in \mathbb{R}^{n \times |h|}$, where n is the number of all examples from seen classes and $|h|$ is the size of the hidden dimensions. Note that we will still use x instead of h to refer to an example for brevity. Given the test example x_t, the meta-classifier first looks up the actual continuous representations $x_{a_{1:k}}$ of the top-k examples for a seen class. Then the meta-classifier computes the similarity score between x_t and each x_{a_i} $(1 \le i \le k)$ individually via a 1-vs-many matching layer as described next.

2.1.2 1-vs-many Matching Layer. To compute the overall probability between a test example and a seen class, a 1-vs-many matching layer in the meta-classifier first computes the individual similarity score between the test example and each of the top-k retrieved examples of the seen class. The 1-vs-many matching layer essentially consists of k shared matching networks as indicated by big yellow triangles in Fig. 1. We denote each matching network as $f(\cdot,\cdot)$ and compute similarity scores $r_{1:k}$ for all top-k examples $r_{1:k} = f(x_t, x_{a_{1:k}})$.

The matching network first transforms the test example x_t and x_{a_i} from the continuous representation space to a single example in a similarity space. We leverage two similarity functions to obtain the similarity space. The first function is the absolute values of the element-wise subtraction: $f_{\text{abssub}}(x_t, x_{a_i}) = |x_t - x_{a_i}|$. The second one is the element-wise summation: $f_{\text{sum}}(x_t, x_{a_i}) = x_t + x_{a_i}$. Then the final similarity space is the concatenation of these two functions' results: $f_{\text{sim}}(x_t, x_{a_i}) = f_{\text{abssub}}(x_t, x_{a_i}) \oplus f_{\text{sum}}(x_t, x_{a_i})$, where $\oplus$ denotes the concatenation operation. We then pass the result to two fully-connected layers (one with Relu activation) and a sigmoid function:

$$r_i = f(x_t, x_{a_i}) = \sigma\Big(W_2 \cdot \text{Relu}\big(W_1 \cdot f_{\text{sim}}(x_t, x_{a_i}) + b_1\big) + b_2\Big). \quad (1)$$

Since there are k nearest examples, we have k similarity scores denoted as $r_{1:k}$. The hyper-parameters are detailed in Sec. 3.

2.1.3 Open-world Learning via Aggregation Layer. After getting the individual similarity scores, an aggregation layer in the meta-classifier merges the k similarity scores into a single probability indicating whether the test example x_t belongs to the seen class. By having the aggregation layer, the meta-classifier essentially has a *parametric voting mechanism* so that it can learn how to vote on multiple nearest examples (rather than a single example) from a seen class to decide the probability. As a result, the meta-classifier can have more reliable predictions, which is studied in Sec. 3.

We adopt a (many-to-one) BiLSTM [15, 27] as the aggregation layer. We set the output size of BiLSTM to 2 (1 per direction of LSTM). Then the output of BiLSTM is connected to a fully-connected layer followed by a sigmoid function that outputs the probability. The computation of the meta-classifier for a given test example x_t and $x_{a_{1:k}}$ for a seen class c can be summarized as:

$$p(c|x_t, x_{a_{1:k}}) = \sigma\big(W \cdot \text{BiLSTM}(r_{1:k}) + b\big). \quad (2)$$

Inspired by DOC [30], for each class $c \in S$, we evaluate Eq. 2 as:

$$\hat{y} = \begin{cases} \textit{reject}, \text{ if } \max_{c \in S} p(c|x_t, x_{a_{1:k}}) \le 0.5; \\ \\ \arg\max_{c \in S} p(c|x_t, x_{a_{1:k}}), \text{ otherwise.} \end{cases} \quad (3)$$

If none of existing seen classes S gives a probability above 0.5, we *reject* x_t as an example from some unseen class. Note that given a large number of classes, eq. 3 can be efficiently implemented in parallel. We leave this to future work. To make L2AC an easily

accessible approach, we use 0.5 as the threshold naturally and do not introduce an extra hyper-parameter that needs to be artificially tuned. Note also that as discussed earlier, the seen class set S and its examples can be dynamically maintained (e.g., one can add to or remove from S any class). So the meta-classifier simply performs open-world classification over the current seen class set S.

2.2 Training of Meta-Classifier

Since the meta-classifier is a general classifier that is supposed to work for any class, training the meta-classifier $p_\theta(c|x_t, x_{a_{1:k}|x_t}, c)$ requires examples from another set M of classes called *meta-training classes*. A large $|M|$ is desirable so that meta-training classes have good coverage of features for seen and unseen classes in testing, which is in similar spirit to few-shot learning [19]. We also enforce $(S \cup U) \cap M = \varnothing$ in Sec. 3, so that all seen and unseen classes are totally unknown to the meta-classifier.

Next, we formulate the meta-training examples from M, which consist of a set of pairs (with positive and negative labels). The first component of a pair is a training document x_q from a class in M, and the second component is a sequence of top-k nearest examples also from a class in M.

We assume every example (document) of a class in M can be a training document x_q. Assuming x_q is from class $c \in M$, a positive training pair is $(x_q, x_{a_{1:k}|x_q,c})$, where $x_{a_{1:k}|x_q,c}$ are top-k examples from class c that are most similar or nearest to x_q; a negative training pair is $(x_q, x_{a_{1:k}|x_q,c'})$, where $c' \in M$, $c \neq c'$ and $x_{a_{1:k}|x_q,c'}$ are top-k examples from class c' that are nearest to x_q. We call c' one *negative class* for x_q. Since there are many negative classes $c' \in M \backslash c$ for x_q, we keep top-n negative classes for each training example x_q. That is, each x_q has one positive training pair and n negative training pairs. To balance the classes in the training loss, we give a weight ratio $n : 1$ for a positive and a negative pair, respectively.

Training the meta-classifier also requires validation classes for model selection (during optimization) and hyper-parameters (k and n) tuning (as detailed in Experiments). Since the classes tested by the meta-classifier are unexpected, we further use a set of *validation classes* $M' \cap M = \varnothing$ (also $M' \cap (S \cup U) = \varnothing$), to ensure generalization on the seen/unseen classes.

3 EXPERIMENTS

We want to address the following Research Questions (RQs): **RQ1** - what is the performance of the meta-classifier with different settings of top-k examples and n negative classes? **RQ2** - How is the performance of L2AC compared with state-of-the-art text classifiers for open-world classification (which all need some forms of re-training).

3.1 Dataset

We leverage the huge amount of product descriptions from the Amazon Datasets [14] and form the OWL task as the following. Amazon.com maintains a tree-structured category system. We consider each path to a leaf node as a class. We removed products belonging to multiple classes to ensure the classes have no overlapping. This gives us 2598 classes, where 1018 classes have more than 400 products per class. We randomly choose 1000 classes from the 1018 classes with 400 randomly selected products per class as the *encoder training set*; 100 classes with 150 products per class are used as the (classification) *test set*, including both seen classes S and unseen classes U; another 1000 classes with 100 products per class are used as the *meta-training set* (including both M and M'). For the 100 classes of the test set, we further hold out 50 examples (products) from each class as test examples. The rest 100 examples are training data for baselines, or seen classes examples to be read by the meta-classifier (which only reads those examples but is not trained on those examples). To train the meta-classifier, we further split the meta-training set as 900 *meta-training classes* (M) and 100 *validation classes* (M').

For all datasets, we use NLTK[2] as the tokenizer, and regard all words that appear more than once as the vocabulary. This gives us 17,526 unique words. We take the maximum length of each document as 120 since the majority of product descriptions are under 100 words.

3.2 Ranker

We use cosine similarity to rank the examples in each seen (or meta-training) class for a given test (or meta-training) example x_t (or x_q)[3]. We apply cosine directly on the hidden representations of the encoder as $cosine(h_*, h_{a_i}) = \frac{h_* \cdot h_{a_i}}{|h_*|_2 |h_{a_i}|_2}$, where $*$ can be either t or q, $|\cdot|_2$ denotes the l-2 norm and $\cdot$ denotes the dot product of two examples.

Training the meta-classifier also requires a ranking of negative classes for a meta-training example x_q, as discussed in Sec. 2.2. We first compute a *class vector* for each meta-training class. This class vector is averaged over all encoded representations of examples of that class. Then we rank classes by computing cosine similarity between the class vectors and the meta-training example x_q. The top-n (defined in the previous section) classes are selected as negative classes for x_q. We explore different settings of n later.

3.3 Evaluation

Similar to [30], we choose 25, 50, and 75 classes from the (classification) test set of 100 classes as the seen classes for three (3) experiments. Note that each class in the test set has 150 examples, where 100 examples are for the training of baseline methods or used as seen class examples for L2AC and 50 examples are for testing both the baselines and L2AC. We evaluate the results on all 100 classes for those three (3) experiments. For example, when there are 25 seen classes, testing examples from the rest 75 unseen classes are taken as from one *rejection class* c_{rej}, as in [30].

Besides using macro F1 as used in [30], we also use weighted F1 score overall classes (including seen and the rejection class) as the evaluation metric. Weighted F1 is computed as

$$\sum_{c \in S \cup \{c_{\text{rej}}\}} \frac{N_c}{\sum_{c \in S \cup \{c_{\text{rej}}\}} N_c} \cdot \text{F1}_c, \tag{4}$$

where N_c is the number of examples for class c and F1_c is the F1 score of that class. We use this metric because macro F1 has a bias on the importance of rejection when the seen class set is small

[2] https://www.nltk.org/

[3] Given many examples to process, the ranker can be implemented in a fully parallel fashion to speed up the processing, which we leave to future work as it is beyond the scope of this work.

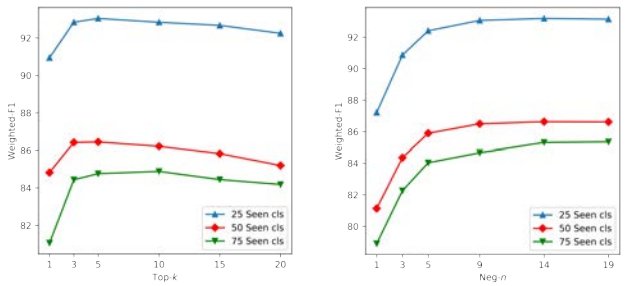

Figure 2: Weighted F1 scores for different k's ($n = 9$) and different n's ($k = 5$).

(macro F1 treats the rejection class as equally important as one seen class). For example, when the number of seen classes is small, the rejection class should have a higher weight as a classifier on a small seen set is more likely challenged by examples from unseen classes. Further, to stabilize the results, we train all models with 10 different initializations and average the results.

3.4 Hyper-parameters

For simplicity, we leverage a BiLSTM [15, 27] on top of a GloVe [23] embedding (840b.300d) layer as the encoder (other choices are also possible). Similar to feature encoders trained from ImageNet [25], we train classification over the encoder training set with 1000 classes and use 5% of the encoding training data as encoder validation data. We apply dropout rates of 0.5 to all layers of the encoder. The classification accuracy of the encoder on validation data is **81.76%**. The matching network (the shared network within the 1-vs-many matching layer) has two fully-connected layers, where the size of the hidden dimension is 512 with a dropout rate of 0.5. We set the batch size of meta-training as 256.

To answer RQ1 on two hyper-parameters k (number of nearest examples from each class) and n (number of negative classes), we use the 100 validation classes to determine these two hyper-parameters. We formulate the validation data similar to the testing experiment on 50 seen classes. For each validation class, we select 50 examples for validation. The rest 50 examples from each validation seen class are used to find top-k nearest examples. We perform grid search of averaged weighted F1 over 10 runs for $k \in \{1, 3, 5, 10, 15, 20\}$ and $n \in \{1, 3, 5, 9\}$, where $k = 5$ and $n = 9$ reach a reasonably well weighted F1 (87.60%). Further increasing n gives limited improvements (e.g., 87.69% for $n = 14$ and 87.68% for $n = 19$, when $k = 5$). But a large n significantly increases the number of training examples (e.g., $n = 14$ ended with more than 1 million meta-training examples) and thus training time. So we decide to select $k = 5$ and $n = 9$ for all ablation studies below. Note the validation classes are also used to compute (formulated in a way similar to the meta-training classes) the validation loss for selecting the best model during Adam [16] optimization.

3.5 Compared Methods

To the best of our knowledge, DOC [30] is the only state-of-the-art baseline for open-world learning (with rejection) for text classification. It has been shown in [30] that DOC significantly outperforms the methods CL-cbsSVM and cbsSVM in [9] and OpenMax in [3]. OpenMax is a state-of-the-art method for image classification with rejection capability.

To answer RQ2, we use DOC and its variants to show that the proposed method has comparable performance with the best open-world learning method with re-training. Note that DOC cannot incrementally add new classes. So we re-train DOC over different sets of seen classes from scratch every time new classes are added to that set. It is thus actually unfair to compare our method with DOC because DOC is trained on the actual training examples of all classes. However, our method still performs better in general. We used the original code of DOC and created six (6) variants of it.

DOC-CNN: CNN implementation as in the original DOC paper without Gaussian fitting (using 0.5 as the threshold for rejection). It operates directly on a sequence of tokens.
DOC-LSTM: a variant of DOC-CNN, where we replace CNN with BiLSTM to encode the input sequence for fair comparison. BiLSTM is trainable and the input is still a sequence of tokens.
DOC-Enc: this is adapted from DOC-CNN, where we remove the feature learning part of DOC-CNN and feed the hidden representation from our encoder directly to the fully-connected layers of DOC for a fair comparison with L2AC.
DOC-*-Gaus: applying Gaussian fitting proposed in [30] on the above three baselines, we have 3 more DOC baselines. Note that these 3 baselines have exactly the same models as above respectively. They only differ in the thresholds used for rejection. Gaussian fitting in [30] is used to set a good threshold for rejection. We use these baselines to show that the Gaussian fitted threshold improves the rejection performance of DOC significantly but may lower the performance of seen class classification. The original DOC is **DOC-CNN-Gaus** here.

The following baselines are variants of L2AC.
L2AC-n9-NoVote: this is a variant of the proposed L2AC that only takes one most similar example (from each class), i.e., $k = 1$, with one positive class paired with $n = 9$ negative classes in meta-training ($n = 9$ has the best performance as indicated in answering RQ1 above). We use this baseline to show that the performance of taking only one sample may not be good enough. This baseline clearly does not have/need the aggregation layer and only has a single matching network in the 1-vs-many layer.
L2AC-n9-Vote3: this baseline uses exactly the same model as L2AC-n9-NoVote. But during evaluation, we allow a non-parametric voting process (like kNN) for prediction. We report the results of voting over top-3 examples per seen class as it has the best result (ranging from 3 to 10). If the average of the top-3 similar examples in a seen class has example scores with more than 0.5, L2AC believes the testing example belongs to that class. We use this baseline to show that the aggregation layer is effective in learning to vote and L2AC can use more similar examples and get better performance.
L2AC-k5-n9-AbsSub/Sum: To show that using two similarity functions ($f_{\text{abssub}}(\cdot,\cdot)$ and $f_{\text{sum}}(\cdot,\cdot)$) gives better results, we further perform ablation study by using only one of those similarity functions at a time, which gives us two baselines.
L2AC-k5-n9/14/19: this baseline has the best $k = 5$ and $n = 9$ on the validation classes, as indicated in the previous subsection. Interestingly, further increasing k may reduce the performance as

Table 1: Weighted F1 (WF1) and macro F1 (MF1) scores on a test set with 100 classes with 3 settings: 25, 50, and 75 seen classes. The set of seen classes are incrementally expanded from 25 to 75 classes (or gradually shrunk from 75 to 25 classes). The results are the averages over 10 runs with standard deviations in parenthesis.

L2AC-k5-n19	93.15(0.24)	86.9(0.45)	86.62(0.49)	86.48(0.43)	**85.36**(0.66)	88.79(0.52)

L2AC may focus on not-so-similar examples. We also report results on $n = 14$ or 19 to show that the results do not get much better.

3.6 Results Analysis

From Table 1, we can see that L2AC outperforms DOC, especially when the number of seen classes is small. First, from Fig. 2 we can see that $k = 5$ and $n = 9$ gets reasonably good results. Increasing k may harm the performance as taking in more examples from a class may let L2AC focus on not-so-similar examples, which is bad for classification. More negative classes give L2AC better performance in general but further increasing n beyond 9 has little impact.

Next, we can see that as we incrementally add more classes, L2AC gradually drops its performance (which is reasonable due to more classes) but it still yields better performance than DOC. Considering that L2AC needs no training with additional classes, while DOC needs full training from scratch, L2AC represents a major advance. Note that testing on 25 seen classes is more about testing a model's rejection capability while testing on 75 seen classes is more about the classification performance of seen class examples. From Table 1, we notice that L2AC can effectively leverage multiple nearest examples and negative classes. In contrast, the non-parametric voting of L2AC-n9-Vote3 over top-3 examples may not improve the performance but introduce higher variances. Our best $k = 5$ indicates that the meta-classifier can dynamically leverage multiple nearest examples instead of solely relying on a single example. As an ablation study on the choices of similarity functions, running L2AC on a single similarity function gives poorer results as indicated by either L2AC-k5-n9-AbsSub or L2AC-k5-n9-Sum.

DOC without encoder (DOC-CNN or DOC-LSTM) performs poorly when the number of seen classes is small. Without Gaussian fitting, DOC's (DOC-CNN, DOC-LSTM or DOC-Enc) performance increases as more classes are added as seen classes. This is reasonable as DOC is more challenged by fewer seen training classes and more unseen classes during testing. As such, Gaussian fitting (DOC-*-Gaus) alleviates the weakness of DOC on a small number of seen training classes.

4 RELATED WORK

Open-world learning has been studied in text mining and computer vision (where it is called open-set recognition) [2, 7, 9]. Most existing approaches focus on building a classifier that can predict examples from unseen classes into a (hidden) *rejection class*. These solutions are built on top of closed-world classification models [2, 3, 30]. Since a closed-world classifier cannot detect/reject examples from unseen classes (they will be classified into some seen classes), some thresholds are used so that these closed-world models can also be used to do rejection. However, as discussed earlier, when incrementally learning new classes, they also need some form of re-training, either full re-training from scratch [3, 30] or partial re-training in an incremental manner [2, 9].

Our work is also related to class incremental learning [21, 24, 26], where new classes can be added dynamically to the classifier. For example, iCaRL [24] maintains some exemplary data for each class and incrementally tunes the classifier to support more new classes. However, they also require training when each new class is added.

Our work is clearly related to meta-learning (or learning to learn) [32], which turns the machine learning tasks themselves as training data to train a meta-model and has been successfully applied to many machine learning tasks lately, such as [1, 8, 10–12]. Our proposed framework focuses on learning the similarity between an example and an arbitrary class and we are not aware of any open-world learning work based on meta-learning.

The proposed framework is also related to zero-shot learning [20, 22, 31] (in that we do not require training but need to read training examples), k-nearest neighbors (kNN) (with additional rejection capability, metric learning [34] and learning to vote), and Siamese networks [4, 17, 33] (regarding processing a pair of examples). However, all those techniques work in closed-worlds with no rejection capability.

Product classification has been studied in [5, 6, 13, 18, 28, 29], mostly in a multi-level (or hierarchical) setting. However, given the dynamic taxonomy in nature, product classification has not been studied as an open-world learning problem.

5 CONCLUSIONS

In this paper, we proposed a meta-learning framework called L2AC for open-world learning. L2AC has been applied to product classification. Compared to traditional closed-world classifiers, our meta-classifier can incrementally accept new classes by simply adding new class examples without re-training. Compared to other open-world learning methods, the rejection capability of L2AC is trained rather than realized using some empirically set thresholds. Our experiments showed superior performances to strong baselines.

ABSTRACT

Thanks to the advancing mobile location services, people nowadays can post about places to share visiting experience on-the-go. A large place graph not only helps users explore interesting destinations, but also provides opportunities for understanding and modeling the real world. To improve coverage and flexibility of the place graph, many platforms import places data from multiple sources, which unfortunately leads to the emergence of numerous duplicated places that severely hinder subsequent location-related services. In this work, we take the anonymous place graph from Facebook as an example to systematically study the problem of place deduplication: We carefully formulate the problem, study its connections to various related tasks that lead to several promising basic models, and arrive at a systematic two-step data-driven pipeline based on place embedding with multiple novel techniques that works significantly better than the state-of-the-art.

1 INTRODUCTION

With the prevalence of mobile devices and online social platforms, maps and location related apps have become an integral part of people's everyday life. It has encouraged the development of various location-oriented infrastructures and services [13, 23–25, 36, 52, 53]. For most of them, one key task is the maintenance of a high-quality map database (*a.k.a. place graph*), which consists of various real-world places and their attributes. On one hand, such a database can support various map-based activities like *search*, *like*, *check-in* and *post*. Improving the efficiency and quality of such activities is beneficial to various stakeholders including business owners, advertisement agencies, and common users. On the other hand, the frequent location-based activity data generated by users provide an invaluable opportunity to improve the representation and understanding of the real world, and may further shed light on the capturing and modeling of various real-world activities.

However, since place pages are usually created from multiple sources whose qualities are hard to verify upon creation, the place graphs are often subject to large amounts of duplications, which hurts the quality of subsequent location-based services. For example, when a user touring in New York City wants to make a post at Times Square, if the system returns a list of places like "New York Time Square" "Manhattan, Time Square" "TimeSquare, NYC", the user will get confused about which one to post on. Worse still, if the user also wants to explore restaurants or shopping malls around Times Square, then she/he may need to manually combine multiple lists of stores to get a full picture of all available choices.

Such user experiences are mainly due to the problem of duplicated places. To ease users' exploration of places and sharing of experiences, in this work, we take the *massive* anonymous place graph from Facebook as an example to systematically study the problem of *place deduplication*, and comprehensively evaluate the performance of different methods through extensive experiments on *duplication candidate fetch* and *pair-wise duplication prediction*.

Specifically, we start with *large-scale* unsupervised feature generation to encode various ad-hoc place attributes through *embedding learning* and *network-based embedding smoothing*. Upon that, we develop an effective supervised metric learning framework to find the most useful features indicating place duplications. To fully leverage the noisy labeled data, we novelly pack the model with a series of techniques including *batch-wise hard sampling*, *source-oriented attentive training*, and *soft clustering-based label denoising*. Extensive experiments on real-world place data show that our pipeline can outperform state-of-the-art industry-level baselines by significant margins, while each of our novel model components effectively pushes the limit of the overall pipeline.

Note that, although we focus on the example of Facebook data, our place deduplication pipeline is *general* and ready to be applied to any online platform with place data or other deduplication tasks. Full implementation of our place embedding pipeline based on PyTorch will be released after the acceptance of this work.

2 PROBLEM FORMULATION

Nowadays, many online platforms maintain a *place graph* to map the real world. The building blocks of such place graphs, however, instead of actual places, are usually *online place pages* that capture certain attributes of actual places, as illustrated in Figure 1. Since such online places can be created by users, imported from third-party companies or scraped from the Web, many of them are *duplicated*, as they in fact describe the same real-world places. In this work, to improve the quality of place graphs, we aim at the following novel but emergent problem.

Definition 1. *Place Deduplication. Given a large set of online place pages, find those describing the same real-world places.*

Input. Given a set of online places $\mathcal{P}$, we represent the attributes of each place $p_i \in \mathcal{P}$ as $\mathbf{a}_i \in \mathcal{A}$. Such attributes can be ad-hoc, for example, place names, addresses, phone numbers, visitor histories, images, relevant posts and so on, which are essentially combinations of numerical, categorical, textual and even visual features. Moreover, due to the reality, many attributes can be missing and inaccurate.

Figure 1: Example input with ad-hoc page features.

Output. For each place $p_i \in \mathcal{P}$, we aim to compute a unique fixed-sized low-dimensional vector (*a.k.a.* embedding) $\mathbf{u}_i \in \mathcal{U}$, to encode its ad-hoc attributes $\mathbf{a}_i \in \mathcal{A}$. After getting such embeddings, various related tasks can be efficiently addressed through off-the-shelf machine learning algorithms. For example, duplication candidate fetch (find places that may be potentially duplicated) can be done through fast k-NN search [14, 20], pair-wise duplication prediction (decide if two places are duplications) simply involves the computation of pair-wise Euclidean distances, and meta-page discovery (find common actual places among all online places) can be achieved using clustering techniques such as k-means [17].

Labels. To learn the proper place embedding $\mathcal{U}$ that facilitates place deduplication, besides place attributes $\mathcal{A}$, we also aim to leverage some labeled data $\mathcal{L}$, which are mainly from curation, crowdsourcing, and feedbacks. The labels are usually in the form of place pairs like $l = \{(a, b), y_l\}$, where a and b are two probe places. $y_l = 1$ denotes a positive pair, meaning a and b are labeled as duplications, and $y_l = 0$ denotes a negative pair. Labels from different sources can have varying qualities and biases.

Present work. Taking the ad-hoc raw place attributes $\mathcal{A}$, we firstly transform them into fixed-sized numerical vectors $\mathcal{X}$ with unsupervised learning techniques, which captures the key information in $\mathcal{A}$ and can be easily processed by subsequent machine learning algorithms. Guided by labeled place pairs in $\mathcal{L}$, we then explore the feature representation $\mathcal{X}$ through supervised learning techniques and learn the final place embeddings $\mathcal{F}$ as vectors in a metric space where labeled duplicated places are close and non-duplicated places lie far apart. While we focus on place deduplication, the concepts and methods developed in this work are not bounded to the particular problem, but can be generally useful for deduplicating various objects like texts and users with similar types of attributes.

3 RELATED WORK AND MOTIVATIONS

We find the place deduplication problem closely related to several key tasks that heavily rely on advanced machine learning techniques, especially in the domains of computer vision (CV) and natural language processing (NLP).

3.1 CV: Person Re-Identification

One of the key tasks in CV is person re-identification [4–6, 12, 38, 46], also referred to as face recognition [37, 41, 42]. Given a large number of human images, the task is to find images of the same person. In concept, this task is quite close to ours as defined in Section 2.

In CV, mainstream algorithms often tackle re-identification by projecting the images into a latent embedding space, while tuning the embedding space based on labeled data with a *triplet loss* to enforce the correct order for each probe image. Their conceptual optimization objective can be expressed as follows.

$$\mathcal{J}_{tr} = \sum_{t=(a,p,n)} \max(0, d(\mathbf{u}_a, \mathbf{u}_p) - d(\mathbf{u}_a, \mathbf{u}_n) + \alpha), \qquad (1)$$

where $\mathbf{u} = \mathbf{f}(\mathbf{x})$ and $d(\mathbf{u}_i, \mathbf{u}_j) = d_e(\mathbf{u}_i, \mathbf{u}_j) = ||\mathbf{u}_i - \mathbf{v}_j||_2^2$. $\mathbf{x}$ is the original image features (*e.g.*, 96×96 pixels), $\mathbf{f}(\cdot)$ denotes the embedding projection function (*e.g.*, a deep CNN), α is the margin hyper-parameter, and $||\cdot||_2^2$ denotes the Frobenius norm.

However, while images naturally come with rich visual features that can be well explored by the CNN models, the attributes of our places are much more ad-hoc and hard to capture. Another limitation of their models is the requirement of training data to be accurate and in the form of *triplets*, *i.e.*, $t = (a, p, n)$, where a is the probe image, p is the positive image and n is the negative image. In person re-identification, the labels are often generated from image collections taken of the same persons. Therefore, while the quality of input images may be different, the labels are often accurate, and the triplet requirement is easy to be satisfied.

In our scenario of place deduplication, labels are generated from different sources like curation and crowdsource based on samples of all possible place pairs, and are thus prone to varying qualities and biases. Moreover, instead of triplets, the training data naturally come as *pairs*, in the form of $l = \{(a, b), y_l\}$, as defined in Section 2. Finally, place duplication labels are extremely sparse– in our case, only about 10^{-5} percent of place pairs are labeled. It requires non-trivial adaptions of the CV models to work for place deduplication, which we will talk about in Section 5 and 6.

3.2 NLP: Entity Resolution

If we only consider place names, the problem is close to synonym detection. However, as most algorithms leverage sentence-level contexts to learn word similarities [32, 33, 35, 39, 43, 47], they are not directly applicable to place deduplication where such contexts

are often not available. Instead, we may consider direct matching of place names, which can be done using deep neural networks [3, 15, 19, 30, 40, 45, 49]. However, these models are known to be more suitable for longer sentences with more complex structures, rather than the short simple place names, and they require large amounts of training data, which is extremely hard to acquire for place deduplication [7, 9, 31]. Finally, by considering additional place attributes like location, ad-hoc models have been developed based on heuristic feature engineering [8, 10, 22], but their flexibility is limited to take more different place attributes, such as address and category. Thus, it is desirable for us to develop our own systematic and flexible place deduplication pipeline beyond the existing works on entity resolution, as we will discuss in Section 5 and 6.

Interestingly, another particular trend of entity resolution is to construct the word networks from search engine query logs and compute network clustering to detect synonym sets [2, 18, 34]. Since it is non-trivial to put everything we have into a single network, their methods are not directly applicable. Nonetheless, we find the ideas of network construction and clustering intriguing, and are able to leverage both of them in Section 5 and 6, respectively.

4 DATA AND EXPERIMENTAL SETUPS

In this section, we describe the massive dataset we use, upon which place deduplication is desired. It is a subset of the anonymous real-world place graph from Facebook including a total of 730M online place pages. In this work, we take the Facebook place graph as an example to show the effectiveness and efficiency of the methods we develop, while they are generally applicable to any online platforms with place data or other deduplication tasks.

4.1 Data Preparation

As we discussed in Section 2, places can have various ad-hoc attributes with varying qualities and incompleteness, which need to be leveraged through specifically designed methods, as we will show in Section 5.

We process and generate training data of about 4.6M pairs of places from 19 different sources, including curation, crowdsourcing, feedbacks and so on. Labels from curation are generally of higher qualities, while most of the others like feedbacks generated through surveys and crowdsourcing produced by cheap labors may be rather *noisy*. They cover a total of about 4M places. Among them, about 1.1M pages are labeled with duplications and 3M pages with non-duplications. The average number of duplications is 0.35, whereas the maximum number of duplications is 297. The average number of non-duplications is 1.98, and the maximum number of non-duplications is over 1K. Therefore, the training data are *sparse* and *biased*, and such sparsity and bias are different across the sources. In Section 6, we will discuss how to leverage such training data with varying noise, sparsity, and bias.

4.2 Evaluation Methods

The testing data we use is a golden set of 47K pages completely separate from the training data, which is deliberately curated for place quality evaluation for production. It contains different place pages from the training data.

To compare different embedding models, we firstly compute the vector representations $\mathcal{U}$ of all places in the testing set. For the set of places labeled with both duplications and non-duplications (*i.e.*, $a \in \Omega$), we compute the average pair-wise accuracy as follows:

$$\text{ACC} = \frac{1}{|\Omega|} \sum_{a \in \Omega} \frac{1}{|\Phi_a||\Psi_a|} \sum_{p \in \Phi_a, n \in \Psi_a} \mathbb{I}(||\mathbf{u}_a - \mathbf{u}_p||_2^2 < ||\mathbf{u}_a - \mathbf{u}_n||_2^2),$$

where Φ_a and Ψ_a are the sets of labeled duplications and non-duplications of place a, respectively. This metric measures the utility of the embedding for the task of pair-wise duplication prediction.

Besides ACC, we also compute the nearest neighbors of each place through fast k-NN [20], and compute the precision and recall at K based on the set of places labeled with duplications (*i.e.*, $a \in \Theta$), to measure the utility of the embedding for the task of point-wise duplication candidate fetch.

5 UNSUPERVISED FEATURE GENERATION

The key place attributes we aim to leverage in this work are name, address, coordinate and category, while other attributes can also be easily incorporated in the future. Among them, name and address are textual, coordinate is numerical, and category is categorical, which need to be handled differently. Moreover, many of them are noisy and incomplete, requiring the model to be robust and flexible.

5.1 Encoding Name

We start with place name, because it is often the primary and most indicative feature towards deduplication(*e.g.*, "Metropolitan Museum of Art" and "The MET"). Motivated by the success of word embedding in NLP, we propose to capture the place name semantics through embedding. The idea is to leverage the distributional information about words and infer word semantic similarities based on the context, so as to recognize common misspellings (*e.g.*, "capitol" as "capital", "corner" as "conner"), acronyms (*e.g.*, "street" as "st"), synonyms (*e.g.*, "plaza" and "square") and *etc.*

Method 1: *Skip-gram* + place name corpus. We firstly train a simple word embedding model on all place names we have, which include 730M short texts. For preprocessing, we prune all place names into the shortest name variants by removing all location prefixes and suffixes in the names (*e.g.*, remove "New York" from "Time Square New York"); we also normalize all place names by replacing special characters with spaces (*e.g.*, replace "$" or emojis with a single space) and change all letters to lower cases.

Since place names are often quite short (on average only 3.11 words after preprocessing), we directly apply the *Skip-gram* model [28] by sampling word-context pairs from place names. Place embedding is then computed as the average of word embedding.

This method, while efficiently providing numerical place name representations that can be processed by subsequent machine learning algorithms, has quite a few drawbacks as listed below.

- Limited distributional information: The training corpus, although is quite large, provides rather limited statistics around words and their contexts, since the corpus is chunked into short texts.
- Biased samples: Unlike sampling word-context pairs from fixed-sized sliding windows, when sampling from the place names, it is hard to avoid the bias towards either shorter or longer names.

- Ignorance of word internal structure: Standard word vectors ignore word internal structure that contains rich information, which might be especially useful for rare or misspelled words.

Method 2: *Fast-text* + Facebook post corpus. To ameliorate the above limitations, we adopt the advanced *Fast-text* method [27], with strategies including position-dependent weighting, phrase generation and subword enrichment [1, 21]. Moreover, to capture more casual languages used by social network users who frequently create the place pages, instead of training the *Fast-text* model on standard NLP corpus like Wikipedia[1], we use anonymized word embeddings derived from the public posts on Facebook in 10 years. The corpus has around 1.9T words in total, which is about 3 times bigger than the massive Common Crawl data[2] used to train the state-of-the-art public word embedding [27].

5.2 Incorporating Address

In our place graph, about two-thirds of the places have address information. It is especially useful in differentiating branches of the same stores (*e.g.*, the different Starbucks in a city). Compared with names, addresses are more often incomplete, but less noisy, because most of them are validated and filtered before recorded. Therefore, we observe much fewer misspellings and abbreviations. Moreover, addresses are often longer than names, which naturally provides richer distributional information and allows less biased samples. Finally, in addresses, we do not really want semantically similar words to be close– for example, different words like "street", "avenue" and "boulevard" in the address should indicate different places although their semantic meanings are similar. We use the same two approaches for place names to embed place addresses.

5.3 Leveraging Coordinate and Category

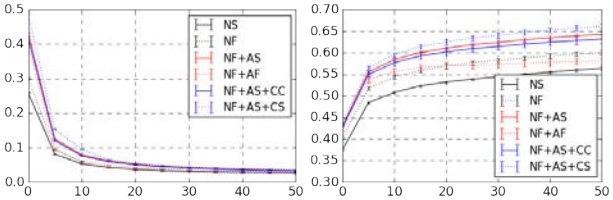
Place coordinates and categories provide additional information about duplications. Coordinates are just 2-dim numerical vectors, whereas categories can be converted to 0-1 dummy variables. In this work, we focus on 19 common ones such as Shopping and Restaurant, while the algorithm can generalize to any other appropriate subsets of categories.

A simple way to leverage place coordinate and category is to concatenate the 2-dim numerical coordinate and 19-dim 0-1 dummy vector of category to the place embedding. However, in practice, we find such concatenation not helpful and even lead to worse performance as can be seen later, probably because such variables are not compatible with the word embeddings.

Motivated by a recent work on place recommendation [50], we refine the place embedding through unsupervised embedding smoothing on a place network. The idea is to require the embeddings of places that have similar coordinates or same categories to be close.

Specifically, we construct a place network $\mathcal{N} = \{\mathcal{P}, \mathcal{E}\}$, where $\mathcal{P}$ is the set of all places. We then construct two types of edges $\mathcal{E} = \mathcal{E}_1 \cup \mathcal{E}_2$ based on coordinates and categories, respectively. Following the grid-based binning approach in [51], we group places into squared bins based on coordinates, and add a coordinate edge $e_i \in \mathcal{E}_1$ between places in the same bins; a category edge $e_j \in \mathcal{E}_2$ is added between places belonging to the same categories.

Following [50], we derive the loss that enforces smoothness among places that are close on the place network as



$$\begin{aligned}\mathcal{J}_{sm} &= -\sum_{(p_i,p_c)} \log p(p_c|p_i) \\ &= -\sum_{(p_i,p_c)} \log[\phi_c^T \mathbf{g}(\mathbf{a}_i) - \log \sum_{p'_c \in \mathcal{P}} \exp(\phi_{c'}^T \mathbf{g}(\mathbf{a}_i))] \\ &= -\mathbb{E}_{(p_i,p_c,\gamma)} \log \sigma(\gamma \phi_c^T \mathbf{g}(\mathbf{a}_i)). \end{aligned} \quad (2)$$

In the first line, we firstly formulate the standard *Skip-gram* objective adapted to predict the correct graph context of place based on coordinates and categories, which is then decomposed into the second line, where ϕ_c is the learnable context embedding of place p_c, $\mathbf{g}(\cdot)$ is a learnable smoothing function (*e.g.*, a single layer perceptron with the same input and output sizes) that maps the original place embedding $\mathbf{a}_i$ to the smoothed embedding space. This objective is hard to estimate due to the summation over all contexts in $\mathcal{P}$ in the second term, so we write it into an equivalent expectation over the distribution of $p(p_i, p_c, \gamma)$ in the third line, where $\sigma(x) = 1/(1 + e^{-x})$, and approximate it by applying the popular negative sampling approach [28].

5.4 Experimental Evaluations

We compare the following combinations to comprehensively show the overall effectiveness of our framework as well as how each of the model components helps in improving the embedding quality.

- **NS:** 50-dim place *Name* embedding produced by the *Skip-gram* model trained on the place name corpus.
- **NF:** 300-dim place *Name* embedding produced by the *Fast-text* model trained on the Facebook post corpus.
- **NF+AS:** *NF* concatenated with the 50-dim place *Address* embedding produced by the *Skip-gram* model trained on the place address corpus.
- **NF+AF:** *NF* concatenated with the 300-dim place *Address* embedding produced by the *Fast-text* model trained on the Facebook post corpus.
- **NF+AS+CC:** *NF+AS Concatenated* with the 21-dim place *Coordinate and category* vectors.
- **NF+AS+CS:** *NF+AS Smoothed* on the place network constructed *w.r.t.* place *Coordinate and category*.

Figure 2: Performance of feature generation methods.

Figure 2 and Table 1 show the performance of different feature generation methods. As can be clearly observed: 1) When we only consider the place name, *NF* performs significantly better than *NS* regarding all metrics, which supports our idea of training the advanced *Fast-text* model on the massive Facebook post corpus; 2) Incorporating place address is generally helpful, but the simple *AS*

NF+AS+CS	.05508 ± .00024	.6476 ± .0058	.6989 ± .0135

Table 1: Performance of feature generation methods.

model we advocate for produces more significant improvements than the heavy *AF* model, which tells the importance of choosing the proper model rather than the complex one; 3) To leverage place coordinate and category, our proposed network-based embedding smoothing method (*CS*) is much more effective than the direct vector concatenation (*CC*).

The *avg.* PRE and *avg.* REC are taken over the 100 measures of PRE@K and REC@K when K varies from 1 to 100, to directly compare and reveal the relative effectiveness of different methods. The absolute values of *avg.* PRE are pretty low because the numbers of labeled duplications are low in our testing data. Based on such results, we will use *NF+AS+CS* as our feature generation model and use its output $\mathcal{X}$ as the input of subsequent supervised metric learning models. Note that, other than places with the particular attributes as we focus on in this work, the methods developed here can be combined in different ways to capture textual, categorical and numerical attributes of various real-world objects.

6 SUPERVISED METRIC LEARNING

Besides place attributes, we also aim to leverage labeled place pairs through supervised metric learning. The idea is to learn a non-linear projection function $\mathcal{F}$, which transforms the place features $\mathcal{X}$ into a metric space, where duplicated places are close and non-duplicated places are far apart. Therefore, the model should be able to explore and stress the important features that indicate duplications.

6.1 Basic Models

We construct the basic metric learning models by applying simple MLP upon the place embedding $\mathcal{X}$. However, since direct leverage of standard triplet loss commonly used in person re-identification [37] and entity resolution [33] in Eq. 1 requires the sampling of the third place based on our pair-wise place labels, which can introduce a lot of non-relevant and trivial training data, we propose to replace the triplet loss with a pair-wise contrastive loss as

$$\mathcal{J}_{pr} = \sum_{l=\{(a,b),y_l\}} [y_l d(\mathbf{u}_a, \mathbf{u}_b) + (1 - y_l) \max(0, \alpha - d(\mathbf{u}_a, \mathbf{u}_b))],$$

where $d = d_e$ is the same as in Eq. 1. Besides the Euclidean distance function, we also tried various other distance functions including cosine similarity and learnable bilinear distance [33].

We comprehensively evaluated the performance of various basic models, and found that the *PE* (Pair-wise loss with Euclidean distance function) constantly performs the best, indicating the effectiveness of replacing the standard triplet loss in traditional CV and NLP tasks. Based on such observation, we will focus on further improving the *PE* model in the rest of this work.

6.2 Hard Sampling

Training the model with our massive noisy labeled place pairs can take quite significant time, most of which is wasted on trivial samples. To this end, we design the following novel criteria for dynamic batch-wise hard sampling towards our pair-wise loss.

$$C_{l=(a,b)} = \mathbb{I}\,[y_l d(\mathbf{u}_a, \mathbf{u}_b) - (1 - y_l) d(\mathbf{u}_a, \mathbf{u}_b) > \frac{\beta}{|B|} \sum_{l' \in B} y_{l'} d(\mathbf{u}_{a'}, \mathbf{u}_{b'}) - (1 - y_{l'}) d(\mathbf{u}_{a'}, \mathbf{u}_{b'})], \quad (3)$$

where B denotes the set of samples in a batch, β is the slack hyper-parameter controlling the amount of hard samples, and $d(\cdot)$ can be implemented with either $d_f(\cdot)$ or $d_b(\cdot)$. A sample pair l is selected to contribute to the loss for gradient computation when $C_l = 1$. The idea is to only focus on the hard samples where the model fails to put the labeled duplications close enough or non-duplications far away, compared with the average distances.

6.3 Attentive Training

Our labeled data are from different sources, which may have varying quality and bias. For example, data curated by a particular team at a certain time might be biased towards specific metrics. This often happens when people recognize the ignorance of particular situations and aim to improve them upon iterating to the next period of curation. Moreover, data labeled by the professional curation teams and rookie crowdsourcing workers can have quite different qualities. Therefore, it is intuitive to automatically assign different weights to the samples from different sources during training.

To deal with the varying quality and bias of training samples from multiple sources, we design a novel source-oriented attentive training technique based on the idea of self-attention [11, 44], which has shown to be effective in various deep learning scenarios.

For each place p_i, rather than learning a single embedding vector $\mathbf{f}(\mathbf{x}_i)$, we learn two embedding vectors $\mathbf{k}(\mathbf{x}_i)$ and $\mathbf{v}(\mathbf{x}_i)$, which we call the *key embedding* and *value embedding*, respectively. In practice, we can implement both $\mathbf{k}(\cdot)$ and $\mathbf{v}(\cdot)$ as FNNs and let them share a few layers. Besides, we also learn a global source embedding $\mathbf{q}(s_j)$ for each training source s_j, which can be implemented as an embedding look-up table. The size of $\mathbf{q}(\cdot)$ is twice as $\mathbf{k}(\cdot)$. Subsequently, we design the weight of the training sample $l = (a, b)$ from source s as

$$w_{ls} = \frac{\exp([\mathbf{k}(\mathbf{x}_a), \mathbf{k}(\mathbf{x}_b)]^T \mathbf{q}(s))}{\sum_{s'} \exp([\mathbf{k}(\mathbf{x}_a), \mathbf{k}(\mathbf{x}_b)]^T \mathbf{q}(s'))}, \quad (4)$$

where $[\cdot]$ denotes vector concatenation. With $\mathcal{W}$ defined, we rewrite our loss function in Eq. 3 into

$$\mathcal{J}'_{pr} = \sum_{s} \sum_{l=\{(a,b),y_l\} \in \mathcal{T}_s} w_{ls} [y_l d(\mathbf{v}(\mathbf{x}_a), \mathbf{v}(\mathbf{x}_b)) + (1 - y_l) \max(0, \alpha - d(\mathbf{v}(\mathbf{x}_a), \mathbf{v}(\mathbf{x}_b)))], \quad (5)$$

where $\mathcal{T}_s$ denotes the set of training samples from source s.

Training with Eq. 5 allows the model to learn a source-oriented self-attention weight for each training pair. To be specific, if similar samples keep appearing in a certain source, they are likely redundant and less useful, and the model will automatically reduce their contribution to the loss. However, if similar samples appear across different sources, the model will put more trust on their correctness by relatively increasing their attention weights. Finally, unseen samples will likely get higher attention.

6.4 Label Denoising

Place deduplication can be essentially regarded as a semi-supervised clustering problem, where pages of the same places should naturally form clusters in the embedding space. This is true mainly because the duplication relationship is *transitive*. While such clusters are ideal for duplication detection, they can also help reduce the noise within training data, *i.e.*, labels that conflict with the cluster structures are likely noisy. To leverage this insight, we design a novel soft clustering-based label denoising module based on the idea of self-training neural networks [16, 29, 48]. Particularly, we introduce a loss based on the KL-divergence

$$\mathcal{J}_{dn} = \rho \, \mathrm{KL}(C||\mathcal{D}) = \rho \sum_i \sum_k c_{ik} \log \frac{c_{ik}}{d_{ik}}, \tag{6}$$

where ρ is a hyper-parameter. $d_{ik} \in \mathcal{D}$ is the probability of assigning place p_i to the kth cluster, under the assumption of Student's t-distribution with degree of freedom set to 1 [26], *i.e.*,

$$d_{ik} = \frac{(1 + ||\mathbf{f}(\mathbf{x}_i) - \mathbf{u}_k||^2)^{-1}}{\sum_j (1 + ||\mathbf{f}(\mathbf{x}_i) - \mathbf{u}_j||^2)^{-1}}. \tag{7}$$

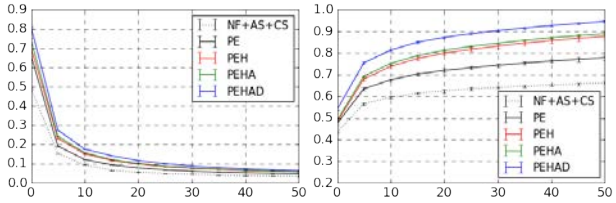
It is basically a kernel function that measures the similarity between the embedding of place p_i and the cluster center u_k. C is an auxiliary target distribution defined as

$$c_{ik} = \frac{d_{ik}^2 / g_k}{\sum_{k'} d_{ik'}^2 / g_{k'}}, \tag{8}$$

where $g_k = \sum_i d_{ik}$ is the total number of places softly assigned to the kth cluster. Raising $\mathcal{D}$ to the second power and then dividing by the number of places per cluster allows the target distribution C to improve cluster purity and leverage the confident assignments to help reduce the influence of noisy labels.

6.5 Experimental Evaluations

We compare the following methods to demonstrate the effectiveness of our proposed supervised metric learning techniques.



- **NF+AS+CS:** The best place features we got through unsupervised feature generation in Section 5, which is also the input of the following metric learning methods.
- **PE:** The best basic metric learning method adapted from CV and NLP with the *Pair-wise contrastive loss* and *Euclidean distance function*, as discussed in Section 6.1.
- **PEH:** *PE* improved with batch-wise hard sampling.
- **PEHA:** *PEH* improved with our novel source-oriented attentive training technique.
- **PEHAD:** *PEHA* improved with our novel soft clustering-based label denoising technique.

We also compare our models with several state-of-the-art classification algorithms that can be applied for pair-wise duplication prediction, *i.e.*, logistic regression (*LR*), support vector machine (*SVM*), random forest (*RF*) and gradient boosting decision tree (*GBDT*). These algorithms do not produce place embeddings and thus cannot be efficiently evaluated through fast k-NN in datasets with hundreds of millions of places. Therefore, we only compute their standard classification accuracy of duplication prediction on the testing data, as shown in Table 2.

Figure 3 and Table 3 show the performance of compared models. As we can see, our supervised metric learning framework can significantly improve the place embedding quality, because labeled data allow the models to pick out the more important features that differentiate duplication pairs from non-duplications. Moreover, each of our proposed model components further boosts the overall model performance, and their coherent combination (*PEHAD*) has the best performance regarding all metrics in the evaluation. Our models also significantly outperform all of the state-of-the-art non-embedding algorithms in Table 2– *PEHAD* achieves over 18% relative improvement on *GBDT* (the strongest baseline).

Table 3: Performance of our metric learning methods.

(a) PRE@K (b) REC@K

Figure 4: Training loss and testing accuracy curves.

To better understand how each of the components contributes to the overall model, we also closely observe the training loss and testing accuracy during the training of different models. As we can see in Figure 4: 1) Hard sampling is effective in speeding up the convergence of training loss, and allows the model to keep learning after the loss seems to converge; 2) Attentive training leads to lower losses due to the additional weights. It does not lead to significant performance gain on top of the basic *PE* model with hard sampling, but it does make the training process more stable and reduce the performance variance across different trains of the same model; 3) Label denoising empowers the model to rapidly remove the influence of noisy labels and achieve the peak performance after a small number of training iterations, which may further allow efficient model training with early stop.

Finally, all techniques here are also not bounded to the problem of place deduplication, but can rather be combined to leverage noisy pair-wise labels from multiple sources in various other domains.

7 CONCLUSIONS

In this paper, we collect data from the real-world place graph of Facebook as an example to systematically study the novel problem of place deduplication and comprehensively evaluate the effectiveness of our proposed place embedding pipeline. The concepts and methods developed, although do not provide an end-solution for place deduplication, successfully improve the quality of place embedding for intermediate tasks like duplication prediction and candidate fetch, which largely facilitates further place deduplication.

As for future work, it is interesting to further improve both the unsupervised feature generation model to incorporate more attributes, and the supervised metric learning model to leverage various training signals with efficiency. It is also interesting to apply the learned place embedding to facilitate other tasks related to place graph quality such as junk place prediction and common place clustering, as well as downstream applications including next destination recommendation and location-based ads ranking.

ABSTRACT

The potentially detrimental effects of cyberbullying have led to the development of numerous automated, data–driven approaches, with emphasis on classification accuracy. Cyberbullying, as a form of abusive online behavior, although not well–defined, is a repetitive process, i.e., a sequence of aggressive messages sent from a bully to a victim over a period of time with the intent to harm the victim. Existing work has focused on harassment (i.e., using profanity to classify toxic comments independently) as an indicator of cyberbullying, disregarding the repetitive nature of this harassing process. However, raising a cyberbullying alert immediately after an aggressive comment is detected can lead to a high number of false positives. At the same time, two key practical challenges remain unaddressed: (i) detection timeliness, which is necessary to support victims as early as possible, and (ii) scalability to the staggering rates at which content is generated in online social networks.

In this work, we introduce *CONcISE*, a novel approach for timely and accurate Cyberbullying detectiON on Instagram media SEssions. We propose a sequential hypothesis testing formulation that seeks to drastically reduce the number of features used in classifying each comment while maintaining high classification accuracy. *CONcISE* raises an alert only after a certain number of detections have been made. Extensive experiments on a real–world Instagram dataset with $\sim 4M$ users and $\sim 10M$ comments demonstrate the effectiveness, scalability, and timeliness of our approach and its benefits over existing methods.

1 INTRODUCTION

Cyberbullying, a type of cyberharassment, can take many forms [34], typically however, refers to **repetitive hostile behavior** using digital media (e.g., hurtful comments, videos and images) in an effort to intentionally and repeatedly harass or harm individuals [1, 20]. Cyberbullying is permanent (i.e., content remains accessible online unless removed) and potentially widespread[1] (i.e., online social media provide a wide audience, and quick spread of online posts) [10].

The potentially devastating real–world consequences to victims (including learning difficulties, psychological suffering and isolation, escalated physical confrontations, suicide) [12, 13] have resulted in numerous cyberharassmet classification methods with a focus on detection accuracy [5, 16, 27–29, 33, 43, 44]. While high accuracy is undoubted, the state–of–the–art relies on a **fixed** set of features learned during training for **offline** detection (i.e., after all correspondence has become available), hindering the ability to respond in a **timely** manner (i.e., as soon as possible) to cyberbullying events. Moreover, the **scalability** of existing methods to the staggering rates at which content is generated (e.g., 95 million photos and videos are shared on Instagram per day[2]) has largely remained unaddressed.

Present Work. We propose a two–stage **online** approach designed to reduce the time to raise a cyberbullying alert by (i) sequentially examining comments as they become available over time, and (ii) minimizing the number of feature evaluations necessary for a decision to be made for each comment. We formalize the problem as a sequential hypothesis testing problem, and propose a novel algorithm that satisfies four **key properties**: *accuracy*, *repetitiveness*, *timeliness*, and *efficiency*. We focus on hateful comments, captions and hashtags on Instagram, the online social media platform with the highest percentage of users reporting experiencing cyberbullying [10]. Instagram has more than 800 million registered users as of Sep. 2017, and over 40 billion uploaded photos as of Oct. 2015. To ensure the **reproducibility** of our work, we make the source code of our approach available at https://github.com/IDIASLab/CONcISE.

Outline. The rest of this paper is organized as follows. We first review prior and related work in Section 2. We then formulate the problem of cyberbullying detection in online social networks, define

[2] 33 Mind–Boggling Instagram Stats & Facts for 2018: https://www.wordstream.com/blog/ws/2017/04/20/instagram-statistics

our optimization function, and derive the optimal stopping rule and classification strategy in Section 3. We describe our evaluation methodology and results on a real–world Instagram dataset in Section 4. We conclude with a discussion of our results, limitations, and possible future directions in Section 5.

2 RELATED WORK

In this section, we briefly summarize prior and related work, which mainly constitutes 3 main bodies of research: (i) state–of–the–art cyberbullying detection, (ii) online streaming feature selection (OSFS) methods, and (iii) online learning algorithms for classification.

Cyberbullying Detection. An excellent review of existing cyberbullying detection methods is provided in [1]. More recent approaches include [5, 24, 27, 29, 44]. Meanwhile, only a few approaches have been proposed for cyberbullying detection on Instagram [7, 16, 27, 29, 30, 39, 45]. However, all existing works focus on classification accuracy, neglecting the equally important aspects of scalability and timeliness. With the exception of an incremental cyberbullying detection method to improve detection responsiveness [27], and our proposed approach, no prior or related work has studied cyberbullying as a repetitive process.

Online Classification Methods. Machine learning methods are usually trained offline and deployed without further updates once training is complete. Once deployed, the accuracy of offline–trained models however, deteriorates with time, whereas their retraining may be prohibitive if data is large and/or evolving. At the same time, online learning algorithms [4, 9, 19, 36, 41, 42] that examine data points one at a time, updating their model parameters as new samples arrive, are facing scalability constraints [14]. Nevertheless, most existing methods assume high data quality, a property that is often violated in streaming data, in which noise and missing values are the norm [14]. Although related, our framework fundamentally differs from online classification methods in that the belief on a classification outcome is updated at each time step, allowing detection in real–time.

Online Streaming Feature Selection Methods. Feature selection methods are often employed to identify a small subset of informative features that can globally describe the data well so as to reduce training time, memory requirements and ultimately improve classification accuracy [11, 17, 22, 23, 25, 31]. In contrast to offline feature selection methods, which require all features to be available upfront, online streaming feature selection (OSFS) methods [21, 38, 40, 46] fix the size of the training data, and strive to maintain a feature subset that is sequentially updated with the arrival of each new feature based on relevancy and redundancy [38, 46] and group membership [21, 40]. Unlike OSFS methods, online feature selection methods (e.g., [15, 18, 26, 37]) may update the subset of features with the arrival of new data points (as opposed to new features) while assuming that the full feature space remains unchanged.

To the best of our knowledge, all existing feature selection methods, both off– and on–line, and batch or streaming, output a global subset of discriminatory features to be used for classification (i.e. the same set of features is used after selection for classifying all data points). This is in stark contrast to our approach that conducts online streaming feature selection and classification simultaneously for each new data point, resulting in a potentially different number of features used to classify each data point. Figure 1 illustrates this difference between existing classification methods (Figure 1.a) and our framework (Figure 1.b).

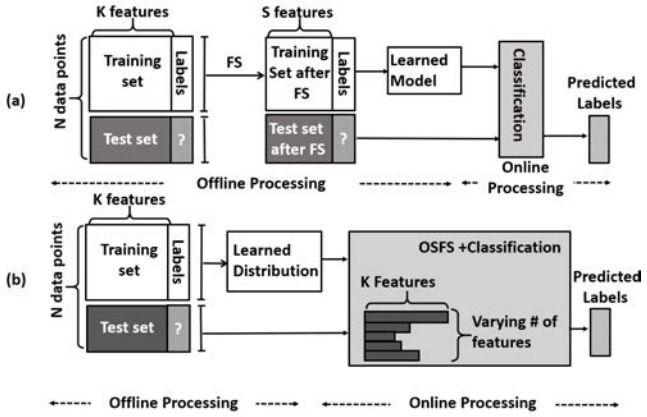

Figure 1: Given a $N \times K$ data matrix and column vector Y of labels, feature selection (FS) is applied to select $S << K$ features before training and classification in (a) existing classification methods. Compare this with (b) our framework, where a model is trained offline once on all features, and online streaming feature selection (OSFS) and classification are performed simultaneously, resulting in a variable number of features used for each data point.

3 PROPOSED METHOD

We use a general data representation, applicable to a wide variety of social media platforms as follows. Each media session $s \in \mathcal{M}$ belongs to a user $u \in \mathcal{U}$, has an associated media object (i.e., image or video) along with its corresponding caption and hashtags, and a set of comments $\{m_1, \ldots, m_{N_s}\}$ from users in $\mathcal{U}$, where N_s denotes the number of comments in s. Our main idea is to formulate cyberbullying detection on Instagram media sessions as a two–stage, online framework with the following desired properties:

- **High Accuracy:** Following [16, 27], we differentiate between **cyberbullying** (i.e., an act of aggression that is repeated over time) and **cyberaggression** (i.e., harassment manifested as one–off profanity). Each media session s is only considered as cyberbullying if more than a given number of aggressive comments have been posted, so that the number of false positives can be reduced.
- **Timeliness:** All comments in a media session are ordered in time. As a result, earlier detection using a **partial** set of the media session (i.e., a small number of comments) allows for timely alerts to be raised. In our approach, we encode the belief of a media session to be indicative of cyberbullying as the number of identified aggressive comments. We measure timeliness as the number of comments "saved" in comparison to a baseline. Figure 4 illustrates this metric.
- **Efficiency:** Given the soaring amount of daily Instagram sessions and comments, classification must be scalable.

To achieve the aforementioned desired properties, we propose a two–stage approach for cyberbullying detection on Instagram as

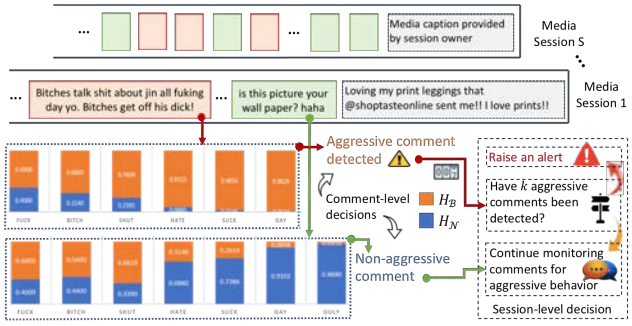

Figure 2: Overview of the proposed approach. Given a set of media sessions $\mathcal{M}$, and an alert threshold, our approach examines comments as they become available over time and raises an alert only after the number of comment–level detections surpasses the threshold. The posterior probability evolution of an aggressive (upper) and non–aggressive (lower) comment as more features are examined is provided for illustration purposes. Notice that the number of features used to make a decision in each case differs.

shown in Figure 2. In the first stage, comments in s are examined and classified sequentially as aggressive or non–aggressive. Whenever an aggressive comment is detected, a comment–level decision is made. In the second stage, before a new comment is examined, the number of comment–level detections is compared to a predefined threshold, and the media session is classified as cyberbullying when the threshold is exceeded.

Next, we introduce our proposed optimization framework that automatically computes the probability of a comment to be indicative of aggression with high accuracy, while accounting for the effort of the framework in improving its chances of reaching a highly accurate conclusion.

3.1 Problem Formulation

In our hypothesis testing formulation, only two hypotheses exist: (i) $H_{\mathcal{B}}$, which denotes the true hypothesis that m is an aggressive comment, and (ii) $H_{\mathcal{N}}$, which represents the case where m is a non–aggressive comment. Each comment m is described by a vector of features $f(m) = \{y_1, y_2, \ldots, y_K\}$, where K is the total number of features, and $y_k \in \mathcal{Y}$. For each feature y_n, the probability $p(y_n|H_{\mathcal{B}})$ (similarly $p(y_n|H_{\mathcal{N}})$) of the evaluation of the nth feature to observe value y_n when the true hypothesis is $H_{\mathcal{B}}$ (similarly when the true hypothesis is $H_{\mathcal{N}}$) is empirically computed. Similarly, the *a priori* probability $P(H_{\mathcal{B}}) = p$ of m being an aggressive comment is also estimated empirically. The probability of m being a non–aggressive comment can be computed as $P(H_{\mathcal{N}}) = 1 - p$.

To calculate the belief for m, the framework evaluates features $f(m)$ sequentially as illustrated in Figure 2. When examining each comment, at each step, the framework has to select between stopping and continuing the evaluation process based on the accumulated information thus far and the cost of reviewing additional features. The cost coefficient $c_n > 0$, where $n = 1, \ldots, K$ represents the value of time and effort spent evaluating the nth feature. We additionally consider misclassification costs $C_{ij} \geq 0, i = \mathcal{B}, \mathcal{N}, j = 1, \ldots, L$, where C_{ij} denotes the cost of selecting possibility j when the true hypothesis is H_i, and L denotes the number of decision choices (e.g., aggressive or non–aggressive). We factor misclassification costs into our approach to quantify the relative importance of detection errors.

We now formally describe our proposed sequential evaluation process to minimize the number of features used to accurately classify each comment m. Specifically, our proposed sequential evaluation process comprises a pair (R, D_R) of random variables. Random variable R takes values in the set $\{0, \ldots, K\}$, and indicates the feature that the framework stops at, and 0 indicates that no features were evaluated. Hence it is referred to as *stopping time* in decision theory [32]. Random variable D_R denotes the possibility to select among L possible choices. Assuming that the random variables y_n are *independent under each hypothesis* $H_i, i = \{\mathcal{B}, \mathcal{N}\}$, the conditional joint probability of $\{y_1, \ldots, y_n\}$ can be computed as $P(y_1, \ldots, y_n|H_i) = \prod_{k=1}^{n} p(y_k|H_i), i = \mathcal{B}, \mathcal{N}$. Both the decision to stop at stage n (i.e., the event $\{R = n\}$), and the selection of possibility j (i.e., $\{D_R = j\}$) depend only on the accumulated information $\{y_1, \ldots, y_R\}$ by the stopping time R. Equivalently, features that may be examined in the future are not used.

3.2 Optimization Setup

Our goal is to use the least number of features for detecting aggression at the comment–level without sacrificing accuracy. To minimize the number of features considered, the stopping time R and the classification rule D_R have to be selected. To this end, we first define the following cost function:

$$J(R, D_R) = \mathbb{E}\left\{ \sum_{n=1}^{R} c_n + \sum_{j=1}^{L} \sum_{i=\mathcal{B},\mathcal{N}} C_{ij} P(D_R = j, H_i) \right\}. \quad (1)$$

The first expression in the cost function regularizes the number of features, whereas the second expression, commonly referred to as Bayes Risk, penalizes the average cost of the classification rule. Our goal can be interpreted as finding the minimum average cost with respect to both random variables R and D_R, i.e., $\min_{R, D_R} J(R, D_R)$, to derive the optimal stopping and classification rules. Intuitively, the optimal rule is to stop at corresponding stopping time R, and use the optimum classification rule D_R. Once the optimal classification rule has been established, the resulting cost becomes only a function of R, and can thus be optimized with respect to R.

3.3 Classification Rule

The classification rule D_R depends only on the accumulated information $\{y_1, \ldots, y_R\}$ by stopping time R. Such accumulated information increases as more features are evaluated, thus, it becomes infeasible to optimize the cost function in Eq. (1). Instead, the *a posteriori probability* $\pi_n \triangleq P(H_{\mathcal{B}}|y_1, \ldots, y_R)$, which corresponds to a sufficient statistic of the accumulated information, can be used to reach the same solution in Eq. (1) without having to consider all $|\mathcal{Y}|^R$ possible combinations in the accumulated information. Specifically, the posterior probability, π_n, at stage n, where the nth feature is extracted and evaluated to generate outcome y_n, can be iteratively computed as:

$$\pi_n = \frac{p(y_n|H_{\mathcal{B}})\pi_{n-1}}{\pi_{n-1}p(y_n|H_{\mathcal{B}}) + (1 - \pi_{n-1})p(y_n|H_{\mathcal{N}})}, \quad (2)$$

where π_{n-1} denotes the posterior probability of a comment being an aggressive comment given the first $n-1$ features, and $\pi_0 = p$.

Using Eq. (2) and the fact that $x_R = \sum_{n=0}^{K} x_n \mathbb{1}_{\{R=n\}}$ for any sequence of random variables $\{x_n\}$, where $\mathbb{1}_A$ is the indicator function for event A (i.e., $\mathbb{1}_A = 1$ when A occurs, and 0 otherwise), the average cost in Eq. (1) can be written compactly as:

$$J(R, D_R) = \mathbb{E}\left\{ \sum_{n=1}^{R} c_n \right\} + \mathbb{E}\left\{ \sum_{j=1}^{L} (C_{Bj}\pi_R + C_{Nj}(1-\pi_R)) \mathbb{1}_{\{D_R=j\}} \right\}. \tag{3}$$

In order to obtain the optimal classification rule D_R for any stopping time R (i.e., find the optimum Bayes test given that the values of the first R features $y_1, \ldots, y_R$ are observed), an independent of D_R lower bound for the second part of Eq. (3) is needed. Since D_R contributes only to this portion of the average cost, the optimal classification rule D_R for a given stopping time R can then be derived. Specifically, for any classification rule D_R given stopping time R, $\sum_{j=1}^{L} (C_{Bj}\pi_R + C_{Nj}(1-\pi_R)) \mathbb{1}_{\{D_R=j\}} \geq g(\pi_R)$, where $g(\pi_R) \triangleq \min_{1 \leqslant j \leqslant L} \left[C_{\mathcal{B}j}\pi_R + C_{\mathcal{N}j}(1-\pi_R) \right]$. The optimal rule is thus defined as follows:

$$\mathcal{D}_R^{optimal} = \arg\min_{1 \leqslant j \leqslant L} \left[C_{\mathcal{B}j}\pi_R + C_{\mathcal{N}j}(1-\pi_R) \right]. \tag{4}$$

From Eq. (4), we deduce that $J(R, \mathcal{D}_R^{optimal}) \leq J(R, D_R)$ since the optimal classification rule results to the smallest average cost. Based on the last observation, Eq. (3) can be written as:

$$\tilde{J}_R \triangleq J(R, \mathcal{D}_R^{optimal}) = \min_{D_R} J(R, D_R) = \mathbb{E}\left\{ \sum_{n=1}^{R} c_n + g(\pi_R) \right\}, \tag{5}$$

which depends only on the stopping time R.

3.4 Stopping Rule

The solution for optimizing $\tilde{J}$ in Eq. (5) with respect to R can be determined by solving the optimization problem $\min_{R \geq 0} \tilde{J}_R = \min_{R \geq 0} \mathbb{E}\left\{ \sum_{n=1}^{R} c_n + g(\pi_R) \right\}$. This constitutes a classical problem in optimal stopping theory for Markov processes [32]. Since the stopping time R can take values in $\{0, 1, \ldots, K\}$, the optimum strategy will consist of a maximum of $K+1$ stages. In addition, Bellman's principle of optimality [2] states that the solution we seek must also be optimum, if instead of the first stage we start from any intermediate stage and continue toward the final stage. We derive our optimal stopping rule, $R^{optimal}$, as follows:

$$R^{optimal} = \min \left\{ 0 \leq n \leq K | S_n = \tilde{J}_n \right\}, \tag{6}$$

where for $n = K-1, \ldots, 0$, the n–th stage cost $S_n(\pi_n)$ is related to $S_{n+1}(\pi_{n+1})$ through the following recursion:

$$S_n(\pi_n) = \min \left[g(\pi_n), c_n + \int A_n(y_{n+1}) \times S_{n+1}\left(\frac{p(y_{n+1}|H_{\mathcal{B}})\pi_n}{A_n(y_{n+1})} \right) dy_{n+1} \right], \tag{7}$$

$A_n(y_{n+1}) \triangleq \pi_n p(y_{n+1}|H_{\mathcal{B}}) + (1-\pi_n) p(y_{n+1}|H_{\mathcal{N}})$ and $S_K(\pi_K) = g(\pi_K)$.

The optimal stopping rule derived by Eq. (7) has a very intuitive structure. *i.e.,* stop at the stage where the cost of stopping (the first expression in the minimization) is no greater than the expected cost of continuing given all information accumulated at the current stage (the second expression in the minimization).

3.5 Practical Considerations

In this section, we describe *CONcISE*, a novel algorithm for cyberbullying detection on Instagram media sessions based on Eq. (4) and Eq. (6). For each media session $s \in \mathcal{M}$, we maintain the number of aggressive comments identified at any given time along with the time of that classification. We use this information to decide when to raise an alert. Specifically, we set a threshold, and raise an alert the first time the number of comment–level detections surpasses that threshold. This design provides the flexibility of trading timeliness for false positives. To select the threshold t, we performed a grid search over values $\{2, 3, \ldots, 10\}$ and computed Area Under Receiver Operating Characteristic curves (AUC) scores of *CONcISE* as a function of t so as to optimize the precision–recall trade–off [3]. We found that best precision and recall is achieved when $t = 5$ (c.f. Section 4).

Within a given session s, the posterior probability π_0 of a given comment m is initially set to the prior probability p of a comment being an instance of aggression, and the two terms in Eq. (7) are compared. If the first term is less than the second, *CONcISE* classifies the comment based on the optimal rule of Eq. (4). Otherwise, the first feature is extracted from the comment and evaluated. *CONcISE* repeats these steps until either it decides to classify the given comment using $< K$ features, or all K features are examined.

4 EXPERIMENTAL EVALUATION

In this section, we provide a thorough experimental analysis to evaluate our proposed approach. All methods are implemented in Python, and all experiments were performed on a 64–bit machine with a dual–core Intel processor @2.7GHz and 16GB memory.

4.1 Baseline Methods

State–of–the–art Cyberbullying Detection Methods. We evaluate the effectiveness of *CONcISE* against the state–of–the–art for cyberbullying detection on Instagram, i.e., **DRFS [16]**, the best performing approach for cyberbullying detection on Twitter, **RF [6]** (i.e., **R**andom **F**orest classifier), adapted for Instagram with the best performing features used in [16], **DLR [27]** (i.e., **D**ynamic **L**ogistic **R**egression), the method for incremental cyberbullying detection on Vine [27], and **TM [7]**, a method that uses the entire history of all comments in a media session to derive a **T**emporal **M**odel for classification. Note that with the exception of [27], no research exists in the literature that addresses the challenge of timely cyberbullying detection by examining cyberbullying as a repetitive process.

Online Streaming Feature Selection Methods. Since our proposed approach, *CONcISE*, sequentially examines features one–by–one, as opposed to indiscriminately using a common set of features for all comments, we compare *CONcISE* with **SAOLA [40]** and **OFS–Density [46]**, i.e., the two best performing online streaming feature selection methods in terms of accuracy and scalability.

4.2 Dataset

We use the Instagram dataset collected by Hosseinmardi et al. [16]. The dataset has been originally collected using snowball sampling starting from a random seed node. For each user, all media the user shared, users who commented on the media, and the comments posted on the media have been collected. In total, the dataset contains 3,829,756 users and 9,828,760 comments. Of all media sessions which contain at least 40% profanities, 47.5% have been manually labeled as positive if "*there are negative words and/or comments with intent to harm someone or other, and the posts include two or more repeated negativity against a victim*" [16].

We augmented this dataset with $\sim 10K$ comment–level labels obtained from 10 experts. The comments span in total 22.1% of the media sessions with 40% or more profanity. We use this small subset of labeled comments for training, and the remaining unlabeled comments (i.e., 77.9% of labeled media sessions in the original dataset from [16]) for testing.

4.3 Offensive Language Dictionaries

For a fair comparison with **DRFS**, we use the exact same features (i.e., the counts of keywords 'ugly', 'shut', 'suck', 'gay', 'beautiful', 'sick', 'bitch', 'work', 'hate', and 'fuck') after removing punctuation marks and stopwords. To directly compare our approach with **DLR** [27], we consider the frequencies of 1,384 **profane** unigrams and bigrams [35]. We further consider a dictionary of 349 offensive unigrams and bigrams (**Noswearing**) [8] to examine the robustness of *CONcISE* on the dictionary used for detection. This results in three variants of *CONcISE*: **CONcISE–10**, **CONcISE–Profane**, and **CONcISE–Noswearing**, respectively, that use the corresponding dictionaries.

4.4 Comparison with Cyberbullying Detection State–of–the–art.

Table 1 summarizes the performance of *CONcISE* as compared to the state–of–the–art for cyberbullying detection, in terms of accuracy, recall and precision of the bullying class, area under the ROC curve (AUC), the average number (and standard deviation) of features used by our approach in detecting aggressive comments (similarly for the number of comments needed to detect a cyberbullying session). The best performing method is marked in bold.

Clearly, all three variants of *CONcISE* outperform the baselines, often by a considerable margin. At the same time, *CONcISE* significantly reduces both the average number of features used to classify individual comments as well as the number of comments examined before determining if a session is an instance of cyberbullying. Even though RDFS achieves the highest precision among all approaches, *CONcISE* consistently achieves the highest (or closely follows the highest) performance, with the additive advantage of using only a small percent of all features. Specifically, *CONcISE* uses up to 99.7% less features on average than the total number of features available (i.e., for Noswearing) to make a comment–level decision. Similarly, *CONcISE* uses at least 20.5% less comments on average than the best performing baseline (i.e., RF–comment with 33.07 comments on average) to make a decision at the media session level.

Table 1: Performance comparison of *CONcISE* with state–of–the–art cyberbullying detection methods.

Method	Accuracy	Recall	Precision	AUC	Avg. # of features (std.)	Avg. # of comments (std.)
RDFS	0.751	0.449	**0.858**	**0.877**	10 (0)	83
RF	0.791	0.703	0.749	0.862	13 (0)	83
DLR	0.497	0.651	0.616	0.521	4 (0)	35.90 (45.43)
DLR–10	0.733	0.463	0.760	0.684	10 (0)	35.37 (36.54)
DLR–Profane	0.522	0.644	0.638	0.541	1,384 (0)	47.70 (53.71)
DLR–Noswearing	0.762	0.598	0.743	0.733	349 (0)	45.26 (32.49)
TM	0.749	0.783	0.649	0.816	115(0)	83(0)
CONcISE–10	0.783	**0.794**	0.695	0.864	**2.97 (1.17)**	**26.68 (16.92)**
CONcISE–Profane	**0.806**	0.769	0.745	0.860	3.76 (3.19)	30.62 (21.82)
CONcISE–Noswearing	**0.806**	0.776	0.742	0.862	3.92 (2.16)	29.75 (21.09)

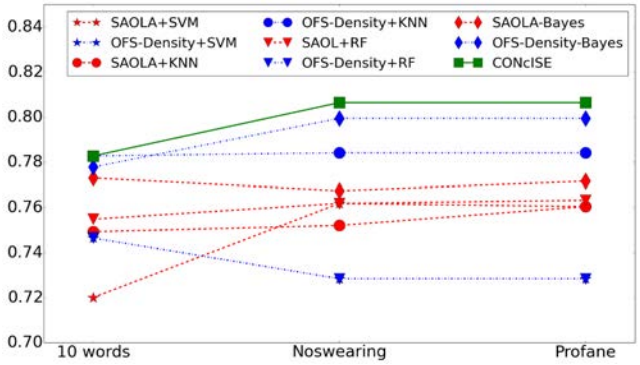

Figure 3: Accuracy comparison of *CONcISE*, SAOLA, and OFS–Density.

4.5 Comparison with State–of–the–art OSFS.

Next, we compare *CONcISE* to the baselines in terms of feature selection quality, over the feature space defined by the corresponding disctionary used, i.e., 10 unigrams, Noswearing and Profane dictionaries respectively. As SAOLA and OFS-Density do not perform classification in conjuction to feature selection, we use KNN, SVM, Random Forest and Standard Bayes for both baselines; KNN and SVM have previously been shown to achieve the highest classification performance in [40, 46]. We report the accuracy of *CONcISE*, as well as all combinations of baselines and classifiers. Figure 3 shows that *CONcISE* consistently outperforms OFS-Density and SAOLA over all 3 feature spaces.

4.6 Timeliness

To compare the best performing variance of *CONcISE*, namely, *CONcISE–Noswearing*, against baselines with respect to *timeliness*, we introduce a measure "# of saved comments" (as illustrated in Figure 4), defined as $i - j$ where i and j, respectively, denotes the number of comments that *CONcISE* and a given baseline have to inspect before raising an alert.

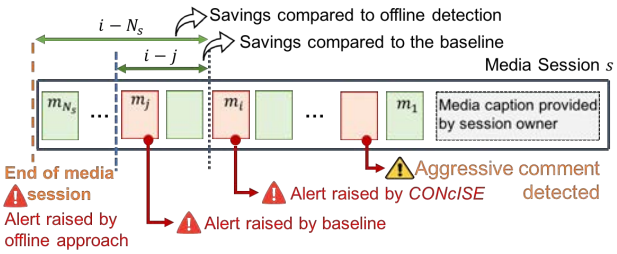

Figure 4: Illustration of timeliness, i.e., the number of comments "saved".

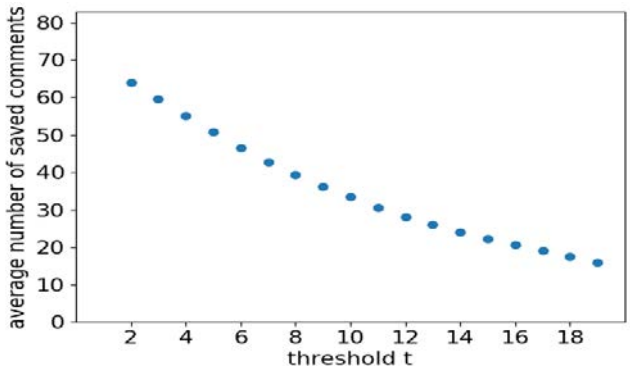

Figure 5: Average number of saved comments with respect to RDFS (a static method) as the threshold for comments detected as harassment content used to raise an alert increases.

By this definition, we respectively compare the timeliness of *CONcISE–Noswearing* to the best performing offline (i.e., RDFS) and online approaches (i.e., DLR–Noswearing), with respect to accuracy for varying threshold t. Figure 5 shows the absolute number of comments "saved" by CONcISE as compared to RDFS. As expected, the higher the threshold the more comments must be marked for harassment before an alert can be raised. Hence, the higher the threshold, the less the savings. Figure 6 shows the distribution of density of the number of saved comments as compared to DLR–Noswearing and provides strong evidence that *CONcISE–Noswearing* can detect cyberbullying media sessions faster than DLR–Noswearing (in addition to being more accurate) for all thresholds considered.

4.7 Scalability Analysis

We found baselines RDFS, RF, and TM to be the fastest among all methods with respect to runtime for session–level decisions, for an average of 0.0021, 0.0011, and 0.002 seconds respectively in making a session level decision. However, such "speed" is meaningless if considered in isolation to timeliness. Both RDFS, RF, and TM require all comments of a media session to be available for classification, making them offline for all practical purposes. The rest of the methods achieve similar runtime (s), ranging from 0.0077 to 0.0153 second per media session, with *CONcISE–10* being the fastest. Even though the difference may seem negligible for this dataset, considering a real–world scenario where a million media sessions are to be evaluated in real–time.

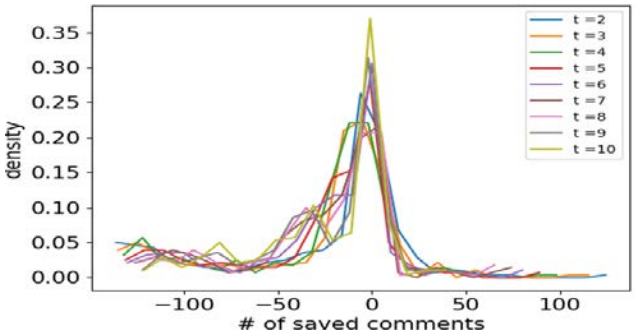

Figure 6: Distribution of average number of saved comments with respect to DLR–Noswearing for various thresholds.

5 CONCLUSION

Contributions. In this paper, we have proposed a novel approach for online cyberbullying detection on Instagram which can achieve *timely* and *accurate* detection while being *scalable* to the staggering rates at which content is generated. To achieve this goal, our two–stage approach begins by classifying comments in a media session as they become available, and an alert at the session level is raised when a threshold is exceeded. Our sequential hypothesis testing formulation drastically reduces the number of features used for classification, while maintaining high accuracy. Extensive evaluation experiments using a large–scale, real–world dataset from Instagram demonstrate the effectiveness of our proposed approach with respect to accuracy, timeliness, efficiency, and robustness, and show that it consistently outperforms the state–of–the–art, often by a considerable margin.

Limitations. Next, we would like to note the limitations of our present work that point to interesting future research directions. For one, our experimental evaluation is limited to a single dataset and therefore the performance of our approach should not be generalized to other platforms. Additionally, the inability to validate the labels in the dataset provided by [16] prevents us from obtaining a more granular understanding of the effect of false positives (similarly false negatives) on the accuracy of our approach. More importantly, comment–level labels, even though imperative for capturing the repetitive nature of cyberbullying as a process over a period of time, can be costly or time consuming to obtain.

Future Directions. There are several opportunities to build on this work. First, we plan to explore features such as user– and network–information and the sequence of conversations to further improve classification accuracy. We are also planning to evaluate the performance of our approach on additional datasets from diverse platforms including Ask.fm and Twitter, which are reported to be key social networking venues where users frequently become victims of cyberbullying. Given the broad definition of cyberbullying, we may also design detection strategies grounded in a more nuanced, multi–dimensional representation of repetitive harassment instead of striving for a global and/or simplified indicator of cyberbullying.

ABSTRACT

With the increasing of online shopping services, fashion recommendation plays an important role in daily online shopping scenes. A lot of recommender systems have been developed with visual information. However, few works take into account compatibility relationship when they are generating recommendations. The challenge is that fashion concept is often subtle and subjective for different customers. In this paper, we propose a fashion compatibility knowledge learning method that incorporates visual compatibility relationships as well as style information. We also propose a fashion recommendation method with domain adaptation strategy to alleviate the distribution gap between the items in target domain and the items of external compatible outfits. Our results indicate that the proposed method is capable of learning visual compatibility knowledge and outperforms all the baselines.

1 INTRODUCTION

A large portion of sales in the e-commerce are affected by fashion and lifestyle, which constitute apparel, footwear, bags, accessories, etc. Intelligent fashion recommendation received a lot of attention in computer vision and machine learning community [3, 9, 22]. They have huge potential profits for the fashion industry. A lot of companies have established their own recommender systems to give users advice to enhance their shopping experience, such as Amazon, Alibaba and eBay [14, 23].

Many approaches have been proposed to analyze user preferences on fashion criterion and generate personalized recommendation. Most of fashion recommendation approaches take into account characteristics of image, as visual information is one of the most important factor in describing fashion items [5, 9, 13]. Such approaches can substantially improve recommendation accuracy than others without visual information.

However, a few of them considers the problem of compatibility of fashion items. We know that when we choose a piece of clothing, it is not just a matter of considering the style of the dress. We also need to consider its effect with other clothes we wear. Some examples of compatibility and incompatibility outfits have been shown in Figure 1. Normally one would not pair a red T-shirt with green pants. Moreover, a black robe is incompatible with a pair of pink running shoes. This is partially because it is difficult to model compatibility relationship between fashion items.

When designing this recommendation system, we mainly consider the problem of learning visual compatibility relationship of items on pixel level. The visual compatibility relationship that needs to be learnt is whether fashion matching between one item and another item conforms to the human aesthetic by understanding the picture. In the traditional fashion recommendation, authors often only consider the styles and categories of clothes and ignore the sense of harmony between items as an outfit. In this paper, our approach considers visual compatibility relationship to recommend fashion items, which is closer to the actual needs of people.

(a) compatible outfits.

(b) incompatible outfits.

Figure 1: Examples of compatible and incompatible outfits.

In order to learn the knowledge of the matching model between fashion items, we face two challenges: 1) How to learn the common domain knowledge about fashion compatibility relationship between items. In other words, there are a few of outfits that we observed on the online shopping website for a single person and fashion concept is often subtle and subjective for different customers. 2) How to incorporate the learnt domain knowledge into our recommender system. For the first challenge, we propose a novel method to incorporate the compatibility relationship knowledge into the image representation. Our method allows learning an embedding from the images of the fashion items to a latent space, so that two items that is a good match are close in this latent space and items that don't match are far apart. An external dataset which contains a number of outfits being given by experts is also been used to train our model. For the second challenge, we adjust the popular Bayesian personalized ranking (BPR) [17] model to include the compatibility relationship knowledge that we learnt. Moreover, because we use the external dataset to learn the domain knowledge between the items in order to solve the problem of the distribution gap between the source domain and target domain, we propose a domain adaptation method to alleviate this difference.

In this paper, our contributions are as follows:

- We propose a fashion compatibility relationship learning method that incorporates visual compatibility relationships as well as style information into a visual embedding.
- We propose a fashion recommendation method with domain adaptation strategy to alleviate the distribution gap between the items in target domain and the items of external compatible outfits.
- We conduct a case study to illustrate how our method understands images. Furthermore, through an extensive set of experiments on several datasets, we demonstrate our method significantly outperforms several alternative methods.

The rest of this paper is organized as follows. In Section 2, we review some of the relevant methods. Section 3 introduces some notations and presents our approach in detail. The experiments and results analysis are demonstrated in Section 4. Lastly, conclusions and future work are discussed in Section 5.

2 RELATED WORK

In this section, we first review current approaches about visual fashion compatibility learning. Then we have a survey about fashion recommendation.

2.1 Visual Fashion Compatibility Learning

Visual compatibility measures whether fashion items complement one another across visual categories [1, 12, 20, 24]. For example, in Figure 1, a brown jacket is more compatible with a black casual pants. Oramas and Tuytelaars [15] introduced a hierarchical method to model visual compatibility by discovering mid-level visual elements. Li et al. [10] incorporated the appearances and metadata into their automatic composition system using an end-to-end deep neural network. Veit et al. [21] proposed a learning framework to recover a style space for fashion items from co-occurrence information and category labels which is able to learns compatibility between items. Han et al. [4] jointly train a Bi-LSTM model and a visual-sematic embedding for fashion compatibility learning. All of these methods are designed to generate outfits in which each item belongs to different categories. However, on one hand, category information is not accessible in many situations. On the other hand, these methods require a prior knowledge about which two categories can be put together. In contrast to these approaches, our method learns the compatibility relationships without a strict constraint of categories.

2.2 Fashion Recommendation

As mentioned above, there are a few approaches for recommending fashion items. One of the most famous method is visual Bayesian personalized ranking (VBPR) which learns user visual preference from implicit feedback [5]. The preference predictor in VBPR can be formulated as follows:

$$\hat{r}_{u,i} = \alpha + \beta_u + \beta_i + \gamma_u^T \gamma_i + \theta_u^T \theta_i \tag{1}$$

where α is the global offset, β_u and β_i are user/item bias, and γ_u and γ_i are latent feature vectors describing user u and item i, respectively, θ_u and θ_i are visual feature vectors of user u and item i. The inner product $\gamma_u^T \gamma_i$ and $\theta_u^T \theta_i$ indicates the scores that user u assigned to item i in terms of latent aspect and visual aspect.

This work improves the performance of recommender system significantly. The reason is that it incorporates visual information into the preference prediction model. However, in this approach, the authors did not consider the compatibility relationship between fashion items.

There are also other approaches which concentrate on fashion recommendation [2, 7, 8, 18]. Hu et al. [6] proposed a functional tensor factorization method to recommend outfits to users by learning from the interactions between user and fashion items. Packer et al. [16] learnt an interpretable image representation and modelled the dynamics of personalized users' visual preference to generate clothing recommendation. Liu et al. [11] separated style and category information from the image representation using a multilayer

Table 1: Major Notations Used in This Paper

Notation	Description
$\mathcal{U}, \mathcal{I}$	user set, item set
$\mathcal{V}$	image set of items
R	implicit feedback matrix
X	the set of images in clothing collocation dataset
C	clothing collocation pair list
$\mathcal{P}_u, \mathcal{V}_u, T_u$	positive item set of user u in training/validation/test sets
f_i	image representation vector of image i
γ_u, γ_i	latent features of user u, item i
θ_u, θ_i	visual features of user u, item i
W_{enc}, W_{dec}	weights of encoders and decoders, respectively

perceptron. However, all these methods only considered visual information and co-occurrence information from the online shopping website. It cannot sufficient learn compatibility relationship knowledge. In this paper, we utilize an external expert fashion collection dataset which contains a lot of good matches and propose a domain adaptation method to transfer the knowledge from the external dataset to our recommendation scene.

3 NOTATIONS AND PROBLEM FORMULATION

We first explain the symbols used in the next paper. We will consider $\mathcal{U}$ be the set of all users and $\mathcal{I}$ the set of all items. For each item, we have a corresponding images $\mathcal{V}_i$ which can represent this product. $R \subseteq len(\mathcal{U}) \times len(\mathcal{V})$ is the implicit feedback matrix whose rows correspond to customers and whose columns correspond to products. This means that $R_{ui} = 1$ stands for user u has bought item i, and 0 otherwise. We also have a hand-crafted clothing collocation dataset $X = \{x_1, x_2, ..., x_n\}$ labelled by experts which contains a set of clothing images and a clothing collocation pair list $C = \{(x_i, x_j)|x_i, x_j \in X\}$. Note that despite in the item set $\mathcal{V}$ and clothing collocation set X are both contains clothing images, the images in this two datasets are differences and no overlapped items. Furthermore, we can incorporate additional information like category data of products or demographic data about customers. However, we just focus on sales and visual information which is very important in fashion recommendation. Table 1 lists the major notations used throughout this paper.

The fashion recommendation task with visual compatibility relationship to be solved in this paper is to provide a personalized ranking list to each user with the help of visual information. First, given a set of fashion items $X = \{x_1, x_2, ...\}$ and collocations using these items C, learning visual compatibility knowledge is to learn an embedding $\mathcal{F}$ where the distance between item i and j, $d(\mathcal{F}(x_i), \mathcal{F}(x_i))$, is as small as possible if $(x_i, x_j) \in C$. After that, with user interaction records and item images, we try to learn the user's preference towards collaborative information and visual information to generate a ranking list for each user.

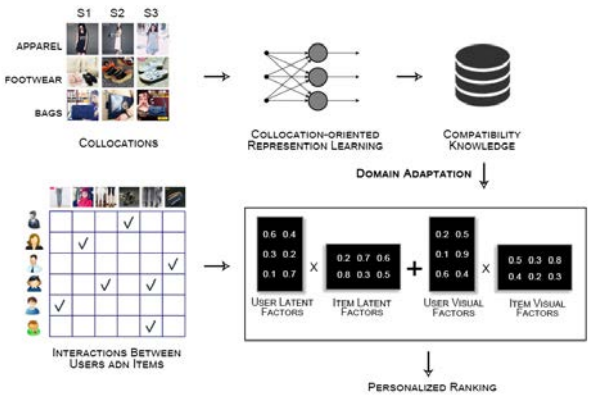

Figure 2: The proposed framework of our method.

4 ENHANCING FASHION RECOMMENDATION WITH VISUAL COMPATIBILITY RELATIONSHIP

We propose a fashion recommendation method which considers compatibility relationship between fashion items. In this method, we combine the collaborative information among users and items with compatibility knowledge. In order to allow the algorithm to understand the aesthetics of humans, we carefully construct an image representation model, through which we can determine what kind of information the resulting representation contains. This makes the computer learn the compatibility knowledge that people understand. After that, we incorporate the generated compatibility knowledge into our recommendation framework with a domain adaptation strategy. The framework of the entire recommender system is shown in Figure 2.

4.1 Learning visual compatibility knowledge from fashion items

In this section, our goal is to learn the visual compatibility relationships between fashion items. Conventional methods are mostly relying on category information to learn image representations. Instead of annotating images with labels or categories, which is costly, we leverage the weakly-labeled web data provided by the external dataset to learn compatibility knowledge.

Since there is no fixed category for the tasks we are going to perform, we cannot use the softmax-based cross entropy loss function for training. So, we chose triplet network to learn the image representation. The advantage of the triplet network is the distinction of details, that is, when the two inputs are similar, the triplet network can better model the details, which is equivalent to adding two measures of the difference of the input differences to learn a better representation of the input. The structure of the network is shown in the Figure 3.

In our task, we take the first item in an item pair in list C as an anchor, the second item as a positive sample, and select an item that is not in the list as the negative sample. More specifically, we can't randomly select negative samples on the entire candidate set, because this will cause $d(A, N)$ to be much larger than $d(A, P)$,

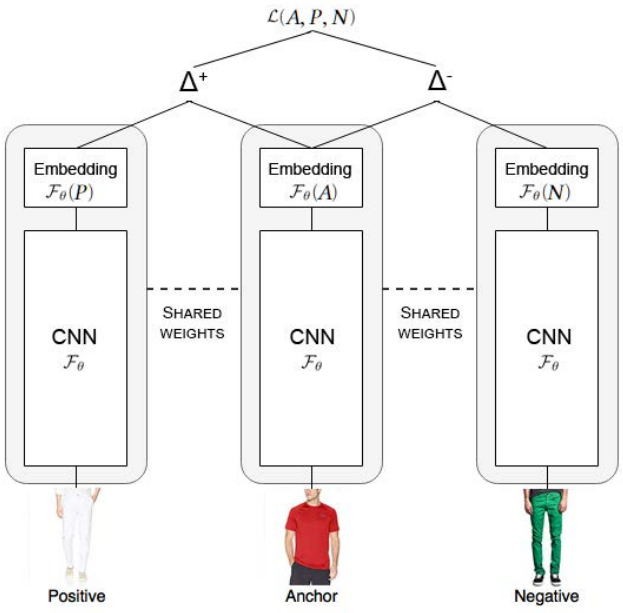

Figure 3: The illustration of our model for learning compatibility knowledge.

which will make the model unable to fully train and enter the prematurely. The state of the joint. So at each training, we need to choose a negative sample with $d(A, P)$ as close as possible to $d(A, N)$. This may make the model as difficult as possible to reduce the risk of overfitting.

Given a fashion image set, $X = \{x_1, x_2, ...\}$, x_i is a picture containing the t-th item. Also give a list $C = \{(x_i, x_j)|x_i \in X\}$ which denotes clothing collocation pairs. We need to learn a x_i to f_i mapping function, so that x_i and x_j are as close as possible, if the two items have good compatibility, and by contrast, the distance between f_i and f_j is as far as possible is i and j are not good compatibility. In other words, we try to learn a new representation of images. More formally, we minimize the following objective function:

$$\mathcal{L}(A, P, N) = max(||\mathcal{F}(A) - \mathcal{F}(P)||_2 - ||\mathcal{F}(A) - \mathcal{F}(N)||_2 + \alpha, 0) \quad (2)$$

where $\mathcal{F}$ is the mapping function. A is the anchor item, P is the item which have good compatibility with A, and N is not a good compatibility. α is the threshold parameter.

As shown in Figure 3, the network contains three sub-networks which shares weights with each other. In each sub-network, we encode the item image with Convolutional Neural Networks. There are many ConvNets architectures to choose from, and we use a variant of AlexNet for simplicity. The AlexNet variant, is the same as the original, except that we do not use pretrained weights and we replace local response normalization with batch normalization. We use the output of the fc6 layer as the encoding feature of the input image. The dimension of the image encoding is 4096.

Using more powerful architectures (e.g. [19]), may achieve better performance; however, we found that AlexNet is sufficient to show the effectiveness of our method. Because this network has fewer parameters, it can be trained more easily and reduces the risk of overfitting during training.

4.2 Fashion recommender system with visual compatibility knowledge

As mentioned above, the recommendation task can be regard as a ranking problem according to the user's preference. Our preference predictor is based on the basis of Matrix Factorization, which is the most promising model for rating prediction as well as modeling implicit feedback. The most related work to this problem is the VBPR model proposed in [5], which learns the visual user preference predictor using a pairwise ranking optimization framework.

