ABSTRACT

Taxonomies are important building blocks of structured knowledge bases, and their construction from text sources and Wikipedia has received much attention. In this paper we focus on the construction of taxonomies for fictional domains, using noisy category systems from fan wikis or text extraction as input. Such fictional domains are archetypes of entity universes that are poorly covered by Wikipedia, such as also enterprise-specific knowledge bases or highly specialized verticals. Our fiction-targeted approach, called TiFi, consists of three phases: (i) category cleaning, by identifying candidate categories that truly represent classes in the domain of interest, (ii) edge cleaning, by selecting subcategory relationships that correspond to class subsumption, and (iii) top-level construction, by mapping classes onto a subset of high-level WordNet categories. A comprehensive evaluation shows that TiFi is able to construct taxonomies for a diverse range of fictional domains such as Lord of the Rings, The Simpsons or Greek Mythology with very high precision and that it outperforms state-of-the-art baselines for taxonomy induction by a substantial margin.

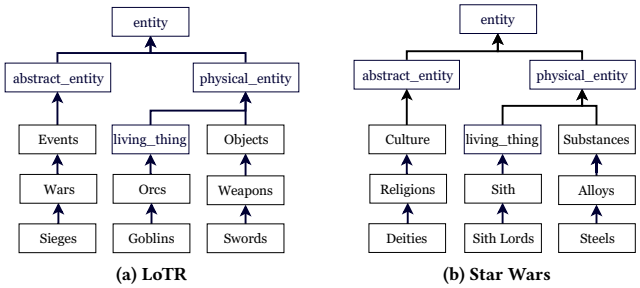
1 INTRODUCTION



1.1 Motivation and Problem

Taxonomy Induction: Taxonomies, also known as type systems or class subsumption hierarchies, are an important resource for a variety of tasks related to text comprehension, such as information extraction, entity search or question answering. They represent structured knowledge about the subsumption of classes, for instance, that `electric guitar players` are `rock musicians` and that `state governors` are `politicans`. Taxonomies are a core piece of large knowledge graphs (KGs) such as DBpedia, Wikidata, Yago and industrial KGs at Google, Microsoft Bing, Amazon, etc. When search engines receive user queries about classes of entities, they can often find answers by combining instances of taxonomic classes. For example, a query about "left-handed electric guitar players" can be answered by intersecting the classes `left-handed people`, `guitar players` and `rock musicians`; a query about "actors who became politicans" can include instances from the intersection of `state governors` and `movie stars` such as Schwarzenegger. Also, taxonomic class systems are very useful for type-checking answer candidates for semantic search and question answering [27]. Taxonomies can be hand-crafted, examples being WordNet [13], SUMO [31] or MeSH and UMLS [4], or automatically constructed by *taxonomy induction* from textual or semi-structured cues about type instances and subtype relations. Methods for the latter include text mining using Hearst patterns [20] or bootstrapped with Hearst patterns (e.g., [47]), harvesting and learning from Wikipedia categories as a noisy seed network (e.g., [8, 14, 16, 35–37, 44, 46]), and inducing type hierarchies from query-and-click logs (e.g., [18, 32, 34]).

The Case for Fictional Domains: Fiction and fantasy are a core part of human culture, spanning from traditional literature to movies, TV series and video games. Well known fictional domains are, for instance, the Greek mythology, the Mahabharata, Tolkien's Middle-earth, the world of Harry Potter, or the Simpsons. These universes contain many hundreds or even thousands of entities and types, and are subject of search-engine queries – by fans as well as cultural analysts. For example, fans may query about Muggles who are students of the House of Gryffindor (within the Harry Potter universe). Analysts may be interested in understanding character relationships [3, 24, 43], learning story patterns [5, 6] or investigating gender bias in different cultures [1]. Thus, organizing entities and classes from fictional domains into clean taxonomies (see example in Fig. 1) is of great value.