We conduct our model based on pairwise learning. We defined the preference predictor as same as VBPR except for the reduce dimension method. To avoid missing information, we use an autoencoder to process dimension reducing. The formulation of encoder and decoder of autoencoder are as follows:

$$Enc(\mathcal{I}) = W_{enc} \cdot \mathcal{F}(\mathcal{I}) + b_{enc} \quad (3)$$

$$Dec(\mathcal{I}) = W_{dec} \cdot Enc(\mathcal{I}) + b_{dec} \quad (4)$$

Thus, the final preference predictor are as follows:

$$\hat{r}_{u,i} = \alpha + \beta_u + \beta_i + \gamma_u^T \gamma_i + \theta_u^T Enc(f_i) \quad (5)$$

For this implicit feedback ranking problem, we conduct the pairwise ranking optimization framework to train the model. The objective is as follows:

$$\max_\theta \sum_{(u,i,j) \in D_S} \ln \sigma\left(\hat{r}_{uij}\right) - \lambda_\Theta ||\Theta||^2 + ||f_i - \hat{f}_i||^2 + ||f_j - \hat{f}_j||^2 \quad (6)$$

where $\hat{r}_{uij} = \hat{r}_{u,i} - \hat{r}_{u,j}$.

Because the compatibility knowledge is learned from an external dataset also called source domain, images from the external dataset and the target dataset belong to different feature space. For example, in our experiments, the backgrounds of images in the source domain are very excursive. But in the target domain, the backgrounds are very clean and neat. Thus, we propose a domain adaption method which uses the domain adaptation technique to ensure that knowledge extracted from the source domain is consistent with the target domain and that knowledge transfer is positive.

When two items are bought by a customer at the same time, it regards as a co-occurrence pair. Most of the time, in the domain of fashion recommendation, we can assumption that the co-occurrence items should be a good clothing matching. Thus, we add the co-occurrence similarity into the objective above as follows to alleviate the distribution gap between source domain and target domain:

$$D_{i,j} = Frequent_{i,j} * ||Enc(f_i - f_j)|| \quad (7)$$

where $Frequent_{i,j}$ is the frequency of co-occurrence in the train set. When item i and item j are bought in a same bundle, we assume

that they are a good match, and the distance between them should be very closer.

In the training procedure, the training set D_S consists of triples in the form of (u, i, j, c), where u denotes the user and item i which they expressed positive feedback, and a non-observed item j. c is the co-occurrence frequency. It can be formalized by:

$$D_S = (u, i, j, c)|i \in I_u^+ \wedge j \in I_u^+ \tag{8}$$

The final formulation is as follows:

$$\sum_{(u,i,j)\in D_S} \ln \sigma\left(\hat{r}_{uij}\right) - \lambda_\Theta \|\Theta\|^2 + ||f_i - \hat{f}_i|| + ||f_j - \hat{f}_j|| + D_{i,j} \tag{9}$$

5 EXPERIMENTS AND ANALYSIS

We perform experiments on several datasets to evaluate the performance of the proposed method. All experiments were conducted on a workstation with a 6-core Intel CPU and two Titan-X (Pascal) graphics cards. Although there is a huge number of images and transaction records, it is still possible to train our model in half of day.

5.1 Datasets and evaluation metrics

The first dataset was provided by *Taobao.com* which is one of the most famous Chinese website for online shopping. It consists of clothing collocation suggestions from fashion experts, image data of Taobao items, and user behavior data. In this dataset, each line represents an item list which delimited by semicolon, every semicolon refers to a Collocation set. Every collocation set includes several goods, delimited by comma. We formatted this dataset into a pair-wise format, which means these two items is a good matching.

Another group of datasets contains user transaction records from two different sources. The first one were introduced in [5] and consist of reviews of clothing items crawled from *Amazon.com*. It was separated into 4 subcategories, named *Amazon Fashion*, *Amazon Women* and *Amazon Men*. The other one was crawled from *Tradesy.com*, which includes serveral kinds of feedback, like clicks, purchases, sales, etc.

The statistical information for the four datasets is provided in Table 2.

Table 2: Dataset statistics

Dataset	Users	Items	Interactions
Amazon Fashion	64,583	234,892	513,367
Amazon Women	97,678	347,591	827,678
Amazon Men	34,244	110,636	254,870
Tradesy.com	33,864	326,393	655,409

We measure recommendation performance of our method by calculating AUC and diversity. The AUC measures the quality of a ranking based on pairwise comparisons. Formally, we have

$$AUC = \frac{1}{|\mathcal{U}|} \sum_{u\in\mathcal{U}} \frac{1}{|\mathcal{D}_u|} \sum_{(i,j)\in\mathcal{D}_u} \xi\left(r_{u,i} > r_{u,j}\right) \tag{10}$$

where $\mathcal{D}_u = \{(i,j)|(u,i) \in \mathcal{T}_u \wedge (u,j) \notin (\mathcal{P}_u \cup \mathcal{V}_u \cup T_u)\}$. In other words, we are calculating the fraction of times that the 'observed' items i are preferred over 'non-observed' item j.

AUC is a typical metric to assess the recommendation performance in reproducing known user opinions that have been removed from the test dataset. The risk of such a metric is that, with recommendations based on similarity and overlap, customers will be exposed to a narrowing band of popular commodities. In other words, we also need other metrics to evaluate the recommendation performance.

Personalization, also named Inter-user diversity, considers the uniqueness of different customers' recommendation list. Given two users i and j, the different between their recommendation lists can be measured by the inter-list distance,

$$h_{ij}(L) = 1 - \frac{q_{ij}(L)}{L} \tag{11}$$

where $q_{ij}(L)$ is the number of common items in the top L places of the both lists: if the two lists are identical, $q_{ij}(L) = 0$ will equals 0 whereas completely different lists have $q_{ij}(L) = 1$.

Averaging $h_{ij}(L)$ over all pairs of users we obtain the mean distance $h(L)$, for which greater or lesser values mean, respectively, greater or lesser personalization of users' recommendation lists.

5.2 Experimental settings and baselines

We compared the proposed method in terms of accuracy and diversity against the following baselines:

- PopRank: Always recommends the top-k most popular items to users.
- BPR-MF (2009): This is a content-free algorithm based on matrix factorization which is designed for top-k recommendation tasks [17]. It optimizes pair-wise preferences between observed and unobserved items.
- VBPR (2016): It is a state-of-the-art image-based recommender system proposed by [5] for implicit feedback. The authors incorporate visual information provided by a pre-trained CNN.
- DVBPR (2017): This is the extension of VBPR by learning 'fashion aware' image representations directly [9].
- CO-BPR: Our method proposed in this paper.

We carefully choose the hyper-parameters and tuned them via grid search for each baseline method. For BPR-MF, VBPR, DVBPR and CO-BPR, we used a mini-batch size of 32 for all experiments. The number of latent factor selected from {6, 8, 10, 12, 14, 16, 18, 20}. We set it to be 12 in all experiments.

5.3 Results

We evaluated our proposed method by comparing it to state-of-the-art methods using some real-world datasets. We report recommendation performance in terms of the AUC and diversity in Table 3. Data with three sparsity ratios in target domain are chosen as training set. Comparing all the methods on these four datasets, we make the following observations:

Table 3: Recommendation Performance in Terms of AUC and Diversity with different sparsity

		AUC			Diversity		
		D=0.0010	D = 0.0005	D = 0.0001	D=0.0010	D = 0.0005	D = 0.0001

	BPR-MF	0.5969	0.6269	0.6447	0.5655	0.4583	0.3501
	VBPR	0.6754	0.6857	0.7164	0.9716	0.9760	0.9870
	DVBPR	0.6270	0.6471	0.6726	0.9796	0.9788	0.9797
	CO-BPR	**0.6815**	**0.6982**	**0.7358**	**0.9836**	**0.9902**	**0.9961**
Tradesy.com	*POPRANK*	0.4105	0.3939	0.4756	0.0000	0.0000	0.0000
	BPR-MF	0.5830	0.5763	0.5317	0.8522	0.8813	0.8694
	VBPR	0.6553	0.6819	0.6927	**0.9923**	**0.9964**	**0.9931**
	DVBPR	0.6134	0.6199	0.6497	0.9826	0.9920	0.9856
	CO-BPR	**0.6718**	**0.6873**	**0.7106**	0.9874	0.9901	0.9920

1) Compared with POPRANK method on Amazon datasets, the value of AUC increase with the increase of sparsity ratio. It tells us that customer more likely to purchase popular items on Amazon. However, on Tradesy.com, customers prefer to choose unpopular items.

2) Compared with methods without visual information, we can see that visual information substantially improve recommendation accuracy and diversity.

3) Compared with VBPR and DVBPR, we can see that learning visual compatibility relationship from an external dataset is very effective. Our proposed method CO-BPR outperforms all the comparison methods on all the four datasets. This demonstrates the significant benefits of generating recommendations with visual compatibility relationship.

Furthermore, to investigate the dimensionality sensitivity, we illustrate the performance of VBPR, DVBPR and CO-BPR with varying dimensionality in Figure 4. It is clear that both latent dimensionality and visual dimensionality are note very sensitive.

(a) latent dimensionality (b) visual dimensionality

Figure 4: Performance of VBPR, DVBPR and CO-BPR with varying dimensionality measured by AUC.

6 CONCLUSIONS AND FUTURE WORK

In this paper, we have introduced a novel method for the fashion recommendation task with learning compatibility knowledge in visual aspect. A triplet network is used to learn compatibility knowledge from an external dataset. Domain adaptation strategy is used to alleviate the distribution gap between source domain and target domain. The experimental results show that our method is superior to several baselines in the AUC and diversity indicators.

In the future work, we intend to combine the learned image representation with the human understandable semantics to improve the interpretability of the model. In addition, we will use the image segmentation method to learn collocation knowledge from unmarked street photos on the web, thus reducing the reliance on manual labeling datasets.

ABSTRACT

The recent increase in online user generated content (UGC) has led to the availability of a large number of posts about products and services. Often, these posts contain complaints that the consumers purchasing the products and services have. However, discovering and summarizing product defects and the related knowledge from large quantities of user posts is a difficult task. Traditional aspect opinion mining models, that aim to discover the product aspects and their corresponding opinions, are not sufficient to discover the product defect information from the user posts. In this paper, we propose the Product Defect Latent Dirichlet Allocation model (PDLDA), a probabilistic model that identifies domain-specific knowledge about product issues using interdependent three-dimensional topics: Component, Symptom, and Resolution. A Gibbs sampling based inference method for PDLDA is also introduced. To evaluate our model, we introduce three novel product review datasets. Both qualitative and quantitative evaluations show that the proposed model results in apparent improvement in the quality of discovered product defect information. Our model has the potential to benefit customers, manufacturers, and policy makers, by automatically discovering product defects from online data.

1 INTRODUCTION

The number of Internet users almost tripled (4.2 Billion in Dec. 2018) in the past decade, and 3.4 Billion among them are social media users [1]. As a result, a vast volume of online UGC, including product defect related posts, is produced every day. For example, the official database of National Highway Traffic Safety Administration (NHTSA) has more than 1 million complaints related to the automobile industry. Even more posts are submitted to vehicle quality forums such as `toyotanation.com` and `honda-tech.com`. Large numbers of complaints occur in the customer service logs of manufacturers as well. This feedback can be useful for new customers to make purchase decisions, for existing customers to find resolutions to the problems, and for the manufacturers to improve the quality of products and services. Thus, identifying and summarizing product defect and resolution information from online user generated content has wide utility.

I have a 2002 Ford Explorer. **The o/d light was flashing and the transmission was slipping**. *We took it to our mechanic and it was diagnosed that the transmission needed to replace*	**I have an application completely stuck off screen. When I click on it main screen comes back but not the application!** *What app is it? try starting in safe mode (depress shift key when starting). That startup takes a while*.

Figure 1: Examples of product defect posts (bold: symptom, *italic*: resolution).

Two product defect posts from NHTSA and Apple MacBook forum, containing defect and solution, are shown in Figure 1. There are two important types of sentences in the posts: sentences in bold which describe the symptoms of the problem, and sentences in italics which illustrate resolution efforts to diagnose and fix the issue. In addition, there are component words, which may occur in both symptom and resolution sentences, and which give focus to a part, aspect, or subsystem of the product. Component, symptom, and resolution characterize product defects, and often occur as key entities in (or attributes of) product defect posts.

Domain-specific product defect mining can be treated as a natural extension of aspect opinion mining. Pioneered by the success of LDA-based models [3] in discovering latent representations of text,

[1] https://www.internetworldstats.com/emarketing.htm;
https://www.brandwatch.com/blog/amazing-social-media-statistics-and-facts/

most of the aspect-opinion mining research uses two-dimensional topic models following an "aspect + opinion" pattern, to summarize users' comments on a specific aspect [4, 11, 14, 15, 25]. In a sample post *The screen is very clear and great* [21], *screen* is an aspect, while *clear* and *great* are positive opinions.

The following three considerations explicate the distinctions between aspect opinion mining and product defect mining.

- *Component* (or *aspect*) is important in both types of mining; defects are always related to some property/feature of a product.
- The *opinion* entity is not sufficient to describe the other essential types of defect information. A product post usually contains information on *symptom* and *resolution*, which state how the defect manifests, and the fixes users/mechanics tried, respectively. Instead of *{aspect, opinion}*, an entity pattern of the form *{component, symptom, resolution}* is needed for modeling defects.
- The occurrence pattern of the key entities in consumer posts is distinctive. Traditional aspect opinion mining classifies text into "aspect" and "opinion" entities at the word level, which often occur as **word pairs** (e.g., "screen" and "clear" in the last example) [11]. But product defect mining needs to segment entities (especially "symptom" and "resolution") at the sentence level. Instead of occurring as word pairs, entities appear as **word groups** of varied sizes in posts.

Considering the unique characteristics of the product defect mining problem, we develop PDLDA, a three-dimensional LDA-based probabilistic model, which has the following primary contributions:

- The proposed model identifies the key entities of product defects – *component*, *symptom*, and *resolution* – from user posts as interdependent three-dimensional topics. For each entity of a defect, we have a corresponding topic. These topics are connected by the dependencies among entities.
- In contrast to the traditional aspect-opinion models, the proposed PDLDA model does not require word pairs. Existing LDA models for aspect summarization [10, 20, 22] usually take word pairs (e.g., an aspect word and an opinion word) as input. In contrast, PDLDA accepts user posts which have varying numbers of component, symptom, and resolution words, and even those without symptom or resolution entities.
- We share new datasets with practical utility that also can be employed in future studies.

2 PROPOSED MODEL

2.1 Problem Definition

Our work aims to build a model that can effectively identify three key entities of defects: *component*, *symptom*, and *resolution*. Component words (e.g., "engine", "brake", "power train") point out the flawed units which may cause the defect. Symptom words (e.g., "acceleration", "hesitate", "fail") describe what a product defect looks like. In contrast, resolution words (e.g., "check", "replace", "reset") show how people attempt to diagnose and fix the issues. Each of these entities is comprised of words, which usually follow a multinomial distribution across post documents. Furthermore, both symptom words and resolution words rely on the defective components. Therefore, our **research problem** is: given a dataset with D posts, the PDLDA model should produce a component topic φ for each of the K defects, which is the core entity. The component topic should be followed by symptom topics ψ and resolution topics τ which depend on it. Together, these joint topics should provide comprehensive information about a defect.

Table 1: Notation used in this paper.

K	number of topics
D	number of posts (documents)
V_c, V_s, V_r	size of component, symptom, and resolution word vocabularies, respectively
N_c, N_s, N_r	number of component, symptom, and resolution words in a post, respectively
C, S, R	Component, Symptom, and Resolution words in the corpus
H	stands for parameters of all Dirichlet distributions, including α, β, δ, γ, ϵ in the graphical diagram
φ, ψ, τ	word distributions (multinomial) over component, symptom, and resolution topics
θ, η, π	component topic distribution (multinomial) over documents, symptom topic distribution over component topics, and resolution topic distribution over component topics
λ_s, λ_r	Bernoulli distribution which decides whether a regular or a background topic is assigned to a word
t_s, t_r	indicator variables that decide whether a word is generated from a regular ($t = 0$) or a background topic ($t = 1$), for symptom and resolution words
z_i, y_i, x_i	topic assigned to the i^{Th} component, symptom, or resolution word
$z^{\neg i}$,$y^{\neg i}$, $x^{\neg i}$	topic assignment vector for various types of words in the corpus excluding the i^{th} word
$n_c^T(d, k)$	number of component words in document d assigned to topic k; T represents topic distribution
$n_c^W(k, v_c)$	number of component words v_c assigned to component topic k; W represents word distribution
$n_s^T(k, l)$	number of symptom words assigned to topic l, whose corresponding component topic is k
$n_s^W(l, v_s)$	number of symptom words v_s assigned to symptom topic l
$n_r^T(k, m)$	number of resolution words assigned to topic m, whose corresponding component topic is k
$n_r^W(m, v_r)$	number of resolution words v_r assigned to resolution topic m
NTI_s, NTI_r	normalized $TF * IDF$ value of symptom or resolution word

2.2 Entity Extraction

When multiple types of entities are involved, we have to separate words of various types. In our case, we need to find the words belonging to component, symptom, and resolution entities, given a post. Some researchers [10, 20, 22, 24] classify words into categories before entering them into LDA models, while others assign a type to each word with the generative process [2, 16]. The first strategy is more efficient for product defect mining, since words in one sentence usually belong to the same entity (except that a component word may appear in symptom and resolution sentences). The entity extraction methods are introduced in Section 3.1.2 in detail.

2.3 PDLDA Model

As shown in Figure 2, PDLDA models key entities (component, symptom, and resolution) of defects with interdependent topics. There are three types of observed entities in the graphical model: component words (W_c), symptom words (W_s), and resolution words (W_r). The topics assigned to these words are z, y, and x, respectively. We use two conditional probability distributions η and π to model the dependence between symptom and resolution with the component. The notation used in our paper is described in Table 1. The post generation process is illustrated in Algorithm 1.

In the first five 1st-level loops, PDLDA determines the word distributions. For each component topic, a word distribution φ is

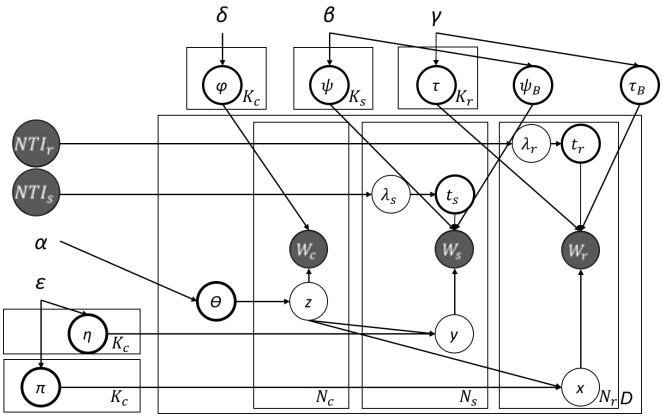

Figure 2: Plate notation of PDLDA model.

sampled from Dirichlet distribution δ. We also sample two corresponding symptom and resolution topic distributions, η and π, which depend on the component topic, from the Dirichlet distribution ϵ. They are used to create the dependence matrices. Word distributions ψ and τ for each symptom and resolution topic (both regular and background topics) are sampled, respectively.

The topic assignment is determined in the last 1st-level loop. Given a post d, we first sample a component topic z from Multinomial θ for each of the N_c component words in a document d. The component topic sampling is the same as with standard LDA. As a result, we get a set of topics, $Z_d = \{z_1, z_2, \cdots, z_{N_c}\}$. Next, to choose a y for each symptom word W_s, a component topic z' is randomly drawn from the component topic set Z_d, since we assume y depends on a certain z'. Then, we identify whether W_s is a *background* or *regular* symptom word by sampling an indicator t_s from a Bernoulli distribution λ_s. If the word is a regular symptom word ($t_s = 0$), we sample a symptom topic y from Multinomial $\eta_{z'}$ (a multinomial distribution assuming the current component topic is z') for each symptom word W_s, then sample the word from Multinomial ψ_y; otherwise ($t_s = 1$), the background symptom topic is assigned to the word, and we sample it from Multinomial ψ_B. The same sampling process is used during the generation of each resolution word W_r. Note PDLDA can be applied to a set of posts as long as they have a component entity; they do not have to have all three entities. PDLDA can sample topics for the existing entities even when a post has zero or one of: symptom or resolution entities.

A special feature of the PDLDA model is the presence of two switch variables t_s and t_r, which are designed to reduce overlap between different symptom (or resolution) topics. In particular, we give the most common words high probability of being assigned into a background symptom (or resolution) topic. Thus, a background topic will be formed by the words which are common to all the defects, such as "problem", "work", "stop". The TF-IDF value of a word is used to decide whether it is a background or a regular word. Specifically, we draw indicators t_s and t_r from Bernoulli distributions λ_s and λ_r, respectively. The parameter of these distribution is initialized by the Normalized TF-IDF value (NTI_s or NTI_r) of that word, in particular, $P(t_s = 0) = normalized\ TF * IDF$.

Algorithm 1: Post generation process of PDLDA

for *each component topic* **do**

  for *each comp word* W_c *of d* **do**
    Sample a *comp* topic $z \sim Multinomial(\theta_d)$
    Sample $W_c \sim Multinomial(\varphi_z)$
  for *each symp word* W_s *of d* **do**
    Draw a *comp* topic z' from the set of z
    Sample an indicator $t_s \sim Bernoulli(\lambda_s)$
    if $t_s = 0$ **then**
      Sample a *symp* topic $y \sim Multinomial(\eta_{z'})$
      Sample $W_s \sim Multinomial(\psi_y)$
    else if $t_s = 1$ **then**
      Sample $W_s \sim Multinomial(\psi_B)$
  for *each reso word* W_r *of d* **do**
    Draw a *comp* topic z' from the set of z
    Sample an indicator $t_r \sim Bernoulli(\lambda_r)$
    if $t_r = 0$ **then**
      Sample a *reso* topic $x \sim Multinomial(\pi_{z'})$
      Sample $W_r \sim Multinomial(\tau_x)$
    else if $t_r = 1$ **then**
      Sample $W_r \sim Multinomial(\tau_B)$

Using this sampling strategy, especially sampling a component topic for related symptom and resolution topics, we eliminate a key drawback of the existing aspect mining LDA models [10, 20, 22] which require word pairs. For these methods, the opinion topic sampling for an opinion word relies on the aspect topic assigned to the aspect word in that word pair[2].

2.4 Model Inference

We will now provide the details of the inference of the proposed model which uses collapsed Gibbs sampling. The Gibbs updating rules discussed below show how PDLDA assigns topics to the component, symptom, and resolution words in a post.

The Gibbs updating rule for a component word i is:

$$P(z_i = k|z^{\neg i}, C, H) \propto \frac{n_c^T(d,k) + \alpha_k - 1}{\sum_{k'=1}^{K}(n_c^T(d,k') + \alpha_{k'}) - 1} \cdot \frac{n_c^W(k, v_c) + \delta_{v_c} - 1}{\sum_{v'=1}^{V_c}(n_c^W(k,v') + \delta_{v'}) - 1} \quad (1)$$

[2]This is the main reason why these models only accept word pairs as input.

Table 2: Datasets used in our evaluation.

Datasets	All	Labeled	
	Posts	Posts	Clusters
FOCUS (98-04)	10,099	1,941	4
MACBOOK	2,098	413	5
Patient.info	43,928	43,928	10

Assuming the corresponding component topic of symptom word i is k, the Gibbs updating rule for symptom words is:

$$P(y_i = l|z, y^{\neg i}, S, H) \propto \frac{n_s^T(k,l) + \epsilon_l - 1}{\sum_{l'=1}^{K}(n_s^T(k,l') + \epsilon_{l'}) - 1} \cdot \frac{n_s^W(l, v_s) + \beta_{v_s} - 1}{\sum_{v'=1}^{V_s}(n_s^W(l,v') + \beta_{v'}) - 1} \quad (2)$$

Assuming the corresponding component topic of resolution word i is k, the Gibbs updating rule for resolution words is:

$$P(x_i = m|z, x^{\neg i}, R, H) \propto \frac{n_r^T(k,m) + \epsilon_m - 1}{\sum_{m'=1}^{K}(n_r^T(k,m') + \epsilon_{m'}) - 1} \cdot \frac{n_r^W(m, v_r) + \gamma_{v_r} - 1}{\sum_{v'=1}^{V_r}(n_r^W(m,v') + \gamma_{v'}) - 1} \quad (3)$$

As mentioned before, the model decides whether a symptom (or resolution) word should be assigned with a background or regular symptom (or resolution) topic based on its TF-IDF value. The TF-IDF value is normalized for each post and used to set the parameter of the Bernoulli distribution λ_s or λ_r, from which we sample the type (background or regular) of that word.

3 EVALUATION

3.1 Experimental Setup

3.1.1 Datasets. To evaluate the usability of our model on different kinds of data, we use a wide range of datasets for our evaluation, including the complaint database of NHTSA[3], the problem discussion threads in the official forum of Apple[4], and the disease discussion threads in the Patient.info forum[5]. In the NHTSA and Apple datasets, we aim to discover the product defects and resolutions. In the Patient.info dataset, the human diseases can be considered analogous to product defects, and we aim to find their treatments, which are analogous to defect resolutions. Products which received the most complaints are selected from those data sources, and a post dataset is constructed for each, shown in Table 2. Specifically, we select posts of FORD FOCUS (1998-2004), Apple MacBook, and Patient.info to create 3 datasets. The entire datasets are used for topic coherence and qualitative evaluation. In addition, subsets of these datasets are manually labeled for post clustering evaluation. The post clusters are manually tagged by four Virginia Tech undergraduate students (each post tagged by 2 students), with an inter-annotator agreement rate of 81.2%. The post and cluster count of subsets are shown in columns 3 and 4 in Table 2.

[3]https://www-odi.nhtsa.dot.gov/downloads/flatfiles.cfm
[4]https://discussions.apple.com
[5]https://patient.info/forums

3.1.2 Data Preprocessing. Since this research primarily focusses more on the design of the topic model, rather than segmentation of the entities, we used light weight methods to implement entity segmentation. The frequent item set mining approach is used to extract components in all the datasets, by following the method introduced in [8]. Regarding the extraction of symptom and resolution entities, different strategies are used on various datasets.

- For the Apple forum and Patient.info datasets, we rely on the thread structure to separate them. Each forum thread is taken as a document. Then, we take the sentences in the first post as symptom sentences and those in the "most recommended solution" post as resolution sentences.
- A lexicon-based method is applied to the NHTSA datasets. Three types of sentences exist in the NHTSA posts: ownership, symptom, and resolution. We go through the sentences of a small dataset which has 400 posts of different vehicle models, find the feature words (e.g., "buy", "purchase", and "own") of ownership sentences, and find the feature words (e.g., "fix", "remedy", and "resolve") of resolution sentences. In this way, two lexicons are created, which will help decide the sentence type according to the lexicon word occurrence.

Topic models are quite sensitive to noise such as stop-words. Thus, a filter based on POS tagging further removes less-informative candidate symptom and resolution words. Based on our observations, we assume the most informative words are nouns, verbs, and adjectives. We apply the Stanford POS tagger [18] to symptom and resolution sentences, keeping only nouns, verbs, and adjectives. Then, we can provide observations (three entities for each post) to the PDLDA model.

3.1.3 Implementation and Parameter Setting. PDLDA is implemented in Java. We use symmetric priors for the Dirichlet distribution parameters $\alpha, \beta, \delta, \gamma$, and ϵ, and set them with empirically derived values $\alpha = 0.01$, $\beta = \gamma = \delta = \epsilon = 0.001$.

3.2 Performance Evaluation

3.2.1 Evaluation Criteria. Both quantitative and qualitative evaluations are conducted for the evaluation of the proposed PDLDA model.

- *Entity Clustering Accuracy*: Precision, Recall, and F-Measure [11] metrics are selected to measure entity (e.g., symptom and resolution) clustering performance. We follow the process introduced in [23] to calculate them.
- *Topic Coherence*: The Pointwise Mutual Information (PMI) metric [12] is chosen for topic coherence measurement.
- *Qualitative Evaluation*: The defects of different product models are identified from posts as joint topics.

3.2.2 Baseline Methods.

- *Standard LDA* [3]: After entity extraction using the methods in the last section, we run standard LDA on the words of three entities separately to get three kinds of topics.
- *ILDA* [10]: We get the component (aspect) and the symptom (opinion) topics by taking symptom sentences as input, and get the component (aspect) and the resolution (opinion) topics from resolution sentences. A dependency parser [5] is used to extract aspect and opinion entities.

Table 3: Average Precision, Recall, and F-1 (%) of post entity clustering.

Dataset	FORD FOCUS						APPLE MacBook						Patient.info					
Entity	Symptom			Resolution			Symptom			Resolution			Symptom			Resolution		
Method	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F

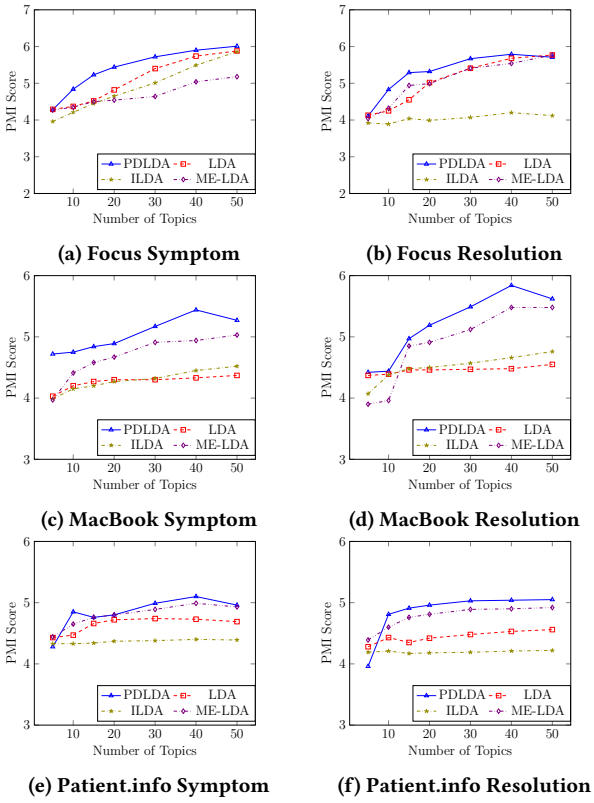
PDLDA	**88.82**	**57.08**	**59.24**	**91.36**	**33.34**	**43.51**	**57.7**	32.84	**35.29**	**49.62**	30.25	**33.69**	**53.82**	**43.82**	**44.52**	**36.96**	**30.56**	**31.15**

- *ME-LDA* [25]: We use the same input used in ILDA to produce topics by ME-LDA. Our own component lexicon and the opinion lexicon in [8] are used to label word types.



3.3 Experimental Results

3.3.1 Post Clustering. For this evaluation, the posts are clustered along two dimensions. First, they are clustered according to the symptom entity, then according to the resolution entity, using different models. When clustering symptom entities of posts, we take the symptom topic ID assigned to the majority of symptom words of a post as its symptom cluster. A similar clustering process occurs when the posts are clustered according to their resolution entities.

The clustering performance on the three datasets is shown in Table 3. We can see the precision and F-measure of PDLDA are better than the baselines, for both symptom and resolution clustering on all the datasets. ME-LDA has better recall on the MacBook dataset. Since PDLDA jointly models the three entities, it leverages the influence of component entities when clustering dependent entities. Therefore, it outperforms the standard LDA. In addition, PDLDA extracts more reasonable words on product defects than ILDA and ME-LDA; thus it captures more important features when clustering post entities. Also, the clustering performance on resolution entities is low for all of the models, compared to the symptom entities. This reveals that the words in resolution sentences are more difficult to separate. We observe that the words describing problem fixing measures are quite common, especially when we exclude the component words.

3.3.2 Topic Coherence. The topic coherence scores over 3 datasets are shown in Figure 3. Since the sampling of component topics in PDLDA is the same as the standard LDA, they perform quite similarly in terms of the topic coherence of components. Thus we only show the topic coherence of symptom and resolution topics. PDLDA outperforms the baseline methods in most cases, especially when the number of topics is over 15. Both the topic interdependency and entity identification mechanisms contribute to this. The PMI of PDLDA stops increasing and converges to the baselines when the topic number is very large. A possible reason is, the actual number of topics in the datasets is limited; thus, more overlap among topics occurs along with the topic number increase, which may prevent the PMI increase. ME-LDA outperforms LDA and ILDA, as it benefits from incorporating prior knowledge (i.e., tagged word types) when identifying word types. Simple models (LDA and ILDA) perform better when the number of topics is small (e.g., 5 topics).

3.3.3 Qualitative Evaluation. While capturing critical defects of a vehicle model, PDLDA uses joint topics, composed of the most probable component, symptom, and resolution words, to show the defect information. In our output, each defect is led by its

(a) Focus Symptom (b) Focus Resolution

(c) MacBook Symptom (d) MacBook Resolution

(e) Patient.info Symptom (f) Patient.info Resolution

Figure 3: PMI coherence of symptom and resolution topics.

component topic, followed by relevant symptom and resolution topics. The component topic distribution $p(\theta_{d,k})$ in document d is determined by Eq. (4). Given the component topic k, the most relevant symptom topic l can be obtained by sorting $\eta_{k,l}$, which is calculated by Eq. (5). Similarly, the most relevant resolution topic m given component topic k is obtained by sorting $\pi_{k,m}$, which is calculated by Eq. (6). The keywords of all types of topics can be figured out using the second part of the Gibbs updating rules.

$$\theta_{d,k} = \frac{n_c^T(d,k) + \alpha_k}{\sum_{k'=1}^{K}(n_c^T(d,k') + \alpha_{k'})} \tag{4}$$

$$\eta_{k,l} = \frac{n_s^T(k,l) + \epsilon_l}{\sum_{l'=1}^{K}(n_s^T(k,l') + \epsilon_{l'})} \tag{5}$$

$$\pi_{k,m} = \frac{n_r^T(k,m) + \epsilon_m}{\sum_{m'=1}^{K}(n_r^T(k,m') + \epsilon_{m'})} \tag{6}$$

Table 4: Example of topics extracted by LDA, ILDA, ME-LDA, and PDLDA (Nonrelevant words of each topic are underlined).

Component				Symptom				Resolution			
LDA	**ILDA**	**ME-LDA**	**PDLDA**	**LDA**	**ILDA**	**ME-LDA**	**PDLDA**	**LDA**	**ILDA**	**ME-LDA**	**PDLDA**
ignition	key	lock	ignition	turn	ford	turn	turn	dealer	have	replace	tow
key	focus	steer	key	lock	start	ignition	lock	contact	ford	ignition	lock
cylinder	car	remove	cylinder	start	turn	steer	key	repair	take	key	key
lock	vehicle	rotor	lock	steer	key	wheel	insert	maker	numerous	turn	locksmith
wheel	problem	open	wheel	key	put	lock	park	failure	recall	tow	call
				stick	get	start	stick	shop	resolve	start	drill
				unable	insert	key	remove	aware	receive	lock	common
				put	go	work	place	local	ignition	work	tumbler
				set	ignition	attempt	unlock	advise	get	call	advise
				unlock	common	stick	freeze	owner	defective	leave	aaa

Due to space constraints, Table 4 shows joint topics only for the "ignition" issue of FOCUS 98-04. The top 5 words are shown for component topics, while the top 10 words are shown for symptom/resolution topics. Looking at the joint topics produced by PDLDA, we see that the ignition component problem caused the key stuck in the lock so it could not turn, which was resolved by car towing and locksmith service. For each defect, users can locate the flawed units by reading the component topic, then learn what happens and how it is fixed, by reading the dependent topics. The nonrelevant words in the topics are underlined, through which we can see the topics generated by PDLDA have fewer nonrelevant and general words (e.g., "put" and "get" in column 6).

As demonstrated above, PDLDA can effectively and accurately identify defects and related solutions of products from online UGC, especially for products which people can fix by themselves, such as vehicles, electronics, etc. And it can also help patients find the symptoms and related treatments of diseases. Based on them, customers can make purchase decisions, manufacturers can improve products, governments can undertake administrative actions, and patients can find useful information for disease diagnosis and treatment.

4 RELATED WORK

Product defect mining is an extension of aspect-based opinion mining which has not been thoroughly investigated in the literature. Earlier works on product defect mining [1] classified product defects, as discussed in online forums, according to the level of severity. This method attempted to discover whether a defect exists in a review, or the severity of the defect, but did not account for the details of the defect (e.g. symptoms). Later, Tutubalina and Ivanov [19] extracted key phrases on product problems from user reviews according to the syntax dependencies among words. But, it relies on pre-defined syntax dependency rules, which is hard to generalize.

LDA based models have been successfully used for aspect-based opinion mining, and have incorporated various related factors, due to the unsupervised and flexible characteristics of LDA. Titov and McDonald [17] separated global and local opinion topics using a multiple-grain LDA model. Lin and He [9] pointed out the importance of sentiment in terms of opinion mining and added it as a key latent variable in their topic model. Zhao et al. [25] proposed a Maximum Entropy-LDA hybrid model to separate aspect words and aspect-specific opinion words. Ahuja et al. [2] incorporated Geotaggers into their aspect-opinion model by assuming people living in different places may discuss different topics and hold varied opinions. Park et al. [13] proposed an LDA model which connected Mobile Application (APP) descriptions with corresponding reviews in order to improve mobile APP searching. A holistic model which included most of the above key entities (e.g., aspect, opinion, sentiment, and granularity) was proposed by Wang et al. [21]. They further boosted their LDA model with domain knowledge learned by lifelong machine learning, which can be regarded as an extension of [7] and [6]. Rakesh et al. [16] suggested a spike-and-slab prior over the document-topic distribution, which generates fine-grained summaries of online reviews. However, the entities captured by these traditional aspect opinion mining models are not specific enough for product defect mining. In addition, these models cannot adapt to the characteristics of defect description (e.g., key entity locations).

5 CONCLUSION

This paper addresses the problem of product defect identification. To identify the key information of product defects, we develop a PDLDA model which extracts interdependent topics (component, symptom, and resolution) from UGC. This model differs from existing aspect summarization models as it jointly identifies the key entities of product defects as interdependent three-dimensional topics. In addition, PDLDA eliminates the dependence on word pairs that are required by the existing models. Collapsed Gibbs sampling is used for model inference. Both quantitative and qualitative evaluations are performed. PDLDA is shown to effectively identify product defects and to outperform existing methods. Since the (three) types of entities modeled by PDLDA frequently exist in the posts on different products, it can be easily generalized to health applications as well as other products, especially to products which people can fix by themselves, such as software, cell phones, cameras, etc. As future work, we plan to explore other entities related to product defects, such as user requirements and product improvements. The datasets and code will be released on Github[6].

ABSTRACT

Due to its anonymity, there has been a dramatic growth of underground drug markets hosted in the darknet (e.g., Dream Market and Valhalla). To combat drug trafficking (a.k.a. illicit drug trading) in the cyberspace, there is an urgent need for automatic analysis of participants in darknet markets. However, one of the key challenges is that drug traffickers (i.e., vendors) may maintain multiple accounts across different markets or within the same market. To address this issue, in this paper, we propose and develop an intelligent system named *uStyle-uID* leveraging both writing and photography styles for drug trafficker identification at the first attempt. At the core of *uStyle-uID* is an attributed heterogeneous information network (AHIN) which elegantly integrates both writing and photography styles along with the text and photo contents, as well as other supporting attributes (i.e., trafficker and drug information) and various kinds of relations. Built on the constructed AHIN, to efficiently measure the relatedness over nodes (i.e., traffickers) in the constructed AHIN, we propose a new network embedding model *Vendor2Vec* to learn the low-dimensional representations for the nodes in AHIN, which leverages complementary attribute information attached in the nodes to guide the meta-path based random walk for path instances sampling. After that, we devise a learning model named *vIdentifier* to classify if a given pair of traffickers are the same individual. Comprehensive experiments on the data collections from four different darknet markets are conducted to validate the effectiveness of *uStyle-uID* which integrates our proposed method in drug trafficker identification by comparisons with alternative approaches.

1 INTRODUCTION

The market of illicit drugs (e.g., cannabis, cocaine, heroin) is considerably lucrative - i.e., the estimated yearly revenue for the global market reached about $426-$652 billion in 2017 [23]. Driven by such remarkable profits, the crime of drug trafficking (a.k.a. illicit drug trading) has never stopped but co-evolved along with the advance of modern technologies [4, 16, 17, 28, 32, 38, 39]. Darknet, as a hidden part of the Internet, employs advanced encryption techniques to protect the anonymity of its users. The markets hosted in the darknet are built on The Onion Router (TOR) service to hide the IP address, the escrow system, the encrypted communication tools like Pretty Good Privacy (PGP), and the virtually untraceable cryptocurrency (e.g., bitcoin) to facilitate anonymous transactions among participants. Figure 1.(a) illustrates a typical transaction in darknet markets. Due to its anonymity, there has been a dramatic growth of underground drug markets hosted in the darknet (e.g., Silk Road 3 [33], Dream Market [27], Valhalla [37], known as "eBay of drugs" or "Amazon of drugs"). Illegal trading of drugs in these markets has turned into a serious global concern because of its severe consequences on society (e.g., violent crimes) and public health at regional, national and international levels [8].

To combat drug trafficking in the cyberspace, there is an urgent need for analysis of participants in darknet markets, as it could provide valuable insight to the investigation of drug trafficking ecosystem and prediction of future incidents while building proactive defenses [6]. However, one of the key challenges is that drug traffickers may maintain multiple accounts across different markets or in the same market for the reasons [2, 4, 34] such as ripper (i.e.,

(a) A typical transaction in darknet market.

(b) Illicit drug advertised by a trafficker (i.e., vender) in darknet market.

(c) Illustration of writing & photography styles.

Figure 1: Illustration of drug trafficking in Darknet market.

an old account has lost the trust of other members), branding (i.e., a vendor creates an alias to positively review his/her own products or services), and anonymity. Linking different accounts to the same individuals is essential to track their status and better understand the online drug trafficking ecosystem [40]. Given the growing scale of darknet markets and the large number of user accounts, it is simply impossible to manually link suspicious accounts and track their latest status. Therefore, it is highly desirable to develop novel methodologies that can automatically link multiple accounts of the same individuals in darknet markets.

To automate the process, some of existing approaches [2, 5, 20] relied on stylometry analysis which aims at linking different accounts to the same user based on his/her writing styles (e.g., as illustrated in Figure 1.(b) and (c), the vendor likes using specific emoticon in the product description). Since drug traffickers in darkent markets have to prove the possession of illegal drugs by posting their own product photos, their distinct photography styles might be revealed by the posted photos. A recent research [40] proposed to link multiple accounts of the same vendors in different darknet markets based on their distinct photography styles (e.g., the way to display products and camera model as shown in Figure 1.(c)). Though each kind of analysis has shown success in fingerprinting underground market participants, using them respectively may suffer different challenges (e.g., stylometry analysis only is sensitive to the language of content [40], while photography style analysis only may face the challenge of intrinsic ambiguity arising from resale or photo plagiarizing). *Can we leverage both writing and photography styles to develop an integrated framework for drug trafficker identification in darknet markets?* To the best of our knowledge, this has yet studied in the open literature.

In this paper, we propose to leverage both writing and photography styles to develop an intelligent system (named *uStyle-uID*) to automatically link multiple accounts of the same individuals for drug trafficker identification in darknet markets. In *uStyle-uID*, given a pair of vendors (denoted by their usernames in the related markets), to determine whether they are the same individual, we not only analyze their posted contents (i.e., including their posted texts and photos), but also consider their writing styles and photography styles as well as other supporting attributes (i.e., vendor and drug information) and various kinds of relations. To depict vendors, drugs, texts, photos and their associated attributes as well as the rich relations among them, we present an attributed heterogeneous information network (AHIN) [26] for modeling. To tackle the challenge of high computation cost and memory constraint of measuring the relatedness over vendors in the constructed AHIN, we propose a new network embedding model named *Vendor2Vec* to learn low-dimensional attribute-aware embeddings for the nodes in AHIN. The proposed *Vendor2Vec* model leverages complementary attribute information of each node to guide the meta-path based random walk for path-instance sampling; then a skip-gram model [30] is utilized to learn effective node representations for AHIN. Finally, based on the learned latent representations of the nodes (i.e., vendors) in AHIN, we devise a learning model named *vIdentifier* to classify whether a given pair of vendors are the same individual.

2 PROPOSED METHOD

The overview of our developed system *uStyle-uID* for drug trafficker identification in darknet markets is shown in Figure 2. In this section, we will introduce the detailed approaches which are integrated in *uStyle-uID* for drug trafficker identification.

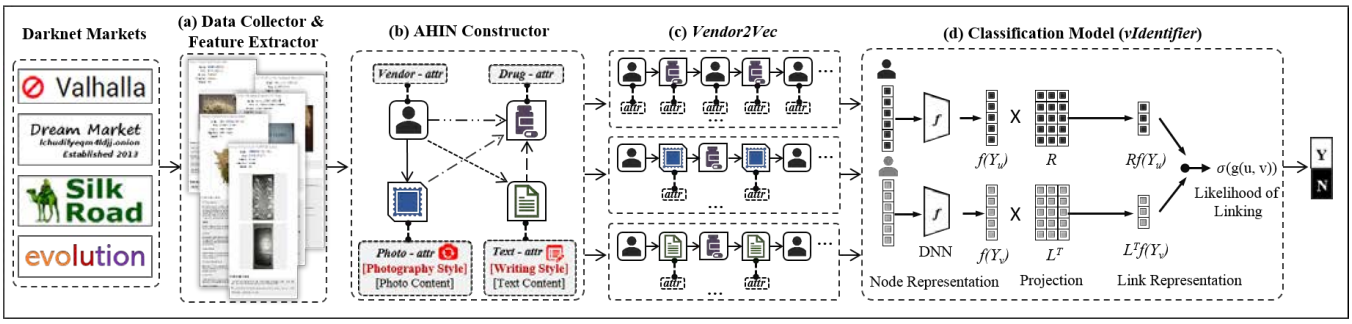

Figure 2: System architecture of *uStyle-uID*.

2.1 Feature Extraction

We propose to characterize vendors in darknet markets in a comprehensive view by extracting various features.

(1) Posted text and writing style extraction. To fingerprint a vendor based on his/her posted texts, we consider both his/her posted text content and writing style. For text content, we apply *doc2vec* [25] to convert each text of variant size into a fixed length feature vector (empirically, we set the dimension to 100). For writing style [2, 20], we propose to extract multi-scale stylometry features at three different levels as follows: 1) ***Lexical features*** can be further divided into character-based and word-based groups to capture stylistic traits. At this level, we extract *i*) number of characters, *ii*) number of digits/white spaces/special characters, *iii*) number of words, *iv*) average word length, and *v*) vocabulary richness [36]. 2) ***Syntactic features*** capture the writing style from the sentence structure. In this category, we adopt *i*) frequency of punctuation, *ii*) frequency of function word, *iii*) number of sentences beginning with a capital letter, and *iv*) frequency of parts-of-speech *n*-grams (we set $n = 3$ in our case). 3) ***Structural features*** represent the way an author organizes the layout of his/her posted text. We consider *i*) total number of paragraphs, *ii*) indentation of paragraph, *iii*) whether there's separator between paragraphs, and *iv*) number of words/sentences/characters per paragraph. For each posted text, we then concatenate its converted feature vector representing the posted text content and the feature vector describing its writing style as an attribute associated with this posted text.

(2) Posted photo and photography style extraction. To represent the content of a posted photo, we propose to utilize *image2vec* [15] to convert it into a fixed length feature vector (empirically, we set the dimension to 100). Since drug traffickers in darkent markets have to prove the possession of illegal drugs by posting their own product photos, their distinct photography style might be revealed by the posted photos. We propose to capture the photography style by extracting its *low-level* and *high-level* features. 1) ***Low-level features*** refer to the information that can be directly obtained from a photo's exchangeable image file format (EXIF) data, which include *i*) camera make and model, *ii*) camera angle, *iii*) exposure time, *iv*) focal length, and *v*) image size. 2) ***High-level features*** are extracted from the photo's original content. We first convert the photo into its HSV (hue, saturation, value) representation and then extract the following five types of high-level features: *i*) colorfulness, *ii*) exposure of light, *iii*) saturation, *iv*) hue count, and *v*) contrast. In our current implementation, colorfulness, exposure of light and saturation are calculated using the method in [7]; while hue count and contrast are measured by [24]. For each posted photo by a vendor, we then concatenate its converted feature vector representing the posted photo content and the feature vector describing its photography style as an attribute associated with this posted photo.

(3) Attributed features of vendors and drugs. Besides the above extracted features, vendors' basic information and drugs they sell also play an important role in resolving their identities. Therefore, we further extract three kinds of features to depict each vendor: *username*, *PGP key* and *contact information*. Note that, for username, we first apply standard string matching techniques to measure the similarity of two usernames, if their similarity is greater than a user-specific threshold, we regard these two usernames as the same (e.g., "MF***Jones" and "MF***J0nes"). For each drug, we further extract its *category, escrow information* and *shipping information* (e.g., from where and to where). Then, we apply one-hot encoding [41] to convert the extracted features to a binary feature vector to be an attribute associated with each vendor/drug.

(4) Relation-based Features. In order to characterize the rich relations among vendors, drugs, posted texts and photos, we further extract the following relation-based features: 1) ***R1***: the *vendor-sell-drug* relation indicates whether a vendor sells a drug; 2) ***R2***: the *vendor-write-text* relation denotes if a vendor writes a text; 3) ***R3***: the *vendor-post-photo* relation indicates whether a vendor posts a photo; 4) ***R4***: the *text-describe-drug* relation denotes whether a text describes a drug; 5) ***R5***: the *photo-characterize-drug* relation indicates if a photo characterizes a drug.

2.2 AHIN Construction

Though heterogeneous information network (HIN) [35] has shown the success of modeling different types of entities and relations, it has limited capability of modeling additional attributes attached to entities. Thus, to depict vendors, drugs, texts, photos and their associated attributes as well as the rich relationships among them, we propose to use attributed HIN (AHIN) for representation.

Definition 2.1. ***Attributed heterogeneous information network (AHIN)*** [26]. Let $\mathcal{T} = \{T_1, ..., T_m\}$ be a set of m entity types. For each entity type T_i, let $\mathcal{X}_i$ be the set of entities of type T_i and A_i be the set of attributes defined for entities of type T_i. An entity x_j of type T_i is associated with an attribute vector $\mathbf{f}_j = (f_{j1}, f_{j2}, ..., f_{j|A_i|})$. An AHIN is defined by a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{A})$ with an *entity* type

mapping $\phi: \mathcal{V} \rightarrow \mathcal{T}$ and a *relation* type mapping $\psi: \mathcal{E} \rightarrow \mathcal{R}$, where $\mathcal{V} = \bigcup_{i=1}^{m} \mathcal{X}_i$ denotes the entity set and $\mathcal{E}$ is the relation set, $\mathcal{T}$ denotes the entity type set and $\mathcal{R}$ is the relation type set, $\mathcal{A} = \bigcup_{i=1}^{m} A_i$, and the number of entity types $|\mathcal{T}| > 1$ or the number of relation types $|\mathcal{R}| > 1$. The ***network schema*** [26] for an AHIN $\mathcal{G}$, denoted by $\mathcal{T}_\mathcal{G} = (\mathcal{T}, \mathcal{R})$, is a graph with nodes as entity types from $\mathcal{T}$ and edges as relation types from $\mathcal{R}$.

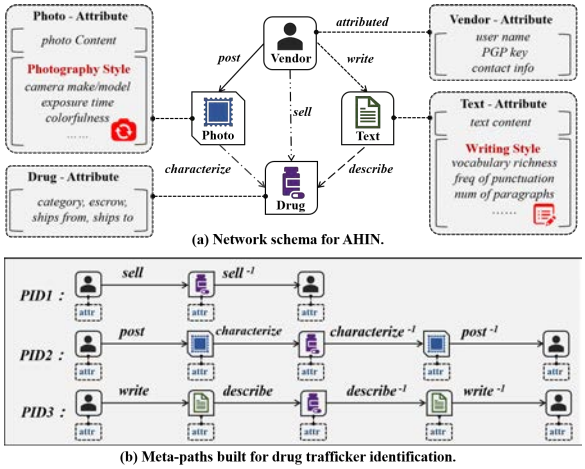

Figure 3: Network schema and meta-paths.

In our application, we have four entity types and five types of relations among them; meantime, each entity is also attached with an extracted feature vector representing its associated attributes. Based on the definitions above, the network schema for AHIN in our case is shown in Figure 3.(a) (to facilitate the illustration, attribute information is shown in its original form). Then, we adopt the concept of meta-path [35] to formulate higher-order relationships among entities in AHIN. In our application, we focus on three most meaningful meta-paths (i.e., ***PID1-PID3*** as shown in Figure 3.(b)) to jointly characterize the relatedness between two vendors from different views: (1) ***PID1*** means that two vendors can be connected through the path that they both sell the same kind of drug (e.g., heroin); (2) ***PID2*** denotes that two vendors can be linked if their posted photos describe the same kind of drug (e.g., as shown in Figure 1.(c), the vendor with username of "sp3***" in SilkRoad2 and the vendor with username of "sho***" in Evolution can be linked via this meta-path); (3) ***PID3*** indicates that two vendors can be connected if their written texts describe the same kind of drug.

2.3 *Vendor2Vec*

To reduce the computation and space cost in network mining, scalable representation learning method [10, 14] for AHIN is in need. We formalize the AHIN representation learning problem as below.

Definition 2.2. ***AHIN Representation Learning*** [10, 14]. Given an AHIN $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{A})$, the representation learning task is to learn a function $f: \mathcal{V} \rightarrow \mathbb{R}^D$ that maps each node $v \in \mathcal{V}$ to a vector in a D-dimensional space $\mathbb{R}^D$, $D \ll |\mathcal{V}|$ that are capable of preserving both structural and semantic relations among them.

To solve this problem, we propose a novel *attribute-aware* AHIN embedding model named *Vendor2Vec* which consists of attribute-aware meta-path random walk and skip-gram model. Given an AHIN $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{A})$ with schema $\mathcal{T}_\mathcal{G} = (\mathcal{T}, \mathcal{R})$, and a meta-path scheme $\mathcal{P}$ in the basic form: $T_1 \rightarrow \cdots T_t \rightarrow T_{t+1} \cdots \rightarrow T_L \rightarrow T_{L+1}$, we use attribute-aware meta-path to guide a random walker in AHIN, the transition probability at step i is calculated as:

$$p(v^{i+1}|v_t^i, \mathcal{P}) = \begin{cases} \frac{sim(\mathbf{f}_{v'}, \mathbf{f}_{v^{i+1}})}{\sum_{v^c \in N_{T_{t+1}}(v_t^i)} sim(\mathbf{f}_{v'}, \mathbf{f}_{v^c})} & (v_t^i, v^{i+1}) \in \mathcal{E}, \phi(v^{i+1}) = \phi(v') = T_{t+1} \\ \frac{1}{|N_{T_{t+1}}(v_t^i)|} & (v_t^i, v^{i+1}) \in \mathcal{E}, \phi(v^{i+1}) = T_{t+1}, v' = \emptyset \\ 0 & \text{otherwise,} \end{cases} \tag{1}$$

where v' denotes the latest entity the walker visited is with the same type of v^{i+1}, $sim(\mathbf{f}_{v^i}, \mathbf{f}_{v^j})$ is the similarity between two entities' attribute vectors (e.g, it can be calculated by using cosine similarity measure), ϕ is the node type mapping function, $N_{T_{t+1}}(v_t^i)$ denote T_{t+1} type of neighborhood of node v_t^i, v^c denotes a node in $N_{T_{t+1}}(v_t^i)$. Since we have three different meta-paths, we simply combine the path instances sampled via each meta-path, and feed them into the skip-gram model [29] to learn the node embeddings.

2.4 Classification Model

The problem of determining if a given pair of vendors are the same individual can be considered as a link prediction in an AHIN. In this paper, motivated by [1], we propose to devise a classification model for AHIN (named *vIdentifier* as shown in Figure 2.(d)) to predict the likelihood of the link between two nodes.

We first apply a Deep Neural Network (DNN) into node embedding to learn $f_\theta: \mathbb{R}^D \rightarrow \mathbb{R}^d$ that maps a vendor's learned latent representation onto a low-dimensional manifold. The mapping function f_θ is defined as [1]:

$$\begin{aligned} f_\theta: Y_u &\rightarrow FC_{\{\mathbf{W}_1, \mathbf{b}_1\}} \rightarrow BatchNorm \rightarrow relu \\ &\rightarrow FC_{\{\mathbf{W}_2, \mathbf{b}_2\}} \rightarrow BatchNorm \rightarrow f_\theta(Y_u), \end{aligned} \tag{2}$$

where $FC_{\{\mathbf{W}, \mathbf{b}\}}$ is a fully-connected layer with weight matrix $\mathbf{W}$ and bias vector $\mathbf{b}$, BatchNorm is described in [22], $relu(x) = max(0, x)$ is an element-wise activation function, and $\theta = \{\mathbf{W}_1, \mathbf{b}_1, \mathbf{W}_2, \mathbf{b}_2, ...\}$.

Given a pair of vendors, to define a general link function $g(u, v) \in \mathbb{R}$, we consider a low-rank affine projection in the manifold space [1]: $g(u, v) = f(Y_u)^T \times M \times f(Y_v)$, where the low-rank projection matrix $M = L \times R$ with $L \in \mathbb{R}^{d \times b}$ and $R \in \mathbb{R}^{b \times d}$, $b < d < D$. We can factor $g(u, v)$ into an inner product $\langle L^T f(Y_u), Rf(Y_v) \rangle$.

Then, we utilize the method proposed in [1] to conduct the optimization. The function is devised as following:

$$Pr(\mathcal{G}) \propto \prod_{u,v \in \mathcal{V}} \sigma(g(u, v))^{D_{uv} f(u,v)} (1 - \sigma(g(u, v)))^{1 - f(u,v)}, \tag{3}$$

where $\sigma(x) = 1/(1 + exp(-x))$ is the standard logistic,

$$f(u, v) = \begin{cases} 1 & \text{if } u \text{ and } v \text{ are the same individual} \\ 0 & \text{otherwise,} \end{cases} \tag{4}$$

D_{uv} is the frequency that vendors u and v co-occur within a specific window in the path instances sampled by our above proposed attribute-aware meta-path random walk.

3 EXPERIMENTAL RESULTS AND ANALYSIS

In this section, we conduct three sets of experiments using data collections from darknet markets to fully evaluate the performance of our developed system *uStyle-uID* for drug trafficker identification.

3.1 Experimental Setup

To fully evaluate our proposed method, we have collected the data from four different darknet markets *Valhalla*, *Dream Market*, *SilkRoad2* and *Evolution*. For the former two darknet markets, we develop a set of crawling tools to scrape weekly snapshots from June 2017 to August 2017. For the rest of markets, we collect their public data dumps. After data collection, we merely retain the vendors who at least posted two different drugs, each of which should be at least with one transaction. We summarize the collected data in Table 1. Due to the anonymity of darknet markets, it is difficult to access the actual ground-truth. Similar to the approach used in [40], we propose an alternative solution: for a given vendor, we randomly split his/her posted texts and photos into two even parts to form a positive example; then we randomly match this given vendor to the other in the same darknet market to generate a negative example. In this pseudo setting, the attribute vector attached to each vendor node is set as null. In the following experiments, we conduct ten-fold cross validations and use accuracy (*ACC*) and *F1* as performance measures to evaluate different methods. The parameters for *Vendor2Vec* are empirically set as follows: node dimension $D = 100$, walks per node $r = 10$, walk length $l = 80$ and window size $w = 10$, while for the parameter of d in *vIdentifier* is set as 30 and the remaining ones are consistent with [1].

Table 1: Information of the dataset.

Dataset	Vendors	Drugs	Entities	Relations
Valhalla (Val)	522	13,150	27,535	54,698
Dream Market (DM)	2,547	67,270	139,493	281,080
SilkRoad2 (SR2)	681	15,231	31,354	66,648
Evolution (Evol)	1,650	36,798	79,451	164,792

3.2 Comparisons of Different Features

In this set of experiments, we first evaluate the effectiveness of different features for drug trafficker identification.

- **Text-based features**: (1) *text content only* (***f-1***), (2) *writing style only* (***f-2***), and (3) *text content and writing style* (***f-3***).
- **Photo-based features**: (1) *photo content* (***f-4***), (2) *photography style* (***f-5***), and (3) *photo content and photography style* (***f-6***).

The experimental results are illustrated in Table 2, from which we can see that different features show different performances. To put this into perspective, (1) the relatedness over vendors depicted by style-based correlations (***f-2*** and ***f-5***) perform better than content-based correlations (***f-1*** and ***f-4***); (2) feature engineering (***f-3*** and ***f-6***) helps the performance; (3) the photo-based features (***f-4***, ***f-5***, and ***f-6***) perform better than the text-based ones (***f-1***, ***f-2***, and ***f-3***); (4) our proposed method *uStyle-uID* which integrates different levels of semantics, leveraging both writing and photograph styles, obtains a significantly better performance.

Table 2: Comparisons of different features.

Metric	Method	Feature	Val	DM	SR2	Evol
ACC	Text-based	***f-1***	0.780	0.798	0.782	0.792
		f-2	0.792	0.807	0.795	0.805
		f-3	0.803	0.819	0.806	0.815
	Photo-based	***f-4***	0.795	0.808	0.796	0.805
		f-5	0.807	0.817	0.808	0.816
		f-6	0.818	0.828	0.819	0.827

3.3 Network Embedding Model Comparisons

In this set of experiments, we evaluate our proposed method *Vendor2Vec* by comparisons with several state-of-the-art network embedding models including **DeepWalk** [31], **node2vec** [18] and **metapath2vec** [10]. For these embedding methods, we use the same parameters as *Vendor2Vec*. The results from Table 3 show that *Vendor2Vec* consistently and significantly outperforms all state-of-the-art embedding models. The success of *Vendor2Vec* lies in: (1) the proper consideration and accommodation of the heterogeneous property of AHIN; (2) the advantage of the attribute setting and the proposed attribute-aware meta-path guided random walk for sampling the high-quality path instances (i.e., without the attribute information such as writing and photography styles, the generated path instances are of low quality and less useful to our application).

Table 3: Comparisons of network embedding models.

Metric	Method	Val	DM	SR2	Evol
ACC	DeepWalk	0.703	0.714	0.699	0.707
	node2vec	0.726	0.731	0.722	0.729
	metapath2vec	0.741	0.754	0.744	0.748
	Vendor2Vec	**0.876**	**0.903**	**0.881**	**0.889**
F1	DeepWalk	0.682	0.688	0.669	0.679
	node2vec	0.703	0.710	0.692	0.709
	metapath2vec	0.718	0.735	0.727	0.731
	Vendor2Vec	**0.865**	**0.894**	**0.868**	**0.879**

3.4 Comparisons with Alternative Approaches

In this set of experiments, based on our collected datasets, we compare our developed system *uStyle-uID* with alternative approaches:

(1) feeding all the features (i.e., ***f-3***, ***f-6***, and feature vectors of vendors and drugs) into a generic DNN [19] to make the identification (denoted as *Hybrid-DNN*); (2) replacing the *vIdentifier* in *uStyle-uID* by a generic DNN (denoted as *AHIN-DNN*); (3) replacing the *vIdentifier* in *uStyle-uID* by SVM (denote as *AHIN-SVM*). For the generic DNN, we implement the model in Keras [40] and retain the default parameters. The experimental results are illustrated in Table 4. From the results we can observe that *AHIN-DNN* added the knowledge represented as AHIN performs better than *Hybrid-DNN*, which shows that using meta-path based approach over AHIN is able to build the higher-level semantic connection between vendors with a more expressive view. We also note that *uStyle-uID* significantly outperforms other baselines, which demonstrates that *uIdentifier* indeed helps the performance compared with the generic DNN and state-of-the-art shallow learning classification model.

Table 4: Comparisons of other alternative approaches.

Metric	Method	Val	DM	SR2	Evol
ACC	Hybrid-DNN	0.831	0.839	0.833	0.838
	AHIN-DNN	0.854	0.876	0.856	0.863
	AHIN-SVM	0.843	0.851	0.847	0.848
	uStyle-uID	**0.876**	**0.903**	**0.881**	**0.889**
F1	Hybrid-DNN	0.809	0.818	0.812	0.814
	AHIN-DNN	0.841	0.864	0.845	0.855

4 CROSS-MARKET DRUG TRAFFICKER IDENTIFICATION AND CASE STUDIES

To better understand and gain deeper insights into the ecosystem of drug trafficking in darknet markets, we further apply our developed system *uStyle-uID* for cross-market drug trafficker identification. For the detected cross-market vendor pairs, we further sample 798 pairs and validate them using conclusive evidences. Among these 798 detected cross-market pairs, 726 pairs (90.09%) are with high confidence that they are the same individuals and 22 pairs are uncertain (2.76%). As shown in Figure 4, for one of our detected cross-market vendor pairs, though "The***shop" on Evolution and "***Store" on Valhalla have different usernames, PGP keys and contact information, they sell similar drugs (i.e., heroin and MDMA) with similar writing and photography styles. After further investigation , we find that "The***shop" and "***Store" are both the members of a group named "***DrugShop" in Finland according to the description in the terms and conditions of vendors. This indicates that they might work together as an organization and we can link them to the same group of drug traffickers. Such kind of information can provide investigative insight for law enforcement to trace their activities and thus to build proactive defenses.

5 RELATED WORK

To combat drug trafficking in darknet markets, there have been many research efforts on darknet market data analysis [3, 9, 20, 40]. Among these studies, there have been some methods proposed

(a) Vendor "The***shop" on Evolution (b) Vendor "***Store" on Valhalla

Figure 4: An example of detected cross-market vendor pair.

to tackle the challenges of authorship identification such as [20, 40]. However, these approaches mainly relied on either stylometry analysis or photography style analysis. Different from existing works, we propose to leverage both writing and photography styles together with their contents for drug trafficker identification.

In order to depict different entities, associated attributes and the rich relationships among them, it is important to model them properly. Though HIN has shown the success of modeling different types of entities and relations [11–13, 21, 35, 42, 43], it has limited capability of modeling additional attributes attached to entities. To address this challenge, we propose to use AHIN for representation. To better address representation learning for HIN, many efficient network embedding methods have been proposed such as metagraph2vec [11], metapath2vec [10], HIN2vec [14]. However, these models are unable to deal with the attribute information associated with each entity. To address this issue, we propose *Vendor2Vec* to learn the desirable node representations in AHIN.

6 CONCLUSION

To combat drug trafficking, in this paper, we design and develop an intelligent system named *uStyle-uID* to automate drug trafficker identification in darknet markets. In *uStyle-uID*, we propose to leverage both writing and photography styles at the first attempt. To depict vendors, drugs, texts, photos and their associated attributes as well as the rich relationships among them, we present a structural AHIN to model them which gives the vendors higher-level semantic representations. Then, a meta-path based approach is used to characterize the semantic relatedness over vendors. To efficiently measure the relatedness over vendors in AHIN, we propose a new network embedding model *Vendor2Vec* which leverages complementary attribute information attached in the nodes to guide the meta-path based random walk for path instances sampling. Then, we transform the identification task into a link prediction problem and further present a learning model named *vIdentifier* to solve the problem. The promising experimental results on the collected datasets from four darknet markets demonstrate that *uStyle-uID* outperforms alternative approaches.

ABSTRACT

Abstractive meeting summarization is a challenging problem in natural language understanding, which automatically generates the condensed summary covering the important points in the meeting conversation. However, the existing abstractive summarization works mainly focus on the structured text documents, which may be ineffectively applied to the meeting summarization task due to the lack of modeling the unstructured long-form conversational contents. In this paper, we consider the problem of abstractive meeting summarization from the viewpoint of hierarchical adaptive segmental encoder-decoder network learning. We propose the hierarchical neural encoder based on adaptive recurrent networks to learn the semantic representation of meeting conversation with adaptive conversation segmentation. We then develop the reinforced decoder network to generate the high-quality summaries for abstractive meeting summarization. We conduct the extensive experiments on the well-known AMI meeting conversation dataset to validate the effectiveness of our proposed method.

1 INTRODUCTION

Abstractive meeting summarization is a challenging task in natural language understanding, which could be of great value to the users by providing quick access to the important content of past meetings [24]. The essential problem of abstractive meeting summarization is to automatically generate the condensed summary covering the important points in the meeting conversation. In order to provide the high-quality summaries, many existing works learn the semantic representation to capture the overall content of the conversation for abstractive meeting summarization. Currently, the existing meeting summarization works [2, 10, 12, 16, 21, 24] generate the meeting summaries mainly based on the extracted semantic rules, which suffer from the low maintainability [23]. On the other hand, most of the existing abstractive summarization approaches [3, 14, 26] mainly focus on the structured text documents, which learn the semantic representation of text documents and then generate the summaries for abstractive document summarization. Although these works have achieved great performance in abstractive document summarization, they may still be ineffectively applied to meeting summarization due to the lack of modeling the unstructured long-form meeting conversation contents.

The meeting conversation contents are the sequential collection of unstructured utterances, which have long-term semantic dependencies [24]. Recently, the hierarchical neural encoder [8] has been proposed to learn the paragraph-level semantic representation for document modeling. We then employ the hierarchical neural encoder to learn the high-level semantic representation that models the long-term semantic dependencies in the meeting conversation contents. On the other hand, although the sequential utterances in

the meeting conversation are topically consistent, they are unstructured and have different semantic contents. To tackle this issue, we employ the binary neurons [4] and then develop the hierarchical recurrent encoder based on adaptive binary neural networks. The adaptive hierarchical encoder network then learns the high-level semantic representation of meeting conversation with adaptive conversation segmentation. Thus, leveraging hierarchical neural encoder with adaptive binary neural networks is important for modeling the unstructured long-form meeting conversation contents for abstractive meeting summarization.

In this paper, we present the problem of abstractive meeting summarization from the viewpoint of hierarchical adaptive segmental encoder-decoder network learning. We first propose the hierarchical neural encoder with adaptive recurrent networks to learn the high-level semantic representation of meeting conversation contents with adaptive conversation segmentation. We then develop the the reinforced decoder networks to generate the high-quality summaries for abstractive meeting summarization. We next devise the Hierarchical encoder-decoder network learning framework with Adaptive conversation Segmentation for abstractive meeting summarization, named as HAS. When a certain meeting conversation is issued, HAS can automatically generate the natural language summaries for it based on its conversation contents. The main contributions of this paper are as follows:

- Unlike the previous studies, we study the problem of abstractive meeting summarization from the viewpoint of hierarchical encoder-decoder network learning framework with adaptive conversation segmentation.
- We propose the hierarchical adaptive encoder to learn the high-level semantic representation of meeting conversation contents, and then devise the reinforced decoder network to generate the summaries for abstractive meeting summarization.
- We validate the effectiveness of our proposed method through extensive experiments on the well-known AMI meeting conversation dataset.

The rest of this paper is organized as follows. In Section 2, we introduce the problem of abstractive meeting summarization from the viewpoint of hierarchical encoder-decoder network learning framework with adaptive conversation segmentation. A variety of experimental results are presented in Section 3. We provide a brief review of the related work about meeting summarization and abstractive document summarization in Section 4. Finally, we provide some concluding remarks in Section 5.

2 ABSTRACTIVE MEETING SUMMARIZATION VIA HIERARCHICAL ADAPTIVE SEGMENTAL NETWORKS

In this section, we first present the problem of abstractive meeting summarization from the viewpoint of hierarchical adaptive segmental encoder-decoder network learning framework. We then introduce the hierarchical adaptive segmental encoder networks that learn the high-level semantic representation of meeting conversation contents. We next illustrate the reinforced decoder networks to generate the summaries for abstractive meeting summarization.

2.1 The Problem

Before presenting the learning framework, we first introduce some basic notions and terminologies. We denote the utterances in meeting conversation by $\mathbf{u} \in U$ and its meeting summary by $\mathbf{z} \in Z$, where U and Z are the sets of meeting conversations and meeting summaries. The sequential collection of utterances in meeting conversation are denoted by $\mathbf{u} = (\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n)$, where $\mathbf{u}_i$ is the i-th utterance and n is the number of utterances in meeting conversation $\mathbf{u}$. The word-level representation of utterance $\mathbf{u}_i$ is denoted by $\mathbf{u}_i = (\mathbf{u}_{(i,1)}, \mathbf{u}_{(i,2)}, \ldots, \mathbf{u}_{(i,m_i)})$, where $\mathbf{u}_{(i,j)}$ is the embedding vector for the j-th word and m_i is the number of the words in utterance $\mathbf{u}_i$. The word-level representation of meeting summary $\mathbf{z}$ is given by $\mathbf{z} = (z_1, z_2, \ldots, z_{l_z})$, where z_j is the j-th word and l_z is the number of words in summary $\mathbf{z}$. Since the meeting conversation and its utterances are sequential data with variant length, it is natural to choose the variant recurrent neural network called long-short term memory network (LSTM) [7] to learn their feature representations by

$$\mathbf{i}_t = \delta(\mathbf{W}_i \mathbf{x}_t + \mathbf{G}_i \mathbf{h}_{t-1} + \mathbf{b}_i) \quad (1)$$

$$\hat{\mathbf{c}}_t = tanh(\mathbf{W}_c \mathbf{x}_t + \mathbf{G}_t \mathbf{h}_{t-1} + \mathbf{b}_f) \quad (2)$$

$$\mathbf{f}_t = \delta(\mathbf{W}_f \mathbf{x}_t + \mathbf{G}_f \mathbf{h}_{t-1} + \mathbf{b}_f) \quad (3)$$

$$\mathbf{c}_t = \mathbf{i}_t \cdot \hat{\mathbf{c}}_t + \mathbf{f}_t \cdot \mathbf{c}_{t-1} \quad (4)$$

$$\mathbf{o}_t = \delta(\mathbf{W}_o \mathbf{x}_t + \mathbf{G}_o \mathbf{h}_{t-1} + \mathbf{b}_o) \quad (5)$$

$$\mathbf{h}_t = \mathbf{o}_t \cdot tanh(\mathbf{c}_t) \quad (6)$$

where δ represents the sigmoid activation function; $\mathbf{W}$s, $\mathbf{G}$s are the weight matrices, and $\mathbf{b}$s are the bias vectors. The memory cell $\mathbf{c}_t$ maintains the history of the inputs observed up to the timestep. Update operations on the memory cell are modulated by three gates $\mathbf{i}_t$, $\mathbf{f}_t$ and $\mathbf{o}_t$, which are all computed as a combination of the current input $\mathbf{x}_t$ and of the previous hidden state $\mathbf{h}_{t-1}$, followed by a sigmoid activation. The input gate $\mathbf{i}_t$ controls how the current input should be added to the memory cell; the forget gate $\mathbf{f}_t$ is used to control what the cell will forget from the previous memory $\mathbf{c}_{t-1}$, and the output gate $\mathbf{o}_t$ controls whether the current memory cell should be passed as output.

Specifically, we learn the semantic representation of utterance $\mathbf{u}_i$ by word-level bi-directional LSTM networks, which consists of a forward LSTM and a backward LSTM. The backward LSTM has the same network structure with the forward one while its input sequence is reversed. We denote the hidden state of the forward LSTM for the t-th word in utterance $\mathbf{u}_i$ by $\mathbf{h}_{(i,t)}^{(w,f)}$, and the hidden state of this word in the backward LSTM by $\mathbf{h}_{(i,m_i-t)}^{(w,b)}$. Thus, we take the output of the last bi-directional LSTM cell, $\mathbf{h}_{(i,m_i)}^{(w)} = [\mathbf{h}_{(i,m_i)}^{(w,f)}, \mathbf{h}_{(i,1)}^{(w,b)}]$ as the semantic representation of utterance $\mathbf{u}_i$. The semantic representation of the sequential collection of the utterances in the meeting conversation is given by utterance-level LSTM networks, denoted by $\mathbf{h}^{(u)} = (\mathbf{h}_1^{(u)}, \mathbf{h}_2^{(u)}, \ldots, \mathbf{h}_n^{(u)})$, where $\mathbf{h}_i^{(u)}$ is the hidden state in the utterance-level LSTM network.

Using the notations above, the problem of abstractive meeting summarization is formulated as follows. Given the collection of utterances in the meeting conversation $\mathbf{u}$, our goal is to learn the

encoder-decoder network model $g(f(\mathbf{u}))$, where the encoder network $f(\mathbf{u})$ learns the semantic representation of the meeting conversation contents, and the decoder network $\hat{\mathbf{z}} = g(f(\mathbf{u}))$ generates natural language summary $\hat{\mathbf{z}}$ for abstractive meeting summarization. We present the details of the hierarchical adaptive segmental encoder-decoder network learning framework in Figure 1.

2.2 Adaptive Encoder Networks

In this section, we propose the hierarchical adaptive segmental encoder $f(\cdot)$ to learn the high-level semantic representation of meeting conversation contents with adaptive conversation segmentation.

The meeting conversation contents contain a sequential collection of unstructured utterances, which have long-term semantic dependencies [24]. Furthermore, although the utterance in the meeting conversation are topically consistent, they have different conversational contents. Inspired by binary neurons [4], we propose the hierarchical adaptive encoder networks that learn the semantic representation of meeting conversation contents with adaptive conversation segmentation. We learn the semantic representation of sequential utterance collection from utterance-level LSTM networks by $\mathbf{h}^{(u)}(\mathbf{h}_1^{(u)}, \mathbf{h}_2^{(u)}, \ldots, \mathbf{h}_n^{(u)})$. When a certain conversational topic change is estimated in the current utterance, the conversation segmentation can be done by resetting the LSTM parameters of the next utterance. To enable the conversation segmentation, we define an adaptive recurrent neural networks with binary gate function, which decides whether to transfer the LSTM parameters (i.e., hidden state $\mathbf{h}_t^{(u)}$ and memory cell $\mathbf{c}_t^{(u)}$) of current utterance to update the LSTM parameters of the next utterance (i.e., hidden state $\mathbf{h}_{t+1}^{(u)}$ and memory cell $\mathbf{c}_{t+1}^{(u)}$) by Equations (1), (2), (3), (4) and (5). Therefore, the adaptive recurrent neural networks enable the conversation segment with variable number of utterances in the encoder network. Formally, the t-th binary gate $\alpha_t(\cdot)$ is defined as a step function, which is computed as a non-linear combination of the semantic representation of the the $t+1$-th utterance from the word-level LSTM networks (i.e., $\mathbf{h}^{(w)}_{(t+1,m_{t+1})}$), and the semantic representation of the tth utterance from the utterance-level LSTM networks (i.e., $\mathbf{h}_t^{(u)}$), given by

$$\begin{aligned}&\alpha_t(\mathbf{h}^{(w)}_{(t+1,m_{t+1})}, \mathbf{h}_t^{(u)}) = \\ &1[\delta(\mathbf{w}_\alpha^T(\mathbf{W}_{\alpha w}\mathbf{h}^{(w)}_{(t+1,m_{t+1})} + \mathbf{W}_{\alpha u}\mathbf{h}_t^{(u)} \\ &+\mathbf{b}_\alpha)) > 0.5].\end{aligned}$$

The $1[\cdot]$ is a step function and $\delta(\cdot)$ is a sigmoid function. The $\mathbf{w}_g$ is a learnable row vector, $\mathbf{W}_{\alpha w}$, $\mathbf{W}_{\alpha u}$ and $\mathbf{b}_\alpha$ are the learnable weights and biases. For example, the inputs of binary gate $\alpha_2(\mathbf{h}^{(w)}_{3,3}, \mathbf{h}_2^u)$ are the semantic representation of utterance $\mathbf{h}_2^u$ from the utterance-level LSTM networks and the semantic representation of utterance $\mathbf{h}^{(w)}_{3,3}$ from the word-level LSTM networks in Figure 1. Given the sequential representation of utterances $(\mathbf{h}_1^{(u)}, \mathbf{h}_2^{(u)}, \ldots, \mathbf{h}_n^{(u)})$ with the values of binary gate $(\alpha_1, \alpha_2, \ldots, \alpha_{n-1})$, we develop the segment-level LSTM networks as follows. If the value of binary gate $\alpha_t(\cdot) = 1$, the hidden state of utterance-level LSTM networks at time $t+1$, $\mathbf{h}_{t+1}^{(u)}$, is passed as the input to the segment-level LSTM networks. For example, the hidden states $\mathbf{h}_3^{(u)}$, $\mathbf{h}_6^{(u)}$, ..., $\mathbf{h}_N^{(u)}$ in utterance-level LSTM networks are passed as the inputs to the segment-level LSTM networks in Figure 1. We denote semantic representation of the sequential segment collection from meeting conversation contents in the segment-level LSTM networks by $\mathbf{h}^{(s)} = (\mathbf{h}_1^{(s)}, \mathbf{h}_2^{(s)}, \ldots, \mathbf{h}_k^{(s)})$, where $\mathbf{h}_j^{(s)}$ is the hidden state in the segment-level LSTM network and k is the number of conversational segments. Therefore, hierarchical adaptive segmental encoder network is given by $f(\mathbf{u}) = (\mathbf{h}_1^{(s)}, \mathbf{h}_2^{(s)}, \ldots, \mathbf{h}_k^{(s)})$. We note that the hierarchical adaptive segmental encoder network learns the semantic representation of meeting conversation contents from conversational segments with variable number of utterances.

2.3 Reinforced Decoder Networks

In this section, we propose the reinforced decoder network $g(\cdot)$ based on segment-level LSTM networks to generate the natural language summary for abstractive meeting summarization.

Given the encoded semantic representation of meeting conversation contents $f(\mathbf{u}) = (\mathbf{h}_1^{(s)}, \mathbf{h}_2^{(s)}, \ldots, \mathbf{h}_k^{(s)})$ from the segment-level LSTM networks, the decoder predicts the next word in summary by sampling $z_t \sim p_\theta(z_t|\mathbf{z}_{1:t-1}, f(\mathbf{u})) = g_t(\mathbf{h}_t^{(g)}, \mathbf{v}_t, f(\mathbf{u}))$, where $g_t(\cdot)$ is the recurrent generator. The $\mathbf{h}_t^{(g)}$ is the decoder state and $\mathbf{v}_t$ is the context vector at the t-th decoder step. The context vector $\mathbf{v}_t$ is computed as the weighted sum of the encoded semantic representation from the segment-level LSTM networks by $\mathbf{v}_t = \sum_{i=1}^k \beta_{ti}\mathbf{h}_i^{(s)}$. The attention weight β_{ti} is given by $\beta_{ti} = \frac{\exp((\mathbf{h}_{t-1}^{(g)})^T\mathbf{h}_i^{(s)})}{\sum_{i=1}^k \exp((\mathbf{h}_{t-1}^{(g)})^T\mathbf{h}_i^{(s)})}$. One common approach for training the decoder network is based on the maximum likelihood estimation, given by

$$\mathcal{L}_{ML}(g(f(\mathbf{u}))) = \sum_{t=1}^{l} \log p_\theta(z_t|\mathbf{z}_{1:t-1}, f(\mathbf{u})). \tag{7}$$

We note that when computing the conditional probability $p_\theta(z_t|\mathbf{z}_{1:t-1}, f(\mathbf{u}))$, the previous word in the human-authored summaries rather than the generated word is chosen for training in maximum likelihood estimation. However, this makes the learnt decoder network suboptimal [1]. To tackle this problem, we employ the reinforcement learning framework for training the decoder network.

In the setting of reinforcement learning, we define the generation of next word as action and the decoding probability $p_\theta(\hat{z}_t|\hat{\mathbf{z}}_{1:t-1}, f(\mathbf{u}))$ as the policy. In the task of abstractive meeting summarization, the reward is usually received at the end of the generated summaries. We then choose the ROUGE [9] as the reward function $R_\mathbf{z}(\hat{\mathbf{z}})$, which is calculated by comparing the generated summary $\hat{\mathbf{z}}$ with the human-written summary $\mathbf{z}$. Specifically, we define the expected cumulative reward at each time step using value function by $Q(\hat{z}_t|\hat{\mathbf{z}}_{1:t-1}, f(\mathbf{u})) = E_{p_\theta(\hat{\mathbf{z}}_{t+1:T}|\hat{\mathbf{z}}_{1:t}, f(\mathbf{u}))}R_\mathbf{z}(\hat{\mathbf{z}})$. The value function $Q(z_t|\mathbf{z}_{1:t-1}, f(\mathbf{u}))$ is then estimated by aggregating the Monte-Carlo simulation at each time step, given by

$$\begin{aligned}&Q(\hat{z}_t|\hat{\mathbf{z}}_{1:t-1}, f(\mathbf{u})) \approx \\ &\begin{cases} \frac{1}{N}\sum_{n=1}^N R_\mathbf{z}([\hat{\mathbf{z}}_{1:t-1}, z_t, \hat{\mathbf{z}}^n_{t+1:l_z}]), & t < l \\ R_\mathbf{z}([\hat{\mathbf{z}}_{1:t-1}, \hat{z}_t]). & t = l_z \end{cases}\end{aligned} \tag{8}$$

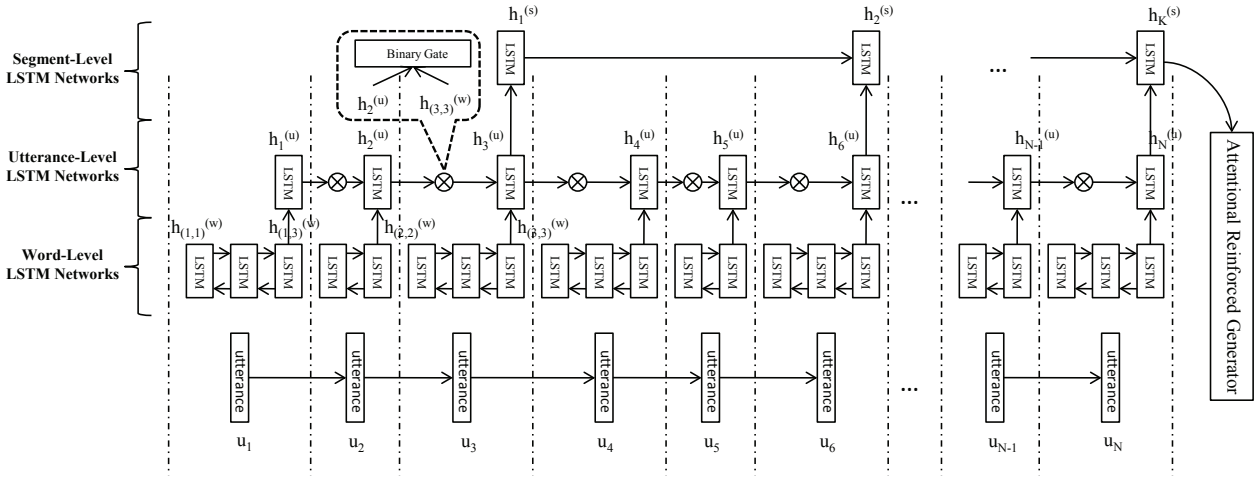

Figure 1: The Framework of Abstractive Meeting Summarization via Hierarchical Adaptive Segmental Encoder-Decoder Networks. The hierarchical encoder network learns the semantic representation of meeting conversation contents with adaptive conversation segmentation. The reinforced recurrent decoder network then generates the summaries for abstractive meeting summarization.

We denote that $\{\hat{\mathbf{z}}^1_{t+1,l_z}, \ldots, \hat{\mathbf{z}}^N_{t+1:l_z}\} \sim p_\theta(\hat{\mathbf{z}}_{t+1:l}|\hat{\mathbf{z}}_{1:t}, f(\mathbf{u}))$ as the set of simulated generated summaries, which are randomly sampled starting from the $t+1$-th time step on the current state and action. According to the policy gradient theorem, the gradients of the reinforced decoder network can be estimated by

$$\nabla_\theta \mathcal{L}_{RL}(g(f(\mathbf{u}))) = \sum_{t=1}^{l} \nabla_\theta \log p_\theta(\hat{z}_t|\hat{\mathbf{z}}_{1:t-1}, f(\mathbf{u})) Q(\hat{z}_t|\hat{\mathbf{z}}_{1:t-1}, f(\mathbf{u})). \quad (9)$$

3 EXPERIMENTS

In this section, we conduct several experiments on the AMI meeting corpus [6], to show the effectiveness of our approach for the problem of abstractive meeting summarization.

3.1 Experimental Setting

We first present the details of AMI meeting corpus dataset. The AMI meeting corpus is a collection of 142 meeting records along with their corresponding human-authored abstractive summaries. In each meeting, the group of people are engaged in a team and each speak assumes a certain role in a team. Following the experimental setting in [16, 21], we use 100 dialogs as training set, 20 dialogs as validation set and the remaining 22 dialogs as the testing set. So the training, validation and testing data do not have overlap. For evaluation, we employ ROUGE [9], which compares machine summaries with human gold-standard summaries using n-gram overlap and skip-gram overlap. We train the proposed method on machines with Linux OS, Intel(R) Core i7-5930K 3.5GHz and two GTX TITIAN X graphic cards. The initial learning rate of our method is set to 1, the decay rate is set to 0.5 and the drop rate is set to 0.5. The vocabulary size of our method is set to 10,517.

3.2 Experimental Comparisons

We evaluate the performance of our proposed method based on three widely-used evaluation for the problem of abstractive meeting summarization [10, 16], i.e., ROUGE-1, ROUGE-2 and ROUGE-SU. We compare our proposed method with other five state-of-the-art methods for the problem of abstractive meeting summarization as follows:

- **TextRank** method [11] is the extractive meeting summarization model which selects the important utterances from the meeting conversations for summarization.
- **Fusion** method [10] is the abstractive meeting summarization model which aggregates the most relevant sentences in the word graph and then selects the best paths as abstractive summaries.
- **TG** method [16] extends multi-sentence fusion algorithm to select the best templates for generating abstractive summarizes, which is based on the relationship between summaries and their source meeting transcripts.
- **AED-RNN** method [14] is under the encoder-decoder framework that generates the abstractive summaries for meeting conversation with attentional recurrent neural networks.
- **PGN** method [20] is the pointer-generator network, which is current state-of-art model in general abstractive text summarization task.
- **SEASS** method [26] is the selective encoding model based on sequence-to-sequence framework for abstractive summarization.
- **HAS-ML** method is the adaptive segmental network model that jointly segments the meeting conversation and generates the abstractive summaries, which is trained by maximum likelihood estimation.
- **HAS-RL** method is the adaptive segmental network model, which is trained by reinforcement learning.

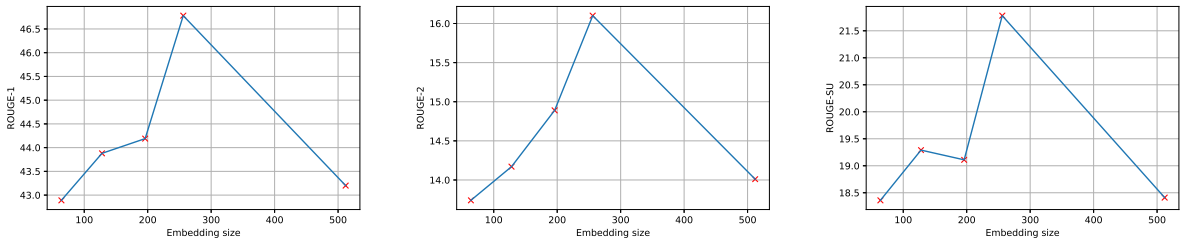

Figure 2: Effect of the dimension of word embedding on ROUGE-1, ROUGE-2 and ROUGE-SU

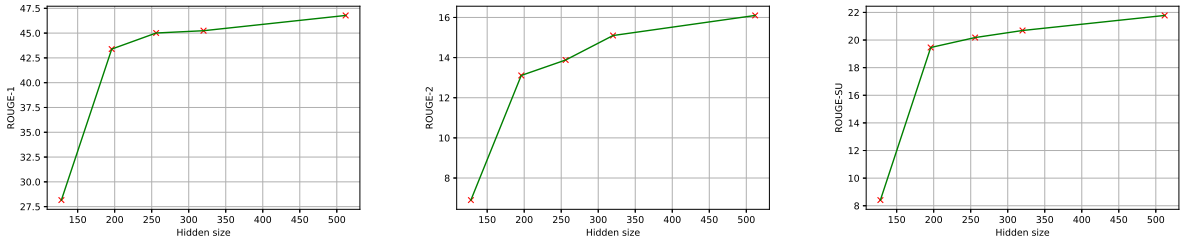

Figure 3: Effect of the dimension of LSTM hidden state on ROUGE-1, ROUGE-2 and ROUGE-SU

Table 1: Experimental results on ROUGE-1, ROUGE-2 and ROUGE-SU.

Method	ROUGE-1	ROUGE-2	ROUGE-SU
TextRank	25.12	3.37	6.61
Fusion	32.30	4.80	8.10
TG	31.50	6.70	11.40
AED-RNN	39.74	14.29	15.16
PGN	41.52	14.89	17.01
SEASS	43.93	14.29	19.10
HAS-ML	46.78	16.10	21.78
HAS-RL	**48.64**	**17.45**	**22.13**

Among them, methods TextRank, Fusion, TG, HAS-ML and HAS-RL are proposed for meeting summarization while methods AED-RNN and SEASS are designed for document summarization. The methods Fusion, TF generate the abstractive summaries for meeting conversation based on the constructed word graph. The methods ADE-RNN, PGN, and SEASS are under the encoder-decoder framework, which generates the abstractive summaries with attentional recurrent neural networks. Unlike the previous abstractive summarization methods, our HAS model jointly segments the meeting conversation and generates the abstractive summaries for meeting conversation. To exploit the effect of different training process, we denote our HAS model based on maximum likelihood by HAS-ML, and the one based on reinforcement learning by HAS-RL. We choose the ROUGE-SU evaluation criteria as the reward in the reinforcement learning for HAS-RL. The input words of our methods are initialized by pre-trained word embeddings and the weights of LSTMs are randomly by a Gaussian distribution with zero mean.

Table 1 shows the overall experimental results of the methods for abstractive meeting summarization on ROUGE-1, ROUGE-2 and ROUGE-SU, respectively. The hyperparameters and parameters are chosen to conduct the testing evaluation. We report the average value of all the methods on three evaluation criteria. The experimental results reveal a number of interesting points:

- The methods based on abstractive summarization, Fusion, TG, AED-RNN, SEASS, HAS-ML and HAS-RL outperform the extractive-based method TextRank, which suggests that the generation-based approach is critical for the problem.
- The methods based on recurrent neural networks, AED-RNN and SEASS achieve better performance than other baselines. This suggests that the deep representation of meeting conversation also improves the performance of abstractive meeting summarization.
- In all the cases, both of our HAS-ML and HAS-RL methods achieve the best performance. This fact shows that the adaptive segmental network learning framework that joint exploit the conversation segmentation and abstractive summarization generation can further improves the performance of abstractive meeting summarization.
- The HAS model trained by reinforcement learning, HAS-RL, outperforms the one trained by maximum likelihood, HAS-ML, which suggests that reinforcement learning is effective for generating the summaries in the problem of abstractive meeting summarization.

In our approach, there is two essential parameters, which are the dimension of hidden LSTM state and word embedding size. We first study the effect of word embedding on our method by varying the dimension of word embedding from 64 to 512 on ROUGE-1, ROUGE-2 and ROUGE-SU in Figures 2(a), 2(b) and 2(c). We can see that our method achieves the best performance when the size of word

Human-Authored Summary
the project manager acquainted the team with the tools and equipment around them and then had the team members introduce themselves by name and what role they had in the project. the project manager then introduced the upcoming project along with more tools and equipment to the team members. the team members then participated in an exercise in which they drew their favorite animals. after the drawing exercise, the project manager talked about the project finances and production costs. the team then discussed their experiences with remotes and various features to consider when producing a remote
Summary Generated by HAS-ML
the project manager opened the meeting and introduced the project, to design a remote control. the team members then participated in an exercise in which they each drew their favorite animal and discussed why they liked the animal. the project manager then led the team in calculating the production costs of the remote and what features they would like to include in the remote they are to create. the team discussed the interior workings of a remote and how to make the remote more technologically innovative but decided to use a spongy material in their design
Summary Generated by HAS-RL
the project manager opened the meeting and introduced the project, to design a remote control. the project manager then introduced the upcoming project to the team members and then the team members participated in an exercise in which they each drew their favorite animal and discussed what they liked about the animal. the project manager then led the team in calculating the production costs of the remote and what features they would like to include in the remote they are to create. the project manager briefed the team on some new requirements and led them in a discussion on their experiences with remotes and various features to consider in making the remote

Figure 4: A comparison between a human-authored summary and the summaries created by methods HAS-ML and HAS-RL.

embedding is set to 256. We then investigate the effect of hidden LSTM state on our method by varying the dimension of hidden LSTM state from 128 to 512 on ROUGE-1, ROUGE-2 and ROUGE-SU in Figures 3(a), 3(b) and 3(c), respectively. We can observe that the performance trend of our method becomes convergent after the dimension of hidden LSTM state greater than 256.

Finally, we demonstrate the effectiveness of the summaries generated by our HAS model with a human-authored one in Figure 4. We can observe that, compared with the human-authored summary, both the summaries generated by HAS-ML and HAS-RL methods also cover the main points in the meeting conversation well. Compared with the summary generated HAS-ML method, the summary generated by HAS-RL method are more fluent and natural.

4 RELATED WORK

In this section, we briefly review some related work on meeting summarization and abstract document summarization.

The existing work for the problem of meeting summarization can be mainly categorized as extractive-based approaches [5, 18, 25] and abstractive-based approaches [2, 10, 12, 16, 21, 24]. Xie et al. [25] treat extractive meeting summarization task as a binary classification problem. Bui et al. [5] investigate the directed graphical models for extractive meeting summarization. Riedhammer et al. [18] propose the unsupervised method for extractive meeting summarization. A recent study [13] revealed that people generally prefer abstractive summaries to the extracted ones for meeting summarization. Mehdad et al. [10] build the entailment graph for meeting summarization. Wang et al. [24] apply multiple-sequence alignment to generate templates for abstractive meeting summarization. Oya et al. [16] leverage the relationship between human-authored summaries and their source meeting transcriptions to select the templates for generating abstractive summaries for meetings. Murray et al. [12] formulate the abstractive meeting summarization as a Markov Decision Process and value iteration is used for natural language generation. Banerjee et al. [2] generate abstractive summaries by fusing important content from several utterances with dependency graph. Singla et al. [21] develop the abstractive summarization systems with automatic communities for spoken conversation summarization. Unlike previous studies, we formulate the problem of meeting summarization from the viewpoint of adaptive segmental encoding, which can be solved by recurrent neural networks with policy gradient learning.

Abstractive document summarization is the process of automatically generating natural language summaries from an input document while retaining the important points [3]. Banerjee et al. [3] tackle the abstractive summarization with integer linear programming based on word graph. Rush et al. [19] develop the neural attention-based summarization model based on neural machine translation. Tan et al. [22] propose the graph-based attention mechanism for abstractive document summarization. See et al. [20] present the hybrid pointer-generator architecture with coverage for text summarization. Paulus et al. [17] propose the neural summarization method that combines supervised word prediction and reinforcement learning. Nema et al. [15] introduce the query-based abstractive summarization task. Zhou et al. [26] develop the selective encoding for abstractive sentence summarization. However, the problem formulation of abstractive meeting summarization is different from the problem of document summarization, because of the unstructured long meeting conversation contents. Therefore, the existing abstractive document summarization methods may not be directly applied to our problem.

5 CONCLUSION

In this paper, we present the problem of abstractive meeting summarization from the viewpoint of hierarchical adaptive segmental encoder-decoder network learning framework. We first propose the adaptive segmental encoder networks that learn the semantic representation of meeting conversation contents with adaptive conversation segmentation. We then devise the reinforced decoder networks to generate the natural language summaries for abstractive meeting summarization. We evaluate the effectiveness of our method through extensive experiments on the well-known AMI meeting conversation dataset.

ABSTRACT

Point-of-interest (POI) recommendation is essential to a variety of services for both users and business. An extensive number of models have been developed to improve the recommendation performance by exploiting various characteristics and relations among POIs (e.g., spatio-temporal, social, etc.). However, very few studies closely look into the underlying mechanism accounting for why users prefer certain POIs to others. In this work, we initiate the first attempt to learn the distribution of user latent preference by proposing an *Adversarial POI Recommendation (APOIR)* model, consisting of two major components: (1) the *recommender* (*R*) which suggests POIs based on the learned distribution by maximizing the probabilities that these POIs are predicted as unvisited and potentially interested; and (2) the *discriminator* (*D*) which distinguishes the recommended POIs from the true check-ins and provides gradients as the guidance to improve *R* in a rewarding framework. Two components are co-trained by playing a minimax game towards improving itself while pushing the other to the boundary. By further integrating geographical and social relations among POIs into the reward function as well as optimizing *R* in a reinforcement learning manner, APOIR obtains significant performance improvement in four standard metrics compared to the state of the art methods.

1 INTRODUCTION AND MOTIVATION

Location-based recommendation systems primarily aim at suggesting spatial entities (i.e., point-of-interest (POI)) to users, and have recently spurred a significant research interests in both academia and industry. Different variations of POI recommendations have been explored, including next POI recommendation [4, 7], time-aware POI recommendation [13] and out-of-town POI recommendation [21].

A body of existing works has focused on improving the POI recommendation performance by exploiting various implicit context features embedded in check-ins, such as their spatial information [13, 14, 17]; semantics [9]; social relations [5, 11, 36]; temporal characteristics [18, 33]; and sequential dependence [6, 19, 27, 35]. Complementary to these, approaches that model user preference through mining various features for POI recommendation have been proposed – e.g., Matrix Factorization (MF) [11, 13, 14, 17], Context Embedding (CE) [15, 27, 33] and Pairwise Ranking (PR) [4, 12, 22, 33]. A recent work [16] summarized that geographical information and social influence are the two most effective factors for modeling user preference, while MF based methods such as GeoMF and RankGeoFM exhibit superior performance on POI recommendation. Some of the existing methods make simple but proven-to-be effective assumptions for POI recommendation.

At the heart of our motivation is the observation that many of the existing studies lack formal underlying mechanisms to understand essential user check-in behavior, which may often lead to elusive results. Inspired by recent advances in deep generative models [8, 25] that are successfully and widely used in the areas of computer vision and information retrieval, we attempt to learn user latent preference in a generative way, rather than extracting different features and quantitatively analyzing their impact on POI recommendation as done in most of the existing works.

Towards that, we propose a novel POI recommendation approach, called *Adversarial POI Recommendation (APOIR)*, which learns the underlying check-in distribution in an adversarial manner by simultaneously training two synergistic components. Specifically, we model a user u and his check-in locations l in a generative way, with two neural network components: *recommender* (*R*) and *discriminator* (*D*) – being co-trained alternatively, to optimize the generative process of $u \rightarrow l$. *R* recommends POIs based on the currently learned user preference distribution, while *D*, acting as a catalyzer, judges whether the recommended POIs are true locations visited by that user and provides guidance to improve *R*. Two effective features (geographical and social influence) are also incorporated into the APOIR to further improve the performance. Note that our model can be generalized to include other features.

To train APOIR, we alternate the updates of the recommender and the discriminator as follows. Given the currently learned preference distribution, a set of POIs are sampled to update the R using the policy gradient method. Subsequently, D is updated using user u's true check-ins along with the ones sampled from the updated R. After an equilibrium is reached – which is, the true user preference distribution is close enough to the empirical learned distribution, a list of POIs with high probabilities based on the learned distribution are generated and eventually recommended. Our main contributions can be summarized as follows:

- We address the POI recommendation in a generative way, which is a novel approach in the area of spatial mining and POI recommendation.
- We propose a method – APOIR – to learn underlying user preference distribution, which significantly boosts the recommendation performance. In addition, APOIR successfully unifies reinforcement learning and matrix factorization methods into an adversarial learning framework for POI recommendation.
- We evaluate our method on three public location-based social network (LBSN) datasets and compare it to several state-of-the-art models. The results show that the APOIR approach performs well, e.g., achieving 10.17%, 11.7% and 10.0% improvement over the best baseline on Gowalla, Foursquare and Yelp datasets in terms of Precision@5.

2 RELATED LITERATURE

ML based POI Recommendation Matrix Factorization (MF) and its variants are prevalent techniques in traditional POI recommendation. Typically, a user-POI matrix is factorized to identify user latent references. For example, in [14] user and POI latent factors in the factorization model are augmented with activity area vectors of users and influence vectors of POIs, to deal with the challenge of matrix sparsity. User interest and check-in behavior [12], user preference ranking and metric embedding [4], as well as POI semantic categories [9] are also taken into account for POI recommendation in the MF-based framework.

An extensive experimental evaluation [16] has been recently conducted to compare 12 representative POI recommendation models and draw relevant findings, among which are: (a) geographical information [13, 14]; and (b) implicit feedback of user preference [17], are the most relevant factors to the recommendation performance. According to their results, RankGeoFM [13], IRenMF [17] and GeoMF [14] are the three state-of-the-art POI recommendation models. Our work differs from these methods in that we propose a generative model to learn underlying user preference distribution in an adversarial manner.

GAN and POI Recommendation Generative adversarial networks (GANs) have gained recent popularity due to their successes in natural image generation [8]. GANs have also been used for modeling sequential data, such as discrete token generation [29] and have been applied in information retrieval [25]. However, few efforts have been made towards recommending POIs in LBSNs with adversarial networks due to the following challenges: (1) data sparsity inherent in LBSN data, e.g., the density of the check-ins used in POI recommendation is usually around 0.1% [16]; (2) complexity. Various complicated, latent, and mixed-typed factors, including geographical, spatio-temporal, sequential, social influence, etc., need to be combined into a unified framework for addressing POI recommendation. Our proposed method APOIR provides a fundamentally different way for POI recommendation by learning the user preference distribution, and thus opens up a new perspective for addressing POI recommendation problems – e.g., adversarial time-aware POI recommendation and next POI recommendation.

3 PROBLEM FORMULATION AND PRELIMINARIES

Given a set of POIs $\mathcal{L}$ ($|\mathcal{L}| = M$) and a set of users $\mathcal{U}$ ($|\mathcal{U}| = N$), each with associations to multiple historical check-ins $\mathcal{L}^{u_i}$, POI recommendation aims at recommending each user $u_i \in \mathcal{U}$ with *top-K new* POIs in the set of $\widetilde{\mathcal{L}}^{u_i} = \mathcal{L} - \mathcal{L}^{u_i}$ that u_i is likely to be interested in but has never visited before.

Matrix Factorization (MF): [10] decomposes the user check-in matrix $\mathbf{C} \in \mathbb{R}^{N \times M}$ into a user matrix $\mathbf{U} \in \mathbb{R}^{N \times Q}$ and a POI matrix $\mathbf{L} \in \mathbb{R}^{M \times Q}$ with Q-dimensional latent factors by:

$$\arg\min_{\mathbf{U},\mathbf{L}} \|\mathbf{C} - \mathbf{U}\mathbf{L}^\intercal\|_F^2 + \kappa^u \|\mathbf{U}\|_F^2 + \kappa^l \|\mathbf{L}\|_F^2 \tag{1}$$

where κ^u and κ^l are regularization coefficients, N is the number of users and M is the number of check-ins. The probability of recommending a POI l_j to user u_i is thus derived based on the inner product between the latent factor of user $\mathbf{u}_i$ and that of POI $\mathbf{l}_j$ (denoted as $\mathbf{u}_i\mathbf{l}_j^\intercal$). The preference score vector of u_i over all POIs is denoted $\mathbf{u}_i\mathbf{L}^\intercal$.

Gated Recurrent Units (GRU): [3] is a variant of recurrent neural network (RNN) models consisting of gating mechanisms that control the influence of the hidden state of previous unit h_{t-1} on the state h_t at time step t, i.e., learning to ignore the previous units if necessary. Specifically,

$$\begin{aligned} g_t &= \sigma(W\mathbf{l}_j + Uh_{t-1}) \\ s_t &= \sigma(W\mathbf{l}_j + Uh_{t-1}) \\ \tilde{h}_t &= \tanh(W\mathbf{l}_j + U(s_t \odot h_{t-1})) \\ h_t &= (1 - g_t)h_{t-1} + g_t\tilde{h}_t \end{aligned} \tag{2}$$

where g_t and s_t are update and reset gates, respectively; $\tilde{h}_t$ is a candidate hidden state; W and U are parameter matrices of respective units; σ and tanh are sigmoid and hyperbolic tangent functions, respectively; $\odot$ is element-wise product.

Generative Adversarial Nets (GAN): [8] aims at obtaining the Nash equilibrium between a discriminator D and a generator G by optimizing the following minimax objective :

$$\mathcal{J}_{GAN} = \mathop{\mathbb{E}}_{x \sim p_x}[\log(D(x))] + \mathop{\mathbb{E}}_{\tilde{x} \sim p_g}[\log(1 - D(\tilde{x}))] \tag{3}$$

where p_x is the data distribution and p_g is the model distribution implicitly defined by $\tilde{x} = G(z)$, and $\mathcal{J}_{GAN}$ is maximized w.r.t $D(x)$ and minimized w.r.t. $D(G(\tilde{x}))$. The generator G takes a noise prior distribution $z \sim p(z)$ (e.g., uniform or Gaussian) as input and upon which a sample is generated using a deep neural network. The discriminator D_ϕ – usually another neural network – plays the role of classifier and distinguishes that a certain sample coming

from the true distribution p_x or the generator G. It has been demonstrated that this game achieves global equilibrium if and only if $p_g(x) = p_x(x)$, where p_g is the defined distribution and the optimal discriminator is $D^*(x) = p_x(x)/(p_x(x) + p_g(x))$ [8].

4 OUR PROPOSED APPROACH: APOIR

We now discuss in detail our proposed method, and feature modeling and training details.

Temporal & sequential preference modeling. Before presenting the APOIR method, we first leverage a variant of GRU, combined with MF, to capture both temporal and sequential preference of users. Given a sequence of POIs $l_1, l_2, \cdots, l_t$, each associated with a check-in time $\tau_1, \tau_2, \cdots, \tau_t$, we compute the time interval between adjacent POIs as $\Delta_{\tau_t} = \tau_i - \tau_{i-1}$, $i \in [1, t]$. Then, we can modify the candidate hidden state of Eq.(2) with a time gate T_t as:

$$\begin{aligned} T_t &= \sigma_t(W\mathbf{l}_j + \sigma([\Delta_{\tau_t}; \tau_t]W_t)) \\ \tilde{h}_t &= \tanh(W\mathbf{l}_j + U(s_t \odot T_t \odot h_{t-1})) \end{aligned} \tag{4}$$

where $[\Delta_{\tau_t}; \tau_t]$ is a concatenation of time interval between two successive check-ins and the current check-in time. Now time gate T_t captures the temporal preference of users, as well as POI representation $\mathbf{l}_j$, and is used to control the influence of previous hidden state h_{t-1} in Eq.(4). Finally, a user's temporal and sequential preferences are coded in the last hidden state h_t, which is then used to update user representation with an element-wise product as $\hat{\mathbf{u}}_i = \mathbf{u}_i \odot h_t$. The new user latent factor representation $\hat{\mathbf{u}}_i$ would be used in the following adversarial learning.

Note that above temporal GRU is similar to recent advances on recurrent unit modification [18, 19, 37] towards capture contextual information associated with input data in RNN, except that we only consider temporal features here because we would learn other important factors in an adversarial manner later.

4.1 Adversarial Learning

In this work, we use a generative process $u_i \rightarrow \mathcal{L}$ to model the relationship between a user u_i and the set of POIs $\mathcal{L}$. The underlying true distribution of the user preferences over POIs (expressed as a conditional probability $p_{true}(\mathcal{L}|u_i)$) will be learned by alternatively optimizing two competing components: *Recommender* and *Discriminator*.

4.1.1 Recommender. $R_\theta(l^R|u_i)$, parameterized by θ, is used to recommend a set of unvisited but potentially interested POIs l^R for u_i. The recommender R_θ here is a generator analogue in GAN where it mainly fits a true distribution of data $p_{true}(\mathcal{L}|u_i)$. Similar to this, the POIs recommended by R_θ are based on a process of sampling from the learned empirical distribution $R_\theta(\mathcal{L}|u_i)$. Such a user-POI preference distribution is approximated using the pairwise bayesian personalized ranking (BPR) [22], where user representation is obtained via above described temporal GRU. The objective is to learn a R_θ where the true distribution is close enough to the empirical one so that it is difficult for the discriminator to decide whether the POI is generated by R_θ or from the true distribution.

4.1.2 Discriminator. $D_\phi(u_i, l^R)$, parameterized by ϕ, is used to discriminate whether the recommended POI l^R matches the true preference $\mathcal{L}^{u_i}$ of user u_i. In other words, it constructs a binary vector where 1 denotes that the recommended POI is exactly the true check-ins (positive example) while 0 means a mismatch (non-visited example). The goal of $D_\phi(u_i, l^R)$ is to improve its ability to distinguish historical check-ins from the recommended ones upon R_θ, for a given user u_i.

4.1.3 Objective. According to the GAN paradigm [8], the above two models can be unified into a minimax game: $R_\theta(l^R|u_i)$ maximizes the probability of $D_\phi(u_i, l^R)$ not being able to discriminate recommended POIs l^R from the truth. Correspondingly, $D_\phi(u_i, l^R)$ judges and improves the recommendation performance of $R_\theta(\mathcal{L}|u_i)$. Eventually, $R_\theta(l^R|u_i)$ recommends POIs for user u_i with high quality once an equilibrium reaches, in which $D_\phi(u_i, l^R)$ cannot distinguish the recommended POIs from the truth. Formally, we have the following objective trained alternatively between the recommender R_θ and the discriminator D_ϕ:

$$\begin{aligned} \mathcal{J}^{R^*, D^*} = \min_\theta \max_\phi \sum_{u_i \in \mathcal{U}} \Big(& \mathbb{E}_{l^+ \sim \mathcal{L}^{u_i}}[\log D_\phi(u_i, l^+)] \\ & + \mathbb{E}_{l^R \sim R_\theta(l^R|u_i)}[\log(1 - D_\phi(u_i, l^R))] \Big) \end{aligned} \tag{5}$$

where l^+ is the set of visited (positive) check-ins, and discriminator $D_\phi(u_i, l^R)$ estimates the probability of POIs l^R being preferred/visited by user u_i. We use the sigmoid function $\sigma(D_\phi(u_i, l^R))$ as the discrimination score, similar to [25].

As shown in Eq.(5), both the discriminator and the recommender are iteratively optimized in a minimax game, and we now describe them in details.

4.1.4 Training Discriminator. The objective of the discriminator is to maximize the probability of correctly distinguishing the true check-in locations from the generated recommended POIs by the recommender, given positive samples from true preference distribution and non-visited samples from the recommender. That is, the training objective of D_ϕ is to find an optimal ϕ^* by maximizing:

$$\begin{aligned} \phi^* = \arg\max_\phi \sum_{u_i \in \mathcal{U}} \Big(& \mathbb{E}_{l^+ \sim \mathcal{L}^{u_i}}[\log D_\phi(u_i, l^+)] \\ & + \mathbb{E}_{l^R \sim R_{\theta^*}(l^R|u_i)}[\log(1 - D_\phi(u_i, l^R))] \Big) \end{aligned} \tag{6}$$

where $l^R \sim R_{\theta^*}(l^R|u_i)$ is the generated POIs by the current optimal R_θ , and $l^+ \sim \mathcal{L}^{u_i}$ are the positive samples. $D_\phi(u_i, l^R)$ can also be considered as the probability of R_θ assigning correct labels to recommended POIs l^R. Since function $D_\phi(\cdot)$ is differentiable w.r.t parameters ϕ, the above objective can be solved by stochastic gradient descent [25].

4.1.5 Training Recommender. Similarly to SeqGAN [29], the recommender R_θ generates (selects) a list of ranked POIs for user u_i. Specifically, given the current D_ϕ which is fixed after Eq.(6), we can minimize the following objective to find an optimal θ^*:

$$\begin{aligned} \theta^* &= \arg\min_\theta \sum_{u_i \in \mathcal{U}} \mathbb{E}_{l^R \sim R_\theta(l^R|u_i)} \log(1 - \sigma(D_\phi(u_i, l^R))) \\ &= \arg\max_\theta \sum_{u_i \in \mathcal{U}} \mathbb{E}_{l^R \sim R_\theta(l^R|u_i)} \log(1 + \exp(D_\phi(u_i, l^R))) \end{aligned} \tag{7}$$

which is the objective considered in previous works [25, 34]. However, it does not consider the contexts associated with items, or POIs

in our case. To explicitly explore the rewards from POI contexts, we modify above objective as:

$$\theta^* = \arg\max_\theta \sum_{u_i \in \mathcal{U}} \mathbb{E}_{l^R \sim R_\theta(l^R|u_i)} \log(\lambda + \exp(D_\phi(u_i, l^R)))$$
$$= \arg\max_\theta \sum_{u_i \in \mathcal{U}} \underbrace{\mathbb{E}_{l^R \sim R_\theta(l^R|u_i)} \log \mathcal{R}}_{\mathcal{J}^R(u_i)}$$

where we add a factor λ which is a constant for each u_i, and a defined reward $\mathcal{R} = \lambda + \exp(D_\phi(u_i, l^R))$ will be used as the reward (will explain it later).

Since the POIs l^R sampled from the recommender R_θ is discrete, $\mathcal{J}^R(u_i)$ cannot be directly optimized with gradient descent as in continuous GANs [8]. Following the discrete GANs [25, 29, 34] where the gradient descent is not available, we use the probability of being sampled for each POI to replace the discrete POI as:

$$\nabla_\theta \mathcal{J}^R(u_i) = \nabla_\theta \mathbb{E}_{l^R \sim R_\theta(l^R|u_i)} \log \mathcal{R} = \sum_{j=1}^{M} \nabla_\theta R_\theta(l^j|u_i) \log \mathcal{R}$$
$$= \sum_{j=1}^{M} R_\theta(l^j|u_i) \nabla_\theta \log \mathcal{R} = \mathbb{E}_{l^R \sim R_\theta(l^R|u_i)}[\nabla_\theta \log \mathcal{R}]$$
$$\backsimeq \frac{1}{K} \sum_{k=1}^{K} \nabla_\theta \log R_\theta(l^k|u_i) \log \mathcal{R} \quad (8)$$

where K is the number of POIs sampled by the recommender and l^k is the k^{th} sampled POI. Eq.(8) shows that we use policy gradient based REINFORCE algorithm [26] to derive the gradient. In the context of reinforcement learning [23], $\log(\lambda + \exp(D_\phi(u_i, l^k)))$ acts as the *reward* for the *policy* $R_\theta(l^k|u_i)$ when taking *action* of recommending POI l^k in the *environment* u_i.

4.2 Modeling Reward

We note that above reinforcement learning based likelihood sampling is also used in previous work [25, 29, 34] for sequential data generation and information retrieval. However, these work did not explicitly model the reward of Eq.(8). Instead, they can be considered as optimizations for various methods, e.g., IRGAN [25] is essentially an adversarial optimization method for MF in item recommendation.

In this section, we proceed with modeling the context of POIs and the implicit feedback into the reward function. In this work, we exploit two most important factors [16], i.e., geographical and social influence, for explicitly measuring reward of candidate POIs. Specifically, we consider following reward λ in Eq.(8):

$$\lambda = \alpha \mathcal{R}_{geo} + (1 - \alpha)\mathcal{R}_{soc} \quad (9)$$

where $\mathcal{R}_{geo}$ and $\mathcal{R}_{soc}$ are the reward from the geographical and social factors, respectively. Hyperparameter α is used for scaling the two factors. $\mathcal{R}_{geo}$ and $\mathcal{R}_{soc}$ are in fact two 1-D vectors ($\mathcal{R}_{geo}, \mathcal{R}_{soc} \in \mathbb{R}^{1\times M}$) constructed as follows:

– **Geographical reward** $\mathcal{R}_{geo}$ is initialized with 0 in each column. We set the j^{th} item $l^j \in \mathcal{R}_{geo}$ as 1 if POI l^j is within a distance d to *any* visited POIs for user u_i. That is, we are interested in including the nearby POIs $\mathcal{N}(l^j)$ for all check-ins of user u_i into the candidate list and magnify its importance since people are normally visiting the neighboring POIs [14, 16, 17, 31].

– **Social reward** $\mathcal{R}_{soc}$ is generated in a similar way by setting the j^{th} column $u^j \in \mathcal{R}_{soc}$ to 1 if corresponding POI has been visited by u_i's friend $u_j \in \mathcal{F}(u_i)$, where $\mathcal{F}(u_i)$ denotes the friends of u_i – motivated by the observation that people may visit the POIs where their friends have visited before [2, 11, 16, 31].

4.2.1 Overall Rewards. Note that the second term $\exp(D_\phi(u_i, l^k))$ in the reward of Eq.(8), the function of the discriminator, is also a reward item ($1 \times M$ vector) . Now, we have the following overall reward:

$$\mathcal{R} = \beta(\alpha \mathcal{R}_{geo} + (1 - \alpha)\mathcal{R}_{soc}) + (1 - \beta)\mathcal{R}_D \quad (10)$$

where hyperparameter β controls the effect from POI context and the discriminator $\mathcal{R}_D = \exp(D_\phi(u_i, l^k))$, both of which can be learned from the data. Then, Eq.(8) can be reformulated as:

$$\nabla_\theta \mathcal{J}^R(u_i) \backsimeq \frac{1}{K} \sum_{k=1}^{K} \nabla_\theta \log R_\theta(l^k|u_i) \log(\beta(\alpha \mathcal{R}_{geo}$$
$$+ (1 - \alpha)\mathcal{R}_{soc}) + (1 - \beta) \exp(D_\phi(u_i, l^k))) \quad (11)$$

Essentially, reward $\mathcal{R}$ acts as a regularizer to the recommended POIs from the recommender $R_\theta(l^k|u_i)$ – which outputs the user preference probability over POIs (also a $1\times M$ vector). As the training process goes, $\mathcal{R}$ may gradually push recommender R_θ to produce the POIs matching the preference of the user. It has been proved that if we know the true preference distribution of users, the above adversarial minimax training of APOIR can achieve Nash equilibrium [8] – the recommender exactly fits the true distribution of the user preference, i.e., $R_\theta(\mathcal{L}|u_i) = p_{true}(\mathcal{L}|u_i)$, the discriminator cannot distinguish the recommended POIs from the truth, i.e., the probability of l^R being preferred by u_i based on $D_\phi(u_i, l^R)$ is close to 0.5.

The overall logic of adversarial POI recommendation is summarized in Algorithm 1.

4.3 Discussion

The complexity of the APOIR training is linear in the number of GAN iterations, each of which has a time complexity $O(NK|\widetilde{\mathcal{L}}^{u_i}|)$ in terms of the number of candidate POIs $\widetilde{\mathcal{L}}^{u_i}$. We note that possible improvements can result from reducing the size of $|\widetilde{\mathcal{L}}^{u_i}|$ through filtering the POIs by considering spatial and/or categorical ranking influence [9].

Although both APOIR and IRGAN [25] leverage REINFORCE method for training the generator (recommender for APOIR), we highlight their fundamental differences: (1) APOIR explicitly models the POI reward which can help better understanding and interpreting the recommendation methods; In contrast, IRGAN is a GAN based optimization method for MF; and (2) APOIR additionally incorporates a temporal GRU for modeling the user dynamic preference.

We also note that the reward $\mathcal{R}$ in APOIR only explicitly considers two POI contexts (arguably, the most important two [16]), whereas temporal and sequential factors have been incorporated in the context GRU units. Other factors such as categorical information of POIs have been used in the literature [9]. Incorporating them into the reward function Eq.(9) for better understanding of the POI context, along with incorporating POI embedding [27, 33]

Algorithm 1: Adversarial POI Recommendation.

Input: Recommender R_θ, Discriminator D_ϕ, training data S.

Initialize R_θ and D_ϕ with random parameters θ and ϕ.
Pretrain R_θ on S with MF.
repeat
  Sample K POIs l^R for each user via R_θ;
  foreach $l^k \in l^R$ **do**
    Calculate reward $\mathcal{R}$ of l^k using Eq.(10);
  end
  Update R_θ parameters via policy gradient Eq.(11);
  Recommend POIs for each user using updated R'_θ;
  Sample a set of true locations: $l^+ \sim \mathcal{L}^{u_i}$;
  Update D_ϕ parameters via Eq.(6) with l^+ and l^R;
until *converge*

Output: Recommend *top-K* POIs based on the optimal R_θ for $u_i \in \mathcal{U}$.

for capturing the context of POIs, are also potential sources of improving the Interpretability. However, it may introduce more hyperparameters to tune. How to learn the weights of different contextual factors in the reward function remains an open problem. Such explainable considerations regarding the recommendation model are subject of our future work.

5 EXPERIMENTAL OBSERVATIONS

In this section, we compare the performance of APOIR to baselines using three real-world datasets.

The hyperparameters of APOIR are empirically tuned as: $\alpha = 0.4$, $\beta = 0.7$ for all experiments. The geographical distance parameter d is set to $50km$ following [2].

Table 1: Statistics of three datasets used in experiments.

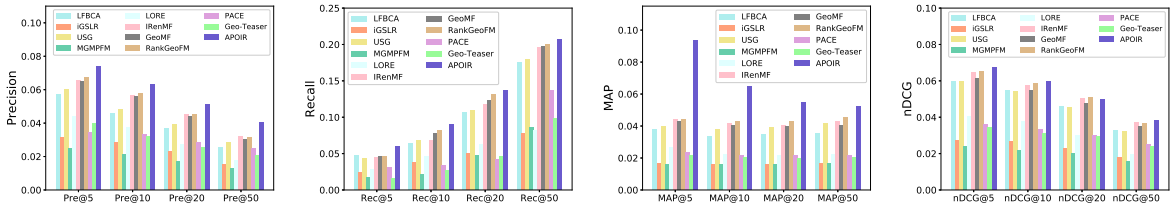
Dataset	#Users	#POIs	#Check-ins	Sparsity
Gowalla	18,737	32,510	1,278,274	99.865%
Foursquare	24,941	28,593	1,196,248	99.900%
Yelp	30,887	18,995	860,888	99.860%

Datasets: We conducted our experiments on three publicly available LBSN datasets[1]: Gowalla, Foursquare and Yelp. For all datasets, we filter out those POIs with fewer than 10 visitors and those users (usually aka. the colder-start users) with fewer than 15 check-in POIs. Since Foursquare data does not have social information, we only report results from those not considering social information. Therefore, we remove the social factor $\mathcal{R}_{soc}$ in Eq.(9) for comparison on Foursquare. And Yelp data does not have check-ins time. Thus, we replace the temporal GRU in APOIR with a matrix factorization based user representation. The datasets after pre-processing are described in Table 1.

Following previous works [16, 27], we partition each dataset into training set and test set. For each user, we use the earlier 75% check-ins as the training data and the most recent 25% check-ins as the test data. All datasets are very sparse (the frequency of most POIs being visited is extremely low). Since a POI recommender system typically aims at recommending POIs that a user has not visited before, we further merge repetitive check-ins and use the earliest one. This can also avoid a testing interaction appearing in the training set.

Baselines: We compare APOIR with 10 approaches, covering from the most popular/representative POI recommendation techniques to models using different kinds of context information:

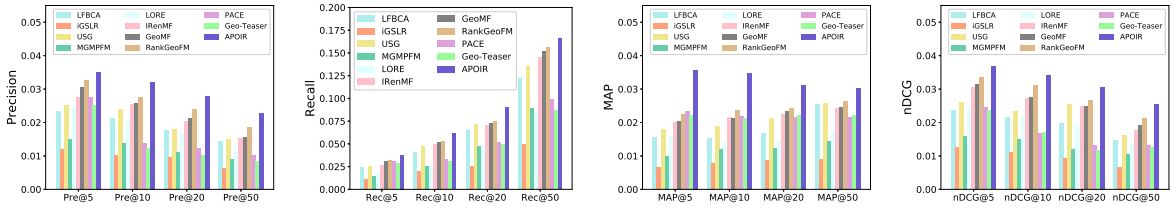
– **USG** [28]: is a collaborative filtering-based recommendation with user preference, social influence and geographical influence simultaneously incorporated.
– **MGMPFM** [1]: combines Poisson factor model and a multi-center Gaussian based geographical modeling method.
– **LFBCA** [24]: is a link-based method that constructs a graph to model users and their relations.
– **iGSLR** [30]: exploits personalized geographical preference and social influence with FCF (friend-based CF) and KDE (kernel density estimation).
– **LORE** [32]: considers sequential influence in addition to social and geographical influence by FCF, KDE and MF.
– **IRenMF** [17]: incorporates characteristics of neighboring POIs in both individual level and region level into weighted matrix factorization for POI recommendation.
– **GeoMF** [14]: integrates spatial influence in user geographical regions and its propagation.
– **RankGeoFM** [13]: is a ranking based geographical factorization method incorporating the spatial-temporal factors.
– **GeoTeaser** [33]: a temporal POI embedding model to capture the contextual check-in information and the temporal characteristics using word2vec framework.
– **PACE** [27]: builds a word2vec-based architecture to jointly learn the embeddings of users and POIs to predict both user preference over POIs and context associated with users and POIs.



We exclude many MF-based approaches, since they have already been shown to be inferior to RankGeoFM [13]. Several recent approaches such as SG-CWARP [15] and ASMF [11] are also excluded because of their worse performance as compared to GeoTeaser [33] and PACE [27].

Metrics: We compare the model performance using four standard metrics in POI recommendation, i.e., Pre@K (precision), Rec@K (recall), nDCG@K (normalized discounted cumulative gain), and MAP@K (mean average precision) [16, 27]. They show different perspectives of the performance evaluation. Precision and recall measure the number of correct recommendations, while nDCG and MAP consider the rank of the recommendations by assigning higher score to hits at higher positions. We report the average score for all methods, and perform one-sample paired t-test to judge the statistical significance where necessary.

5.1 Results



Overall Performance: Figures 1-3 illustrate the comparisons among different methods.From the results, we have following observations: **(1)** APOIR consistently performs the best and significantly improves the POI recommendation performance over the baselines on all metrics across datasets. Take the Yelp data for example (Figure 2), APOIR achives 10.0% on Pre@5, 16.0% on Rec@5, 23.3% on MAP@5 and 9.4% on nDCG@5 over RankGeoFM which performs

the second best. **(2)** The strength of APOIR comes from its capability of capturing user preference with an adversarial learning process. Figure 4(a) plots the training process of APOIR. We observe in experiments that discriminator exhibits strong ability at the beginning of the training but deteriorates as the recommender grows to produce more competitive POIs – Figure 4(b) compares the performance with or without adversarial training. **(3)** MF-based methods, such as IRenMF, GeoMF and RankGeoFM, outperform other baselines which proves the effectiveness of MF in modeling latent features underpinning the complex interactions between users and POIs and the implicit feedback from the geographical information. **(4)** The most recent context embedding-based models such as GeoTeaser and PACE do not exhibit the performance as expected. We conjecture that the dataset used in their released implementation is relatively small and dense. Thus, it is difficult to obtain similar performance with larger and sparser datasets – having more POIs and more low-frequency visited POIs may result in worse embedding in word2vec[20].

6 CONCLUSIONS

We proposed a novel approach – APOIR – for POI recommendation by learning the underlying user preference over POIs in an adversarial manner. APOIR leverages different contexts into the rewards in the reinforcement learning and adopts a generative framework for training two competing components: a recommender and a discriminator. By pushing each other to be close to its limit, the recommender may approach the true preference of users (upon which POIs are sampled and recommended), reaching an equilibrium where it becomes difficult for the discriminator to distinguish these generated POIs from the truly visited ones. Comprehensive experiments on three datasets have demonstrated the effectiveness

of APOIR, with a significant performance improvement on POI recommendation when compared to existing methods.

ABSTRACT

Unveiling human mobility patterns is an important task for many downstream applications like point-of-interest (POI) recommendation and personalized trip planning. Compelling results exist in various sequential modeling methods and representation techniques. However, discovering and exploiting the *context* of trajectories in terms of abstract topics associated with the motion can provide a more comprehensive understanding of the dynamics of patterns. We propose a new paradigm for moving pattern mining based on learning trajectory context, and a method – *Context-Aware Variational Trajectory Encoding and Human Mobility Inference (CATHI)* – for learning user trajectory representation via a framework consisting of: (1) a variational encoder and a recurrent encoder; (2) a variational attention layer; (3) two decoders. We simultaneously tackle two subtasks: (T1) recovering user routes (*trajectory reconstruction*); and (T2) predicting the trip that the user would travel (*trajectory prediction*). We show that the encoded contextual trajectory vectors efficiently characterize the hierarchical mobility semantics, from which one can decode the implicit meanings of trajectories. We evaluate our method on several public datasets and demonstrate that the proposed CATHI can efficiently improve the performance of both subtasks, compared to state-of-the-art approaches.

1 INTRODUCTION

The past decade has witnessed a rapid growth of both academic and practical interest on mining human mobility patterns from location-based social networks (LBSN) such as Twitter and Foursquare. Availability of large volumes of LBSN data has spurred research in studying user behavior and movement patterns [13, 31], point-of-interest (POI) recommendation [16], trip planning [22], along with various privacy-preserving issues [28].

Majority of the existing studies focus on modeling the sequential patterns at *location-* or *POI*-level. Various techniques such as leveraging Markov Chain (MC), Matrix Factorization (MF), Recurrent Neural Networks (RNN), or the word2vec framework have been developed towards various application tasks. For example, in POI recommendation, the state-of-the-art methods are MF [20] and RNN [26] based models that learn user preference over POIs and include the contextual influence of neighboring POIs for generating implicit user-location feedback matrices [25]. More recently, the representation learning such as word2vec [27] has been introduced for embedding POI (and associated features) into latent space [12, 13, 40]. These approaches operate at a fine-grained POI level – which is also the case for trip recommendations, where a sequence of POIs are organized as an itinerary, with various other features (e.g., location, time, distance, user profile and social interactions, etc.) incorporated. In addition, it is expected to learn the POI transitions with MC model [6] or maximize the reward of the selected POIs, e.g., through Monte Carlo Tree Search (MCTS) [21].

Complementary to these, some trajectory mining tasks aim at uncovering implicit mobility patterns, clustering or classifying trajectories – which are typically reduced to location-level learning. For example, sequential and periodic pattern [9, 35] mining requires measuring location or trajectory (a sequence of locations) similarity with various time-series metrics [8], while trajectory clustering groups together similar ones. However, the *Trajectory Context Learning (TCL)* focuses on understanding and encoding the semantics of a trajectory at *trajectory level*. As a higher level of mobility semantic learning, discovering the context of trajectories may enable more comprehensive understanding of the human mobility patterns and provide additional benefits for downstream applications such as POI/trip recommendation.

In this paper, we take initial steps towards learning trajectory context by adapting the problem to an encoder-decoder framework,

inspired by recent progress of representation learning in natural languages processing (NLP). Specifically, we investigate the TCL problem by simultaneously addressing two (sub)tasks: (T1) recovering the user's route by (*Trajectory Reconstruction*) and (T2) predicting the trip that she would travel (*Trajectory Prediction*). To accomplish this, we propose the *Context-Aware Variational Trajectory Encoding and Human Mobility Inference (CATHI)* method for embedding the contexts of trajectories in an unsupervised manner within a seq2seq framework which consists of two encoders and two decoders, tuned with a novel variational attention mechanism. The two sub-tasks of TCL problem are then trained in parallel with the proposed model. In summary, our main contributions are:

- We address the TCL problem in LBSN applications as a novel learning paradigm for analyzing human mobility patterns. We propose an approach for encoding the semantics of trajectories and inferring the trajectory context, which is the first context-aware trajectory learning model and opens a new perspective for understanding user check-in behaviors.
- The proposed CATHI method leverages two variational latent factors which are respectively the traditional latent variables and the variational hidden state attention, for learning trajectory-level context. This novel variational architecture is not only capable of estimating the probability density and optimizing the lower bound of the data likelihood, but also captures the sequential and temporal characteristics of human mobility.
- We address the trajectory prediction and reconstruction simultaneously using the proposed CATHI method, which is evaluated on several public LBSN datasets and compared to competing models, demonstrating that it achieves state-of-the-art performance, which also reflects upon the efficiency of TCL.

2 OUR PROPOSED METHOD: CATHI

We now formally define the TCL problem and introduce the CATHI method consisting of two subtasks – (T1): trajectory reconstruction and (T2): trajectory prediction.

Given a set of POIs $\{l_1, l_2, ..., l_m\}$ and a set of trajectories $\mathbf{T} = \{T_1, T_2, ..., T_n\}$, where T_i is a sequence of POIs generated by a particular user, let $\mathbf{T}^r$ denote the training data consisting of a set of variable-length trajectories generated by certain users in a particular area (e.g., in a city or a scenic spot). We denote the t^{th} POI for trajectory T_i as l_i^t and its embedding vector (with word2vec [27]) as $\mathbf{v}_i^t \in \mathbb{R}^d$, where d is the POI embedding dimensionality.

2.1 Overview

The main objective of TCL is to produce two surrounding trajectories $\mathbf{T}_i^s = \{T_{i-1}, T_{i+1}\}$ for a given trajectory $T_i \in \mathbf{T}^r$. Generally, given a tuple $< T_{i-1}, T_i, T_{i+1} >$, where T_i is the i^{th} trajectory in $\mathbf{T}^r$, we are interested in coupling the reconstruction of T_{i-1} and prediction of T_{i+1}. That is, let $T_i = \{l_i^1, l_i^2, ..., l_i^N\}$ be a trajectory with N POIs, TCL tries to construct the previous trajectory $T_{i-1} = \{l_{i-1}^1, l_{i-1}^2, ..., l_{i-1}^Q\}$ and predict the next trajectory $T_{i+1} = \{l_{i+1}^1, l_{i+1}^2, ..., l_{i+1}^M\}$, respectively.

To this end, our CATHI model consists of four components (shown in Figure 1): (1) *recurrent encoder*, (2) *variational encoder*, (3) *variational attention layer*, and (4) *two decoders*. More specifically, a recurrent encoder maps a sequence of POIs to a set of hidden states $\{\mathbf{h}_i^1, \mathbf{h}_i^2, ..., \mathbf{h}_i^N\}$. Meanwhile, a variational encoder learns the distribution of the latent variable z. Subsequently, a variational attention on the hidden states of recurrent encoder learns the distribution of another latent variable $\mathbf{c}$. Finally, two decoders, conditioned on two latent variables z and $\mathbf{c}$, are employed to generate the previous trajectory and the next one respectively. Both decoders have a two-layer architecture in which the first-layer decoder $\texttt{Dec}_1$ alone can be employed to reconstruct the surrounding trajectories, and the second-layer decoder $\texttt{Dec}_2$ is added to refine the results of $\texttt{Dec}_1$.

2.2 Trajectory Context Encoding

Throughout this work, the Trajectory Context Encoding (TCE) relies on variational autoencoder [19] and Long Short-Term Memory (LSTM) [18] – one spatio-temporal LSTM for the encoder and two variants of LSTM for the decoders. Details will be presented below.

2.2.1 Recurrent Trajectory Encoder. The recurrent encoder is a bi-directional LSTM. At each time step t, one can obtain an annotation for each POI by concatenating the forward and backward hidden states, i.e., $\mathbf{h}_i^t = [\overrightarrow{\mathbf{h}}_i^t; \overleftarrow{\mathbf{h}}_i^t]$, interpreted as the representation of the trajectory $l_i^1, l_i^2, ..., l_i^t$. The last hidden state $\mathbf{h}_i^N$ thus represents the full trajectory T_i.

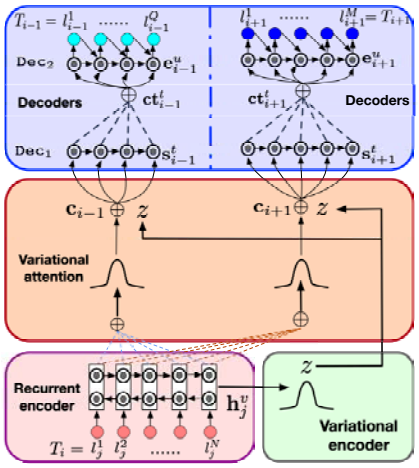

Figure 1: Trajectory context encoding with two encoders and two decoders with each having two layers.

Previous analysis shows that POIs' contextual information, such as geographical location and social information, has influence over user check-in behavior. Integrating them into the model might be helpful for better representation of users. However, vanilla LSTM does not consider the contextual information associated with POIs. To address this limitation, we present an extension of LSTM that is capable of encoding the spatio-temporal features in check-ins.

Given a sequence of check-ins $l_i^1, \cdots, l_i^t, \cdots, l_i^N$, each l_i^t associated with a check-in time τ_i^t and a geo-location g_i^t, we compute both time interval and distance between adjacent check-ins as $\Delta_{\tau_i^t} = \tau_i^t - \tau_i^{t-1}$ and $\Delta_{g_i^t} = g_i^t - g_i^{t-1}$, $t \in [1, N]$. Then we add a time gate $\mathbf{t}_i^t$ and a geographical gate $\mathbf{g}_i^t$ and modify the candidate

gate $\tilde{\mathbf{h}}_i^t$ as

$$\begin{aligned}
\mathbf{t}_i^t &= \sigma(W_t \mathbf{v}_i^t + \sigma([\Delta_{\tau_i^t}; \tau_i^t] W_t) + b_t) \\
\mathbf{g}_i^t &= \sigma(W_g \mathbf{v}_i^t + \sigma(\Delta_{g_i^t} W_g) + b_g) \\
[\mathbf{i}_i^t, \mathbf{f}_i^t, \mathbf{o}_i^t] &= \sigma(W \mathbf{v}_i^t + U \mathbf{h}_i^{t-1}) \\
\tilde{\mathbf{h}_i^t} &= \tanh(W' \mathbf{v}_i^t + U'(\mathbf{t}_i^t \odot \mathbf{g}_i^t \odot \mathbf{h}_i^{t-1})) \\
\mathbf{m}_i^t &= \mathbf{f}_i^t \mathbf{m}_{i-1}^t + \mathbf{i}_i^t \tilde{\mathbf{h}_i^t} \\
\mathbf{h}_i^t &= \tanh(\mathbf{m}_i^t) \odot \mathbf{o}_i^t
\end{aligned} \tag{1}$$

where $\mathbf{v}_i^t$ is the embedding vector of the POI l_i^t, $[\Delta_{\tau_t^t}; \tau_t^t]$ is a concatenation of time interval and the current check-in time; $\mathbf{i}_i^t, \mathbf{f}_i^t, \mathbf{o}_i^t$ are input, forget and output gates in vanilla LSTM; W and U are parameter matrices w.r.t different gates. Now the two new gates capture spatio-temporal preference of users, which is used to control the influence of previous hidden state $\mathbf{h}_i^{t-1}$ in Eq.(1).

Note that above contextual LSTM is employed in the recurrent encoder. The hidden state $\mathbf{h}_i^t$ contains the information from both the preceding POIs and the following POIs in T_i. Due to the tendency of RNNs to better represent recent inputs, the hidden state $\mathbf{h}_i^t$ will focus more on the POIs around current check-in l_i^t (cf. [1]). Instead of only attention to different words in NLP encoder such as [5], we follow the typical assumption in trajectory modeling that adjacent POIs have more (related) information than long-distance ones, both temporally and geographically. Such constraints are achieved by the proposed spatio-temporal gates. This sequence of hidden states, combined with the following variational variables, can later be used to compute context vectors in the decoder.

2.2.2 Variational Trajectory Encoder. We use a variational encoder [19] for encoding the trajectory as a latent variable z, which is then used to reconstruct the original trajectory under the generative model: given a trajectory T_i, its likelihood is

$$\begin{aligned}
\log p_\theta(T_i) &= \log p_\theta(T_i) \int_z q_\phi(z|T_i) \mathrm{d}z \geq \triangleq \mathcal{L}(T_i) \\
&= \mathbb{E}_{z \sim q_\phi(z|T_i)}[\log p_\theta(T_i|z)] - \mathbb{KL}\left[q_\phi(z|T_i)||p_\theta(z)\right]
\end{aligned} \tag{2}$$

where $q_\phi(z|T_i)$ is an approximation to the true posterior $p_\theta(z|T_i)$ (a.k.a *recognition model* or *encoder*) parameterized by ϕ. $\mathbb{KL}\left[q_\phi(\cdot)||p_\theta(\cdot)\right]$ is the KL divergence between the learned latent posterior distribution $q(z|T_i)$ and the prior $p(z)$ (for brevity, we will omit the parameters ϕ and θ in subsequent formulas). Since the objective (of the model) is to minimize the KL divergence between the proposal $q(z|T_i)$ and the true distribution $p(z|T_i)$ – we can alternatively maximize the evidence lower bound (ELBO) $\mathcal{L}(T_i)$ w.r.t. both θ and ϕ, which are jointly trained with separate neural networks such as multi-layer perceptrons.

2.2.3 Variational attention. Traditional attention mechanisms [1] are used for dynamically aligning the input and output sequences. Specifically, we compute a probabilistic distribution by

$$\gamma_{vt} = \frac{\exp(\mathbf{s}_{i\pm1}^v W^\intercal \mathbf{h}_i^t)}{\sum_{t'=1}^N \exp(\mathbf{s}_{i\pm1}^v W^\intercal \mathbf{h}_i^{t'})} \tag{3}$$

where $\mathbf{s}_{i\pm1}^v$ denotes the v^{th} hidden state of previous (next) trajectory, $\mathbf{h}_i^t$ is t^{th} hidden hidden state of recurrent encoder, and W is the parameter matrix needed to be learneded. Then, the attention vector $\mathbf{c}_{i\pm1}$ is calculated by summing the weighted input:

$$\mathbf{c}_{i\pm1}^v = \sum_{t=1}^N \gamma_{vt} \mathbf{h}_i^t \tag{4}$$

which is fed into the decoder at v^{th} step. We will denote the attention vector as $\mathbf{c}$ for simplicity.

However, if we directly use above attention vector $\mathbf{c}$, this deterministic attention is powerful enough to reconstruct the input and may eliminate the influence of the variational encoder – a.k.a. "bypassing" phenomena in combining VAE and seq2seq models [3]. Therefore, we introduce a variational attention on the hidden states of the recurrent encoder inspired by [2]. That is, the attention vector $\mathbf{c}$ is also treated as a latent factor as z, both of which are combined to reconstruct the input data by maximizing the ELBO:

$$\begin{aligned}
\mathcal{L}(T_i) &= \mathbb{E}[\log p(T_i|z, \mathbf{c})] - \mathbb{KL}\left[q(z, \mathbf{c}|T_i)||p(z, \mathbf{c})\right] \\
&= \mathbb{E}[\log p(T_i|z, \mathbf{c})] - \rho \mathbb{KL}\left[q(z|T_i)||p(z)\right] \\
&\quad - \psi \mathbb{KL}\left[q(\mathbf{c}|T_i)||p(\mathbf{c})\right]
\end{aligned} \tag{5}$$

which is derived based on the fact that $\mathbf{c}$ and z are conditionally independent given T_i. The prior $p(\mathbf{c})$ is initialized via a Gaussian $p(\mathbf{c}) = \mathcal{N}(\bar{\mathbf{h}}_i, \mathbf{I})$ with $\bar{\mathbf{h}}_i$ as the mean of the hidden states of the recurrent encoder. At the early stage of variational training, the terms $\mathbb{KL}\left[q(\cdot|T_i)||p(\cdot)\right]$ in Eq.(5) may discourage encoding interesting information into the latent variables z and $\mathbf{c}$, thereby easily resulting in model collapse – largely because of the strong learning capability of autoregressive models such as RNN as observed in [3]. One efficient solution is to control the weight of KL-divergence term by gradually increasing its co-efficiencies ρ and ψ (from 0 to 1), which is also called KL cost annealing [3].

2.2.4 Trajectory Decoders. As mentioned above, there are two decoders in CATHI: two LSTMs trained to reconstruct the previous trajectory T_{i-1} and predict the next trajectory T_{i+1}, respectively.
– **Decoder 1.** In the case of trajectory T_{i+1} decoding, the first decoder $\texttt{Dec}_1$ predict next POI l_{i+1}^t given: (1) all the previously predicted POIs $\{l_{i+1}^1, l_{i+1}^2, ..., l_{i+1}^{t-1}\}$; (2) the variational attention vector $\mathbf{c}$; and (3) the variational latent variable z. For example, the decoder is trained to maximize the probability of $\{l_{i+1}^1, l_{i+1}^2, ..., l_{i+1}^M\}$ given trajectory T_i which can be decomposed into the ordered conditional probabilities:

$$p(\{l_{i+1}^1, l_{i+1}^2, ..., l_{i+1}^M\}) = \prod_{t=1}^M p(l_{i+1}^t | l_{i+1}^{<t}, \mathbf{c}, z) \tag{6}$$

where $l_*^{<t}$ denote previous $t-1$ POIs in the next trajectory. Each conditional probability $p(l_{i+1}^t | l_{i+1}^{<t}, \mathbf{c}, z)$ depends on the context vectors $\mathbf{c}$, z and all the previous POIs $\{l_{i+1}^1, l_{i+1}^2, ..., l_{i+1}^{t-1}\}$. With the first LSTM decoder, the conditional probability can be modeled as:

$$p(l_{i+1}^t | l_{i+1}^{<t}, \mathbf{c}, z) = \mathrm{LSTM}(\mathbf{v}_{i+1}^{t-1}, \mathbf{c}, z, \mathbf{s}_{i+1}^{t-1}) \tag{7}$$

where $\mathbf{s}_{i+1}^{t-1}$ is the hidden state of the decoder LSTM.

Therefore, given a tuple $< T_{i-1}, T_i, T_{i+1} >$, the objective of trajectory context encoding is to maximize the log-probabilities for the previous and next trajectories of T_i:

$$\mathcal{J} = \log \prod_t p(l_{i+1}^t | l_{i+1}^{<t}, \mathbf{c}_{i+1}, z) p(l_{i-1}^t | l_{i-1}^{<t}, \mathbf{c}_{i-1}, z) \tag{8}$$

where the two decoders (for T_{i+1} and T_{i-1}) focus on different POIs in T_i with distinct context vectors $\mathbf{c}_{i\pm1}$, iterating through all the tuples in the dataset during each epoch of the TCL training.

– Decoder 2. Intuitively, the first decoder(s) already can be employed to reconstruct the surrounding trajectories of T_i. However, the generated trajectories (both previous and next one) suffer the "myopic" posterior in the sense that the POIs generated previously at time step t are not informed about the whole future in the sequence – recall that at time step t, only the POIs $l_*^{<t}$ are used in Equation (8) without considering possible POIs $l_*^{>t}$ thereafter. We now introduce a refinement process to CATHI when inferring the around trajectories.

Specifically, we add a second decoder $\texttt{Dec}_2$ upon the first decoder $\texttt{Dec}_1$ to refine the final trajectory. In contrast to $\texttt{Dec}_1$, $\texttt{Dec}_2$ exploits the information regarding all the POIs of the generated trajectories by $\texttt{Dec}_1$ at each time step. In addition to the previous hidden state and previously generated POIs, $\texttt{Dec}_2$ leverages the context vector $\mathbf{ct}_{i\pm1}^t$, the weighted sum of the hidden states of $\texttt{Dec}_1$, to "polish" the generated trajectory, i.e., T_{i-1} and T_{i+1}. That is, $\texttt{Dec}_2$ updates the context vector $\mathbf{ct}_{i+1}^t$ at time step t as:

$$\mathbf{ct}_{i+1}^t = \sum_{u=1}^{M} \beta_{ut} \mathbf{s}_{i+1}^u$$

This is actually another attention vector on the first decoder weighted by a probabilistic distribution

$$\beta_{ut} \propto \exp\{\mathbf{e}_{i+1}^u W^\intercal \mathbf{s}_{i+1}^t\} \tag{9}$$

where $\mathbf{e}_{i+1}^u$ is the hidden state of $\texttt{Dec}_2$ and $\mathbf{s}_{i+1}^t$ is the hidden state of $\texttt{Dec}_1$.

2.2.5 Inference. After describing how to learn the context of trajectories, we now turn our attention from training to trajectory inference for addressing the two subtasks – trajectory reconstruction and trajectory prediction. In many seq2seq based tasks such as neural machine translation [1] and dialogue generation [3], beam search is the *de facto* decoding method at test time, due to the shrunk search space and reduced computational complexity. Beam search maintains a set of B highest-scoring beams which are prefixes of trajectories. At each time step, every possible POI is added to every existing beam, yielding a total of $B \times D$ beams where D is the number of all possible POIs. Then we discard all but the B most likely beams according to the log-likelihood of the trained model. This procedure is repeated until a segment ends with the end-of-trajectory token or reaches the preset maximum length of trajectories. The segment that ends with end-of-trajectory token will then be moved to the set of complete hypotheses. Finally, we choose the one with highest probability from the hypotheses.

3 EVALUATION

We now present the results of our evaluation regarding the performance of TCL solutions with the two context-aware trajectory inference tasks: trajectory reconstruction and prediction.

Datasets. We conducted our experiments on three datasets shown in Table 1. The trajectories extracted from Flickr photos and videos are typically used for trip recommendation [6, 21, 22]. **Toronto, Osaka, Glasgow and Edinburgh** data were built by Lim et al. [22]; **Melbourne** data were built by [6], and **Cali.Adv, Hollywood, Epcot, DisneyLand and MagicKing** data were built by [21]. **Foursquare** dataset [34] is often used for POI recommendation and contains 573,703 check-ins in Tokyo collected for approximately 10 months (from 12 April 2012 to 16 February 2013). We randomly selected 400 users and their historical trajectories for evaluation. **Geolife** dataset [38] was collected in Microsoft Geolife project in a period of over five years (from April 2007 to August 2012). Since the trajectories in original Geolife dataset contain only GPS points (longitude and latitude), we cluster all points based on their locations to obtain 4,796 POIs – that is, we save the two digits after the decimal point of longitude and latitude. For all the datasets, we randomly chose 90% trajectories for training and the rest for testing.

Table 1: Descriptives of datasets.

Dataset	#POI	#Trajectory	#User
Flickr@Edinburgh	29	5,028	1,454
Flickr@Glasgow	29	2,227	601
Flickr@Melbourne	87	5,106	1,000
Flickr@Osaka	29	1,115	450
Flickr@Toronto	30	6,057	1,395
Flickr@Cali.Adv	25	6,907	2,593
Flickr@Hollywood	13	3,858	1,972
Flickr@Epcot	17	5,816	2,725
Flickr@Disneyland	31	11,758	3,704
Flickr@MagicKing	27	8,126	3,342
Foursquare@Tokyo	30	1,1254	400
Geolife	4,796	24,943	179

We note that the two tasks evaluated in our experiments are predicting and reconstructing a sequence, which are more complicated than location prediction and/or recommendation which requires predicting/recommending a point. Thus, for the two tasks, the datasets are large enough to evaluate the methods, which is quite different from the datasets used in venue recommendation/prediction [9, 26].

Baselines. Since TCL is a novel problem proposed in this work, we compare our method with several state-of-the-art approaches from the area of sequential pattern modeling and trajectory recommendation, with two metrics for measuring accuracy and visiting-order of POIs in each reconstructed and predicted trajectory. The baselines consist of:

- **Random**: A naive approach chooses at random to construct a trajectory with desired length.
- **POIPopu** [11]: It selects the most popular and unvisited POI at each time.
- **POIRank** [6]: It plans a trajectory by first ranking POIs with rankSVM and then connects them according to ranking scores.
- **Markov and MRank** [6]: Markov considers the POI-POI transition probabilities and plans a trajectory by maximizing the transition likelihood. Markov-Rank learns both POI ranking and Markov transition.
- **MPath and MPRank** [6]: MarkovPath (MPath) and MarkovPath-Rank (MPRank) eliminate sub-tours in Markov and Markov-Rank by finding the best path using an integer programming.
- **ST-RNN** [23]: is a RNN-based method incorporating spatial and temporal context for predicting the next location.

- **DeepMove** [9]: a most recent POI prediction method learning user periodical patterns with attention mechanism and the sequential patterns within the recurrent neural networks.
- **CARA** [26]: a most recent POI recommendation method jointly learns the user dynamic preference and contextual information associated with check-ins under the GRU [7] architecture.

Note that the last three methods (ST-RNN, DeepMove and CARA) are not targeting sequence learning. We extend them to infer a trajectory by predicting (or reconstruct) a sequence of POIs iteratively – e.g., after predicting POI l_*^{i+1}, we incorporate l_*^{i+1} into a LSTM for predicting l_*^{i+2}, and so on.

Metrics We use F_1 and pairs-F_1 score to evaluate the two subtasks in TCL following previous works [6, 21].

3.1 Experimental Observations

Overall performance: Table 2 and 3 respectively show the experimental results of trajectory reconstruction and trajectory prediction on 10 Flickr datasets, while Table 4 shows the results on Geolife and Foursquare (we exclude others due to the limited space). Note that the values before and after '±' are respectively the mean and the standard deviation.

Firstly, CATHI consistently yields the best performance on two subtasks for both metrics, while exhibiting significant improvement over the baselines. The effectiveness of CATHI lies in its trajectory-level embedding which simultaneously encodes the context information and captures the sequential patterns of trajectories (at both POI-level and trajectory-level). On the contrary, ST-RNN, DeepMove and CARA are deep learning based methods learning mobility at the POI-level and usually exhibit the secondary performance. In addition, one can also observe that CATHI achieves the lower value of standard deviation than other methods (except Random which samples around the mean and thus has minimum value of standard deviation), which means that the results of CATHI are more stable.

On the other hand, CATHI employs contextual recurrent networks as the encoders and decoders and proves their superior performance compared to MC-based models, especially in terms of trajectory ordering (measured by pairs-F_1). Note that the performance of MC-based models may even drop to the same level (if not worse) of random and greedy methods. This is because MC (or its variants) learns the transition patterns at the POI-level and works well when predicting the next one or previous one POI. However, both two subtasks in our work require to form a POI sequence.

Moreover, we observe that the performance of trajectory reconstruction is slightly better than the trajectory prediction, which is also true for other baselines. This phenomenon motivates a decomposition of the subtasks into two steps: (1) reconstruct the trajectories of individuals, and (2) incorporate the results to improve the prediction accuracy.

Validity of components: Recall that our CATHI model consists of several functional parts. In order to investigate the effectiveness of each component, we compare a series of variants of CATHI, including: (1) CATHI-1, which uses a basic seq2seq model, with contextual LSTM for trajectory context learning; (2) CATHI-2, which incorporates a deterministic attention mechanism into CATHI-1; (3) CATHI-3, which further incorporates variational encoder-decoder into CATHI-2; (4) CATHI-4, which considers attention vector as another variational variable; and (5) the CATHI, which can be considered as adding the second decoder on CATHI-4. Obviously, these methods gradually builds up our CATHI method. Thus, we can understand the rationale behind by scrutinizing the performance of each module.

Figure 2 plots the performance of the five methods on five Flickr datasets. From the trajectory prediction task, we can see that each component of CATHI contributes to the trajectory context learning. Among various modules, deterministic attention is the most influential one. We also observe that our variational attention works well across all comparisons which proves that variational encoder-decoder can be used to enhance seq2seq model, but should consider the attention vectors as variational variables. Finally, CATHI outperforming CATHI-4 demonstrates that the second decoder indeed improve the TCL performance by refining the results of using one decoder, especially for better learning visiting order – it largely improves the pairs-F_1 results.

and trip planning. The sequential patterns of check-ins are usually modeled by various machine learning techniques, such as Markov Chains (MC) [6, 17], matrix/tensor factorization [20], pairwise ranking model [16], Recurrent Neural Networks (RNN) [9, 13, 13, 23, 26] and distributed representation methods [10, 24, 32, 33, 37] (e.g. word2vec [27]). Trip planning leverages the spatio-temporal check-ins for recommending a sequence of POIs (POI-level modeling paradigm) and a use of MC to model the POI→POI transition by learning from historical behavior and trajectories have been discussed in [6, 21]. This line of researches focuses on modeling the sequential patterns of POIs (combined with various features of POIs and users) for solving different application tasks. However, they fail to incorporate the *context of trajectories* which is the objective of our work.

Figure 2: Comparison of modules in CATHI.

Trajectory Pattern Learning. Uncovering semantic patterns characterizing human trajectory has been studied extensively, and the results can be categorized into: (1) *statistical patterns learning*: measuring and quantifying models such as continuous-time random-walk [4] and Lévy flight [15], accounting for characteristics of individual human trajectories [29]. (2) *similarity mining*: measuring the similarity or distance between two trajectories, such as Dynamic Time Warping or Edit distance [8] – which may exploit the uniqueness and regularity of human mobility. (3) *periodical pattern mining*: finding (sub-)sequences and periodical motion patterns, enabling travel recommendation [6, 21], life pattern understanding [23, 30, 36], recovering trajectories associated with users [13, 39] and next location prediction [9, 14, 23]. The numerous works in semantic trajectory mining have not formally defined (and addressed) the *trajectory context learning (TCL)*, which is part of our study. Our proposed CATHI is also different from conventional approaches in that it captures higher level of semantics and provides more comprehensive understanding of human mobility by learning long-short term dependency at the trajectory level.

5 CONCLUSIONS

We introduced a novel problem – Trajectory Context Learning (TCL) – aiming at mining of high-level human motion patterns. Towards its solution, we relied on Trajectory Context Embedding and proposed CATHI – a method for jointly learning hierarchical and sequential patterns of trajectories, beneficial for many downstream tasks needing inference of human trajectories. As demonstrated, TCL provides valuable insights and promising guidelines for further investigations of intricacies of motion patterns. As part of our future work we plan to investigate how to leverage it for modeling the topics of sequential patterns, and its use in a wider range of applications, such as POI recommendation and road planning.

ABSTRACT

We present a novel generative Session-Based Recommendation (SBR) framework, called VAriational SEssion-based Recommendation (VASER) – a non-linear probabilistic methodology allowing Bayesian inference for flexible parameter estimation of sequential recommendations. Instead of directly applying extended Variational AutoEncoders (VAE) to SBR, the proposed method introduces normalizing flows to estimate the probabilistic posterior, which is more effective than the agnostic presumed prior approximation used in existing deep generative recommendation approaches. VASER explores soft attention mechanism to upweight the important clicks in a session. We empirically demonstrate that the proposed model significantly outperforms several state-of-the-art baselines, including the recently-proposed RNN/VAE-based approaches on real-world datasets.

1 INTRODUCTION

Session-based recommendation (SBR) [18, 36] aims at predicting user's next action based on a series of recent actions. It is a kind of sequence learning/recommendation task where longer-term user historical activities are usually unavailable and the recommendations need to be made in accordance with an assumed short-term interests of the (anonymous) user.It has been widely used in various applications, such as news recommendation, e-commerce, video and classified advertisement recommendation [10, 36].

Recent advances in deep learning have spurred the use of recurrent neural networks (RNNs) based methods to model SBR [17, 18, 28, 33], achieving significant improvement on recommendation accuracy over traditional sequence-based models such as factorizing personalized Markov chains (FPMC) [16, 38] and feature-based matrix factorization (MF) [5, 51]. Specifically, GRU4Rec [18] – a first application of augmented gated recurrent units (GRUs) [8] – was developed to address SBR by encoding user's preference and learning it for next-click prediction. Subsequently, a few improvements to GRU4Rec have been proposed – e.g., incorporating attention mechanism [28]; employing hierarchical recurrent networks [28]; augmenting data with additional features associated with items [19]; prioritizing short attention/memory [33]; and introducing more sophisticated ranking algorithms [17].

Complementary to these works, recent efforts on incorporating stochastic latent variables trained by deep generative models (e.g., variational autoencoders (VAE) [25, 40]) have enabled significant progress in many natural language processing tasks (e.g., dialogue generation and machine translation [2, 3, 11, 14, 21]). Similarly, Various generative models including VAEs have demonstrated potential for learning effective non-linear representations of user-item interactions [7, 23, 27, 30, 32] in collaborative filtering settings. For the most part, they either model the generation process of auxiliary information (e.g., content and ratings) [7, 27, 30] or build a probabilistic latent-variable framework that shares statistical strength among users and items [7, 23, 32].

Despite the improvements over conventional item recommendation, the aforementioned Bayesian models cannot be directly generalized to SBR due to the following reasons:
(1) **Data availability**: the lack of users' profile information and long-term interaction data makes these models not work well in SBR settings.
(2) **Bypassing issue**: autoregressive models (e.g., LSTM [20] and GRU [8]) combined with the soft attention mechanisms [1] have capabilities of reconstructing an encoded session on their own. This

may weaken the effects of the incorporated latent factors [3], which can potentially reduce the performance of the VAE-based models. (3) **Biased inference**: VAE based models usually assume a predefined prior for latent factors [24], e.g., multivariate Gaussian which might result in the inferred approximate posterior greatly deviating from the true distribution.

We extend VAEs to model implicit feedbacks of user-item interactions in a session, and present the *VAriational SEssion-based Recommendation (VASER)*. While retaining the *Bayesian inference* of VAEs and enabling exploration of *non-linear* probabilistic latent-variable models, the VASER model: (1) effectively addresses the problem of unimodal and simple parametric problems of existing SBR methods; and (2) largely ameliorates the bias inference problem of existing VAE based recommendation methods. Specifically, we make the following contributions:

- VASER augments the RNNs based SBR models with stochastic latent variables, enabling stable and effective approximate inference of a high-level "objective" of an entire session from the observed clicks.
- We exploit the flows to approximate the real posterior of stochastic latent factors, which can largely alleviate the inference bias in existing VAE based recommendation models and improve the next click prediction accuracy.
- We demonstrate that VASER achieves improvements in SBR performance over the baselines on several real-world datasets.

2 PRELIMINARIES

We now introduce the basic notation used in the rest of the paper and formally define the problem. Recalling that SBR aims at predicting which item an anonymous user would like to click next given his current sequence of interaction data, we also provide an overview of the RNN based approaches.

2.1 Problem Definition

Formally, we have a set of sessions $\mathbf{S}$, and each session $\mathbf{s}_i \in \mathbf{S}$, consists of a sequence of user actions (e.g., click, purchase, etc.). $\mathbf{s}_i = [x_{i,1}, \cdots, x_{i,N}]$ (interchangeably denoted by $x_{i,(1:N)}$), where $x_{i,j} \in \mathbb{R}$ ($1 \leq j \leq N$, N is the length of the session.) is an interaction with item j in the session, assumed to be mapped to the domain $\mathbb{R}$. When no ambiguity arises, we will omit the index of the session – thus, given the prefix $\mathbf{s}' = [x_1, \cdots, x_{N-1}]$ of a session $\mathbf{s}$, the SBR model predicts the label(s) of the next action x_N by learning a classification distribution $\mathbf{y} = [\hat{y}_1, \cdots, \hat{y}_M]$ over M items, where $\hat{y}_j$ refers to a (predicted) probability or a ranking score for the N^{th} interaction with item j. Note that in practice, usually more than one recommendation is made, which is often referred to *top-k* session-based recommendation [28, 52].

2.2 SBR with RNNs

Existing RNN based models, with or without attention, train the sessions in a seq2seq manner. The main differences among them are how to decode the latent factors (or more precisely the last hidden state of the RNN) and how to embed the items. In "vanilla" GRU based models [17–19], decoding reconstructs the session and embedding is a separate layer of training. In attentive RNN-based models [30, 33], however, the encoder acts as an embedding layer

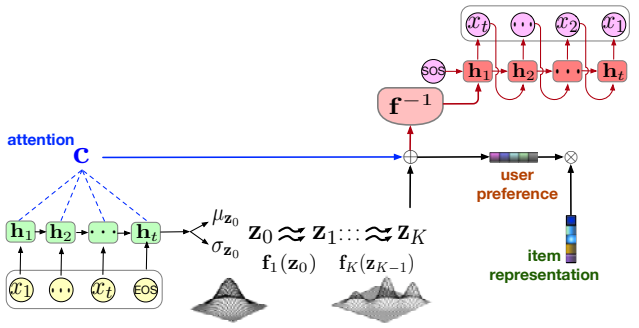

Figure 1: Overview of VASER. Recommendation is made based on the posterior $q(\mathbf{z}_K)$ of the last hidden state and the attention vector. Items are represented by embedding vectors.

– i.e., they train item embedding along with calculating loss of training sessions. Therefore, this type of *supervised* training may indeed "memorize" the sequential information of a given session, which may be "conducted" in the testing phase as the items in testing sessions would look-up the embedding matrix. As observed in the experiments in [30], this dynamic embedding method may significantly improve the performance.

An important observation is that all these works train the model in an *explicit autoregressive* fashion, i.e., they split the sessions (both training and testing) into a set of sub-sessions. Thus, a session $\mathbf{s} = [x_1, \cdots, x_N]$ would be divided into $N-1$ sub-sessions: $\mathbf{s}^1 = [x_1, \cdots, x_{N-1}]$, $\mathbf{s}^2 = [x_1, \cdots, x_{N-2}]$, $\cdots$, $\mathbf{s}^{N-1} = [x_1, x_2]$ and the original session $\mathbf{s}$ – all of which would be fed into the models for training or testing. Although not explicitly specified, this kind of autoregressive training improves the overall performance of the models, since a longer session actually contains (and thus "memorizes") the sub-sessions. We note that this autoregressive training trick has also been explored in recent CNN based SBR models [45, 52].

3 MAIN METHODOLOGIES

We propose the VASER model, as illustrated in Figure 1, consisting of two main components, namely GRU module and attention module. The GRU module captures sequential preferences, and the hidden state can exploit the non-linear preferences. The attention module is used to enhance the GRU network by dynamically selecting and linearly combining different parts of the input sequence. VASER employs a deterministic attention mechanism. VASER incorporates the normalizing flows for flexible posterior approximation. In the sequel, we present the general framework of VASER with theoretical background and training procedure.

3.1 Session Generative Model

We consider a click session generative process as follows. For each session $\mathbf{s} = [x_1, \cdots, x_N]$, the model samples $d-$dimensional latent representation from an appropriate *prior* distribution $p(\mathbf{z})$. The latent factor $\mathbf{z}$ is then transformed via a non-linear function $f_\theta(\mathbf{z})$ – a suitable likelihood function parameterized by θ – to produce a probability distribution $\pi(\mathbf{z})$ (e.g., a *multinomial* distribution) over

M candidate items, from which a session $\mathbf{s}$ is assumed to have been drawn ($\mathbf{z} \sim p(\mathbf{z}); \pi(\mathbf{z}) \propto \exp\{f_\theta(\mathbf{z})\}$):

$$\mathbf{s} \sim f_\theta(\mathbf{z}) = p_\theta(\mathbf{s}|\mathbf{z}) = \prod_{t=2}^{N} p_\theta(x_t|x_{1:t-1}, \mathbf{z}) \tag{1}$$

where $x_{1:t-1}$ indicates the prefix click sequence preceding current click x_t, and $f_\theta(\mathbf{z})$ is a deep neural networks such as a multilayer perceptron (MLP). Thus, the session generation involves making a sequence of discrete decisions, each of which samples an item from a multinomial distribution with a softmax function, to produce a probability vector $\pi(\mathbf{z})$ over the entire item set. The multinomial distribution has been demonstrated to model click data well (cf. [26, 32], although these work were originally designed for CF based recommendation).

This generative process is similar to the sentence generation in [21] and trajectory generation in [53], except that we do not take side-information (e.g., item category, click time, etc.) into account. However, it is straightforward to add additional latent factors to capture various item features, if available, for disentangling the representation.

3.2 Variational Session Inference

In general, the marginal log-likelihood of a session s $\log p_\theta(\mathbf{s}) = \log \int_{\mathbf{z}} p_\theta(\mathbf{s}|\mathbf{z})p(\mathbf{z})\mathrm{d}\mathbf{z}$ is intractable to compute or differentiate directly for flexible generative models, especially for high-dimensional latent variables. Instead, one usually resorts to variational inference by defining a simple parametric distribution over the latent variables (e.g, a factorized Gaussian) $q_\phi(\mathbf{z}|\mathbf{s})$, and maximizing the evidence lower bound (ELBO) on the marginal log-likelihood of each observation:

$$\log p_\theta(\mathbf{s}) = \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{s})} \log \left[\frac{p_\theta(\mathbf{s}, \mathbf{z})}{q_\phi(\mathbf{z}|\mathbf{s})}\right] + \mathbb{KL}\left[q_\phi(\mathbf{z}|\mathbf{s})||p_\theta(\mathbf{z}|\mathbf{s})\right] \tag{2}$$

$$\geq \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{s})}\left[\log p_\theta(\mathbf{s}, \mathbf{z}) - \log q_\phi(\mathbf{z}|\mathbf{s})\right] \triangleq \mathcal{L}(\mathbf{s}; \theta, \phi) \tag{3}$$

There are numerous ways to optimize the ELBO, among which VAEs [25] use a parametric inference network and reparameterization of $q_\phi(\mathbf{z}|\mathbf{s})$ to alternatively maximize following reformulation:

$$\begin{aligned}\mathcal{L}_{\text{VAE}}(\mathbf{s}; \theta, \phi) &= \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{s})}[\log p_\theta(\mathbf{s}) + \log p_\theta(\mathbf{z}|\mathbf{s}) - \log q_\phi(\mathbf{z}|\mathbf{s})] \\ &= \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{s})}[\log p_\theta(\mathbf{s})] - \mathbb{KL}\left[q_\phi(\mathbf{z}|\mathbf{s})||p_\theta(\mathbf{z}|\mathbf{s})\right] \end{aligned} \tag{4}$$

Since the first term is a constant, then the objective of maximizing ELOB $\mathcal{L}_{\text{VAE}}(\mathbf{s}; \theta, \phi))$ of $\log p_\theta(\mathbf{s})$ becomes to minimize the Kullback-Leibler (KL) divergence between $q_\phi(\mathbf{z}|\mathbf{s})$ and the true distribution $p_\theta(\mathbf{z}|\mathbf{s})$ (which is always ≥ 0). For brevity, we will sometimes omit the parameters ϕ and θ in subsequent formulae.

3.3 Inference with Normalizing Flows

It is desirable to reduce the (non-negligible) inference gaps, and various improved posterior approximations have been effective in improving variational inference. Although none of the existing methods is able to completely close the gap between approximate posterior and true posterior [6], employing richer posterior/prior distributions can effectively reduce it. The approximation gap, caused by the encoding cost $\mathbb{KL}\left[q_\phi(\mathbf{z}|\mathbf{s})||p_\theta(\mathbf{z}|\mathbf{s})\right]$, is largely due to the improper assumption of the probabilistic distribution [9, 24].

We leverage the flow method [39] to construct more accurate posterior approximation of the session distributions, rather than simple Gaussian assumption in existing works [4, 49]. Normalizing Flows (NF) [39] is a powerful framework for building flexible posterior distributions through an iterative procedure. The main idea is to transform a simple distribution into a complex one through a series of invertible mappings which, in theory, can approximate any complex distribution. Given a variable $\mathbf{z}_0$ with known probability distribution $p_0(\mathbf{z}_0)$ (e.g., Gaussian here) and a chain of invertible transformations $\mathbf{f} = [\mathbf{f}_1, \cdots, \mathbf{f}_K]$, then $\mathbf{z}_k$ can be calculated by composing the transformations from $\mathbf{f}$ as:

$$\mathbf{z}_K = \mathbf{f}_K(\mathbf{z}_{K-1}) = \mathbf{f}_K(\mathbf{f}_{K-1}(\mathbf{z}_{K-2})) = \mathbf{f}_K(\mathbf{f}_{K-1}(\cdots \mathbf{f}_1(\mathbf{z}_0))) \tag{5}$$

Given that each $\mathbf{f}_k \in \mathbf{f}$ is invertible (i.e., $\mathbf{z}_{k-1} = \mathbf{f}_k^{-1}(\mathbf{z}_k)$), and according to the definition of probability $\int p_k(\mathbf{z}_k)d\mathbf{z}_k = \int p_{k-1}(\mathbf{z}_{k-1})d\mathbf{z}_{k-1} = 1$, for a collection of variables $\mathbf{z} = [\mathbf{z}_0, \ldots, \mathbf{z}_K]$, we can obtain the distributions $p_K(\mathbf{z}_K)$ more flexibly:

$$p_K(\mathbf{z}_K) = p_0(\mathbf{z}_0)\left|\det \frac{d\mathbf{z}_K}{d\mathbf{z}_0}\right|^{-1} \tag{6}$$

where $\det \frac{d\mathbf{f}}{d\mathbf{z}}$ is the Jacobian determinant of $\mathbf{f}$.

The path traversed by the random variables $\mathbf{z}_k = \mathbf{f}_k(\mathbf{z}_{k-1})$ with initial distribution $p_0(\mathbf{z}_0)$ is called the *flow*, and the whole path formed by the successive distributions $p_K(\mathbf{z}_K)$ refers to a *normalizing flow*. To ensure Eq.(6) is tractable, it should satisfy that (a) the transformation $\mathbf{f}_k$ must be easy to invert, and (2) the determinant of its Jacobian is easy to compute [39]. The two constraints allow the transformation to be made deeper by composing multiple instances of it, and the result will still be a valid normalizing flow. Now the log-likelihood of approximate posterior $q_K(\mathbf{z}_K|\mathbf{s})$ can be computed iteratively by using the log on both sides of Eq.(6)

$$\log q_K(\mathbf{z}_K|\mathbf{s}) = \log q_0(\mathbf{z}_0|\mathbf{s}) - \sum_{k=1}^{K} \log \det \left|\frac{d\mathbf{z}_k}{d\mathbf{z}_{k-1}}\right| \tag{7}$$

where the base distribution $\mathbf{z}_0 \sim q_\phi(\mathbf{z}_0|\mathbf{s})$ is a Gaussian in our implementation.

One of the flow transformations is the *planar flow* introduced in [39], given by:

$$\mathbf{f}(\mathbf{z}) = \mathbf{z} + \mathbf{u}\sigma(\mathbf{w}^\intercal \mathbf{z} + b) \tag{8}$$

where $\mathbf{u}, \mathbf{w} \in \mathbb{R}^d$ and $b \in \mathbb{R}$ are parameters, and σ is a suitable smooth non-linear activation function (e.g., tanh). According to the *Matrix determinant lemma*, the Jacobian of this transformation is:

$$\left|\det \frac{\partial \mathbf{f}}{\partial \mathbf{z}}\right| = \left|1 + \mathbf{u}^\intercal \sigma'(\mathbf{w}^\intercal \mathbf{z} + b)\mathbf{w}\right|,$$

where σ' is the derivative activation and can be computed in $O(d)$ time – d is the dimension of $\mathbf{z}$.

In this paper, we use the planar flow as the invertible transformation for its simplicity and efficiency. We parameterize the approximation posterior $q_\phi(\mathbf{z}|\mathbf{s})$ with a flow, i.e., $q_\phi(\mathbf{z}|\mathbf{s}) := q(\mathbf{z}_K)$, the ELBO of Eq.(2) can be modified as

$$\begin{aligned}\mathcal{L}(\mathbf{s}; \theta, \phi) =& \mathbb{E}_{q(\mathbf{z}_0)}\left[\log p_\theta(\mathbf{s}|\mathbf{z}_K)\right] - \mathbb{E}_{q(\mathbf{z}_0)}\left[\log q(\mathbf{z}_0)\right] + \beta \mathbb{E}_{q(\mathbf{z}_0)}\left[\log p_\theta(\mathbf{z}_K)\right] \\ &+ \beta \mathbb{E}_{q(\mathbf{z}_0)}\left[\sum_{k=1}^{K} \log \det \left|\frac{d\mathbf{z}_k}{d\mathbf{z}_{k-1}}\right|^{-1}\right] \end{aligned} \tag{9}$$

where the first term is trained to reconstruct the sessions; the second term is a constant; and the last two terms are the flows. The coefficient β is a regularizer of the flows, which is very similar to the annealing factor for regularizing KL-divergence [3].

4 EXPERIMENTAL OBSERVATIONS

We now describe the experimental settings and report the empirical evaluation results.

Table 1: Statistics of the datasets.

Datasets	YOOCHOOSE 1/64	YOOCHOOSE 1/4
#clicks	557,248	832,6407
#train sessions	355,385	621,6184
#test sessions	52,956	56,616
#items	17,626	30,903
avg. session length	6.27	5.83

4.1 Datasets

For fair comparison, we evaluate different methods on a real-world transaction datasets YOOCHOOSE[1], which has been widely used for evaluating SBR approaches. Following previous works [28, 33, 44], we preprocess the primary data as follows: (1) We filter out sessions of length 1 and items that appear less than 5 times for the two datasets; (2) We respectively use the sessions of subsequent day for testing, and then filter out clicks from the test set where the clicked items did not appear in the training set; and (3) We sort the training sequences by time and train all models on more recent fractions (i.e., 1/64 and 1/4) of training sessions. Table 1 shows the statistics of the datasets.

4.2 Baselines

To demonstrate the effectiveness of our model, we conduct extensive comparisons to the following state-of-the-art methods:

- **Item-KNN** [42]: It is an item-to-item model that recommends items that are similar to previously visited items based on cosine similarity.
- **GRU4Rec**[2] [18]: It is an RNN-based deep learning model for session-based recommendation. It employs GRU units to capture sequential patterns and utilizes session-parallel minibatching trick and ranking-based loss functions during the training.
- **NARM**[3] [28]: It is an RNN-based model employing (deterministic) attention mechanism to capture main purpose from the hidden states and combines it with the sequential behavior as the final representation to generate recommendations.
- **STAMP** [33]: It is a priority model which captures users' general interests from the long-term memory of a session context, and current interests from the short-term memory of recent clicks.
- **ReLaVaR** [4]: It is a Bayesian version of GRU4Rec which treats the network recurrent units as stochastic latent variables with some prior distributions and infers the corresponding posteriors for prediction and recommendation generation. This is an item-level variational inference based SBR method which uses independent Gaussian as the prior for items.
- **VRM** [49]: It is a recent proposed method directly applying VAE on session-based recommendation. Unlike ReLaVaR, an item-level variational method, VRM models the stochastic inference on the session-level.

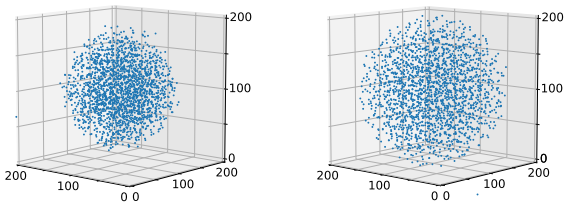
[1]http://2015.recsyschallenge.com/challenge.html
[2]https://github.com/hidasib/GRU4Rec
[3]https://github.com/lijingsdu/sessionRec_NARM

4.3 Metrics

Following previous works [16, 17, 28, 33], the primary evaluation metric is Recall@20 – i.e., the proportion of cases having the desired item falling into the top-20 predicted items in all test cases. Note that the Recall score is equal to the Hit-Precision score used in [33]. The second metric is MRR@20 (Mean Reciprocal Rank) – i.e., the average of reciprocal ranks of the desired items. The reciprocal rank is set to zero if the rank is lower than top-20. MRR takes into account the rank of the item, which is important when the order of recommendations matters. Note that the higher the Recall@20 and MRR@20, the better the performance.

4.4 Settings

For all methods, the embedding size of items is set to 50. The number of hidden units in GRU layer is set to 100. All models are trained with Adam and the mini-batch size is fixed at 512. Following [28, 33], we truncated BPTT using a fixed window of 30 time-steps for the two YOOCHOOSE datasets. Also following [28, 33], 10% of the training data are used as the validation set. For the VASER model, parameters d, K and β are respectively 100, 16 and 0.2, if not specified.



4.5 Overall Performance

Table 2: Performance comparison among all session-based recommendation methods over two datasets.

	YOOCHOOSE1/64		YOOCHOOSE1/4	
	Recall@20(%)	MRR@20(%)	Recall@20(%)	MRR@20(%)
item-KNN	53.12	22.13	52.43	21.75
GRU4REC	62.40	25.36	59.58	22.62
NARM	70.13	29.38	69.75	29.30
STAMP	70.21	29.22	70.45	29.47
ReLaVaR	64.32	25.26	60.53	22.76
CRM	69.32	28.75	68.22	28.35
VASER	71.85	30.05	70.74	29.75

4.5.1 Comparison against SBR baselines (Q1). : Table 2 shows the results of comparison to the existing state-of-the-art SBR methods, from which we can clearly observe that the proposed model perform the best on two metrics throughout two datasets.

Overall, the RNN based methods, including ours, consistently outperform the traditional baselines, which demonstrates that autoregressive models are good at learning sequential user click behaviors.

(a) NARM. (b) VASER.

Figure 2: Visualization of the encoding space obtained via NARM and VASER on YOOCHOOSE 1/64. For better viewing, we randomly select 2,048 test sessions and plot the encoding space using t-SNE.

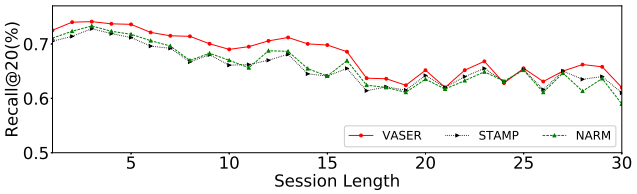


Figure 3: Impact of session length (YOOCHOOSE 1/64).

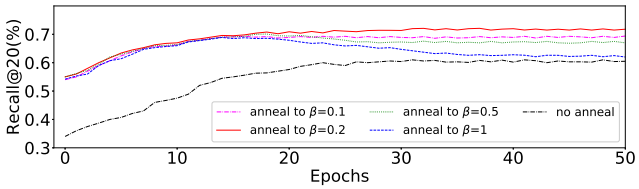
Nevertheless, RNN models alone cannot deal with complicate user-click sessions which usually have unintended clicks and/or contain one or more browse themes. This problem can be largely overcome by incorporating the attention mechanism in recent methods like NARM and STAMP. The most recent work GRU4Rec++ does not exhibit expected results on the two datasets, regardless that it can improve their original method (GRU4Rec) with the sampling trick. This result also proves one of our motivations that autoregressive models are constrained with their capability of modeling sparse and high-dimensional data.

By modeling session generation in a probabilistic generative latent variable framework, our model outperform the best baseline (either NARM or STAMP) by a significant margin. Note that in our reimplementation, the two baselines (NARM or STAMP) exhibit higher scores than their original reporting on two YOOCHOOSE datasets.

The benefit of VASER can be visualized in Figure 2, where the encoding space of NARM and VASER is plotted with t-SNE. Recall that both methods predict the last item x_N based on the learned representation of prefix session $\mathbf{s}' = [x_1, \cdots, x_{N-1}]$. The main difference is that the encoding space of NARM is the concatenation of deterministic attention $\mathbf{c}$ and the last hidden state $\mathbf{h}_{N-1}$ of GRU, while the encoding space of VASER is the combination of the posterior of hidden state $q(\mathbf{z}_K)$ and the posterior of attention $q(\mathbf{c}_k)$. Apparently, VASER explores more space for encoding the sessions and exhibits more scattered distribution. The benefits of such encoding can be understood intuitively, i.e., the more inseparable the sessions, the more difficult for the models to discriminate the spatial adjacent ones, which, consequently, are more prone to making wrong predictions.

We also investigated the impact of session length on the recommendation performance. Intuitively, the longer the sessions, the worse the prediction performance on average. The results on YOOCHOOSE 1/64 are shown in Figure 3 (results on YOOCHOOSE 1/4 are consistent, but omitted due to the lack of space), whereby we compared to the two best baselines. Our model slightly improve the recommendation performance over the baselines. However, we argue that due to the vanishing gradient problem of autoregressive model, it is hard for RNNs-based methods to further improve the performance on modeling extremely long-term dependencies.

4.5.2 Effect of Components in VASER (Q2). By comparing to the methods directly applying VAE on SBR, both item-level and session-level, we can clearly see the importance of the flow based posterior approximation used in VASER.



Another important observation is that directly applying VAE on modeling items or sessions is not competitive. ReLaVaR, operating stochastic inference on item-level, is less effective than VRM, which models sessions in a variational seq2seq manner. Note that we omit comparison with CVRM, a variant of VRM, which takes the category information into account, due to the *extremely* sparse category labels on the YOOCHOOSE dataset. In fact, the category information plays a less important role in improving the recommendation performance according to the results in [49]. Although allowing Bayesian inference, the two models may incur larger inference gaps and underfitting problem due to the amortized inference alone used for posterior approximation [9]. This is in accordance with the findings in modeling language with vanilla VAEs [3, 21], i.e., the autoregressive models are powerful enough to decode the entire sequence, resulting in uselessness of stochastic latent factors. More importantly, these methods approximate an improper assumed distribution $q_\phi(\mathbf{z}|\mathbf{s})$, e.g., the choice of diagonal-covariance Gaussian in [3, 21], and thus are subjected to heavy bias inference problem, as explained in Sec. 3.2. In contrast, our VASER model can largely alleviate this problem benefiting from the normalizing flows with flexible posterior approximation.

4.6 Impact of Parameters (Q3)

There are two important factors affecting the performance of the VASER model, i.e., the coefficient β regularizing the flows and the determinant of Jacobian matrix, and K, the number of invertible transformations.

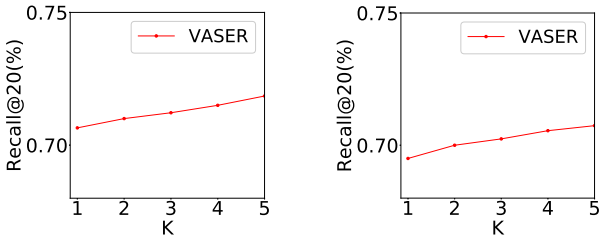


Figure 4 shows the impact of β on VASER, where β is gradually annealed to the value of 0.1, 0.2, 0.5 and 1. We observe in our experiments that the flow terms are usually ordered larger than the reconstruction term. Without annealing or annealing to a larger value, the performance of VASER model are not appealing, and even experience overfitting problem. On the contrary, if the value of β is too small (e.g., below 0.2, the flows does not take effect as the decoder RNN will make the model converge, when the model rely less on the latent factors. As a consequence, there is a significant performance decline. As we explained earlier, this is caused by the overpower performance of RNN decoder. In addition to cost annealing, another possible way of alleviating this problem is to replace RNN with the dilated CNN suggested by [21].

Figure 5 investigates the impact of K on two datasets. The planar flows used in VASER modifies the initial density by applying a series

(a) YOOCHOOSE 1/64.

Figure 4: The impact of β.

(a) YOOCHOOSE 1/64. (b) YOOCHOOSE 1/4.

Figure 5: The impact of K.

of contractions and expansions in the original space. Although, in theory, more transformations could approximate more complicated distribution, a smaller value is enough for the model. Since the RHS of Eq.(8) can be interpreted as a *single-neuron* MLP, it may result in the information going through a single bottleneck. As the volume of the space grows exponentially with the number of dimensions d, it requires many coupling layers to transform a simple base distribution into a complex one [24]. This is demonstrated by the results on YOOCHOOSE 1/64 dataset in Figure 5(a), where the model require more transformations to obtain higher performance.

5 RELATED WORK

5.1 Sequential Recommendation

SBR is essentially a sequence learning problem including typical scenarios such as click/purchase recommendation in e-commerce, music/video recommendation, news items etc. Since only short-term interaction data are available and there is lack of user profile, CF based latent factor models fail to work in these scenarios. Non-parametric methods, such as k-Nearest Neighbor (KNN) and context tree can be used to estimate the user/item similarity for recommending the most similar items to the ones that have been visited/clicked by a user [12, 15, 22, 35, 42]. Naturally, other sophisticated sequence learning approaches can also be adapted to solve the session-based recommendation problem, which incurs MC based models [48] and hybrid CF models like FPMF [16, 38], etc.

RNN models have been successfully applied in many sequence learning tasks, such as machine translation [1], human mobility learning [13], and session-based recommendation [17, 18, 28, 31, 33, 37]. GRU4Rec [18] is a representative RNN based method for SBR, which embeds the clicks into the final hidden state of GRU to represent the current preference. This method has achieved significant improvement against previous sequence learning approaches like FPMC and item similarity based KNN. Several works have been proposed to improve GRU4Rec with various models. For example, NARM and EDRec [28, 34] employ soft attention mechanism [1] to capture the user's main purpose in the current session, which is combined with the last hidden state of GRU to compute the recommendation scores for each candidate item. Hidasi et al. [17] improved their GRU4Rec model by introducing tailored ranking loss functions.

5.2 Deep Generative Recommendation

Although there exist many deep recommendation models as mentioned above, relatively few works in the literature focus on applying generative models in the recommendation systems. Previous autoencoder based models [29, 41, 43, 46, 47, 50] show promising performance but are restricted to learning representation of items, and thus are difficult for Bayesian inference due to lack of Bayesian nature or high computational cost. Several recent works extend the ideas of applying VAEs to CF-based recommendation but mainly focus on combining various auxiliary features [7, 23]. The most related work are ReLaVaR [4] and VRM/CVRM [49], both of which apply VAE on the SBR tasks. ReLaVaR is an item-level stochastic inference method while VRM/CVRM are modeling session in a stochastic seq2seq manner. As sequential VAE models, they can be considered as directly applying VAEs in the SBR scenario.

Compared to existing sequential recommendation approaches, we model the problem within a probabilistic recommendation setting which allows our model for Bayesian inference. In addition, we derive novel flow-based model tailored for SBR task with the flexible posterior approximation, rather than presumed Gaussian distribution in previous work.

6 CONCLUSIONS AND FUTURE WORK

We presented VASER, a flow based generative framework for learning sequential click patterns. A distinct feature of the proposed model implementing VASER is that it enables learning non-linear interactions between user-clicks while allowing Bayesian inference. As demonstrated by the experiments, VASER achieves significant improvements for the session-based recommendation problem in comparison to existing methods. One of the most important implications of the results from this work is that instead of using amortized inference as in existing collaborative/sequential variational recommendation methods, flow based techniques could effectively improve the density approximation and deserves more attention in the recommendation community. In our future work, we are planning to focus on augmenting VASER to consider auxiliary information – e.g., coupling sequential information with other related contexts (category, price and click time), and on tackling the overall efficiency (e.g., by incorporating CNNs).

ABSTRACT

In this paper, we propose a Joint Collaborative Autoencoder framework that learns both user-user and item-item correlations simultaneously, leading to a more robust model and improved top-K recommendation performance. More specifically, we show how to model these user-item correlations and demonstrate the importance of careful normalization to alleviate the influence of feedback heterogeneity. Further, we adopt a pairwise hinge-based objective function to maximize the top-K precision and recall directly for top-K recommenders. Finally, a mini-batch optimization algorithm is proposed to train the proposed model. Extensive experiments on three public datasets show the effectiveness of the proposed framework over state-of-the-art non-neural and neural alternatives.

1 INTRODUCTION

Since feedback like user clicks, purchases, and views is much more widespread than explicit ratings, implicit top-K recommenders offer great opportunities for far-reaching impact [6, 7, 17]. One of the most influential approaches is collaborative filtering (CF) [19], which learns the preference coherence among users (user-user CF) or the rating correlations among items (item-item CF). Recently, we have seen a series of works that aim to extend CF to new neural network frameworks that offer the promise of flexibility, non-linearity, and structural complexity, leading to more expressiveness and state-of-the-art recommendation performance [4, 5, 18, 20].

While promising, one limitation of these new neural neighborhood-based models is that they typically attempt to learn low-dimension embeddings of only users or only items, without careful consideration of the important interactions between users and items. As a result, the quality of recommendation may be restricted. In contrast, effective modeling of user-item interactions could lead to improved recommendation, as has been demonstrated in earlier non-neural approaches [16, 22, 25, 26]. We experimentally confirm this intuition in Section 3.3, where we find that while user-based and item-based Autoencoders do agree on many recommendations, there is a significant amount of disagreement between the two.