Challenges: While taxonomy construction for encyclopedic knowledge about the real world has received considerable attention already, taxonomy construction for fictional domains is a new problem that comes with specific challenges:

1. State-of-the-art methods for taxonomy induction make assumptions on entity-class and subclass relations that are often invalid for fictional domains. For example, they assume that certain classes are disjoint (e.g., living beings and abstract entities, the oracle of Delphi being a counterexample). Also, assumptions

about the surface forms of entity names (e.g., on person names: with or without first name, starting with Mr., Mrs., Dr., etc.) and typical phrases for classes (e.g., noun phrases in plural form) do not apply to fictional domains.

2. Prior methods for taxonomy induction intensively leveraged Wikipedia categories, either as a content source or for distant supervision. However, the coverage of fiction and fantasy in Wikipedia is very limited, and their categories are fairly ad-hoc. For example, Lord Voldemort is in categories like `Fictional cult leaders` (i.e., people), `J.K. Rowling characters` (i.e., a meta-category) and `Narcissism in fiction` (i.e., an abstraction). And whereas Harry Potter is reasonably covered in Wikipedia, fan websites feature many more characters and domains such as House of Cards (a TV series) or Hyperion Cantos (a 4-volume science fiction book) that are hardly captured in Wikipedia.
3. Both Wikipedia and other content sources like fan-community forums cover an ad-hoc mixture of in-domain and out-of-domain entities and types. For example, they discuss both the fictional characters (e.g., Voldemort) and the actors of movies (e.g., Ralph Fiennes) and other aspects of the film-making or book-writing.

The same difficulties arise also when constructing enterprise-specific taxonomies from highly heterogeneous and noisy contents, or when organizing types for highly specialized verticals such as medieval history, the Maya culture, neurodegenerative diseases, or nano-technology material science. Methodology for tackling such domains is badly missing. We believe that our approach to fictional domains has great potential for being carried over to such real-life settings. This paper focuses on fiction and fantasy, though, where raw content sources are publicly available.

1.2 Approach and Contribution

In this paper we develop the first taxonomy construction method specifically geared for fictional domains. We refer to our method as the **TiFi** system, for **T**axonomy **i**nduction for **Fi**ction. We address Challenge 1 by developing a classifier for categories and subcategory relationships that combines rule-based lexical and numerical contextual features. This technique is able to deal with difficult cases arising from non-standard entity names and class names. Challenge 2 is addressed by tapping into fan community Wikis (e.g., `harrypotter.wikia.com`). This allows us to overcome the limitations of Wikipedia. Finally, Challenge 3 is addressed by constructing a supervised classifier for distinguishing in-domain vs. out-of-domain types, using a feature model specifically designed for fictional domains.

Moreover, we integrate our taxonomies with an upper-level taxonomy provided by WordNet, for generalizations and abstract classes. This adds value for searching by entities and classes. Our method outperforms the state-of-the-art taxonomy induction system for the first two steps, HEAD [16], by 21-23% and 6-8% percentage points in F1-score, respectively. An extrinsic evaluation based on entity search shows the value that can be derived from our taxonomies, where, for different queries, our taxonomies return answers with 24% higher precision than the input category systems. TiFi datasets and code are available at https://www.mpi-inf.mpg.de/yago-naga/tifi.

2 RELATED WORK

Text Analysis and Fiction. Analysis and interpretation of fictional texts are an important part of cultural and language research, both for the intrinsic interest in understanding themes and creativity [5, 6], and for extrinsic reasons such as predicting human behaviour [12] or measuring discrimination [1]. Other recurrent topics are, for instance, to discover character relationships [3, 24, 43], to model social networks [3, 9], or to describe personalities and emotions [10, 26].

Taxonomy Induction from Text. A seminal contribution towards their automated construction was the discovery of Hearst patterns [20], simple syntactic patterns like *"X is a Y"* that achieve remarkable precision, and are conceptually still part of many advanced approaches. Subsequent works aim to automate the process of discovering useful patterns [38, 42], devise probabilistic models and graph-flow algorithms [15], utilize distributional representations of types [30, 39, 45, 49], or aim to infer pairwise or hierarchical hypernymy [30, 49].