Hence, we propose in this paper a new Joint Collaborative Autoencoder (JCA) model that *jointly learns* user-user and item-item correlations simultaneously so that recommenders can take advantage of as much hidden information as possible for better recommendation quality. We show how to model these user-item interactions in JCA and demonstrate the importance of careful normalization to alleviate the influence of feedback heterogeneity (without which, naive methods may recommend items a user dislikes). Further, JCA adopts a pairwise hinge-based objective function for implicit top-K recommenders, which is especially designed for maximizing precision and recall for top-K recommendation. Through extensive experiments over three public datasets, we demonstrate how the proposed JCA model improves upon both non-neural and neural methods alike.

In sum, the contributions of this paper are as follows: (i) we propose a neural neighborhood-based CF approach called Joint Collaborative Autoencoder (JCA) that captures both user-user and item-item correlations simultaneously. (ii) We adopt a pairwise hinge-based objective function to optimize top-K precision and recall directly. (iii) We present a mini-batch optimization algorithm so that JCA can be trained on large datasets, without the (impractical) need to load the entire rating matrix as in a naive batch learning approach. (iv) Finally, through extensive experiments, we show that the proposed framework outperforms state-of-the-art neural and non-neural baselines.

2 RELATED WORK

Due to the flourishing development of neural networks, instead of focusing on the traditional non-neural algorithms [6, 7, 7, 12, 15, 17], more recent efforts have been dedicated to building neural based methods for implicit top-K recommendation. For example, Wu et al. [24] proposed a Collaborative Denoising Autoencoder (CDAE) model, which implements a neural version of the influential non-neural method SVD++ [9]. He el at. [5] presented a two-pathway architecture named NCF, ensembling a neural-based implementation of matrix factorization named Generalized Matrix Factorization (GMF) and a Multi-Layer Perceptron (MLP). Furthermore, there are many neural models for contextual recommenders [2, 3, 11, 14, 21] because neural models can be naturally extended to integrate auxiliary information. For example, Niu et al. [14] proposed a pairwise neural model integrating two GMF structures to implement BPR for

image recommendation, and considered visual, topic and geography information as contextual features. Similar to these existing neural-based recommenders, the model proposed in this paper is designed to take advantage of the flexibility, non-linearity, and structural complexity of neural architectures. Besides, we also demonstrate how to jointly learn from both user-user and item-item correlations for improved recommendation quality.

Previous works [16, 22, 25, 26] have identified the potential of combining user-based and item-based collaborative filtering models to improve recommendation. Although their motivations are similar to our proposed model, there are three main differences: (i) we focus on implicit top-K recommenders; (ii) we adopt an Autoencoder-based framework as the model foundation which is a neural-based algorithm; and (iii) we fuse the user-based and item-based models by jointly training them in a unified learning process, while previous work typically combines the two models via heuristics.

3 PRELIMINARIES

In this section, we define the implicit top-K recommendation problem, introduce the basics of an Autoencoder-based recommender, and empirically show that traditional user-based and item-based Autoencoder-based recommenders are complementary, which motivates the design of our proposed model.

3.1 Implicit top-K Recommendation

Formally, we denote the set of users as $\mathbb{U} = \{1, 2, \ldots, N\}$, the set of items as $\mathbb{I} = \{1, 2, \ldots, M\}$, and the set of historical feedback from the users to the items as $\mathbb{O} = \{u, i, r_{u,i}\}$ where u indexes one user, i indexes one item, and $r_{u,i}$ represents the rating from the user u to the item i.[1] For implicit top-K recommenders, there are usually only positive feedback signals, which means we only know which items user u likes but have no idea which items user u dislikes, i.e. all $r_{u,i}$ are 1. Based on this historical feedback, our goal is to predict the preference of each user u to the items they have not interacted with and recommend the items with the highest predicted scores to user u. Furthermore, we denote $\mathbb{O}_u^+$ as the set of items user u has given positive feedback to, and $\mathbb{O}_u^-$ denotes the set of items user u has not given feedback to. In practice, we will randomly sample a subset of the unrated items to train the model, hence in this paper we use $\mathbb{O}_u^-$ to denote the randomly selected negative samples.

3.2 Autoencoders for Recommendation

Toward tackling the implicit top-K recommendation problem, Autoencoder based models [20, 24] have shown promising performance in comparison with non-neural and other neural models. We input to an Autoencoder the rating vectors of users (or items) with 1 denoting a positive interaction, and 0 denoting a missing (or unknown) interaction. Then the Autoencoder outputs the corresponding completed rating vectors. Such an Autoencoder-based recommender called AutoRec has been proposed in [20], whose model can be written as:

$$\widehat{\mathbf{R}} = f(g(\mathbf{RV} + \mathbf{b}_1)\mathbf{W} + \mathbf{b}_2),$$

where the binary implicit feedback matrix $\mathbf{R}$ is input into AutoRec, and $\widehat{\mathbf{R}}$ is the predicted preference matrix. If we set both $f(\cdot)$ and $g(\cdot)$ as identity functions, and we also ignore the bias nodes, then AutoRec becomes: $\widehat{\mathbf{R}} = \mathbf{RVW}$, which is equivalent to the user-based neighborhood model with two factorized matrices as the similarity measurement (similar to the FISM model proposed in [7]). As a result, when we feed user rating vectors $\mathbf{R}^U \in \mathbb{R}^{N \times M}$ as the input (that is, user rating vectors are the rows), AutoRec learns the similarity among items. We refer to this model as user-based AutoRec (or U-AutoRec). In a similar fashion, we can input item rating vectors $\mathbf{R}^I \in \mathbb{R}^{M \times N}$ and learn similarity among users. We refer to this model as item-based AutoRec (or I-AutoRec).

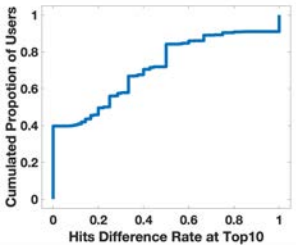

Figure 1: The CDF of the corresponding Hits Difference Rate between user-based AutoRec and item-based AutoRec.

3.3 User-based AutoRec and Item-based AutoRec Are Complementary

Sarwar showed in [19] that traditional (non-neural) user and item-based CF models are fundamentally different. Here, we investigate the difference between a neural neighborhood-based CF methods (U-AutoRec and I-AutoRec). More specifically, we explore whether different information from the same dataset captured by different models can produce complementary recommendations.

In order to answer this question, we run U-AutoRec and I-AutoRec on the same MovieLens 1M dataset (the details of this dataset and the model parameter settings are introduced in Section 5.1 and 5.2). For each user in this dataset, these two models will recommend two lists of ranked movies; we focus here on the top-10 ranked movies in the two lists. We consider the *hits* of a model as the set of movies that are in the recommended 10 movies and also in the test set, i.e. the ground truth of the user's preference. We denote the hits of U-AutoRec as $\mathbb{H}_U$ and of I-AutoRec as $\mathbb{H}_I$. Then we define the *hits difference rate* of these two model for one user as:

$$\text{HitsDifferenceRate} = \frac{size(\mathbb{H}_U \cup \mathbb{H}_I) - size(\mathbb{H}_U \cap \mathbb{H}_I)}{size(\mathbb{H}_U \cup \mathbb{H}_I)}.$$

where $size(\cdot)$ calculates the number of elements in a set, $\cap$ and $\cup$ are set intersection and union operators. The hits difference rate demonstrates the difference in correct recommendations between two models: a large difference rate indicates the two models provide complementary recommendations. The CDF of the hits difference rate for the users in MovieLens is presented in Figure 1. We can observe that more than 60% of users have a hits difference rate larger than 20%, with some users (around 30%) having a hits difference rate larger than 50%. Therefore, based on the observations from Figure 1

[1] In this paper, matrices are denoted by boldface uppercase letters like $\mathbf{A}$, and vectors are denoted by boldface lowercase letters like $\mathbf{a}$. $\mathbf{A}_i$ represents the row vector of the i-th row of matrix $\mathbf{A}$, and $(\mathbf{A}^\top)_j$ represents the row vector of the j-th column of matrix $\mathbf{A}$. We denote a user-item-rating matrix with N users and M items as $\mathbf{R} \in \mathbb{R}^{N \times M}$. $\mathbf{R}_u \in \mathbb{R}^{1 \times M}$ is the rating vector of user u, $(\mathbf{R}^\top)_i \in \mathbb{R}^{1 \times N}$ is the rating vector of item i. Besides, we use the syntax similar to Python to denote the matrix slicing operation, for example $\mathbf{A}[:, [1, 2]]$ denotes the first two columns of matrix $\mathbf{A}$.

Table 1: Comparison between U-AutoRec, I-AutoRec and the average model of them – UI-AutoRec, where the best results are marked in bold. P represents precision, R represents recall, and F represent F1 score.

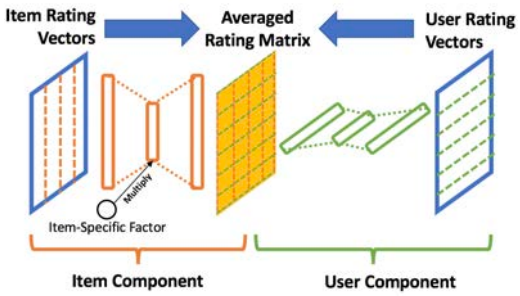

Figure 2: Overview of JCA: The Joint Collaborative Autoencoder takes both the Item Component with item rating vectors (left) and the User Component with user rating vectors (right) to recover the complete rating matrix (middle).

we can conclude that U-AutoRec and I-AutoRec generate different recommendations which are complementary to each other.

We further verify the conclusion that U-AutoRec and I-AutoRec are complementary by comparing the recommendation quality of U-AutoRec, I-AutoRec, and a simple averaging model of them (named UI-AutoRec, which averages the outputs of separately trained U-AutoRec and I-AutoRec to be the final result). In experiments over three datasets (details introduced in Section 5.1 and 5.2), we observe in Table 1 that the simple average of U-AutoRec and I-AutoRec can improve the top-10 recommendation quality, compared to either of the solo models, further indicating that U-AutoRec and I-AutoRec are complementary to each other. Therefore, combining the two models together to simultaneously explore both sides of information is promising for improved top-K recommendation.

4 PROPOSED MODEL

In this section, we present the design of a new **J**oint **C**ollaborative **A**utoencoder (**JCA**) model with a pairwise hinge-based objective function. In addition, we present a mini-batch optimization algorithm to optimize the JCA model.

4.1 Joint Collaborative Autoencoder

The intuition of JCA is to directly model both users and items simultaneously, rather than treating users and items in isolation. Further, naive combination of users and items without consideration of the heterogeneity of feedback can lead to overestimation of predicted scores in the output layer even for items a user dislikes. Hence, we describe in the following the design of the JCA structure with a special item normalization factor (to handle feedback heterogeneity), leading to the model shown in Figure 2.

Joint User-Item Correlations Modeling. Given N users and M items, the proposed JCA takes the whole rating matrix $\mathbf{R} \in \mathbb{R}^{N \times M}$ as a dual input. As illustrated in Figure 2, the rating matrix is input to the model on both the lefthand and righthand sides. The key difference is in how the matrix is sliced: the lefthand side takes as input one item rating vector $(\mathbf{R}^\top)_i \in \mathbb{R}^{1 \times N}$ as one sample (i.e. one column of $\mathbf{R}$), while the righthand side takes as input one user rating vector $\mathbf{R}_u \in \mathbb{R}^{1 \times M}$ as one sample (i.e. one row of $\mathbf{R}$). In essence, there are two components to the model, the first taking $\mathbf{R}_u$ as one input sample, which we name the *User Component*, and the other one with $(\mathbf{R}^\top)_i$ as one input sample, which we name the *Item Component*. The two components are two Autoencoder structures, which predict and recover the rating matrix independently. The first-layer weights of the user and item components are denoted as $\mathbf{V}^U \in \mathbb{R}^{M \times H^U}$ and $\mathbf{V}^I \in \mathbb{R}^{N \times H^I}$ respectively, where H^U and H^I represent the dimensions of the hidden layers of the two components. In the same way, we denote the second-layer weights as $\mathbf{W}^U \in \mathbb{R}^{H^U \times M}$ and $\mathbf{W}^I \in \mathbb{R}^{H^I \times N}$. The biases for the hidden layers and output layers are denoted as $\mathbf{b}_1^U$ and $\mathbf{b}_2^U$ for the user component, $\mathbf{b}_1^I$ and $\mathbf{b}_2^I$ for the item component. We set the sigmoid function as the activation function for hidden layers and output layers in both components.

Unlike the traditional user-based or item-based AutoRec, which inputs one or several incomplete rating vectors of a user or item and outputs the completed rating vectors, this Joint Collaborative Autoencoder takes the whole rating matrix as input, and outputs the whole completed rating matrix. The user component and item component output two completed rating matrices independently, and we combine the two outputs to be the final output as:

$$\widehat{\mathbf{R}} = \frac{1}{2}[h_{item}(\mathbf{R}) + h_{user}(\mathbf{R})], \tag{1}$$

where $\widehat{\mathbf{R}}$ is the predicted rating matrix, $h_{item}(\cdot)$ is the item component output, and $h_{user}(\cdot)$ is the user component output.

Learnable Item Normalization Factor. One challenge with traditional Autoencoder-based recommenders is that there is no normalization for the hidden layer. As a result, the heterogeneity of feedback can create problems. Take the user-based AutoRec as an example, inputting a user rating vector with more positive feedback into the AutoRec model results in a hidden layer with a larger norm, which leads to higher predicted scores in the output layer even for the items the user dislikes. A similar situation arises for the item-based AutoRec, where an item with more positive feedback has overall higher predicted scores even for the users who dislike it. Inspired by FISM [7] which adopts a user specific normalization constant, we add a learnable item normalization factor to alleviate the influence of this item feedback heterogeneity.

Specifically, we add a learnable *Item Normalization Factor* $\mathbf{f} \in \mathbb{R}^{M \times 1}$ multiplied to the hidden layer of the item component. This parameter is to normalize the norm of the latent factor for each item to solve the problem that items with more feedback will have higher predicted ratings. The user component does not need a normalization factor because the recommender ranks the predicted preference scores and recommends the top-K items for each user independently. Hence the norm of the rating vector of each user has no influence to the recommendation result.

The JCA Model. Combining the joint user-item correlations model with this learnable item normalization factor leads to the full Joint

Collaborative Autoencoder model:

$$\widehat{\mathbf{R}} = \frac{1}{2}[\sigma(\sigma(\mathbf{R}\mathbf{V}^U + \mathbf{b}_1^U)\mathbf{W}^U + \mathbf{b}_2^U) + \sigma(\sigma((\mathbf{R}^\top\mathbf{V}^I + \mathbf{b}_1^I) \circ \mathbf{f})\mathbf{W}^I + \mathbf{b}_2^I)^\top], \tag{2}$$

where $\sigma(x) = 1/(1+e^{-x})$ is the sigmoid function, $\circ$ is the element-wise product (because $\mathbf{f}$ is a column vector, $\circ$ multiplies each entry of $\mathbf{f}$ to each corresponding row of $(\mathbf{R}^\top\mathbf{V}^I + \mathbf{b}_1^I)$).

4.2 Pairwise Hinge-based Objective Function for Implicit Top-K Recommenders

We could learn the described model parameters by optimizing a traditional objective function for recommenders. Nevertheless, many of these conventional objective functions attempt to optimize MSE or AUC [17, 20, 24], which are not aligned with top-K recommendation metrics. As a result, we introduce a pairwise hinge-based objective function to directly optimize implicit top-K recommendation performance. In addition, we will show how the hinge-based objective function links to top-K precision and recall.

Inspired by [23] and [13], which proposed new objective functions to optimize position sensitive ranking loss functions such as ADG and NDCG, we adopt a pairwise hinge-based objective function to optimize top-K ranking result, shown in Equation (3):

$$\underset{\mathbf{\Theta}}{\text{minimize}} \quad \mathcal{L} = \sum_{u\in\mathbb{U}} \sum_{\substack{i\in\mathbb{O}_u^+ \\ j\in\mathbb{O}_u^-}} max(0, \widehat{r}_{u,j} - \widehat{r}_{u,i} + d) + \frac{\lambda}{2}\|\mathbf{\Theta}\|_F^2, \tag{3}$$

where $\widehat{r}_{u,i}$ and $\widehat{r}_{u,j}$ are the predicted ratings for user u to item i with positive feedback and j from negative sampling; λ is the trade-off parameter of the L2-norm regularization term; $\mathbf{\Theta}$ represents all the parameters; d is a hyper-parameter determining how large the margin between positive feedback and random negative samples can be; and $\|\cdot\|_F$ is the Frobenius norm.

Because in practice we can not use all unobserved entries as the negative samples, we set a constant margin d for the random negative samples and positive feedback to counteract the influence from random negative sampling strategy.

Analogies to Precision@k and Recall@k. *Precision@k* (*P@k*) and *Recall@k* (*R@k*) are two most commonly used metrics to evaluate implicit top-K recommenders. They are defined as:

$$P@k = |\mathbb{O}_u^k \cap \mathbb{O}_u^+|/k, \quad |\mathbb{O}_u^k \cap \mathbb{O}_u^+|/|\mathbb{O}_u^+|, \tag{4}$$

where $\mathbb{O}_u^k$ is the set of items with the top k predicted preference scores for user u, and $|\cdot|$ calculates the number of elements in a set.

If we set $k = |\mathbb{O}_u^+|$, then *Precision@k* and *Recall@k* will be the same, and we can rewrite the formula as:

$$P@k = R@k = 1 - (\sum_{i\in\mathbb{O}_u^+} \delta((\sum_{j\in\mathbb{O}_u^-} (\widehat{r}_{u,j} - \widehat{r}_{u,i})) > 0))/|\mathbb{O}_u^+|, \tag{5}$$

where $\delta(x)$ is the Heaviside function, which returns 1 if x is true, otherwise 0.

The analogy between (5) and (3) is clear. To maximize the top-K precision and recall shown in Equation (5) is equivalent to minimizing $\sum_{i\in\mathbb{O}_u^+} \delta((\sum_{j\in\mathbb{O}_u^-} (\widehat{r}_{u,j} - \widehat{r}_{u,i})) > 0)$, which is equivalent to minimizing $\sum_{i\in\mathbb{O}_u^+, j\in\mathbb{O}_u^-} max(0, \widehat{r}_{u,j} - \widehat{r}_{u,i} + d)$ in Equation (3). Here, we use the differentiable Hinge loss function to replace the non-differentiable Heaviside function.

4.3 Mini-batch Optimization Algorithm

We can use any popular optimization algorithm to train the proposed JCA. However, one challenge is that in each training iteration, the whole user-item-rating matrix is used for training, which is not practical especially for large datasets. As a result, we propose a mini-batch optimization algorithm for handling large datasets.

For the mini-batch optimization algorithm, in each training iteration, we need to feed a mini-batch consisting of n user rating vectors denoted as $\mathbf{B}^U = \mathbf{R}[\mathbf{p}, :] \in \mathbb{R}^{n\times M}$ into the user component, where $\mathbf{p}$ is a list of n randomly sampled row indexes; and another mini-batch consisting of m item rating vectors denoted as $\mathbf{B}^I = \mathbf{R}[:, \mathbf{q}]^\top \in \mathbb{R}^{m\times N}$ into the item component, where $\mathbf{q}$ is a list of m randomly sampled column indexes. The user component recovers and outputs $\widehat{\mathbf{B}}^U$, and item component outputs $\widehat{\mathbf{B}}^I$. Due to the distinct shapes of $\widehat{\mathbf{B}}^U$ and $\widehat{\mathbf{B}}^I$, we can not simply average the them as Equation (2). Nevertheless, there are $n \times m$ common entries covered by both of $\widehat{\mathbf{B}}^U$ and $\widehat{\mathbf{B}}^I$, and we denote this commonly covered part as a matrix $\mathbf{C} \in \mathbb{R}^{n\times m}$. In this way, the whole rating matrix will be decomposed into several small matrices. We can consider one small matrix as one mini-batch. Then during each training iteration, one mini-batch $\mathbf{C}$ will be used for one time of updating, where only the weights connecting the training samples in $\mathbf{C}$ will be updated. Hence, the model formulation in (2) can be rewritten in the mini-batch format:

$$\begin{aligned}
\widehat{\mathbf{C}} &= \frac{1}{2}(\widehat{\mathbf{B}}^U[:, \mathbf{q}] + \widehat{\mathbf{B}}^I[\mathbf{p}, :]),\\
\widehat{\mathbf{B}}^U &= \sigma(\sigma(\mathbf{B}^U\mathbf{V}^U + \mathbf{b}_1^U)\mathbf{W}^U + \mathbf{b}_2^U),\\
\widehat{\mathbf{B}}^I &= \sigma(\sigma(((\mathbf{B}^I)^\top\mathbf{V}^I + \mathbf{b}_1^I) \circ \mathbf{f})\mathbf{W}^I + \mathbf{b}_2^I)^\top,
\end{aligned}$$

where $\widehat{\mathbf{B}}^U$, $\widehat{\mathbf{B}}^I$, and $\widehat{\mathbf{C}}$ are the predicted user mini-batch matrix, item mini-batch matrix, and the combined predicted mini-batch matrix, respectively; $\widehat{\mathbf{B}}^U[:, \mathbf{q}]$ means the columns indexed by $\mathbf{q}$ in $\widehat{\mathbf{B}}^U$, and $\widehat{\mathbf{B}}^I[\mathbf{p}, :]$ represents the rows indexed by $\mathbf{p}$ in $\widehat{\mathbf{B}}^I$.

The objective function (3) can be rewritten as:

$$\underset{\mathbf{\Theta}}{\text{minimize}} \quad \mathcal{L} = \sum_{u\in{}^{\mathbf{C}}\mathbb{U}} \sum_{\substack{i\in{}^{\mathbf{C}}\mathbb{O}_u^+ \\ j\in{}^{\mathbf{C}}\mathbb{O}_u^-}} max(0, \widehat{r}_{u,j} - \widehat{r}_{u,i} + d) + \frac{\lambda}{2}\|\mathbf{\Theta}\|_F^2,$$

where ${}^{\mathbf{C}}\mathbb{U}$ is the users set in mini-batch matrix $\mathbf{C}$, ${}^{\mathbf{C}}\mathbb{O}_u^+$ is the items set that user u gives positive feedback to in $\mathbf{C}$, and ${}^{\mathbf{C}}\mathbb{O}_u^-$ is the negative samples of user u in $\mathbf{C}$. This approach has the benefit of only needing to load the sampled user and item rating vectors into memory rather than storing the whole rating matrix as the batch learning algorithm does.

5 EXPERIMENTS

In this section, we empirically evaluate the proposed model in comparison with state-of-the-art non-neural and neural approaches over three datasets. We aim to answer two key questions: (i) How does the proposed JCA framework perform compared with other approaches for implicit top-K recommendation? and (ii) Are the proposed Joint Collaborative Autoencoder structure JCA and the pairwise hinge-based objective function effective?

	Users	Items	Ratings	Sparsity(%)
MovieLens 1M (ML1M)	6,027	3,062	574,026	3.11
Yelp	12,705	9,245	318,314	0.271
Video Games (Games)	19,056	9,073	184,609	0.107

Table 2: Characteristics of the three datasets.

5.1 Datasets

We use three public datasets from different domains for our experiments: MovieLens 1M[2] (ML1M), Yelp[3], and Video Games[4] (customer reviews from the Video Games category on Amazon). For ML1M and Yelp, we treat ratings higher or equal to 4 as positive feedback, and consider all other ratings as missing entries. For Game, we consider all purchase behaviors as positive feedback. These strategies are widely used for evaluating implicit recommenders [7, 17, 27]. Then we iteratively remove users and items with fewer than 5 positive feedback. Finally, we split the datasets into 20% for testing and 80% for training. In the training set, we further hold 10% as a validation set. The datasets are summarized in Table 2.

5.2 Experimental Setup

Metrics. We adopt *Precision@k* and *Recall@k* averaged across all users as the evaluation metrics for personalized ranking (recall Equation (4)). We also report the *F1@k*, which is defined as:

$$F1@k = (2 \cdot P@k \cdot R@k)/(P@k + R@k).$$

Baselines. To evaluate the proposed model, we consider eight state-of-the-art methods including neural and traditional models:

MF [10]. The conventional matrix factorization model with MSE objective function and Alternating Least Squares (ALS) optimizer.

BPR [17]. BPR learns an MF model by the pairwise ranking objective function. We use Gradient Descent to optimize the objective function.

CDAE [24]. This is an Autoencoder-based model, which implements the neural version of SVD++. We adopt the sigmoid function as the activation functions in both the hidden layer and output layer, and use MSE as the objective function.

U-AutoRec [20]. This is a user-based AutoRec model, which takes user rating vectors as inputs and learns item-item correlations. It uses the MSE loss function.

I-AutoRec [20]. Similar to U-AutoRec, but takes item rating vectors as inputs and learns user-user correlations.

UI-AutoRec. This model averages the outputs of U-AutoRec and I-AutoRec.

NCF [5]. This model combines a neural version of MF model (named GMF) and a multi-layer perceptron (MLP) model. The model structure configuration is similar according to the original paper where MLP has four hidden layers with 8, 16, 32, and 64 hidden neurons, respectively.

NPR [14]. This is a neural version of BPR with two GMFs to implement the pairwise structure and the BPR objective function.

Reproducibility. All code, data, and experimental settings can be found at https://github.com/Zziwei/Joint-Collaborative-Autoencoder. We implement the proposed model based on Tensorflow [1] and use Adam [8] optimizer. We set the learning rate 0.003 for all methods.

Table 3: F1@k comparison between the proposed JCA and eight state-of-the-art baselines, where the results of proposed method and the best baselines are marked in bold.

For the mini-batch size, we set 256 for single side based methods (AutoRec and CDAE), and 1,500 for other methods (both bs^U and bs^I are set to be 1500 for JCA). For the regularization trade-off parameter, we grid search the best ones over [0.5, 0.1, 0.05, 0.01, 0.005, 0.001] for each model by the validation set. For ML1M dataset: we set $\lambda = 0.001$ for JCA, 0.05 for JCA-MSE, and 0.01 for JCA-BPR; for Yelp dataset: $\lambda = 0.005$ for JCA, 0.05 for JCA-MSE, and 0.001 for JCA-BPR; for Games dataset $\lambda = 0.001$ for JCA, 0.001 for JCA-MSE, and 0.001 for JCA-BPR. Moreover, we set the margin parameter $d = 0.15$ for JCA. We grid search hidden layer dimension over [40, 80, 120, 160, 200, 240] and set 160 hidden neurons for JCA (we set the hidden dimensions the same for both user and item component, fine tuning the dimensions separately may provide better performance). We re-sample negative samples in each epoch and set the negative sampling rate 1 for all models. Other model-specific hyper-parameters of baselines are fine-tuned over validation sets.

5.3 Proposed Model vs. State-of-the-art Models

We begin by investigating the recommendation quality of JCA compared with eight baselines over three datasets. The precision and recall results are presented in Figure 3 and Figure 4. For both metrics, we see that JCA produces the best performance. Besides, we also calculate the F1-score to further evaluate the recommendation quality as shown in Table 3, where the F1 scores for the proposed method and the best baselines are marked in bold, and the improvement rates are calculated for all settings. In terms of average *F1@k* result (across three different values of k), JCA can outperform the best baseline by around 5.5% on the MovieLens dataset, around 6.9% on the Yelp dataset, and around 8% on the Games dataset. We further do a t-test on the small improvement cases (ML1M @5 and @10), where we find the p-value is smaller than 1.5% for both, showing the statistical significance of the performance improvement.

In addition, we observe that: (i) the performance improvement is larger for sparser datasets, which may be because in high sparsity scenarios, user-user correlations or item-item correlations alone are not enough, while joint learning of user-item correlations can extract more useful information; (ii) the performance improvement is larger for smaller k (k defines how many items to be recommended to users), which indicates that JCA is more competitive when limited number of items should be recommended to users.

5.4 Proposed Model and Objective Function

To demonstrate the effectiveness of the proposed JCA structure and the pairwise hinge-based objective function, we implement two variations of JCA using alternative objective functions (MSE and

BPR), and compare the performance with other models using the same objective functions. We've argued in Section 4.2 that these objective functions are not aligned with top-K recommendation, so we seek to untangle their impact. We denote the model combine JCA structure with MSE objective function as JCA-MSE, and the one with BPR loss function as JCA-BPR.

Here we report the comparison between the JCA variations (JCA-MSE and JCA-BPR) and the best three models using the MSE objective function – CDAE, UI-AutoRec and NCF – and the models using the BPR objective function – NPR and BPR. We follow the same parameter tuning process as introduced in 5.2 for the two JCA variations. We report the Precision, Recall and F1 at top 10, but note that the results for top 1 and 5 have similar patterns.

First, let's focus on the comparison between JCA variations and other models with the same objective functions to evaluate the effectiveness of the JCA structure. Table 4 shows that JCA-MSE produces better performance than CDAE, UI-AutoRec and NCF for all three datasets in terms of F1@10 and Precision@10. From the perspective of recall, there are only one exceptional case: on ML1M dataset UI-AutoRec is 1.8% better than JCA-MSE for Recall@10. For the BPR objective function, JCA-BPR outperforms NPR and BPR significantly. Based on these comparisons, we can conclude that the proposed JCA model is effective for implicit top-K recommenders, regardless of the choice of objective function.

Table 6: Comparison between JCA models with/without the learnable item normalization factor, where the best results are marked in bold.

Next, we turn to investigate whether the pairwise hinge-based objective function is effective or not. Comparing the results of the three variations of JCA in Table 5, we can observe the recommendation performance trend: JCA > JCA-MSE > JCA-BPR for all three metrics and all three datasets. This provides empirical evidence that the proposed hinge objective function is more effective and suitable for implicit top-K recommenders.

Further, to validate the effectiveness of the learnable item normalization factor in the proposed JCA structure, we also implement a variation of JCA without the item normalization factor named JCA-NF in comparison with JCA. The result is presented in Table 6, which shows that JCA model with the item normalization factor produces better recommendation performance for all three datasets, and the performance improvement rate is around 5%.

6 CONCLUSION AND FUTURE WORK

In this paper, we show that user-based AutoRec and item-based AutoRec models explore different information from the data and produce complementary recommendations. Based on this observation, we propose the Joint Collaborative Autoencoder framework that learns both user-user and item-item correlations simultaneously, leading to improved implicit top-K recommendation quality. Besides, the proposed JCA adopts a pairwise hinge-based objective function to optimize the top-K precision and recall. We also present a mini-batch optimization algorithm so that JCA can be trained on large datasets without the (impractical) need to load the entire rating matrix as in naive batch learning approach. By extensive experiments on three public datasets, we show that the proposed framework outperforms state-of-the-art baselines. In our continuing work, we are exploring how to incorporate auxiliary information, such as textual and visual information, into the framework to further improve the recommendation quality.

Acknowledgments. This work is supported in part by NSF IIS-1841138.

Demonstrations Track Chairs' Welcome

It is our great pleasure to welcome you to the *WWW 2019 Demonstrations Track*. We received 58 proposals from all around the world covering a broad range of topics. We evaluated them regarding relevance, quality, and novelty, selecting 27 demo papers that will be presented along with the poster session during two afternoon sessions.

Review and acceptance statistics are as follows:

Submission Type	Reviewed	Accepted	Acceptance Rate
Demos	58	27	46.55%

Number of Reviewers	Average Assignments Per Reviewer
59	3.95

Number of Submissions	Minimum number of reviewers per paper	Majority number of reviewers per paper
58	3	4

We wish that you will find the demo program interesting, providing you with a valuable opportunity to learn and share ideas with other researchers and practitioners from institutions around the world.

ABSTRACT

This paper introduces **RecBoard**, a unified web-based platform that facilitates researchers and practitioners to train, test, deploy, and monitor recommendation systems. RecBoard streamlines the end-to-end process of building recommendation systems by providing a collaborative user interface that automates repetitive tasks related to dataset management, model training, visualization, deployments, and monitoring. Our demo prototype demonstrates how RecBoard can empower common tasks in research and development. RecBoard will be open-sourced and publicly available upon publication.

CCS CONCEPTS

• **Information systems → Recommender systems**.

Recommender Systems; Machine Learning; Web Platforms

ACM Reference Format:
Mohit Chawla, Kriti Singh, Longqi Yang, and Deborah Estrin. 2019. RecBoard: A Web-based Platform for Recommendation System Research and Development. In *Proceedings of the 2019 World Wide Web Conference (WWW '19), May 13–17, 2019, San Francisco, CA, USA.* ACM, New York, NY, USA, 5 pages. https://doi.org/10.1145/3308558.3314133

1 INTRODUCTION

To innovate on and deploy recommender systems, researchers often need to perform a series of repetitive tasks that involve dataset loading, dataset management, model monitoring, visualization, and deployment, as shown in Fig. 1. These repetitive tasks lead to significant overhead for model development and maintenance.

However, existing platforms are limited in addressing this overhead. On one hand, many solutions are focused on limited stages of the development pipeline (Fig. 1). For example, OpenRec [12] supports systematic model training, TensorFlow serving [9] and Clipper [1] enable model deployment in production, and AutoML [3] automates the process of searching for model configurations. On the other hand, existing systems that attempt to consolidate different development stages have a steep learning curve and are restricted to limited use cases — BigML [5] does not offer any recommendation model; Amazon's SageMaker [4] offers a train-test-deploy pipeline only in a hosted notebook environment, and MLBase [6] requires using a task language to declare machine learning tasks and does not provide deployment supports.

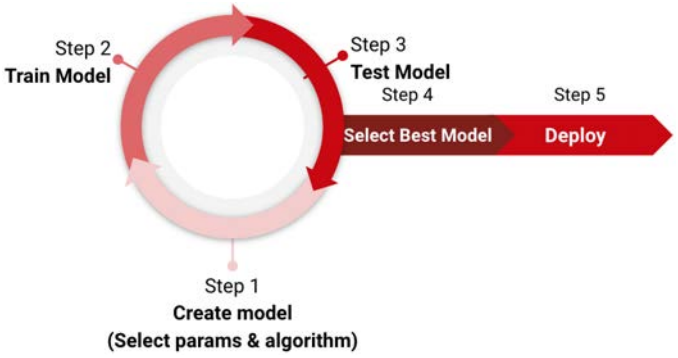

Figure 1: End-to-end process of developing recommender systems. It comprises of various stages: selecting parameters and algorithm, training the model, testing and selecting the best model, and deploying the best model into production.

In this paper, we develop **RecBoard**, an open-sourced and web-based platform that eases the end-to-end process of creating, testing, deploying, and monitoring recommendation models. It unifies five tasks in productionizing a recommendation system: (1) selecting dataset, model and model parameters, (2) training and testing the model, (3) visualizing the training progress (e.g., loss and precision) in real time, (4) collaborating with peers, (5) deploying the model, and (6) monitoring the deployed model. RecBoard is intended for researchers who aspire to create or productionize recommendation systems while collaborating with their peers.

2 SYSTEM FEATURES

RecBoard eliminates operational inefficiencies across all stages of productionizing recommendation models. In this section, we present its major functionalities and features.

2.1 Training

RecBoard facilitates users to train models using the user interface as shown in Fig. 2 and enables them to monitor training progress (e.g., loss, precision, and recall) in real-time, as shown in Fig. 3. Since our core training library, OpenRec [12] is based on TensorFlow, we use TensorBoard [11] as the default visualizer. RecBoard allows users to plug in their custom visualization solutions.

2.2 Deployment

RecBoard allows users to deploy a model as a REST API using TensorFlow Serving [9]. This leads to fast, automated and easy to manage deployments. The *Deployment Manager* can be configured to use other deployment solutions, such as Clipper [1].

2.3 Monitoring

RecBoard enables users to monitor metrics and keep track of a model, which is deployed as a REST API. For debugging purposes, an input form is provided, and it enables the user to quickly test if the API of the deployed model is working, as shown in Fig. 4.

2.4 Collaboration

RecBoard enables users to collaborate via features such as dataset sharing, model visualization sharing (Fig. 5).

Figure 5: Sharing a model's visualization with peers

2.5 Management

RecBoard provides better model management by introducing workspaces, and model and dataset sharing and tagging.

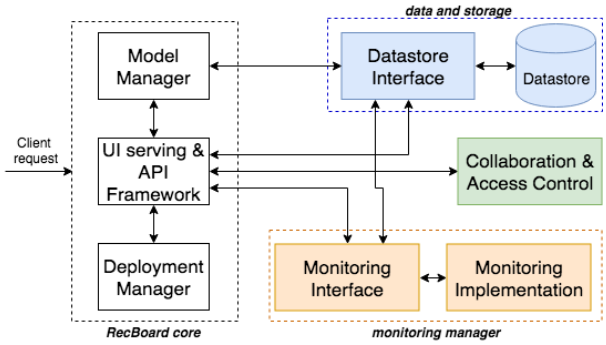

Figure 6: The architecture of RecBoard. All components are designed to automate repetitive tasks in different stages of developing recommender systems.

3 ARCHITECTURE OVERVIEW

The architecture of RecBoard is shown in Fig. 6, which highlights the major components of the system. RecBoard views the process of developing recommender systems as a multi-stage pipeline (Fig. 1) and provides user interfaces to perform tasks relevant to each stage of the pipeline. The tasks include managing datasets, training and testing model(s), organizing models into workspace(s), deploying model(s), and monitoring deployed models. *RecBoard core* is the central component that handles model management (via *Model Manager*), serves the user interface and handles model deployment.

3.1 Modular Design

To make the pipeline efficient, we define reusable components by identifying repetitive tasks and clustering those tasks, as shown in Fig. 7. For example, *Model Manager* automates repetitive tasks such as loading datasets, initializing model, and starting training. Furthermore, RecBoard is modularised in a way that its components can be replaced by custom modules by advanced users. For example, a different database can be connected easily and custom monitoring solutions can be added. Since each model training task is independent of others and is executed outside of the HTTP request-response cycle, we leverage distributed task queues to parallelize model training related operations. A task queue handles invoking

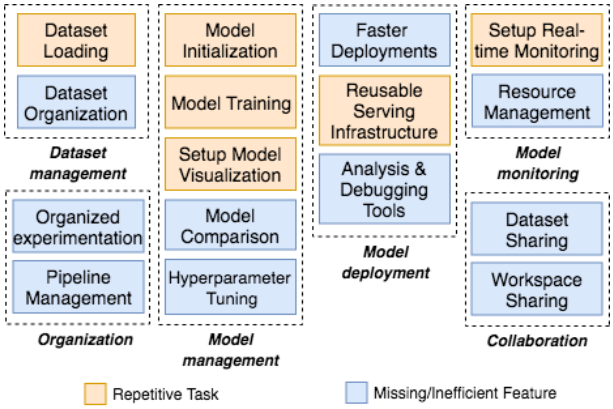

Figure 7: There are a number of repetitive tasks in end-to-end process and some missing features in existing platforms. These can be clustered into reusable components.

code that trains the model, processes results and stores them in a persistent database for later use. This architecture supports an on-premise solution so that users with constraints around data sharing can use RecBoard.

3.2 Components

RecBoard core consists of Model Manager, Deployment Manager and UI Serving & API framework. For a request from client, **UI Serving & API framework** interacts with other components of system and serves the user interface. **Model Manager** provides mechanisms to manage all model related tasks such as training, visualization, testing, management (create, delete, and edit), and download. **Deployment Manager** provides infrastructure for deploying (and un-deploying) a trained model and managing cloud configurations. **Monitoring Manager** provides infrastructure support for monitoring metrics (e.g., requests and up-time) of a deployed model via a monitoring interface. Mechanisms for monitoring are provided by a default implementation. The **Data and storage** component is part of persistence layer and provides an interface which can be implemented by any database wrapper. We used MongoDB in the initial prototype. The **Collaboration and access control** component provides infrastructure for collaboration via features such as: sharing training visualization and sharing datasets.

4 SAMPLE USER WORKFLOWS/EXPERIENCE

This section describes examples of user experience for different tasks performed via RecBoard.

4.1 Developing Recommendation Systems for Online Supermarket

A researcher R_1 at an online supermarket company wants to create a recommender system for clothes and deploy it as a REST API so that other teams in the company can use it to provide clothes' recommendations to users. She opens RecBoard and creates a workspace named "*Clothes Experiments*" to organize all recommender models related to clothes. She splits a dataset into training, validation and testing, uploads them to RecBoard, and adds tags (clothes,

train/test/eval) to them. She decides to create and deploy a Probabilistic Matrix Factorization (PMF) [8] based model. For experimentation, she chooses 3 sets of hyper-parameters to test upon and deploy the best of these. Using the *Add Model to Workspace* Section (Fig. 2), she selects a recommender and other hyper-parameters to add 3 models to the workspace. Now she can monitor key training indicators (e.g., loss, precision, and recall) of these 3 models in real time. After some time, all models are trained and the Model 2's results are the best. She decides to deploy it. To do so, she adds configurations for deployment corresponding to a cloud provider. Next, she clicks the *Deploy* button to deploy the model. After the model is deployed, she sees model testing UI along with API URL (Fig. 4) and decides to test if API is working. To test, she wants to know the output of the model for users with ids 2, 90 for items with ids 3, 81. So, she enters these ids and clicks the *TestAPI* button. She sees responses from the server and verifies that the API is working fine. So, she shares the API URL with other teams.

4.2 Collaborating on Recommendation Systems Development

R_1's team member is a recommender systems developer, R_2. R_2 proposes to experiment with recommenders other than PMF (deployed already). So, R_1 wants to collaborate with R_2. To do so, R_1 shares the "*Clothes Experiments*" workspace (created earlier) using the *Share Workspace* button and entering R_2's email. Now, R_2 has access to the workspace and she creates other models based on Bayesian Personalized Ranking (BPR). She trains new models and finds that, say, one of her models performs better than the model deployed earlier. So, she decides to deploy this model and update other teams with new API URL. Once other teams migrate to this new API, she undeploys previous model using *Undeploy* button (Fig. 4).

5 EVALUATION

In this section, we evaluate RecBoard in terms of efficiency and present examples to demonstrate how users can customize modules and add new recommendation algorithms as per their use case.

5.1 Efficiency: RecBoard as a platform for efficient and organized experimentation

Previously, the end-to-end process was inefficient because it involved writing multiple lines of glue code for repetitive tasks (shown in orange in Fig. 7) and manually setting up pipelines for commonly needed features (shown in blue in Fig. 7). Now, the user can perform the same tasks by a few clicks in the UI, which leads to increased efficiency.

5.2 Extensibility and Maintainability: Adapting RecBoard by customizing existing implementation

It is important that the existing implementation is extensible because users might need additional features and custom implementations of modules. RecBoard provides ways to adapt the platform to custom use cases. For example, additional recommendation algorithms can be added by adding a file similar to the ones in the *recommenders* folder, different datastore (Fig. 6) can be added by extending implementation of the *RecboardDB* class.

As shown above, the existing implementation of RecBoard is extensible and maintainable as it is modular, based on DRY [2] and SOLID [7] principles, and is testable.

6 DEMO OVERVIEW

We plan to demonstrate RecBoard using a user-item interaction dataset with 5551 users and 16980 items. This dataset, *citeulike-a*, was collected by Wang et al. [10] from CiteULike and Google Scholar. CiteULike allows users to create their own collections of articles. There are abstracts, titles, and tags for each article. Auxiliary information such as authors, groups, posting time, and keywords is not used. The details can be found at www.citeulike.ort/faq/data.adp.

The demonstration starts by logging in as a registered user and creating a workspace using *Create New* button in left panel and entering workspace name (e.g., MyWorkspace). This creates a workspace, as shown in Fig. 2. This is followed by uploading the dataset into workspace created above using the *Upload* button. Once the dataset is uploaded, a model is trained by selecting hyper-parameters and other details and clicking *Create and Start Training* button. This would show training process with real-time graphs as shown in Fig. 3. Once training is completed, *Deploy* button is clicked, which deploys the model on local server and presents an API URL along with UI component to test the deployed model's REST API (Fig. 4). We show that deployed model is working by inputing comma-separated sample user-ids and item-ids followed by clicking *Test* button. This shows sample response from the deployed model.

7 CONCLUSION AND FUTURE WORK

RecBoard contributes towards reducing operational inefficiencies in the process of creating recommendation systems. This is made feasible by (1) identifying repetitive tasks in the pipeline, (2) defining reusable components for these tasks, and (3) creating a user interface to automate these tasks using the components defined. This can improve the speed at which recommender models can be productionized, irrespective of production environment or cloud provider. In the future, we plan to improve RecBoard by adding features for dataset visualization, cross-validation and comparison of deployed models. We also plan to explore the idea of a similar platform in other domains, such as Computer Vision, and Natural Language Processing.

ABSTRACT

This paper demonstrates a novel analytics service, CrowdPT, for capturing the key information, price target (PT), of individual investors on social media. PT, which is mentioned as a conclusion in most of analysts' reports, indicates not only the market sentiment (bullish/bearish) of investors, but also the analysis results. In order to provide the latest opinions of individual investors, we monitor Twitter in real time and update the information in price chart daily. For all component stocks in Dow Jones Industrial Average, textual information from numerous tweets is summarized into a single number, PT, in CrowdPT. Case studies confirm the effectiveness of our analytics service in the financial domain, and show that capturing the PT of individual investors is promising for stock price prediction. The Web API of CrowdPT is also provided for academic purpose.

CCS CONCEPTS

• **Information systems** → **Information extraction**.

KEYWORDS

price target, financial social media, crowd opinion

1 INTRODUCTION

The application of artificial intelligence technologies to financial domain has attracted much attention in recent years. A variety of related tasks and researches are addressed in the shared tasks and workshops collocated with predominant conferences, including SemEval-2017 Task 5, FiQA-2018, FNP-2018, ECONLP-2018, and FinNum-2019.

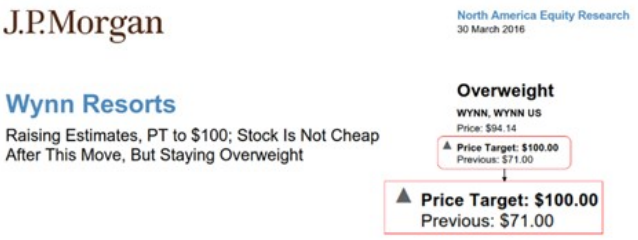

Figure 1: Example of professional analyst's report.

According to the important information embedded in the numerals in financial narratives, it has caught many researchers' eyes [1, 2, 4]. Especially, forecasting the price target (PT), the price level that the price of a financial instrument will reach, is one of the major goals of analyzing financial instrument. As shown in Figure 1, most of professional analysts show their PTs in the top of the first page of analyst reports for the customers to capture their analysis results at a glance. In the left side of Figure 1, the analyst uses a piece of short text to summarize the report, and mentions the PT. In the right side of Figure 1, the analyst shows the analysis results in a table with the information such as the overweight comment and the PT. However, social media data is unstructured, and the PT information in tweets could only be extracted with natural language processing technique. Since PT is an extremely crucial indicator in the procedure of financial analysis, capturing the PT based on the crowd opinions is an important topic to investigate.

Sometimes the institutional investors may not release the report for a certain company. At this time, the price target forecasted by individual investors can be used to complement the missing information. For example, Bloomberg does not record the price targets of the analyst for $AXP in August, October, and November in 2017. With the PT sorted out by our system, the information can be filled up. Even though PT is quite meaningful for presenting the opinions and analysis results of investors, to the best of our

other	110.2	$FB (**110.20**) is starting to show some relative strength and signs of potential B/O on the daily.

knowledge, none of the previous systems provide the function for extracting the PTs of individual investors. Once the PT is extracted, the user gets not only the market sentiment, but also the degree of the market sentiment, calculating by the difference between the PT and the newest close price. Moreover, the expected value of a certain financial instrument is estimated. Many in-depth empirical experiments can be extended with the PT extracted from social media text.

This work presents CrowdPT, a service providing the PTs of individual investors based on social media text. For each stock, our system provides the PT extracted from social media text. Case studies show that PT from social media data is useful for investors when making decisions, and provides more insights for the behavior of investors.

Our contributions are three-fold: (1) We propose CrowdPT, a novel Fintech application based on natural language processing, and demonstrate its potential values. (2) In addition to the demonstration website, we also provide our model as a cloud service for downstream applications and extended research. (3) CrowdPT provides the real-time market information for all component stocks in Dow Jones Industrial Average. The case studies show the PTs of individual investors based on financial social media data help investors make investment decisions.

2 SYSTEM OVERVIEW

Figure 2 shows a screenshot of CrowdPT. The red bar and green bar, called candlestick chart, are used to show the daily open, high, low, and close price of a stock. The red line shows the average of the PTs from financial tweets, which can be easily compared with the market price shown in the candlestick chart. For those days on which no numerals are classified as PT, approximate PTs are shown with dotted lines. In Figure 2, we use $GE, General Electric Company, as an example. On Oct 25, the price of $GE was about 12, and the PT that we sorted out from the financial tweets was about 10.5. It shows that individual investors forecast the price will fall down to 10.5 in the future. On Oct 30, $GE's stock price came to the PT on Oct 25. Moreover, individual investors modified their PT to about 7 on Nov 2. Then, the price matched this PT on Nov 12, and descended to crowd's PT on Nov 15. These cases show the usefulness of crowd price target and indicate that CrowdPT provides the leading indicator for stock market prediction.

CrowdPT summarizes the textual information from financial tweets into single numeral (PT), and provides the real-time information for all component stocks in Dow Jones Industrial Average. The market sentiment, bullish or bearish, can be captured at a glance with the price chart. When the PT is higher than the close price, it means that individual investors take bullish market sentiment

toward the stock. On the other hand, investors have bearish market sentiment to the stock when the PT is lower than the close price. Beyond market sentiment, CrowdPT provides more fine-grained information for individual investors' opinions. With the PTs sorted out, not only the degree of the market sentiment but also the expected price level would be captured.

Additionally, we provide the Web API for disambiguating the meaning of the numerals in financial tweet. We follow the taxonomy tailor-made for the numerals in financial social media data [1]. Categories and subcategories are shown in Figure 3. Table 1 shows the example tweets for each subcategory.

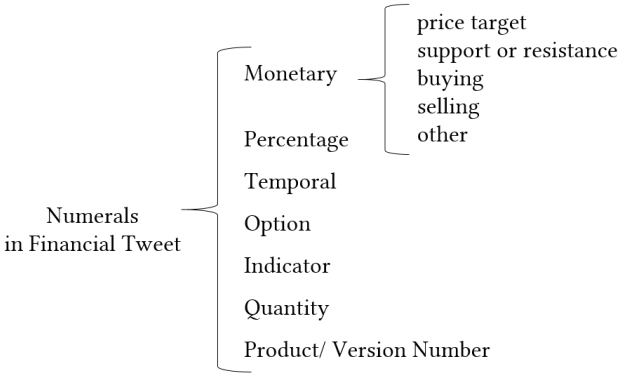

Figure 3: Numeral taxonomy in financial tweets.

3 TECHNICAL IMPLEMENTATION

In CrowdPT, we adopt the word-based CNN model for financial numeral understanding [1]. Here, we merge the subcategories that do not imply any subjective opinions of investors, including "money", "quote", "change", and the rare subcategory, "stop loss" in Monetary category into one class, called "other".

3.1 Dataset

We adopt FinNum dataset for experiments [1]. Three experts in the financial domain are involved to annotate the numerals in the SemEval-2017 Task 5 dataset, in which financial tweets from Twitter and StockTwits are collected and labeled with market sentiment. Total 1,341 numerals are annotated. The average agreement of the annotation on price target achieves kappa value of 65.59%, which is considered as substantial agreement [3].

3.2 System Flow

Figure 4 illustrates the flowchart of price target extraction. Firstly, we use tweepy [1] , a Python library, to monitor the latest tweets published in Twitter. Only the tweets mentioning the cashtags of the constituent stocks of Dow Jones Index will be crawled. Secondly, the price target filter is performed at the end of the day (GMT -8) to sort out the price target for each cashtag. Then, a classifier based on convolutional neural network (CNN) is adopted for extracting the price target. Finally, we collect the close price from Yahoo Finance

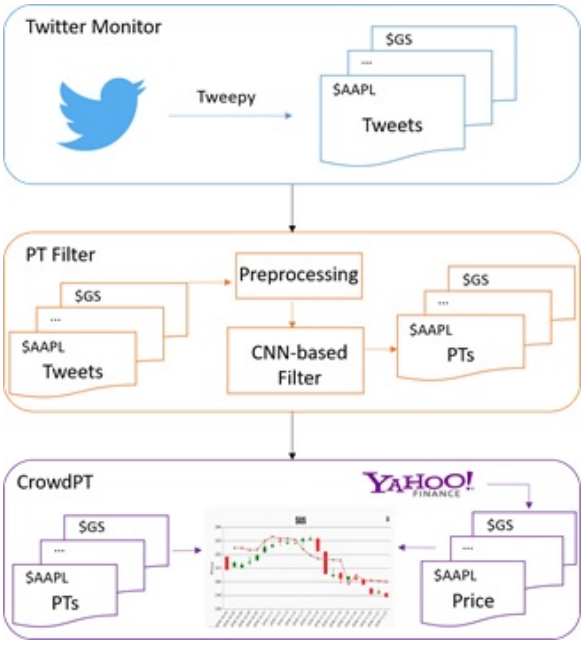

Figure 4: System flowchart of price target extraction.

Table 2: Experimental results of subcategory classification.

	target	sup/res	buying	selling	other
P	42.50	41.34	36.80	35.36	50.66
R	50.90	30.68	27.29	54.05	80.53
F1	45.32	34.27	28.55	40.17	61.51

with the fix_yahoo_finance [2] and render the price chart. Our system also provides the analysis results in json format via Web APIs.

3.3 Results of Numeral Disambiguation

In the 7-way category classification task, our word-based CNN model achieves an accuracy of 67.61%, which significantly outperforms other models with RNN structures under 95% confidence level. Please refer to our previous work [1] for more details of model setting and comparison. In the subcategory classification task, the precision, recall and F1-score for each subcategory are shown in Table 2.

4 DETAILS OF WEB API

Our Web API returns the classification results of the numerals in input financial tweets. A financial tweet should contain at least one cashtag, and our target tweets are those financial tweets that have at least one numeral. In this paper, we demonstrate the usefulness of the extracted PT, and more empirical studies could be extended based on other (sub)categories.

The participants of the financial market can be separated into two groups, institutional investors and individual investors. Yet, only the

[1] http://www.tweepy.org/

[2] https://github.com/ranaroussi/fix-yahoo-finance

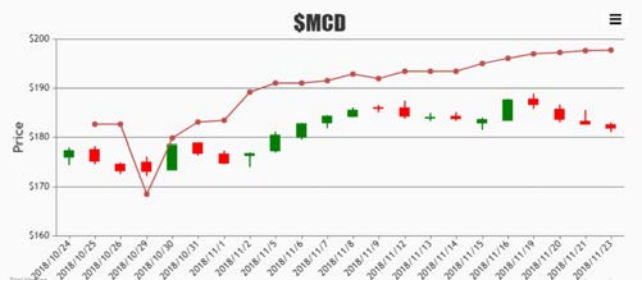

Figure 5: Correlation of stock price and crowd's PT.

Figure 6: Evidence for crowd's PT as leading indicator.

analysis results of institutional investors are recorded in structural format by market information providers like Bloomberg. None of previous systems attempts to summarize the textual information on the financial social media data into price target. In CrowdPT, the latest PT from individual investors can be obtained and be compared with the latest close price in the provided price chart.

5 INVESTIGATION OF CROWD PRICE TARGET

We perform backtesting of the PT of both institutional and individual investors in 2017, and discuss our findings as follows. The performances of both institutional investors and individual investors can be compared within CrowdPT. For example, the price of $DWDP reached the September price target of institutional investors, but did not reach their November price target until now. In contrast, the price did not reach the September price target of individual investors, but reached their November price target. That shows the information of both institutional investors and individual investors may be comparable. With CrowdPT, investors can obtain more insights than before and develop new trading strategies.

Figure 5 shows the correlation between stock price and crowd's PT. The price did not match the PT during November, but the close prices follow the trend of PT. In other words, the crowds upgrade the PT first and the close price of $MCD rises toward the PT. Figure 6 shows that CrowdPT not only provides the bullish information but also the bearish information. It also shows that the crowd's PT can be the leading indicator for stock market movement prediction. The cases in Figure 2, 5, 6 show the evidence that CrowdPT provide

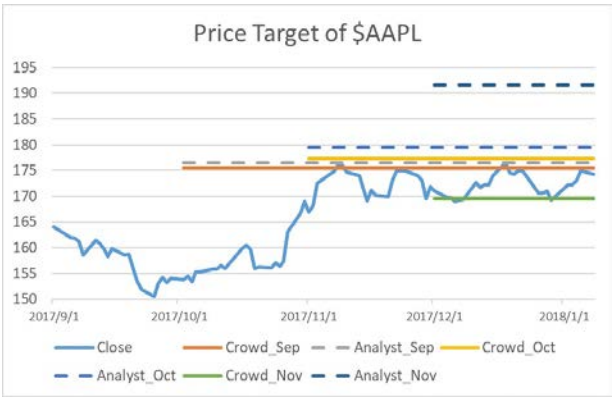

Figure 7: Price target of $AAPL.

the longer-term market movement forecast, which is more sensible for investment, and different from previous work [5] focus on speculation (predict the short-term price movement).

More empirical studies can be conducted with the analysis results of CrowdPT. For instance, the difference of the tendency of setting price target between institutional investors and individual investors can be investigated. Figure 7 shows the comparison of the price target of $AAPL in September, October, and November. We find that the price targets of the analysts are always higher than that of the crowd. That shows the analysts may be more optimistic than individual investors, or individual investors may tend to focus on the short-term prediction. According to this finding, investors could consider to follow the opinions of the crowd for short-term trading and follow the opinions of analysts for long-term investment.

6 CONCLUSION

We present CrowdPT [3], a service aiming at providing price-target oriented analysis results based on financial social media text. Novel applications based on our model are demonstrated. Investors can benefit from the information provided by our system. In particular, trading strategies combine the price targets of institutional investors and individual investors have great potential for further studies. With our Web API [4], users can get the fine-grained classification results based on the tailor-made taxonomy for numerals in financial social media data.

ABSTRACT

We introduce and demonstrate the usefulness of a tool that automatically annotates therapist utterances in real-time according to the therapeutic role that they perform in an evidence-based psychological dialogue. This is implemented within the context of an on-line service that supports the delivery of one-to-one therapy. When combined with patient outcome measures, this tool allows us to discover the active ingredients in psychotherapy. In particular, we show that particular measures of therapy content are more strongly correlated with patient improvement than others, suggesting that they are a critical part of psychotherapy. As this tool gives us interpretable measures of therapy content, it can enable services to quality control the therapy delivered. Furthermore, we show how specific insights can be presented to the therapist so they can reflect on and improve their practice.

1 INTRODUCTION

Mental health is a substantial healthcare concern for the world's population. It is estimated that one in four people are affected by a mental illness during their lifetime and that mental illness costs the global economy $1 trillion per year in lost productivity alone. Psychotherapy is an effective intervention for a range of mental health problems. In particular, cognitive behavioural therapy (CBT) is a popular and effective evidence-based talking therapy that teaches patients the skills and techniques needed to help overcome and manage their symptoms. While CBT has been shown to be as effective as medication on a range of disorders, only half of those diagnoseable with a specific condition actually recover. In fact, the recovery rates for CBT have largely been stagnant, or even decreasing [8], in the last 30 years. Furthermore, given that the vast majority of therapy happens behind closed doors, it is difficult to objectively measure the quality of therapy being delivered or to identify the aspects of therapy that are most effective.

While there has been a technological revolution in the area of physical health in the last 50 years, where practitioners have been equipped with more accurate instruments, diagnostic tests, and medical devices (e.g. x-rays, MRI, blood tests, DNA sequencing), there has been very little change in how psychotherapy has been delivered. However, it is increasingly being recognised that online applications have a crucial role to play in increasing access to services, alleviating the burden on existing mental health services, and in driving innovation in the mental health domain.

One recent development in the mental healthcare sector in the UK is the use of online systems to support the delivery of psychotherapy. One particular case is internet-enabled CBT (IECBT) which allows a therapist to deliver CBT to a patient over their mobile device via real-time text-based conversation. This is an important development as it means that every interaction between a therapist and patient is recorded. In this work, we present a tool[1] that uses deep learning to automatically categorise therapist utterances according to the role that they play in therapy. In order to train and evaluate our model, human annotations were gathered from 290 hours of therapy. We then applied our tool to a large-scale dataset containing session transcripts from over 14,000 cases of IECBT (approximately 90,000 hours of therapy) to calculate a quantifiable measure of treatment delivered. Finally, using a logistic regression analysis, we investigated the relationship between the quantity (or âĂŸdosageâĂŹ) of each aspect of therapy delivered and clinical outcomes.

2 BACKGROUND AND ONLINE CBT

While there has been an increase in online forums and web-based applications for mental healthcare, in most cases these deliver self-help materials for patients with mild symptoms and are not a replacement for one-to-one therapy. In IECBT, a patient communicates one-to-one with a qualified CBT therapist using a real-time text-based message system. IECBT has been shown to be clinically effective for the treatment of depression [5] and is currently commissioned in the UK by the National Health Service (NHS) under the Improving Access to Psychological Therapies (IAPT) [2] programme. As CBT is a short-term goal-orientated intervention, the typical number of sessions is between five and 20. As mandated by IAPT, symptoms are measured before each therapy session using self-reported instruments i.e. Patient Health Questionnaire (PHQ-9) and Generalised Anxiety Disorder Assessment (GAD-7). An example segment of therapy delivered using this modality is shown in Figure 1.

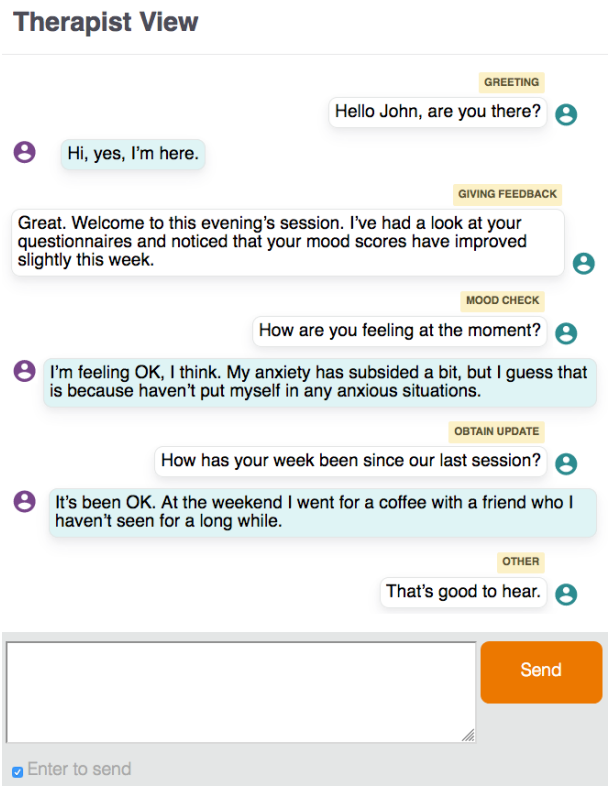

Figure 1: A screenshot of an example therapy session with labels being applied in real-time to each therapist utterance by our deep learning model (TIM).

Some related work [6, 11] has developed a dialog-act modelling approach for motivational interviewing conducted on spoken transcripts; the aim of which is to measure the fidelity of the session to the therapy model. This differs from our work in terms of the psychotherapy domain, the modality, and the fact that they do not aim to discover which aspects of therapy are most effective.

Table 1: Categories of therapist utterances (* means that the category is stylistic and was determined by a regular expression)

Change Methods	*Therapeutic Empathy
Perceptions of Change	*Therapeutic Praise
Set Homework	*Collaboration

3 HUMAN ANNOTATION

In conjunction with an experience clinically trained CBT practitioner, a research psychologist developed a set of 19 content-based categories and five stylistic categories that capture the role that therapist utterances play in CBT. The research psychologist annotated 290 hours of therapy (11,221 utterances) applying one or more of the 19 content-based categories to each utterance. The five stylistic categories were identified using regular expressions. A list of all the therapy categories used in the annotation effort are shown in Table 1. Using the annotated data, we trained a deep learning model using 8,859 utterances from 230 therapy sessions with the remaining data being kept for validation (30 transcripts) and testing purposes (30 transcripts). The deep learning model is described in the next section.

4 DEEP LEARNING ARCHITECTURE

We developed a deep learning model (see Figure 2) to automatically classify each utterance into one or more of the 24 categories. Firstly, we used word2vec [10] on a preprocessed version of the entire data set of over 90,000 transcripts (approx. 200M words) to learn word embeddings that are suited to the domain of psychotherapy. We preprocessed our data by tokenizing according to whitespace and punctuation and then by lower-casing all tokens (we kept punctuation symbols as separate tokens). This resulted in a vocabulary of 89,260 words, each represented as a continuous dense vector of length 200.

We modelled each utterance in a transcript as a sequence of word embeddings and fed these into a bidirectional long short-term memory [7] (BiLSTM). We used max-pooling over the hidden states of the BiLSTM to encode each utterance as a fixed-length vector. In order to model each utterance in the context of the entire transcript, we fed each of the fixed-length utterance representations in a transcript into another BiLSTM and used the hidden state at each time-step to feed into our final output layer. For both our BiLSTM stages, we used a hidden dimension of 400 and used dropout of 0.5 [4]. A fully connected layer maps each fixed length utterance-in-context representation into a vector of length 23 (23 classes with

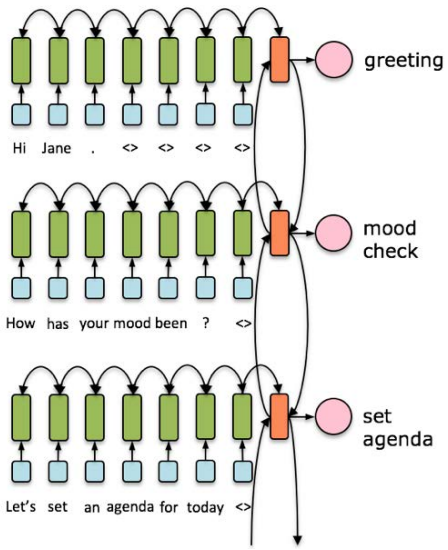

Figure 2: A diagram of the deep learning architecture where word representations (blue) are transformed via an LSTM into word-in-context representations (green) which are max-pooled into utterance representations (orange) and are fed into another LSTM to create utterance-in-context representations (pink).

the 'Other' class modelled as all zeros) with a sigmoid activation function used on this output. Conceptually, each category is modelled as a binary classifier. The training labels were obtained from manual annotation for 19 of the categories, and from high-precision regular expression for the remaining five categories. We call our model TIM (Therapy Insights Model).

5 EXPERIMENTS

We compared our model to a number of other baseline systems for sentence classification. As a simple baseline, we used a multilayer perceptron (MLP) that uses simple unigram lexical features as input. This MLP had one hidden layer the size of which was tuned on the validation set. As a more advanced baseline we used StarSpace [12] which is reported to outperform FastText [9] on a number of classification tasks. On the validation set, we found that a bigram model worked best. We also used a BiLSTM with max-pooling as another baseline [3]. For this baseline, we tuned the hidden dimension and dropout on the validation set. These three baselines treat each utterance in isolation and have no wider contextual information available during classification.

5.1 Classification Results

Table 2 shows the results (F1-score) of the various automated approaches to the utterance annotation task for the 19 manually annotated categories. The MLP that uses the simple lexical features is the worst performing model. The best non-contextual model is the BiLSTM. Overall, the best performing model is TIM which uses contextual information from the wider transcript when annotating an utterance.

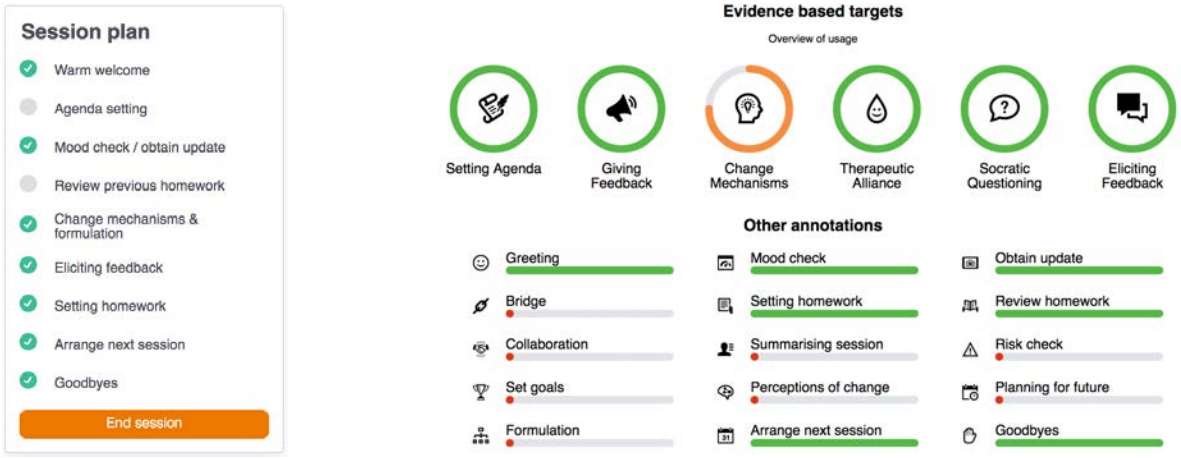

Table 2: F1 scores for the manually annotated categories on test data for the three baselines and TIM.

6 OUTCOME RELATED INSIGHTS

In order to understand the therapy features that are associated with reduced symptoms, we performed a logistic regression on statistically reliable improvement. Patients are defined as having reliably improved if they have dropped by 6 points on the PHQ-9 scale or 4 points on the GAD-7 scale (with no reliable increase in the other) [2]. Patients scoring above 9 on the PHQ-9 or above 7 on the GAD-7 were classed as meeting the clinical threshold at assessment and were included in this regression analysis (approx. 14,000 cases). The TIM tool was used to automatically annotate all sessions (excluding the final session) for those patients (approx. 90,000 hours of therapy). Then the number of words of each therapy feature in Table 1, averaged over all sessions attended by a patient (excluding the final session), was used as a measure of the 'dosage' of that feature administered to that patient (case), while controlling for the number of sessions and other patient variables [1].

The results revealed a significant relationship between a number of features and statistically reliable improvement. 'Therapeutic Praise', 'Planning for the Future', 'Perceptions of Change', 'Set Agenda', 'Elicit Feedback', 'Review Homework' and 'Give Feedback' were all positively associated with reliable improvement. 'Change Methods' - a CBT-specific feature of therapy was also positively related with improvement. By contrast, increases in'non-therapy' related content ('Other', 'Greeting' and 'Goodbye') were negatively related with improvement, as were 'Therapeutic Empathy', 'Risk Check' and 'Bridge'. The output from this analysis can be used in a number of important clinical ways, including quality control, clinical decision support, and clinical supervision.

(a) clinical decision support **(b) therapist feedback**

Figure 3: A screen-shot of in-session clinical decision support (a) and of therapist feedback (b) after a particular session (green indicates a suitable amount of that particular content was delivered).

6.1 Automated Quality Control

The output of the logistic regression model enables automated quality assurance. Using the logistic regression model as a predictive model, we can estimate the probability of recovery for any therapy session based on the quantity of the specific categories. Space limits the inclusion of a screen-shot of the output of a daily ranking of sessions.

6.2 Clinical Decision Support

The real-time nature of the automatic annotation tool allows us to monitor the delivery of crucial elements in live therapy. For example, therapists can be reminded to set an agenda or to set homework when they have not done so. Figure 3a shows an example of this in terms of a session plan which is updated as items are addressed by the therapist.

6.3 Automated Clinical Supervision

Clinical supervision allows therapists to discuss their practice with an experienced supervisor as part of their professional development. Given the data-driven nature of our insights, we can supply our therapists with summaries and insights for every session that they deliver. Figure 3b is an example of a session summary presented after a session which indicates which aspects of therapy are sufficient and which may be lacking. This can help therapists reflect on the specific session or on the therapy they deliver more generally.

7 CONCLUSION

This paper demonstrates a tool (TIM) that automatically annotates CBT transcripts. Along with paired outcome data, it engenders a sea-change in how psychotherapy can evolve in the digital age. We have demonstrated how it can be used to inform clinical best practice and furthermore, we outline three use cases for how this technology can be used in practice.

ABSTRACT

We present QAnswer, a Question Answering system which queries at the same time 3 core datasets of the Semantic Web, that are relevant for end-users. These datasets are Wikidata with Lexemes, LinkedGeodata and Musicbrainz. Additionally, it is possible to query these datasets in English, German, French, Italian, Spanish, Pourtuguese, Arabic and Chinese. Moreover, QAnswer includes a fallback option to the search engine Qwant when the answer to a question cannot be found in the datasets mentioned above. These features make QAnswer as the first prototype of a Question Answering System over a considerable part of the LOD cloud.

CCS CONCEPTS

• **Information systems → Web search engines**; **Information retrieval**; *Resource Description Framework (RDF).*

1 INTRODUCTION

In the last decade, some new datasets adhering to Semantic Web standards were published on the Web. This growth can be seen by looking at the Linked Open Data Cloud[1] (LOD cloud), which collects datasets that have been published using Semantic Web Technologies. Though in 2007, the LOD cloud contained 12 datasets, it now contains 1,231[2] datasets. The LOD cloud does not only contain a lot of datasets, but at the same time some of these datasets are very large. A dump of the LOD cloud called LOD-a-lot[3] contains around 5 TB of structured data in uncompressed N-triples format. While Semantic Web standards are designed to make data to be machine comprehensible, they do not allow, at the same time, easy accessibility of the data to non experts and in particular to end-users. Question Answering (QA) is seen as the technology that can allow to bridge this gap between Semantic Web data and end-users. While the industry presents QA solutions on their proprietary Knowledge Base (such as Google and Baidu), no system reached a point which allows querying a substantial part of the LOD cloud.
Table 1 shows a list of QA systems which we are aware of, that are available online and query part of the LOD cloud. We indicate the datasets which they are able to query and the languages which are supported. For a general list and an overview of QA systems over KB, we refer to [4]. QAnswer represents a breakthrough since it allows to query many more datasets, at the same time, in real-time and in many more languages. The main algorithm behind QAnswer is described in [3]. In the following text, we show how the algorithm in [3] was implemented to create a first prototype of a QA System over the Semantic Web and which are the improvements over previous works.

2 DESCRIPTION

The algorithm behind QAnswer is described in [3]. It was shown that it has the following distinctive features:

- **Multilingual**, it supports multiple languages. In the previous work, it was shown that the algorithm works for English, German, French, Italian, Spanish, Portuguese. Moreover, the algorithm can easily be adapted to new languages.
- **Robust**, users ask questions using keywords, natural language questions and even malformed questions, i.e., syntactically wrong questions. The algorithm is robust enough to deal with all these scenarios, but not to spelling mistakes.

Table 1: List of Question Answering systems that query part of the LOD cloud and that are available online.

- **Real-time**, the algorithm can answer questions in real-time, i.e., on existing benchmarks like QALD and SimpleQuestions an average run-time of 2 seconds per query is realistic.
- **Low hardware footprint**, the algorithm uses specific indexes that guarantee low disk and memory footprint. Our demo will show that QAnswer can query 700Gb of n-triples and can be run on a (standard) laptop having 4 cores and 16 Gb of RAM.
- **Portable**, making question answering over a new dataset can be difficult. Some approaches need a lot of training data, other are not designed to be portable at all. Our system is designed such that any new dataset can be used as a base for a new QA system.
- **Multi-Knowledge-base**, the algorithm allows to query multiple Knowledge-bases at the same time.
- **Precision and Recall**, the algorithm was tested on multiple benchmarks and can compete with most of the existing approaches [3].

We are using the algorithm described in [3] to query what we believe are the three more significant datasets in the LOD cloud for end-users: Wikidata, LinkedGeoData and MusicBrainz. While, DBpedia and Freebase can also be queried, we consider these datasets as outdated since both are not maintained anymore.

We now describe the improvements over previous works brought by QAnswer.

- Non-european languages: While it was shown that the algorithm in [3] can be used to answer questions in multiple languages, it was only tested over European languages. Recently, we could also successfully apply it to two non-european languages, namely Chinese and Arabic. Example requests that can now be addressed are:

Figure 1: Screenshot of QAnswer for فيلم ذيب.

  - زوجه باراك اوباما, i.e., asking for the wife of Obama in Arabic.
  - "巴黎的博物馆", i.e., searching in Chinese for the museums in Paris.

  A screenshot of an example can be seen in Figure 1.

- LinkedGeoData: One of the largest open databases for geographical information is OpenStreetMap (OSM). It collects geographical information thanks to more than 2 million registered users. It contains information about streets, buildings, points of interest (like shops, restaurants, museums, fountains), cities, regions and many more. The data is natively stored in a PostgreSQL database with PostGIS extension. LinkedGeoData is the RDF extract of OSM data. The last public extraction was performed in 2015. We extracted a new export, covering entire Europe, and made the dataset queriable by QAnswer. Note that there is no online demo querying geo-spatial data and we are aware of only one work tackling this problem, which is presented in [7]. Some example requests that can be answered using this dataset are:
  - "Steinwenden", i.e. searching for a city
  - "Worms Renzstraße", i.e. searching for a street in a city
  - "give me fountains in Saarbrücken", i.e. searching for a point of interest in a city

  A screenshot of an example can be seen in Figure 2.

- Lexemes: In the previous work, the algorithm presented in [3] was used to query Wikidata. When Wikidata was new, it contained only Q-items, i.e., resources describing a thing or an idea, but not the word describing it. Since 2018, Wikidata was extended to also store new information such as words, phrases and sentences, in many languages. This information is stored in new types of entities, called Lexemes (L), Forms

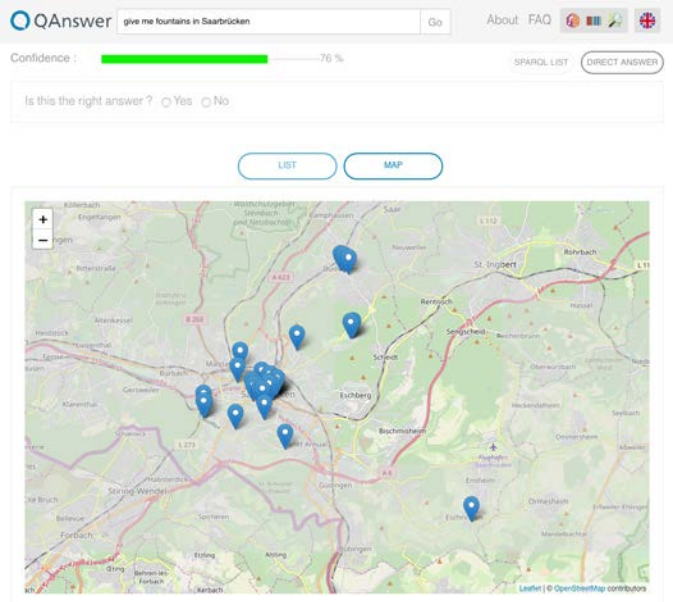

Figure 2: Screen shot of QAnswer for "give me fountains in Saarbrücken"

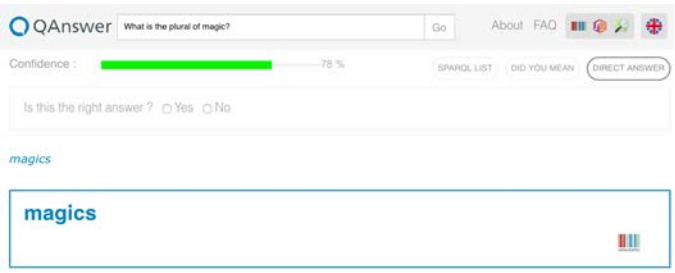

Figure 3: Screen shot of QAnswer for "What is the plural of magic?"

(F) and Senses (S). The Lexeme extension can be seen as a structured representation of the Wiktionary[4]. There exists an earlier attempt to semantify wiktionary by DBpedia project[5]. This project is unfortunately not maintained anymore and the extraction framework does not work anymore due to changes in the structure of Wiktionary. While the Lexemes in Wikidata still represent a small portion of the information contained in Wiktionary, we believe that the active Wikidata community will be able to fill this gap. Example questions that can be answered using this data are:

- "what is the pronunciation of magic?", i.e. searching for the pronunciation of a word
- "What is the plural of magic?", i.e., searching for forms of a word

A screenshot of an example can be seen in Figure 3.

[4]https://www.wiktionary.org
[5]https://wiki.dbpedia.org/wiktionary-rdf-extraction

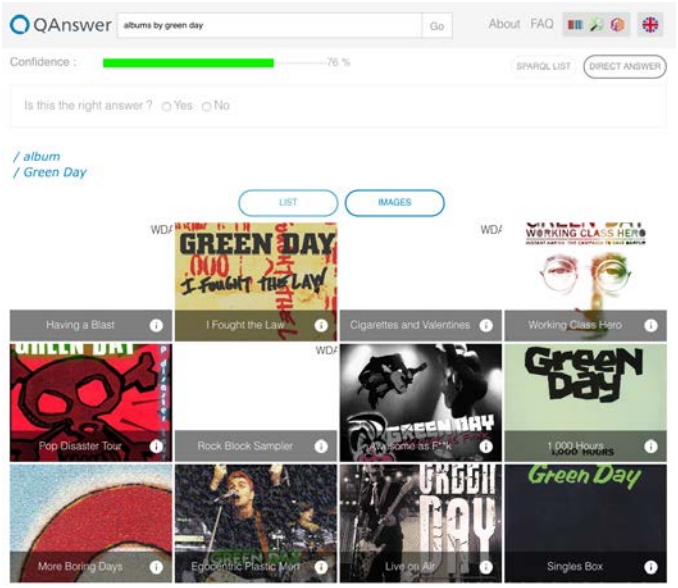

Figure 4: Screen shot of QAnswer for "albums by Green Day"

- Musicbrainz: Musicbrainz is one of the largest music databases that is open and available online. The data is natively stored in a relational database (i.e. a PostgreSQL database). In previous work, it was already possible to query MusicBrainz, but it relied on the dump provided by the following RML mappings: https://github.com/LinkedBrainz/MusicBrainz-R2RML. We improved the mappings in different ways. The most radical change was related to how some information is organized. For example in the original LinkedBrainz dump every album appears multiple times (every time for each publication year and country where it was released). The same problem appears for songs. In particular the dump didn't allow to recognize that the different publications of the albums and songs were in fact referring to the same album and song. This means that when asking for albums or songs, many duplicates appeared, a behaviour that is not expected by users and also not explicable for them. We therefore restructured the export to avoid this. Other changes represent a better coverage to external links like to Wikipedia, Wikidata and Social Media. Moreover, the dump is enriched with the links to the covers of albums from http://coverartarchive.org. Finally, we enriched the artists, albums and songs with links to youtube so that users can effectively hear the pieces they are querying. Example requests where Musicbrainz is used to answer some queries are:
  - "albums by green day", i.e., searching for albums of a band
  - "record label from turin", i.e. searching for record labels in a city,
  - "songs blink-182", i.e., searching for songs of a band

  A screenshot of an example can be seen in Figure 4.

- Qwant: While the Semantic Web grew very fast in the last years, it contains only a fraction of the information contained

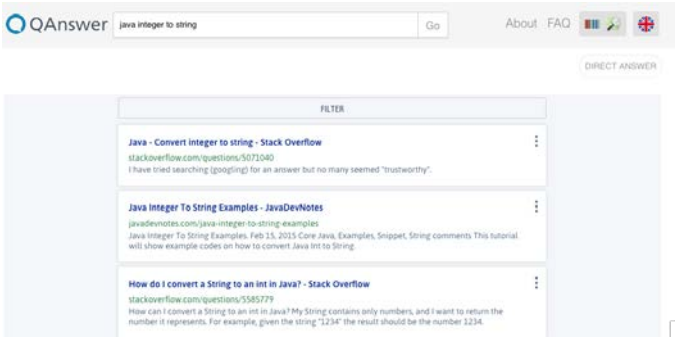

Figure 5: Screen shot of QAnswer for "java integer to string"

in the web. Whereas, most of the information is stored in a non-structured format, i.e., in the form of HTML pages. This information is typically accessed with traditional information retrieval techniques [6].

We therefore integrated, a fall back option, which is a traditional search engine, namely Qwant[6]. This means that when we cannot find the information requested by the users in one of the underlying datasets, we search for an answer using Qwant. Note that this represents a new problem in the area of QA over Knowledge Bases. Current benchmarks only contain questions whose answer can be found in the underlying knowledge base. There are a few exceptions in the QALD benchmark where less than 1% of the questions are not answerable. However, in a real scenario many of the questions asked by an end-user are not contained in the underlying Knowledge-Base. This means that recognizing when a question should not be answered (because it is not answerable considering the underlying knowledge-base) is an important and not well studied problem. Technically speaking this comes down to the fact that in current benchmarks only the macro F-measure is evaluated and the micro F-measure is generally ignored.

We chose Qwant as a fall-back option since it does not rely on a Knowledge Graph to provide direct answers. Moreover, the main distinctive feature as compared to other existing search engines is that Qwant does not track users and does not personalize search results and therefore users are not trapped in a filter bubble. Example requests where Qwant is used as a fall-back are:

- "How many legs has a horse?"
- "With how many degrees should I cook a pizza?"
- "java integer to string"

A screenshot of an example can be seen in Figure 5.

3 DEMO

A demo of the current version can be found under:

http://qanswer.eu/qa

Moreover, by clicking on the above examples you will be redirected to the online demo.

4 CONCLUSION

We presented QAnswer a QA system which queries 3 key Semantic Web datasets at the same time, namely, Wikidata with lexemes, LinkedGeoData and Musicbrainz. These datasets contain a huge amount of information like books, films, persons, music, streets, points of interest and many more. The data can be queried using natural language in 8 different languages, namely English, German, French, Italian, Spanish, Pourtuguese, Arabic and Chinese. In particular two non-European languages, Arabic and Chinese, are included. All together this represents a first prototype of a QA system querying a considerable part of the Semantic Web.

This represents also a step towards new challenges in this area like: correctly selecting which Knowledge Base to query, new scalability scenarios, making use of links between the datasets to deal with redundant information, studying the impact of the dataset quality on the QA performance, and studying the problem of not answering a question.

In future, we would like to make the algorithm and infrastructure publicly available via web APIs so that new RDF datasets can be indexed and accessed using natural language. We believe that this work will further boost the publication of RDF data and therefore the expansion of the Semantic Web.

ABSTRACT

We describe Voyageur, which is an application of experiential search to the domain of travel. Unlike traditional search engines for online services, experiential search focuses on the experiential aspects of the service under consideration. In particular, Voyageur needs to handle queries for subjective aspects of the service (e.g., quiet hotel, friendly staff) and combine these with objective attributes, such as price and location. Voyageur also highlights interesting facts and tips about the services the user is considering to provide them with further insights into their choices.

CCS CONCEPTS

• **Information systems** → **Search interfaces**; **Structured text search**; *Information retrieval*; • **Computing methodologies** → **Information extraction**; *Natural language processing*.

1 INTRODUCTION

The rise of e-commerce enables us to plan many of our future experiences with online search engines. For example, sites for searching hotels, flights, restaurants, attractions or jobs bring a wealth of information to our fingertips, thereby giving us the ability to plan our vacations, restaurant gatherings, or future career moves. Unfortunately, current search engines completely ignore any experiential aspect of the plans they are helping you create. Instead, they are primarily database-backed interfaces that focus on searching based on objective attributes of services, such as price range, location, or cuisine.

The need for experiential search. An experiential search engine is based on the observation that at a fundamental level, users seek to satisfy an experiential need. For example, a restaurant search is meant to fulfill a social purpose, be it romantic, work-related or a reunion with rowdy friends from college. A vacation trip plan is meant to accomplish a family or couple need such as a relaxing location with easy access to fun activities and highlights of local cuisine. To satisfy these needs effectively, the user should be able to search on experiential attributes, such as whether a hotel is romantic or has clean rooms, or whether a restaurant has a good view of the sunset or has a quiet ambience.

Table 1 shows a snippet from a preliminary study that investigates which attributes users care about. We asked human workers on Amazon Mechanical Turk [1] to provide the most important criteria in making their decisions in 7 common verticals. We then conservatively judge whether each criterion is an experiential one or not. As the table shows, the majority of attributes of interest are experiential.

To the best of our knowledge, online services for these domains today lack support for directly searching over experiential attributes. The gap between a users' experiential needs and search

Table 1: Experiential attributes in different domains.

Domain	%Exp. Attr	Some examples
Hotel	69.0%	cleanliness, food, comfortable
Restaurant	64.3%	food, ambiance, variety, service
Vacation	82.6%	weather, safety, culture, nightlife
College	77.4%	dorm quality, faculty, diversity
Home	68.8%	space, good schools, quiet, safe
Career	65.8%	work-life balance, colleagues, culture
Car	56.0%	comfortable, safety, reliability

capabilities raises an important challenge: *can we build search systems that place the experience the user is planning at the center of the search process?*

Challenges. Supporting search on experiential aspects of services is challenging for several reasons. First, the universe of experiential attributes is vast, their precise meaning is often vague, and they are expressed in text using many linguistic variations. The experience of "quiet hotel rooms" can be described simply as "quiet room" or "we enjoyed the peaceful nights" in hotel reviews. Second, by definition, experiential attributes of a service are *subjective* and personal, and database systems do not gracefully handle such data. Third, the experiential aspect of a service may depend on how they relate to other services. For example, a significant component of a hotel experience is whether it is close to the main destinations the user plans to visit. Finally, unlike objective attributes that can be faithfully provided by the service owner, users expect that the data for experiential attributes come from other customers. Currently, such data is expressed in text in online reviews and in social media. Booking sites have made significant efforts to aggregate and surface comments from reviews. Still, while these comments are visible when a user inspects a particular hotel or restaurant, users still cannot search by these attributes.

This paper describes Voyageur, the first search engine that explicitly models experiential attributes of services and supports searching them. We chose to build Voyageur in the domain of travel because it is complex and highly experiential, but its ideas also apply to other verticals.

The first idea underlying Voyageur is that the experiential aspects of the service under consideration need to be part of the database model and visible to the user. For example, when we model a hotel, we'll also consider the time it takes to get there from the airport and nearby activities that can be done before check-in in case of an early arrival. Furthermore, Voyageur will fuse information about multiple services. So the proximity of the hotel from the attractions of interest to the user is part of how the system models a hotel. Of course, while many of the common experiential aspects can be anticipated in advance, it is impractical that we can cover them all. Hence, the second main idea in Voyageur is that its schema should be easily extensible, it should be able to handle imprecise queries, and be able to fall back on unstructured data when its database model is insufficient.

Even with the above two principles, Voyageur still faces the challenge of selecting which information to show to the user about a particular entity (e.g., hotel or attraction). Ideally, Voyageur should display to the user aspects of the entity that are most relevant to the decision she is trying to make. Voyageur includes algorithms for discovering items from reviews that best summarize an entity, highlight the most unique things about them, and useful actionable tips.

2 OVERVIEW OF VOYAGEUR

We illustrate the main ideas of Voyageur. Specifically, we show how Voyageur supports experiential queries and how these queries assist a user in selecting a hotel.

User scenario. Elle Rios is a marketing executive living in Tokyo. She is planning a vacation to *San Francisco* in early October. Her goal is to have a relaxing experience during the vacation. Her entire travel experience will be influenced by a variety of services, including flights, hotels, local attractions, and restaurants. Elle visits the Voyageur website and first enters the destination with the travel period. Voyageur then displays a series of screens with recommendations for each of these services.

In searching for hotels, Elle's experiential goal to have a relaxing stay is achieved by a balance of her *objective* constraints (her budget for hotels is *$250-350 per night*) and *subjective* criteria; she is an introvert and she knows that *quiet* hotels with *friendly staff* will help her relax[1]. In addition, Elle also cares about whether the hotel is conveniently located for reaching the famous and historic attractions she wants to visit and the high-quality vegetarian restaurants she is interested in.

Figure 1 shows a screenshot of Voyageur, where Elle can plan a trip that satisfies her requirements. (The screens for attraction and restaurant search are similar). The screenshot shows how Voyageur emphasizes the experiential aspects of trip planning. First, Voyageur allows users to express their subjective criteria (in addition to their objective criteria) and generates recommendations accordingly through the *experiential search* function (Box A). Second, Voyageur tailors the display of *interesting facts and tips* and *summary of reviews* based on the search criteria entered (Boxes B and C). Third, Voyageur supports a series of additional features, such as map view and travel wallet, to further improve the user's experience in the hotel search (Box D). The map view provides a holistic view of the trip by putting together all recommended entities of different types. The travel wallet, as we explain later, takes into consideration the user's travel history and preferences if the user chooses to share them with Voyageur.

Experiential search. Elle expresses her objective and experiential/subjective criteria as query predicates to Voyageur's interface. While the objective requirements like "$250 to 300 per night" can be directly modeled and queried in a typical hotel database, answering predicates like *"quiet"* and *"friendly staff"* is challenging as these are subjective terms and cannot be immediately modeled in a traditional database system. Voyageur addresses this challenge with a subjective database engine that explicitly models the subjective attributes and answers subjective query predicates. Voyageur extracts subjective attributes such as *room quietness* and *staff quality* from hotel customer reviews, builds a summary of the variations of these terms, and then matches those attributes with the input query predicates.

[1]Elle can also directly search for hotels with relaxing atmosphere in Voyageur.

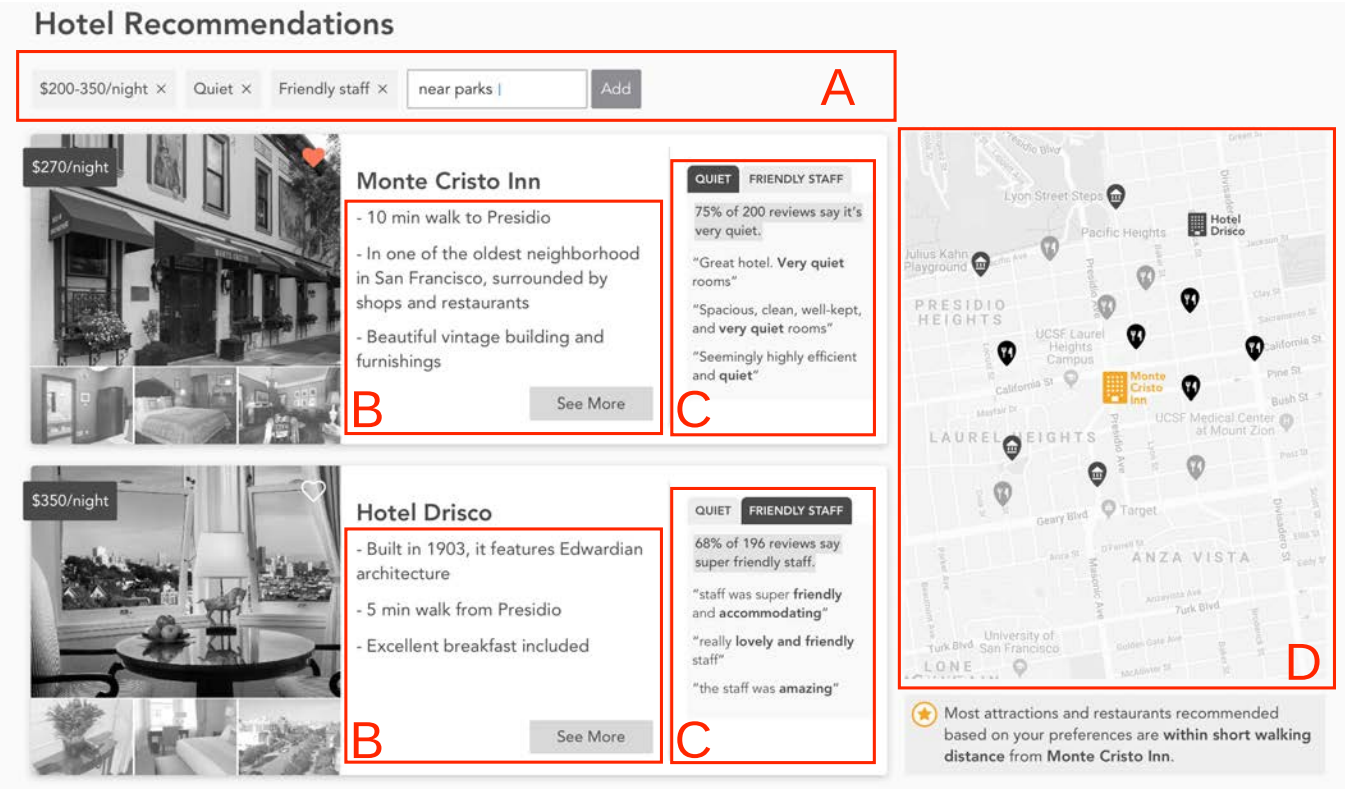

Figure 1: A screenshot of the hotel recommendation screen of Voyageur. The user can interactively customize the search (Box A), to view interesting facts/tips (Box B) and a *review summary* (Box C) of each recommended hotel and to check out a *map view* (Box D) of the recommendations.

In Figure 1, Voyageur generates a ranked list of hotels by matching the query predicates specified by Elle with the subjective attributes extracted from the underlying hotel reviews. The review summaries (Box C) show that the selected hotels are clearly good matches. Specifically, Voyageur recommends Monte Cristo since 75% of 200 reviewers agree that it is very quiet and it has friendly staff (not shown). Hotel Drisco, next on the list, is recommended because 68% of 196 reviewers agree that it has friendly staff and the it is also very quiet (not shown).

Interesting facts and tips. Along with the search results, Voyageur shows snippets of travel tips and/or interesting facts of each result (Box B) it thinks is relevant for Elle. An interesting fact typically highlights an unusual or unique experience about the service. For example, being very close to Presidio Park (one of the largest parks in San Francisco) is unique to Monte Cristo Inn and Hotel Drisco and is thus an interesting fact to show for each hotel. The fact that Monte Cristo Inn is a "beautiful vintage building and furnishings" is unique only to Monte Cristo Inn. Such interesting facts can be important for decision making. It also enables Elle to better anticipate the type of experiences that will be encountered at the hotel [8]. On the other hand, tips are snippets of information that propose a potential action the user may take to either avoid a negative experience or create a positive one [2]. For example, a useful tip for a hotel may be that there is free parking two blocks away.

While the interesting facts and tips are useful, they are not always available for every service and can be incomplete. Existing work [2, 6] proposed mining useful travel tips from customer reviews with promising results. In Voyageur, we formulate the problem of finding tips and interesting facts as a query-sentence matching problem to find tips and interesting facts relevant to the users' query. Our algorithms prefer to select sentence snippets from reviews to match the user's query. The challenge we face is that users' query predicates and the tips/facts in reviews are described in different vocabularies and linguistic forms. Moreover, labeled data for the matching task is generally not available. Thus, novel techniques are needed to construct good matching functions between queries and sentence snippets.

Review summarization. The summary of reviews (Box C) provides Elle with an explanation of why the specific hotel is recommended and the summary saves her from reading the repetitive and lengthy reviews. Voyageur summarizes the reviews of each recommended hotel in two different formats: (1) statistical statements and (2) sample review snippets. For example, in Figure 1, Voyageur summarizes the room quietness attribute of Monte Cristo Inn with the statistical statement "75% of 200 reviews say it is very quiet" and 3 randomly selected sample review snippets that match the *quiet* requirement.

Additional features. The following features further improve Elle's ability to create a positive travel experience:

- **Map view.** In each recommendation screen, a map view (Box D of Figure 1) marks the locations of the recommended

hotels. Whenever a hotel is selected, the map view is centered at a chosen hotel and shows the recommended local attractions and restaurants so the user can better plan how to travel between these places.

- **Travel wallet.** Users have the option of creating a *travel wallet*, which is similar to the Wallet feature on many smartphones. It contains information about the user that she shares only when she chooses to. In the case of a travel wallet, this information records her travel preferences. The travel wallet can be created explicitly by answering questions or can be collected automatically from previous travels. The travel wallet is used by Voyageur to further personalize the search results.
- **Trip summary.** Finally, after making several choices (flight, hotel, attractions, etc.) through all the recommendation screens, the user can view a summary of the trip underlying the key experiential components. In Elle's case, the summary includes a timeline with important dates, transportation methods to/from the airport, and tips/facts about the chosen hotel and each planned tourist attractions.

3 IMPLEMENTATION OF VOYAGEUR

We briefly touch upon the technology underlying Voyageur.

3.1 A subjective database engine

As mentioned, the main challenge of building a successful experiential search engine is the modeling and querying of the *subjective attributes*, where there is typically no ground truth to the values of such attributes. Examples of such attributes include the cleanliness of hotel rooms, quality of the food served, and cultural value of tourist attractions. They are not explicitly modeled in today's search engines and therefore not directly queryable.

Voyageur is developed on top of OpineDB [3], a *subjective database engine*. OpineDB goes beyond traditional database engines by supporting the modeling, extraction, aggregating, and effective query processing of the subjective data. Next, we illustrate the key design elements of OpineDB by showcasing its application to hotel search in Voyageur.

Data model, extraction, and aggregation. The main challenge in modeling subjective attributes is the wide range of linguistic variations with which the attributes are described in text. Consider an attribute `room_quietness` of hotels. The review text can be of various forms such as (1) "*the neighborhood seems very quiet at night*", (2) "*on busy street with traffic noise*", or (3) "*quiet and peaceful location*". In addition, OpineDB needs to *aggregate* these phrases into a meaningful signal for answering queries, which may themselves include new linguistic variations.

OpineDB models subjective attributes with a new data type called the *linguistic domain* and provides an aggregated view of the linguistic domain through a *marker summary*. The linguistic domain of an attribute contains all phrases for describing the attribute from the reviews. E.g., "quiet at night", "traffic noise", and "peaceful location". A subset of phrases is then chosen as the *domain markers* (or *markers* for short) for each linguistic domain. The phrases are aggregated based on the markers to constitute the marker summary.

For quietness, the markers might be [very_quiet, average, noisy, very_noisy]. To construct the marker summary of a hotel's quietness, OpineDB needs to assign each quietness phrase to its closest marker and compute the frequencies of the markers. For example, the summary [very_quiet:20, average: 70, noisy:30, very_noisy:10] for a hotel would represent that the hotel is closer to being `average` in quietness than to the other markers.

The linguistic domain is obtained by extracting phrases from reviews. Various techniques are available for this task in opinion mining and sentiment analysis [4, 7]. The marker summaries are currently histograms computed from the extraction relations. However, we can also leverage more complex aggregate functions.

Query processing. The query predicates from Box A is formulated as an SQL-like query for OpineDB to process.

```
select  *  from Hotels h
where   price_pn ≤ 350 and price_pn ≥ 200 and
        "quiet" and "friendly staff"
```

Here, price_pn is an objective attribute of the Hotels relation while "*quiet*" and "*friendly staff*" are subjective predicates. OpineDB needs to interpret these predicates using the linguistic domains in order to find the best subjective attributes of the Hotels relation that can be used to answer them. In general, this is not a trivial matching problem since the query terms may not be directly modeled in the schema. For example, the user may ask for "romantic hotels", but the attribute for romance might not be in the schema. For such cases, OpineDB leverages a combination of NLP and IR techniques to find a best-effort reformulation of the query term into a combination of schema attributes. For example, for "romantic hotels", OpineDB will match it to a combination of "exceptional service" and "luxurious bathrooms" which are modeled by the schema.

After computing the interpretation, OpineDB uses the marker summaries to compute a *membership score* for each pair of hotel and query predicate. Finally, OpineDB combines multiple predicates using a variant of fuzzy logic.

3.2 Mining interesting facts and tips

We formulate the problem of finding useful travel tips and interesting facts as a query-sentence matching problem. We adopt an approach similar to an existing work for mining travel tips from reviews [2]. The approach consists of a *filtering phase* and a *ranking phase*.

Filtering phase. This phase constructs a set of candidate tip/fact sentences by applying filters and classifiers to all the review sentences. According to [2], effective filters for tips include phrase patterns (e.g, sentences containing "make sure to") and part-of-speech tags (e.g, sentences starting with verbs). For constructing the candidate set of interesting facts, we select sentences that contain a least one *informative token*, which are words or short phrases frequently mentioned in reviews of the target entity but not frequently mentioned in reviews of similar entities. We also found that an interesting fact is more likely to appear in sentences with an extreme sentiment (very positive or negative). So we also apply sentiment analysis to select such sentences. For both tips and interesting facts, we further refine the candidate sets by removing duplicates, i.e., sentences of similar meaning or the unimportant

ones. We do so by applying TextRank [5], a classic algorithm for sentence summarization.

Ranking phase. Instead of simply selecting candidates for interesting facts/tips, sets, we implemented a novel ranking function for finding candidates that best match the user's query predicates. The ranking function considers not only the *significance* of a candidate as computed in the filtering phase but also the *relevance* of the candidate with the query. Measuring the relevance is not trivial since the tips/interesting facts can use vocabularies different from the ones used in the query. In the previous example, a fact that matches the query "near park" is "10 min walk to Presidio" which has no exact-matched word. The similarity function leverages a combination of NLP and IR techniques, analogous to query interpretation in OpineDB.

3.3 Datasets and tools

The Voyageur demo will serve hotels, attractions, and restaurants search in the San Francisco area in a browser-based web app. We collected the underlying data from two datasets: the Google Local Reviews[2] and the TripAdvisor datasets[3]. Our dataset consists of 18,500 reviews of 227 hotels, 6,256 reviews of 545 attractions and 67,382 reviews of 4,007 restaurants. We implemented the front end of Voyageur using the JavaScript library React.

4 CONCLUSION

The motivation for Voyageur is based on the discrepancy between the needs of users searching for services and the current state of search engines. The ideas of Voyageur are applicable to many other verticals beyond travel. At the core of the technical challenges that Voyageur and systems like it need to address is the ability to discover and aggregate evidence from textual reviews in response to user queries. This is a technical challenge that draws upon techniques from NLP, IR and Database technologies.

ABSTRACT

In order to accurately populate and curate Knowledge Graphs (KGs), it is important to distinguish $\langle s\ p\ o\rangle$ facts that can be traced back to sources from facts that cannot be verified. Manually validating each fact is time-consuming. Prior work on automating this task relied on numerical confidence scores which might not be easily interpreted. To overcome this limitation, we present Tracy, a novel tool that generates human-comprehensible explanations for candidate facts. Our tool relies on background knowledge in the form of rules to rewrite the fact in question into other easier-to-spot facts. These rewritings are then used to reason over the candidate fact creating semantic traces that can aid KG curators. The goal of our demonstration is to illustrate the main features of our system and to show how the semantic traces can be computed over both text and knowledge graphs with a simple and intuitive user interface.

1 INTRODUCTION

Motivation and Problem. Knowledge Graphs (KGs) are repositories of factual knowledge in the form of $\langle s\ p\ o\rangle$ facts where s, o are entities and p specifies a semantic relation between them, e.g., $\langle$*London capitalOf UK*$\rangle$. Currently, a large number of KGs are publicly available on the Web (e.g., Wikidata [16], YAGO [15]) but some of them might contain doubtful if not incorrect facts as they are partly built by automatic information extraction, crowd-sourcing, or other noisy methods [12, 18]. Due to the increasing usage of KGs for tasks like query-answering, dialog systems, etc., it is important to validate each candidate fact to ensure the correctness of the KG.

This paper is published under the Creative Commons Attribution 4.0 International (CC-BY 4.0) license. Authors reserve their rights to disseminate the work on their personal and corporate Web sites with the appropriate attribution.

This task, which is often referred to as *fact-checking* or *truth discovery* [8], can be performed manually by KG curators but this is time-consuming. Therefore, the automation of this process is gaining more attention. Existing methods for automatic fact-checking (e.g., [5, 8, 9, 11, 13]) usually proceed in two steps as follows: First, they search for explicit mentions of the fact in the Web sources like news or other textual corpora. For example, for a fact such as $\langle$*Sadiq_Khan citizenOf UK*$\rangle$, they search for *"khan is a citizen of UK"* or *"Khan's nationality is British"*. Then, the extracted evidence is used to infer whether the candidate fact can indeed be verified.

Existing approaches have two main limitations: First, they quantify the confidence using numerical scores, which is not adequate in case the final decision is made by KG curators. Indeed, such scores are hard to understand or justify without explanations. Only few approaches (*e.g.*, [1, 5]) attempt to explain the results. For example, Defacto [5] shows the sources used in computing the scores as an explanation and [1] reports a comparison between computed scores to explain its final decision for humans. Second, searching for explicit mentions is often not sufficient since textual sources are *incomplete* and *biased* in what is stated explicitly. For instance, the citizenship of London's mayor Sadiq Khan would rarely be mentioned. Moreover, some predicates (*e.g.*, *influencedBy*) are ambiguous and their interpretation is domain-specific.

Proposed Approach. We introduce Tracy, a tool designed to support KG curators in deciding the correctness of the candidate facts. The main novelty of our tool consists of finding *semantically related evidence* in textual sources and the underlying KG, and providing *human-comprehensible explanations* for the facts. In Tracy, the semantically related evidence is extracted according to intentional background knowledge given as rules of the form $H \leftarrow B_1, B_2, \ldots, B_n$ which can be either specified by humans or automatically extracted using rule mining methods [14] By utilizing rules, Tracy enables users to combine clues from different resources (structured and unstructured) thus overcoming the problem that arises when the fact is never explicitly mentioned. For example, consider the rule

$$citizenOf(X, Y) \leftarrow mayorOf(X, Z), locatedIn(Z, Y)$$

which intuitively states that mayors of cities are normally citizens of countries where these cities are located. This rule can be used by our tool to verify the fact $\langle$*Sadiq_Khan citizenOf UK*$\rangle$ by searching in news articles whether he is a major of some city and then looking up the city's corresponding country in the KG. The combination

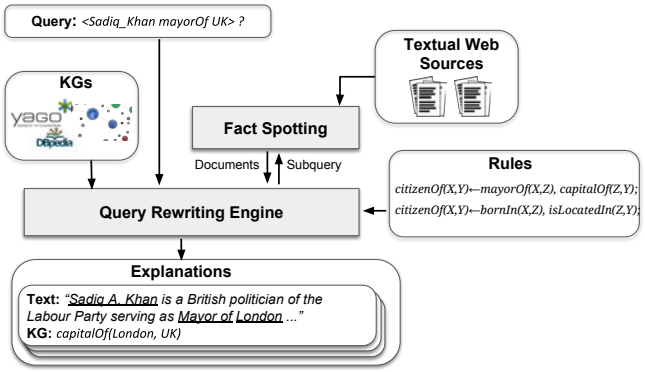

Figure 1: Tracy system overview.

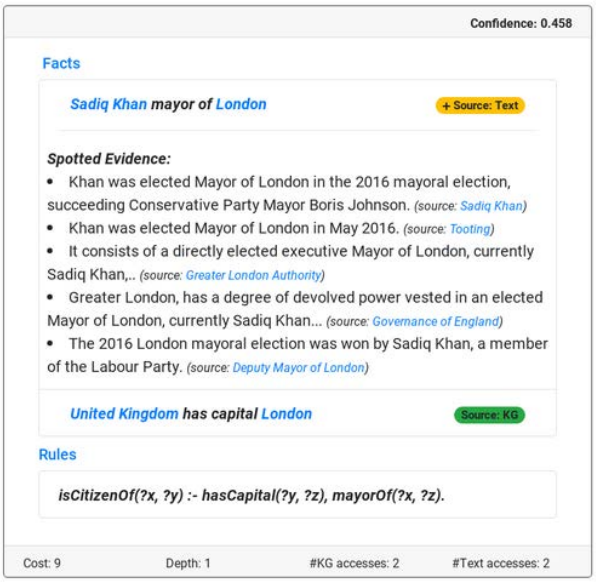

Figure 2: Example explanation returned by Tracy.

of these two semantically-related facts allows us to construct a human-readable explanation for the correctness of the fact.

As illustrated by the above example, Tracy uses the rules to decompose the spotting of an input fact into more frequently stated and thus easier-to-spot related facts. The search for evidence for the rule's body might trigger the execution of other rules, and this effectively creates semantic traces that *explain*, in a human-readable format, why a fact is likely to be true. These traces are presented to a KG curator in a comprehensible format in order to make a final decision about the truth value of the fact in question.

Outline. In the remaining, we briefly describe the framework underlying Tracy and the realization of the main components. Afterwards, we illustrate the features offered by the demonstrated graphical user interface, allowing users to experience different usage scenarios. Our demo is made available under the following link https://www.mpi-inf.mpg.de/impact/exfakt#Tracy.

2 SYSTEM OVERVIEW

Tracy follows ExFaKT framework introduced in our earlier work [3]. Tracy implements two main components: (i) *Query Rewriting Engine (QRE)*, which is responsible for rewriting facts and generating explanations, and (ii) *Fact Spotting (FS)*, which is the component that finds evidences in Web sources. Fig. 1 shows a graphical representation of this architecture.

Our framework receives as input a candidate fact (*i.e.*, the query), a set of rules, and two knowledge sources: (i) a KG, which we view as a *reliable* source; and (ii) an unstructured collection of text corpora, which we consider as an *unreliable* source, since its extractions by *FS* might be noisy.

Rules are Horn clauses of the form of $H \leftarrow B_1, \ldots, B_n$ where H is the rule's head and $B_1, \ldots, B_n$ is the body of the rule. In general, rules can be automatically extracted from KGs using systems such as [2, 4, 6, 17]. However, extracted rules are restricted to the predicates in the KG. Thus, Tracy also accepts manually specified rules with user-defined predicates, which later can be spotted in the text.

The workflow of our system is as follows: First, a user submits an input fact Q (*i.e.*, the query) to *QRE*. Then, this component possibly rewrites it into easier facts according to the logic specified by the rules contacting *FS* every time it cannot find evidences in the KG. If a sufficient number of evidences is found, then QRE uses them to return one or more explanations for Q.

2.1 Query Rewriting Engine

The process starts by considering rules, whose head predicates are the same as in the query. Then, it visits the rules' bodies and effectively rewrites the query into additional subqueries. The subqueries might trigger new rules and this results in a recursive process until all subqueries are answered. Such rule-based evaluation strategy is well-known in logic programming and commonly used for query answering. Indeed, our system implements an adaptation of a set-based version of standard SLD resolution [7].

Our adaption consists of three modifications which are crucial for our scenario of interest: First, we impose a maximum depth onto the recursive process to ensure termination. Second, the system attempts to answer the query consulting *FS* whenever it cannot be answered relying on the KG. Third, we care about the quality of the sources; and hence, we still rewrite the fact if the evidence source is not trustful seeking more reliable evidences. These two last modifications are particularly important: In fact, it is well-known that KGs are highly incomplete and a conventional query answering engine would simply fail when evidence is not found. In contrast, the ability of our system to also include extractions from additional sources overcomes this problem and enables the construction of explanations even when the content of the KG is not sufficient.

Once this process is finished, the answers (either from the KG or Web sources) are used to compute the explanations. This is done by revisiting the rules bottom-up. Fig. 2 shows an extract of an example explanation provided by Tracy. In this case, the explanation illustrates that the fact that *Sadiq Khan is a citizen of UK* is likely to be true according to the rule

$$isCitizenOf(X, Y) \leftarrow mayorOf(X, Z),\ hasCapital(Y, Z)$$

and additional evidence found both in the KG and textual corpora.

Note that a given query might have multiple complex explanations or a single *trivial* one, i.e., the fact itself. Moreover, some explanations may be subsumed by others. Ideally, we aim at computing non-trivial explanations that are (i) **concise** with a small number of atoms; (ii) **close to the query**, i.e., obtained by using few rules; (iii) **reliable**, i.e., contain as many facts from the KG as possible, since KGs are usually more reliable than text.

In order to recognize these explanations, we compute a confidence score for each explanation E, defined as:

$$confidence(E) = \frac{1}{|E|} \sum_{a \in E} \frac{trust(sources[a])}{depth[a]}$$

where a is the atom of the explanation E. This confidence score is directly correlated with the quality of the sources containing a ($trust(sources[a])$) and inversely correlated with the depth of the rewriting performed to reach the atom a (*i.e.*, the number of used rewriting rules) and the number of distinct atoms in the explanation.

2.2 Fact Spotting

Tracy follows a modular design allowing integrating any fact-spotting method. As default, we implemented a dictionary based fact-spotting procedure similar to [9, 13]. It is a simple and highly scalable method that does not require training. The main idea consists of first converting the SPO query into a textual representation (*i.e.*, verbalization) using a paraphrasing dictionary. Then, queries with the paraphrases are issued to a spotting engine to retrieve documents that mention them.

We used two types of dictionaries, depending on whether the used KG is YAGO or Wikidata (these are the only two which are currently supported). With YAGO, we use the paraphrases learned by PATTY [10] after some manual filtering. With Wikidata, we exploit the name aliases included in the KG.

We also implemented two types of spotting engines, one that uses a *local* text corpus and another one that consults a *remote* one:

- **Local corpus:** We used Elasticsearch [1] to index all Wikipedia articles. As a prepossessing step, we filtered the textual parts in the articles by removing semi-structured parts such as tables and info-boxes. Then, we index the article sentences separately along with the title. For spotting an SPO query, we issue a boolean query with the paraphrases of each part of the SPO separately. Then, we collect the *top-5* matching sentences as evidence for the query.
- **Remote corpus:** We also provide the option for searching the Web using Bing Web search API [2]. To query the API, we compose a string query containing all possible paraphrases of SPO and use the *top-5* search results as evidence.

2.3 Experimental Results

To illustrate the potential of our system, we report the results of an experiment using the YAGO KG. We simulated the case where we need to verify 300 unseen candidate facts, uniformly distributed over six different relations *influences*, *isPoliticianOf*, *wroteMusicFor*, *mayorOf*, *actedWith*, and *countryWonPrize*. A rule set was compiled for each predicate by selecting the top-ranked rules mined by AMIE [4] and adding other manually created rules involving new predicates that do not exist in YAGO.

Table 1: Direct fact-spotting vs Tracy explanations

	Textual Source	Recall	Prec@5	F1@5
Direct-spotting	Wikipedia	0.25	0.85	0.40
Tracy		0.50	0.87	0.64
Direct-spotting	Web Search	0.41	0.85	0.55
Tracy		0.90	0.97	0.93

Then, we used our system to extract explanations for the candidates over YAGO using either the Wikipedia articles (local fact-spotting) or Web search (remote fact-spotting). Later, we asked MTurk workers to judge the correctness of each candidate fact based on the provided explanations. Based on these annotations, we computed *recall*, *precision@5 (Prec@5)*, and F_1*@5* score.

Table 1 shows a comparison between the results of using Tracy against the baseline method which consists of using only *direct fact-spotting* (thus without any rewriting). We can observe that Tracy doubles the recall while slightly increasing the precision@5. This leads to significant enhancement in the F_1 score. These results are encouraging, as they show that our system is 1) indeed capable of finding additional evidence that might not be directly mentioned and that 2) the explanations are actually valuable for human annotators for judging the correctness of candidate facts. More detailed experimental results can be found in [3].

3 DEMONSTRATION

We built a Web interface to allow an easy interaction with the system. Fig. 3 shows a screenshot illustrating its main components.

System options. The left-hand side of Fig. 3 shows the *system options menu*, which is the part where the user can select from a predefined list of KGs and textual sources to work with. Moreover, the interface allows the user to tune the QRE procedure by specifying a *trust* value for each textual source and the limit on the number of used rules and output explanations.

Input. The top part in Fig. 3 contains the *input form* with three fields for the SPO *query* and a text area for the *rules*. In the *query* fields, the user can select the subject and the object of the fact in question from a set of KG entities and specify the predicate, which might be out of KG. In the *rules* text area, the user is expected to input the rules using the standard logic programming syntax. For example, a rule expressing that "*a person is a citizen of a country if he was born in one of its cities*" is written as:

$$isCitizenOf(?x, ?y) \text{ :- } bornIn(?x, ?z),\ isA(?z, \text{`}City\text{'}),\ in(?z, ?y)$$

where $?x, ?y, ?z$ are variables, '$City$' is a constant, *isCitizenOf* is a head predicate and the rest are body predicates. These rules can also involve out-of-KG predicates, which Tracy spots in the text.

Output. Below the rules text area, Tracy returns the list of explanations for the input fact. Each *explanation* card contains:

- A set of facts that support the correctness of the query;

[1] https://www.elastic.co/

[2] http://azure.microsoft.com/en-us/services/cognitive-services/bing-web-search-api

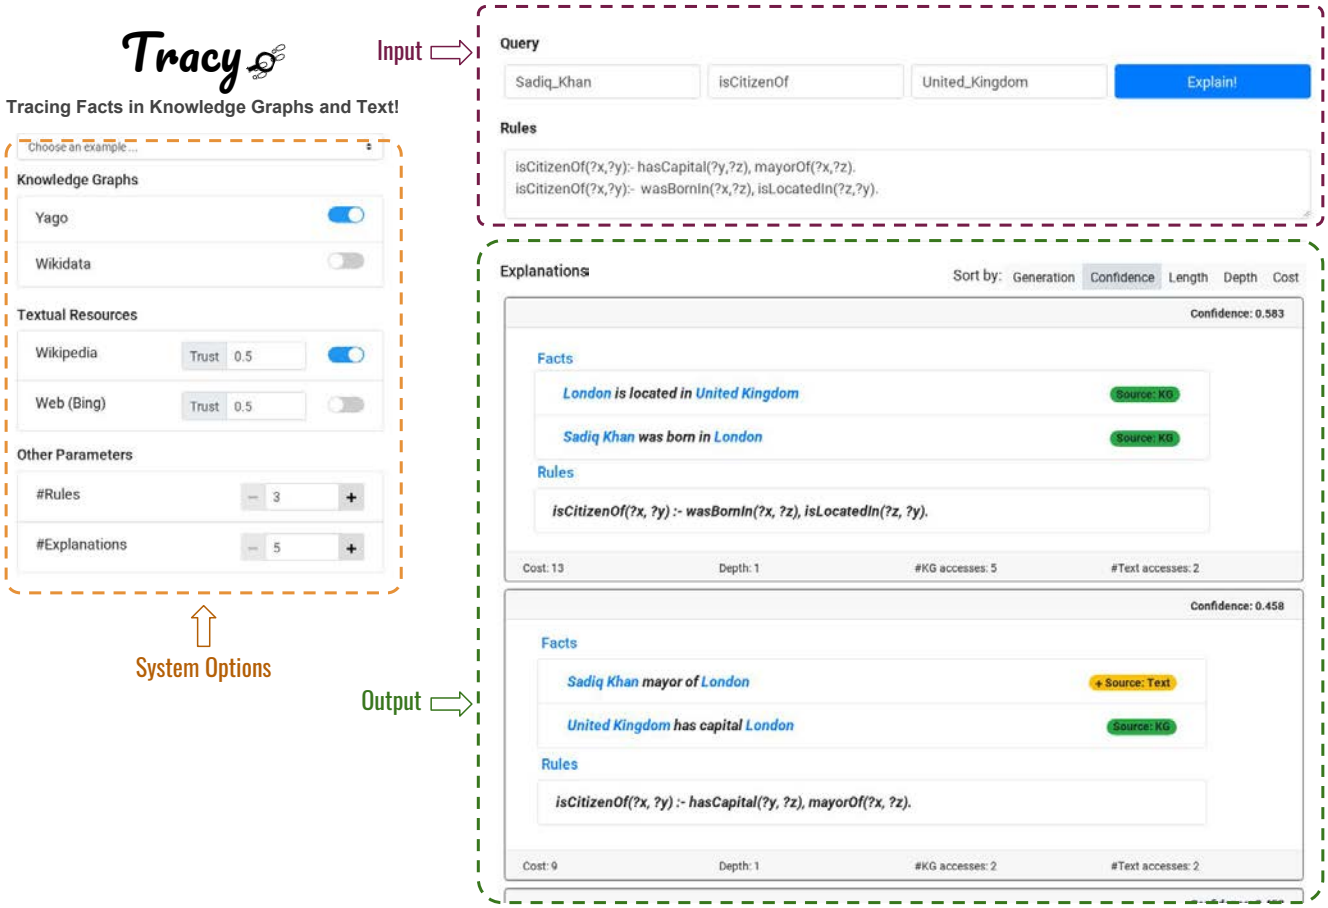

Figure 3: Tracy Web interface.

- In case the explanation includes facts with textual evidence, the user can view top-5 matching sentences with the links to the Web-pages where they have been found;
- The set of rules used by Tracy to find the evidence;
- Explanation confidence score computed as described in Section 2.1 and some execution insights (*e.g.*, resources accesses).

Explanations can be sorted based on their generation order, quality, length, rewriting depth, or cost.

During the demonstration session, We will showcase how Tracy can be used to extract non-trivial explanations for several hard to spot queries in different domains (*e.g.*, art, sport, and politicians). Users will have the chance to observe the results of changing the ruleset and other parameters to experience the performance of Tracy in different scenarios.

Users will also have the possibility to test Tracy with some arbitrary queries and/or other rule sets. We will encourage them to first try to collect related evidence manually before using Tracy with the same query. This illustrates how Tracy facilitates the discovery of related evidence required for judging the correctness of the query.

4 CONCLUSION

Our tool represents a first step towards producing more human understandable evidence for unverified facts. Tracy can help curators judging the correctness of new facts faster and more accurately. As future work, it is interesting to enhance our tool to support more complex rules, *e.g.*, with negations. Such rules are useful to represent additional background knowledge. Moreover, developing a more robust spotting engine that is capable of recognizing negative mentions of facts would allow more complex reasoning. Finally, we plan to further enhance the interface to make our system easier to use for KG curators.

ABSTRACT

How do learners schedule their online learning? This issue is concerned by both course instructors and researchers, especially in the context of self-paced online learning environment. Many indicators and methods have been proposed to understand and improve the time management of learning activities, however, there are few tools of visualizing, comparing and exploring the time management to gain intuitive understanding. In this demo, we introduce the **LearnExp**, an interactive visual analytic system designed to explore the temporal patterns of learning activities and explain the relationships between academic performance and these patterns. This system will help instructors to comparatively explore the distribution of learner activities from multiple aspects, and to visually explain the time management of different learner groups with the prediction of learning performance.

CCS CONCEPTS

1 INTRODUCTION

Accessing world class educational resources without geographical and social boundaries has become the daily behavior of online learners. With the advantages of learning anywhere and anytime, learners can schedule their learning at their own pace. However, this self-scheduled learning process also challenges their time management [1, 14]. In the less supervised online learning environment, the inappropriate scheduling of study time (e.g., absence, procrastination, etc.) may lead to reduced learning performance and even exam failures [16], which in turn would result in reduced completion rate and course rating [1]. Therefore, understanding the time management pattern of online learning activities has been an important issue for both learners and instructors.

With the support of learning management system (LMS), the detailed learning activities can be tracked via logs (e.g., viewing videos, reading materials, posting threads, etc.). Existing studies have proposed many indicators and models based on these logs to measure the time management features, such as the interval time between two tasks [1], the time that students spent on a certain task and LMS [4, 9], the remaining time between the deadlines [7], the aggregated daily activity count [14], etc. By using these indictors, recent studies examined the learners' behavioral patterns [12], self-regulated learning strategic [10, 11, 15], the influences on learning performance [16], visualization tools for supporting self-regulated learning [7], etc. These indicators and methods provide basis for measuring and improving the time management. In addition, many visualization tools have been developed to further investigate the patterns of student engagement, including SST [6], moocRP [13], DropoutSeer [3], PeakVisor [2] and iForum [5], etc.

Theses systems demonstrate the student engagement from different perspectives. However, the instructor has limited tools to customize student groups and explore each student's complete study history freely. To address this issue, we introduce the LearnerExp system for the instructor to explore the time management intuitively. First, we propose the activity vector to represent daily learning activities based on well-studied indicators and existing models. Moreover, we embed the activity vector in the calendar-like activity matrix to facilitate users understand the learning process intuitively. Second, we use grade point prediction model based on convolutional neural network to explain the relationships between learning performance and time management. Third and last, we develop a visual analytic system for course instructors to explore the temporal activity patterns of different learner groups. Main contributions of this work are summarized as follows.

- A learner activity model for describing and analyzing the time management in learning activities, which not only captures the temporal aspect of learning activities, but also supports visual exploration.
- A web-based interactive visual analytic system for exploring and explaining the time management of online learning activity based on the proposed learner activity model.

2 LEARNER ACTIVITY MODEL

In this section, we introduce the learner activity representation and the prediction model for analyzing the time management.

2.1 The Learner Activity Representation

In online courses, the time-stamped learner-generated events are recorded by the LMS and saved in log files on a daily basis to describe the learning activity of each day, which consist of event timestamp, learner identifier, course information, operation and other data recorded by JavaScript script embedded in the LMS. With these log files, we count the day activity of each learner based on well-studied indicators. As shown in Figure 1(a), the day activity is measured by a set of indicators, including daily interaction counts of learner-course, learner-learner and learner-system, video viewing time, session time [4, 8, 14] etc.

Based on the day activity, the history of whole activities in a semester can be represented as the activity vector (Figure 1(b)). In terms of notation, we let $\boldsymbol{x}_i$ be the activity vector for learner i, where $i = 1, ..., N$. The dimensionality of activity vector $\boldsymbol{x}_i$ is $D \times K$, where K is the number of indicators and D is the number of days in the semester. The activity vector $\boldsymbol{x}_i$ is a complete representation of a learner's detailed activities on a daily basis, which captures the temporal aspect of learning activities. It can be further used in predicting learning performance to analyze the patterns of time management. However, this representation is not suitable for users to gain an intuitive understanding.

In order to visualize the activity vector, we first compress the $D \times K$-dimensional activity vector $\boldsymbol{x}_i$ into $D \times 1$-dimensional vector, and then embed this compressed vector in the calendar-based $W \times 7$-dimensional activity matrix by date, where W represents the number of weeks in a semester (usually $W < 28$). As shown in Figure 1(c), the compressed day activity is represented as a color-encoded cell (the darker the higher, indicates that the activity on the corresponding date is more frequent). There are many ways to compress the day activity vector, such as linear weighted aggregation, PCA-based selection, etc. In this demo, we use a weighted sum of all indicators to compress day activity according to the suggestions from instructors.

This calendar-like representation of activity matrix is consistent with the calendar that users often use. By adding some auxiliary graphical elements (e.g., segment lines, week numbers, etc.), the user can clearly understand learners' study histories throughout the semester. As shown in Figure 1(d), the learning activity history of five learners are fully recorded by the activity matrix, and different patterns of time management can be intuitively presented.

2.2 The Grade Point Prediction Model

Since the grade point is often used in management to evaluate the learning performance, we convert exam scores into grade points from 0 to 4, which is consistent with our school practice (0 indicates unqualified, 1 to 4 respectively indicates from passing to excellent). To capture the temporal aspects of learner activity representation, we use a grade point prediction model based on convolutional neural network to analyze the relationship between time management patterns and grade point.

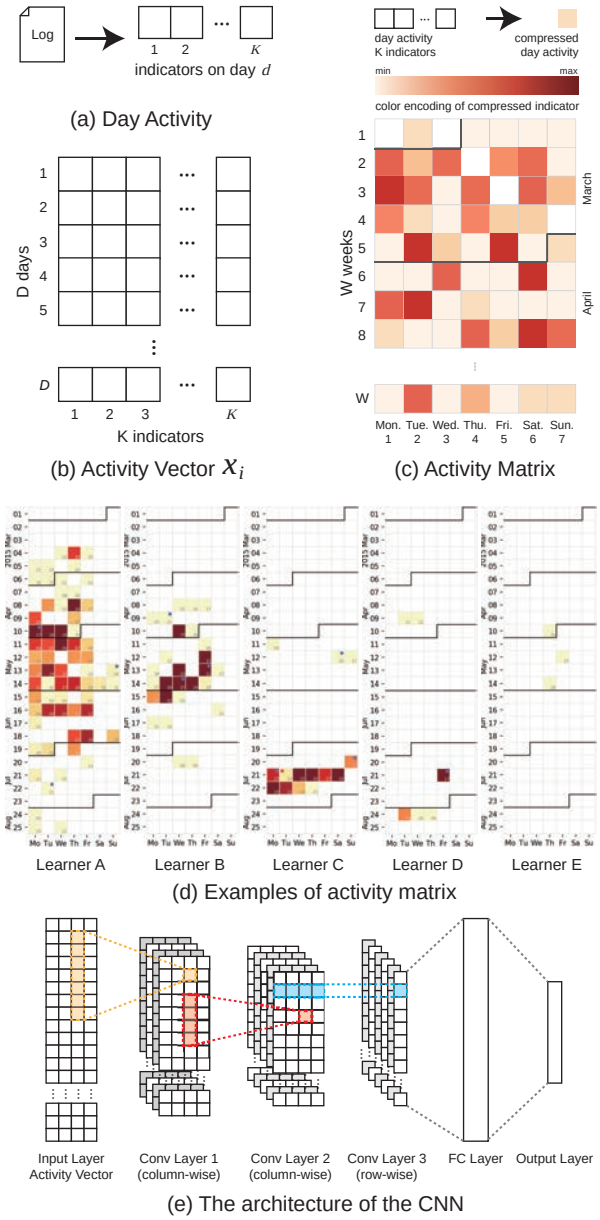

Figure 1: The learner activity representation and the prediction model based on convolutional neural network

As shown in Figure 1(e), the model consists of three convolutional layers using the rectified linear unit (ReLU) as activation function to capture the temporal features of the activity vector. Specifically, the first two column-wise convolutional layers take convolutions that capture the short-term (e.g., 1 cell = 7 days) and long-term (e.g., 1 cell = 4 weeks) patterns of learning activity, respectively. The third row-wise convolutional layer takes convolutions that capture the pattern of activity indicators at each timepoint. Then, the fully-connected layer extracts latent representation from the convolutional layer via a sigmoid function. Finally, the last layer outputs the probabilities of each grade point by a softmax function.

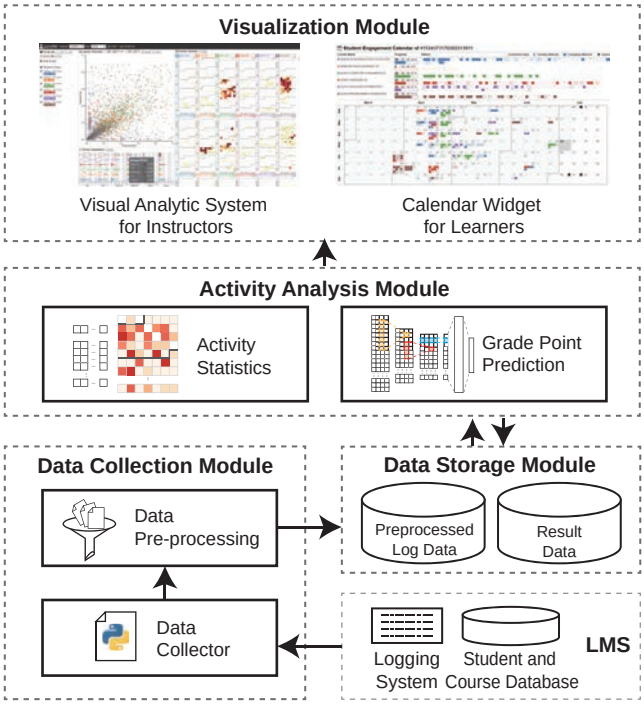

Figure 2: The architecture of the LearnerExp system

We trained this model on the dataset from the online undergraduate program of our university, which consists of 10,529 students and their learning logs in the first semester (14,942,964 lines). The average accuracy of current trained model is 72.2% and we will improve it in future research. The prediction results will be used in the exploration of the relationship between time management patterns and grade points in the LearnerExp system.

3 THE LEARNEREXP SYSTEM

3.1 The Architecture

The architecture of LearnerExp system is shown in Figure 2. It consists of four major components: *data collection module*, *data storage module*, *activity analysis module* and *visualization module*. Since we separate the different functions into modules, each module can be executed independently or integrated into the subsystem of the LMS. For example, the calendar widget in visualization module is integrated in learner's dashboard of the LMS.

Data collection and data storage module. In data collection module, we use Python scripts to collect course data and raw learner logs from the LMS. After filtering irrelevant information and filling missing fields, the preprocessed learner log data is saved in the data storage module. The personal identification information in log data is removed and will be not saved for privacy concerns. In addition, to facilitate access from the visualization module, the intermediate results of statistics and predictions are also saved in the data storage module.

Activity analysis module. This module includes two submodules: the activity statistics module measures the activity vector of each learner and generates the activity matrix defined in Section 2.1. Then, the grade point prediction module predicts the probability of each learner's grade points based on the pre-trained model mentioned in Section 2.2. The learners with a higher probability of grade 0 (i.e., failing the exam) will be grouped by the probability value for further analysis in the visualization module.

Visualization module. To make full use of the analysis results, we developed a web-based visual analytic system that enables course instructors to explore the engagement distribution and the temporal patterns of learners' activities from various aspects (Figure 3). In addition, we developed a web-based calendar widget to help learners understand their own learning activity history (Figure 2). This widget is integrated in the dashboard of the LMS, learners can check their activity history immediately after login.

3.2 Visual Design

In this section, we illustrate the visual design of the LearnerExp system and the interactions among the views. As shown in Figure 3, there are four coordinated views to show the analysis results from different perspectives: the Group List (Figure 3(a) and (b)), the Learner Overview (Figure 3(c)), the Group Comparison view (Figure 3(d)) and the Activity Calendar view (Figure 3(e)).

The Learner Overview and The Group List. To provide course instructors with intuitive impression on the overall activity distribution of all learners, we use scatter plot to present the statistics on the entire semester (Figure 3(c)). The values of each indicator over the entire semester are aggregated to represent learner's overall performance. For example, as shown in Figure 3(c), the *attendance rate* represents the ratio of the total number of daily videos watched to the total number of course videos. In this chart, each gray dot represents a learner, while each colored dot represents a learner who belongs to a specific learner group. Both the x-axis and the y-axis can be set to a specified indicator to see the distribution of same population under different indicators.

There are two types of learner groups in our system: the prediction groups generated by the model described in Section 2.2, and the temporary groups customized by selecting learners on the Leaner Overview. We developed an interactive selector to make it easier for users to intuitively select specific learners of interest (Figure 3(f)). By drawing a closed shape on the scatter plot with mouse, users can create a group of the selected dots within the shape. The newly created group will be automatically named and displayed in the "Temporary Groups" of the Group List (Figure 3(b)). To facilitate identification of learner groups in different views, the color-encoding used in the Group List is also used in other views.

The Group Comparison View. This view presents a set of box charts to simultaneously compare the distribution differences in learner groups across multiple indicators. As shown in Figure 3(d), from left to right, each box chart displays an indicator, in which each series represents a learner group from top to bottom. The color of each series is consistent with the color displayed in the Group List. When the mouse is over the series, the detailed statistics of the group on this indicator will be displayed.

The Activity Calendar View. In this view, the activity matrix defined in Section 2.1 is displayed to explore the details of learner's learning activity history. This view displays the learner groups in columns from left to right, in which the activity matrix of each

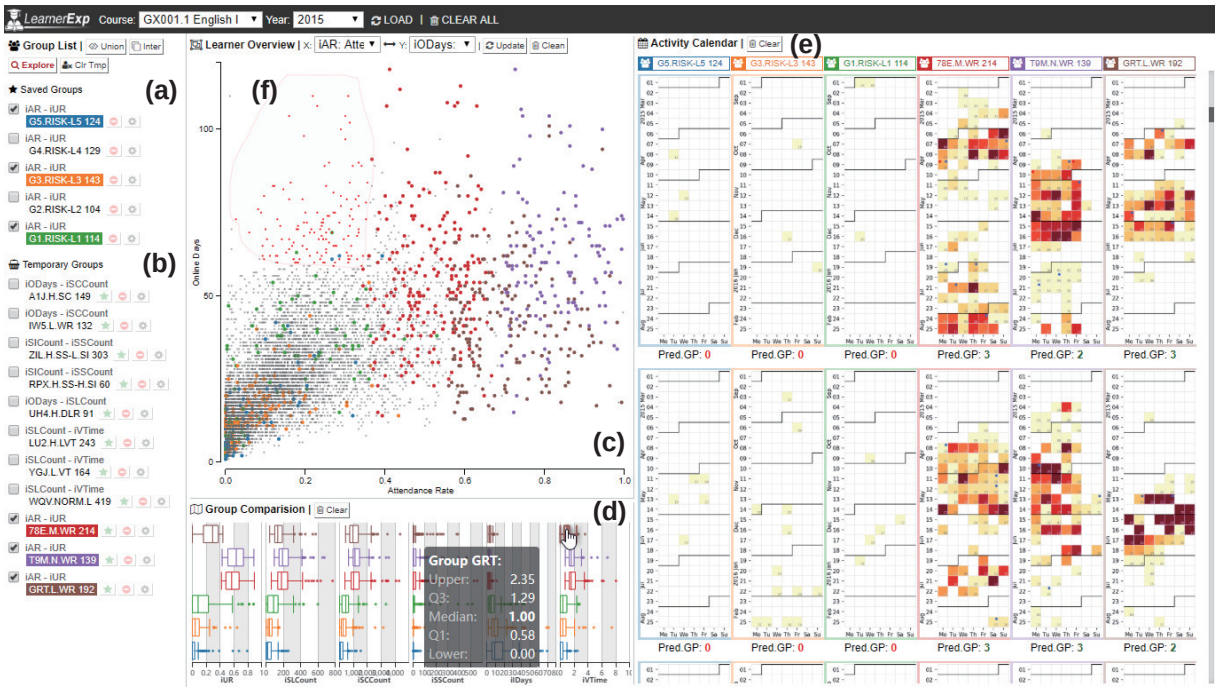

Figure 3: Screenshot of the LearnerExp system. (a) The saved group list. (b) The temporary group List. (c) The Learner Overview. (d) The Group Comparation View. (e) The Activity Calendar view. (f) A group of learners selected by the interactive selector.

learner is shown from top to bottom. When the mouse is over each activity matrix, the corresponding dot in the Learner Overview will be enlarged, and the corresponding location in each box chart will be marked to show the learner's relative performance in the whole population and in the group.

4 DEMONSTRATION

During the demonstration the attendee will evaluate LearnerExp [1] with a real dataset from our university, which is the same dataset as we mentioned in Section 2.2 but without personal privacy information. Additionally, we provide an exemplified scenario in which the course instructor wants to find the learners who may fail the posttest exam [2]. The demonstration scenario is the following.

(1) The user starts by loading data. After selecting the course in the "Course" drop-down list and clicking the "Load" button, the corresponding dataset will be loaded into the web page. All the learners of this course will be shown in the Learner Overview, and the prediction groups with different probability of failing the exam will be listed in the Group List. Figure 3(a) shows five groups, which are listed by the probability of failure of the exam from high to low.

(2) Next, the user can select groups and click the "Explore" button. Then, the selected groups will be colored, and the details will be displayed in each view. As shown in Figure 3, the learner dots belong to each group are colored and enlarged to show their relative position in the Leaner Overview (Figure 3(c)), and their study histories are listed in the Activity Calendar View (Figure 3(e)). For example, learners in the red, purple, and brown groups show regular time management characteristics and their predicted score points are higher than the blue, orange, and green groups.

(3) In addition to the prediction groups, the user can customize groups of interested learners for comparative exploration with the interactive selector (Figure 3(f)). After creating new groups, the user can select these newly created groups from the "Temporary Groups" and click the "Explore" button to continue exploring.

(4) Finally, after repeatedly exploring different groups, the user may be interested in a few customized groups and plan to analyze them in the future. By clicking the star-icon button next to the group label in the Group List, the corresponding temporary group will be saved and moved to the "Saved Groups".

5 CONCLUSION AND FUTURE WORK

In this demo, we present an interactive visual analytic system, LearnerExp, for visually exploring the patterns of online learning engagement and time management based on our proposed learner activity model. In future research, we will further expand the features of the LearnerExp and investigate the impact of different time management patterns on learning performance.

ABSTRACT

Usually considered as a classification problem, entity resolution can be very challenging on real data due to the prevalence of dirty values. The state-of-the-art solutions for ER were built on a variety of learning models (most notably deep neural networks), which require lots of accurately labeled training data. Unfortunately, high-quality labeled data usually require expensive manual work, and are therefore not readily available in many real scenarios. In this demo, we propose a novel learning paradigm for ER, called *gradual machine learning*, which aims to enable effective machine labeling without the requirement for manual labeling effort. It begins with some easy instances in a task, which can be automatically labeled by the machine with high accuracy, and then gradually labels more challenging instances based on iterative factor graph inference. In gradual machine learning, the hard instances in a task are gradually labeled in small stages based on the estimated evidential certainty provided by the labeled easier instances. Our extensive experiments on real data have shown that the proposed approach performs considerably better than its unsupervised alternatives, and its performance is also highly competitive compared to the state-of-the-art supervised techniques. Using ER as a test case, we demonstrate that gradual machine learning is a promising paradigm potentially applicable to other challenging classification tasks requiring extensive labeling effort.

1 INTRODUCTION

The task of entity resolution (ER) aims at finding the records that refer to the same real-world entity [5]. Consider the example shown in Figure 1. ER needs to match the paper records between two tables T_1 and T_2. The pair of $< r_{1i}, r_{2j} >$, in which r_{1i} and r_{2j} denote a record in T_1 and T_2 respectively, is called a *matching* pair if and only if r_{1i} and r_{2j} refer to the same paper. In the example, r_{11} and r_{21} are *matching* while r_{11} and r_{22} are *unmatching*. The state-of-the-art solutions for ER were built on a variety of learning models (e.g., deep neural network [9]), which require lots of accurately labeled training data. Unfortunately, high-quality labeled data usually require expensive manual work, are therefore not easily available.

Figure 1: An ER Example

It can be observed that the dependence of the popular learning models (e.g., DNN) on high-quality labeled data is not limited to the task of ER. The dependence is actually crucial for their success in various domains (e.g., image and speech recognition [13]). However, in the real scenarios, where high-quality labeled data is scarce, their efficacy can be severely compromised. To address the limitation resulting from such dependence, we propose a novel learning paradigm for ER, called *gradual machine learning*, in which *gradual* means proceeding in small stages. Inspired by the gradual nature of human learning, which is adept at solving the problems with increasing hardness, gradual machine learning begins with some easy instances in a task, which can be automatically labeled by the machine with high accuracy, and then gradually reasons about the labels of the more challenging instances based on the observations provided by the labeled instances.

We note that there already exist many learning paradigms for a variety of classification tasks, including transfer learning [10], lifelong learning [4], curriculum learning [2] and self-training learning [8] to name a few. Transfer learning focused on using the labeled training data in a domain to help learning in another target domain. Lifelong learning studied how to leverage the knowledge mined from past tasks for the current task. Curriculum learning

investigated how to organize a curriculum (the presenting order of training examples) for better performance. Self-training learning aimed to improve the performance of a supervised learning algorithm by incorporating unlabeled data into the training data set. More recently, Snorkel [11] aimed to enable automatic and massive machine labeling by specifying a wide variety of labeling functions, whose results are supposed to be fed to DNN models.

However, the following two properties of gradual machine learning make it fundamentally different from the existing learning paradigms:

- Distribution misalignment between easy and hard instances in a task. The scenario of gradual machine learning does not satisfy the i.i.d (independent and identically distributed) assumption underlying most machine learning models: the labeled easy instances are not representative of the unlabeled hard instances. The distribution misalignment between the labeled and unlabeled instances renders most existing learning models unfit for gradual machine learning.
- Gradual learning by small stages in a task. Gradual machine learning proceeds in small stages. At each stage, it chooses to only label the instance with the highest degree of evidential certainty in a task based on the observations provided by the labeled instances. The process of iterative labeling can be performed in an unsupervised manner without requiring any human intervention.

The contributions of this demo can be summarized as follows: (1) a general paradigm of gradual machine learning **(Section 2)**; (2) a solution for ER based on the proposed paradigm **(Section 3)**; (3) an empirical study validating the efficacy of the proposed solution **(Section 4)**.

2 LEARNING PARADIGM

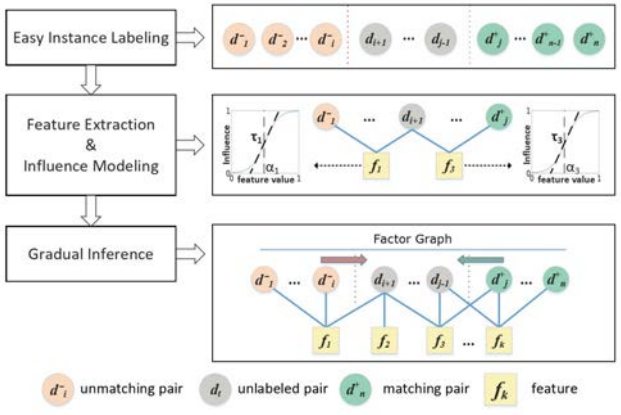

Figure 2: Paradigm Overview.

The paradigm of gradual machine learning, as shown in Figure 2, consists of the following three essential steps:

- **Easy Instance Labeling.** Given a classification task, it is usually very challenging to accurately label all the instances in the task without good-coverage training examples. However, the work can become much easier if we only need to automatically label some easy instances in the task. In the case of ER, while the pairs with the medium similarities are usually challenging for machine labeling, highly similar (resp. dissimilar) pairs have fairly high probabilities to be equivalent (resp. inequivalent). They can therefore be chosen as easy instances. In real scenarios, easy instance labeling can be performed based on the simple user-specified rules or the existing unsupervised learning techniques. Gradual machine learning begins with the observations provided by the labels of easy instances. Therefore, the high accuracy of automatic machine labeling on easy instances is critical for its ultimate performance on a given task.
- **Feature Extraction and Influence Modeling.** Features serve as the medium to convey the knowledge obtained from the labeled easy instances to the unlabeled harder ones. This step extracts the common features shared by the labeled and unlabeled instances. To facilitate effective knowledge conveyance, it is desirable that a wide variety of features are extracted to capture as much information as possible. For each extracted feature, this step also needs to model its influence over the labels of its relevant instances.
- **Gradual Inference.** This step gradually labels the instances with increasing hardness in a task. Since the scenario of gradual learning does not satisfy the i.i.d assumption, we propose to fulfill gradual learning from the perspective of evidential certainty. As shown in Figure 2, we construct a factor graph, which consisting of the labeled and unlabeled instances and their common features. Gradual learning is conducted over the factor graph by iterative factor graph inference. At each iteration, it chooses the unlabeled instance with the highest degree of evidential certainty for labeling. The iteration is repeatedly invoked until all the instances in a task are labeled. Note that in gradual inference, a newly labeled instance at the current iteration would serve as an evidence observation in the following iterations.

3 SOLUTION FOR ER

3.1 Easy Instance Labeling

Given an ER task consisting of record pairs, the solution identifies the easy instances by the simple rules specified on record similarity. The set of easy instances labeled as *matching* is generated by setting a high lowerbound on record similarity. Similarly, the set of easy instances labeled as *unmatching* is generated by setting a low upperbound on record similarity. The effectiveness of the rule-based approach can be explained by the monotonicity assumption of precision [1]. With the metric of pair similarity, the underlying intuition of monotonicity assumption is that the more similar two records are, the more likely they refer to the same real-world entity. According to the monotonicity assumption, we can *statistically* state that a pair with a high (resp. low) similarity has a correspondingly high probability of being an equivalent (resp. inequivalent) pair. These record pairs can be deemed to be easy in that they can be automatically labeled by the machine with high accuracy. In comparison, the instance pairs having the medium similarities are more challenging because labeling them either way by the machine would introduce considerable errors.

3.2 Feature Extraction and Influence Modeling

Given an ER workload, we extract three types of features from its pairs, which include:

(1) Attribute value similarity. Different attributes may require different similarity metrics.
(2) Similarity based on the maximal number of common consecutive tokens in string attributes. Consecutive tokens can usually provide additional information besides that implied by the attribute value similarity features.
(3) The tokens occurring in both records or in one and only one record. Representing a token by o_i, we denote the feature of o_i occurring in both records by *Same(o_i)*, and the feature of o_i occurring in one and only one record by *Diff(o_i)*.Unlike the previous two types of features, which treat an attribute value as a whole, this type of feature considers the influence of each individual token on pair equivalence probability.

These three types of features can provide good coverage of the information contained in record pairs. We observe that all the three types of features can be supposed to satisfy the monotonicity assumption of precision. Therefore, for each feature f, we model its influence over pair labels by a monotonous sigmoid function with two parameters, α_f and τ_f as shown in Figure 2, which denote the x-value of the function's midpoint and the steepness of the curve respectively. Formally, given a feature f and a pair d, the influence of f w.r.t d is represented by

$$P_f(d) = \frac{1}{1 + e^{-\tau_f(x_f(d)-\alpha_f)}}, \tag{1}$$

in which $x_f(d)$ represents f's value w.r.t d. Since the third type of features has the constant value of 1, we first align them with record similarity and then model their influence by sigmoid functions. It is worthy to point out that monotonicity of precision is a universal assumption underlying the effectiveness of the existing machine metrics for classification tasks. Our proposed solution for feature influence modeling can, therefore, be potentially generalized for other classification tasks.

3.3 Gradual Inference

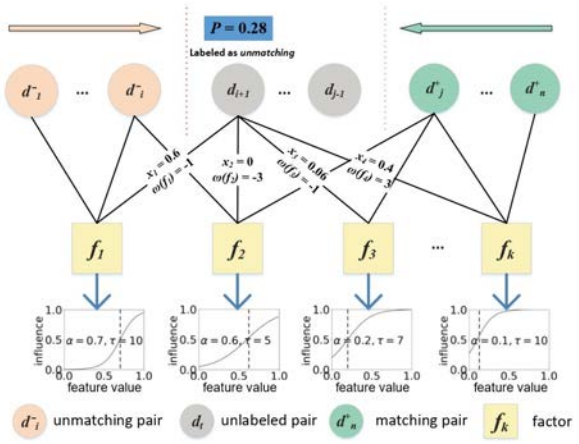

Figure 3: An Example of Factor Graph.

To enable gradual machine learning, we construct a factor graph, G, which consists of the labeled easy instances, the unlabeled hard instances and their common features. Gradual machine learning is attained by iterative factor graph inference on G. In G, the labeled easy instances are represented by the *evidence variables*, the unlabeled hard instances by the *inference variables*, and the features by the *factors*. The value of each variable represents its corresponding pair's equivalence probability. An evidence variable has the constant value of 0 or 1, which indicate the status of *unmatching* and *matching* respectively. It participates in gradual inference, but its value remains unchanged during the inference process. The values of the inference variables should instead be inferred based on G. An example of factor graph inference has been shown in Figure 3.

Note that the influence of a feature over a pair is specified by the sigmoid function as shown in Eq. 1. Therefore, in the factor graph, we represent the factor weigh of f w.r.t d by

$$\omega_f(d) = \theta_f(d) \cdot \log(\frac{P_f(d)}{1 - P_f(d)}) = \theta_f(d) \cdot \tau_f(x_f(d) - \alpha_f), \tag{2}$$

in which $\log(\cdot)$ codes the estimated influence of f on d by sigmoid regression, and $\theta_f(d)$ represents the confidence on influence estimation. We consider $\theta_f(d)$ as the confidence on the regression result provided by its corresponding sigmoid function, and estimate it based on the theory of regression error bound [3].

A factor graph infers the equivalence probability of a pair d, $P(d)$, by:

$$P(d) = \frac{\prod\limits_{f \in F_d} e^{\omega_f(d)}}{1 + \prod\limits_{f \in F_d} e^{\omega_f(d)}}, \tag{3}$$

in which F_d denotes the feature set of the pair d. The process of gradual inference essentially learns the parameter values (α and τ) of all the features such that the inferred results maximally match the evidence observations on the labeled instances. Formally, the objective function can be represented by

$$(\hat{\alpha}, \hat{\tau}) = \arg\min_{\alpha,\tau} -\log \sum_{V_I} P_{\alpha,\tau}(\Lambda, V_I), \tag{4}$$

in which Λ denotes the observed labels of evidence variables, V_I denotes the inference variables in G, and $P_{\alpha,\tau}(\Lambda, V_I)$ denotes the joint probability of the variables in G. Since the variables in G are conditionally independent, $P_{\alpha,\tau}(\Lambda, V_I)$ can therefore be represented by:

$$P_{\alpha,\tau}(\Lambda, V_I) = \prod_{d \in \Lambda \cup V_I} P_{\alpha,\tau}(d). \tag{5}$$

Accordingly, the objective function can be simplified into

$$(\hat{\alpha}, \hat{\tau}) = \arg\min_{\alpha,\tau} -\log \sum_{d \in \Lambda} P_{\alpha,\tau}(d). \tag{6}$$

Given a factor graph, G, at each stage, gradual inference first reasons about the parameter values of the features and the equivalence probabilities of the unlabeled pairs by maximum likelihood, and then labels the unlabeled pair with the highest degree of evidential certainty. We define evidential certainty as the inverse of entropy [12], which is formally defined by

$$H(d) = -(P(d) \cdot \log_2 P(d) + (1 - P(d)) \cdot \log_2(1 - P(d))), \tag{7}$$

in which $H(d)$ denotes the entropy of d. An inference variable once labeled would become an evidence variable and serve as an evidence observation in the following iterations. The iteration is repeatedly invoked until all the inference variables are labeled. In our programs, we deploy SciPy [7] to implement the process of factor graph inference.

However, repeated inference by maximum likelihood estimation over a large-sized factor graph of the whole variables is usually very time-consuming [14]. It is also unnecessary because at each iteration, only the inference variables receiving considerable evidential support from evidence variables need to be considered for labeling. Therefore, we have proposed a scalable solution for gradual inference. It first selects the top-m unlabeled variables with the most evidential support in G as the candidates for labeling. To reduce the invocation frequency of factor graph inference, it then approximates probability estimation on the m candidates by a more efficient algorithm. Finally, it infers via maximum likelihood the probabilities of only the top-k most promising variables among the m candidates. For each variable in the final set of k candidates, its probability is not inferred over the entire graph of G, but over a potentially much smaller subgraph. More technical details of scalable gradual inference can be found in our technical report [6], but omitted here due to space limit.

4 EMPIRICAL EVALUATION & DEMO PLAN

In this section, we empirically evaluate the performance of our proposed approach (denoted by GML) on real data. We have empirically compared the proposed solution with four alternatives, including unsupervised rule-based (UR), unsupervised clustering (UC), support vector machine (SVM) and deep neural network (DNN) [9]. Our evaluation was conducted on 3 real datasets, DBLP-Scholar[1](denoted by DS), Abt-Buy[2] (denoted by AB) and Songs[3] (denoted by SG).

The detailed evaluation results are presented in Table 1, in which r and p stand for recall and precision respectively, and the results on F-1 have been highlighted. For the supervised approaches of SVM and DNN, we report their performance provided with different sizes of training data, which are measured by the fraction of training data among the whole workload. For DNN, the training data consists of the data used for model training and the data used for validation. Therefore, we report the fractions of both parts in the table. It can be observed that GML performs considerably better than the unsupervised alternatives, UR and UC. In most cases, their performance differences on F-1 are larger than 5%. The performance of GML in terms of F-1 is also highly competitive compared to both supervised approaches of SVM and DNN. GML beats SVM (with the maximum training data size at 30%) on all the three test datasets; GML also beats DNN (with the maximum training data size at 30%) on both AB and SG.

Demo Plan. We have implemented a demo system for gradual machine learning, whose screenshots are shown in Fig. 4. It consists of four components: Easy Instance Labeling (EIL), Feature Extraction(FE), Gradual Inference (GI) and finally Result Report (RR). EIL labels easy instances. FE extracts features, models the influence of features and constructs factor graph. GI demonstrates the process of scalable gradual inference, which includes top-m candidate selection based on evidential support measurement, efficient entropy estimation and approximate factor graph inference. In GI, we have also designed an animation to visualize the iterative labeling process of GML. Finally, RR reports the experimental results. The attendees will be invited to operate the demo system step by step on a laptop using various datasets. They will be able to look into the details of the visualized process of GML.

ABSTRACT

In this paper, we introduce **Dixit**, an interactive visual storytelling system that the user interacts with iteratively to compose a short story for a photo sequence. The user initiates the process by uploading a sequence of photos. Dixit first extracts text *terms* from each photo which describe the objects (e.g., boy, bike) or actions (e.g., sleep) in the photo, and then allows the user to add new terms or remove existing terms. Dixit then generates a short story based on these terms. Behind the scenes, Dixit uses an LSTM-based model trained on image caption data and FrameNet to distill terms from each image, and utilizes a transformer decoder to compose a context-coherent story. Users change images or terms iteratively with Dixit to create the most ideal story. Dixit also allows users to manually edit and rate stories. The proposed procedure opens up possibilities for *interpretable* and *controllable* visual storytelling, allowing users to understand the story formation rationale and to intervene in the generation process.

1 INTRODUCTION

In visual storytelling, as introduced by Huang et al. [5], we take a sequence of photos as input and attempt to generate a short story narrating the sequence. This is an interdisciplinary task comprising image semantic reasoning and structural text generation. In contrast to image captioning or video captioning, which have less annotation variation across annotators, authors of visual stories can set down totally different stories for a given image sequence based on their preference and imagination. Instead of generating one story and leaving it *to* the user, we believe that working on a story draft together and iterating *with* the user results in much better story quality. In this paper, we introduce ***Dixit***[1], an *interactive* visual storytelling system. The purpose of Dixit is to enable users to control the story generation process and create their preferred stories. This system is inspired by our observation that people often start their short visual story with the key objects or actions in the pictures, and then build connections between these terms to form the final story. However, recent studies using deep neural networks (DNNs) are generally designed in an end-to-end fashion without intermediate human-recognizable representations [5, 11]. This closed process prevents users from adjusting intermediate variables and thus makes it impossible to create diverse stories from a given image sequence. In addition, as story generation is a subjective process depending on one's imagination, there is no ground truth given identical inputs, and automatic metrics fail to evaluate the quality of the story with an absolute score. In sum, we have the following four main issues:

First, **lack of interpretability in intermediate DNN Layers.** Because of the end-to-end DNN model's powerful ability as a universal approximator, in recent years it has achieved significant improvements in many fields, including computer vision and natural language processing. However, though some studies have attempted to get inside the DNN black box, it is difficult to clearly explain what information propagates to the next layer in a DNN model. For example, in visual storytelling, how exactly an end-to-end framework selects entities from images remains a mystery and the model's behavior is difficult to interpret. Second, **inability to modify generated stories.** With an end-to-end model, another problem is that the same input always yields the same result. That is,

[1]Dixit is available at https://dixitdemo.github.io/index.html . The web page will be responsive and can be used via mobile devices upon demo.

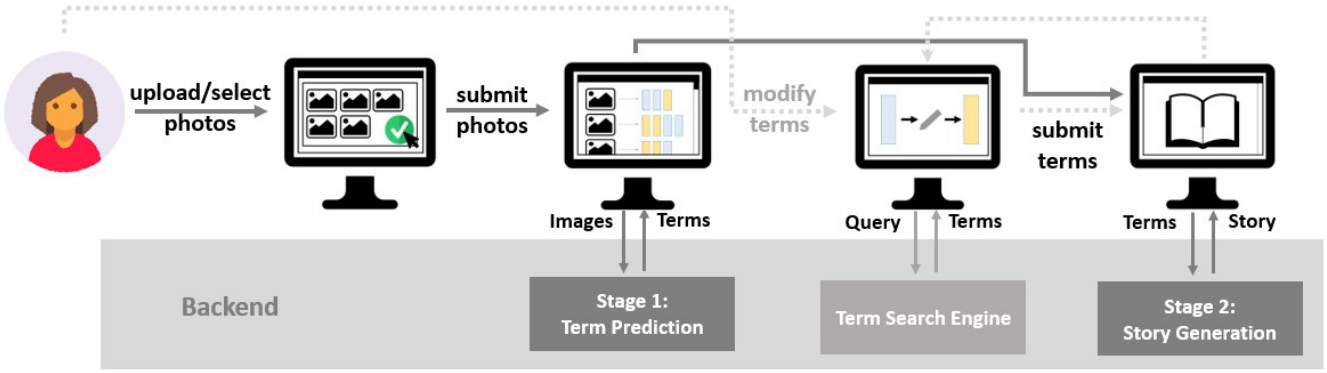

Figure 1: System architecture. The user initiates the process by uploading a sequence of photos. Dixit first extracts text *terms* from each photo which describe the objects or actions in the photo, and then allows the user to add new terms or remove existing terms. Dixit then generates a short story based on these terms.

we can obtain only a single story given the same image sequence – but this goes against the creative nature of storytelling. Although some generative models such as the variational autoencoder and the generative adversarial network produce more results by sampling from a prior distribution, they cannot generate storylines in the desired direction. Third, **difficulty in automatic evaluation.** Automatic metrics such as BLEU and METEOR have been shown to be insufficient to evaluate the quality of a visual story generation system [11]. Due to its subjective characteristics, human evaluation, which takes money and time, has become an essential part of the storytelling task. Finally, **data scarcity.** The quantity of image-story pair data is relatively insufficient because visual storytelling is an complex task; thus data annotation is expensive and time consuming.

To address these four issues, we introduce a two-stage interactive visual story generation system with which (i) users can understand what model sees in the images as predicted terms represent the objects and actions in the images, and also observe how these terms influence story generation , (ii) users can modify terms in the first stage to control the story generation, (iii) we can obtain human evaluation by asking users to score the quality of the generated story and the whole user-system interaction record in a turn is saved for future usage, and (iv) the modular nature of the two-stage framework, which utilizes image caption data and story corpora separately, allows us to train the visual storytelling model without image-story pair data.

2 RELATED WORK

Whereas end-to-end text generation from visual contents has been widely explored for tasks such as image caption, video caption, and visual storytelling, recent work has also been done on two-stage frameworks. Alexander et al. propose two-stage style transfer for image captioning. They first extract objects and verbs from an image and generate a stylish caption using an RNN trained on story corpora [7]. However, each such caption is only a single story-like sentence and is independent of other captions; put together, the captions do not constitute a context-coherent story. Xu et al. propose a skeleton-based narrative story generation method which in the first stage extracts the skeleton of the input sentence after which they generate the next sentence according to the given skeleton, one-by-one [12]. Although this framework shares with our system the insight that key phrases are important for generating a coherent story, its skeleton is extracted from pure text and does not serve as the grounding for the story. Moreover, as the framework generates the skeleton after generating the sentence, it lacks the ability to consider all important terms together to create the best fit.

3 SYSTEM

Workflow. Users of our system either upload images from their devices or choose from an image pool. After five images are uploaded or chosen, the first stage uses a term prediction model that captures terms – i.e., the objects and actions in images – to help users understand what the model sees in the current photos. As explained in Section 4, the actions are represented by verb frames. In the second stage, the predicted terms are then concatenated and fed into a story generator to construct a story with appropriate and coherent context. Note that the terms can be modified arbitrarily to control the story generation. If users want a story that depicts objects other than those detected from the images, they can remove the terms and add desired terms; to this end the system also includes a term search function. After the story is generated, the users are asked to rate the story; the complete interaction record (including image selection and term modification) is saved in the database. We expect the routine of modifying terms and generating a story to be repeated many times, as the user controls the story generation process and gradually gets better at creating good stories. For instance, in Table 1, the generated story in the second row is not perfect because some predicted terms are, although reasonable, not preferred. However, after removing these terms and adding better ones, users create a better story. This auto-labeling is an efficient way to provide samples for the training of future story models.

User Interface. A screenshot of the user interface is shown in Figure 2. The user's work flow starts at the left-top block, where the

					
Predicted Terms	"man", "Placing", "bike"	"motorcycle", "rider", "Emptying", "bike"	"trees", "sign", "Preventing_or_letting",	"man", "Placing", "bench"	"boy", "seat", "Placing"
Story	the man was sitting on his bike.	he was riding his bike with a rider on his motorcycle.	he stopped at a stop sign from a trees.	the man sat on the bench.	the boy sat in his seat.
Modified Terms	"boy", "Placing", "bike"	"rider", "bike"	"Seeking", "trees", "forest"	"bike", "dock"	"Sleep", "seat"
New Story	the boy sat down at his bike.	he was riding his bike like a rider.	he went into the forest looking for trees.	he threw his bike at the dock.	he went back to his seat to sleep.

Table 1: Via term adjustment, story generation is focused on specific objects or actions

user is asked to upload their own images or choose from the image pool. After the users submit images to the system, the predicted terms are shown in the left-bottom block. We meanwhile provide a term searching area (right bottom) using which the user searches for and modifies predicted terms. Term search is used for nouns and verb frames. For nouns, the search function retrieves nouns containing the query sub-string. For instance, for the query *wood*, the search engine returns *wood*, *woods*, *firewood*, *woodworker*, *woodworking*, and *plywood*. While searching for verb frames, instead of directly querying by the frame name, we search for lexical units of the verb frame. Results for the query *watch* would include *seeking*, of which *watch* is a lexical unit of *seeking*. After clicking the magic wand icon in the left-bottom area, the selected terms are sent to our story generation module, after which the generated story is retrieved and shown in the left middle area. The user is then asked to rate the story via the star icons. Since the concept of terms can be unfamiliar to users, we provide a term description area in the right-top corner. When user hovers the pointer over a term, the description of that term is displayed in the term description area. For noun terms, the descriptions are related images illustrating that noun, whereas for verb terms, the descriptions are textual explanations of the verbs. In the middle, on the right, a storage area is provided for the user to temporarily store unused terms.

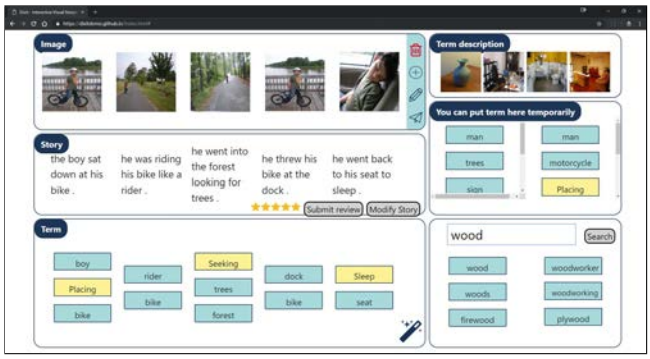

Figure 2: System user interface

4 DATA PREPARATION

Due to the modular nature of the proposed system, we train the model in two stages4 separately, without parallel data.

To train the term prediction model, we extract terms from captions in the COCO dataset [6] as the gold labels for the first stage to identity terms in images. The selection of terms is inspired by Semstyle [7]. Each sentence is represented as a combination of several noun (objects) and verb (actions) terms, which preserves the most crucial information needed to generate stories. Given a sentence, we extract verb terms by using Open-SESAME [9] to predict verb frames and leave nouns as noun terms. Frames are defined in FrameNet [1], a lexical database of semantic frame. The basic idea of FrameNet is straightforward: each frame is a description of a type of event, relation, or entity, and the participants in it.

To train the story generator, we use ROCStories Corpora [8], which contains stories with five sentences. For each story, we use a technique similar to back-translation to build our term-to-story corpora. That is, we transform stories to their corresponding terms, and then use these term-story pairs to train the story generator.

5 IMAGE-TO-TERM PREDICTION

As shown in Figure 3, the image-to-term prediction process can be considered a simplified image captioning problem which instead predicts the terms of an image. Given an image, we first convert it to the RGB format and resize it to 3x224x224 (channel * width * height) and then utilize a pre-trained Resnet-152 [3] model to extract image features. Resnet is a very deep neural network model with residual links between layers, originally pre-trained for image classification. The literature has suggested that it captures image features from low-level components like arcs to high-level concepts. With the image features produced in the previous step, we feed image features into an LSTM [4] to generate terms. Note that as

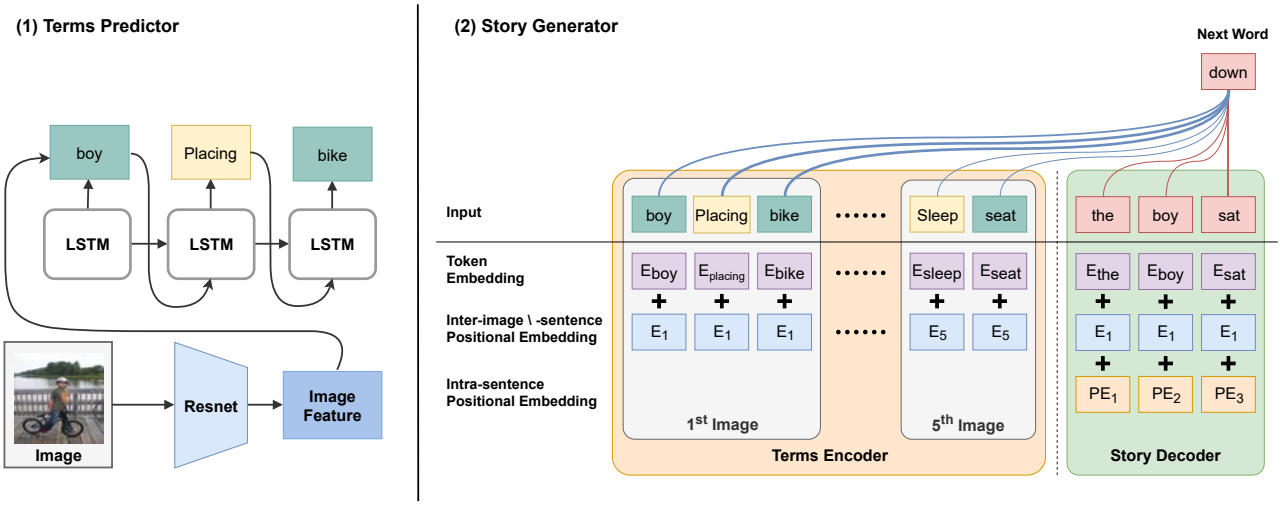

Figure 3: Architecture of (1) term prediction model and (2) story generation model. Predicted terms in green boxes denote noun terms, and terms in yellow boxes denote verb frames. In the training process, which uses the a single vocabulary, we treat both noun terms and verb frames equally. Term box colors are used here to emphasize their different origins.

described in Section 4, the LSTM model is trained with images and terms extracted from their corresponding captions in the COCO dataset; this pipeline is similar to that depicted in [7].

6 TERM-TO-STORY GENERATION

Transformer [10] is used as the basic model for story generation. In the Transformer paper, Vaswani et al. propose positional embedding as sequential information to replace the recurrent neural network. Here, we extend Transformer to be sentence-aware with the addition of an inter-sentence positional embedding to indicate the order of sentences within a story. This is shown in Figure 3. We do not consider the order of the input terms because terms represent only what appears in the images and need no sequential signal. At decoding time, an input embedding is the summation of the token embedding, the inter-image/-sentence positional embedding (InterPE), and the intra-sentence positional embedding (IntraPE). In particular,

- The InterPE is randomly initialized and updated during the training procedure. Similar to the segment embedding in BERT [2], we differentiate sentences/images by adding E_s to token embeddings of the s-th sentence/image; s denotes the order of a sentence/image in a story. $s \in \{1, 2, 3, 4, 5\}$.
- For IntraPE, we follow the Transformer implementation:

$$\text{IntraPE}_{(pos,\,2i)} = sin(pos/10000^{2i/d_{model}})$$
$$\text{IntraPE}_{(pos,\,2i+1)} = cos(pos/10000^{2i/d_{model}})$$

  where pos is the position and i is the dimension. d_{model} denotes the dimension of the input and output token. The IntraPE parameters are fixed, and the sinusoidal representation allows the model to extrapolate the sentence length that is longer than the training instances. The IntraPE PE_s is added to the s-th token embedding in a sentence. $s \in \{1, 2, ..., n\}$ and n is the max sentence length.

Based on the terms predicted for each image in the first step, we concatenate terms predicted for the five images as the input to the story generator. While decoding the story at every time step, the sentence-aware Transformer generates the context-coherent story conditioned on all input terms and the prior words of the story.

7 CONCLUSION AND FUTURE WORK

In this paper, we propose a two-stage interactive visual storytelling system that extracts terms (nouns and verb frames) and generates stories based on these terms. Users interactively adjust the terms to produce the desired story, and then record and rate the story quality for later model improvement. By splitting the task into two steps and their middle semantic term layer, the training data are not limited to the pair of images and their story, but include more accessible images with captions, and the text stories themselves. In addition, the process of visual story generation becomes interpretable. We believe this is a worthy direction for the advance of visual storytelling.

ABSTRACT

We present Exam Keeper, a tool to measure the availability of answers to exam questions for ESL students. Exam Keeper targets two major sources of answers: the web, and apps. ESL teachers can use it to estimate which questions are easily answered by information on the web or by using automatic question answering systems, which should help teachers avoid such questions on their exams or homework to prevent students from misusing technology. The demo video is available at https://youtu.be/rgq0UXOkb8o [1]

CCS CONCEPTS

• **Information systems → Decision support systems**; **Data analytics**.

KEYWORDS

Question Answering, Information Retrieval, Web Application

1 INTRODUCTION

The goal of the teacher is not always the same as that of the student, especially for short term goals. Although teachers always hope that their students really understand the knowledge they are imparting, students sometimes just want to complete their assignments with as little effort as possible. This, in the day when students can find answers with a quick web search, or use problem-solving, educational apps to find the answers. In addition, with the recent wide success of artificial intelligence, many worry that machines will soon be able to replace them in their jobs. This highlights the importance of practicing on problems that machines cannot easily solve.

However, from our observation, the advantage in this competition between teacher and student is with the latter. Many models and tools have been created to assist students to find answers, but as far as we know, there is no tool for teachers to monitor this process. Hence, we present Exam Keeper, which utilizes both retrieval-based and learning-based question answering techniques to provide a reference for teachers to know which questions have answers that are easily found on the web or using apps. Teachers can use this information to design their tests or homework problem sets accordingly to reduce the incidence of students copying answers, and hence to achieve the goal of effective practice and evaluation.

2 RELATED WORK

In the literature, there are several mobile applications which students can use to get answers, including *yuansouti*[2] and *afanti*[3]. The motivation behind such tools is to help students find answers when they are stuck on their homework assignments. However, many default to using these tools as soon as they see the questions, without even trying to solve the questions by themselves. Thus, these "time-saving" apps have become a nightmare for parents and teachers.

Researchers have also developed exam robots for high-school level exams such as AI-MATHS[4] for math exams in China and Todai[5] for the University of Tokyo entrance exam. Though these systems show the current level of AI systems for exams, they are neither open to the public nor used for educational purposes.

Previous systems for answering English exams have used a variety of different models to answer different types of questions. Examples include a state-of-the-art language model (LM)[6] trained on large datasets such as the One Billion Word Corpus [1] to answer fill-in-the-blank questions on English Exams, the reading strategies model [6] for reading comprehension, and the OpenAI transformer language model [4] for fit-the-best-sentence questions. With the invention of BERT [2], these questions can be answered more easily than before. Moreover, even for document-level questions such as SQuAD[5], BERT also achieves state-of-the-art performance. As a result, our system uses fine-tuned BERT models to predict the answer for each type of question.

3 SYSTEM

Fig. 1 illustrates the Exam Keeper framework. The first step is providing the exam questions and the answer keys. Exam Keeper provides two ways for users to input their data for examination: uploading existing files or using Exam Creator. Using the former method, teachers upload two files: one with the exam questions and the other with the answer keys. The two files should be formatted according to the instructions on the website. Teachers can also design and check exam questions one-by-one in the question design

*Equal contribution.

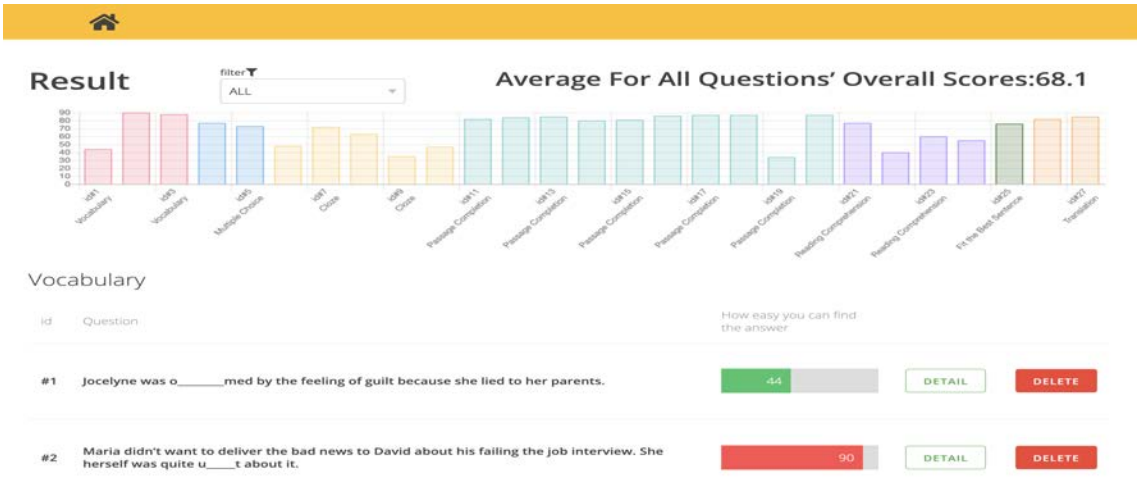

Figure 2: Result page

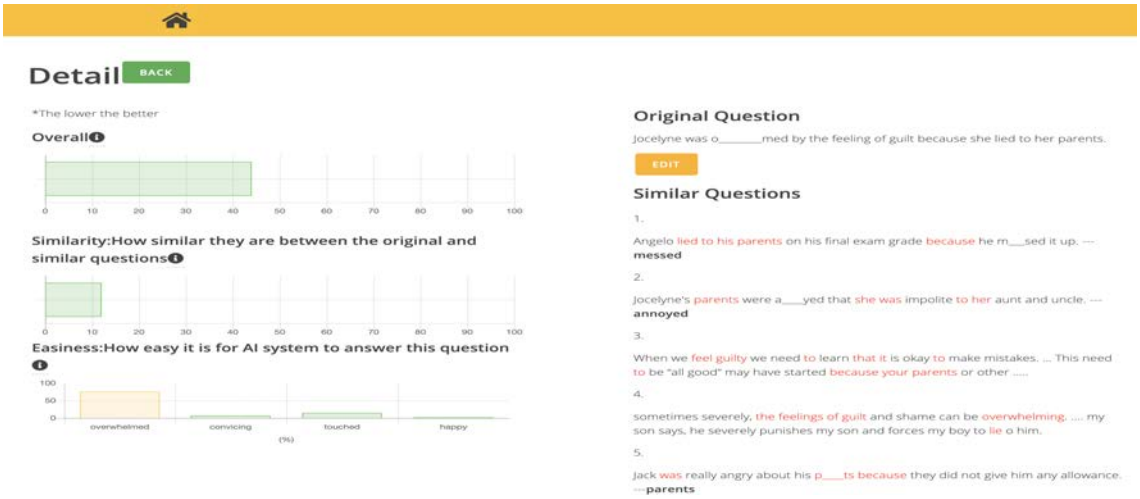

Figure 3: Question details interface

procedure by Exam Creator provided by Exam Keeper. Using Exam Creator, teachers can *test* the question and edit it accordingly until they are satisfied.

The current version of Exam Keeper supports the following question types: vocabulary, multiple-choice, cloze, passage completion, fit the best sentence, reading comprehension, and translation. Table 1 shows an example question for each type.

Exam Keeper represents the examination results at different granularities over several pages. As an overview, the top of the result page shown in Fig. 2 shows the overall accessibility of the answers in the exam and the corresponding score for each question, followed by the submitted questions with their individual scores. We mark each score with a color for straightforward visualization: red for easily-found answers (the teacher should reconsider this question), yellow for medium, and green for hard (should be good to use). The lower the score, the better the question.

The detailed calculation of the question score can be viewed clicking the *detail* button, which shows three scores: Overall, Similarity, and Easiness, as well as similar questions found on the Web and in the exam questions database. The Overall score is the average of the Similarity and Easiness. Similarity is based on how similar the original question is to the retrieved questions; it is measured in relation to answers found on the web. Easiness is measured in relation to answers found using the available QA systems or apps. Fig. 3 illustrates an example details page of a Vocabulary question, which also provides an editing function for question refinement. After going through all the questions, the teacher can download the exam sheet from Exam Creator.

4 MODELS

Exam Keeper includes several models: a retrieval-based model to retrieve similar question-answer pairs and one learning-based model for each type of question. To train these models and retrieve similar questions, we use the CLOTH [8] dataset for cloze questions, the RACE [3] dataset for reading comprehension, and the SWAG [9] dataset for fit-the-best-sentence questions. For the other types of questions, we collect raw data from free and public websites in China, Japan and Taiwan that gather exams created by English teachers.

4.1 Retrieval Based Model

We use Apache Solr[7], an extension of Apache Lucene[8], to retrieve similar questions for each input question. When a query is searched, Solr will return the documents ranked by modified Vector Space Model(VSM) score[9] with the query. VSM score of document d for query q is the Cosine Similarity of the weighted query vectors $V(q)$ and $V(d)$ whose weights are tf-idf values. Solr uses modified VSM score formula to rank documents that is not between 0 and 1. However, because we hope that the value of a score is between 0 and 1, we change it back to the original one.

The collected datasets are fed into Solr with the question type represented using the *question_type* field in Solr. For each question query, we search using Google Search and add the top ten snippets

Table 1: Example question types

Vocabulary
Maria did not want to deliver the bad news to David about his failing the job interview. She herself was quite u_____t about it.
Multiple Choice
Mangoes are a _____ fruit here in Taiwan; most of them reach their peak of sweetness in July. (A) mature (B) usual (C) seasonal (D) particular
Cloze
It is believed that taking breaks from a problem can help __1__ a moment of insight or stimulate new ideas. Unconventional solutions can also be explored. That is why some of the most successful companies in the world, such as 3M and Google, encourage their employees to __2__ all sorts of relaxing activities, such as playing pinball and wandering about the campus. 1. (A) spark (B) carve (C) drill (D) grind 2. (A) refer to (B) answer for (C) take part in (D) put up with
Passage Completion
One of these stories __1__ the Fortune cookie's origin back to 13th- and 14th-century China, which was then occupied by the Mongols. According to the legend, notes of __2__ plans for a revolution to overthrow the Mongols were hidden in mooncakes that would ordinarily have been stuffed with sweet bean paste. The revolution turned out to be __3__ and eventually led to the formation of the Ming Dynasty. (A) account (B) appeared (C) competing (D) contained (E) replaced (F) secret (G) successful (H) tastes (I) traces (J) treats
Fit the Best Sentence
On stage, a woman takes a seat at the piano. She _____ (A) sits on a bench as her sister plays with the doll. (B) smiles with someone as the music plays. (C) is in the crowd, watching the dancers. (D) nervously sets her fingers on the keys.
Reading Comprehension
For more than two hundred years, the White House has stood as a symbol of the United States Presidency, the U.S. government, and the American people. (...Skipped...) 1. What is this passage mainly about? (A) The design of the White House. (B) The location of the White House. (C) The importance of the White House. (D) The history of the White House. 2. Who initiated the construction of the White House? (A) John Adams. (B) James Hoban. (C) George Washington. (D) Thomas Jefferson.
Translation
Please translate the following sentences to English (This could be any language other than English) 1. 軍主導の暫定政権が来月予定していた総選挙の延期を示唆したことに 2. 相較於他們父母的世代，現今年輕人享受較多的自由和繁榮。 3. 成功的人都有着清晰的愿景。

[7] http://lucene.apache.org/solr/
[8] http://lucene.apache.org
[9] http://lucene.apache.org/core/7_4_0/core/org/apache/lucene/search/similarities/TFIDFSimilarity.html

into Solr according to the question type. Then we query the question in Solr and propose the top five results as similar questions. The top question's VSM score is used as the question's Similarity score in the details page.

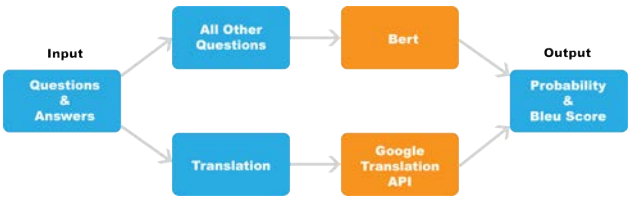

Figure 4: Model training flow

4.2 Learning Based Model

When Exam Keeper takes questions as input, based on the user-specified sections in the input file, we assign each question to one of the four categories, i.e., fill-in-the-blank, fit-the-best-sentence, reading comprehension, and translation. Models are then applied to questions by category. Fig. 4 illustrates the flow of the training process.

4.2.1 Fill-in-the-blank. This category includes four types of questions: vocabulary, multiple-choice, cloze, and passage completion. Though they appear different, they are transformed into the same format when they are input into the model: one blank masks at least one word off in a context and the model predicts the word(s). We utilize the current state-of-the-art to provide the most appropriate reference information by adopting the fine-tuned BERT [2][10] model, which is designed to solve cloze questions. After putting the context into the model, for each blank we retrieve the values for each word from BERT's dictionary. For vocabulary questions, we first search for the most likely words for the blank, and keep those words with the same first and last character given by the question. Then the top four candidates with their corresponding output values are selected. That with the maximum value is the proposed answer; the other three are also provided in the details page for teachers to use as they are similar semantically but are more difficult (for the learning models to answer). For the other questions, the softmax probability serves as the score for each answer candidate.

4.2.2 Fit-the-best-sentence. We use the BERT model designed for this type of question.

4.2.3 Reading Comprehension. During BERT's training process, in order to nail down the relationship between the contexts of two sentences, a binarized next-sentence prediction task is pretrained. This is the task we utilize to examine the reading comprehension question. In this task, the two context sentences A and B are stacked together and put into the BERT model, which predicts whether B is the next context sentence of A. In this sense, when performing downstream tasks that require information on two context sentences, we can put them into BERT as A and B and use the output of BERT's final layer for fine-tuning on each specific task.

[10]https://github.com/laiguokun/bert-cloth

Here, for reading comprehension questions, we set the article as A and each answer candidate as B, feed them to the pretrained BERT-Large model, and take the final hidden vector $C_i \in R^H$ corresponding to the first input token for each answer candidate i. The same procedure is followed for the article and question to yield C_q. In the fine-tuning stage, we use element-wise subtraction and multiplication [7] and concatenate the output of $C_q \ominus C_i$ and $C_q \otimes C_i$ to build matching representations $M_i \in R^{2H}$ for the article, question, and answer candidate. $\ominus$ and $\otimes$ are the element-wise vector subtraction and multiplication operations.

$$M_i = \begin{bmatrix} C_q \ominus C_i \\ C_q \otimes C_i \end{bmatrix} \tag{1}$$

Finally, we take the dot product of M_i and vector $V \in R^{2H}$ to get the score of i^{th} choice, where V is the only parameter needed to be trained for fine-tuning BERT on this task. Then we obtain the probability of each choice by applying softmax function over the scores of K choices.

$$Pi = \frac{e^{V \cdot M_i}}{\sum_{j=1}^{K} e^{V \cdot M_j}}. \tag{2}$$

4.2.4 Translation. We connect our application to the Google Translation API[11] and use the BLEU score between the generated translation sentence and the answer sentence to obtain the score. This score then is used as a measure of how easy it is for students to find the correct translation using Google Translate.

5 CONCLUSION

In this paper, we propose Exam Keeper, a system which calculates how easy it is for students to find exam answers. We hope this system benefits teachers in an era when technology distracts students from learning. Our future plan is to extend the application area of Exam Keeper to more subjects and to deploy it to different learning groups. In the end, we believe this is a worthwhile direction to explore for NLP techniques to improve educational environments.

ABSTRACT

Web pages and other documents often contain tables to provide numerical details in a structured manner. Typically, the text explains and highlights important quantities, often using approximate numbers and aggregates such as totals, averages or ratios. For a human reader, it is crucial to navigate between text and tables to understand the key information in its context, drill down into tables when details are needed, and obtain explanations on specific figures from the accompanying text.

In this demo, we present ExQuisiTe: a system to align quantity mentions in the text with related quantity mentions in tables, and enable extractive summarization that considers table contents. ExQuisiTe links quantity mentions in the text with quantities in tables, to support user-friendly exploration. ExQuisiTe handles exact single-cell references as well as rounded or truncated numbers and aggregations such as row or column totals.

CCS CONCEPTS

1 INTRODUCTION

Motivation. The Web contains a wealth of pages with embedded tables, and reports with spreadsheets are abundant in enterprises. Such documents, with financial or statistical data, are challenging to read, as they are often packed with numbers and tables. For example, in a financial report, a reader can stumble upon a statement like "..overall revenues were up 21 percent year-over-year... ", giving rise to questions such as: "What was the revenue of the previous year?" or "Which particular product or sector contributed to this increase?". In such cases, the table(s) accompanying the text can provide answers. However, long documents contain several tables, and table cells are referenced at many spots throughout the report. Moreover, many textual references round or truncate numbers, or refer to aggregates such as row or column totals, which are not explicitly given in the table(s). Therefore, it is tedious work to navigate between text and tables to answer the reader's questions.

Generally, what a reader would desire is an easy and seamless way of drilling down from text passages to the relevant table cells for additional detail, and zooming out from tables to the relevant sentences that explain the numbers.

Contribution. To address the above desiderata, we propose *ExQuisiTe*, a system that identifies relations between quantities in text and tables. ExQuisiTe automatically detects these relations and generates an easy-to-read document where numbers in text are linked to their source tables and respective cells. It identifies simple mentions of single-cell table quantities as well as mentions of aggregate quantities. For example, in Figure 1 the mention "1,683" in the text refers to a simple quantity in the table; and in Figure 2

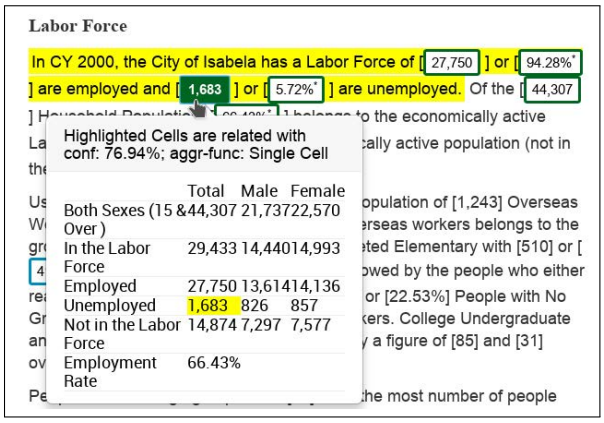

Figure (1) Simple quantity reference.