Taxonomy Construction using Wikipedia. A popular structured source for taxonomy construction is the Wikipedia category network (WCN) for taxonomy induction. One project, WikiTaxonomy [36, 37] aims to classify subcategory relations in the WCN as *subclass* and *not-subclass* relations. They investigate heuristics based on lexical matching between categories, lexico-syntactic patterns and the structure of the category network for that purpose. YAGO [22, 44] uses a very simple criterion to decide whether a category represents a class, namely to check whether it is in plural form. It also provides linking to WordNet [13] categories, choosing in case of ambiguity simply the meaning appearing topmost in WordNet. WiBi (Wikipedia Bitaxonomy) [14] proceeds in two steps: It first builds a taxonomy from Wikipedia pages by extracting and disambiguating lemmas from the first sentence of pages, then combines the page taxonomy and the original Wikipedia category network to induce the final taxonomy. A recent system, HEAD [16], exploits multiple lexical and structural rules towards classifying subcategory relations.

Domain-specific Taxonomies. TAXIFY is an unsupervised approach to domain-specific taxonomy construction from text [2]. Relying on distributional semantics, TAXIFY creates subclass candidates, which in a second step are filtered based on a custom graph algorithm. Similarly, Liu et al. [28] construct domain-specific taxonomies from keyword phrases augmented with relative knowledge and contexts. Compared with taxonomy construction from structured resources, these text-based approaches usually deliver comparably flat taxonomies.

Fan Wikis. Fans are organizing content on fictional universes on a multitude of webspaces. Particularly relevant for our problem are fan Wikis, i.e., community-built web content constructed using generic Wiki frameworks. Some notable examples of such Wikis are *tolkiengateway.net/wiki*, with 12k articles, *www.mariowiki.com* with 21k articles, or *en.brickimedia.org* with 29k articles. Particularly relevant are also Wiki farms, like Wikia[1] and Gamepedia[2], which host Wikis for 380k and 2k different fictional universes, and have Alexa rank 49 and 340, respectively.

[1] www.wikia.com/fandom
[2] www.gamepedia.com

These Wikis, like on Wikipedia, come with support for categories, the *The Lord of the Rings* Wiki, for instance, having over 900 categories and over 1000 subcategory relationships, the *Star Wars* Wiki having 11k and 14k of each, respectively. Similarly as on Wikipedia, these category networks do not represent clean taxonomies in the ontological sense, containing for instance meta categories such as `1980 films`, or relations such as `Death in Battle` being a subcategory of `Character`.

3 DESIGN RATIONALE AND OVERVIEW

3.1 Design Space and Choices

Input: The input of TiFi is a noisy category/tag tree or graph for a given set of entities (with textual description), from a domain of interest. Entities are easily available in many forums incl. Wikipedia, wikis of fan communities or scholarly collaborations, and other online media. Tags and categories, including some form of category hierarchy, are available in various kinds of wikis – typically in very noisy form, though, with a fair amount of uninformative and misleading connections. When such sites merely provide tags for entities, we can harness subsumptions between tags (e.g., simple association rules) to derive a *folksonomy* (see, e.g., [11, 23, 25]) and use this as an initial category system. When only text is available, we can use Hearst patterns and other text-based techniques [7, 20, 40] to generate categories and construct a subsumption-based tree.

Output: The goal of TiFi is to construct a clean taxonomy that preserves the valid and appropriate classes and their instance-of and subclass-of relationships but removes all invalid or misleading categories and connections. Formally, the output of TiFi is a directed acyclic graph (DAG) $G = (V, E)$ with vertices V and edges E such that (i) non-leaf vertices are semantic classes relevant for the domain, (ii) leaf vertices are entities, (iii) edges between leaves and their parents denote which entities belong to which classes, (iv) edges among non-leaf vertices denote subclass-of relationships.