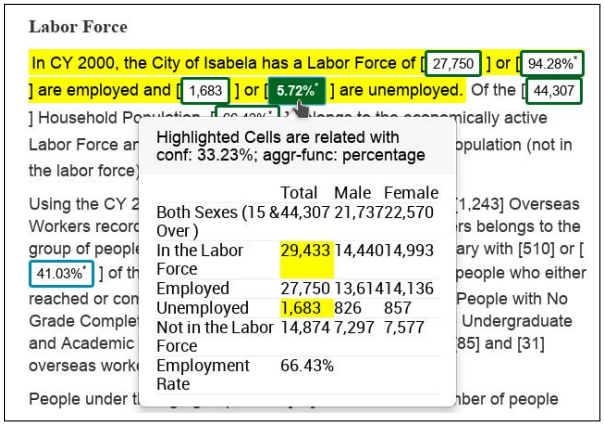

Figure (2) Aggregate quantity reference.

This paper is published under the Creative Commons Attribution 4.0 International (CC-BY 4.0) license. Authors reserve their rights to disseminate the work on their personal and corporate Web sites with the appropriate attribution.

https://doi.org/10.1145/3308558.3314134

the mention "5.72%" refers to an aggregate quantity (percentage) in the same table.

Furthermore, ExQuisiTe can guide *Extractive Text Summarization (ETS)* systems by emphasizing sentences with aggregate quantities. Current summarization systems [2, 9] do not include table data, and ExQuisiTe opens the opportunity for them to harness table data. Once ExQuisiTe identifies references of simple and aggregate table quantities in the text, it can suggest sentences with aggregations to be included in the summary generated by the ETS algorithm.

For example, in Figure 2 the highlighted sentence covers more cells in the table than the other sentences. It contains more aggregate mentions, and hence it provides a better summary, with judicious consideration of the numbers in the tables. ExQuisiTe is base on the BriQ algorithm [6], and consists of four configurable stages: (i) Document Extraction, (ii) Local Resolution, (iii) Global Resolution, and (iv) Markup and Summary Generation. The first stage extracts text segments and their possible related tables using string similarity measures. The second stage identifies potential alignments between quantity mentions in text and tables based on local features. Then, the third stage collectively aligns quantities in the text to their relevant quantities in tables. Finally, the system generates markup for the document with the inferred alignments and selects important sentences for summarization.

The code of ExQuisiTe as well as all the annotated data used for training is available on the project web page [1]. Our main contributions are:

- an end-to-end system for quantity alignment,
- a system that generates salient suggestions for a downstream ETS method,
- an open-source efficient pipeline that can be flexibly configured on a Spark cluster for online document processing.

2 COMPUTATIONAL MODEL

Our algorithm handles the following inputs:

- a piece of text, like a (part of a) web page, with a set of m text mentions of quantities $X = \{x_i : i = 1, \ldots, m\}$,
- a table q with r rows and c columns and a set of n mentions of quantities $T = \{t_j : j = 1, \ldots, n\}$.

Text mentions include terms containing numbers or numerals such as "123 patients", "37K EUR", "1.5%" or "twenty pounds".
Table mentions include two types of quantities. The first are *simple mentions*, such as '1,683' in Figure 1. Given a table with r rows and c columns we have at most $r \cdot c$ single-cell quantity mentions. The second type is *aggregate mentions*, computed as an aggregation of one or more table cells, such as '5.72%' in Figure 2.

In this demo we consider the following *aggregate functions*: average, sum, difference, percentage, and change ratio.

For aligning quantity mentions between text and tables, we aim to compute as output a subset of mention pairs $\langle x_i, t_j \rangle$ where $x_i \in X$ is a text mention and $t_j \in T$ is a table mention, including aggregate quantities. These pairs should denote the same quantity with high confidence.

[1] https://www.mpi-inf.mpg.de/briq/

3 SYSTEM COMPONENTS

3.1 Document Extraction

Long web pages can cover a variety of thematic aspects, along with several tables. Therefore, we decompose the input web page into coherent segments which we refer to as *documents*. We define a coherent document to be a paragraph together with all "related" tables from the same web page. Each document can be processed independently from the other documents. Hence, we can leverage a distributed computing framework, Spark, for online page processing.

This module first decomposes the input web page into paragraphs, then recognizes related tables for each paragraph using pairwise similarities between all paragraphs and all tables in the web page.

3.1.1 Quantity Extraction. For each document, quantity mentions are extracted from the text and the tables, using regular expressions. Our method pays particular attention to the challenges of aggregated quantities (e.g., column totals). Therefore, we generate table candidates as combinations of cells with an associated aggregate function. For example, we generate aggregate mention for a column total even if the table does not explicitly show the total. Aggregate quantities are automatically generated by considering (i) all rows and columns for totals and averages and (ii) all pairs of cells in the same row or column for difference, percentage, and change ratio. We prune the aggregate quantity candidate, to ensure computational tractability and to control spurious matches.

3.2 Local Resolution

This module first computes features for each text mention and each table mention by analyzing the surrounding context. Then, it computes similarity-based features for each pair of text mention and table mention including aggregate quantities. After that, it uses a binary classifier that accepts or rejects candidate mention-pairs. This binary classifier assigns a confidence score to each mention-pair, and we use this score in the following steps. At the end of this module, we filter the candidate mention-pairs according to their confidence score and other measures which we will explain later.

3.2.1 Mention-Pair Classification. We use manually annotated web pages with ground-truth alignment to train a *Random Forest (RF)* classifier. The classifier operates *locally* in the sense that it predicts the alignment confidence for each mention-cell pair in isolation, It serves two purposes: First, it enables the subsequent filtering step, which significantly reduces the number of candidate pairs for achieving an acceptable running time in the global resolution step. Second, it provides a prior for that global resolution step.

3.2.2 Classifier Feature. For the mention-pair classifier, we designed a variety of features that capture information a human reader would use in order to determine if text mention x and table cell t denote the same quantity. This includes *surface form similarities*, *context features*, and *quantity features*. For more details refer to Ibrahim et al. [6].

3.2.3 Adaptive Filtering. This stage reduces the number of mention-pair candidates from 1000s of candidates to 100s for tractability of global inference algorithms. We design the *adaptive filtering*

Sales were up 5% on both a reported and organic basis, compared with the second quarter of 2012. Segment profit was up 11% and segment margins increased 60 bps to 13.3%.

Table 1: Transportation Systems

($ Millions)	2Q 2012	2Q 2013	% Change
Sales	900	947	5%
Segment Profit	114	126	11%
Segment Margin	12.7%	13.3%	60 bps

Table 2: Automation & Control

($ Millions)	2Q 2012	2Q 2013	% Change
Sales	3,962	4,065	3%
Segment Profit	525	585	11%
Segment Margin	13.3%	14.4%	110 bps

Figure (3) Example with Coupled Quantities

algorithm to work in two stages. In the first stage, we develop a *text mention tagger* to predict the aggregation function for each text mention or tag the mention as a single-cell match. Then, we prune mention-pairs based on this tagger's outcome. In the second stage, we prune mention-pairs based on *value difference* and *unit mismatch*. Finally, we sort mention-pairs according to classifier scores and select top-k mention-pairs for each quantity mention based on *mention type* and *score distribution*. For more details refer to Ibrahim et al. [6].

3.3 Global Resolution

This module takes as input the candidate mention-pairs from the classifier and outputs the alignment of quantity mentions. We harness dependencies among mentions to resolve ambiguities. Consider the example in Figure 3. The text mentions "11%" and "13.3%" have exact matches in both of the shown tables, and local-resolution algorithms cannot infer the proper alignment. However, when considering these two mentions jointly with "60 bps" and "5%", it becomes clear that all of these refer to the first table.

We devised an unsupervised algorithm for this kind of global resolution. The algorithm encodes dependencies among mentions into a graph and uses *Random Walks with Restarts(RWRs)* to infer the best joint alignment.

3.3.1 Graph Construction. We construct an undirected weighted graph $G = (V, E)$ for each document:

- The node set V consists of all quantity mentions in the document's text and tables.
- The edge set E consists of three kinds of edges connecting related nodes: text-text edges, table-table edges, and text-table edges as explained below.

(i) Text-text edges: connects each pair of text quantity mentions that are within a certain proximity or have similar surface forms. Edge weights are computed based on a linear combination of proximity and string similarity. *(ii) Table-table edges:* connects each pair of table quantity mentions in the same row or the same column of the same table, and edge weights are set uniformly. *(iii) Text-table edges:* connects each pair of text and table mention that is kept by the adaptive filtering stage, and edge weights are set to the confidence scores returned by the classifier. After this initial graph construction, all edge weights are normalized to obtain a stochastic graph, via dividing each node's outgoing weights by the total weight of these edges.

3.3.2 Graph Algorithm. In our setting, we employ random walks with restart: starting from a text mention, the graph is stochastically traversed, with a certain probability of jumping back to the initial node. This technique is also known as topic-specific or personalized PageRank [4]. Our implementation iterates RWRs for each text mention until the estimated visiting probabilities of the candidate table mentions change by less than a specified convergence bound. This way we obtain a ranked list of table mentions for each text mention x.

Alignment decisions: The RWR from text mention x computes the stationary probability $\pi(t|x)$ for each table mention t. Pair $\langle x, t^* \rangle$ forms an alignment if and only if (i) t^* is the table mention with the highest overall score, and (ii) its overall score exceeds the defined confidence threshold. We then exploit the alignment decisions to update the graph, such that after identifying an alignment $\langle x, t^* \rangle$, x we modify the graph by removing all edges (x, t) for any $t \neq t^*$.(If no alignment is found for x, then all text-table edges adjacent to x are removed.)

3.4 Markup and Summarization

This module integrates the output of our system with the content of the web page and displays the results to the user in the form of an HTML page. This module is also responsible for analyzing the aligned quantities and highlighting the important sentences for the summarization engine. It estimates the importance of a sentence based on its coverage of table cells.

We define the *coverage of a quantity mention* in the text to be the number of individual single-cells it refers to. For mentions referring to an aggregate table quantity such as the sum of a column, we include all the individual single-cells in this column. Then, we compute the *coverage of a sentence* as the sum of the coverage of its mentions.

For each table, we extract all the sentences that reference it. Then, we compute a score for each sentence based on its coverage. After that, we highlight the sentence with the maximum score in the generated HTML. For example in Figure 4 even though the second sentence has more simple quantity references to the table than the last sentence, the latter provides a better summary of the table. The last sentence discusses the overall CO2 emission in the world and has the highest coverage of table cells, while the second sentence only discusses the emission of India and the EU.

4 EXPERIMENTAL RESULTS

We trained and evaluated our system on a manually annotated corpus of 495 web pages. The F1 score of our system is 79% for the simple quantity mentions, and 40% for the aggregate mentions. We carried out a run time analysis on a Spark cluster with 10 executors, each with 6 cores and 30GB of memory, and with 50GB of driver memory. The throughput of our system is 2.5K documents per minute. For full evaluation results refer to Ibrahim et al. [6].

5 DEMO OVERVIEW

In this demonstration, we will show how ExQuisiTe aligns quantity mentions in web pages. ExQuisiTe is web-based therefore it only requires a modern web browser. It has two main views: the first view is for configuring the system and selecting the type of input document, and the second view is for displaying the alignment results.

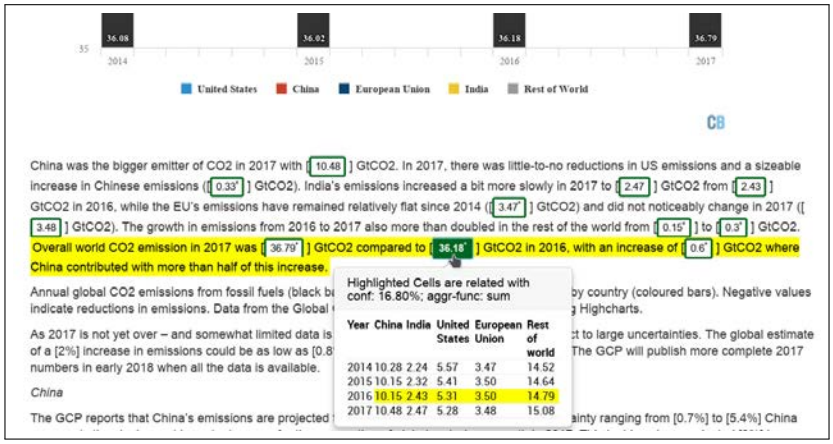

Figure (4) The figure shows the results of the system as described in Section 5

Configuration and Input. ExQuisiTe gives the user control over the settings of the different components. The user can select the type of input she wants to process. Currently, we support HTML input given as a valid page URL or a file containing the HTML content.

For the global resolution the user can choose either (i) Random Walk With Restart (RWR) or (ii) No Global Resolution. RWR is the default option. The second option deactivates the global resolution module and uses only the outcome of the classifier. It uses the confidence value given by the classifier to select the highest-confidence table mention for each text mention.

The user can adjust the threshold for the final confidence score: mapping the text mention to a table mention or to a NIL. In the case of local resolution only, this threshold is applied to the classifier's confidence score. In the case of RWR global resolution, the threshold is applied to the RWR outcome. Finally, there is an option to turn adaptive filtering on or off.

Results Display and Interactive Exploration. The system processes the document according to the user's configuration. Then, it displays the results embedded in the original HTML document as shown in Figure 4.

The text quantity mentions appear between square bracket. Each text mention is hyperlinked to its aligned table mention using a colored button with the mention's surface form as the hypertext. The color of the button is determined by the table, such that each table is assigned a color and all its related mentions in the text are assigned the same color.

The system marks the aggregate quantity mentions with a '*' superscript. When a text mention is clicked, the system displays a pop-up with the table. This pop-up includes—in addition to the table—the confidence of the alignment, the type of alignment, and the related cells in the table. The type of alignment can take one of the following values: single-cell, average, sum, difference, percentage, and change ratio.

The system marks the salient sentences for downstream summarization with yellow background. For each table, the system marks the sentence with the highest coverage. In Figure 4, the last sentence has the highest coverage of table cells.

6 RELATED WORK

Although information extraction research has targeted Web tables, no prior work has examined the relation between mentions in the text and tables within a document. Quantity annotation has been addressed in [5, 12], but these methods rely on external knowledge bases, linking table cells to entries in the knowledge base. Further methods focused on named entities, by annotating table cells with entities and classes from the knowledge base [1, 3, 8, 10, 11]. Table data fusion for search and schema inference was studied in [7, 13–15].

Our work differs from all these prior works in two main aspects: (i) we do not rely on any external knowledge base, and (ii) we handle approximate and aggregated quantities mentions which do not have exact matches.

ABSTRACT

This demonstration paper presents an argument-inducing online forum that stimulates participants with lack of premises for their claim in online discussions. The proposed forum provides its participants the following two subsystems: (1) **Argument estimator** for online discussions automatically generates a visualization of the argument structures in posts based on argument mining. The forum indicates structures such as claim-premise relations in real time by exploiting a state-of-the-art deep learning model. (2) **Argument-inducing agent for online discussion (AIAD)** automatically generates a reply post based on the argument estimator requesting further reasons to improve the argumentation of participants.

Our experimental discussion demonstrates that the argument estimator can detect the argument structures from online discussions, and AIAD can induce premises from the participants. To the best of our knowledge, our argument-inducing online forum is the first approach to either visualize or request a real-time argument for online discussions. Our forum can be used to collect and induce claim–reasons pairs rather than only opinions to understand various lines of reasoning in online arguments such as civic discussions, online debates, and education objectives. The argument estimator code is available at
https://github.com/EdoFrank/EMNLP2018-ArgMining-Morio
and the demonstration video is available at
https://youtu.be/T9fNJfneQV8.

1 INTRODUCTION

Online forums are some of the best places to gather divergent perspectives on a controversial topic because many participants can discuss a topic without being limited by time or location. However, most participants in online forums are less likely to show premises (i.e., reasons) for their claims [3, 5]. For example, Figure 1 shows a histogram of the number of corresponding premises of a claim in an online civic discussion [3]. The figure illustrates that claims with zero or a single premise account for a large fraction, indicating that online discussions generally lack premises.

To address this issue, we propose a novel argument-inducing online forum (Figure 2) that can be used to not only collect but also induce reasoning in online discussions. The basic architecture of the proposed forum is almost the same as that of a classic forum comprising threads, where the forum has a log-in system, and participants can freely post their comments in threads. However, the proposed forum has the following two novel key features:
(1) **Argument estimator** is a visualizer of an argument structure based on argument mining. Argument mining is a newly emerging discipline that focuses on extracting claims and premises and inferring their structures from a discourse. In this work, we extended the solid argument mining scheme presented by Stab et al. [9]. We consider each post has independent arguments (an argument consists of one claim and possibly empty premises), and inferred the argument structure via a state-of-the-art deep learning model [4]. Then, we visualized the inferred arguments in the online forum in real time, indicating a color-coded claim or premise sentences and *reasoning* links that are indicated by arrows to ensure that the participants can recognize their argument.
(2) **The argument-inducing agent for online discussion (AIAD)** is a template-based agent that uses the inferred argument structure

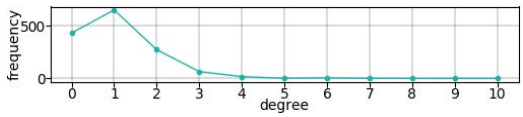

Figure 1: Histogram of a claim's degree for an online discussion. The horizontal axis indicates the claim's degree, where 0 denotes that claims without corresponding premises are counted.

that is intended to induce reasoning from participants. The agent is similar to debater agents, whereas the AIAD responds to a participant when a post contains a claim but with two or less premises. On a dialectical level, AIAD asks: "*Can you give me an additional argument for your claim?*" and encourages the user to answer a new argument accordingly.

Our experimental result demonstrates that the argument visualization and AIAD effectively support online discussions.

2 RELATED WORKS

Argumentation mining is a multi-disciplinary research field used to investigate reasoning processes such as logic, natural language processing, and machine learning. Additionally, argument mining is expected to be applicable for performing difficult tasks that require an understanding of human reasoning processes, not only for an automatic essay scoring [10] and debater system (e.g., IBM Project Debater) but also for supporting online discussions. Sato et al. [7] proposed an end-to-end debater that can generate argumentation for some values by specifying a controversial proposition. Although the debaters are successful applications of argument mining, few applications are available for online forums.

Gurkan et al. [2] proposed a deliberatorium, which is a platform for large-scale online discussions, to consider argumentation in a discussion. The platform introduces a logic-centered argumentation map, and it differs from other platforms such as Wikipedia and chat systems. Their experimental results indicated that the system can successfully provide summaries but cannot commit to mediating a discussion.

3 SYSTEM OVERVIEW

The proposed system has the following important subsystems: i) an argument estimator that functions as a visualizer of argument structures and ii) an AIAD that functions as an argument-inducing agent.

After inputting the username and password, the participants can post their opinions to a thread (Figure 2). The full thread is available on the left side of the figure. Clicking on one thread can lead to another. Moreover, creating a new thread with a controversial topic by clicking the "CREATE NEW TOPIC " button at the top right or top left in Figure 2 is permissible.

When a thread appears on the web page, the visualized argument structure discriminated by the argument estimator is shown. By focusing on the cursor of a post, we can understand the argument structure presented in the post. Each sentence or clause is color-coded, where the blue sentence indicates a premise and red indiactes a claim. The color-coded arrows in posts point out the inner-post relationship that represents a support or attack reasoning: the arrow direction is a conclusion, while the tail is a premise. Because we introduce the scheme of an argument tree, an argument comprises one claim and a (possibly empty) set of premises, and a maximum of one relation source for each sentence is allowed; the relationships are always trees. In addition, we can understand the inter-post interaction (IPI) that represents a support or attack relation from the sentences of the focused post. For example, a kangaroo's post involves two premises, two claims, and one post-to-post relationship between the post and its parent post, as shown in Figure 2.

Figure 3 shows an overview of the system's flow when the participants post comments on a forum. Our forum comprises the following four parts: user interface on a web browser, server-side database, argument estimator, and AIAD. We developed an original user interface and APIs that operate through the following six steps: (1) The participant posts a comment to our forum. (2) The document in the post is parsed into sentences or propositions and recorded into the database. (3) The argument estimator module detects the change of record in the database, discriminating either claim or premise and relations between the claim and premises in the thread. (4) The inferred argument structure is recorded by the database; thus, the argument is visualized on the user interface. (5) The AIAD, in turn, detects the change in the argument structure in the database. (6) The AIAD generates a comment and responds to a poorly reasoned post.

3.1 Argument Estimator

Argument estimator predicts argument structures through machine learning. Given that our forum supports Japanese and English discussions, we introduced a different technique and dataset for each language to train the estimator.

In Japanese discussions, we use the same dataset of Morio et al. [3]. Because the dataset automatically separates a document into sentences, we can consider that argument component candidates are already given. In this work, we employ a state-of-the-art model: parallel constrained pointer architectures (PCPAs) [4], which analyzes the sentence-level argument structure in threads. PCPA is a neural architecture that uses pointer networks [6], where PCPA can effectively discriminate between sentence types (i.e., claim, premise, or non-argumentative) and relations (inner-post relation (IPR) as well as IPI) in the thread.

PCPA achieves a significant reduction in its time complexity because it constrains the search space when discriminating between IPR and IPI. Formally, given n_p and n_s, which are the averages of the number of posts per thread and sentences per post, respectively, the standard approach needs $O({n_p}^2 * {n_s}^2)$ during computation. However, PCPA uses only $O(n_p * {n_s}^2)$. Therefore, our argument estimator provides a rapid result during testing, thus supporting a real-time inference. Generally, the inference process consumes less than 1 s.

In English discussions, we use an original token-level dataset obtained from *ChangeMyView*[1] in Reddit.[2] The dataset is annotated in token level (but not sentence level). Therefore, we should point

[1]https://www.reddit.com/r/changemyview/

[2]The dataset is not yet publicly available; however, we will make it public soon.

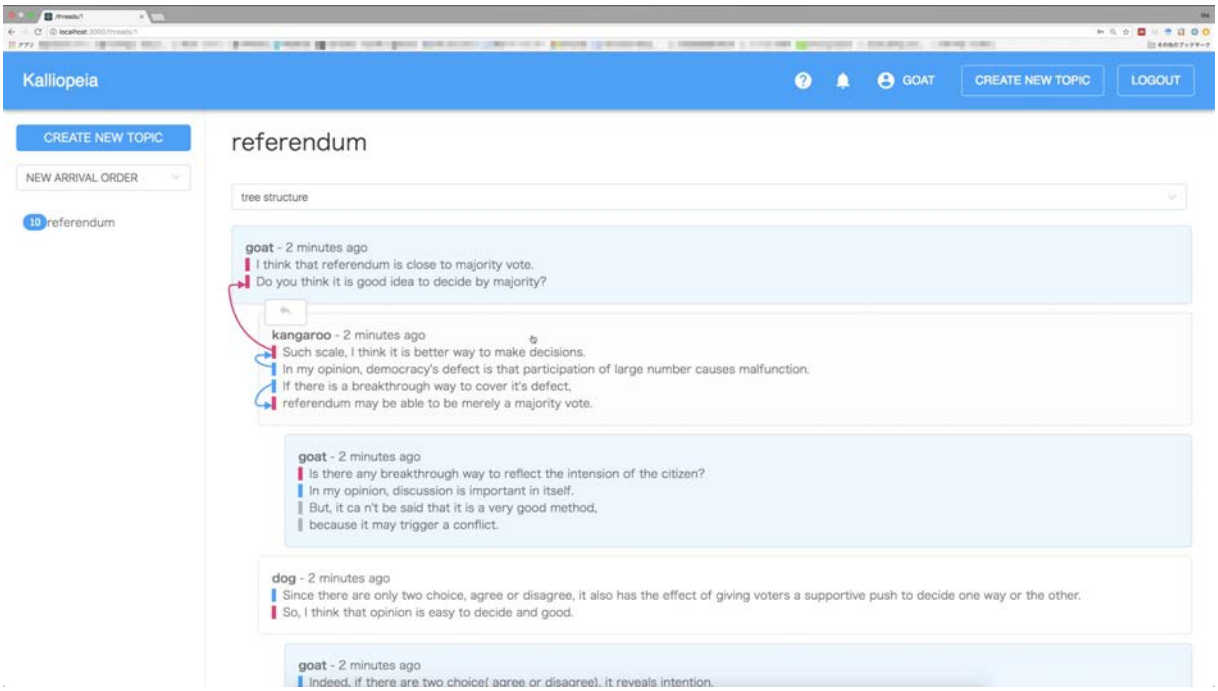

Figure 2: Thread view of our online forum. Arrows appear only when the cursor is placed above a post. The discussion was conducted in Japanese. Therefore, all posts are translated from Japanese into English; however, this forum can also support English discussions.

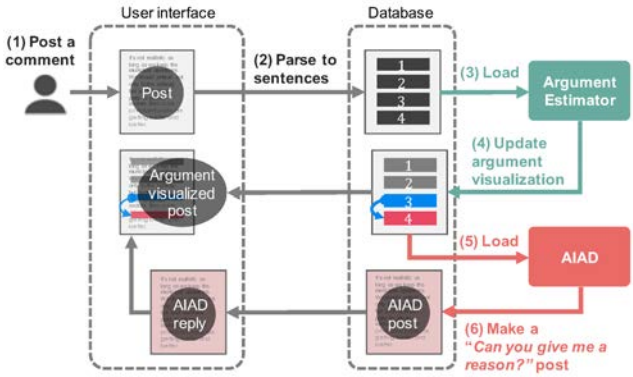

Figure 3: System Overview

out the proposition boundaries before using PCPA because PCPA assumes that propositions are given.[3] Hence, the task is considered to be a sequence tagging problem (this procedure corresponds to (2) in Figure 2). We exploit the bi-directional LSTM (BiLSTM) and conditional random fields (CRFs), which is commonly used for the argument mining task [1, 8]. After proposition detection, we employed PCPA in the same manner as in the Japanese discussion.

[3]This approach is not anomalous. Potash et al. [6] also provided the assumption that proposition boundaries are already given.

3.2 AIAD

According to the results obtained from the argument estimator, the AIAD module, in turn, generates a response to a participant to drill down the claim by inducing its premises behind a claim, forming a *Can you give me a reason?* sentence. The possible target sentence to which AIAD responds is determined using a simple rule-based technique. The target sentence should be in the newest post for each participant, and the following restrictions are considered based on our preliminary experiments.

- The target sentence should be a claim and have fewer than two premises.
- The target post is not a reply to the AIAD.
- The target post has more than one reply after the AIAD's comments.

We generate a comment by using a template-based technique. The comment comprise the target sentence (i.e., claim sentence), greetings, and *Can you give me an additional argument for your claim?* or *Do you have any premise or evidence for this claim?*, as presented:

> Thanks for your comment!
> >> "*the target claim sentence*"
> Do you have any premise or evidence for this claim?

When	Yes	Sometimes	No
creating an own claim	4	3	9
reading other posts	7	7	2
looking back a discussion	9	3	4

Table 1: Survey related to "When did you view the argument visualization in a discussion?"

Group	A		B	
Discussion topic	1-AIAD	2-Baseline	2-AIAD	1-Baseline
#Sentences per post	3.46	2.9	2.6	1.79
#Premises per claim	2.6	1.2	2.33	0.69
Premise (%) per post	61	54	48	27

Table 2: Statistics of the participant replies to AIAD

4 EXPERIMENTS

4.1 Experimental Setting

A total of 16 Japanese undergraduate students participate in the online discussion. The participants are randomly divided into two groups (i.e., "Group-A "and "Group-B "), and the participants in each group discussed the following two topics: The first is "Limitation of activity time of a club in middle and high schools in Japan," and the second is "Ban on agreement about the starting date of companies' recruitment activities in Japan." Further, we introduce the random-inducing agent as a baseline. This agent randomly chooses the target sentence from the last post of each participant. The AIAD joins the former topic discussion of Group-A and the latter topic discussion of Group-B. The random inducing agent joins the latter topic discussion of Group-A and the former topic discussion of Group-B. In addition, the participants do not know that the comments by the agents are automatically generated.

4.2 Experimental Result

Finally, 585 posts are submitted in the discussions. Based on the survey after the discussions, 14 of the 16 participants answered that our forum is accessible for discussions. Table 1 summarizes the effectiveness of the argument visualization. The table shows that the argument estimator is extensively used when the discussion flow is reviewed.

Figure 4 shows the representative of the AIAD's response post, which can capture the Squirrel's claim and induce the participant's premises. Table 2 summarizes the statistics of participant's replies to AIAD. It presents that the participant's replying posts to AIAD tend to contain a large number of sentences, including the premises.

5 DEMONSTRATION SCENARIO

In the demonstration, we will present how our online forum works for English users. Further, the online forum will be opened during the conference dates. We will show the argument visualization using the argument estimator and then immediately present the argument structures. In addition, the argument-inducing agent (AIAD) will ask *Can you give me an additional argument for your claim?* when the reasoning is insufficient. Generally, the actual discussions occur during the demonstration.

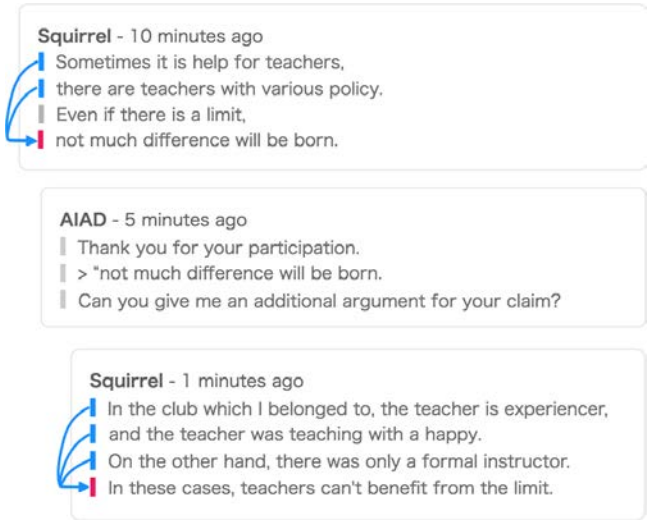

Figure 4: Post of AIAD, which successfully induced squirrel's premises. This discussion was conducted in Japanese language and then translated to English, as presented in the figure.

6 CONCLUSION

This paper presented a novel online discussion forum that can encourage participants and induce additional arguments by using argument visualization and an argument-inducing agent based on argument mining. The argument visualization subsystem visualizes the argument structures that contain claims, premises, and reasoning relations by using a state-of-the-art deep learning technique. The agent that employs a template-based technique induces the premises of their claims by replying to a participant when the premises in their comments are insufficient. The experimental results demonstrated that the AIAD is effective for inducing premises in online discussions. The future work involves proposing a more effective visualization method, thereby improving the template algorithms and a large-scale English discussion.

ABSTRACT

In the past few years, numerous privacy vulnerabilities have been discovered in the WiFi standards and their implementations for mobile devices. These vulnerabilities allow an attacker to collect large amounts of data on the device user, which could be used to infer sensitive information such as religion, gender, and sexual orientation. Solutions for these vulnerabilities are often hard to design and typically require many years to be widely adopted, leaving many devices at risk.

In this paper, we present UNVEIL – an interactive and extendable platform to demonstrate the consequences of these attacks. The platform performs passive and active attacks on smartphones to collect and analyze data leaked through WiFi and communicate the analysis results to users through simple and interactive visualizations.

The platform currently performs two attacks. First, it captures probe requests sent by nearby devices and combines them with public WiFi location databases to generate a map of locations previously visited by the device users. Second, it creates rogue access points with SSIDs of popular public WiFis (e.g. _Heathrow WiFi, Railways WiFi) and records the resulting internet traffic. This data is then analyzed and presented in a format that highlights the privacy leakage. The platform has been designed to be easily extendable to include more attacks and to be easily deployable in public spaces. We hope that UNVEIL will help raise public awareness of privacy risks of WiFi networks.

1 INTRODUCTION

Mobile devices like smartphones and tablets have become extremely popular over the past 10 years. Market research company Newzoo [11] reported that more than 3.3 billion smartphones and 230 million tablets were in use at the end of last year. WiFi is a core component of mobile devices, enabling them to connect to the internet. However, several vulnerabilities and design flaws have been discovered in WiFi protocols and their implementations over the years. These flaws can be exploited to track individuals [16] and to obtain sensitive information, such as religion, gender, and sexual orientation about them [1, 12].

Multiple experiments have been designed to illustrate the data leakage in WiFi networks. However, all previous approaches demonstrate specific vulnerabilities or require a user to install an application. Projects such as Wombat [8], Probr [15], and the Digital Marauder's Map [5] have demonstrated how WiFi can be used to track people's movements in real time. The Haystack Project [14] introduced an Android app to analyze mobile traffic and help individuals identify privacy leaks on their device. MITMProxy [3] is an open source and interactive HTTPS proxy that can be used to reverse-engineer installed applications and detect if any personal information is being leaked by the apps [2].

Our platform, UNVEIL, aims to raise awareness of the privacy risks of WiFi vulnerabilities through an interactive demonstration. The data is collected from nearby mobile devices (unless the owner opts out), analyzed, and the results can be viewed on installed screens. The platform modularity ensures that it can be deployed easily in public spaces like museums or train stations, making it accessible for general public.

UNVEIL currently supports two attacks:

- Generation of a map of locations visited by nearby mobile devices, using probe requests broadcasted by them;
- Profiling of users connected to our rogue access points, using the internet traffic generated by the device.

Neither attack requires users to download an app or perform any action. Moreover, the platform can be easily extended to include new attacks.

2 DATA

In this section, we describe in detail the types of data collected by UNVEIL.

2.1 Probe Requests

Probe requests are sent by WiFi-enabled devices to discover the surrounding available WiFi access points (AP). Discovering the network by scanning all possible channels and listening to beacons is not considered to be very efficient (*passive scanning*). To enhance

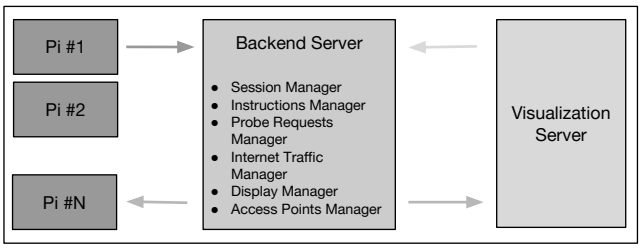

Figure 1: System architecture. UNVEIL has 3 components: Raspberry Pis, Backend Server, and Visualization Server.

this discovery process, devices often use what is called *active scanning*. In active scanning, a device still goes through each channel, but instead of passively listening to the signals on that frequency, they broadcast *probe requests* asking which known networks are available on that channel and receive responses from the APs. These probe requests contain the (possibly randomized) MAC address of the device along with the name of the AP (SSID) being probed. The device keeps a list of SSIDs of previously connected APs. We query publicly available WiFi Location databases to associate SSIDs with geographic coordinates [17, 18].

Some devices use randomized MAC addresses to prevent leaking location history through probe requests [9]. However, recent studies have shown that MAC address randomization policies are neither universally implemented nor necessarily addressing privacy concerns [7]. For instance, timing attacks such as the one described in [10] can be used to group together the probe requests (using different randomized MAC addresses) coming from the same device.

2.2 Internet Traffic

Typically, mobile devices are set by default to automatically connect to known WiFi SSIDs, without any interaction required from the user. UNVEIL creates rogue WiFi access points using popular public network SSIDs that many devices are likely to connect to. Internet traffic generated by any device connected to UNVEIL's access point is sniffed and recorded. The DNS and HTTP requests are analyzed to profile the user. The DNS requests made by the device contain the websites visited by the user and the applications they use. These might contain information allowing an attacker to infer sensitive user attributes such as gender, age group, sexual orientation, religion, mental health, race, and nationality. The HTTP requests, furthermore include the user agent, which often contains details regarding the device manufacturer, model, and version of the OS (see Fig. 3).

3 SYSTEM ARCHITECTURE

The UNVEIL platform is designed to be modular and easily extendable. It is structured into three main components: Raspberry Pis, a Backend Server, and a Visualization Server. Figure 1 shows a high-level representation of the architecture. Raspberry Pis are responsible for collecting the data. The Backend Server manages the Pis and analyzes the data. The Visualization Server runs the frontend component that retrieves the analysis results from the Backend Server and showcases them. The Visualization Server also provides the controller screen for managing the overall system. The communication between all the components takes place via the REST APIs.

3.1 Raspberry Pi

Raspberry Pis are responsible for collecting the WiFi data and for sending it to the Backend Server for analysis. The inbuilt WiFi antenna in the Pi is used to provide internet connectivity for the Pi itself, while an external USB antenna is used to collect the probe requests and make the rogue access point available.

Each Pi runs a Pi-Controller process that starts during the boot. This process runs two subprocesses in parallel. One subprocess checks and updates the state of the Pi every 10 seconds. State is represented by the mode, SSID and channel the external USB antenna is operating in. The other subprocess periodically requests the Backend Server for the instructions to be executed on the Pi and sends back acknowledgement on successful execution. The Pi-Controller maintains an extendable instruction set of operations that can be successfully executed on the Pi.

The Pi can operate external USB antenna in two modes: listening to probe requests or creating an access point depending on the instruction fetched from the Backend Server:

- *ProbeReq* - This mode is used while listening for probe requests. The operating channel changes periodically (every 5 seconds) to capture probe requests across all the commonly used channels (1, 6 and 11). SSID for the state is set to null in this mode.
- *AccessPoint* - In this mode, Pi creates an access point with the SSID and channel received from the Backend Server. It sniffs and collects all the traffic passing through, along with the MAC address of the device.

The Pi instruction set currently supports 5 operations:

- *Start ProbeReq*. Start the probe request collection.
- *Stop ProbeReq*. Stop the probe request collection.
- *Start AccessPoint*. Get an SSID and channel number from the Backend Server and create an access point.
- *Stop AccessPoint*. Stop the access point.
- *Stop All*. Stop the data collection process, if any.

Whenever any *Stop* instruction is executed, the collected data is sent to the Backend Server for analysis and is deleted from the Pi.

We use the Raspberry Pi 3B+[1] with external antenna USB WiFi adapter Alfa Network AWUS036NHA[2] and Kali Linux as the OS. The Pi-Controller provides various modules to control WiFi antennas. It is implemented in Python 3.6 and is designed to work on any device running Kali Linux with two wifi antennas. We use hostapd[3] and dnsmasq[4] to create access points and Wireshark to collect the data.

Figure 2: Visualization of the probe requests analysis. The top left corner shows the global map with markers denoting the location of all the observed SSIDs. The text in the center left contains geographic addresses of the SSIDs. The table on the bottom left displays the count of devices per manufacturer, with the most frequent ones at the top. The figure on the right contains the map of UK with the estimated count of the number of number of devices in each detected location. For privacy reasons, the numbers shown in this figure are fake. (Maps provided by ©OpenStreetMap [13])

3.2 Backend Server

The Backend Server is responsible for managing the demonstration, components, data, and analyses in the experiment (Fig. 1). Session Manager is responsible for starting, managing, and ending the demonstration session as well as archiving and cleaning the collected data once the session ends. Instruction Manager maintains a queue of instructions for each pi. The first instruction in the queue is sent when requested by the Pi. The queue is then locked for next 30 seconds or until the acknowledgment of successful execution is not received from the Pi. While the queue is locked, no instruction can be added during that interval. On receipt of successful execution, the instruction is removed from the queue.

Probe Requests Manager and Internet Traffic Manager are responsible for analysis of the captured probe requests and the internet traffic data. Probe Requests Manager associates each SSID with its geographic location (if available) and estimates a count of devices which are near the Pi and probing that SSID. Internet Traffic Manager analyzes the data generated by the devices connected to our rogue access points. All the analysis results for each session for each mode are stored in the database for visualization.

Display Manager is responsible for handling the communications with the Visualization Server. It manages the content to be displayed on the web browser based on the presenter's selections made through the control screen. The Backend Server is implemented in Python 3.6 using Django [4] and MongoDB [6].

3.3 Visualization Server

The Visualization Server is responsible for serving the web pages that visualize the results of data analyses and allow to control the demonstration. The control screen provides controls to start and stop the demonstration, display the live status of the Pis, and select which data to show on the visualization screens. The selected data is retrieved from the Backend Server for visualization.

Figure 2 illustrates the result of the probe requests analysis. The analysis shows the location of the captured SSIDs with the estimated count of the devices associated with those SSIDs.

Figure 3 shows the profile created for a connected user. Each user data is composed of 3 sections: Device Details, DNS Queries, and Internet Traffic. Device Details section displays the MAC address, manufacturer, model number, and OS of the device. DNS queries are used to identify which websites the user visited and which apps are running (including those in background). We filter out the common DNS queries (e.g. Whatsapp, Facebook, Google) to display user-specific ones. The Internet Traffic section is further separated into HTTP and HTTPS requests. HTTP requests reveal the complete URL of the request, which is shown in the visualization.

The control screen can be accessed on a browser, preferably on a laptop or a tablet. It provides buttons to start and stop the demonstration, select data to be visualized, and zoom in and out of the map illustrating the probe requests analysis.

Figure 3: Visualization of the connected users. The top section illustrates the retrieved mobile device details. The center section shows relevant DNS queries generated from the user. The bottom section shows the details of the internet traffic generated by the user. For privacy reasons, the data shown in this figure is fake.

The Visualization Server has been developed using ReactJS[5], Leaflet.js[6], and OpenStreetMap [13].

[5]https://reactjs.org/
[6]https://leafletjs.com/

3.4 Extending the Platform

The platform can be easily extended to demonstrate other data leakages in WiFi networks. The Pi instruction set can be appended with new instructions. These can be designed using the existing modules in Pi-Controller. Backend Server can be extended by adding new analysis managers which can use the available infrastructure of the database, session and instruction management, helping streamline the development and deployment process. A new web page can be added to the Visualization Server to show the analysis results and buttons can be added to the control screen for interacting with the display.

4 DEMONSTRATION

We demonstrate the platform by collecting data in real time and visualizing it. Mobile device users can interact with the geographic data using the buttons on the control screen, as well as try to infer characteristics of the profiled users from the collected data.

A session runs with only one Raspberry Pi collecting probe requests while other Pis operate as rogue access points posing as common UK public WiFis. We provide an option for the user to opt out by entering the MAC Address of their device on our website. Instructions to opt out are clearly publicized with posters around the demonstration space.

A live demonstration requires deploying Raspberry Pis around the space and at least two screens to view the results. Screens should be large enough (preferably 4K) for the audience to view the data. Control screen will be available on the tablet for the audience to zoom into the probe requests map, and see if the data from their smartphones is being captured. The users can also see if their phone has connected to our access points and what data has been collected. All the data (raw and results of analyses) are deleted at the end of each demonstration session.

The demonstration can be deployed in any public or closed space and only requires (wireless) internet connection, electricity supply for the Raspberry Pis, and two screens for visualization. Through this demonstration, we hope to show how sensitive individual-level data can be collected and processed with only £75 worth of hardware.

The platform will be open sourced before the demonstration, along with instructions to deploy and extend it. It will be made available at https://cpg.doc.ic.ac.uk/blog/unveil.

5 CONCLUSION

We have designed and developed a platform to demonstrate privacy attacks on mobile device WiFi. The platform can be easily deployed in public spaces to help raise awareness of the privacy risks in WiFi networks.

ABSTRACT

Containerized web-applications have gained popularity recently due to the advantages provided by the containers including light-weight, packaged, fast start up and shut down and easy scalability. As there are more than 267 cloud providers, finding a flexible deployment option for containerized web-applications is very difficult as each cloud offers numerous deployment infrastructure. Benchmarking is one of the eminent options to evaluate the provisioned resources before product-level deployment. However, benchmarking the massive infrastructure resources provisioned by various cloud providers is a time consuming, tedious and costly process and is not practical to accomplish manually.

In this demonstration, we present **Smart D**ocker **B**enchmarking **O**rchestrator (**SmartDBO**), a general orchestration framework that automatically benchmarks (deploys and executes) users' containerized web-applications across different cloud providers while meeting the constraints of budget and deployment configurations. SmartDBO aims to answer two questions: (i) how to automate the benchmarking of containerized web-application across multi-cloud environments?, (ii) how to maximize the diversity in a benchmarking solution which covers maximum numbers of cloud providers and types of provisioned infrastructures without exceeding users' budgets? We evaluate all the features of SmartDBO using SimplCommerce and TPC-W executing across Amazon AWS and Microsoft Azure.

CCS CONCEPTS

1 INTRODUCTION

Web-application have become an integral part of our life providing various functions including social networking, banking, e-commerce, etc. With the growing demand, these applications are becoming complex and follow multi-tier architecture, which makes it hard to develop, debug, deploy and upgrade [4]. However, microservices architecture brings a new approach to overcome the difficulty of developing this large software by breaking it into a suite of small, independent and versioned modular services [2, 9]. Evolution of container technology with different features including self-contained, light weight, fast start up and shut down, easy scalability, etc. provides great support for developing microserviced web-applications [8]. It allows each modular service of the complex web-application to be deployed as an independent containerized web-application. The containerized web-applications can interact with each other through Restful APIs and be easily deployed, upgraded and scaled.

Additionally, cloud has become the main infrastructure for the deployment of containerized web-applications. There are about 267 cloud providers which provide various computing resources for the containerized application using 3 main *Deployment Infrastructures (DI)*: Bare Metal (BM), Virtual Machine (VM) and Container Service (CS) [5]. Each type of DI has the variety of hosts either predefined by cloud providers or user customized. For example, Amazon EC2 provides different types of pre-customized hosts (VMs) for their customers along with the self customized hosts. In the rest of the paper, we use host to represent an instance of the DI. The containerized web-application can be deployed and executed on any type of host.

Various cloud providers provision heterogeneous hosts that may significantly affect the performance of web-applications, which has a strong impact on user satisfaction [3]. Thus, we need to benchmark the hosts before deploying the real applications [6]. Most of the research in benchmarking is focused on developing a better benchmark application in terms of reality of emulation, efficiency and scalability [1, 10]. The challenge of deploying a benchmark

for containerized applications across multiple clouds has not been well explored. If a user manually performs the deployment, it will be tedious, error-prone and requires a lot of time and expertise. Due to the fact that different cloud environments have different accessing schemes and different ways to interact, an orchestrator is desired that can automatically run the benchmark applications across multiple clouds, and collect the required system parameters while providing the flexibility for users to customize their experiment settings.

Previous benchmark frameworks from both academia [1, 7, 10] and industry[1, 2] mainly focus on VM based applications, which is not applicable for containerized web-applications. Also, the variety of cloud providers offer a massive configuration choices of host. For instance, Amazon EC2 provides 43 types of hosts for their customers[3] excluding self customized hosts. Thus, this poses another challenge for the proposed orchestrator, i.e., how to provide an optimized recommendation to help users in selecting the hosts from the provided clouds?

The aforementioned challenges discussed above can be resolved by answering the following research questions:

- *How to automatically orchestrate the benchmark applications across multi-cloud environments based on the user's specification?*
- *How to find an optimal set of hosts for benchmarking in a fixed budget that covers the diversity both within a cloud provider and among the cloud providers?*

To answer these questions, we developed SmartDBO that makes the following contributions:

- We developed a noble orchestrator, SmartDBO that automates the definition and execution of benchmarks for containerized web-applications. In particular, the orchestrator allows the user to choose the benchmark applications and hosts of DI across different cloud providers.
- SmartDBO also has a native feature of optimization that can maximize the utility of a user's budget by maximizing the number of cloud providers and the hosts of the DI.

To demonstrate the effectiveness of SmartDBO, we chose AWS and Azure as the cloud providers. TPC-W[4], a traditional web-application benchmark is used for testing and the workload for testing the benchmark application is generated by the Apache JMeter[5]. Moreover, our SmartDBO captures the live performance of the examined experiments and stores the results in the Database for further analysis and reporting.

2 SYSTEM OVERVIEW

This section discusses the architecture and the implementation details of SmartDBO.

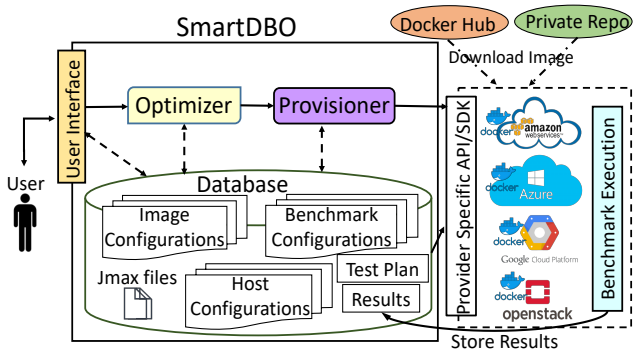

Figure 1: System Architecture of SmartDBO

2.1 SmartDBO Architecture

Figure 1 illustrates the architecture of SmartDBO and the dependencies of each component. SmartDBO is implemented as a web-application that provides a *User Interface* for users to interact, explore and manage their benchmarking experiments. The *User Interface* allows the user to choose an existing benchmark application or customize a new application. Moreover, users can select the available hosts from different cloud providers, define the benchmarking time for each selected host, and specify the total budget for running the experiments via the *User Interface*. Next, this configuration information is stored in a relational Database.

The *Optimizer* is designed to create an optimized host list based on the information provided by the user. It retrieves the necessary information (host configurations, time of benchmark and budget) from the Database and applies a heuristic algorithm to generate an optimized host list for running the benchmarking experiments. More details about the *Optimizer* are given in § 2.2. The generated host list is automatically stored in the Database. If the user chooses to execute the benchmark experiments, the *Provisioner* will be triggered to provision the resources, deploy the benchmark applications and execute the applications based on the user entered information and optimized host list. The benchmark is executed for the specified interval of time and the completion is notified to the *Provisioner*. The results are stored in the Database in real-time for further evaluation and analysis. Finally, the user is notified after completion of the experiment while releasing the cloud resources.

2.2 SmartDBO Implementation

The SmartDBO is mainly implemented by using *Microsoft ASP.NET Core 2.1 C#*[6] programming language. The *User Interface* is built using *CSS*, *JavaScript* and *HTML5* to ensure a good user experience. We aim to provide a unified interface for users to deploy their benchmark applications over multiple clouds, therefore hiding the difficulties of interacting with heterogeneous cloud APIs. Moreover, the SmartDBO also provides an optimized solution for users based on their budgets. These two main features are implemented in the modules of *Optimizer* and *Provisioner* and will be detailed as follows.

[6]https://docs.microsoft.com/en-us/aspnet/core/?view=aspnetcore-2.1

Optimizer. SmartDBO benchmarks containerized web-application in a multi-cloud environment. Let N represent the cloud providers $C_i | i \in \{1, N\}$ where each provider C_i has T type of hosts $v_{i,t} | t \in \{1, T\}$. In our evaluation, we assume a one-to-one mapping between host and container. Consider $C(v_{i,t})$ to be the unit cost of using $v_{i,t}$, $\tau_{i,t}$ is the time units for which $v_{i,t}$ is chosen to run and $\mathcal{B}$ is the user budget for the benchmark, finding an optimal set of hosts for the benchmarking is modeled as a Binary Integer Linear Programming problem (BILP). The defined objective function is shown below,

$$\textbf{maximize:} \sum_{\mathbf{i,t}} \mathbf{x_{i,t}} + \lambda\{\sum_{\mathbf{i}}\{\sum_{\mathbf{t}} \mathbf{x_{i,t}} - \mathbf{T}\}\}$$

where $x_{i,t} | x_{i,t} \in \{0, 1\}$ is a binary variable which represents whether $v_{i,t}$ is selected or not. The first factor of the optimization problem is to comprehend maximum selection of hosts and the second considers a penalizing factor to boost the spanning of the maximum number of cloud providers. λ is a tunable parameter which is incorporated to maintain a balance. There are certain constraints associated with the objective function as given below.

$$\sum_{i,t} C(v_{i,t}) \times \tau_{i,t} \leq \mathcal{B} \tag{1}$$

$$\forall i \forall t \; x_{i,t} \in \{0, 1\}, x_{i,t} = \begin{cases} 1, & \text{when VM, } V_{i,t} \text{ is selected} \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

$$\forall i \forall t \; \tau_{i,t} \geq 0 \tag{3}$$

$$\forall i \; \sum_{t} x_{i,t} \geq 1, \; \forall t \; \sum_{i} x_{i,t} \geq 1 \tag{4}$$

Constraint (1) states that the total cost of benchmarking different containers running inside the host must be less than the defined budget. Also, the cost is calculated only if a host is selected as specified by the constraint (2). Constraint (3) represents variable stability constraints while constraint (4) enforces the selection of at least one cloud provider and at least one host configuration.

We developed and implemented a heuristic algorithm for *Optimizer* to solve the problem formalized above. The algorithm selects an optimized list of hosts while satisfying all the defined constraints. The source code and the implementation details of *Optimizer* is available as an open-source project on github[7]. The advantage of *Optimizer* for selecting hosts in both multi-cloud and single cloud is illustrated in Figure 2. The results show that the solution generated from the *Optimizer* covers more types of host in both single cloud and multi-cloud scenarios, compared to the case of random host selection with a given budget.

Provisioner. Once the *Optimizer* generates a benchmark plan, the user can decide whether he/she wants to submit the plan for execution via the user friendly web interface. If the user agrees to perform the experiment, the functions implemented in *Provisioner* will be triggered. First, the *Provisioner* will check the connection and the requirement of the resources on different clouds. Next, it uses a background process application, Hangfire[8], to create and launch the hosts on the selected cloud providers.

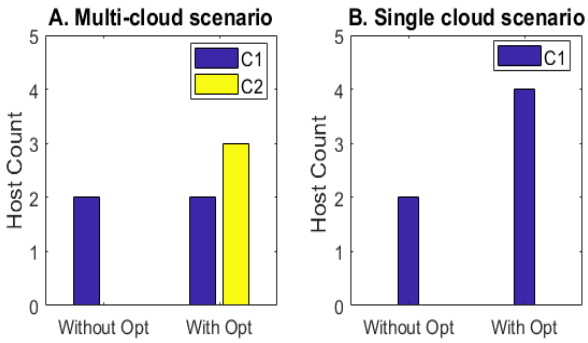

Figure 2: Showing advantage of Optimizer

3 DEMONSTRATION

In this section, we will walk through the execution workflow of SmartDBO by showing the benchmarking of a sample e-commerce web-application, SimplCommerce[9]. The SimplCommerce application is configured with 50 test products to replicate a small real-life e-commerce store.

3.1 Experiment setup

SmartDBO. The proposed orchestrator is implemented in C# language which can be executed in a variety of environments e.g. Linux, Windows, MacOS. In this demonstration, we run our orchestrator on a Lenovo PC with Intel(R) Core(TM) i5-6200U CPU @2.3GHz - 2.4GHz with a memory 16 GB and storage of 512 GB SSD. The system is installed with 64 bit Windows 10 operating system. We execute SmartDBO using Visual Studio 2017[10] IDE. It is open-sourced and the current version of code along with samples and installation details are available on github[7].

Required open-source tools. In this demonstration, we utilized a popular benchmark application called TPC-W[11] to emulate the activities of a sample e-commerce web application. The load on the web-application is created by Apache JMeter[12] according to the test plan defined by the user. To emulate real traffic, JMeter is not configured on the same cloud where the benchmark applications are running. PostgreSQL Database[13] is associated with SmartDBO, and stores different host, benchmark and image configurations for setting up the experiments in real-time.

Cloud providers. We deployed our containerized benchmark application on AWS and Azure with different host configurations. In this demonstration, we use VM as the default host configuration. SmartDBO can provision any types of VMs which are available on the subscribed cloud providers.

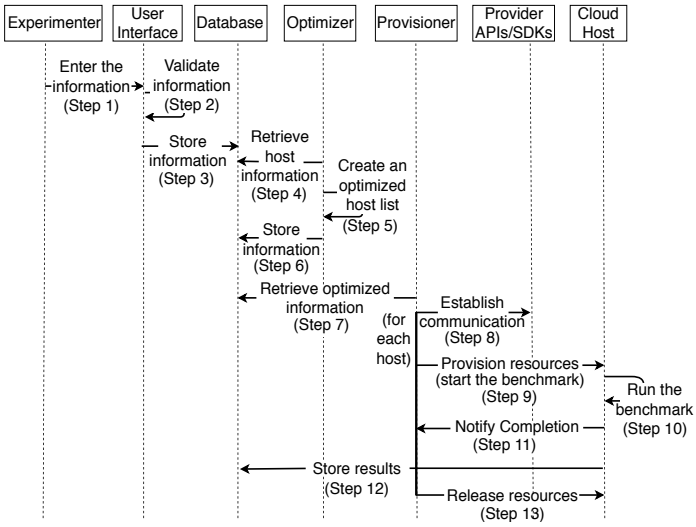

Figure 3: SmartDBO Execution Workflow

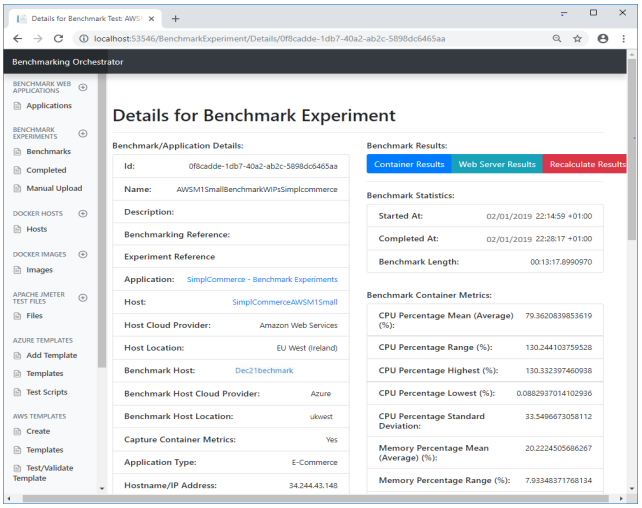

Figure 4: SmartDBO Execution Interface

3.2 The execution workflow

In this subsection, we use an example to demonstrate the process of orchestrating a benchmark application as shown in Figure 3.

Define the benchmark application. At the beginning, SmartDBO is designed for benchmarking different types of web-application. The application is defined in terms of a web-application image and a JMeter workload image using the interactive *User Interface* as depicted in Step 1 of Figure 3. The images are referred from Docker hub or other private repository or created using the provided template. For the demonstration, we create an application using SimplCommerce and a JMeter docker image.

Define the host configuration. When we decide the benchmark application, our SmartDBO allows us to define the host configuration to run the benchmark application. The *User Interface* allows us to choose a name, description, host type (application/benchmark) and cloud-specific (e.g. credentials, template) information as shown in Step 1. It also provides the HTTP and TLS authentication to guarantee secured communication.

Define the test plan. SmartDBO allows us to define the workload using a test plan where we can provide the JMX file for continuous workload generation. New test plans can be easily added by filling the template provided by the framework (Step 1). The plan includes all the parameters for JMeter to generate a continuous load for benchmarking the web-application.

Define the benchmark experiment. Once we have the benchmark application and hosts configured, we can set the whole experiment for performing the benchmarks. Then, we define the benchmark experiment which maps the load generator to the benchmarking host. To this end, we pair a load generator with the host running the benchmark web-application. Along with this, we can specify the execution time and the budget for executing the experiment. The entered data is validated (Step 2) after which it is stored in the Database (Step 3).

Perform optimization. The *Optimizer* retrieves the input host information from the Database (Step 4) to generate an optimized host list for the execution (Step 5). At the same time the optimized host list is stored in the Database (Step 6).

Execute the benchmark. *Provisioner* retrieves the optimized host list from the Database (Step 7), we can then start to execute the experiment. First the communication with the cloud host is established using the provider specific APIs/SDKs (Step 8) and then resources are provisioned for benchmarking (Step 9). The *Provisioner* is notified of the completion (Step 11) and the result is stored in the Database (Step 12) for visualization and further analysis. The experiment result provides different performance metrics including benchmark statistics (e.g. started at, benchmark length), benchmark container metrics (e.g. CPU percentage mean, CPU percentage range, memory percentage mean, network input total, network output total), benchmark web-server metrics (e.g. throughput, average response time, number of requests, number of errors, average latency) and Apdex rating (Apdex count, Apdex rating, Apdex satisfied count,). Finally, the resources are released (Step 13).

Figure 4 shows the overview of a successful execution of TPC-W benchmark using SimplCommerce web-application executing on AWS and Azure, with the obtained result.

Report the result. The benchmark execution results can be easily visualized using the *User Interface*. There are multiple options to report the results in different formats including on-screen, csv file, excel sheet, pdf for further analytics.

The complete demonstration explained here is available as a screencast video on YouTube [14].

ABSTRACT

With the rapid development of location-based social networks (LBSNs), point of interest (POI) recommendation has become an important way to meet users' personalized demands. The aim of POI recommendation is to provide personalized recommendation of POIs for mobile users. However, traditional POI recommendation systems cannot satisfy users' personalized demands. The reason is that the traditional POI recommendation system cannot recommend the next POI to a user based on the user's context information. Also, the traditional POI recommendation system provides no real-time guarantee on performance. In this demo, we propose a novel real-time next POI recommendation system named R2SIGTP which provides more personalized real-time recommendation compared with existing ones. Our system has the following advantages: 1) it has real-time performance; 2) it uses a unified approach to integrate geographic and preference information; 3) it considers the feedback of each single user to provide more personalized recommendation. We have implemented our system. R2SIGTP is easy to use and can be used by the mobile terminal's browser to recommend the next POI to the user in real-time based on the automatically identified user location and current time. The experimental results on real-world LBSNs show that R2SIGTP's performance is satisfactory.

1 INTRODUCTION

POI recommendation is one of the most important tasks in LBSNs, which helps users discover new interesting locations in the LBSNs. POI recommendations using users' check-in history are often influenced by multiple factors such as geography, time, sequence, etc. Geographical influences are the most essential feature that distinguishes POI recommendations from traditional recommendations. Since a user's check-in behavior presents a spatial clustering phenomenon, geographical influence can be modeled by power law distribution[5], Gauss distribution, Poisson distribution, and kernel density estimation[6]. Temporal influence in a POI recommendation system performs in two aspects: periodicity and non-uniformness. And the sequential influence[7] is the result of the interaction of temporal periodicity, adjacency of POIs in geographical space, property of POIs and human habits. At present, most existing POI recommendation systems use the methods based on content, link analysis[1], collaborative filtering[8] or matrix factorization[2] in the recommendation process.

Although POI recommendation system has achieved great success, there are still many challenges for it. 1) Most existing POI recommendation systems use offline modeling and online recommendation system architecture. As the system runs, a large amount of incremental data is generated in real-time. To take advantage of these incremental data, the system must recompute the offline model of the system, which is very time consuming and can seriously affect the operation of the online recommendation. Obviously, this strategy is not suitable for frequent updates and affects the

accuracy of the recommendation system. 2) The user-POI check-in matrix is extremely sparse compared to the user-item matrix of the traditional recommendation system. Because the total number of POIs is quite large, and the number of POIs visited by a single user is very small. 3) Users' reviews are direct feedbacks to POI recommendation results. For a specific POI, most existing POI recommendation systems provide a general solution for all the users by analyzing all the corresponding reviews. Thus, it cannot provide personalized feedback for each single user. 4) Most existing POI recommendation systems integrate multi-aspect informations of check-ins. However, they do not construct a unified recommendation process to integrate these informations, that is, the implicit correlations between the various informations are ignored. 5) Most existing POI recommendation systems use Euclidean distance. This leads to deviations in actual applications and makes POI recommendation systems inaccurate.

Aiming to solve the aforementioned problems, a real-time personalized next POI recommendation system R2SIGTP was designed. R2SIGTP utilizes multi-aspect informations to model user temporal preferences. According to the current location of a user and time , R2SIGTP recommends the next POI which the user is most likely to access. R2SIGTP has the following advantages:

- It leverages a scalable parallel incremental approach to model users' check-in history, making the system real-time scalable.
- It classifies the POIs into users' preferences and uses the preferences to model users' check-in history such that the sparsity of check-in data can be overcome.
- It provides personalized feedback for each single user by using convolution neural network(CNN) to analyze the users' reviews.
- According to users' choices, it integrates geographic and preference information into the unified recommendation process.
- It effectively reduces the deviations by using road network distance for POI recommendation.

2 SYSTEM ARCHITECTURE

In this section, we introduce the architecture and background technologies of R2SIGTP. The architecture of R2SIGTP is shown in Figure 1. The detailed description is as follows.

2.1 User Temporal Preference Modeling

User temporal preference modeling is an important part of the system. The accuracy of users' preferences predicted in different time slots determines the accuracy of our system.Our system uses tensor to model user temporal preference for the following reasons:1) tensor is typically used to recover the missing/sparse data through tensor decomposition; 2) another usage of tensor is to isolate and analyze the patterns hidden in a dataset. Next, we will show the details of tensor construction and decomposition.

Tensor Construction: We define a 3 order-tensor $\chi \in \mathbb{R}^{I \times J \times K}$ to model user temporal preference, where I, J and K denote the size of user, time and preference dimension, respectively. Each entry of the tensor $\chi(i, j, k)$ is a sum of check-in frequencies of all the POIs which belong to preference k and are visited by user i in the time slot j. Note that we divide everyday into 6 time slots (i.e.

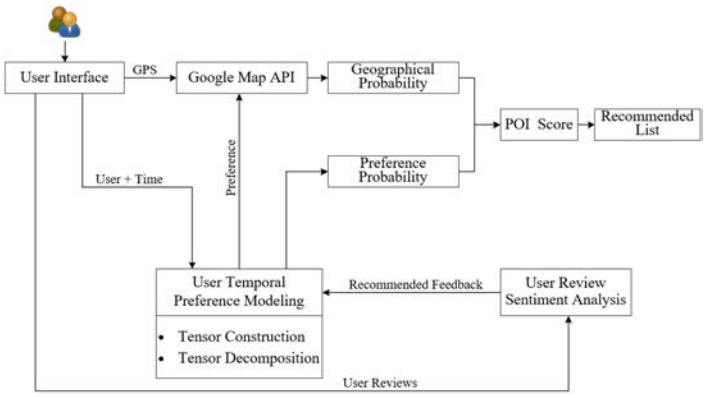

Figure 1: Architecture of R2SIGTP

0:00-7:00, 7:00-9:00, 9:00-12:00, 12:00-14:00, 14:00-18:00, 18:00-0:00). Accordingly, a week is divided into 42 time slots. Each of time slots is represented by a Time ID. In particular, we select preferences instead of the venues used in most tensor models as a dimension, which can greatly overcome the sparsity of check-in data. Because the amount of POIs in the real world is enormous, but only a few hundreds of preferences can describe our real life in detail.

Tensor Decomposition: After the tensor is modeled, our task is to infer missing entries in the tensor. We can extract the latent features of each user, time slot and preference by decomposing the tensor χ into three matrixes A, B, C and a core tensor G. As is shown in Equation (1).

$$\chi \approx G \times_1 A \times_2 B \times_3 C = \sum_{p=1}^{P} \sum_{q=1}^{Q} \sum_{r=1}^{R} g_{pqr} a_p \circ b_q \circ c_r \qquad (1)$$

Here, $A \in \mathbb{R}^{I \times P}$, $B \in \mathbb{R}^{J \times Q}$, and $C \in \mathbb{R}^{K \times R}$ are the factor matrices. $G \in \mathbb{R}^{P \times Q \times R}$ is the core tensor. There are many methods for tensor decomposition. For our system, as a large number of users continue to access POIs, incremental data will continue to emerge. So our tensor is not static. This requires a fast and scalable tensor decomposition method for parallel processing of incremental data. Our system uses the Sambaten method [3] for tensor decomposition, which allows our system to update the user temporal preference model frequently without interrupting recommendations. Therefore, our system has real-time performance.

2.2 User Review Sentiment Analysis

Sentiment analysis of users' reviews requires knowledge in the natural language processing (NLP) field. Deep learning technology in the field of NLP has shown strong effectiveness for the reason that it satisfies various requirements such as multilayer classification representation and feature representation learning.

Our system uses CNN to analyze the users' reviews in TensorFlow. First, we do data preprocessing. The dataset our system used contains 9566 POI review sentences, half positive and half negative. Next, we construct the model(CNN). The first layer embeds words into low-dimensional vectors. The next layer performs convolutions over the embedded word vectors using multiple filter sizes. We

max-pool the result of the convolutional layer into a long feature vector, add dropout regularization, and classify the result using a softmax layer. For details, please refer to Yoon Kim's article[4].

2.3 POI Score Calculation

Generally speaking, there are two main factors considered by users when choosing a POI, preference factor and geographical factor. Specifically, the preference factor denotes the probability of the activities to be chosen by a user in a certain time slot, and the geographical factor represents the influence of distances between the prefer POIs and the user's current location. Therefore, we define POI score as follows:

$$S_{POI} = \alpha * P_p + \beta * P_G \qquad s.t. \quad \alpha + \beta = 1 \tag{2}$$

where, S_{POI} denotes the POI score, P_p is the preference probability, P_G represents geographical probability. α, β are the weights which reflect the priority of preference and geographic factors. Priority can be chosen by the user himself. After obtaining the score of each POI, we will arrange them in a decreasing order and generate a recommendation list for a user. Next, we will show the details of preference probability and geographical probability.

Preference Probability: Given a particular user i and a specific time slot t, we obtain a preference vector $v_{i,t}$ through the approximate tensor $\hat{\chi}$ constructed in subsection 2.1. Normalize $v_{i,t}$ to get $v'_{i,t}$, and each entry $v'_{i,t,j} \in v'_{i,t}$ represents the probability of each preference j which is chosen by the user i in the time slot t.

Geographical Probability: In order to improve the accuracy of the recommendation results, our system uses road network distance instead of Euclidean distance. In reality, Euclidean distance cannot represent the actual distance between two locations. Consider two locations at the two sides of a river, the Euclidean distance is small but the road network distance is relatively large. Arrange entries of $v'_{i,t}$ in a descending order, we select the first x preferences with positive value in $v'_{i,t}$. Then, for each preference, we employ Google Map API to search the corresponding POIs around the user's current location and calculate the road network distances between these POIs and the user's current location. After normalized distance of these POIs, we can generate the geographical probability.

2.4 Recommended Feedback

Users' reviews are the most direct feedback to the POI recommendation results. Most previous systems only provide a binary decision (positive or negative) for a particular POI by analyzing the reviews of all the users. However, such approach is unfair for some users because the analysis results only reflect the preference of the majority and ignore some users with opposite opinions. Therefore, our system focuses on each single user and provides a feedback to the temporal preference model by analyzing his personal reviews, leading to a more personalized recommendation results.

Without loss of generality, a user's review of a POI k would affect the probability of the preference which the POI k belongs to. Thus, our system iteratively adjusts $v'_{i,t,j}$ according to the review of user i to a POI k which belongs to preference j by using Equation (3).

$$v'_{i,t,j} = v'_{i,t,j} \times (1 + s_k * \gamma) \tag{3}$$

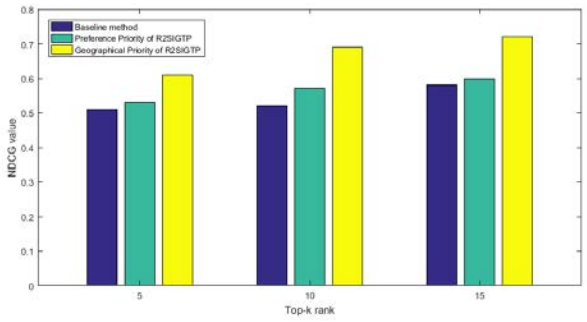

Figure 2: Performance of R2SIGTP and baseline method

where, s_k represents the result of a sentiment analysis of the user i to the POI k and γ is the tuning parameter. When the adjustment is finished, the vector $v'_{i,t}$ is normalized again.

3 EVALUATION

3.1 Dataset and Parameters

We use a collection of Foursquare check-ins of New York lasting for about 11 months (from 8 January 2012 to 27 December 2012). In order to make the recommendation results more accurate, we filter out noise and invalid check-ins. Our dataset contains 238972 check-ins, 37628 venues, and 300 preferences. Based on a lot of experimental tests and data analysis, the parameters of our system are determined as follows:

- $\alpha = 0.7, \beta = 0.3$, if preference is preferred by a user.
- $\alpha = 0.3, \beta = 0.7$, if geography is preferred by a user.
- γ is fixed to 0.1.

3.2 Baseline Method

Our system could provide more personalized POIs recommendation for each single user. The main reason is that our system integrates geographic and preference information into a unified recommendation process. To evaluate the effectiveness of R2SIGTP, we choose the baseline method as a comparison. The baseline approach also takes into account preference and geographical factors, but it does not integrate these two factors into a unified recommendation process. More specifically, the baseline method first ranks the recommendation POIs according to the preference ranking of the user's in current time, and then sorts POIs that belong to the same preference in ascending order of their distance from the current location.

3.3 Recommendation Results Evaluation

In order to accurately evaluate the final recommendation result, R2SIGTP and the baseline method use the same dataset. We selected 200 users to evaluate the performance of the two methods. We generate a Top-k (k=15) recommendation list for every recommendation of each user. We choose Normalized Discounted Cumulative Gain(NDCG) as an evaluation metric to evaluate the performance of the two methods. NDCG is widely used to measure ranking algorithms. Figure 2 shows the NDCG value of R2SIGTP and the baseline method. Since priority can be selected by users in

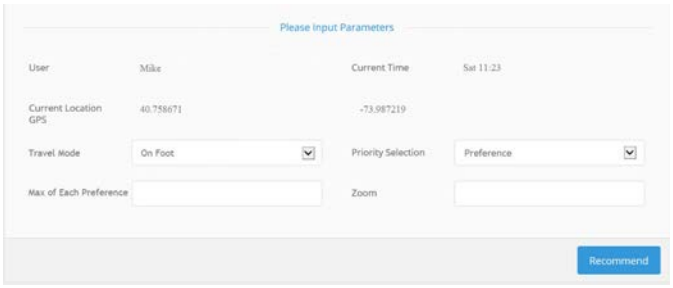

Figure 3: Start page of R2SIGTR

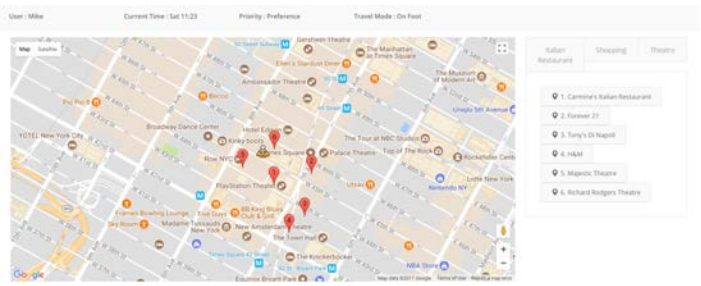

Figure 4: Interface of R2SIGTP

R2SIGTP, we compare the baseline method with R2SIGTP which selected preference priority and geographical priority, respectively. From the results, we can observe that R2SIGTP with preference priority is slightly better than the baseline method, and R2SIGTP with geographical priority is significantly better than the baseline method. This is because R2SIGTP with preference priority is more similar to the baseline method. When R2SIGTP meets the requirements of users to select geographical priority, the baseline method is powerless for users' requirements. Figure 2 demonstrates the final recommendation results of R2SIGTP.

4 DEMONSTRATION

R2SIGTP is composed of a browser frontend and a server backend. The web server is deployed with Apache Tomcat and PHP. Users can use R2SIGTP through a browser on any Internet-enabled terminal.

We show the start page of R2SIGTP in Figure 3. User column needs to fill in a user's account. R2SIGTP can automatically identify the current time and the user's current location and display it in the corresponding position. Priority(preference or geography) and travel mode(on foot or vehicle) can be selected by users. Max of each preference column is used to set the maximum recommended number of POIs for each preference. Zoom column is used to set the scale of the map.

After a user has completed filling and setting, the interface will change to another layout as shown in Figure 4. The user information, the current time, the priority and the travel mode are displayed at the top of the interface. Our system will set different search range for users according to different travel mode. For example, search range of on foot mode is small, and search range of vehicle mode is large. The map which can be zoomed in/out by a user is displayed in the middle of the interface. The map shows the current location of the user and the POIs in the recommendation list. Clicking on each POI on the map will present the corresponding introduction. The right side of the interface shows the top N1 (N1=3 here) preferences and the corresponding recommendation list in current time which shows the top N2 (N2=6 here) POIs.

5 CONCLUSION

In this demo paper, we present a novel real-time recommendation system called R2SIGTP to make next POI recommendation. Compared to the existing systems, our system could provide more personalized POIs recommendation for each single user. The main reason is that our system integrates geographic and preference information into a unified recommendation process. Furthermore, our system also considers the feedback of each single user to adjust the corresponding recommendation. The experimental results show the effectiveness of our system.

ABSTRACT

Data analytics is central to modern online services, particularly those data-driven. Often this entails the processing of large-scale datasets which may contain private, personal and sensitive information relating to individuals and organisations. Particular challenges arise where cloud is used to store and process the sensitive data. In such settings, security and privacy concerns become paramount, as the cloud provider is trusted to guarantee the security of the services they offer, including data confidentiality. Therefore, the issue this work tackles is *"How to securely perform data analytics in a public cloud?"*

To assist this question, we design and implement SGX-PySpark– a secure distributed data analytics system which relies on a trusted execution environment (TEE) such as Intel SGX to provide strong security guarantees. To build SGX-PySpark, we integrate PySpark - a widely used framework for data analytics in industry to support a wide range of queries, with SCONE - a shielded execution framework using Intel SGX.

1 INTRODUCTION

Cloud-based services are used to collect, process and analyze large amounts of user's personal data, some of it highly sensitive, such at that relating to personal finances, political views, health, and so forth. Indeed, we have seen increasing attention of regulators on issues regarding the way in which personal data is handled and processed - the EU's General Data Protection Regulation a case in point. Thus, confidentiality and integrity of the data processing in clouds are becoming more important, not least because of increased demands for accountability regarding service providers, and the potential serious legal consequences (and fines) for the data mishandling, mismanagement and leakage, and more generally, for failing to implement the appropriate security measures [9]. Service providers must ensure that data is always protected, i.e., at rest, during transmission, and computation. Many organisations make use of public cloud services for the processing to reduce time and computation cost. This setting is vulnerable to many security threats, e.g., data breaches [10]. Concerns are compounded when we consider attacks from inside the cloud provider, where attackers might have root privileges and/or physical access to machines deployed at the service providers' premises. Therefore, to protect the sensitive data and the analytics computation over the data, service providers cannot rely solely on the operating system access control nor their security policy-based mechanisms.

An promising approach to helping resolve these security challenges is to make use of Trusted Execution Environments (TEEs), such as Intel Software Guard Extensions (SGX). Intel SGX protects the confidentiality and integrity of application code and data even against privileged attackers with root access and physical access. In general, Intel SGX provides an isolated secure memory area called *enclaves*, where the code and data can be executed safely. These security guarantees are solely provided by the CPU, thus even if system software is compromised, the attacker can never access the enclave's content. This approach supports data analytics at processor speeds while ensuring the security guarantee for both computation and sensitive data.

While promising at first glance, to build a practical secure data analytics system using TEEs, e.g., Intel SGX, we need to deal with several challenges. ($\mathcal{A}$) In the current version, Intel SGX supports only a limited memory space (~ 94MB) for applications running inside enclaves. Meanwhile, most big data analytics systems (e.g., Hadoop and Apache Spark [1]) are extremely memory-intensive, since these systems are almost always based on Java Virtual Machine (JVM). ($\mathcal{B}$) Intel SGX still suffers from side-channel attacks [12]. These side-channel attacks happen both at memory level [12, 16] and network level [16]. ($\mathcal{C}$) Deployment and bootstrapping of a data analytics framework to run inside enclaves is not trivial, in fact, challenging. Securely transferring configuration secrets such as certificates, encryption keys and passwords to start the framework inside enclaves is complicated because these secrets need to be protected on the network as well as securely moved into the enclaves. ($\mathcal{D}$) Typically, Intel SGX requires users to heavily modify the source code of their application to run inside enclaves. Thus, transparently supporting a unmodified distributed data analytics framework to run inside enclaves is not a trivial task.

In the context of building secure data analytics systems using Intel SGX, VC3 [13] is one of the first works that applied SGX technology for Hadoop MapReduce framework. VC3 handles challenges

($\mathcal{A}$) and ($\mathcal{D}$) by using C/C++ to implement the framework and support unmodified Hadoop. However, the challenge ($\mathcal{B}$) is outside the scope of this work. Recently, Opaque [16] overcomes this issue by introducing a oblivious mechanism to hide access patterns at network level. Opaque provides secure data analytics on Apache Spark framework using Intel SGX. It deals with ($\mathcal{A}$) by reimplementing SQL operators for Spark SQL Catalyst engine [6] using C++. These operators run inside enclaves and communicate with Scala code of Spark using a JNI interface. Opaque supports common operators including map, reduce, filter, sort, aggregation, and join, but not all operators of Apache Spark. This means that it does not handle the challenge ($\mathcal{D}$) completely. In addition, it does not support *remote attestation* to verify the integrity of the code running inside SGX enclaves. It also does not handle the challenge (C) since it does not provide a secrets transferring mechanism for execution inside enclaves. Finally, Opaque requires to run Spark master/driver at client side or in a trusted domain. This might affect significantly the performance of the system.

In this work, we overcome these limitations by building a secure data analytics system called SGX-PySpark. We handle the challenge ($\mathcal{A}$) by using PySpark [3], a system built on top of Apache Spark to support data analytics using Python processes. Instead of running a whole JVM inside an enclave to secure Apache Spark or reimplementing operators in C/C++ as Opaque, we run only Python processes inside enclaves since these processes perform analytics over encrypted data. Thus, our system supports out-of-the-box operators of PySpark (the challenge ($\mathcal{D}$)), i.e., users do not need to modify their source code. To run Python processes inside Intel SGX enclaves, our system makes use of SCONE [4, 7] a shielded execution framework which enables unmodified applications to run inside Intel SGX enclaves.

In addition, SGX-PySpark, with the help of SCONE, supports a remote attestation mechanism to ensure the code and data running inside enclaves are correct and not modified by an attacker. SGX-PySpark also copes with challenge (C) by providing a mechanism to securely transfer secrets (keys and certificates) to Python processes running inside enclaves. To handle challenge ($\mathcal{B}$), SGX-PySpark protects its execution against side channel attacks at memory level using a mechanism integrated with SCONE, called Varys [12]. Finally, the design of SGX-PySpark allows users to run the Spark driver/master in the same infrastructure as workers.

2 BACKGROUND

2.1 Intel SGX

Intel SGX is an ISA extension which is a set of special CPU instructions for Trusted Execution Environments (TEE). These instructions enable applications to create *enclaves* – protected areas in the applications address space to provide strong confidentiality and integrity guarantees against adversaries with privileged root access. Intel SGX enables trusted computing by isolating the environment of each enclave from untrusted applications outside the enclave. In addition, by offering the remote attestation mechanism, Intel SGX allows a remote party to attest the application executing inside an enclave [8].

The enclave memory is acquired from Enclave Page Cache (EPC)—a dedicated memory region protected by an on-chip Memory Encryption Engine (MEE). The MEE transparently encrypts cache lines on cache-line evictions and decrypts and verifies cache lines with on cache-line loads. The EPC cannot be directly accessed by non-enclave applications including operating systems. To support multiple enclaves on a system, the EPC is partitioned into 4KB pages which can be assigned to various enclaves. Currently, the size of EPC is limited to 128MB in which only ~ 94MB can be used for user applications and the rest is used to store SGX metadata. Fortunately, SGX supports a secure paging mechanism to an unprotected memory region even though the paging mechanism may introduce significant overheads.

The EPC is managed as the rest of the physical memory by an operating system (or a hypervisor in virtualized environments). The operating system makes use of SGX instructions to allocate and free EPC pages for enclaves. In addition, the operating system is supposed to expose the enclave services (creation and management) to applications. Since the operating system cannot be trusted, the SGX hardware verifies the correctness of EPC pages allocations and denies any operations that would violate the security guarantees. For example, the SGX hardware will not allow the operating system to allocate the same EPC page for different enclaves.

2.2 SCONE

Our system builds on SCONE [7] – a shielded execution framework to enable unmodified applications to run inside SGX enclaves. In the SCONE platform, the source code of an application is recompiled against a modified standard C library (SCONE libc) to facilitate the execution of system calls. The address space of the application stays within an enclave, and the application only can access the untrusted memory via the system call interface.

SCONE uses the compiler-based approach to prepare and build native applications for executing inside SGX enclaves. SCONE applies its mechanism into GNU Compiler Collection (GCC) tool-chain to change the compiling process such that it can build position independent, statically linked code, and eventually linked with the starter program. Therefore, SCONE natively supports C/C++ applications. For Python applications e.g., PySpark executors, we need to compile the CPython/PyPy interpreter with SCONE to run these Python processes inside SGX enclaves. Similarly, to run a Java application inside an enclave, we compile JVM with SCONE.

2.3 PySpark

PySpark is built on top of Apache Spark [1] to provide the Python API for users. Thus, before explaining PySpark, it is useful to understand what is Apache Spark. Apache Spark [1] is an open-source large-scale data analytics framework. Today, it has become the most popular and widely used big data framework in both academia and industry. Comparing to earlier frameworks such as Hadoop MapReduce, Spark is much faster in processing large-scale datasets since it enables the in-memory computing concept where intermediate data is cached in memory to reduce latency [11].

For the in-memory computation, Spark introduces the core abstraction – Resilient Distributed Datasets (RDDs) [15] for distributed data-parallel computing. An RDD is an immutable and fault-tolerant

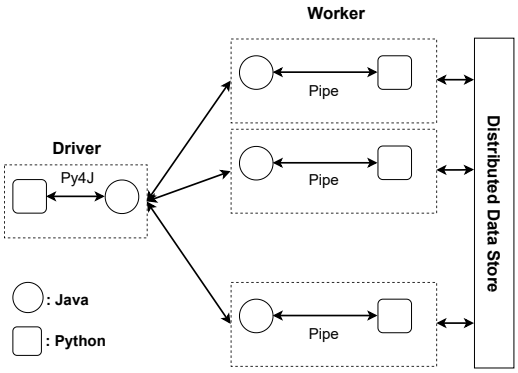

Figure 1: PySpark's architecture.

collection of elements (objects) that is distributed or partitioned across a set of nodes in a cluster [1].

RDDs support two types of operations: `transformations` and `actions`. Transformations return a new RDD, such as *map()* and *filter()*, and actions are operations performed on RDDs that return the output to the driver program or store it in a persistent storage system (e.g *reduce()*, *count()*, *collect()*, *saveAsTextFile()*, etc). Transformations are performed lazily, i.e., they are computed whenever an action operation is invoked [11].

In a deployment, Spark contains a main program called *driver* which coordinates the processes (tasks) executed in other nodes (i.e., workers) in a cluster. When a Spark application is submitted to the driver, it will split the job into tasks and perform scheduling to dispatch tasks to workers. The workers then spawn processes (called *executors*) to handle received tasks.

Since Python supports powerful libraries such as scipy, numpy, scikit-learn, and pandas with a simple and concise syntax, it is a favorite language of data scientists. For that reason, PySpark has been proposed as a Spark programming model to Python. Figure 1 shows the high-level architecture of PySpark.

PySpark extends the Spark runtime to enable executing Python programs on top of Spark. Typically, a PySpark job (a Python process) is submitted, and a JVM is started to communicate with the Python process using Py4J [2]. The Python process creates a *SparkContext* object in the JVM and the SparkContext orchestrates the computation as the regular Spark framework (to reuse almost the same Spark infrastructure). However, the difference is that in PySpark, the executors are Python processes. Each Python process (per CPU core) takes care of the execution of the assigned tasks. Each worker (JVM-based program) submits received tasks to the pool of Python processes and communicates with them using Pipes. The Python processes perform the computation and store back resulting data to an RDD (as pickle objects) in the JVM.

3 SGX-PYSPARK

Our idea to design SGX-PySpark— a secure distributed data analytics system using Intel SGX, is quite simple. We execute only sensitive parts, i.e., the computation parts that process the input sensitive data, inside enclaves. The computation parts outside of enclaves can only access encrypted data. In general, we first encrypt the input data and upload the encrypted data into a distributed storage in an untrusted infrastructure (e.g., a public cloud). Thereafter, SGX-PySpark decrypts and processes the encrypted data inside enclaves in a distributed manner.

Figure 2 illustrates SGX-PySpark's architecture. SGX-PySpark consists of two main components: *(i)* Configuration and attestation service (CAS) component and *(ii)* PySpark with integration with the SCONE library to run inside enclaves. SGX-PySpark maintains the native layout of PySpark (see §2.3).

To secure data analytics computations on top of PySpark, SGX-PySpark runs the driver and the Python processes inside Intel SGX enclaves using the SCONE library. We need to ensure the confidentiality and integrity of the driver, since it is responsible for splitting and scheduling tasks in the system. We protect the Python processes since they are the sensitive computation parts since they directly decrypt and process the input data. Note that in SGX-PySpark, we encrypt not only the input sensitive data but also the computation over it (Python code of analytics jobs).

3.1 Trusted Enclave-based Driver

In PySpark, when we submit a job, the Python driver program makes use of Py4J to start a JVM (Spark driver) and create a JavaSparkContext. This JavaSparkContext orchestrates the job as a regular Spark framework. The JVM-based process takes the responsibility to convert a submitted job into tasks. In detail, it first converts the logical DAG of operations in the submitted job into a physical execution plan, i.e., it divides the DAG into a number of stages. Thereafter, it divides these stages into smaller tasks. Next, the Spark scheduler distributes these tasks to executors (Python processes) deployed on worker nodes for execution (see §2.3).

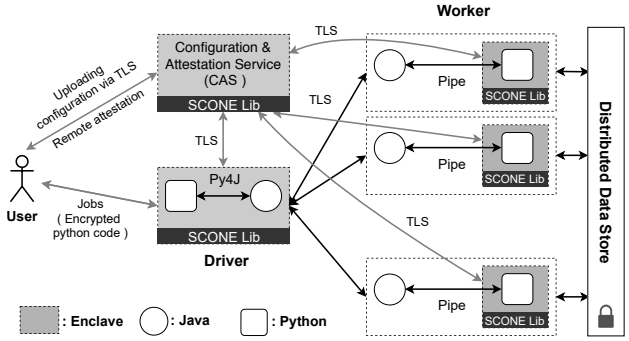

Figure 2: SGX-PySpark's architecture.

To provide secure data analytics, we need to protect the driver as it is the command center of the whole system. To achieve this, in SGX-PySpark, we recompile JVM running in the driver node with the SCONE library to execute the whole driver inside an SGX enclave.

3.2 Trusted Enclave-based Executors

To execute the analytics job (Python code), PySpark launches Python processes (worker processes) and communicates with them using pipes to transfer the user-specified Python code and processed data. Since these Python processes interact directly with the input

data, we protect them against malicious activities, i.e., ensure the integrity and confidentiality by running them inside enclaves with the help of the SCONE platform. Note that, in SGX-PySpark both input data and computation (Python code) are encrypted before upload to the system. They are decrypted inside enclaves using keys transparently obtained from CAS (see §3.3).

3.3 Configuration and Remote Attestation Service

In SGX-PySpark, we need to make sure that the shared secrets such as certificates, passwords to start PySpark, or keys for encrypting/decrypting the input data and computations can never be revealed to untrusted components. Furthermore, we need to securely transfer these secrets to the driver and executors (Python processes) running inside enclaves (see challenge (C) in §1). To achieve these goals, we extend SCONE with a configuration and attestation service (CAS) that transfers security secrets only to the components that have authenticated themselves successfully against it. CAS enhances the Intel attestation service [8] to bootstrap and establish trust across the machines running SGX-PySpark and maintain a secure configuration for the system. In detail, CAS remotely attests the driver and worker processes of PySpark running inside enclaves, before providing encryption/decryption keys and other configuration parameters. CAS is itself launched inside an SGX enclave. A user of SGX-PySpark, first encrypts the input data and his data analytics job and then uploads the secrets (cryptographic keys) and system configurations to CAS. A basic implementation of CAS is presented in [14]. In addition, to guarantee the correctness of computation in SGX-PySpark, we design and implement an auditing service in CAS to keep result logs during runtime. This auditing service protects our data analytics system against rollback attacks.

3.4 Network and File System Protection

File system shield. To protect integrity and confidentiality of the Python codes and the sensitive input data stored on disk, we design in SGX-PySpark a file system shield using SCONE library. In the case SGX-PySpark would write computation results to a file, the shield encrypts the contents before writing. The shield ensures the integrity of these files by keeping their metadata inside CAS (see §3.3). The keys to encrypt the computation content are different from the secrets used by the SGX implementation. They are instead a part of configuration that is uploaded to CAS by users at the startup time of the data analytics system.

Network shield. In SGX-PySpark, to protect the confidentiality of secrets transfered from CAS to computation components running inside enclaves, we need to protect the network communication between CAS and the components to make sure that an attacker cannot observe the network traffic to steal the secrets. To achieve this security requirement, we enhance SGX-PySpark by designing the network shield that wraps the communication between our system components in TLS connections and ensures that all data passes to the connection and is TLS-encrypted. The certificates for TLS connections are saved in a configuration file protected by our file system shield.

4 DEMONSTRATIONS

In this section, we demonstrate how a user can securely perform data analytics using SGX-PySpark[1]. For demonstration purposes, we consider a simple and classical workload of "wordcount". Assume that the user wants to perform data analytics (e.g. wordcount) over a sensitive input data.

4.1 Protecting Data

A straightforward way to securely process the input data is that the user encrypts the data before uploading it to an untrusted domain such as a public cloud. In this demo, we show that this mechanism is not enough to protect secrets inside the input data, since the user needs to decrypt the encrypted data and then process it in memory; an attacker, especially attackers with privileges, can just dump the memory content to steal the secrets. In SGX-PySpark, the input data is encrypted using the file system shield, and then decrypted and processed inside SGX enclaves which cannot be accessed even by strong attackers with root access.

4.2 Protecting Computation

When the user submit a job (Python code) to the system, an attacker might learn what kind of computation the user wants to perform. We show in this demo that by using SGX-PySpark, the user can further encrypt his computation using the same file system shield before uploading to the untrusted domain (e.g., a cloud) for execution. The secret key for decryption is transferred into executors running inside SGX enclaves using the same mechanism as in §4.1.

4.3 Benchmarks

Beside the wordcount workload, we also make use of a standard data analytics benchmark (i.e.,TPC-H [5]) to demonstrate that SGX-PySpark supports a wide range of queries as native PySpark. Figure 3 presents the latency comparison between SGX-PySpark with native PySpark in processing TPC-H queries. The performance overhead incurred when running Python processes inside enclaves is not significant compared to the native PySpark. The reason for this is that the main overhead of SGX-PySpark is introduced by communication between Python processes and JVMs in workers.

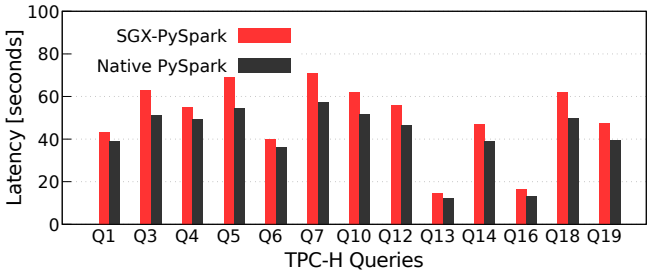

Figure 3: TPC-H benchmark.

ABSTRACT

TweetSenti is a system for analyzing the sentiment of an entity in tweets. A sentence or tweet may contain multiple entities, and they do not always have the same sentiment polarity. Therefore, it is necessary to detect the sentiment for a specific target entity. This type of target-dependent (entity level) sentiment analysis has become attractive and has been used in many applications, but it is still a challenging task. TweetSenti employs a new approach for detecting the entity level sentiment. Our model splits a sentence into a left context and a right context according to the target entity, and it also exploits two different types of word embeddings to represent a word, the general word embedding and the sentiment specific word embedding. A hybrid neural network is used to capture both the sequence and structure information of the two sides of the target entity. The sequence information is learned by attention-based bi-directional LSTM models. The structure information is captured by multi-context CNN models. Based on this algorithm, we built a web-based application that users can interact with and analyze an entity's sentiment in Twitter at real-time.

1 Introduction

With the permeation of social media in our lives, people are expressing their opinions about basically everything on social media platforms, such as Twitter, Facebook and Reddit. Sentiment analysis for entities, such as people, organizations, and products, has applications in various areas. Companies want to find out what consumers think of their products, brands, services or competitors. In public actions, it can be used to analyze online reactions to social and cultural phenomena. In politics, we can use it to keep track of society's opinions on politicians, the government, policy changes, or to predict election results.

There have been many studies on message or sentence level sentiment classification. Traditional sentiment classification approaches use sentiment lexicons to generate various features. Pang et al. [11] treat sentiment classification as a special case of text categorization. Many studies follow Pang's approach by designing features and applying different learning algorithms on them [4, 6, 10]. Feature engineering plays an important role in sentence sentiment classification [9]. Deep learning has also been used in sentence level sentiment analysis, mainly by exploiting word embedding [1, 8].

An entity in a sentence (post or tweet) does not necessarily have the same polarity type as the sentence, and different entities in the same sentence may have different polarities. For example, in the sentence of "*Farmers like Trump more than Hillary*", the two entities, *Trump* and *Hillary*, will have different sentiment polarities. There are some studies on entity level sentiment prediction [5, 2, 3, 14, 15, 18, 17] in the last several years. Jiang et al. [5] use both entity dependent and independent features to assign sentiment polarity to entities. By using POS features and the CRF algorithm, Mitchell et al. [7] identify polarities for people and organizations in tweets. Dong et al. [2] apply adaptive recursive neural network on the entity sentiment classification. The above two approaches use syntax parsers to parse tweets to generate features. Vo and Zhang [15] use target dependent and independent features, and also features based on lexicons.