There is a wealth of prior literature on taxonomy induction methods, and the design space for going about fictitious and other non-standard domains has many options. Our design decisions are driven by three overarching considerations:

- We leverage *whatever input information is available*, even if it comes with a high degree of noise.
- For the output taxonomy, we *prioritize precision over recall*. So our methods mostly focus on removing invalid vertices and edges. Moreover, to make classes for fictitious domains more interpretable and support cross-domain comparisons (e.g., for search), we aim to align the domain-specific classes with appropriate upper-level classes from a general-purpose ontology, using WordNet [13].
- It may seem tempting to cast the problem into an end-to-end machine-learning task. However, this would require sufficient training data in the form of pairs of input datasets and gold-standard output taxonomies. Such training data is not available, and would be hard and expensive to acquire. Instead, we break the overall task down into focused steps at the granularity of individual vertices and individual edges of category graphs. At this level, it is much easier to acquire labeled training data, and to devise features that capture specific context.

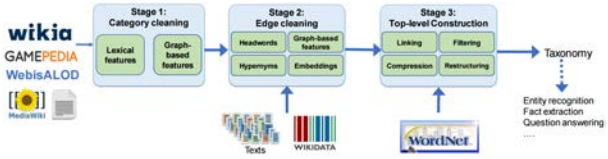

Figure 2: Architecture of TiFi.

3.2 TiFi Architecture

Based on the above considerations, we approach taxonomy induction in three steps, (1) category cleaning, (2) edge cleaning, (3) top-level construction. The architecture of TiFi is depicted in Fig. 2.

The first step, *category cleaning* (Section 4), aims to clean the original set of categories V by identifying categories that truly represent classes within the domain of interest, and by removing categories that represent, for instance, meta-categories used for community or Wikia coordination, or concern topics outside of the fictional domain, like movie or video game adaptions, award wins, and similar. While previous work has tackled this step via syntactic and lexical rules [33, 36, 44], for generalizability, we opt for a supervised classification approach that combines rules from above with additional graph-based features.

The second step, *edge cleaning* (Section 5), identifies the edges from the original category network E that truly represent subcategory relationships. We combine ideas from previous rule-based [17, 36] and embedding-based approaches [30] with various adapted semantic features and novel graph-based features.

For the third step, *top-level construction* (Section 6), we choose to reuse the existing WordNet top-level classes. This comes with the additional advantage of establishing a shared vocabulary across domains, allowing to query, for instance, for *animal species appearing both in LoTR and GoT* (with answers such as dragons).

4 CATEGORY CLEANING

In the first step, we aim to select the categories from the input that actually represent classes in the domain of interest. There are several reasons why a category would not satisfy this criterion, including the following: (i) *Meta-categories:* Wiki platforms typically introduce metacategories related to administration and technical setup, e.g., `Meta` or `Administration`. (ii) *Contextual categories:* Community Wikis usually contain also information about the production of the universes (e.g., inspirations or actors), about the reception (e.g., awards), and about remakes and adaptions, which do not related to the real content of the universes. (iii) *Instances:* Editors frequently create categories that are actually instances, e.g., Arda or Mordor in *The Lord of The Rings*). (iv) *Extensions:* Wikis sometimes also contains fan-made extensions of universes that are not universally agreed upon.

Previous works on Wikipedia remove either only meta-categories or instances by using crafted lexical rules [33, 36, 37]. As our setting has to deal with a wider range of noise, we instead choose the use of supervised classification. We use a logistic regression classifier with binary (0/1) lexical and integer graph-based features, as detailed next.

A. Lexical Features.

Meta-categories: True if a categories' name contains one of 22 manually selected strings, such as `wiki, template, user, portal, disambiguation, articles, administration, file, pages`, etc.
Plural categories: True if the headword of a category is in plural form. We use shallow parsing to extract headwords, for instance, identifying the plural term `Servants` in `Servants of Morgoth`, a strong indicator for a class.
Capitalization: True if a category starts with a capital letter. We introduced this feature as we observed that in fiction, lowercase categories frequently represent non-classes.

B. Graph-based Features.

Instance count: The number of direct instances of a category.
Supercategory/subcategory count: The number of super/subcategories of a category. Categories with more instances, superclasses or subclasses have potentially more relevance.
Average depth: Average upward path length from a category. Categories with short paths above are potentially more likely not relevant.
Connected subgraph size: The maximal size of connected subgraphs which a given category belongs to. Each connected subgraph is extracted by using depth first search on each root of the input category network. Meta-categories are sometimes disconnected from the core classes of a universe.

While the first two are established features, all other features have been newly designed to especially meet the characteristics of fiction. As we show in Section 7, this varied feature set allows to identify in-domain classes with 83%-85% precision.

5 EDGE CLEANING

Once the categories that represent classes in the domain of interest have been identified, the next task is to identify which subcategory relationships also represent subclass relationships. While most previous works rely on rules [8, 14, 16, 36], these are again too inflexible for the diversity of fictional universes. We thus tackle the task using supervised learning, relying on a combination of syntactic, semantic and graph-based features for a regression model.

A. Syntatic Features.

Head Word Matching. Head word matching is arguably the most popular feature for taxonomy induction. Categories sharing the same headword, for instance `Realms` and `Dwarven Realms` are natural candidates for hypernym relationships.

We use a shallow parsing to extract, for a category c, its headword $head(c)$, its prefix $pre(c)$, and its suffix (postfix) $pos(c)$, that is, $c = pre(c) + head(c) + pos(c)$. Consider a subcategory pair (c_1, c_2):

1. If $head(c_1) = head(c_2)$, $head(c_1) + pos(c_1) = head(c_2) + pos(c_2)$ and $pre(c_2) \subseteq pre(c_1)$ then c_2 is a superclass of c_1.
2. If $head(c_1) = head(c_2), pre(c_1)+head(c_1) = pre(c_2)+head(c_2)$ and $pos(c_2) \subseteq pos(c_1)$ then c_2 is a superclass of c_1.
3. If $head(c_1) \neq head(c_2)$ and $head(c_2) \subseteq pre(c_1)$ or $head(c_2) \subseteq pos(c_1)$ then there is no subclass relation between c_1 and c_2.

Case (1) covers the example of `Realms` and `Dwarven Realms`, while case (2) allows to infer, for instance, that `Elves` is a superclass of `Elves of Gondolin`. Case (3) allows to infer that certain categories are not superclasses of each other, e.g., `Gondor` and `Lords of Gondor`. Each of subclass and no-subclass inference are implemented as binary 0/1 features.
Only Plural Parent. True if for a subcategory pair (c_1, c_2), c_1 has no other parent categories, and c_2 is in plural form [16].