Compared to the basic LSTM algorithm, TD-LSTM from [13] improves the sentiment classifier performance by treating an entity as a target. TC-LSTM from [14] extended TD-LSTM by adding target representations, which are word vectors, into the input of the LSTM cell unit. Several studies also explored applying attention mechanism with LSTM, and it has shown performance improvement [3, 16, 17, 18]. Wang et al [16] propose an attention-based LSTM model, ATAE-LSTM, and their experiment shows that attention mechanism is effective. The approach from [3] tries to enhance the attention-based LSTM by exploiting syntactic information to construct a syntax-based attention model.

In our TweetSenti system, we employed a new approach to address this problem. The main difference between our approach and previous studies are as follow: First, previous studies exploit only LSTM (with or without word attention), which captures mainly the sequence information of a sentence. Our approach uses a hybrid approach, which captures both the sequence and structure information of a sentence by integrating the attention-based bi-directional LSTM with the multi-context CNN model. Second, The context of an entity will affect its polarity, and usually an entity has a left context and also a right one. In our approach, we split a sentence into a left context and a right context according to the target entity, and we capture both contexts and also the whole sentence which captures the interaction between the left and the right context, through the multi-context CNN network structure. Third, previous studies use only the general word embedding (WE), such as embedding from word2vec [8] or C&W [1], to represent a word. Our approach uses not only WE but also the sentiment specific word embedding (SSWE) to represent a word.

In the demonstration, we will provide a highly interactive session, in which the audience can interact with the web application of our system. Several scenarios will be demonstrated.

2 TweetSenti System

In the following two subsections, we first describe the high-level workflow of TweetSenti, and then introduce how we build the entity sentiment classification module that supports the system.

2.1 TweetSenti Workflow

Figure 1 shows the high-level workflow of this application. We briefly introduce some of its components below.

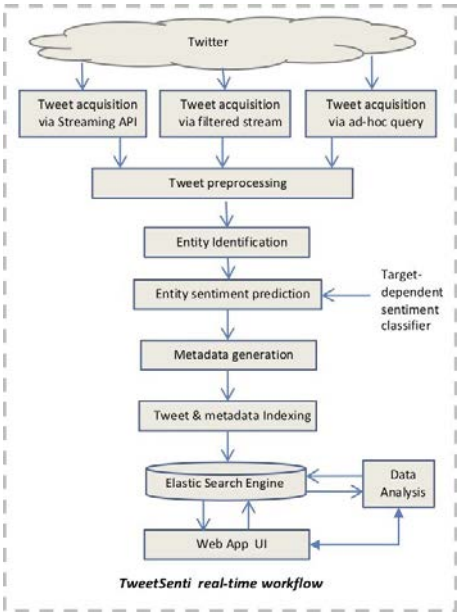

Figure 1: The high-level system real-time workflow

Tweet Acquisition. This system has three channels to acquire tweets from Twitter, all at real time. The main approach is through the Twitter streaming API, and this is done by our backend streaming tool at real-time. The second approach is via the filtered stream, which acquires tweets by monitoring a list of keywords, such as names of companies and political figures. These keywords can be modified at any time, and the system will make changes accordingly. Finally, users can submit queries via the system interface, and TweetSenti will retrieve related tweets on the fly from Twitter.

Tweet Preprocessing. In order for the sentiment classifier to predict the sentiment polarity for an entity, some preprocessing steps are necessary, such as normalizing numbers, and removing URLs and retweet mentions.

Entity Identification. To recognize entities from a tweet, we use TweetNLP package [20]. Some necessary preprocessing steps for entity identification is done by this package itself.

Entity Sentiment Prediction. For each entity extracted by the entity identification module, we use our entity sentiment classifier to predict its sentiment polarity. The polarity value and other metadata will be analyzed and presented to users by TweetSenti.

Metadata Generation. Some metadata are extracted or created in this step, and they will be displayed on UI or used for other analysis. For example, the tweet creation time is extracted and used for displaying the creation time, and generating the sentiment trending chart as well.

Data Indexing. A retrieved tweet and the generated metadata from it by the above components are ingested into an Elastic Search engine cluster (ES) [21] and indexed. We chose ES because it provides all the functions our application needs, and it has good scalability and reliability.

Data Analysis. This module is to analyze the data indexed and stored in the ES engine, and it also generates related information for TweetSenti to present them on the UI. For example, given a set of tweets talking about Trump, this model calculates how the sentiment for *Trump* have changed over a given period of time, and it also identifies a list of terms associated with the positive tweets and negative tweets. These information will be presented to users.

2.2 Entity Sentiment Classification Module

Figure 2 shows the construction process of the entity sentiment classification model. The following three subsections describe the three main components in the classification model construction process: the word embeddings, the framework of the classifier, and how the classifier is the trained.

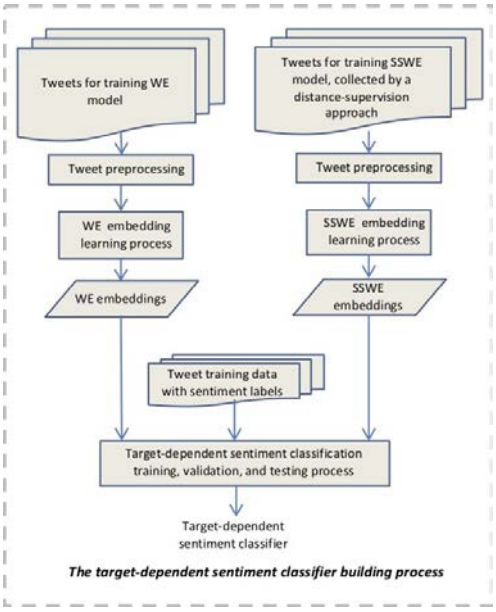

Figure 2: The classification module construction process

2.2.1 Word Embedding.:As mentioned before, we concatenate the WE embedding and the SSWE embedding together to represent a word.

WE model. The general embedding of a word captures both the syntactic structure and semantics of the word. Traditional bag-of-words and bag-of-n-grams hardly capture the semantics of words. Word embedding has been used in many NLP tasks. word2vec [8] is used in our algorithm to generate the WE embedding. About 200 million tweets were collected from Twitter to build the embedding model. A total of 3 billion words were processed, and the embeddings were generated for 3.5 million unique terms. The embedding size, window size and word count threshold were empirically set as 300, 8 and 5, respectively. Appropriate preprocessing steps are conducted on each tweet before it is fed into the learning process, such as removing URLs, normalizing numbers, etc.

SSWE model. SSWE extends the C&W model [1] by incorporating the sentiment information into the neural network to learn the embedding; it captures the sentiment information of sentences as well as the syntactic contexts of words [12]. Given an original (or corrupted) n-gram and the sentiment polarity of a tweet as input, it predicts a two-dimensional vector *(f0, f1)*, for each input n-gram, where *(f0, f1)* are the language model score and sentiment score of the input n-gram, respectively. The training objectives are twofold: the original n-gram should get a higher language model score than the corrupted n-gram, and the polarity score of the original n-gram should be more aligned to the polarity label of the tweet than the corrupted one. The SSWE model was built from tweets using a distance-supervision approach, which uses emotion symbols to determine if a tweet is positive or negative. If the tweet contains one of the following positive symbols, it is treated as a positive tweet: *:) :-) =) :D ;)*. And it is negative tweet if it contains one of these symbols: *:-(:(=(;(*. Eventually, a total of ten million tweets were collected from Twitter, where 5 million of them contain positive emotions and the other 5 million contain negative ones. Mentions and URLs were removed from tweets. The embedding size, window size and word count threshold were empirically set as 50, 3 and 2, respectively [12].

2.2.2 The Classification Model To exploit both the sequence information and structure information of a sentence, we use a hybrid neural network, which combines the attention-based bi-directional LSTM and multi-context CNN models. The high-level network structure is shown in Figure 3. In Figure 3, R_F and R_B are the two attention-based LSTM vectors, learned from the forward and backward information, respectively. Given a target entity in a sentence, we split the sentence into two contexts: its left context and its right context. The target term is also included in each context . This is based on the assumption that the sentiment toward the target is decided by both contexts, and treating them separately will give us more information undiscovered before. C_{left} is the vector learned from the left context by a CNN model, and C_{right} is the vector learned from the right context also through a CNN model. C_{all} is generated from the whole sentence, which reflects the interaction between the left and right contexts of the entity. We concatenate these five vectors together, forming a vector V: $V = [R_F, R_B, C_{left}, C_{right}, C_{all}]$. Then, this vector is fed to the fully connected hidden layers, and a softmax layer is used to predict the sentiment polarity.

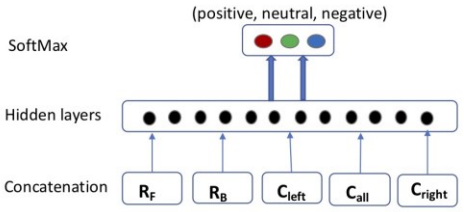

Figure 3: The high-level model structure

2.2.3 Model Training. Because our system works on Twitter, we use tweets to train and build our model. We combine two data sets together. The first data set is from Dong et al. [2014]. This data set was manually annotated with three sentiment polarity labels (positive, neutral and negative) toward target entities. It has 6248 training tweets and 692 testing tweets, with a balanced number of positive, negative, and neutral tweets (25%, 25%, and 50%, respectively). Dong et al. [2014] report that the data set was annotated with 82.5% inter-subject agreement among annotators. This data set has been used in many previous studies. The second data set is from SemEval 2017. It has a total of 50,333 tweets, with 19,902 positive tweets, 22,591 neutral, and 7,840 negative ones [19]. Combining two data sets gave us more training data.

Like previous studies, we use three-fold validation to tune our model and hyper-parameters. Stochastic gradient descent, AdaDelta update, shuffled mini-batch, back-propagation and dropout are used. The WE and SSWE embedding were fine-tuned during the training process of our hybrid neural network. Based on the validation result, we set the feature map (filter) width of

the three CNN layers as 2 and 3, the number of feature map as 300, and batch size as 30.

To see how our model works compared to other methods, we conducted an experiment and compared it to two state-of-the-art entity level sentiment prediction algorithms, AB-LSTM2 from Yang et al. [18], which is an attention-based LSTM approach, and LSTM+SynATT+TarRep from He et al. [3], which is also a variant of the attention-based LSTM model. The result shows that our model slightly outperformed these two methods, with about 3% performance increase, using F1 measure that has been used in previous work [2, 5, 14, 17].

3 System Demonstration

We will provide a highly interactive demonstration, in which the audience can interact with the web application of our system. The following three scenarios will be demonstrated:

#1. A user can input a tweet, or just a sentence, and the system will extract all the entities from the text, analyze their sentiment, and display their sentiment scores. It will also show the sentiment difference between a specific entity and the tweet, i.e. entity level vs. tweet level sentiment.

#2. Our system is connected to Twitter's real-time streaming data. We will demonstrate the real-time sentiment change for some popular people and entities in some hot events that will be happening during the conference period, to make the demonstration more interesting.

#3. Users can also provide an entity (e.g. person, organization), and the system will retrieve the related tweets from the data sources described above. These tweets will be analyzed and the sentiment analysis is conducted for the provided entity at real-time. It will also show the sentiment trending change.

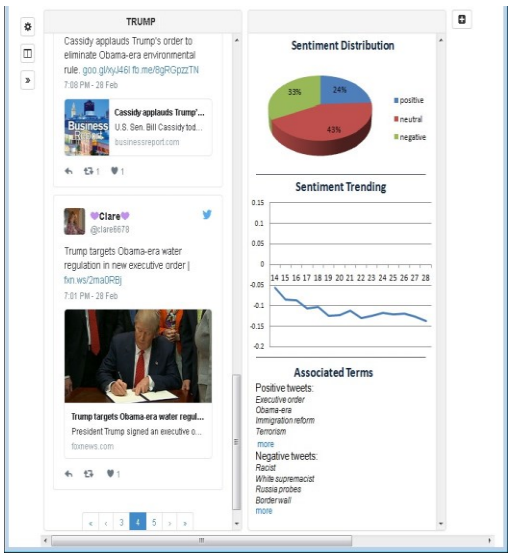

Figure 4: A screenshot showing the sentiment analysis results for "Trump". The panel on the left displays the related tweets, and the one on the right presents the sentiment analysis.

An example of scenario #3: Figure 4 shows how it works for scenario #3 mentioned above. In this example, "*Trump*" is the entity name input by a user. Our system gets the tweets related to Trump from the data sources described before, analyzes their sentiments toward *Trump*, and presents both the tweets and the sentiment analysis result in this window. This screenshot has two panels. The one on the left displays the tweets containing term Trump, and the one on the right presents three types of sentiment analysis results. The top one has a pie chart showing the sentiment distribution of all the tweets collected for *Trump* during the specified time period. Sentiment trending is displayed in the middle of this panel. It shows how the sentiment for *Trump* changed over this period of time. Our sentiment prediction algorithm can output a probability value for each polarity, which is a real number. The value for each day is the average sentiment value of all the related tweets from that day for *Trump*. At the bottom of the panel, it shows a list of terms associated with positive tweets and negative tweets. They are ordered by the strength of their association with the polarity type. By clicking the + icon at the top right corner of this window, one can add more panels to show sentiment analysis for multiple entities in the same window. If we change the time range to minutes or hours, and the "Auto Update" is set as On, we can see the sentiment information displayed in the right panel changing dynamically, as new tweets are being processed at real-time. To get the demo scenario #1 mode, users can click the setting icon at the top left corner and make corresponding changes.

ABSTRACT

Squerall is a tool that allows the querying of heterogeneous, large-scale data sources by leveraging state-of-the-art Big Data processing engines: Spark and Presto. Queries are posed on-demand against a Data Lake, i.e., directly on the original data sources without requiring prior data transformation. We showcase Squerall's ability to query five different data sources, including inter alia the popular Cassandra and MongoDB. In particular, we demonstrate how it can jointly query heterogeneous data sources, and how interested developers can easily extend it to support additional data sources. Graphical user interfaces (GUIs) are offered to support users in (1) building intra-source queries, and (2) creating required input files.

CCS CONCEPTS

1 INTRODUCTION

During the last four decades, a variety of data storage and management techniques have been developed in both research and industry. Today, we benefit from a multitude of storage solutions, varying in their data model (e.g. tabular, document, graph) or their ability to scale storage and querying. There are dozens of continuously evolving storage and data management solutions; for the NoSQL family,

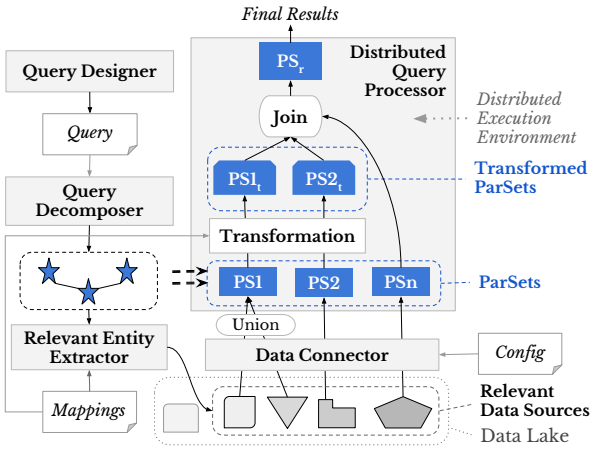

Figure 1: Squerall High-level Architecture.

Cassandra, MongoDB, Couchbase, HBase, Neo4j, DynamoDB, are just a few examples. As a result, users can choose a system that suits their individual application needs.

However, those systems do not inter-operate, every stored datum is locked in the respective system it is stored in. For example, an e-commerce company might store *product* information in a Cassandra database, *offers* in MongoDB to benefit from its capability to store hierarchical multi-level values, and information about *Producers* obtained from an external source in a relational format. Without transforming and moving the data into a unified (scalable) data management solution, the data can hardly be explored and business insights be extracted using ad hoc uniform querying.

We have taken on the mission of bridging this gap and developed Squerall[1], a software that allows to query heterogeneous data directly in its original form and source. We have used standardized and time-proven Semantic Web techniques to enable the uniform querying of heterogeneous data. We support the mapping of terms in the original data to terms in higher-level ontologies, and the querying of the resulting uniform view using SPARQL [13].

Similar efforts to integrate and query large data sources exist in the literature. For instance, [4] defines a mapping language to express access links to NoSQL databases. [12] allows to run CRUD operations over NoSQL databases. [1] proposes a unifying *programming* model to directly access databases using *get*, *put* and *delete* primitives. [8] proposes a SQL-like language containing invocations

[1]Associated website: <https://eis-bonn.github.io/Squerall/>

to the native query interface of relational and NoSQL databases. [7] is a hybrid platform with consideration for both heterogeneous and dynamic data sources (streams). However, Squerall offers the highest number of supported data sources while providing the richest query capability, including joining, aggregation and ordering.

We demonstrate Squerall's ability and efficiency in querying five different data sources (namely: CSV, Parquet, Cassandra, MongoDB and MySQL), and how it can be easily extended to support additional data sources, through several application scenarios.

2 PRINCIPLES AND ARCHITECTURE

In this section we introduce the basic principles and terminology needed to understand the architecture, subsequently described.

- **Mappings:** Squerall implements the so-called Ontology-Based Data Access (OBDA) [11] paradigm. In OBDA, data schemata are mapped to higher-level ontologies, forming a middleware against which SPARQL queries are posed. For example, *Offers(published, closed)* is a MongoDB collection mapped as follows: *(published → bsbm:validFrom, closed → bsbm:validTo, Offers → bsbm:Offer)* with *bsbm:validFrom*, *bsbm:validTo* and *bsbm:Offer* are two properties and a class of the BSBM ontology, respectively. Mappings are a core component of OBDA systems. Therefore, in order for every data source entity (Cassandra tables, MongoDB documents, etc.) to be queried using Squerall, having a mapping is a prerequisite.
- **Distributed Query Execution:** In Squerall, queries are executed in a separate distributed *environment*, which is, in particular, resilient to faults (node failure does not halt the entire query execution), and elastic and horizontally-scalable (more nodes can be added to accommodate more expensive computations). This is required for the following reasons:

- As we are dealing with dispersed data sources, intra-source query execution does not happen locally, but has to be brought into a more resilient, elastic and distributed environment, e.g. HDFS [3], or Spark's RDDs [14]. An exception is when certain sub-queries can be pushed down to the original source, which reduces what is loaded into the query execution environment.
- As we are dealing with large data volumes, query execution cannot be delegated to a single machine, as the intermediate results can overflow both its storage and computational capacity.
- In many modern NoSQL databases, in order to guarantee query performance, certain traditional query operators, e.g., join [10] are dropped. Such missing operations have to be executed in a higher-level capability environment.

- **Enabling joinability:** As data from different sources, e.g., *Product* and *Producer*, is generated by different applications, they may not be able to be readily cross-joined. Thus, modifications on the possible join values ought to be incorporated, e.g., to enable *Product* to join with *Producer*, modify `Product.producer_id` attribute values.

Squerall is comprised of five components (see Figure 1):

(1) **Query Decomposer:** Validates and analyzes SPARQL queries provided by a user. Particularly, the Query Decomposer extracts the Basic Graph Pattern (BGP, i.e., the conjunctive set of triple patterns given in the `where` clause) of the query and decomposes it into star-shaped sub-graph patterns having the same subject, *stars* for short. This component also detects links between stars, e.g., the triple `?product bsbm:producer ?producer` represents a link between the two stars represented by the variables `?product` and `?producer` (e.g., see colored boxes in Figure 1).

(2) **Relevant Entity Extractor:** Each star is analyzed separately; this component searches in the mappings for entities that are mapped to every predicate of the star. For example, given the graph pattern `{ ?x bsbm:validFrom ?y . ?x bsbm:validTo ?z ...}`, the entity *Offers(published, closed)* —a MongoDB collection, and the mappings *(published → bsbm:validFrom, closed → bsbm:validTo)*, this component decides that the entity *Offer* is *relevant* to the star of `?x`. Star type (when present in the query) is taken into account, e.g., `?x a bsbm:Offer`.

(3) **Data Connector:** Once relevant data entities are detected, they are connected to the distributed execution environment. Every detected entity is loaded into what we call a *ParSet* (short of Parallel dataSet), which are data structures that can be distributed and operated on in parallel. The Data Connector expects external users to input the necessary connection metadata, e.g., *user, password, host, port, cluster name*, etc.

(4) **Distributed Query Processor:** Following the principles introduced earlier, queries are executed in parallel. Query execution occurs on and across the ParSets. Links between stars retrieved by the Query Decomposer are transformed into joins between the relevant detected data entities. Figure 2 depicts the process: stars and links between stars (left colored boxes) are mapped to ParSets and joins between ParSets (step I). All stars are incrementally joined forming *Results ParSet* (step II). When disjoinability points are known, join values are altered to enable joinability. We incorporate *transformations* which users need to declare to determine what are the possible changes to make,

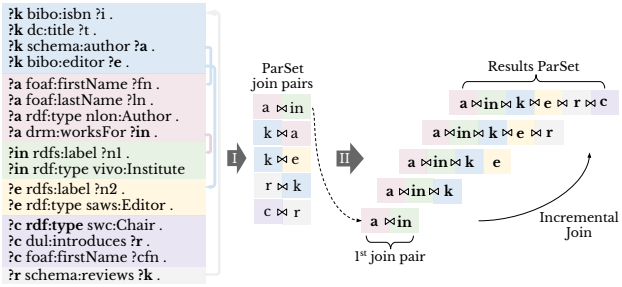

Figure 2: Example of query decomposition, and ParSets join.

Table 1: Query execution times (seconds) using Presto and Spark and the difference percentage between them (%).

	SPARQL SELECT Queries from BSBM (adapted)								
	Q1	**Q2**	**Q3**	**Q4**	**Q5**	**Q6**	**Q7**	**Q8**	**Q10**
– Scale 1: scale factor of 0.5 millions products –

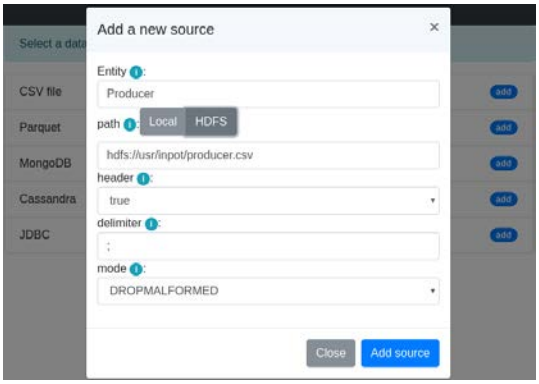

Figure 3: Data Connection GUI.

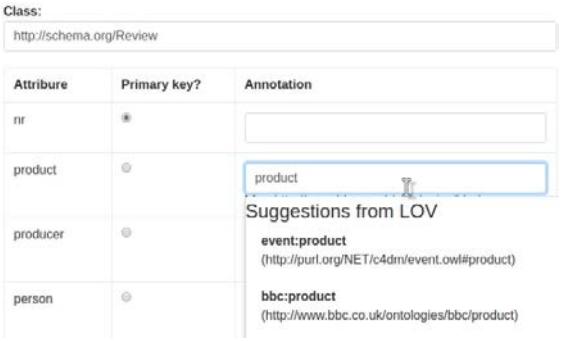

Figure 4: Data Mapping GUI.

e.g., increase the values of the `producer_id` attribute in the *Product* Cassandra table by a constant value.

(5) **Query Designer:** Querying the Data Lake using SPARQL as a uniform query language assumes a minimum level of knowledge about SPARQL. Therefore, we see the necessity of supporting users in their query creation. Users are not expected to provide queries only in plain-text, but can interact with the Query Designer to create correct queries in an intuitive way.

3 ACHIEVED PERFORMANCE

We evaluate the performance of `Squerall` in querying five different data sources: Cassandra, MySQL, MongoDB, Parquet, and CSV. As evaluation data we choose the BSBM [2] benchmark because it allows to (1) generate increasing scales of data (2) generate data in a friendly format, relational, and (3) provide a set of SPARQL queries. We pick five relational tables (*Product, Producer, Offer, Review, and Person*) and load them into the five data sources. To measure accuracy, we load the relational data into a relational database and run equivalent SQL queries. For sizes beyond the relational database capability (query time exceeds 3600s threshold) we self-compare Spark-based and Presto-based `Squerall`. For performance and scalability we evaluate the execution time of BSBM queries against three increasing data sizes: 0.5m, 1,5m and 5m scale factors (number of products). We experiment with all BSBM `SELECT` queries with some adaptation, i.e., queries are modified to involve only the five tables we populated. All the queries have join, from one between 2 data sources to 4 between all the data sources.

The evaluation was carried out in a cluster of three nodes, each having a 16-core DELL PowerEdge processor, 256GB RAM, and 3TB SATA disk. The evaluation results show 100% accuracy across all the three scales. For performance and scalability, `Squerall` exhibits reasonable performance across all three scales (see Table 1). Presto-based `Squerall` exhibits better performance to the Spark-based alternative in the majority of the cases. To measure this difference, we calculate the difference, in percentage, between Presto and Spark execution times (third row under each scale result in Table 1), e.g., for Q2 in the first scale Presto-based `Squerall` is 656% faster.

4 DEMONSTRABLE SCENARIOS

`Squerall` is a realization of the high-level architecture presented in section 2. We here describe its core technologies as well as concrete demonstrable scenarios using it.

1. Core technologies: *RML* [6] along FNO [5] are used to express mappings and to declare query-independent transformations. *Apache Spark* and *Presto* are used to implement both the Data Connector and Distributed Query Processor. Spark is a general-purpose processing engine, and Presto is a distributed SQL query engine for running interactive SQL queries. In Spark, ParSets are represented by *DataFrames*, and the Distributed Execution Environment is the memory pool where DataFrames are stored and transformed. DataFrames are tabular data structures, which are created and queried using *Spark SQL API*. Presto, in the other hand, is used like a database: users directly issue SQL queries without programmatically dealing with its underlying data structure. Thus, ParSets are represented by Presto's internal data structures, which are transparent to the user. Both Spark and Presto provide wrappers, called connectors[2] to connect to a data source. They load the data (fully, or partially if part of the query is pushed down to the data source) to their internal in-memory data structures. Dozens connectors are available relieving developers from creating their own wrappers.

2. User Interfaces: We provide 3 GUIs to help users produce `Squerall`'s inputs: *Config* and *Mappings* files and *SPARQL query*.

(a) **Data Connection** (Figure 3): This interface shows users the query engine-specific options needed to connect to a particular data source, e.g., *user, password, port, host, cluster name,* etc.

(b) **Mapping Creation** (Figure 4): using the connection information from the Data Connection GUI, this interface extracts the data schema and prompts users to map it. It has a built-in search functionality that sends requests to the LOV catalog[3] to search for adequate terms from existing ontologies.

(c) **Query Designing SPARQL** (Figure 5): This interface offers users a number of widgets to interact with. It is able to automatically generate a syntactically correct SPARQL query based on users' input. For example, users are prompted to only enter variable values or to pick from a pre-existing menu list, other

[2] <https://spark-packages.org> and <https://prestodb.io/docs/current/connector.html>
[3] Linked Open Vocabularies is a Web service to publish, search and visualize ontologies <https://lov.linkeddata.es/>.

constant query constructs are pre-entered.

3. Scenarios: Users can explore Squerall through a six-scenario story. They start by using Squerall's 3 GUIs to build the inputs Squerall needs for query execution. Afterwards, they run queries and observe the execution steps and results. Finally, they uncover Squerall's code and learn how it can be extended to support more data sources and query engines. Those scenarios use similar data as the ones used in the performance evaluation section 3.

(1) **Providing connection metadata.** Guided by the dedicated GUI, Figure 3, users provide necessary information to enable Spark and Presto to know and connect to a data source. For example, to load a CSV file, users specify the *delimiter* and select the *strategy* to adopt when the parser encounters a mal-formed line, e.g., dropping the line; or to connect to a MongoDB cluster, users specify the replica-set name.
(2) **Creating mappings.** Users leverage the dedicated interface, Figure 4, to create mappings for the previously connected data. They visualize the data schema and map it to ontology terms (properties and classes). They can try to find terms in existing ontologies using the LOV catalog-powered search; in absence of suitable results, they can input their own terms.
(3) **Building SPARQL queries.** Users explore and use the capabilities of the *Query Designing* GUI, Figure 5. They use the different widgets and incrementally augment their SPARQL query. They start building the query by forming stars (triple patterns of the same subject) and linking them together, then include other query operations like filtering. Users can experiment with the full spectrum of SPARQL fragment supported, which includes *filters, aggregate functions, solution modifiers, and regex*.
(4) **Data Transformation Declaration.** Users are invited to experiment with the two offered options of declaring transformations: (1) *as part of SPARQL query:* they add a new clause at the very end of a SPARQL query; (2) *as part of the mappings:* they amend RML mappings to, instead of mapping an entity attribute, e.g., column `producer_id`, directly to an ontology term, they first modify its values using declared FNO functions. The former is used when transformations vary from a query to query, the latter is used when transformations are fixed.
(5) **Executing SPARQL queries.** Users experiment with querying the data using Squerall. They can either evaluate BSBM queries or their own queries. They explore the query execution steps by visualizing the logs, from query parsing to stars and joins detection, to mapping lookup, and then to query execution.
(6) **Extending Squerall with more data sources and new query engines.** We show how developers can conveniently support more data sources in both Spark and Presto implementations. We also show them how they can programmatically incorporate a new query engine implementation, alongside Spark and Presto, thanks to Squerall's modular code design.

A screencast walking through the various interfaces and the query execution is available[4].

Figure 5: Query Designing GUI.

5 CONCLUSION

Squerall addresses the *Variety* challenge of Big Data, which remains poorly addressed, by making use of Semantic Web standards and best practices. Squerall can conveniently be (pragmatically) extended to embrace new data sources, by making use of the query engines' own wrappers. This approach solves one of the most tedious tasks acknowledged across the literature, i.e., handcrafting wrappers. For example, in addition to the five sources evaluated here, other sources like Couchbase or Elasticsearch can also be easily supported. As a result, Squerall is both innovative and unique in its capability to support a high number of data source types. Additionally, Squerall has been integrated[5] into SANSA [9], a framework for scalable processing and analysis of large-scale RDF data, widening its scope to also access non-RDF data sources. As future work, we plan to expand the supported SPARQL fragment to include OPTIONAL and UNION. Squerall source code is publicly available under an Apache-2.0 license on GitHub[6], accompanied by detailed documentation on installation and usage. This is further facilitated with a Dockerfile to quickly run the BSBM use-case described here (including the input files and adapted queries).

ABSTRACT

Fact checking is an essential task in journalism; its importance has been highlighted due to recently increased concerns and efforts in combating misinformation. In this paper, we present an automated fact checking platform which given a claim, it retrieves relevant textual evidence from a document collection, predicts whether each piece of evidence supports or refutes the claim, and returns a final verdict. We describe the architecture of the system and the user interface, focusing on the choices made to improve its user friendliness and transparency. We conduct a user study of the fact-checking platform in a journalistic setting: we integrated it with a collection of news articles and provide an evaluation of the platform using feedback from journalists in their workflow. We found that the predictions of our platform were correct 58% of the time, and 59% of the returned evidence was relevant.

1 INTRODUCTION

Grounding information on reliable sources is a daunting experience, given the increasing amount of information circulating the web and other media platforms. Nevertheless, checking the veracity of claims is crucial for preserving trust in news sources. Manual verification of claims is a tedious task, that consumes a lot of time and effort from journalists and professional fact-checkers, and it typically requires searching for specific entities and content over large amounts of unstructured text [2, 4].

The rising interest in fact checking has led to the development of a number of approaches and tools automating the task or parts of it, with the motivation of facilitating the work of journalists, and interested readers more broadly [3, 9]. The most popular effort, ClaimBuster [5], proposed a fact checking platform which detects factual claims that are worth checking and then uses APIs to query search engines and databases (Google and Wolfram Alpha respectively). It also compares claims against previously fact checked ones in its database. The latter approach is also used by the system developed by Full Fact, Live, which is used to fact check repeated or paraphrased claims.[1] Neither of these approaches is able to fact check previously unchecked claims, while the queries through existing commercial APIs are not tailored to fact checking, thus retrieving information that is not necessarily relevant. Other approaches rely instead on the detection of rumours based on the spread of readership over social media [7]. However, a rumorous claim is not necessarily false, and vice versa [16]. There is also work that checks claims against tables, such as those released by

[1] https://fullfact.org/blog/2017/jun/automated-fact-checking-full-fact/

Claim:
Tesla builds car factory in Shanghai.

Evidence:
Electric carmaker Tesla has signed an agreement with Chinese authorities to build a factory in Shanghai. "We hope it will be completed very soon," Tesla chief Elon Musk said.

Figure 1: Example of claim and evidence. Extracted named entities in bold: organizations (purple), locations (blue) and people (green).

the World Bank[2], using trained classifiers to select the appropriate tuple [10]. However such approaches are typically restricted to fact checking numerical claims against tabular sources. Finally, some approaches aim at providing a pipeline of tools for information retrieval [14], but do not go as far as to provide an actual fact check mechanism.

In this work, we propose an automated fact checking platform that checks claims by identifying sentences providing evidence in a large document collection. These sentences are classified as supporting, refuting or only related to the claim, and then combined into a final verdict using a state-of-the-art neural network-based approach [15]. The model is trained on the recently released FEVER dataset [11], a large scale fact checking dataset derived from Wikipedia comprising 185K claims. Unlike previous work, our model is able to check novel claims without relying on a database of fact checks. Also, the evidence retrieved and classified as supporting or refuting provides a justification of the verdict, which is likely to be relevant not only to assess the overall correctness of the platform, but also as part of the fact checking research conducted by journalists. Our retrieval model considers more information about a specific claim than generic search engines by leveraging information from words and named entities present in the dataset to obtain the best matching evidence for each claim (see Figure 1).

We thoroughly evaluate the platform through user testing by journalists from the British Broadcasting Corporation (BBC) in the context of their workflow. Of the total 488 evidence passages retrieved by the system, the journalists reported that 58% were relevant and 59% were accurately classified as SUPPORTS/REFUTES/OTHER.

Our platform can be applied to document collections beyond the ones used in this paper and our findings should help inform future research in automated fact checking and computational journalism more broadly.

2 FACT CHECKING SYSTEM

Our fact-checking system comprises three main components: a document retrieval step, a sentence ranking, and a classification model, as shown in Figure 2.

Initially we retrieve documents from a collection of news articles, using a customized search engine based on inverse indexing and retrieval using the Okapi-BM25 algorithm [8]. Data is incrementally indexed from word and entity-level inverted indexes. The document retrieval component searches for documents whose features best match the claim. In the end of this step, we end up with approximately $10K$ documents related to the claim.

[2]https://data.worldbank.org/

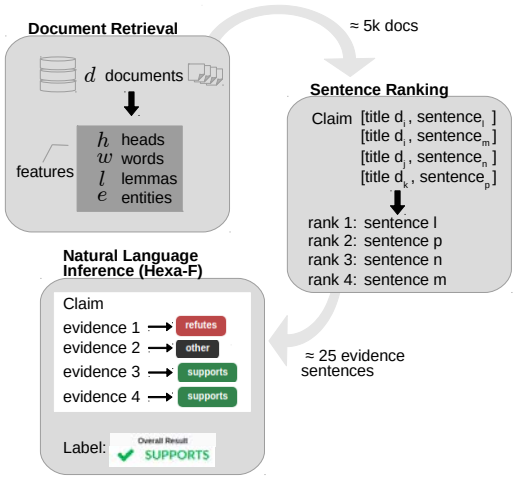

Figure 2: Fact-checking model comprised of three components: a) Document retrieval (top left), b) Sentence ranking (middle right), c) NLI prediction model (bottom).

Following this, we rank the sentences in these documents according to predefined token and feature matching rules. We compute the cosine similarity of the claim with each best candidate sentence, using word embeddings trained on the One Billion Word Benchmark corpus [1], and select those above a threshold tuned during development. This step aims at providing only sentences with high relevance to the claim, reducing the number of potential evidence that may be only marginally related with the claim.

In the final component, we classify each of the extracted candidate evidence in terms of whether they support, refute or are just related to the claim (other). We employ the natural language inference (NLI) model from the Hexa-F system [15] (one of the best performing systems in the FEVER shared task [12]) to classify the relation between the selected evidence sentences and the claim, one of SUPPORTS/REFUTES/OTHER, and a similar label which expresses whether the combined set of evidence sentences SUPPORTS, REFUTES or is simply related to the claim.

2.1 Engineering Considerations

In the first document retrieval component, we use inverted indexes to extract relevant documents, in Figure 3. We select all documents that match features in the claim, such as lemmas, words and extracted named entities [6]. This document retrieval step takes about 50 ms to retrieve around 5k documents out of a dataset with about $445k$ documents.

In the second component, we rank all the sentences from the 5k documents based on how well each sentence feature $\phi(s_i)_j$ matches the claim $\phi(c)_j$, using a positional ranking approach. We use a ranking score based on ordered distances between N matching features in the sentence i: $S_1(s_i, c) = \sum_{j=1}^{N} \exp\left(-d_{i,j}\right)$, where $d_{i,j} = \text{pos}(\phi(s_i)_j) - \text{pos}(\phi(s_i)_{j-1})$ represents the word distance between the position (pos) of each j-th feature. This score is maximized if all words in the sentence match the claim exactly; it decreases exponentially with the word distance between matches. This part takes on average 336 ms. Next, we filter the sentences based on

the following rules: we keep only those sentences with length < 500 words; those that contain all the entities mentioned in the claim, as well as novel words that were not previously seen in previously selected sentences (less than 90% overlap with all words previously encountered). The novelty filter increases the diversity in the evidence passed to the entailment step.

In the end of the second component, we re-rank the sentences by averaging the feature matching score of each sentence S_1 and the cosine similarity between the claim and the sentence embeddings $S_2 = \cos(s_i, c)$. We obtain these embeddings via a weighted average of all words in the sentence, weighted by term-frequency/inverse document frequency. To improve the performance of the sentence re-ranking component, we added the title of the document to each sentence and considered the weighted sum of all words in the title and sentence combined. This part takes about 652 ms, although it could be easily parallelizable. On average, 76 sentences are retrived per claim after these steps.

We further removed all sentences with an averaged similarity score below a given threshold ($(S_1 + S_2)/2 < 0.6$), to ensure high quality evidence. In the end, about 25 sentences on average are selected. After re-ranking, all selected sentences are used as input in the NLI model (third component) which takes about 738 ms to predict labels for each of the sentences and the overall label for the claim.

3 USER INTERFACE

The interface allows end-users to input a claim (black bar at the top of Figure 3), and receive a set of evidence sentences as output. The evidence is displayed in three columns: the top five ranking sentences that are in favour of the claim on the left, the top five that are against the claim in the middle, and the top five other sentences related to the claim on the right. In the bottom, a final overall label is presented to the user as either other, supporting or refuting the claim (label at the bottom). The interface allows users to directly evaluate it, providing feedback for evidence sentence w.r.t. the correctness of the label ("correct label?") and its relevance ("relevant?"), as well as the correctness of the overall prediction. We provide a video with an example of a user interacting with the platform via the interface in https://vimeo.com/309336679.

4 USER EVALUATION DESIGN

11 BBC journalists provided feedback on the overall system and on the classification model. The journalists were asked to interact with the system by providing factual claims and evaluating the output of the model. For each claim, up to 15 evidence sentences were presented to them, 5 per category, each classified as SUPPORTS, REFUTES or OTHER. For each sentence, the journalists provided feedback on two aspects: relevance and correctness.

To assess correctness, for each evidence sentence returned by the system, the journalist inputs the label which, according to his/her research on the subject, would be the correct one via the buttons in the "correct label" box (see Figure 3). This measures primarily the accuracy of the entailment component of the system, assuming that the sentences returned are all related. For the final classification of the model (see Figure 3 (bottom)) they also assessed the overall prediction, to whether the claim was globally supported or refuted considering all the retrieved evidence.

Precision	Class			
	SUPPORTS	REFUTES	OTHER	ALL
Relevant	71%	69%	49%	59 %
Evidence Correctness	48%	27%	70%	58 %
Global Correctness	56%	26%	31%	42 %

Table 1: User evaluation on the full dataset.

To assess relevance, the journalists were also asked to provide feedback as to whether they found each sentence returned relevant (see the buttons in the "relevant ?" box in Figure 3). This part of the feedback aims to evaluate the quality of the retrieved evidence: whether it helps the journalists fact-check the input claim, regardless of the classification label attributed by the system. It also serves as a proxy to measure the precision of the retrieval component, as all sentences shown to the journalists should be relevant (ideally).

The journalists also had access to (i) a Question Answering (QA) [13] tool that could serve as an additional source of information, (ii) the full document's text with annotated entities [6]. The QA implemented in the platform was used by the journalists, but was not evaluated in this paper. We provide an example of the additional information, available for each extracted evidence sentence in Figure 4.

5 RESULTS

Table 1 summarizes the results of the system is the user evaluation conducted. We show precision for each class (row:Relevant) measuring the proportion of the retrieved evidence sentences that were deemed relevant by the journalists, and precision for the predictions of the platform for the relation of each evidence sentence to the claim (row:Evidence) and the global prediction for the claim taking all the evidence into account (Overall result presented in Figure 3) (row:Global). The platform was evaluated on 67 claims in total, with a total of 488 evidence sentences retrieved: 30% supporting, 14% refuting and 56% related to the claim, as classified by our platform.

In 71% of the claims checked by the journalists, it was reported that the evidence shown in the SUPPORTS column was relevant, and so was for 69% of the evidence in the REFUTES columns. We consider these results to be very encouraging, given the difficulty of the task. Retrieving evidence that contradicts a given claim, is not usually as simple as retrieving related evidence by feature matching. Introducing different information, e.g. entities, dates, actions, etc., that could refute the claim requires more complex language understanding methods. We further observe that the precision in predicting evidence as SUPPORTS is 48% in the full dataset and increases to 67% in the subset of evidence deemed relevant (not shown in the table). The same trend is observed for the REFUTES label from 27% to 39%. This result suggests that the retrieval component still requires some improvement, especially for retrieving evidence refuting the claim. Strategies beyond feature matching are needed to improve the retrieval of relevant but opposing arguments. The precision of the classifier predicting the global label of the claim given the evidence also requires further improvement.

Additionally, we received textual feedback from the journalists about the overall quality of the platform. They mentioned that it is helpful for fact checking, despite not being always accurate, both in the retrieval of relevant evidence and in their evaluation. An interesting remark mentioned possible improvements for handling

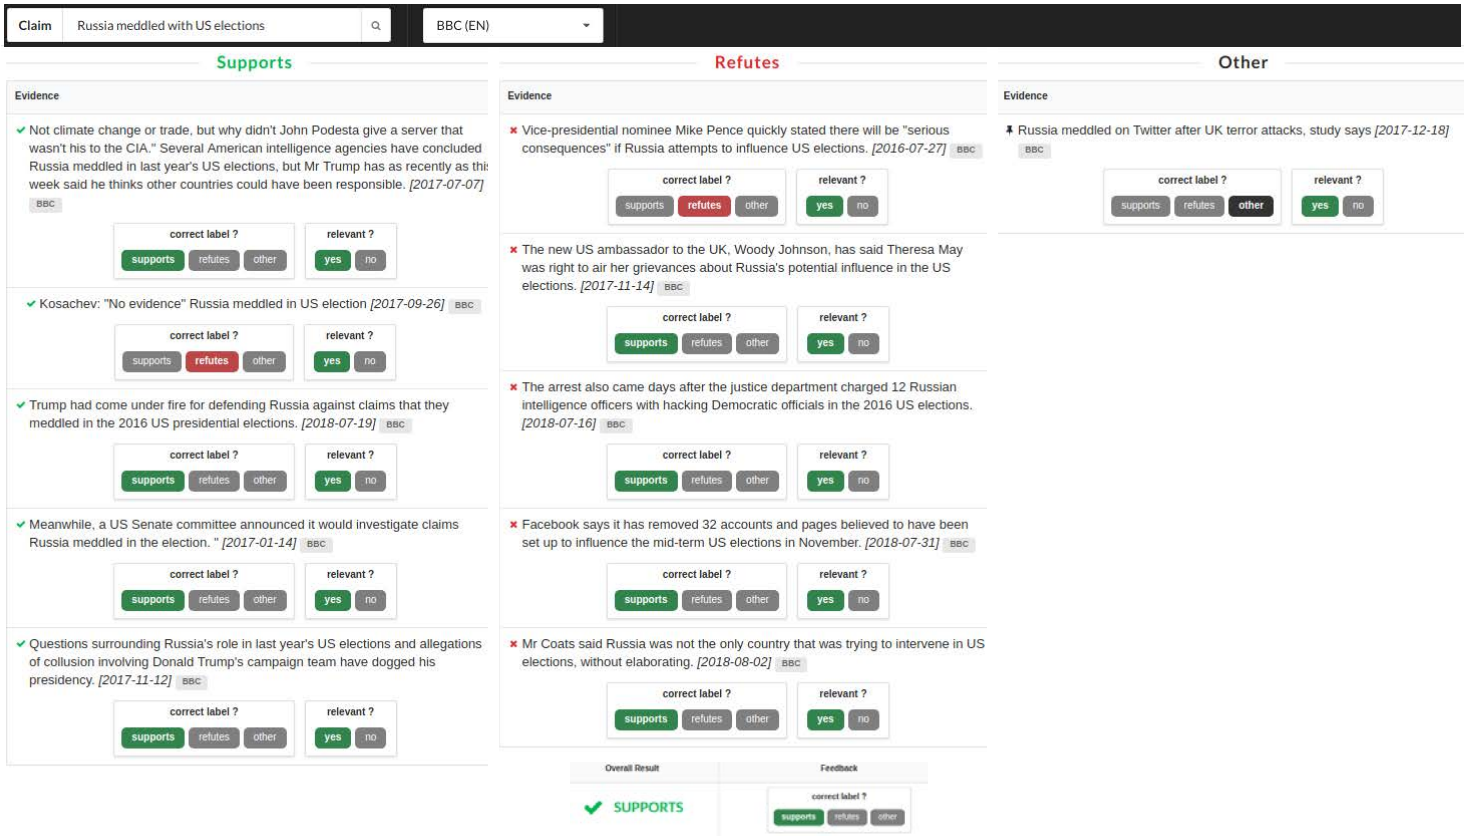

Figure 3: Example of the fact checking interface. Claim: "Russia meddled with US elections" (top). Five maximum evidence sentences for each column: SUPPORTS/REFUTES/OTHER **(middle). Example of final system decision and feedback buttons (bottom).**

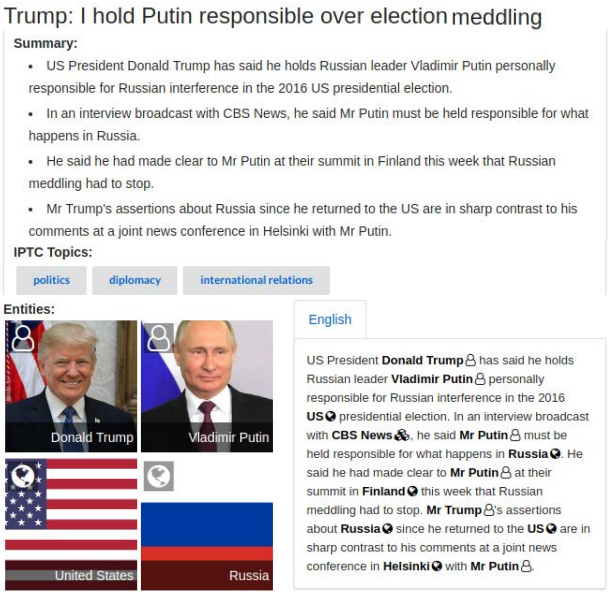

Figure 4: Example of additional information for each evidence. Original document (right) with entities in bold.

time-frames and dates. For instance, claims using the present tense should refer to current events, while those mentioned in the past tense together with dates should refer to that specific time-period only. Also they suggested that presenting the evolution of results over time would be very helpful to substantiate the claim. Handling time constraints in the retrieval process is a very interesting and challenging research direction. On the whole, the journalists reported that the system has a lot of potential to help their work.

This user testing was extremely useful both for BBC journalists to experiment with state-of-the-art technology and for us to receive feedback to improve our platform in the future.

6 CONCLUSIONS AND FUTURE WORK

This paper introduces a novel fact checking platform aimed to assist journalists in their investigative work-flow. Our platform can be used for search of supporting and refuting evidence regarding factual claims. We evaluated using on a journalistic corpus with testing by eleven journalists, which found it to yield relevant results in 59% of the retrieved evidence. The performed user study provided very fruitful feedback to direct future work in automated fact checking. Suggested improvements such as handling temporal remarks, pose an interesting issue that we found very relevant to advance research in the field of information retrieval for fact checking.

ACKNOWLEDGMENTS

The authors would like to thank James Thorne for insightful discussion and the BBC journalists for preforming the user testing and for their valuable feedback. This work is supported by the EU H2020 SUMMA project (grant agreement № 688139), and by Lisbon Regional Operational Programme (Lisboa 2020), under the Portugal 2020 Partnership Agreement, through the European Regional Development Fund (ERDF), within project INSIGHT (№ 033869).

InfraNodus: Generating Insight Using Text Network Analysis

Dmitry Paranyushkin
Nodus Labs, Paris, France, dmitry@noduslabs.com

ABSTRACT

In this paper we present a web-based open source tool and a method for generating insight from any text or discourse using text network analysis. The tool (InfraNodus) can be used by researchers and writers to organize and to better understand their notes, to measure the level of bias in discourse, and to identify the parts of the discourse where there is a potential for insight and new ideas. The method is based on text network analysis algorithm, which represents any text as a network and identifies the most influential words in a discourse based on the terms' co-occurrence. Graph community detection algorithm is then applied in order to identify the different topical clusters, which represent the main topics in the text as well as the relations between them. The community structure is used in conjunction with other measures to identify the level of bias or cognitive diversity of the discourse. Finally, the structural gaps in the graph can indicate the parts of the discourse where the connections are lacking, therefore highlighting the areas where there's a potential for new ideas. The tool can be used as stand-alone software by end users as well as implemented via an API into other tools. Another interesting application is in the field of recommendation systems: structural gaps could indicate potentially interesting non-trivial connections to any connected datasets.

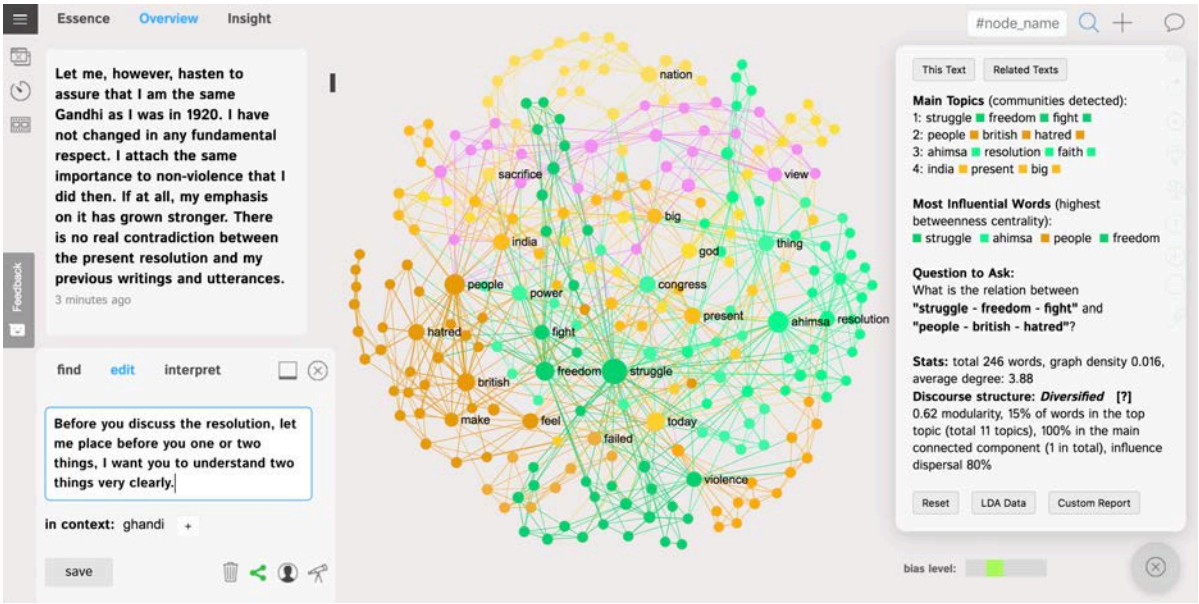

Figure 1: InfraNodus interface visualizing the text, the main topics inside, discourse structure, and bias index.

1 Introduction and Background

Mental models, mental maps and mind maps are often used to represent complex ideas [1], [2] and have a positive impact on teaching and learning [3], [4], [5]. Mental maps can be extracted from texts to produce cognitive maps, which can then be used for sentiment analysis [6], [7]. In the recent years this field has been enhanced with the network metaphor: the nodes are the concepts and the connections are the relations between them [8], [9]. The relations between the concepts can be plotted on the basis of their co-occurrences, which, in turn can facilitate the process of semantic priming — the process by which words tend to be recognized faster when used with the words that have close semantic proximity to them [10], [11], [12], [13]. Text network analysis methods based on this approach have been shown to be successful for better comprehension of texts and topic modeling [14], [15], [6].

In this paper we introduce an open-source tool for text network analysis InfraNodus[1], which can be used to enhance visual representation of ideas, their consequent analysis, and to generate insight. InfraNodus implements a method for text network analysis based on plotting a text as a network graph. The nodes on this graph represent the words and the edges are their co-occurrences [16], [17], [18]. Once a text is represented as a graph in this way, a wide range of tools from network analysis are then applied to detect communities of closely related concepts or topical clusters (topic modeling), identify the most influential nodes (top keywords), perform both quantitative and qualitative analysis of text, evaluate the discourse structure and bias, identify structural gaps, and perform comparative analysis of several texts [16], [19], [20]. Moreover, visual representation of a text as a network used in the process of ideation helps towards a more coherent expression of ideas [21], so the tool may find useful application in creative writing, research, in educational context, and in therapy.

State-of-the-art and its limitations. Similar tools have been presented in scientific literature: iVisClustering [22], TopicNets [23] and VisiRR [24] among others. However, those tools are not available to general public, their source code is closed, they are mainly focused on studying a large corpus of texts, and their application is limited to topic modelling and keyword-based text retrieval. InfraNodus is available both online and as a standalone open-source version. Its interface is specifically designed for real time text processing, providing text network visualization and analysis live as the new data is added. Finally, InfraNodus offers discourse structure analysis providing the measurement of the bias level in discourse and identifying the structural gaps in discourse, which is not available in other tools and methods, to our knowledge.

Relation to other text mining approaches. The approach implemented in InfraNodus can enhance the existing methods of finding structure within text that employ graphical models and topic modeling: latent semantic analysis or LSA [25], pLSA [26], Pachinco allocation [27], latent dirichlet allocation or LDA [28], relational topic models [29], word2vec algorithm [30], [31] and its extension lda2vec [32]. These methods are based on retrieving the topics from text by identifying the clusters of co-occurrent words within them, based on the bag-of-words and skip-gram models. This data can then be used to classify similar documents, improve text indexing and retrieval methods, and to identify evolution of certain topics overs a period of time within a specific text corpus [33].

The method used in InfraNodus is different from the probabilistic methods outlined above (LDA, pLSA, word2vec, lda2vec etc) even though its underlying assumption is similar: identifying the words that occur closer to each other in text can be used for topic modelling. InfraNodus uses graph theory instead of probability distribution to identify the related words and assign them into topical clusters. This application of graph theory helps gain a better understanding of the textual discourse structure and to provide advanced visualization tools, which can be useful both for quantitative and qualitative analysis.

The main difference is that methods like LDA or word2vec will take co-occurrences into account, but they do not provide insight into the structure of a narrative. These methods may ascribe words to the same topic (following bag-of-words model), but there will be no information provided about the relation of these topics to each other: how connected they are, how equally represented they are in a text, etc. The method implemented in InfraNodus provides this insight both qualitatively and quantitatively. Another issue with probabilistic methods is that they often require prior training on a document corpus, and they may be quite difficult to understand, to implement, and to interpret. The complex math behind LDA or word2vec may be difficult to access for the people who cannot afford to go into the technical details. Text network analysis approach used in InfraNodus, on the other side, does not require any training, it can work in real-time during the process of writing on a simple document, it is very intuitive and the math behind it is relatively simple. It is also much easier to understand intuitively as it provides direct visual representation.

At the same time, InfraNodus also offers LDA topic modelling and keyword extraction functionality, so that users can enhance the data obtained using LDA with additional information about the narrative structure and the topical cluster data obtained using network analysis (and vice versa). The method provided in InfraNodus does not compete with other topic modelling methods and does not attempt to outperform them. It provides the ability to get a better understanding of the text network topology, which can yield many other insights about the discourse structure that are not available in LDA or word2vec: how connected a discourse is, whether it's biased towards a certain set of concepts, how dominant a specific topic is towards the whole discourse, whether there are structural gaps that may indicate a potential for new ideas.

2 The Method and Its Implementation

InfraNodus is an open-source software written in JavaScript (Node.Js) using Sigma.Js, Cytoscape and Graphology libraries in the front-end and java-based Neo4J graph database for the backend[2]. It is platform-independent and can run both on desktop (hosted) and mobile (cloud) devices. Its source code is open and is available under the GPL open-source license on www.github.com/noduslabs/infranodus. Users can either install InfraNodus on their own machine or use the cloud-based version on www.infranodus.com. The resulting graphs and results can be embedded on other websites and exported into popular graph formats for further processing and analysis (e.g. Gephi). Some of the functionality is also available via an API, so InfraNodus can be used in conjunction with other text mining and analysis software.

In this section we will demonstrate step-by-step implementation of the text network analysis method as it is applied in InfraNodus. We will also demonstrate the qualitative and quantitative insights that can be obtained by the researchers using this method. For this demonstration we will use a well-known speech by Mahatma Gandhi "Quit India" [34].The interactive network visualization with all the analytics presented in this paper can be accessed via www.infranodus.com/texts/ghandi.

[1] Online: www.infranodus.com, source: github.com/noduslabs/infranodus, video tutorials: www.infranodus.com/#tutorials & https://youtu.be/bMmTRBZpjWw

[2] www.nodejs.org is a JavaScript run-time environment, www.sigmajs.org is a network visualization library created by Alexis Jacomy, graphology.github.io is a library for graph analysis created by Guillaume Plique, Cytoscape.org is a platform for complex network analysis, Neo4J.org is a graph database

2.1 Step 1: Text Normalization

First, all the words in the text are converted into their lemmas to reduce redundancy — keeping the morphological root of each word, bringing the different variations of the same word to the same common denominator (e.g. "books" become "book", "contacted" becomes "contact"). The syntax information (",", ".") is also removed. The paragraph structure is retained.

2.2 Step 2: Stop words Removal

The words that function as liaisons and that do not carry any additional meaning are removed from the text (e.g. "is", "are", "a", "the", etc.) The users can adjust the list of stop words used at that point using the Settings pane in the software or apply the tf–idf method to automatically generate the stopwords relevant to a document corpus.

The result of applying the steps 1 and 2 above is a word sequence, e.g. a sentence that reads:
Before you discuss the resolution, let me place before you one or two things, I want you to understand two things very clearly.

becomes
discuss resolution place thing want understand thing clear

2.3 Step 3: Text-to-Network Conversion

The text is then converted into a directed network graph. The normalized words (lemmas) are the nodes in the network graph and their co-occurrences are the edges.

Two consecutive scans are performed. The first scan creates the connections (graph edges) between the lemmas (nodes) that appear next to each other (bigrams) with the edge weight value of 3. The second scan uses a window of 4 lemmas (4-grams) to add a second layer of connections. The connections between the lemmas that are are only 1 word apart get the edge weight value of 2, while the lemmas that are separated by 2 words get the edge weight value of 1:

[discuss → (weight: 3) → resolution], [discuss → (weight: 2) → place], [discuss → (weight: 1) → thing],
[resolution → (weight: 3) → place], [resolution → (weight: 2) → thing], [resolution → (weight: 1) → want], etc.

These connections are encoded as edges on a directed text graph and are given the proper weight during analysis and visualization. Optionally, the links between the paragraphs can be made, where the last word of the previous paragraph links to the first word of the next one with the edge weight value of 1.

All the connections are unique and are saved even if they appeared earlier in the text. Later, for the purposes of graph visualization and community detection, the weights of the parallel edges are summed up.

2.4 Step 4: Extracting Most Influential Keywords Using Betweenness Centrality

We then apply a ranking algorithm to identify the nodes (the words) with the highest betweenness centrality – these are the nodes that appear most often on the shortest paths between any two randomly chosen nodes in the network [35], [36]. Those words are central for meaning circulation and can be seen as the meaning junctions within the discourse — they are shown bigger on the graph.

In the example Gandhi's text, we obtain these most influential words that have the highest betweenness centrality[3]:
struggle - ahimsa - people - freedom (see Figure 1)

2.5 Step 5: Topic Modelling Using Community Detection and Force-Atlas Layout

We then apply community detection algorithm [37], [38] based on modularity. This is an iterative algorithm that detects the groups of nodes that are more densely connected together than with the rest of the network. As a result, we obtain the groups of nodes (words) which tend to appear together in the text: topical clusters. We then apply Force-Atlas algorithm [39], which aligns densely connected clusters together while pushing the most connected nodes apart, so that the network structure is more visible on the graph. We then get a visual network representation of the text with a clearly defined community structure (using both color and network topology) and the specific topical clusters (see Figure 1).

The topics identified[4] are displayed on the separate Analytics pane:
1 (green): struggle - freedom - fight
2 (brown): people - british - hatred
3 (light green): ahimsa - resolution - faith
4 (orange): india – present - big

2.6 Step 6: Summarization, Visual Text Search and Nonlinear Reading

The graph visualization is interactive. After the main topics are identified, InfraNodus highlights the parts of the text that contain the highest concentration of topics identified (using the Analytics or Essence panes).

The user can also select any nodes on the graph to find the part of the text that mentions the topics selected (see Figure 2). The user can also compare two or more different text graphs using the text "diff" feature.

Therefore, the graph can be used to read through the text in a non-linear way, following the concepts that are relevant — using the graph as a heuristic device to make sense of the text or to look at it from a new perspective.

[3] LDA method (also available in InfraNodus / Analytics pane) yields similar results for the top 4 keywords in this text: "struggle – people – british - ahimsa".
[4] According to LDA, the top 4 topics are "ahimsa – resolution - present", "british – people - hatred", "struggle – freedom - today", "power – india - congress".

2.7 Step 7: Discourse Structure and the Measure of Discourse Bias

InfraNodus also identifies the structure of discourse based on the structure of its text network graph. The algorithm takes into account (1) the graph's modularity (M — a value higher than 0.4 indicates a highly pronounced community structure [38]); (2) the percentage of words in the topical cluster with the most nodes, or in the main connected (giant) component (C), if there are several connected components in the graph; (3) the dispersal of influence among the topical clusters (communities) measured in terms of Shannon entropy (E) for a string that contains a 1-letter code of the community assigned to each of the top 4 most influential keywords (e.g. if each of the top 4 nodes belongs to a different community A, B, C and D, the string will be 'ABCD' and the entropy in bits per symbol will be 2).

Based on these criteria a score is given to the text graph, which can be used to measure the level of bias in discourse:

- **Dispersed**: high modularity (M > 0.65) and (C < 50% and E >= 1.5) - the community structure is highly pronounced, the influential words are distributed among the communities. Therefore, the discourse has several topics, which are weakly related.
- **Diversified**: high modularity (0.6 >= M > 0.4) and (C < 50% and E >= 1.5) - pronounced community structure, the most influential words are distributed among the communities. Therefore, the discourse has several topics, each of them has a relatively high number of nodes in the graph, the topics are connected.
- **Focused**: medium modularity (0.4 > M >= 0.2 and E > 0.5) or (M > 0.4 and C >= 0.5 and 0.25 < E < 0.75) - communities are present but not easily detectable, influential words may be concentrated around one topic, the discourse is focused on a certain perspective, the other perspectives are weakly presented.
- **Biased**: low modularity (M < 0.2), no detectable communities, influential words are concentrated around one subject - the discourse is biased

For example, the structure of the discourse in our example is "Diversified" meaning that it has several distinct topics and that those topics are still connected on the global level, the bias level is low (see Figure 1).

2.8 Step 8: Insight Generation using Structural Gaps

Graph visualization is also used to identify the structural gaps in the graph. This can be done both in a qualitative way by the researchers or automatically by the software's algorithm (detecting the distinct communities that are not well connected). It has been demonstrated [40], [41] that structural gaps are the parts of a graph that indicate the potential for new ideas. Text network visualization can be used to identify those gaps and to propose new connections between different ideas, topics and topical clusters [5].

In the example we use those are
"british" - "people" - "hatred" and *"struggle" - "freedom" - "fight"*

A quick analysis of the text snippets that include those topics and of the graph shows that there is a structural gap between the nationalist sentiment that Ghandi is talking about (in relation to the "hatred" for "British") and at the same time about the fact that, in his opinion, revolutions that are based on violence do not live up to democratic ideals. The algorithm shows that there is an important link between these two ideas (see Figure 3).

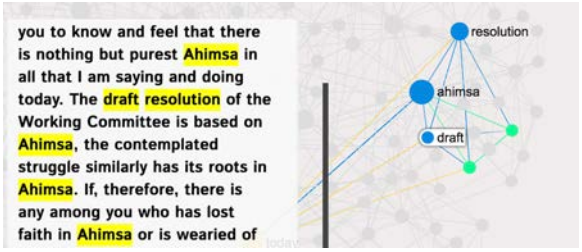

Figure 2: Visual graph text search feature.

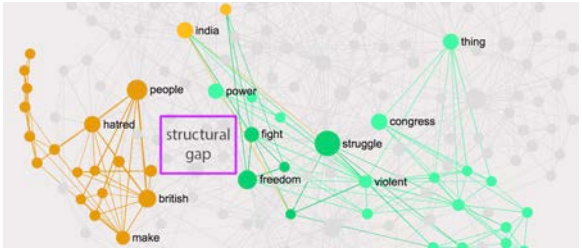

Figure 3: Structural gaps point out potential insights.

3 Conclusion and Practical Applications

In the previous section we demonstrated the implementation of text network visualization and analysis algorithm in InfraNodus software. We have shown how it can used to obtain a visual representation of text, to perform topic modeling, to extract relevant parts using the interactive interface and the visual search, to compare different texts, to analyze the structure of discourse, and to identify the structural gaps to generate new ideas in order to further develop the discourse.

The tool is currently used by researchers, marketing professionals, students, lawyers, artists and activists worldwide (20000 users a year according to Google Analytics for the online version as of December 2018) and it became first available in its beta version in 2014. The range of its practical applications is quite diverse: text categorization, search engine optimization, measure of bias, sentiment analysis, computer-assisted research and creative writing.

The structural gap identification feature can be potentially useful for enhancing recommender systems with non-trivial suggestions based on bridging the different clusters of disconnected datasets together, providing interesting insight for the users.

ACKNOWLEDGMENTS

This research was supported solely by the contributions made by the users of the online version of InfraNodus.

[5] We could also apply the same methodology to the topical clusters identified using LDA topic modelling (see footnote 4)

ABSTRACT

People with visual impairments often rely on screen readers when interacting with computer systems. Increasingly, these individuals also make extensive use of voice-based virtual assistants (VAs). We conducted a survey of 53 people who are legally blind to identify the strengths and weaknesses of both technologies, as well as the unmet opportunities at their intersection. We learned that virtual assistants are convenient and accessible, but lack the ability to deeply engage with content (e.g., read beyond the first few sentences of Wikipedia), and the ability to get a quick overview of the landscape (list alternative search results & suggestions). In contrast, screen readers allow for deep engagement with content (when content is accessible), and provide fine-grained navigation & control, but at the cost of increased complexity, and reduced walk-up-and-use convenience. In this demonstration, we showcase VERSE, a system that combines the positive aspects of VAs and screen readers, and allows other devices (e.g., smart watches) to serve as optional input accelerators. Together, these features allow people with visual impairments to deeply engage with web content through voice interaction.

CCS CONCEPTS

• **Information systems → Search interfaces**; • **Human-centered computing → Accessibility systems and tools**; **Natural language interfaces**; **Sound-based input / output**.

1 INTRODUCTION

People with visual impairments are often expert users of audio-based interfaces, with screen readers being a prime example. Screen readers work by transforming the visual content in a graphical user interface into audio by vocalizing on-screen text. To this end, they are an important accessibility tool for people who are blind – so much so that every major operating system includes screen reader functionality (e.g., VoiceOver[1], TalkBack[2], Narrator[3]), and there is a strong market for third-party offerings (e.g., JAWS[4], NVDA[5]). Despite their importance, screen readers have many limitations. For example, they are complex to master, and depend on the cooperation of content creators to provide accessible markup (e.g., *alt text* for images). This includes the myriad of web page owners who host documents on the Internet.

Voice activated virtual assistants (VAs), such as Apple's Siri, Amazon's Alexa, and Microsoft's Cortana, offer another audio-based interaction paradigm, and are mostly used for everyday tasks such as controlling a music player, checking the weather, and setting up reminders [6]. In addition to these household tasks, however, voice assistants are also used for general purpose web search and information access [4]. Here, in contrast to screen readers, VAs are marketed to a general audience, and are limited to shallow investigations of web content. Being proficient users of audio-based interfaces, people who are blind often use VAs, and would benefit from broader VA capabilities [1, 5]. Additionally, extended VA functionality could be useful for a wider audience during activities such as driving and cooking.

In this work, we explore augmenting a VA interaction model with basic functionality of screen readers to better support free-form, voice-based web search. Through an online survey with 53 blind screen reader and VA users, we investigated what challenges people experience when searching the web with a screen reader and when getting information from a voice assistant. Based on these findings, we developed VERSE (Voice Exploration, Retrieval, and SEarch) – a prototype that employs a VA model, yet provides rich functionality for web exploration. In the remainder of this document we: (1) present a quick overview of the survey findings that motivate the

design of VERSE, (2) present an overview of the VERSE system, and (3) conclude by outlining the hardware and logistics requirements for demonstrating VERSE at TheWebConf'19.

2 ONLINE SURVEY

To better understand the problem space of non-visual web search with screen readers and VAs, we designed an online survey consisting of 44 questions spanning five categories: general demographics, use of screen readers for accessing information in a web browser, use of virtual assistants for retrieving online information, comparisons of screen readers to virtual assistants for information seeking tasks, and possible future integration scenarios (e.g., voice-controlled screen readers).

We recruited adults living in the U.S. who are legally blind and who use both screen readers and voice assistants. Through a collaboration with an online survey organization that specializes in recruiting people with various disabilities, we ensured that all participants could successfully access the survey. The survey took an average of 49 minutes to complete, and participants were compensated $50 for their time. Two researchers iteratively analyzed the open-ended responses using techniques for open coding and affinity diagramming [2] to identify themes.

2.1 Participants

A total of 53 respondents completed the survey (28 female, 25 male). Participants were diverse in age, education level, and employment status. All participants reported being legally blind, and most had experienced visual disability for a prolonged period of time (μ = 31.6 years, σ = 17 years). As such, all but three respondents reported having more than three years of experience with screen reader technology. Likewise, most participants were experienced users of voice assistant technology. 35 respondents (66%) reported having more than three years of experience with such systems, 17 participants (32%) – between one and three years, and one participant (2%) reported having used VA technology for less than a year.

2.2 Findings

We found that respondents made frequent and extensive use of both virtual assistants and screen reader-equipped web browsers to search for information online, but both methods had shortcomings. Moreover, we found transitioning between VAs and browsers introduced additional challenges and opportunities for future integration. Each of these trade-offs is codified by a theme below.

2.2.1 ***Theme 1:*** *Brevity vs. Detail.* The amount of information provided by voice assistants can differ substantially from that returned by a search engine. VAs provide a single answer (suitable for simple question answering but not for exploratory search tasks [8]), that may be short and provide limited insight. This aspect was pointed out by 27 respondents. For example P24 noted that: *"a virtual assistant will only give you one or two choices, and if one of the choices isn't the answer you are seeking, it's hard to find any other information"*. These concerns were echoed concisely by P37: *"you just get one answer and sometimes it's not even the one you were looking for"*, and P30: *"a lot of times, a virtual assistant typically uses one or two sources in order to find the information requested, rather than the entire web"*. In contrast, 20 respondents reported that using a search engine via a screen reader-equipped browser affords access to multiple sources, and access to more details if needed (e.g., P46: *"you can study detailed information more thoroughly"*). But those details come at a price – when using a screen reader a user has to cut through the clutter on web pages before getting to the main content, as mentioned by 8 survey respondents (e.g., P18: *"you don't get the information directly but instead have to sometimes hunt through lots of clutter on a web page to find what you are looking for"*).

2.2.2 ***Theme 2:*** *Granularity of Control vs Ease of Use.* Our survey participants widely recognized that VAs were a convenient tool for performing simple tasks (22 people), but greater control was needed for in-depth exploration (e.g., P38: *"They are good for specific, very tailored tasks."*). This trade-off in control, between VAs and screen reader-equipped browsers, was apparent at all stages of performing a search: query formulation (P30: *"[with VAs] you have to be more exact and precise as to the type of information you are seeking."*), results navigation (P22: "*[with screen readers] I can navigate through [results] as I wish*"), and information management (P51: "*If I use a screen reader for web searching I can bookmark the page and return to it later. I cannot do it with a virtual assistant.*")

Additionally, 15 respondents reported that screen readers are advantageous in that they provide a greater number of navigation modes, each operating at different granularities. For example, P18 reports: *"[with screen readers] you can navigate by heading, landmark or words"*. Similar sentiments are reported by P24: *"It's easier to scan the headings with a screen reader when searching the web"*, and P31: *"one is able to navigate through available results much faster than is possible with virtual assistants."*

Finally, screen readers afford greater control by allowing users to customize multiple settings (speech rate, pitch) to fit people's preferences – a functionality not yet available in voice assistants (P29: *"sometimes you can get what you need quicker by going down a web page, rather then waiting for the assistant to finish speaking"*). The desire for customization of VAs was mentioned by only one participant in our survey, but has been identified as a limitation of VAs in prior work [1].

The increased dexterity of screen readers comes at a price of having to memorize many keyboard commands or touch gestures, whereas VAs require minimal to no training (P38: *"[with VAs] you don't have to remember to use multiple screen reader keyboard commands"*). This specific tradeoff was mentioned by 3 participants.

2.2.3 ***Theme 3:*** *Transitioning between systems.* Another prominent theme detailed the frequent need for users to transition from a VA to a screen reader-equipped web browser. Out of 53 survey respondents, 39 recalled recent situations where they began a session with a VA but then had to switch to using a web browser. Reasons for switching mentioned in participants' incident descriptions included: failure of automatic speech recognition (4 people), a VA response that lacked sufficient details (11 people), or the lack of any relevant response (14 people).

Transitions between system are not well-supported at present, and respondents suggested numerous ways in which this could be improved. For example P24 notes: *"A virtual assistant could give you basic information and then provide a link to view more in depth results using a screen reader."* Likewise P21 suggested that, upon performing in-depth search, the VA "*(could) ask you if you wanted more details.*

If you replied yes, it would open a web page such as Google [in a browser] and perform a search". Such a strategy would save people from having to re-input their query and begin a completely new search session.

2.2.4 ***Theme 4:*** *Incidental vs. Intentional Accessibility.* Finally, one of the valuable features of voice assistants is their audio-first design. Thus, while targeting a general audience, VAs are immediately, and incidentally, accessible to people with visual impairments. This was mentioned by 7 participants. For example, P38 reports: *"You don't have to worry about dealing with inaccessible websites"*, while P42 notes that such an approach *"levels the playing field, as it were [since] everyone searches the same way."*

3 VERSE

Inspired by our survey findings, we created VERSE (Voice Exploration, Retrieval and SEarch), a prototype situated at the intersection of voice-based virtual assistants and screen readers. People interact with VERSE primarily through speech, in a manner similar to existing voice-based agents such as Amazon Alexa or Google Assistant. For example, when asked a direct question VERSE will often respond directly with a concise answer (Figure 1a). However, VERSE differs from existing agents in that it enables an additional set of voice commands that allow users to access different online sources and search engine features (such as related searches), as well as to engage more deeply with content for select sources (for example, allowing navigation over a document's headings).

As with screen readers, VERSE addresses the need to provide shortcuts and accelerators for common actions. To this end, VERSE optionally allows users to perform gestures on a companion device such as a phone or smart watch (see Table 2). For most actions, these companion devices are not strictly necessary. However, to simplify rapid prototyping, we limited microphone activation to gestures, rather than also allowing activation via keyword spotting (e.g., "Hey Google"). Specifically, microphone activation is implemented as a double-tap gesture performed on a companion device (e.g., smartphone or smartwatch). Although hands-free interaction can be a key functionality for VA users [3], a physical activation is a welcomed ancillary, and at times, a preferred option [1]. There are no technological blockers for implementing voice-only activation in the future versions of VERSE.

The following scenario, and the video accompanying this paper [7], illustrate VERSE's capabilities, and indicate how VERSE could be demonstrated at TheWebConf'19.

3.1 Example Demonstration Scenario

Alice recently overheard a conversation about the Challenger Deep and is interested to learn what it is. She is sitting on a couch, her computer is in another room, and a VERSE-enabled speaker is on the coffee table. Alice activates VERSE and asks "What is the Challenger Deep?". The VERSE speaker responds with a quick answer – similar to Alice's other smart speakers – but also notes that VERSE found a number of other web pages, Wikipedia articles, and related searches (Table 1a). Alice decides to explore the Wikipedia articles ("Go to Wikipedia"), and begins navigating the list of related Wikipedia entries ("next") before backtracking to the first article, this time rotating the crown on her smart watch as a shortcut to quickly issue the *previous* command (Table 1b).

Alice decides that the first Wikipedia article sounded good after all, and asks for more details ("Tell me more"). VERSE loads the Wikipedia article and begins reading from the introduction section (Table 1c), but Alice interrupts and asks for a list of section titles ("Read section titles"). Upon hearing that there is a section about the Challenger Deep's history, Alice asks for it by section name ("Read History section").

Finally, Alice wonders if there may be other useful resources beyond Wikipedia, and decides to return to the search results ("Go to search results"). As before, Alice rotates the crown on her smart watch to quickly scroll through the results. Alice identifies an interesting webpage from the list VERSE reads out to her, and decides to explore it more deeply on her phone ("Send this to my phone") and the chosen web page opens on her iPhone (Table 1d) where Alice can navigate it using the phone's screen reader.

3.2 VERSE Design Elements

The design of VERSE was informed by a select set of themes that emerged during the analysis of survey responses. Below we discuss how VERSE addresses each of the themes.

3.2.1 VERSE: Brevity vs. Detail. The design of VERSE addresses *Theme 1* by providing users with an instant concise answer (in a manner similar to VAs) as well as an opportunity to explore multiple sources returned by a web search engine (breadth), and then to engage with individual content items and web sources (depth).

With respect to breadth, VERSE leverages the Bing.com search API[6] to collect results across numerous search verticals: web pages, facts, entities, dictionary definitions, Wikipedia articles, news stories, images, videos, and related search queries. If facts, entities, or definitions are present, VERSE reads them out similar to existing VAs, then follows by summarizing the results available in other verticals (see Table 1a).

With respect to depth, VERSE allows voice- and gesture-based navigation of Wikipedia articles. We chose Wikipedia as it has rich data, is often included among the top results, and has a consistent page structure that facilitates screen reader-like navigation. When a desired Wikipedia article is selected, the user can say "tell me more," or perform an alternative gesture (Table 2) to get a quick summary about the article (e.g., the number of sections and words), then hear narration of the first section. At any time, the user can ask for an overview of the article's sections (*"read section titles,"*), and can ask for a given section by name (*"read <section name>"*). This interaction is illustrated in Table 1c.

3.2.2 VERSE: Granularity vs. Ease of Use. To address *Theme 2* from the survey findings, VERSE allows users a quick and easy way to navigate between search results using either voice commands or touch gestures. By saying *"next"* or *"previous,"* the user is able to move on to the next element in the selected search vertical (Table 1b). A similar effect is achieved by swiping right and left on a companion device (Table 2). These gestures mirror those used by screen readers on popular smart phones.

[6] https://azure.microsoft.com/en-us/services/cognitive-services/bing-web-search-api/

Table 1: Example usage scenario

(a) Initial search

Alice: *(activation)* What is the Challenger Deep?
VERSE: The Challenger Deep is the deepest known point in the Earth's seabed hydrosphere. With the depth 10898 to 10916m by direct measurements from submersibles and slightly more by sonar bathymetry. I also found 2 entities, 9 web pages, 8 related search queries, 10 videos, 10 Wikipedia articles.

(b) Results navigation

Alice: *(activation)* Go to Wikipedia.
VERSE: I found 10 Wikipedia articles. The first one is Challenger Deep, Wikipedia. The Challenger Deep is the...
Alice: *(activation)* next article
VERSE: Article 2. Deepsea Challenger, Wikipedia. Deep Sea Challenger, DCV1, is 7.3 metre, 24 feet...
Alice: (*rotate smartwatch crown to return to previous element*)
VERSE: Article 1. Challenger Deep, Wikipedia. The Challenger Deep is the deepest ...

(c) Wikipedia exploration

Alice: *(activation)* Tell me more.
VERSE: I parsed the Wikipedia article called Challenger Deep. It has 16 sections and 3127 words. Here's the first section. Introduction. The Challenger Deep is the deepest...
Alice: *(activation)* Read section titles.
Verse: Introduction. Section 1: History of depth mapping from the surface. Section 2: Descents. Section 2.1...
Alice: *(activation)* Read History section.
VERSE: Okay, here's the section number 1, titled History of depth mapping from the surface. Over many years, the search for the point of maximum depth...

(d) Transition between modalities

Alice: *(activation)* Go to web results.
VERSE: I found 9 web pages. The first one is Challenger Deep, Wikipedia.
Alice: *(rotates smartwatch crown to advance to next result)*
VERSE: Page 2. Deepest ocean Challenger Deep, Extreme Science. Challenger Deep got its name from...
Alice:*(activation)* Send this to my phone.
VERSE: Opening this link in your phone app. *(Web page opens within VERSE app)*
Alice: *(uses VoiceOver gestures to navigate on the page)*

To switch between different search verticals, a user can say *"go to <search source>"* (e.g., *"Go to Wikipedia."*). VERSE will respond with the number of elements found in the new vertical and start reading the first element (Table 1b). Alternatively, the user can swipe up or down to move along the available search sources.

Finally, when exploring Wikipedia articles, VERSE also supports screen reader-inspired navigation modes (by headings, sentences, paragraphs, and words). The navigation mode then impacts the granularity of navigation commands & gestures, such as *"next"* and *"previous"*. Without loss of generality, one can switch modes by saying *"navigate by headings"*, or can swipe up or down on a companion device to iterate between modes – again, these gestures are familiar to people who use screen readers on mobile devices.

3.2.3 VERSE: Transitioning between modalities. VERSE addresses *Theme 3* by giving users an opportunity to seamlessly transition between voice-based interaction and a more traditional screen reader-equipped web browser. If the user requests an in-depth exploration of a web resource that is not Wikipedia, VERSE will open its url within the VERSE phone application. The user can then explore the web page using the device's built-in screen reader (in our case, VoiceOver). From this point onward, all gestures are routed to the default screen-reader until a "scrub" gesture is performed[7], or a new voice query, is issued. Gesture parity between VERSE and the screen reader ensures a smooth transition. This interaction is illustrated in Table 1d.

3.2.4 VERSE: Incidental vs Intentional Accessibility. Finally, as already noted, VERSE submits user queries, and retrieves results, via Bing.com search API. This allowed us to design a truly audio-first experience consistent with existing VAs, rather than attempting to convert visual web content to auditory format. Likewise, our treatment of Wikipedia allows VERSE to focus on the article's main content rather than on other visual elements. This behaviour is consistent with the brief one or two sentence summaries narrated by existing virtual assistants, but allows convenient and efficient access to the entire article content.

4 EQUIPMENT AND LOGISTICS

We are proposing to run a demonstration that showcases the VERSE prototype system. The demo consists of a few smart speakers, smart watches, and laptops which we will supply. Our demonstration requires that internet connectivity – preferably wireless – be available. The demonstration should not require much physical space (e.g., one table), and can be scaled down as needed. Given the potential for a noisy environment, we will provide headsets with microphones, and will also modify the prototype to accept typed input as a contingency. We will also prepare a video showcasing the system [7]. Exhibit visitors will be free to conduct their own search and browsing sessions – we will not prescribe any particular flow or golden path through the system. Our hope is that the demo will inspire those researching web browser standards to consider new ways to support voice-based navigation of the web.

5 CONCLUSION

We have investigated the challenges that people who are blind experience when searching for information online using screen readers and voice assistants (e.g. Siri, Alexa). To identify the gaps and opportunities for improvement, we ran an online survey with 53 screen reader and voice assistant users. Based on the findings

[7] A standard VoiceOver gesture for "go back".

Table 2: Mapping of voice commands and corresponding gestures in VERSE.

Voice commands	Phone gestures	Watch gesture	Action
(Activation gesture)	Double tap with two fingers	Double tap with one finger	VERSE opens mic
"Cancel"	One tap with two fingers	One tap with one finger	Stop voice output
"Go to <source>"	Up/down swipe	Up/down swipe	Previous/next search source
"Next"/"Previous"	Right/left swipe	Right/left swipe or rotate crown	Next/previous element
"Tell me more"	Double tap with one finger	n/a	Continue reading the most recently mentioned answer / result

from the survey, we created VERSE – a system prototype for non-visual web search and browsing. Design of VERSE combines the advantages of both screen readers and voice assistants, and allows voice-based, as well as gesture-based, interaction.

ABSTRACT

Given the increasing number of heterogeneous data stored in relational databases, file systems or cloud environment, it needs to be easily accessed and semantically connected for further data analytic. The potential of data federation is largely untapped, this paper presents an interactive data federation system (https://vimeo.com/319473546) by applying large-scale techniques including heterogeneous data federation, natural language processing, association rules and semantic web to perform data retrieval and analytics on social network data. The system first creates a Virtual Database (VDB) to virtually integrate data from multiple data sources. Next, a RDF generator is built to unify data, together with SPARQL queries, to support semantic data search over the processed text data by natural language processing (NLP). Association rule analysis is used to discover the patterns and recognize the most important co-occurrences of variables from multiple data sources. The system demonstrates how it facilitates interactive data analytic towards different application scenarios (e.g., sentiment analysis, privacy-concern analysis, community detection).

1 INTRODUCTION

Motivation. The ultra-connected world has been generating massive volumes of heterogeneous data stored in different data sources. And these data sources need to be normalized and interconnected to create a federated database that can be used to analyze, extract useful knowledge, and present it as a valid element for decision making. Semantic web techniques (e.g., RDF, SPARQL) have been widely used for data federation and linkage. However, the primary issue of the semantic web is insufficient integrated solution. To tackle this issue, we applied data federation, semantic web, and data mining technologies to develop this system, which can complement with each other. The system allows users to select data sources, interact with visualized graphs, and run customized queries across federated data to meet specific needs for data analytics.

Related Work. Related with data federation, there exist some popular enterprise data virtualization tools, such as IBM InfoSphere Federation Server (https://ibm.co/2qWQbom) and Oracle Data Service Integrator (https://goo.gl/6MKXkF). As well as some open source frameworks such as Teiid (teiid.jboss.org) which we used in this paper. Similar efforts in data federation have been seen from academia such as BioMart (www.ensembl.org/biomart) and Maelstrom (www.maelstrom-research.org). In the context of RDF and Linked Open Data, various works have been proposed in the literatures [2, 3]. In addition, several tools offering RDF and linked data visualization have been developed e.g., Sgvizler [6], LODWheel [7], IsaViz [1]. RDF-Gravity[2], etc. Also, many researchers used federated SPARQL queries to analyze and visualize linked data[4]. However, considering advanced data analytics across federated data is ignored. In this demo paper, we proposed RDF-supported data visualization framework over federated databases enriched with data mining (e.g., association rules) and NLP techniques (e.g., sentiment analysis). It can efficiently federate and analyze large heterogeneous data sources for general or specific analysis needs (e.g., community detection and the like).

Dataset. We processed one of the largest social science research databases, myPersonality corpus [3], which was collected from over 6 million volunteers on Facebook (FB). The data was anonymized and sampled to share with registered scholars around the world. In this paper, we used four of its data sources including *demographic dataset, personality dataset, political views*, and *FB status updates dataset*. One more *community detection dataset* was inferred based on these four. More information about these data sources is available in the menu of Data Source of the demo system.

Contributions. We build up a federation system, mapping the multiple heterogeneous, distributed, and autonomous data sources

into a unified federated database interface, where user can choose data sources in their area of interest; we provide data analytics including data exploration and search, which empowers users with ability to explore the data via data mining algorithms (i.e., association rules), and search by queries to lead advanced analytics. we implement interactive visualization, which allows users to plot the result in different formats like tables, graphs, scatter plots, and download the results. The system is scalable by adding other data sources, applying other data mining algorithms, and aiming at other data analytic scenarios.

2 SYSTEM DESCRIPTION

The system architecture is shown in Figure 1 with three goals including data federation, data linkage, and data analytics. On the server side, data from multiple data sources were preprocessed and connected through a VDB in the local deployed Teiid server. Different techniques are firstly applied to process raw data including generating RDF from raw data and indexing text-based data (*Process 1*). Association rule analysis is applied to support data exploration, such as exploring hidden patterns and co-occurrences of variables from multiple data sources in visualized ways (*Process 2*). After data exploration, users can go to data search and issue queries across RDF endpoints for general/specific data analytics, which are powered by semantic web techniques (*Process 3*). Based on the three processes mentioned above, on the end-user side, users are enabled to view metadata of data sources, explore the individual and federated data, and further construct simple/advanced queries of their (research) interests, to get data analytic results. Figure 2 presents the user interface.

Ahead of the above procedure, we apply NLP techniques [10] for raw data preprocessing (e.g., data normalization, standardization, non-utf8 characters removal etc.) and infer additional variables such as sentiment analysis and privacy concern based on the given variables. More information about these variables can be found in the menu of *Data Source* in the system.

2.1 Data Federation and Data Linkage

Data Federation. Our data federation component was built based on an open source framework Teiid, which is a data virtualization system that allows applications to use data from multiple, heterogeneous data stores. We created virtual database (VDB) for data federation, where data is accessed and virtually integrated in real-time across distributed data sources without copying or otherwise moving data from its system of record.

Data Linkage. After data federation, we applied semantic web techniques (e.g., RDF, SPARQL) for data linkage, which is a method for publishing structured data using vocabularies like schema.org that can be connected together and interpreted by machines. We created our own RDF generator, which standardizes the raw data to a unified RDF format and stored in RDF database as shown in Figure 1, so they can be read automatically by computers and enable data from different sources to be connected and queried. Afterwards, we apply the inverted indexing schema from ElasticSearch (www.elastic.co) (ES) for data indexing, which is an open source, distributable, and highly scalable search engine. The indexed results are stored to ES database. These two steps are critical to facilitate efficient data analytics in the following.

2.2 Data Analytics

Data Exploration. After getting to understand the data sources, users are guided to apply data mining techniques to explore patterns and correlations over data variables. We take association rules technique as an example to show how data mining techniques discover the relationship between variables in federated data. Association rules technique was initiated by Agrawal [1] to analyze transactional databases. It usually defined as an implication of the form $A \rightarrow B$ such as $A, B \subset I$ and $A \cap B = \emptyset$. Every rule is composed of two different sets of items A and B, where A is called antecedent or left-hand-side (LHS) and B called consequent or right-hand-side (RHS). In order to select interesting rules from the set of all possible rules, constraints on various measures of significance and interest are used. The best-known constraints are minimum thresholds on support and confidence. The support is defined as the proportion of transactions in the database which contain the items A, and the confidence defines how frequently items in B appear in a transaction that contains A. In this system, we apply Apriori algorithm [1] to extract association rules among variables over the federated data. For example, given the FB users with specific variables like age (e.g., 31-40), gender (e.g, female), and relation status (e.g., married), the system may present association rule graph with quantified scores of the fourth variable "personality", which indicates the prone of specific personality (e.g, high-score neuroticism, low-score agreeableness etc.) of these types of users.

Data Search. After exploring the federated data sources, users come to the page of *Data Search* and issue queries over the indexed data on ElasticSearch. As shown in Figure 3, for demonstration purpose, we created two dashboards of *Case-Study 1&2* and *Case-Study 3* for users. Each dashboard provides a search box as well as filter configurations. We have the pure long-text based variable (i.e., FB status update) to support text-based query, and additionally users will add filters to setup constraints for other variables to customize their own query. The third dashboard supports general advanced search (e.g., Boolean search).

3 DEMONSTRATION OF THE SYSTEM

For demonstration, let's say Alice, a psychologist researcher, who wants to research the correlation of personality and stresses in people's life based on social network behaviours. Alice is enabled to apply given data mining algorithms (i.e., association rules) to explore the hidden patterns across selected variables of interests. Next, Alice will further extrapolate the returned results in *Data Search* to have more detailed information of those people. These two steps will be described in case-study 1 and case-study 2 accordingly.

3.1 Case-study 1: association rules based sentiment analysis

In this case study, Alice will select her variables of interests including sentiment_score_subjectivity (sentiS), cNEU (neuroticism), cCON (conscientiousness), cAGR (agreeableness) [8] in the graph

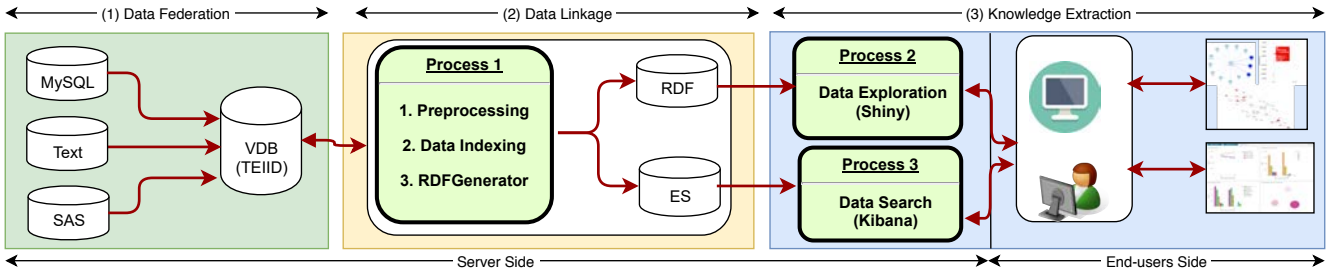

Figure 1: Overview of system architecture: (1) Data Federation, (2) Data Linkage, and (3) Data Analytics.

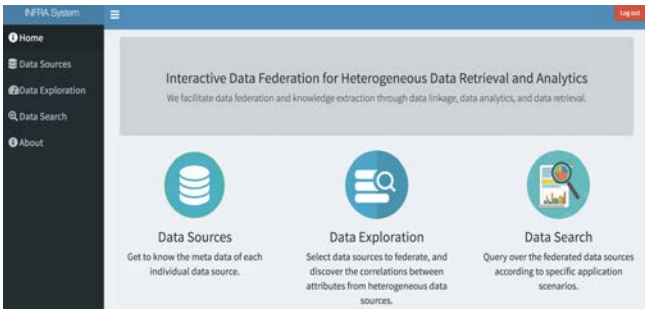

Figure 2: User interface of the system

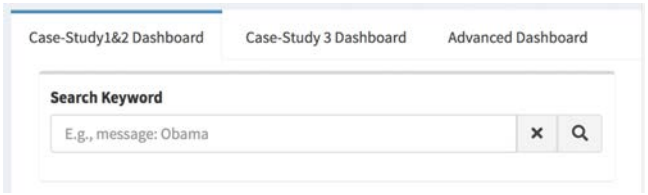

Figure 3: *Data Search* interface of the system

visualization panel (1) to be inferred through association rules. We applied the Apriori algorithm [1] to extract frequent variables, which satisfies the minimum support requirement specified by the user, and then generate association rules based on the user-specified confidence threshold. As shown in Figure 4, in *Data Exploration*, the four variables were chosen to run the inference. Parameter configuration panel (2) was displayed on right side including selecting data source, setting support and confidence thresholds for association rules. Above the configuration panel, a component of "User Guide–Help" gives user guidance of exploring this page. Afterwards, Alice moves to the bottom panel (3) and clicks "association rule graph" tab to see the results like in Figure 5. In this figure, the rectangles represent variables and the circles represent association rules. Larger size of circle imply more data records matching the rule, while the darker circle represent more importance of the rule.

Regarding the research question, Alice found a hidden pattern between three variables regarding neurotic people (cNEU), which is a personality trait that reflects one's ability to deal with emotion states, such as stress and anxiety. The pattern suggests that people who are not agreeableness (N.AGR) and do not have strong purposes in the way they say on FB status (sentiS=0) then most likely they are neurotic people. This hidden pattern however might not be sufficiently significant to draw such a conclusion to define neurotic people. Therefore, Alice will verify this discovered pattern in *Data Search* to confirm this pattern across data sources. The case-study 2 will explain in more detail how Alice confirms the explored pattern.