B. Semantic Features.

WordNet Hypernym Matching. WordNet is a carefully handcrafted lexical database that contains semantic relations between words and word senses (synsets), including hypo/hypernym relations. To leverage this resource, we map categories to WordNet synsets, using context-based similarity to identify the right word sense in the case of ambiguities. To compute the context vectors of categories, we extract their definitions, that is, the first sentence from the Wiki pages of the categories (if existing), and their parent and child class names. As context for WordNet synsets we use the definition (gloss) of each sense. We then compute cosine similarities over the resulting bags-of-words, and link each category with the position-adjusted most similar WordNet synset.Then, given categories c_1 and c_2 with linked WordNet synset s_1 and s_2, respectively, this feature is true if s_2 is a WordNet hypernym of s_1.
Wikidata Hypernym Matching. Similarly to WordNet, Wikidata also contains relations between entities. For example, Wikidata knows that `Maiar` is an instance (P31) of `Middle-earth races` in the *The Lord of the Rings*. While Wikidata's coverage is generally lower than that of Wordnet, its content is sometimes complementary, as WordNet does not know certain concepts, e.g., `Maiar`.
Page Type Matching. One interesting contribution of the WiBi system [14] was to use the first sentence of Wikipedia pages to extract hypernyms. First sentences frequently define concepts, e.g., *"The Haradrim, known in Westron as the Southrons and once as the "Swertings" by Hobbits, were a race of Men from Harad in the region of Middle-earth directly south of Gondor"*. For categories having matching articles in the Wikis, we rely on the first sentence from these. We use the Stanford Parser [29] on the definition of the category to get a dependency tree. By extracting `nsubj, compound` and `conj` dependencies, we get a list of hypernyms for the category. For example, for `Haradrim` we can extract the relation `nsubj(race-13, Haradrim-2)`, hence `race` is a hypernym of `Haradrim`. After getting hypernyms for a category, we link these hypernyms to classes in the taxonomies by using head word matching, and set this feature to true for any pair of categories linked this way.
WordNet Synset Description Type Matching. Similar to page type matching, we also extract superclass candidates from the description of the WordNet synset. For instance, given the WordNet description for `Werewolves`: *"a monster able to change appearance from human to wolf and back again"*, we can identify `Monster` as superclass.
Distributional Similarity. The distributional hypothesis states that similar words share similar contexts [19], and despite the subclass relation being asymmetric, symmetric similarity measures have been found to be useful for taxonomy construction [41]. In this work, we utilize two distributional similarity measures, a symmetric one based on the structure of WordNet, and an asymmetric one based on word embeddings. The first is the symmetric Wu-Palmer score compares the depth of two synsets (the headwords of the categories) with the depth of their least common subsumer,

while the second is the [48]. HyperVec score [30], which not only shows the similarity between a category and its hypernym, but is also directional.

While WordNet only captures similarity between general concepts, embedding-based measures can cover both conceptual and non-conceptual categories, as often needed in the fantasy domain (e.g. similarity between `Valar` and `Maiar`).

C. Graph-based Features.

Common Children Support. Absolute number of common children (categories and instances) of two given categories. Presumably, the more common children two categories have, the more related to each other they are.

Children Depth Ratio. The ratio between the number of child categories of the parent of the edge, and its average depth in the taxonomy. This captures the generality of the parent candidate.

The features for edge cleaning combine existing state-of-the-art features (Head word matching, Page type matching, HyperVec) with adaptations specific to our domain (Wikidata hypernym matching, WordNet synset matching), and new graph-based features. Section 7 shows that this feature set allows to surpass the state-of-the-art in edge cleaning by 6-8% F1-score.

6 TOP-LEVEL CONSTRUCTION

Category systems from Wiki sources often rather resemble forests than trees, i.e., do not reach towards very general classes, and miss useful generalizations such as `man-made structures` or `geographical features` for `fortresses` and `rivers`. While works geared towards Wikipedia typically conclude with having identified classes and subclasses [8, 14, 16, 36, 37], we aim to include generalizations and abstract classes consistently across universes. For this purpose, TiFi employs as third step the integration of selected abstract WordNet classes. The integration proceeds in three steps:

(1) Given the taxonomy constructed so far, nodes are linked to WordNet synsets based on context similarity. Where the linking is successful, WordNet hypernyms are then added as superclasses. For example, the category `Birds` is linked to the WordNet synset `bird%1:05:00::`, whose superclasses are `wn_vertebrate` → `wn_chordate` → `wn_animal` → `wn_organism` → `wn_living_thing` → `wn_whole` → `wn_object` → `wn_physical_entity` → `wn_entity`.
(2) The added classes are then compressed by removing those that have only a single parent and a single child, for instance, `abstract_entity` and `physical_entity` in Fig. **??** (right) would be removed, if they really had only one child.
(3) We correct a few WordNet links that are not suited for the fictional domain, and use a self-built dictionary to remove 125 top-level WordNet synsets that are too abstract to add value, for instance, `whole`, `sphere` and `imagination`.