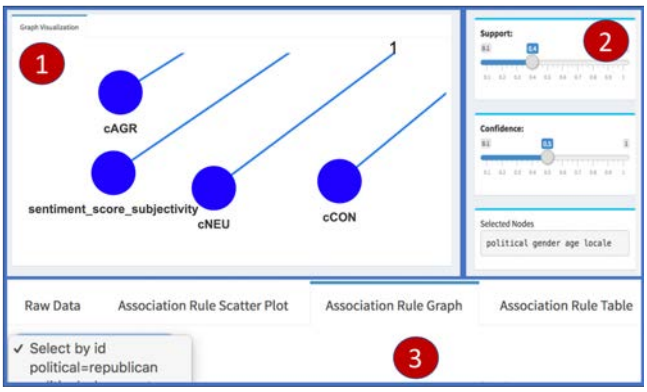

Figure 4: Selected variables on *Data Exploration*

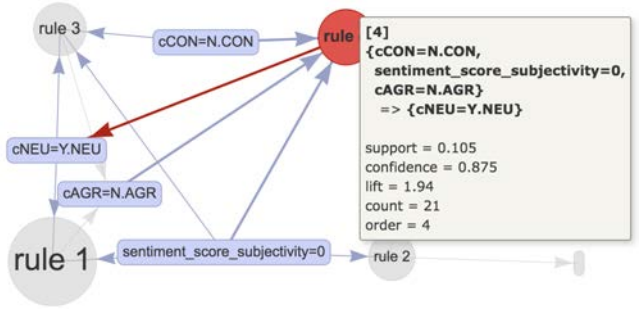

Figure 5: Case study of association rule based sentiment analysis on selected variables.

3.2 Case-study 2: personality and sentiment analysis

In this case study, we show how *Data Search* can be used to confirm the hidden pattern that Alice found out using the association rules. As shown in Figure 6, in *Data Search*, after issuing the query "sentiment_score_subjectivity:0 AND cagr:N.AGR AND ccon:N.CON" (Q1), Alice got a line chart showing the fraction between different personality traits and age group. It clearly shows

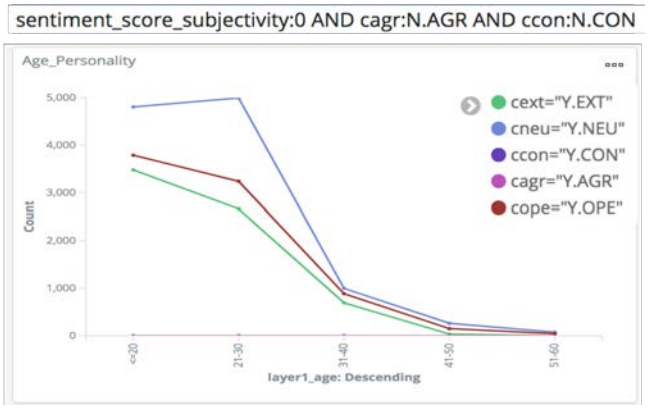

Figure 6: Case study of using *Data Search* to reconfirm the results from *Data Exploration*

that the neurotic group of people is the major group among five personality traits. Furthermore, Alice can find more information related to this group of neurotic people. For instance, a graph called "Age_Political_Views" shows that, mainly *neurotic people* have political views of "doesn't care" and "democratic". This extrapolation is a powerful feature that *Data Search* can provide for data analysts. Due to the limited space, we cannot show all analytic graphs that Alice can see based on her query. Thus, we specially create a dashboard called *Case-Study 1&2 Dashboard* for this demonstration. Anyhow, Alice can also issue the query Q1 to "Advanced Dashboard" and find more related information to the neurotic group of people to confirm the hidden pattern.

Remarks: In order to have a finally verified answer on the research question, Alice must also run a number of statistical analysis to reconfirm the statistical signification of the pattern. Nevertheless, Alice's job now already becomes much easier. In future, we plan to add statistical analysis to the system as well.

3.3 Case-study 3: privacy-concern analysis

This case study shows how privacy-concern analysis is done through community detection and data analysis based on different variables (i.e., age, gender, personality, FB status). It is clearly that privacy-concerns on social network is an important factor to protect people's privacy on personal data [9]. Since there was not any user defined privacy-concerns information in the given dataset, we apply an approach from [10] to infer people's privacy based on their FB status and personality. As shown in Figure 7, in *Data Search*, the *Case-Study 3 Dashboard* displays four different charts to characterize privacy-concerns of people across data sources and their demographic information. The chart (1) shows the personality difference based on different age groups, chart (2) shows the number of communities based on different privacy-concerns, chart (3) shows the correlation between privacy-concerns and age, and chart (4) shows the association between gender, privacy, and sentiment embodied in their FB status. Especially, users can simply search based on keywords. For instance, if a user issues a query "Obama" and sees people's sentiment polarity (e.g., positive, neutral, negative) when they talked about Obama. It is found that 56.9% of users who mentioned the word "Obama" are females, in which 19.95% of them have negative sentiment when they mentioned about Obama. After digging deeper into the raw data, we realized that FB users complained about Obama mainly because of high unemployment rate in USA during his presidency, such as one post saying "because of obama there are no more jobs left in america".

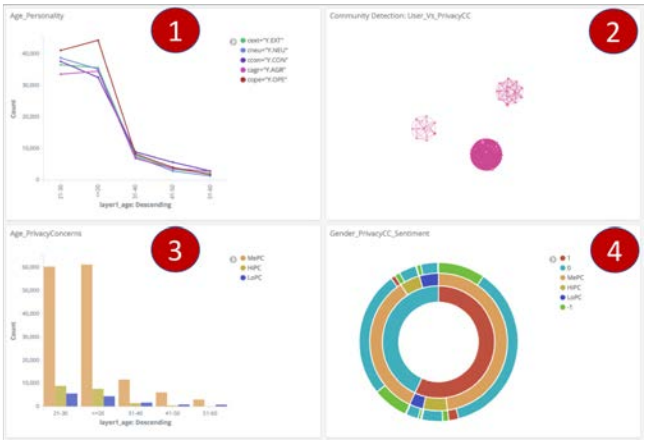

Figure 7: Case study of privacy-concern analysis

3.4 Implementation and demo environment

The system was implemented in Java and R. Data federation mechanism was built on Teiid. We developed the interactive and user-friendly interfaces using R shiny (shiny.rstudio.com/) and ArulesViz [5]. We built our own RDFGenerator to generate RDF files from VDB (Virtual Data Bases), and stored them in Apache Jenna Fuseki (jena.apache.org). To support *Data Search*, we employed ElasticSearch and Kibana for high performance data retrieval. Thanks to the plugin based architecture, Kibana can be easily extended to suit particular needs. For instance, according to the different data analytic requirements from different end-users, we support extended customized dashboard for each user need.

Brief information of the web-based prototype:

- System video URL: https://vimeo.com/319473546
- Multiple Operating System(s): Linux, macOS, Windows
- State-of-the-art browsers e.g., Chrome (recommended)
- Memory: from 1GB

4 CONCLUSION

In this paper, we have proposed a graph-based data federation system for heterogeneous data analytics. It is an open-source SPARQL query builder and result-set visualizer for heterogeneous data sources (i.e., myPersonality corpus) which allows users to easily construct and explore data over heterogeneous data sources. The system is scalable by easily adding new heterogeneous data sources, and customizing data representation and analytics by users, especially researchers based on their own interests. The future work will be adding more text-based data sources, extending more data mining algorithms options for data exploration to accompany data search.

ACKNOWLEDGEMENT

This research is funded by Umeå University in Sweden on federated database research. The authors also thank Michal Kosinski, David Stillwell and the myPersonality project for data sharing.

ABSTRACT

In this demo paper, we present the XFake system, an explainable fake news detector that assists end-users to identify news credibility. To effectively detect and interpret the fakeness of news items, we jointly consider both attributes (e.g., speaker) and statements. Specifically, *MIMIC*, *ATTN* and *PERT* frameworks are designed, where MIMIC is built for attribute analysis, ATTN is for statement semantic analysis and PERT is for statement linguistic analysis. Beyond the explanations extracted from the designed frameworks, relevant supporting examples as well as visualization are further provided to facilitate the interpretation. Our implemented system is demonstrated on a real-world dataset crawled from *PolitiFact*[1], where thousands of verified political news have been collected.

CCS CONCEPTS

• **Human-centered computing** → **Natural language interfaces**; *Graphical user interfaces*; *Web-based interaction.*

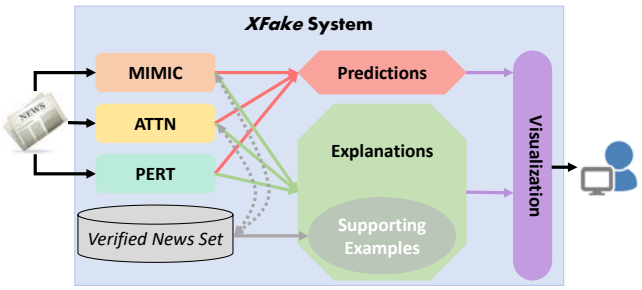

Figure 1: The architecture of XFake system.

1 INTRODUCTION

With the prevalence of web applications, it has become much easier for the public to get access to various news items through different channels, such as news websites and social media. However, this kind of convenience also brings about the wide spread of fake news at the same time [10]. Fake news is detrimental to both individuals and society, and it is usually generated as hoaxes to mislead public through false or biased information. In 2016, the term "Fake News" was even shown as the word of the year by Macquarie Dictionary.

Though increasingly relevant, effective fake news detection is still considered to be challenging due to the following two aspects. First, fakeness of news could come from diversified perspectives [7], which is beyond the boundaries of traditional textual analysis. For example, a fake news item may result from its contexts or speaker, and it may not directly relate to its contents. The source of fakeness is highly dependent on each specific instance. Second, fakeness detection results need further explanation, which is important and necessary for users' final decisions [2]. The explanation could provide evidences on model predictions and further help users better understand why certain news items are classified as fake.

Considering these two challenges, we design and implement an explainable system, named **XFake**, on fake news detection task. Particularly, three different frameworks (i.e., *MIMIC*, *ATTN* and *PERT*) are designed to analyze news items from different perspectives. With MIMIC, we aim to judge each news item from its attribute information, which may include news context, speaker and etc. For ATTN, our goal is to investigate each news statement through its semantic meaning. By employing PERT, we aim to study the linguistic features of news statements for detection. All three designed frameworks are self-explainable, where relevant explanations could be extracted for interpreting detection results. Besides, we also provide supporting examples for each news instance by corresponding matching algorithm, and visualize detection results for user-friendly interaction. Both supporting examples and visualizations further assist users to understand why the system make a certain prediction on a given news. Overall, XFake system is capable of not only giving prediction scores on news fakeness, but also providing relevant explanations as prediction evidences. With the aid of XFake, users would be convenient to identify the news credibility.

To best of our knowledge, XFake is the first explainable fake news detector over multiple perspectives. Corresponding system architecture and demonstration details will be respectively introduced in the following section 2 and section 3.

2 XFAKE ARCHITECTURE

The architecture of XFake is illustrated in Figure 1. The system input is the targeting news with attributes, and the output contains both prediction and explanation results. The whole system is trained on a verified news set. All components will be introduced as below.

MIMIC Framework. MIMIC is designed to analyze the news attributes. Enlightened by [9], we employ a deep neural network as the teacher, and use a shallow model as the student to emulate the teacher's performance for better explainability. Basically, the overall idea is to mimic the performance of neural networks with tree ensemble models, so that we can keep the good performance from neural networks and good explainability from tree ensemble models simultaneously. The structure of MIMIC is illustrated in Figure 2. Specifically, we use GloVe [6] as our word embedding scheme in MIMIC. After obtaining the soft labels from the teacher model, we further use them to train a student model consisting of 80 decision trees. By calculating the node importance of each attribute in the ensemble trees, we could get the significance of each attribute in the input news instance. Further, through the constructed trees and importance scores, users could know what happened inside, which provides an overall transparency towards the model itself.

ATTN Framework. ATTN is designed to analyze news statement simply from semantic perspective. To build an explainable model for semantic analysis with good performance, we employ several techniques, including pre-trained word embedding, convolutional neural network [4], and self-attention mechanism [8]. Self-attention is used because it can capture global relationships between different words efficiently. In addition, the weight matrix generated in attention mechanism is input dependent, which helps provide instance-level explanation. By applying different kernel sizes for the convolutional network, we can get explanations based on one-gram, two-gram or three-gram analysis. The overall illustration

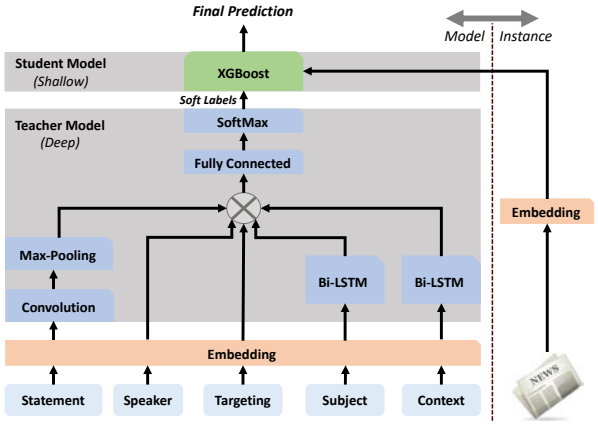

Figure 2: The structure of MIMIC framework.

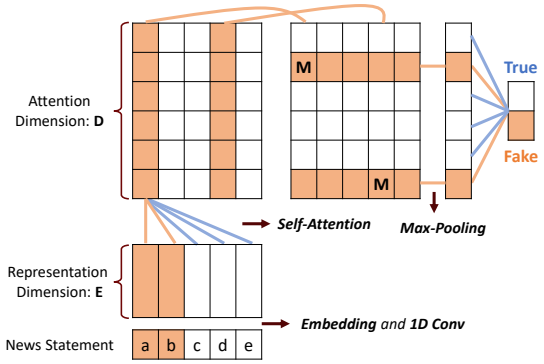

Figure 3: The illustration of ATTN framework.

of ATTN is given by Figure 3. In ATTN, we employ word2vec [5] as the pre-trained embeddings and each vector representation has a dimension of 300 (i.e. $E = 300$). Each spatial location learns a 512-dimensional vector representation for each word (i.e. $D = 512$).

PERT Framework. PERT is designed for news statement analysis as well, but it is uniquely from a linguistic perspective. For effective analysis, we employ eight linguistic features, including *Adjective ratio*, *Noun ratio*, *Verb ratio*, *Propn* (such as Google, etc.) *ratio*, *Sentiment score*, *Normalized text length*, *Whether contains the mark "?"*, *Whether contains the mark "!"* [3]. For each news item in the training set, we extract its linguistic features and train an XGBoost [1] classifier using these features. The trained XGBoost is then used to make predictions for new items. Further, we use perturbation-based method to provide explanations. The idea is that feature importance can be measured by observing how much the score (e.g., accuracy) decreases when the feature is not available. To this end, we can remove a feature from the dataset, and then re-train the classifier for score checking. Since re-training may be computationally expensive, we replace the feature value with random noise, drawn from the same distribution as the original one, instead of removing. The computed prediction difference is utilized as the significance score for the corresponding feature.

Prediction & Explanation. XFake outputs the prediction of news as a unified score, indicating its probability to be fake. The prediction result is the ensemble output from MIMIC, ATTN and PERT,

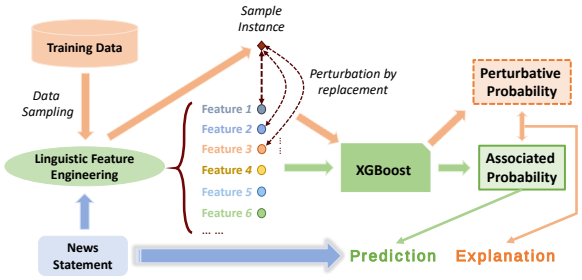

Figure 4: The mechanism of PERT framework.

where different results are combined together in a weighted sum manner. The weights for combination are tuned on a validation set, according to the performance of different frameworks. The higher the prediction score, the higher the probability for fake news. As for the explanation from XFake, it is mainly extracted from three different perspectives enabled by MIMIC, ATTN and PERT. MIMIC could provide explanation by key components of news, ATTN is able to explain predictions by word/phrase attribution, and PERT generates explanation by linguistic features. Beyond this, XFake also explains predictions from data perspective with supporting examples. These examples are generated from both MIMIC and ATTN by retrieving training samples given corresponding explanations (i.e. key attributes or important words/phrases). Showing these training samples which are highly similar to the input news would be helpful for users to understand the working patterns of XFake. Besides, we also assign different similarity scores for different supporting examples based on the matching extent between the input and support. Supporting examples with higher scores would be considered more informative in delivering explanation.

Visualization. To further facilitate the explanability of XFake, we visualize the outputs of both prediction and explanation by *D3 JavaScript*. Visualization mainly lies in three aspects. First, for numerical values, such as prediction score and attribute significance, we visualize them by histograms, which straightforwardly indicate the results and influences. Second, to enhance the explanability for word/phrase attribution, we visualize the outputs by highlighting important words/phrases with heatmaps, where the darkness positively relates to the importance of word/phrase. Third, for better model explanability, the ensemble trees are visualized with interactive diagrams which are capable of showing both overall structure and specific activated paths (depending on the input). Through those visualization schemes, users could have a better sense towards XFake about why certain news are classified as fake or true.

3 SYSTEM DEMONSTRATION

XFake is implemented by *Python* and deployed in *FLASK* with an *HTML* front end. To demonstrate the system, we will first introduce the data source and then go through a specific use case of XFake.

3.1 Data Source

The news data, which is used to train, tune and evaluate XFake, comes from a political fact-checking website, named PolitiFact. It is a Pulitzer prize-winning website containing tons of political news with diversified categories. The reasons why we employ this data source are in three folds. First, PolitiFact provides professional justification and fine-grained labels for all news items, where the core principles in independence, transparency and fairness guarantee its high credibility among the public. Second, the news collected by PolitiFact have various attribute information, which directly meets our data requirement for analysis. Third, raw data in PolitiFact can be effectively crawled through an available API [2], and it is convenient to obtain the customized dataset for system implementation.

When processing the data, we only keep the attributes which are highly related to news fakeness. Specifically, the maintained attributes for XFake include *Subject*, *Context*, *Speaker*, *Targeting* and *Statement*, although some news may not have all five attributes. Besides, to effectively measure the news fakeness and train the system, we transform the original multi-class data to binary data where each news item is labelled as either *True* or *False*[3]. Particularly, labels with *Mostly True*, *Half True*, *No Flip*, *Half Flip* are switched to label *True*, and labels with *Mostly False*, *Pants On Fire*, *Full Flop* are switched to label *False*. Furthermore, as for data statistics, there are *5104* news crawled in total, which are evenly distributed. The training, validation, test set of XFake respectively contain *4083*, *510*, *511* items. The validation set is used to test the performance of different frameworks and further tune the hyper-parameters, while the test set is employed to conduct the overall evaluation.

3.2 Use Cases

With the testing on validation set, we obtain *67.1%*, *67.3%*, *53.2%* accuracy respectively for MIMIC, ATTN and PERT framework. By normalizing weights according to the performance, we fix the coefficients *0.36*, *0.36*, *0.28* in weighted sum correspondingly for all use cases. Considering the fake news identification scenario, we show a specific case demonstration of XFake as follows.

Illustrated by Figure 5, users start by inputting news into the text boxes. In XFake, we provide a button "Random News" to help users explore the system, which is used to retrieve random items from our test set. Similarly, buttons "Fake Examples" and "True Examples" are also provided to help quickly access some representative fake and true news. After clicking "Submit", users would obtain all the outputs including both prediction and explanation in a few seconds. As for the prediction of the example in Figure 5, we get the score 0.76, which means that the given news has the probability 76% to be fake. Regarding to the explanation, we can obtain it from both attribute and statement analysis. Aided by MIMIC, for this example, we know that "Statement" plays the most important role compared with others. Through ATTN, we can easily check those highlighted words, such as "invited" and "Russia", with different darkness, which would also show the contribution scores when mouse is hovering around. PERT gives users a clear view about which linguistic features contribute to fake and which to true. In the example, we observe that features "Propn Ratio", "Adjective Ratio" and "Noun Ratio" mainly contribute this news to be fake.

XFake further provides supporting examples and visualized trees for users to better understand the system. As shown in Figure 6, we give two supporting news for instance, where one is retrieved based on the important attributes (Context & Statement) from MIMIC

[2] http://static.politifact.com.s3.amazonaws.com/api/v2apidoc.html
[3] A news item labelled as False is regarded as the fake news.

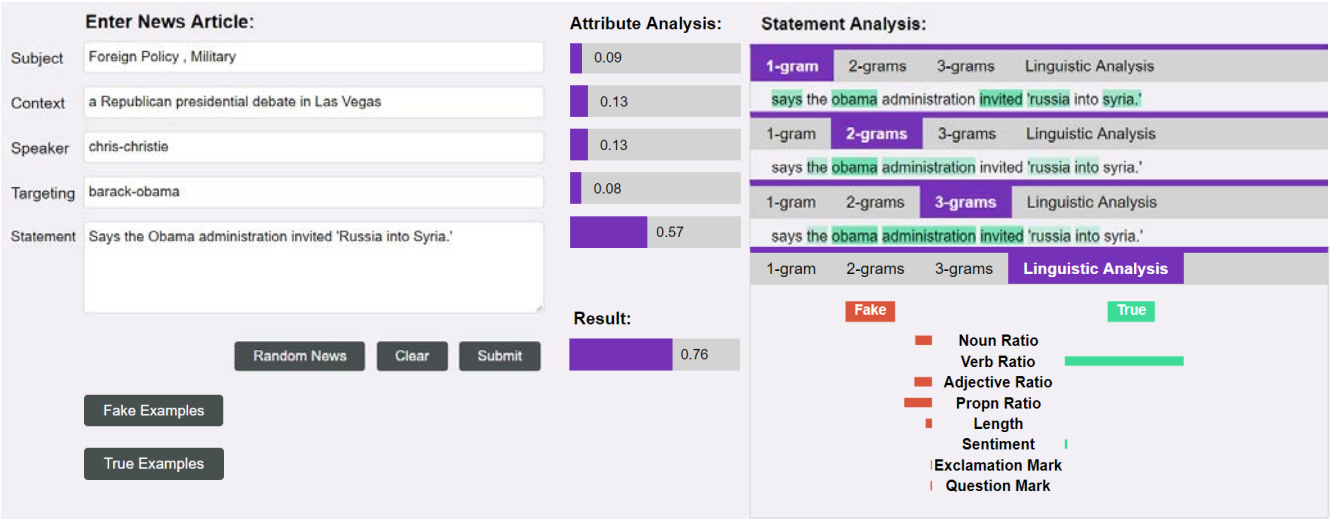

Figure 5: Prediction and explanation from XFake.

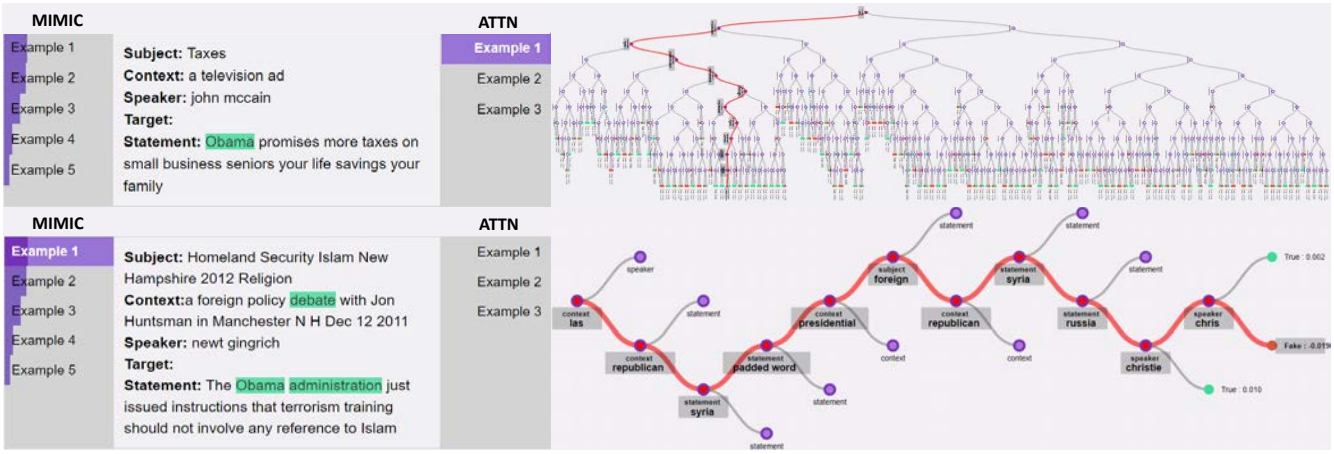

Figure 6: Supporting examples and ensemble trees from XFake.

and the other is obtained by matching significant word ("Obama") from ATTN. For the support extraction with MIMIC, we also attach a similarity score, indicating how much attribute information it overlaps with the input one. Besides, 80 decision trees are visualized with interactive diagrams and highlight the activated path of each tree regarding to the input. In Figure 6, we only show one decision tree for example. We can see that each decision tree can be expanded or compressed flexibly, which allows users to track the decision process closely. Given a certain news, each decision tree has only one activated path, corresponding to one specific decision attached at the end of the path with relevant contribution score. Those visualized trees largely enhance the model explainability of XFake.

To demonstrate the effectiveness of XFake in real cases, we conduct relevant human evaluations by Amazon Mechanical Turk (AMT), with *147* valid testing users in total covering diversified gender, age and education level. The involved user tasks include *Fact Check* and *Prediction Guess*, where the first one is to test the usefulness of the generated explanation and the second one is to indicate the users' understanding towards the system. The evaluation metrics are accuracy and time for user prediction. The human study shows a clear trade-off between the speed and accuracy regarding to generated explanations. On one hand, explanation does help users better understand and predict system behavior. On the other hand, explanation would take users more time to review and interpret detection results for benefits. Due to space constraints, we limit the details of the human evaluation study in this paper.

4 CONCLUSIONS AND FUTURE WORK

We design and implement an explainable fake news detector, named XFake, to help end-users identify the news credibility. XFake is capable of jointly analyzing news items from multiple perspectives, and can effectively provide explanation through attribute importance, word/phrase significance, linguistic features as well as relevant supporting examples. Corresponding visualizations further enhance the explanability of XFake and facilitate the decision making for users. In future, applying XFake to multi-source (i.e., not limited to

the PolitiFact website) or multi-modal (i.e., not limited to textual form) news data could be a promising extension for the system.

ABSTRACT

We present GraviTIE (Global Representation and Visualization of Text and Image Embeddings, pronounced "gravity"), an interactive visualization system for large-scale image datasets. GraviTIE operates on datasets consisting of images equipped with unstructured and semi-structured text, relying on multi-modal unsupervised learning methods to produce an interactive *similarity map*. Users interact with the similarity map through pan and zoom operations, as well as keyword-oriented queries. GraviTIE makes no assumptions about the form, scale, or content of the data, allowing it to be used for exploratory analysis, assessment of unsupervised learning methods, data curation and quality control, data profiling, and other purposes where flexibility and scalability are paramount. We demonstrate GraviTIE on three real datasets: 500k images from the Russian misinformation dataset from Twitter, 2 million art images, and 5 million scientific figures. A screencast video is available at https://vimeo.com/310511187.

Figure 1: Main interface of GraviTIE. GraviTIE (Global Representation and Visualization of Text and Image Embedding) is an interactive web visualization application and discovery engine for large image-text datasets.

1 INTRODUCTION

Countless images exist on the web. These include photographs, memes, art images, scientific figures, and more. Analysis of these image datasets increasingly requires the application of large-scale machine learning methods to answer even relatively straightforward questions. For example, the dataset recently released by Twitter[1] contains rich information about Russian influence, but even conceptually simple questions such as "Do images posted from Russian accounts tend to differ from those posted by other accounts?" require a combination of unsupervised learning (to determine image similarity), NLP methods (to contextualize the image), and structured queries (to compare images by source and year).

These analysis tasks have several defining characteristics. First, tasks increasingly require some form of unsupervised learning. Ground truth labels or other obvious sources of supervision are rarely available. In these situations, interactive, qualitative exploration of the results is the only option. Second, the data is *multimodal*: each record consists of some combination of an image, free text, and a set of structured attributes. Each of these elements may be of arbitrary size, or altogether missing. Third, the datasets are large, making direct-browsing and main-memory approaches infeasible. For example, the Twitter dataset contains 9 million tweets with over 543k images, the Artstor dataset contains more than 2 million high-quality images of artwork along with text descriptions, and the Viziometrics [8] dataset consists of over 9 million figures from the scientific literature, along with their captions.

In this demonstration, we present GraviTIE (**G**lobal **R**epresentation **a**nd **Vi**sualization of **T**ext and **I**mage **E**mbeddings, pronounced "gravity"), an interactive visualization system for large-scale image-text datasets. Fig. 1 shows the interface of GraviTIE.

For pre-processing, GraviTIE takes as input a large set of image-text pairs. It learns an embedding for the pair with clustering objective by running MultiDEC[14] on the text and image, such that the two models tend to produce the same distribution. The properties of MultiDEC are tightly coupled to the design of the interface. In particular, this model 1) accommodates multi-modal heterogeneous data while 2) maintaining reasonable performance at scale. The learned embedding is then dimension-reduced to two dimensions for display purposes.

The GraviTIE interface features a large similarity map to display thousands of nodes, where each of the node represents an image positioned by a multi-modal vector embedding. Similar images are clustered together on this similarity map which helps the users efficiently navigate a large number of images. Users can refine the current view using a combination of free-text queries (with appropriate operators “must include”, “might contain” or “exclude”) and structured query filters. Only a sample of the images is displayed to ensure performance at scale and to afford hover interactions with individual images; displaying all images would lead to extremely dense regions with significant occlusion. Users can pan, zoom, filter, and search iteratively, gradually refining the set of displayed images and inspecting the images in each cluster via hover interactions at any time. Each view is associated with a unique url (i.e. RESTful), making the system stateless and programmable, allowing refinements to be saved and shared with collaborators. The data displayed in each view can be directly downloaded to provide custom curated subsets for specific tasks. For example, an art historian can construct a dataset of impressionist paintings by selecting particular clusters and filtering for a particular time period. The RESTful API design also affords additional downstream applications to be developed using the search and download functions.

GraviTIE is designed to be adaptable to a number of applications across multiple modalities and communities. In its current form, art historians are using GraviTIE to explore influence patterns in art, computer scientists are using it to qualitatively assess unsupervised learning methods, and social scientists are using it to understand the behavior of Russian actors on Twitter.

2 RELATED WORK

Analysis and visualization of large scale images have been receiving great attention from researchers. Hochman et al. [7] explore over 2 million photos on Instagram by sorting the images in terms of their properties (e.g., hue or create time) and showing the complete image sets of different cities to reveal the local culture and social patterns. The T-SNE Map [2], one of Google Arts & Culture experiments by Diagne et al., is a 3D interactive platform created by computing the visual similarity of art works and grouping the art works with t-SNE algorithm. PixPlot[3] extends the idea by applying UMAP [10] algorithm which can scale large data set and cluster million of data points and allows users to implement custom datasets. These applications provide a simple platform to explore large scale image sets, but do not support query and do not exploit text or structured metadata to assist search and curation. Wang et al. [13] introduced iMap, a treemap-based visualization for navigating image search and clustering results, but the number of images displayed is limited. iGraph [5] constructs a similarity graph by computing the affinity between images, the relationship between texts, and the connection between images and texts, which results in a system that requires enormous amount of computation.

[3]http://dhlab.yale.edu/projects/pixplot/

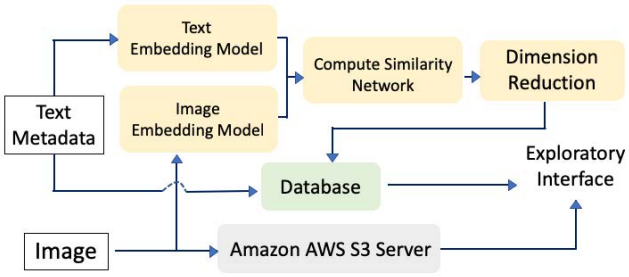

Figure 2: GraviTIE system overview. Yellow: learning the similarity map. Green: learned embeddings and associated metadata are stored in a database. Gray: images are stored in a cloud-based object store.

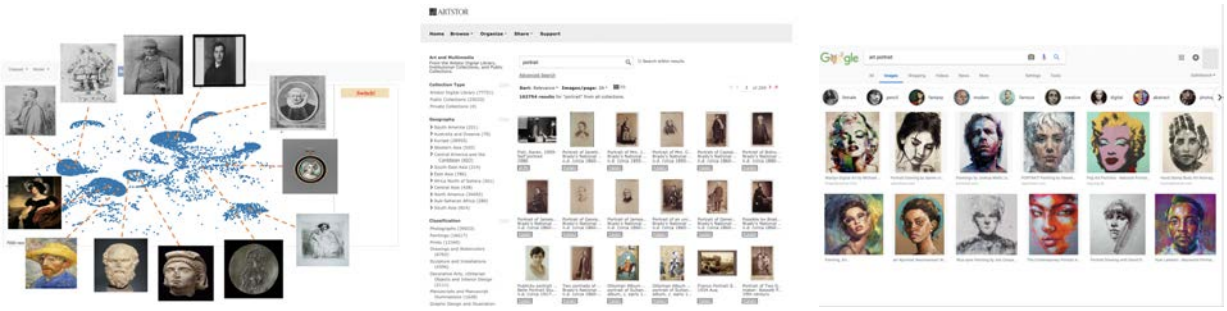
3 GRAVITIE SYSTEM OVERVIEW

Figure 2 summarizes the architecture of GraviTIE. The pipeline can roughly be divided into three parts: Constructing similarity map, textual and numeric data storage, and image storage.



Learning the Similarity Map: The front end interface of GraviTIE takes a 2-d vector of coordinates for each image-text pair to construct the similarity map visualization. In this demonstration, all datasets are pre-processed by the same pipeline in which we first separately embed image and text, acquire a combined representation vector for each text and image pair, and finally apply a dimensional reduction algorithm to obtain the desired 2-d numeric vectors. We use MultiDEC [14] to learn representations of these image-caption pairs. MultiDEC is a method for clustering image-caption pairs by iteratively computing an auxiliary target distribution and matching both image distribution and text distribution to the target. Because MultiDEC produces distinct and semantically meaningful representations for both image and text, it is a natural candidate for this task. Users can also visualize the visual features and textual features alone.

Textual and Numeric Data Storage: The metadata, textual description, and the 2-d numeric vector for each image-text pair is saved in a MySQL database. GraviTIE also utilizes MySQL full text search (boolean mode) to support keyword search.

Image Storage: GraviTIE uses Amazon AWS S3 to store millions of image for display purposes.

4 GRAVITIE DEMONSTRATION DATASETS

We will demonstrate the GraviTIE system on three large-scale datasets to show the versatility and the breadth of GraviTIE.

(a) Search for "portrait" on GraviTIE. (b) Search for "portrait" on Artstor. (c) Search for "portrait" on Google Images.

Figure 3: Search results for "portrait" using (a) GraviTIE, (b) Artstor, and (c) Google Images. GraviTIE summarizes the space of relevant images; different clusters represent different types of portraits. Artstor and Google Images each show only a small set of top-ranked images, and each engine uses a different opaque ranking function, making the results unpredictable.

Russian Tweets. Twitter [4] released over 9 millions tweets from 3,841 accounts that are believed to be connected to Russian Internet Research Agency. This dataset has received significant attention from researchers to understand foreign influence on US politics. We process and display all 543,220 tweets with images on GraviTIE to investigate relationships from a visual perspective.

In this particular demonstration, we first embed images with ResNet-50 [6] model, pre-trained on 1 million ImageNet dataset[4], and acquire a text representation with a Glove [12] model that is pre-trained on 2 billion tweets. We then apply *multiDEC*[15] to learn a joint representation for the combined image-text pair. Finally, UMAP [10] is performed to produce 2-d vectors for visualization.

Art Imagery. GraviTIE includes 2,144,301 art images from the ArtStor collection. Artstor is a non-profit organization that creates digital libraries for scholars arts, humanities, social sciences and architecture. They approached us looking for new ways to explore their large image sets that went beyond simple metadata queries. For these images, the metadata is sparse, so the results of the queries are unreliable. A goal of GraviTIE is to utilize the full coverage of arbitrary data, with no assumptions on completeness. We also want to visually convey the results of unsupervised image clustering. A group of art historians are currently using GraviTIE to find patterns of influence and providing us with feedback.

We extracted visual features for the art images using pre-trained ResNet-50. We concatenate values of title, art classification, creator, repository, and date to serve as the description of each image. We then trained a FastText [2] model based on the description and acquired the textual/meta-data representation for each art work. Similar to the pipeline for the twitter data, we applied *multiDEC* followed by *UMAP* to obtain the final 2-d representation.

Scientific Figures. In addition to the art images and twitter data sets, we use a large database of scientific figures that we have been extracted from PubMed, arXiv and other repositories of the scientific literature. The goal is to understand how the use of different types of figures vary over time and across fields. The example dataset includes over 5 million figures from 800k scientific papers from the arXiv.org. ArXiv provides the raw pdfs; we extract images and captions from these pdfs using pdffigures2.0 [3] and then follow the similarity map pipeline described previously.

5 KEY FEATURES

GraviTIE supports interactive queries and the exploration images *collections*. The central feature is a similarity map supporting mixed queries, panning, zooming and visual inspection of individual images. Each image-text pair is represented as a single glyph colored by a user-configurable attribute and situated in the 2-D plane based on the similarity with other image-text pairs. Users can hover over each glyph to view the corresponding image and text content associated with that image (Fig. 4a). The query system (Fig. 4c) affords dataset refinement and curation via keyword search or structured predicates. Users can customize the current view through a highlighting feature (Fig. 4d). These customizations can easily be saved and shared with other users since each view is associated with a unique url. Below we highlight other features of the system:

Similarity Map. : The similarity map is what distinguishes the design of GraviTIE from other systems for interacting with large image collections. It makes no assumptions about the images (unlike, say Building Rome in A Day [1]), and can make use of multi-modal information if available. The similarity map can also be used as a replacement for conventional list-based search interfaces: by providing a visual summary of all results rather than the top few items in a ranked list, we allow the user to process information and identify patterns faster than scanning a list of textual information [11].

Consider the simple experiment in Figure 3. We search for the keyword *portrait* on three platforms: GraviTIE, Artstor, and Google Images. GraviTIE reveals that there are several dense clusters of similar images, and upon inspection, these clusters are easily identified as corresponding to print portraits, painted portraits, photograph portraits, and other semantic types. However, the Artstor search results display only the top k images ranked by query relevance, which in this case consist entirely of print portraits. The ranking function used by Google Images makes another seemingly arbitrary choice, displaying entirely painted portraits. Not only do both of these sets of results seem incorrect in general, but even for those situations where they are what the user wants, GraviTIE can emulate similar results within a few hover-and-zoom interactions.

(a) Similarity Map: Each point represents an image-text pair. The user can hover on a point to display the visual and textual content.

(b) Direct inspection: When the number of records is less than 300, thumbnail images are displayed instead of glyphs.

(c) Advanced search: Keyword semantics are configurable.

(d) Highlighting: Items with a selected keyword are highlighted.

Figure 4: Some features of GraviTIE: (a) Similarity map, (b) Direct inspection, (c) Advanced search, (d) Highlighting

Scalability, Query, and Reproducibility. : The similarity map also directly affords scalability. By simply applying a sampling mechanism, we can retain the overall structure of the (embedded) image space while controlling system performance and not occluding individual images. By combining offline pre-processing and sampling, we maintain high performance interactions for datasets of arbitrary scale. Cluster-aware sampling approaches and their impact on interactivity and user task performance remain future work.

GraviTIE supports exploring a set of related keywords at a time. Given a set of user-provided search terms, the user can force each term to be included or excluded. For instance, the results of the query result of Fig.4c would definitely include the term *president*, might contain *trump*, *hilary*, *election*, and *obama*, and would exclude *senator*. In addition, selecting a keyword highlights the elements in the similarity map associated with that keyword, as in Fig. 4d. To initialize this interaction, users can toggle between default interesting keywords (eg. Fig. 4b shows the top 20 frequent hashtags) or type their own (eg. Fig. 4d). If an item includes multiple highlighted keywords, it is indicated with a distinguished color.

Every view in GraviTIE is associated with a unique url to afford collaboration, provenance, and sharing. The browser history can be used to retrace steps, and particular views can be saved simply by copying and pasting links. In addition, a user can download the corresponding dataset associated with any view for further analysis. This feature has been valuable in supporting research by providing an easy way to construct high-quality training datasets from important subsets of images. For example, GraviTIE can be used to quickly find a large set of phylogenetic tree images in the scientific literature for information extraction research[9].

6 CONCLUSION

We have built a fully functional prototype of GraviTIE with several large-scale, image sets to explore. The tool is publicly available and easily accessible in both desktop and mobile environments. For the conference, we plan to have several examples of how the tool can be used to identify and zoom into clusters of similar images, the text associated with these images and nuances in the output of these different unsupervised algorithms. Conference attendees will be able to initiate our pre-baked queries but also initiate their own queries. As an example, we will default to the term "portrait" in the art image set. This will illustrate the distinct types of portraits that exits in the 2.5 million ArtStor images, as mentioned above. Early feedback from collaborators in art history suggest that they can use GraviTIE to quickly understand the coverage of the database in certain time periods and styles (e.g., how many portrait archetypes exist in 20th century paintings). Our goal for the demonstration is to show how GraviTIE works and to gather feedback from users on what kind of functionality is needed to help them explore image sets in ways not available.

7 ACKNOWLEDGEMENT

We would like to thank Artstor who provided their valuable art collection to visualize on GraviTIE.

ABSTRACT

The demo presents TaxVis, a visual detection system for tax auditor. The system supports tax evasion group detection based on a two-phase detection approach. Different from the pattern matching based methods, this two-phase method can analyze the suspicious groups automatically without artificial extraction of tax evasion patterns. In the first phase, we use a network embedding method node2vec to learn representations that embed corporations from a Corporation Associated Network (CANet), and use LightGBM to calculate a suspicious score for each corporation. In the second phase, the system use three detection rules to analyze the transaction anomaly around the suspicious corporations. According to these transaction anomalies, we can discover potential suspicious tax evasion groups. We demonstrate TaxVis on tax data of Shaanxi province in China to verify the usefulness of the system.

1 INTRODUCTION

Tax evasion detection is a challenging work for every country. It is reported by the Chinese government that the loss rate of tax revenue in China is above 22 percent [7]. In addition to suspicious individual detection, there is a new tendency that corporations plot together to evade tax [2, 7]. The existing solutions for detecting tax evasion groups are mainly based on graph pattern matching. In these methods, the pattern of tax evasion group must be extracted from massive cases by the tax auditors manually. As a result, there is a limitation that these patterns cannot be constantly updated to keep up with the rapid changes of tax evasion since it takes great effort for tax auditors to identify new patterns.

Given the limitations of the pattern matching based methods, we designed a two-phase approach for detecting tax evasion groups. The first phase is suspicious individual detection which use node2vec and LightGBM to detect suspicious corporations in the CANet. In [2, 6, 7], we can find that the relationships between corporations play an import role in many tax evasion patterns. As show in Figure 1, in order to utilize these relationships, we choose the network embedding method node2vec to automatically embed the corporations from the transaction and investment relationship graph. And then we use LightGBM to calculate a suspicious score for each corporation. The second phase is suspicious group analysis which can inspect whether the corporation belongs to a suspicious tax evasion group. In this phase, we use three rules to detect transaction anomalies around each corporation, and then according to these anomalies we can get some suspicious groups.

We demonstrate TaxVis based on the tax data of Shaanxi province. After selecting the detection year, our system will automatically compute the suspicious score of each corporation. Next, clicking one corporation, the system will display the details of its transactions, which include the transaction volume, the commodity category, and the transaction corporation etc. And then based on these transaction details, we use three rules to analyze the abnormal transaction of the selected corporation in a transaction flow chart. Finally, we can find whether the corporation belongs to a suspicious tax evasion group. A demonstration video is available at the following address: https://youtu.be/46M0talBclo. Our contributions are as following:

- We propose a two-phase approach to calculate the suspicious score based on the representations of corporations in CANet and detects suspicious tax evasion groups automatically.

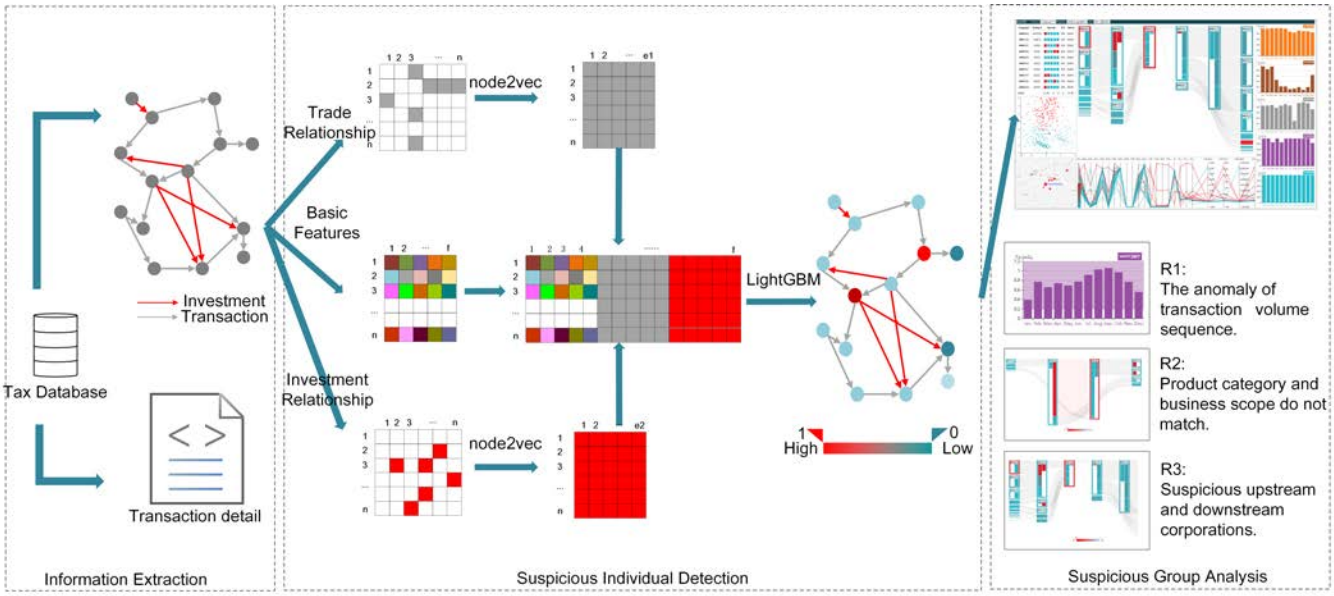

Figure 1: The structure of the TaxVis. First, we extract information from tax database. Then we detect suspicious individuals by node2vec and LightGBM. Finally, we use a visualization system to analyze the suspicious tax evasion groups.

- We design a transaction flow chart to visualize the transaction anomalies around corporations.
- We present a visual analytic system based on our proposed two-phase approach and the transaction flow chart for tax audition officer to discover suspicious tax evasion groups.

2 SYSTEM DESIGN

The structure of this system is shown in Figure 1, which consists of three components.

The first component is the information extraction, which collects all the basic features of corporations and the relationships between them, including transaction and investment relationships. The second component is the suspicious individual detection. It detects suspicious individuals by combining the node representation vectors and basic feature vectors. The last component is the suspicious group analysis. We use three detection rules to detect whether the corporation belongs to a suspicious group. The details of each component are as follows.

2.1 Information Extraction

In this component, we extract the corporationâĂŹs information from tax database. Each corporation's information consists of three parts. The first part is the corporationâĂŹs basic features, including the corporation's registration time, the registration area and the age of the legal representative, etc. The second part is the transaction and investment relationships between corporations. The third part is the transaction detail data that can be used to detect suspicious groups. The transaction detail includes the transaction volume per month, the transaction time and the commodity category, etc. Based on the above data, we build a corporation associated network (CANet) $G = \{V, E_1, E_2, A\}$, where $V = \{V_1, \ldots, V_n\}$ is a set of corporations, $E_1 = \{e_{ij}^1\}$ denotes the transaction relationships between corporations, $E_2 = \{e_{ij}^2\}$ denotes the investment relationships between corporations, and $A = \{a_i\}$ denotes the attributes of corporations.

2.2 Suspicious Individual Detection

In this component, we detect suspicious individuals in the CANet with node2vec and LightGBM. The technical details are as follows.

2.2.1 Node2vec. Node2vec is a network embedding method based on random walk that can learn continuous feature representations for nodes in a network [4]. The method is built on the assumption that the representations of adjacent nodes are approximated. Choosing node2vec is based on the following three reasons.

Transaction and investment relationships are important information in detecting tax evasion. In the previous researches about tax evasion groups, transaction and investment relationships between corporations play an important role in some suspicious tax evasion patterns [7]. Therefore, itâĂŹs necessary to combine these relationship features into the corporation features, and node2vec is suitable to learn relationship representations of corporations in the transaction and investment network.

Low time complexity. The time complexity of node2vec is O(|V|d), where V is the set of the vertices in the graph and d is the representation dimension [3]. Since in practice we have an extremely large CANet that contains millions of corporation nodes, it is necessary to choose node2vec to perform real time detection.

Both Local and global network structure can be extracted. According to the previous studies, some suspicious patterns involve not only local structure, but also global structure in the transaction and investment relationships [2, 7]. Compared with the previous methods, node2vec provides a trade-off between breadth-first (BFS) and depth-first (DFS) graph searches. Through breadth-first search,

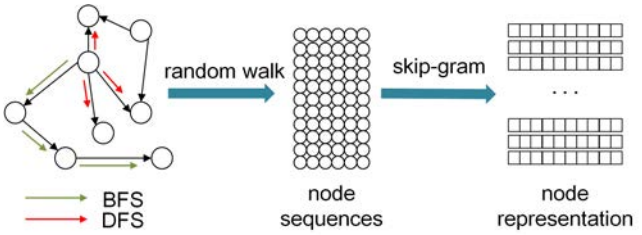

Figure 2: The procedure of the node2vec.

we can get local network structure information, and through depth-first search, we can get global network structure information. In this algorithm, we can get any combination of the two kinds of information by adjusting the parameters.

As is shown in Figure 2, node2vec consists of three steps: computing transition probability matrix, obtaining node sequences in the graph by random walk, and representing the node vectors by the skip-gram algorithm. In this system, we use node2vec to represent the transaction network and the investment network respectively, then combine the representation vectors and the basic features of the nodes, and finally combine these as inputs to LightGBM algorithm to get the suspicious score of each corporation.

2.2.2 LightGBM. LightGBM is a gradient boosting decision tree algorithm, which is effective when the feature dimension is high and data size is large [5]. In the experiment, we tested four classification algorithms (i.e., LightGBM, RandomForest, SVM and AdaBoost) for better performance. For each algorithm, we performed two experiments separately, one uses all the features of the corporation, and the other uses the basic features of the corporation. The result is show in Figure 3, in which the dotted line represents the basic feature experiments, and the solid line represents all feature experiments. As we can see, LightGBM outperforms other algorithms when we use all features. Besides, compare with using basic feature, using all features significantly improved the performances of suspicious individual detection algorithms.

2.3 Suspicious Group Analysis

In this component, we develop a visual analytic system to anticipate the suspicious groups with the following detection rules. **Rule 1: IF the sequence of transaction volume has anomaly, THEN the transaction is fraudulent**. The anomaly of the transaction volume is an important signal for fraud behaviors [1]. Tax evasion case studies found that tax evasion corporations that have been established soon will run away if they open a lot of invoices in a short time. As shown in Figure 4(c), in our system we use the $3-\theta$ principle to detect transaction anomaly. When the trading volume of a month exceeds a range calculated based on the trading volume of past 12 months, the edge in the flow chart will be marked red and the warning message will be shown when mouse moves over the edge.

Rule 2: IF the product category does not meet the business scope of the two parties, THEN the transaction is fraudulent. This rule refers to the fact that some corporations manage to increase their own input costs by purchasing invoices of other category goods. Therefore, in our approach, when a corporation buys

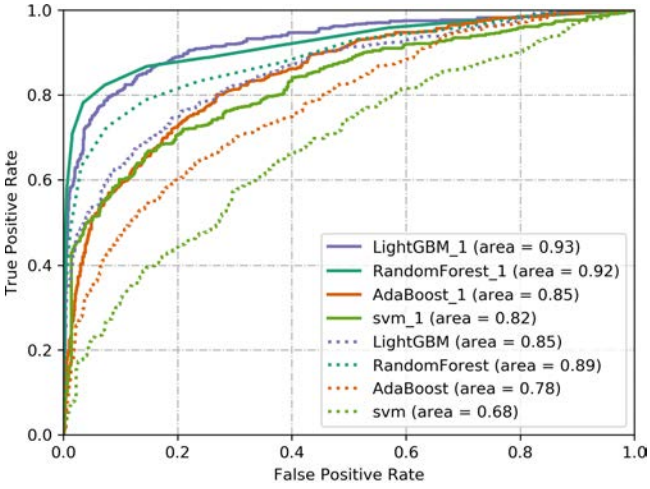

Figure 3: The ROC curves of the four algorithms.

and sells goods and the corporation's business scope do not match, we assume the transaction is fraudulent.

Rule 3: IF there exist suspicious upstream and suspicious downstream corporations, THEN the corporation is suspicious. Due to the special characteristics of the value-added tax (VAT): the amount of tax paid should be the output minus the input. In order to reduce taxes, some corporations may increase the cost of purchasing goods or reduce sales revenue. Therefore, all corporations in the VAT trading chain restrict each other and many tax evasion taxes are carried out in groups [7]. So if there exists suspicious upstream and suspicious downstream corporations, we assume that the corporation is suspicious though its suspicious score is low.

In order to analyze these anomalies, we design a transaction flow chart. As shown in Figure 4(b), the corporations are represented as rectangle blocks, and the transaction edge between corporation nodes are represented as curves. Each rectangle block consists of two components, the border and the internal influence area. The color of the border corresponds to the suspicious score (the darker red indicates higher suspicious score). The internal influence area is divided into two parts. The left area represents the influence of the upstream corporations and the right area represents the influence of the downstream corporations. Each area is divided into several areas according to the relative volume of each corporation. The color of each area represents the suspicious score of the corresponding corporation.

In the transaction flow chart, the gray edge indicates normal transaction, while the red indicates abnormal transaction (Figure 4(b-2)), which represents those transactions match the rule 1 and rule 2 aforementioned. When mouse is over the red edge, users can see the specific abnormal information. In addition, we use a histogram to show the monthly volume of transactions (Figure 4(c)). In addition to the transaction flow chart, this system also designs a parallel coordinate showing the features of all corporations, a classification result chart showing the performance of the detection algorithm and a map chart showing the geographic location of the selected corporation.

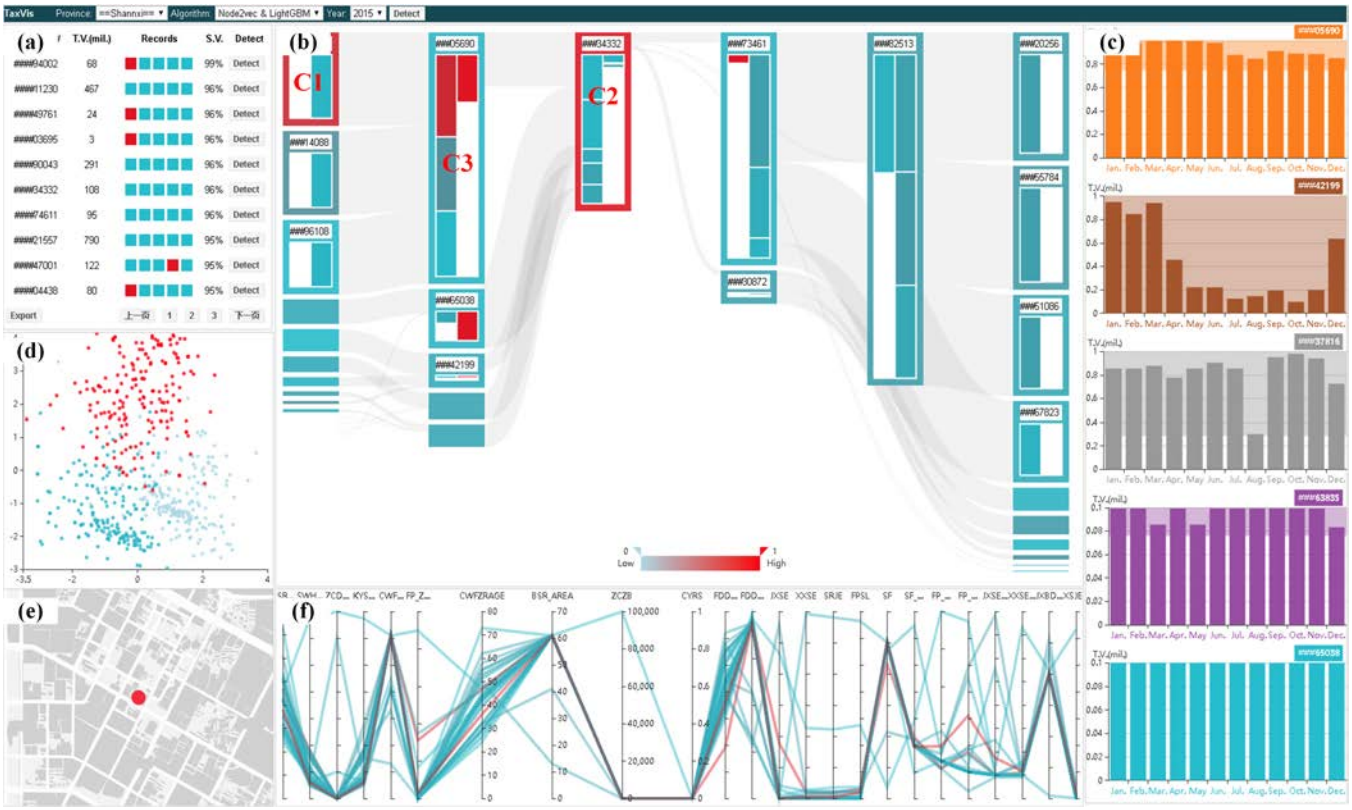

Figure 4: Screenshot of the TaxVis platform, including (a) the suspicious score table showing the suspicious individual detection result in descending order of the suspicious score; (b) the transaction flow chart depicting the trading corporations of the selected corporation and the transaction details between them; (c) the trading volume chart showing the trading volume between the corporations pre month; (d) the classification result chart showing the performance of the detection algorithm; (e) the map chart showing the geographic location of the selected corporation; (f) the parallel coordinate showing the features of all corporations.

3 DEMONSTRATION OUTLINE

We will demonstrate our system based on real tax dataset from Shaanxi province tax data in 2014-2015. There are 10,120 corporations in the dataset.

Detection of tax evasion individual. After selecting the year, our system will automatically show the detection results. The results are listed in descending order of suspicious score. In the result table (Figure 4(a)) each row corresponds to a corporation. The detail consists of the corporation id, the turnover of the past year, the tax evasion record of the past 5 years, and the suspicious score. Selecting one corporation, clicking the detect button and the rest of the page will display the corresponding information for the selected corporation.

Analysis of the tax evasion tax group. According to the previous three rules, we can check the abnormal transaction edges around the suspicious corporation to analyze the suspicious group. For example, as shown in Figure 4(b), the suspicious score of corporation C3 is very low, the suspicious scores of its upstream corporation C1 and downstream corporation C2 are very high. As a result, we can infer that the corporations C1, C2 and C3 may belong to a suspicious tax evasion group.

4 CONCLUSION AND FUTURE WORK

In this demo, we propose a two-phase approach to calculate the suspicious score based on the representations of corporations in CANet and detects suspicious tax evasion groups automatically. In future work, on the one hand, we will use some techniques to discover anomalous transactions in the second phase. On the other hand, we will apply some methods to automatically extract the tax evasion patterns to enhance the pattern matching based methods.

ABSTRACT

Web research, data science, and artificial intelligence have been rapidly changing our life and society. Researchers and practitioners in the fields take a large amount of time to read literature and compare existing approaches. It would significantly improve their efficiency if there was a system that extracted and managed experimental evidences (say, a specific method achieves a score of a specific metric on a specific dataset) from tables of paper PDFs for search, exploration, and analytic. We build such a demonstration system, called *Tablepedia*, that use rule-based and learning-based methods to automate the "reading" of PDF tables. It has three modules: template recognition, unification, and SQL operations. We implement three functions to facilitate research and practice: (1) finding related methods and datasets, (2) finding top-performing baseline methods, and (3) finding conflicting reported numbers. A pointer to a screencast on Vimeo: https://vimeo.com/310162310

1 INTRODUCTION

The motivation of building the proposed system was originally from our literature study on *multilabel classification* which is to predict the labels of objects where multiple labels may be assigned to each object. It cost us as long as 23 days to collect, read, and digest hundreds of related works. We found two papers of this topic that were accepted to ACM SIGKDD 2017 Research Track: PPDSparse [11] and AnneXML [9]. Each of them proposed a new multilabel classification model and compared with baseline methods. They both reproduced and tested existing methods (such as SLEEC, FastXML, PfastreXML, and PDSparse) on publicly available data sets (such as AmazonCat-13K, Delicious-200K, and WikiLSHTC-325K) using standard evaluation metrics (such as Precision@1, P@3, and P@5). Table 1 summarizes and compares the numbers given by the two papers, [11] on the left and [9] on the right. We find out that almost half of the pairs have bigger than 3% difference on the scores, which has been able to be claimed as significant improvement on well-accepted benchmarks. This may be due to the random initialization, parameter settings, or computational environments. We have no idea about the true reason, but we argue that it is worthwhile of investigating the *experimental evidences* in data science literature.

Table 1: Tablepedia found inconsistent numbers by two KDD papers [11] (left) and [9] (right) for multilabel classification. Precision differences of bigger than 3% are underlined. It is worthwhile of attention to the inconsistency.

Dataset	(%)	SLEEC	FastXML	PfastreXML	PDSparse
AmazonCat	P@1	90.56/89.19	94.02/93.10	86.06/89.94	87.43/89.31
-13K	P@3	76.96/75.17	79.93/78.18	86.06/77.24	87.43/74.03
	P@5	62.63/61.09	64.90/63.38	63.65/63.53	56.70/60.11
Delicious	P@1	47.78/47.03	48.85/43.20	26.66/37.62	37.69/34.37
-200K	P@3	42.05/41.67	42.84/38.68	23.56/35.62	30.16/29.48
	P@5	39.29/38.88	39.83/36.21	23.21/34.03	27.01/27.04
WikiLSHTC	P@1	58.34/55.57	50.01/49.75	57.17/58.10	60.70/61.26
-325K	P@3	36.70/33.06	32.83/33.10	37.03/37.61	39.62/39.48
	P@5	26.45/24.07	24.13/24.45	27.19/27.69	29.20/28.79

Again, it took us long long time to make the comparison table (and several other tables that compared methods in other conference or journal papers). Therefore, we aim at building a system to extract and manage such experimental results in the literature. We hope that researchers and practitioners in the fields of data science and artificial intelligence will use it as Wikipedia to satisfy their needs of exploring and analyzing the experimental evidences.

The key challenges lie in automating the "reading" of tables in the experimental sections of paper PDFs. *First*, there was no well-defined structure of experimental evidence. The tables are embedded in the PDF format. It takes careful engineering efforts on cropping, parsing, and cleaning the tables. *Second*, the tables have different kinds of templates, so there was no standard of interpreting the cells. *Third*, the roles of row and column names (such as SLEEC and P@1), say, datasets or methods or metrics, are unknown. The gap between PDF table and queryable database is huge.

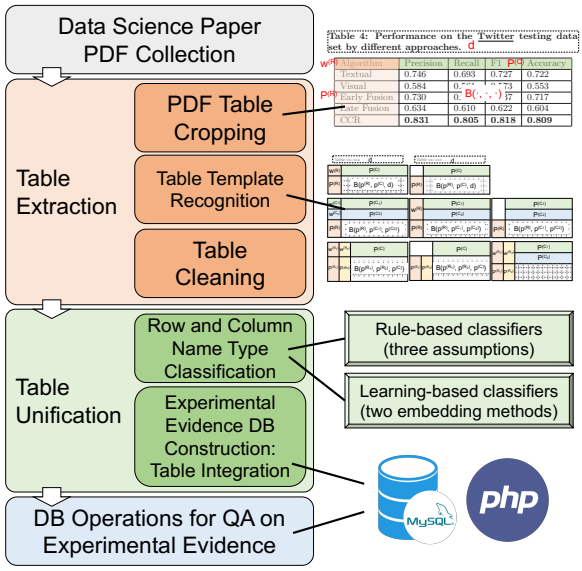

Figure 1: Tablepedia workflow: from PDF collection, to table extraction, to experimental evidence database construction, to database operations and visualization.

Proposed approach. This paper presents a novel system, called Tablepedia, which transforms data science paper PDFs into a structured database of experimental evidences, and support multiple exploratory and analytic functions over the constructed database for knowledge discovery. It has three modules. The first module *table extraction* crops the tables from PDFs and recognize their templates. The second module *table unification* classifies the column names and row names into the three types of labels (method, dataset, and metric) and then unifies each cell into a **(method, dataset, metric, score, source)-tuple**. The score is the cell's value and the source is the PDF file name, page, and number of the table. This module constructs a five-column database of the tuples for every table that contains experimental results. The third module *database operation for QA* uses SQL operations (i.e., *select* and *join*) for question-answering on the experimental result database.

Contributions. The contributions and features of the Tablepedia system are summarized as follows.

- A novel system that extracts experimental evidences from massive literature in PDF format. This builds up the first experimental knowledge base for data science and artificial intelligence research.
- An effort-light framework that leverages both rule-based and learning-based methods to unify the tables of experimental results into (method, dataset, metric, score, source)-tuples.
- Capabilities for exploration and analysis over the structured knowledge base to facilitate research and practice.

The Tablepedia demo system will be made available online for interactive use after its demonstration in the conference. A pointer to a screencast on Vimeo: https://vimeo.com/310052262

2 THE TABLEPEDIA SYSTEM

In this section, we first introduce the workflow of our Tablepedia system and the details of the three modules of the system.

Overview. Figure 1 shows the overflow. Tablepedia collects a set of data science paper PDFs. It has three modules to process the PDF data. It first crops the tables from PDFs, recognizes the table templates, and cleans the table data. Second, it classifies the row and column names of each table into three categories (method, dataset, metric). The experimental evidence database is constructed through the integration of table cells. Lastly, it designs database operations for knowledge exploration in the structured database.

Expected output and impact. Figure 2 shows a snapshot of the experimental evidence database. It has several examples of data records. They are experimental facts that can be found in tables of conference and journal papers on building recommender systems that were published in the same year: TOIS'11 [8], TIST'11 [6], and WSDM'11 [7]. The tables share popular method names such as "User Mean", "NMF", and "PMF". Which method performs the best? Are the reported numbers of their performances consistent in these tables? When the tables were well structured into such a database, the above questions could be easily answered. The number of publications in the field of data science has been tremendously increasing because of the great use of data mining and machine learning in real applications. Practitioners are curious about what method will generate good performance on a specific task and dataset. Researchers are wondering whether the baseline methods are the state-of-the-art and whether the reported numbers on the baselines are correct when they review papers.

2.1 Table Extraction

We use Tabula to extract tabular content from PDF [2]. Tabula was created by Manuel Aristaran *et al.* with the first release made available early 2013 as an open source project. The developers stated that they were inspired by academic papers [12] about analysis and extraction of tabular content. Tabula is available as a Java library [1]. Unfortunately, it does not work for scanned documents, so we filter those files out.

A table $T = \{\mathcal{R}, C, d, \mathcal{B}\}$ has four components: (1) a model of horizontal *Rows* (identifiable by name) $\mathcal{R}$, (2) a model of horizontal *Columns* C, (3) *Caption* and the set of words in the caption d, and (4) cells (data elements) in the table's *Body* $\mathcal{B}$. We observe that the tables can be categorized into eight major templates (with very few exceptions). Figure 3 visualizes the components of each template.

For cleaning the raw tables, we count the number of digit-format cells in the table: we filter out the tables that have fewer than 6 digit cells, and thus, we get rid of more than 99% of the non-experimental result tables. We use [10] to remove the text that was not the table's caption but located around the table.

2.2 Table Unification

We define the set of concept items that can be found as row names or column names:

$$\mathcal{P} = \cup_{T=[\mathcal{R},C,d,\mathcal{B}]} P^{(R_{(\cdot)})} \cup P^{(C_{(\cdot)})}, \quad (1)$$

where T is a table, $P^{(R_{(\cdot)})}$ is the set of row names (no matter single row or double rows), and $P^{(C_{(\cdot)})}$ is the set of column names. We denote by $\mathcal{L}$ by the set of three labels for the concept items:

$$\mathcal{L} = \{\text{“}method\text{”}, \text{“}dataset\text{”}, \text{“}metric\text{”}\}. \quad (2)$$

	A	B	C	D	E
1	**Method**	**Dataset**	**Metric**	**Score**	**Source**
10	UserMean	Epinions	MAE	0.9319	TOIS11-paper7-table3
11	UserMean	Epinions	MAE	0.9285	TIST11-paper3-table3
12	UserMean	Epinions	MAE	0.9285	WSDM11-paper12-table5
109	ItemMean	Epinions	RMSE	1.1973	TOIS11-paper7-table4
110	ItemMean	Epinions	RMSE	1.2584	TIST11-paper3-table3
111	ItemMean	Epinions	RMSE	1.2584	WSDM11-paper12-table5
112	Trust	Epinions	RMSE	1.2132	TIST11-paper3-table3
113	NMF	Epinions	RMSE	1.1832	TOIS11-paper7-table4
114	NMF	Epinions	RMSE	1.1832	TIST11-paper3-table3
115	NMF	Epinions	RMSE	1.1832	WSDM11-paper12-table5
116	SVD	Epinions	RMSE	1.1812	TOIS11-paper7-table4
117	TCF	Epinions	RMSE	1.1761	TIST11-paper3-table3
118	PMF	Epinions	RMSE	1.1760	TOIS11-paper7-table4
119	PMF	Epinions	RMSE	1.1760	TIST11-paper3-table3
120	PMF	Epinions	RMSE	1.1760	WSDM11-paper12-table5

124	SR1VSS	Epinions	RMSE	1.1016	WSDM11-paper12-table5
125	SR1PCC	Epinions	RMSE	1.1013	WSDM11-paper12-table5
126	SR2VSS	Epinions	RMSE	1.0958	WSDM11-paper12-table5
127	SR2PCC	Epinions	RMSE	1.0954	WSDM11-paper12-table5
169	SoRec	MovieLens	RMSE	...	...

Figure 2: Tablepedia generates this experimental evidence database from data science paper PDFs. For a dataset and an evaluation metric, one can use the database to check what the state-of-the-art (highlighted in yellow) is and whether the reported numbers in existing researches are consistent (green box) or conflicting (red box).

Then we define table unification as a two-step problem.

Problem (Table unification). ***Given*** *a set of tables* $\{T\}$ *and each table has been well defined based on its template, (1)* ***classify*** *the concepts into three categories, or say,* ***find*** *a classification function* $f: \mathcal{P} \rightarrow \mathcal{L}$*; (2)* ***unify*** *the cells into (method, dataset, metric, score, source)-tuples, or say,* ***find*** *a function of three variables* $g: P^{(\text{“}method\text{”})} \times P^{(\text{“}dataset\text{”})} \times P^{(\text{“}metric\text{”})} \rightarrow \mathbb{R}$*, where the target value is the score (a real number) as in the Table's body function B.*

Tablepedia develops an ensemble learning approach that iteratively predicts the labels of concept items using two classifiers of different methodologies. The first classifier is an **assumption/rule-based** method. The first assumption is:

Assumption 1 (Row/column header indication). *If the upper-leftmost cell of the table has a specific word (e.g., "Methods", "Dataset"), the names on the corresponding columns/rows are more likely to have the label as the word indicates.*

For example, if the upper top cell of a table has word "Methods", then the row names such as "User Mean", "Item Mean", and "NMF" are likely to be labelled as "method". Then we use these "seed" concept items to label columns, rows, and captions of all the tables. If the columns/rows/captions are partially labelled, we will be able to use the following assumptions to predict the labels of the remaining concepts on the columns/rows/captions:

Assumption 2 (Row/column type consistency). *The concept items on the same column or row are likely to have the same type of label. For example, if we know (1) "NMF" is a "method" and (2) "SVD" locates in the same column/row as "NMF" does, then "SVD" is likely to be a "method".*

Assumption 3 (Cell context completeness). *A table often covers all the three types of labels on its columns, rows, and caption, in order to provide complete contexts [4] to explain the values in the cells. For example, if the caption has a metric name (i.e., "MAE") and the row names are methods, then the column names are likely to be datasets.*

The second classifier is a **learning-based** method. It learns low-dimensional representations (or called *embeddings*) of the concept items for label prediction. It learns (a) *semantic concept embeddings* [5] from the unstructured paper texts and (b) *structural concept embeddings* [3] from the co-occurrences of concepts in the table structures (i.e., columns and rows), and then feeds the concatenated feature vectors into standard multi-class classification models (e.g., random forests, support vector machines, neural networks) to predict the labels. This solution will be likely to assign the same label to different forms of the same concept.

The ensemble learning approach uses the boosting strategy to iteratively learn the classifiers. Relying too much on one classifier may result in lots of errors when the prediction confidence is weak. In each iteration, we only expand the set of classified concepts for next round of training by a certain small number. So after several iterations, we can have precise labels of the concept items.

The next step is to unify the table cells into the tuples and put into the five-column experimental result database (ERD). The ERD's quality relies on the accuracy of concept typing. Tablepedia achieves an F1 score of 0.8477, which is much higher than using rule-based or learning-based method only (0.6542).

2.3 Database Operations for QA

When the ERD was constructed, we would be able to use SQL queries and operations to answer interesting questions. There could be many questions and corresponding SQL queries.

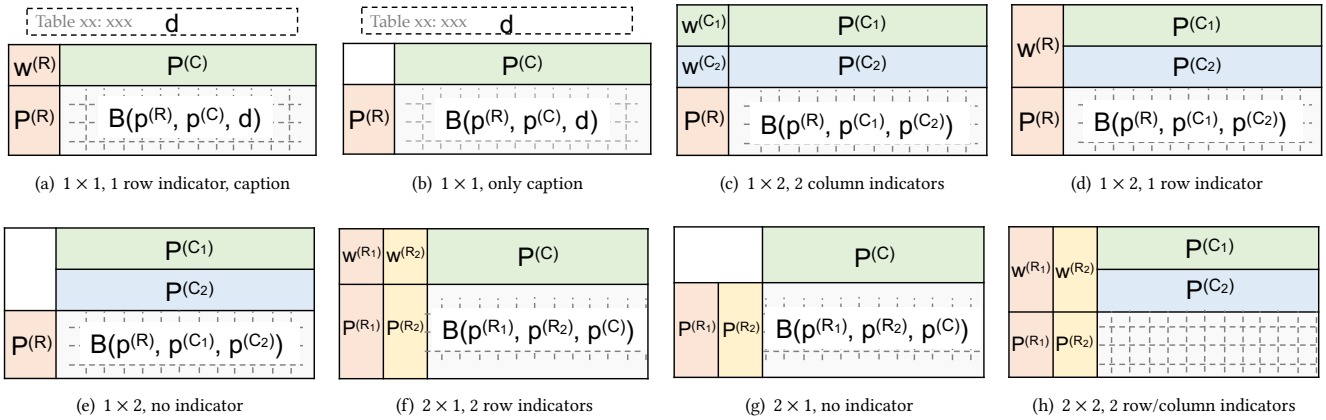
Question 1. How many methods were used/proposed on the Epinions dataset? And how many metrics were used?

Question 2. What are the top three methods on the Epinions dataset if the evaluation metric is RMSE?

Question 3. Are there conflicting reported numbers in the database? What are they?

SQL consists of many types of expressions, predicates and statements such as *select*, *join*, and *distinct*, based upon *relational algebra* and *tuple relational calculus*. Suppose the experimental result data table is constructed and named as "ERD". Here are the SQL queries that find answers to the above questions.

SQL Queries 1.



```
select count(distinct Method) from ERD where Dataset="Epinions";
select count(distinct Metric) from ERD where Dataset="Epinions";
```

SQL Query 2.

```
select * from ERD where Dataset = "Epinions" and Metric = "RMSE" order by Score desc limit 3;
```

SQL Query 3.

```
select distinct d1.Method, d1.Dataset, d1.Metric, d1.Score, d1.Source from ERD as d1, ERD as d2 where d1.Method = d2.Method and d1.Dataset = d2.Dataset and d1.Metric = d2.Metric and d1.Score <> d2.Score order by d1.Method, d1.Dataset, d1.Metric;
```

(a) 1×1, 1 row indicator, caption (b) 1×1, only caption (c) 1×2, 2 column indicators (d) 1×2, 1 row indicator

(e) 1×2, no indicator (f) 2×1, 2 row indicators (g) 2×1, no indicator (h) 2×2, 2 row/column indicators

Figure 3: Eight major table templates: We will use the first seven templates which cover more than 95% of the tables in our dataset. The cells in the table's body are triplets based on rows/columns/caption. (Best view in color)

The term count is used for question "how many"; order by is used for ranking/finding "top three"; and the third query uses *self-join* to compare values in a column ("Score") with other values in the same column in the same table ("ERD").

We developed user-friendly functions in this module to answer the questions. For example, users can fill in the underlined values in the questions, the SQL queries will be updated, and then correct answers will be returned.

3 DATA STATISTICS

We downloaded from web portals such as ACM Digital Libraries a PDF file collection of four data science conference proceedings (WWW, SIGKDD, ICDM, and WSDM) and three ACM transactions (TOIS, TIST, and TKDD) last decade (2008–2017). After careful PDF converting, cropping, and cleaning, we have **456 tables**.

Tablepedia categorized **4,476 concepts** in the 456 tables into three classes, {dataset, method, metric}. The resulting database has as many as **29,081 data records** (or called experimental result facts). The database includes **1,541** unique datasets, **1,685** unique methods, and **450** unique metric names. Each dataset, method, and metric has **18.9**, **17.3**, and **64.6** related data records in average, respectively. The associations between the concepts are rich.

4 DEMO SCENARIOS

Tablepedia uses the database to answer the following questions. This is just to show the power of exploring quantitative knowledge in the experimental result database and the usefulness of our approach. Because the database was constructed with only 456 tables, we are **NOT** claiming that the answers to these questions are the truths all over the tons of literature.

***Question 1:* Find related methods, metrics, and datasets.**

Q-1(a) How many methods were used for the Epinions dataset?
select count(distinct Method) from ERD where Dataset="Epinions";
A-1(a) 36. If one uses more SQL queries to look for the detail, one will see the method names such as "UserMean", "ItemMean", "Trust", "NMF", "SVD", "TCF", "PMF", "SoRec", and "RSTE".

Q1(b) How many metrics were used to evaluate on Epinions?
select count(distinct Metric) from ERD where Dataset="Epinions";
A-1(b) 7. More queries will find the concrete metric names such as "F1 score", "Precision", "Recall", "MAE", and "RMSE".

Q1(c) How many datasets used with Epinions in the same table?
select count(distinct Dataset) from ERD where Source=(select (distinct Source) from ERD where Dataset= "Epinions");
A-1(c) 17. The data names are "Amazon", "Ciao", "Douban", and so on. They are popular datasets for evaluating recommender systems.

***Question 2:* Find top-performing methods on a dataset.**

Q2(a) What are the top 3 methods on Epinions in terms of RMSE?
select Method, Score from ERD where Dataset = "Epinions" and Metric = "RMSE" order by Score desc limit 3; // desc is for the fact that a smaller RMSE means a better performance.
A-2(a) "SR2pcc" (1.0954), "SR2vss" (1.0958), "SR1pcc" (1.1013).

Q2(b) What are the top 3 methods on Amazon in terms of F1?
select Method, Score from ERD where Dataset = "Amazon" and Metric = "F1" order by Score limit 3; // Compared to Q2(a), desc was deleted because a bigger F1 means a better performance.
A-2(b) "LEMON" (0.953), "LEMON-auto" (0.91), "LC" (0.815).

***Question 3:* Find conflicting reported numbers.**

Surprisingly, we found a large set of conflicting records in the database. A number of them are worthy of investigation: *First*, as presented in Table 1, the two KDD 2017 papers on multilabel classification, [11] and [9], gave different numbers for the same set of methods, the same datasets, and the same metrics, respectively. Though variance could happen when reproducing the results, we found many of the precision differences are bigger than 3%, which is often a sufficient margin to claim a new achievement! *Second*, if the dataset is Epinions, *plus* the metric is MAE, *plus* the ratio of training data is 80%, then we have three pairs of conflicting numbers reported by [8] and [6]: (1) UserMean: 0.9319 vs 0.9285, (2) ItemMean: 0.9115 vs 0.9913, (3) Trust: 0.9044 vs 0.9215. The same pairs can be observed for RMSE as well. *Finally*, we also find a number of conflicting pairs that were not correctly aligned because of the missing contexts in the extraction such as the ratio of training data and the number of dimensions. In this demo, while showing the importance of integrating PDF tables, we are aware of tons of challenging and interesting future works.

ABSTRACT

Traffic signal control is an emerging application scenario for reinforcement learning. Besides being as an important problem that affects people's daily life in commuting, traffic signal control poses its unique challenges for reinforcement learning in terms of adapting to dynamic traffic environment and coordinating thousands of agents including vehicles and pedestrians. A key factor in the success of modern reinforcement learning relies on a good simulator to generate a large number of data samples for learning. The most commonly used open-source traffic simulator SUMO is, however, not scalable to large road network and large traffic flow, which hinders the study of reinforcement learning on traffic scenarios. This motivates us to create a new traffic simulator CityFlow with fundamentally optimized data structures and efficient algorithms. CityFlow can support flexible definitions for road network and traffic flow based on synthetic and real-world data. It also provides user-friendly interface for reinforcement learning. Most importantly, CityFlow is more than twenty times faster than SUMO and is capable of supporting city-wide traffic simulation with an interactive render for monitoring. Besides traffic signal control, CityFlow could serve as the base for other transportation studies and can create new possibilities to test machine learning methods in the intelligent transportation domain.

1 INTRODUCTION

Traffic signal control problem, one of the biggest urban problems, is drawing increasing attention in recent years [5, 9, 10]. Recent advances are enabled by large-scale real-time traffic data collected from various sources such as vehicle tracking device, location-based mobile services, and road surveillance cameras through advanced sensing technology and web infrastructure. Traffic signal control is interesting but complex because of the dynamics of traffic flow and the difficulties to coordinate thousands of traffic signals. Reinforcement learning becomes one of the promising approaches to optimize traffic signal plans, as shown in several recent studies [5, 9, 10]. At the same time, traffic signal control is also one of the major real-world application scenarios for reinforcement learning [6].

To successfully deploy reinforcement learning technique for traffic signal control, the traffic simulator becomes the most important factor. Because the learning method relies on a large set of data

samples. These data samples can hardly be collected from the real world directly. Aside from the consequence of bad decisions, a city simply cannot generate enough data samples for learning. If we treat each minute as a data sample, a city can only generate 1,440 (24 hours by 60 minutes) data samples in a day. Such a small size of sample is not enough to train a deep reinforcement learning model to be powerful enough to make good decisions. Thus, it becomes crucial to have a simulator that is fast enough to generate a large set of data samples.

The most popular public traffic simulator SUMO [7] (Simulation of Urban Mobility) has been frequently used in many recent studies. SUMO, however, is not scalable to the size of the road network and the size of traffic flow. For example, it can only perform around three simulation steps per second on a 30×30 grid with tens of thousands of vehicles, the situation is even worse if we use the python interface to get information about the system to support reinforcement learning. A city, however, is often at the size of a thousand intersections (e.g. there are 30×40 intersections of major roads in Hangzhou, China) and hundreds of thousands vehicles, which is beyond the current simulation capacity of SUMO.

To enable the reinforcement learning for intelligent transportation, we create a traffic simulator CityFlow[1], which can be scaled to support the city-wide traffic simulation. One of the major improvements over SUMO is that CityFlow enables multithreading computing. To the best of our knowledge, this is the first open-source simulator that can support city-wide traffic simulator. CityFlow is flexible to define road network, vehicle models, and traffic signal plans. It is more than twenty times faster than SUMO. We have also provided friendly interface for reinforcement learning testbed. We plan to demonstrate these functions at the demo session.

Finally, our scalable traffic simulator CityFlow will open many new possibilities besides traffic signal control scenario. First, it could support various large-scale transportation research studies, such as vehicle routing through mobile app, traffic jam prevention. Second, similar to OpenAI Gym[2] which provides a set of benchmark environments for reinforcement learning, CityFlow could serve as a benchmark reinforcement learning environment for transportation studies. Besides traffic signal control, reinforcement learning has been used in transportation studies such as taxi dispatching [12] and mixed autonomy systems [11]. But all the existing studies either use SUMO or over-simplified traffic simulator. Third, we plan to better calibrate the simulation parameters by learning from real-world observations. This will make the simulator not only generate data samples fast but also generate "real" data samples.

2 BRIEF DESCRIPTION

2.1 System Design

CityFlow is a microscopic traffic simulator which simulates the behavior of each vehicle at each time step, providing highest level of detail in the evolution of traffic. However, microscopic traffic simulators are subject to slow simulation speed [13]. Unlike SUMO, CityFlow uses multithreading to accelerate the simulation. Data structure and simulation algorithm are also optimized to further speedup of the process.

[1]https://github.com/cityflow-project/CityFlow/
[2]https://gym.openai.com/

2.1.1 Road Network. Road network is the basic data structure in CityFlow. **Road** represents a directional road from one **intersection** to another **intersection** with road-specific properties. A **road** may contain multiple **lanes**. Each **lane** holds a Linked List of vehicles. Linked List supports fast insertion and searching of leading vehicles. **Segments** are small fragments of a **lane**. We design segments in order to efficiently find all vehicles within a certain range of the lane. This structure is crucial for fast lane change operation. **Intersection** is where roads intersects. An **intersection** contains several **roadlinks**. Each roadlink connects two roads of the intersection and can be controlled by traffic signals. A **roadlink** contains several **lanelinks**. Each lanelink represents a specific path from one lane of incoming road to one lane of outgoing road. **Cross** represents the cross point between two lanelinks. This structure is crucial for fast intersection logic.

2.1.2 Car Following Model. The car-following model is the core component CityFlow. It computes the desired speed of each vehicle at next step using information like traffic signal, leading vehicles, etc. and ensures that no collisions occur in the system. Currently, the car following model used in CityFlow is a modification of the model proposed by Stephen Krauß [4]. The key idea is that: the vehicle will drive as fast as possible subject to perfect safety regularization (e.g. being able to stop even if leading vehicle stops using maximum deceleration). Unlike SUMO [7], we use ballistic position update rule instead of Euler position update. Ballistic update yields more realistic dynamics for car-following models based on continuous dynamics especially for larger time-steps (e.g. 1 second) [8].

Basically, vehicles are subject to several speed constraints, maximum speed which meets all these constraints will be chosen. Currently, following constraints are considered:

- vehicle and driver's maximum acceleration
- road speed limit
- collision free following speed
- headway time following speed
- intersection related speed

Due to page limit, we only present the detail of collision free speed computation. It takes v_F current speed of following vehicle, v_L current speed of leading vehicle, d_F maximum deceleration of following vehicle, d_L maximum deceleration of leading vehicle, gap current gap between two vehicles, $interval$ the length of each time step as parameters and compute the no-collision-speed s by solving a quadratic equation using equation 1.

$$
\begin{aligned}
c &= \frac{v_F \cdot interval}{2} - \frac{v_L^2}{2 \cdot d_L} - gap \\
a &= \frac{1}{2 \cdot d_F} \\
b &= \frac{interval}{2} \\
s &= \frac{-b + \sqrt{b^2 - 4 \cdot a \cdot c}}{2 \cdot a}
\end{aligned} \tag{1}
$$

Intersection related speed is handled by intersection logic and is illustrated in the next section.

2.1.3 Intersection Logic. The behavior of vehicles in intersection is complex and it requires careful design to efficiently mimic real

world behavior [1, 3]. Basically, vehicles in intersection should obey following two rules:

- fully stop at red signal, stop if possible at yellow signal
- yield to vehicles with higher priority (e.g. turning vehicles should yield straight-moving vehicles)

To avoid collisions at intersection, it is non-trivial to check if there are vehicles on the opposite lane. The simplest method is to use brute force search to find all vehicles within a certain range and check if they will collide within a certain time period. But this method is very time consuming. Instead, we precompute all the cross points between lanelinks in intersection. When a vehicle approaches the intersection, it will notify all cross points in the intersection about its arrival. The cross points is responsible for deciding which vehicle could pass and which vehicle should yield. The time complexity of our algorithm is $O(N_{crosspoints})$. Due to page limit, we omit the detail of our algorithm.

2.1.4 Lane Change Model. Lane change model addresses two questions for a vehicle: when and how to change lane. Vehicles may change lanes when there are more free space on adjacent lanes or a lane change is required to follow its route. Notice that it is slow to traverse all vehicles in adjacent lanes. Instead, by maintaining the vehicle information in **segments** which are small fragments of each lane, we only need to search for related vehicles in adjacent segments in constant time (up to three segments for each lane), which largely reduce time complexity.

When a vehicle decides to change lane, it needs to find a way to notify other vehicles. Here we use a similar mechanism in SUMO. When a vehicle changes lane, the simulation engine will put a copy of it to its destination lane, called shadow vehicle. A shadow vehicle has the same function as a normal vehicle, and it can become the leader of other vehicles in the car following model. The vehicle and its shadow moves consistently, which is guaranteed by the simulation engine in the way that their speed constraints will be applied to each other. After the lane change finishes, the simulation engine will just remove the original vehicle and let its shadow vehicle replace it.

2.2 Python Interface

In order to support multi-agent reinforcement learning, we provide a python interface via *pybind11* [2]. User can perform simulation step by step and get various kinds of information about current state, e.g. number of vehicles on lane, speed of vehicles. Besides, we provide interface to control the elements in simulator at each time step. Currently, users can control traffic signals and add vehicles on-the-fly. We plan to support more types of controlling functions such as vehicle behavior control and road property control in the future. Below is a sample usage of python interface.

Listing 1: usage of python interface

```
import engine
eng = engine.Engine(config_file)
phase = [...] # the traffic signal phase of
    each time step
for step in range(3600):
    eng.set_tl_phase("intersection_1_1",
        phase[step])
    eng.next_step()
    eng.get_current_time()
    eng.get_lane_vehicle_count()
    eng.get_lane_waiting_vehicle_count()
    eng.get_lane_vehicles()
    eng.get_vehicle_speed()
    # do something
```

2.3 Frontend

We provide a web-based Graphic User Interface. User can check the replay output by the simulator. In order to support viewing large-scale simulation, we use *WebGL*-based library *PixiJS*[3] for fast rendering of vehicles and traffic signals. Figure 1 shows some screenshots of the GUI under several scenarios.

3 PERFORMANCE

3.1 Efficiency

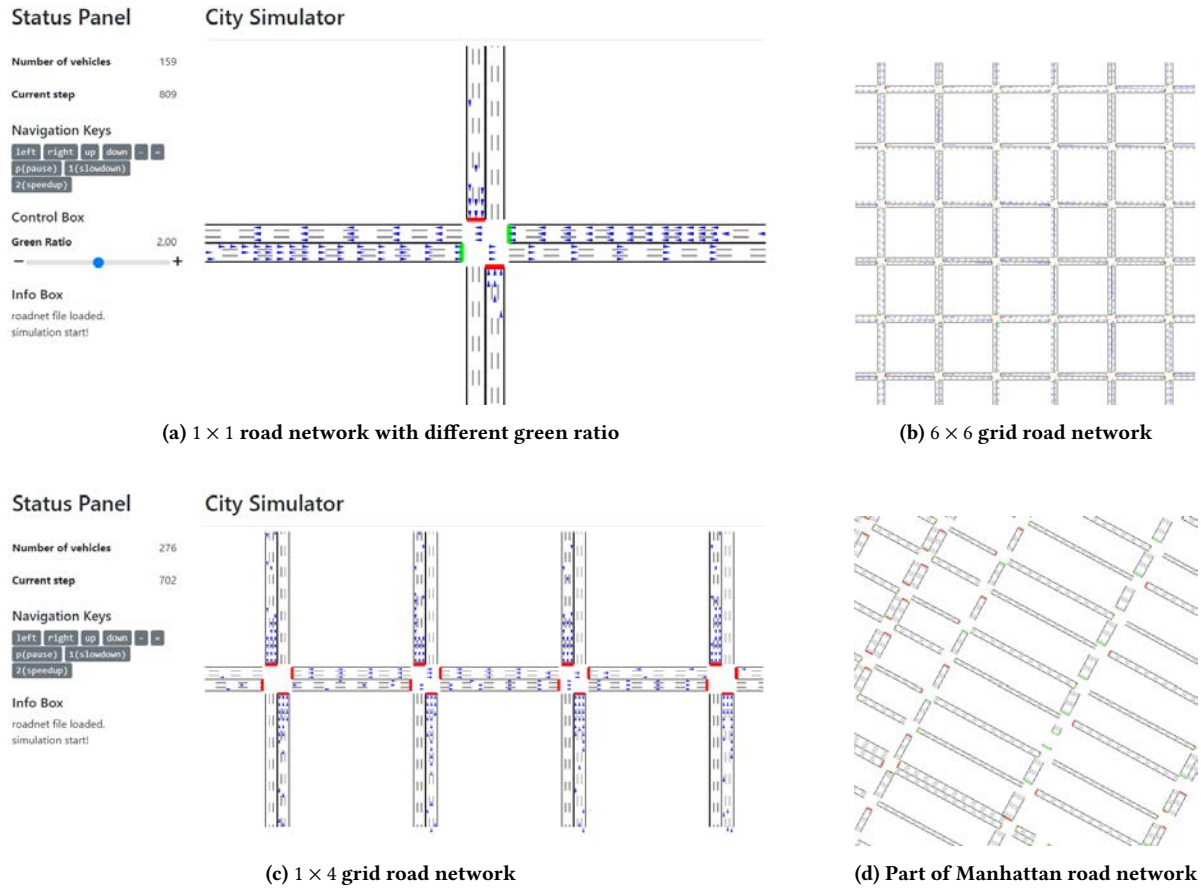
We compare the performance between SUMO and CityFlow under different scenarios. The experiment runs on Intel(R) Xeon(R) CPU E5-2686 v4 @ 2.30GHz. As Figure 2 shows, CityFlow outperforms SUMO in all scenarios from small traffic to large traffic with single thread. The speedup is even more significant with more threads. We achieve about 25 times speedup on large scale 30×30 road networks with tens of thousands of vehicles using 8 threads, which is 72 steps of simulation per second. Besides, CityFlow shows better efficiency when retrieving information of the simulation via python interface. This is mainly because SUMO uses socket for interaction while CityFlow uses *pybind11* for seamless C++ and python integration.

3.2 Effectiveness

We evaluate the effectiveness of CityFlow by comparing to SUMO because SUMO is already a widely-used traffic simulator and its effectiveness is acceptable by domain experts. We compare the average duration of vehicles (time for a vehicle to enter and leave the road network) under different traffic volume settings. As Table 1 shows, the difference is within reasonable range.

Table 1: Duration of vehicles under different traffic volume

Vehicles/Hour	100	200	300	400	500
SUMO	40.76	41.57	42.75	44.08	45.93
CityFlow	40.79	41.58	42.62	43.84	45.45
Difference	0.07%	0.04%	0.30%	0.54%	1.06%



4 DEMO DETAIL

We plan to demonstrate CityFlow in different traffic scenarios and show its capability to serve as reinforcement learning testbed.

The demo consists of following parts:

- Simulating traffic in various scenarios, from synthetic grid scenarios to real world scenarios, and from small road networks with dozens of vehicles to large scale networks with tens of thousands of vehicles.

[3] https://github.com/pixijs/pixi.js

(a) 1×1 **road network with different green ratio**

(b) 6×6 **grid road network**

(c) 1×4 **grid road network**

(d) Part of Manhattan road network

Figure 1: Screenshot of CityFlow in different scenario

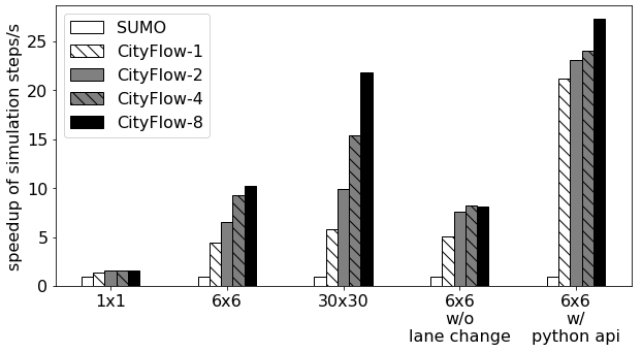


Figure 2: Speedup of CityFlow compared to SUMO

- Show the effectiveness the car-following model, intersection logic and lane change behavior of the simulator.
- Show a complete reinforcement learning training episode of optimizing traffic signal plan. Participants can observe gradual improvement of traffic condition during the training.
- Demo participants can control cycle length, green ratio of traffic signal and change the volume of traffic and see instant feedback of how the traffic condition would change.

We have published a video on Youtube[4], which demonstrate the expected effect. The project is under active development and we are likely to add other features (e.g. more map options, vehicle controls) and demonstrate more functions at the conference.

No special hardware is required since we are demonstrating a software project (learning platform). We will bring our laptop. It would be great if a monitor is provided.

5 SUMMARY

We propose CityFlow, an efficient, multi-agent reinforcement learning environment for large scale city traffic scenario. Researchers can use it as a testbed for traffic signal control problem and conduct research on urban mobility. We will demonstrate the usage and some results of RL-controlled traffic signal plan. Also, we are actively developing the project and plan to support more RL scenarios like dynamic vehicle routing, policy of reversible lane or limited lane as well as open source the project in the near future.