Note that the present step can add subclass relationships between existing classes. For instance, after edge filtering, there is no relation between `Birds` and `Animals`, while after linking to WordNet, the subclass relation between `Birds` and `Animals` is added, making the resulting taxonomy more dense and useful.

Table 1: Input categories from Wikia/Gamepedia.

Universe	# Categories	# Edges
Lord of the Rings (LoTR)	973	1118
Game of Thrones (GoT)	672	1027
Star Wars	11012	14092
Simpsons	2275	4027
World of Warcraft	8249	11403
Greek Mythology	601	411

7 EVALUATION

In this section we evaluate the performance of the individual steps of the TiFi approach, and the ability of the end-to-end system to build high-quality taxonomies. We use 6 universes that cover fantasy (LoTR, GoT), science fiction (Star Wars), animated sitcom (Simpsons), video games (World of Warcraft) and mythology (Greek Mythology). For each of these, we extract their category networks from dump files of Wikia or Gamepedia. The sizes of the respective category networks, the input to TiFi, are shown in Table 1.

Step 1: Category Cleaning. Evaluation data for the first step was created using crowdsourcing, which was used to label all categories in LoTR, GoT, and random 50 from each of the other universes.

As baselines we employ a rule-based approach by Ponzetto & Strube [37], to the best of our knowledge the best performing method for general category cleaning, and recent work by Marius Pasca [33] that targets the aspect of separating classes from instances. Furthermore, we combine both methods into a joint filter. The results of training and testing on LoTR/GoT, respectively, each under 10-fold crossvalidation, are shown in Table 2. TiFi achieves both superior precision (+40%) and F1-score (+22%/+23%), while observing a smaller drop in recall (-18%/-15%). On both fully annotated universes the improvement of TiFi over the combined baseline in terms of F1-score is statistically significant (p-value 2.2^{-16} and 1.9^{-13}, respectively). The considerable difference in precision is explained largely by the limited coverage of the rule-based baseline.

As our approach requires labeled training data, a question is to which extent labeled data from one domain can be used for cleaning categories of another domain. We thus next evaluate the performance when applying models trained on LoTR on the other 5 universes, and the model trained on GoT on LoTR. The results are shown in Table 3, where for universes other than LoTR and GoT, having annotated only 50 samples. As one can see, F1-scores

Table 2: Step 1 - In-domain category cleaning.

Method	Universe	Precision	Recall	F1-score
Pasca 2018 [33]	LoTR	0.33	0.75	0.46
	GoT	0.57	0.85	0.68
Ponzetto & Strube 2011 [37]	LoTR	0.44	**1.0**	0.61
	GoT	0.45	**1.0**	0.62
Pasca + Ponzetto & Strube	LoTR	0.41	0.75	0.53
	GoT	0.64	0.85	0.73
TiFi	LoTR	**0.84**	0.82	**0.83**
	GoT	**0.85**	0.85	**0.85**

drop by only 9%/2% compared with same-domain training, and the F1-score is above 70% even for quite different domains.

To explore the contribution of each feature, we performed an ablation test using recursive feature elimination. The most important feature group were lexical features (30%/10% F1-score drop if removed in LoTR/GoT), with plural form checking being the single most important feature. In contrast, removing the graph-based features lead only to a 10%/0% drop, respectively.

Step 2: Edge Cleaning. We used crowdsourcing to label all edges that remained after cleaning noisy categories from LoTR, GoT, and random 100 edges in each of the other universes.

We compare TiFi with two state-of-the-art systems: (1) HEAD [16], the most recent system for Wikipedia category relationship cleaning, and (2) HyperVec [30], a recent embedding-based hypernym relationship learning system. The results for in-domain evaluation using 10-fold crossvalidation are shown in Table 4. As one can see, TiFi achieves a comparable precision (-2%/+2%), and a superior recall (+15%/+13%), resulting in a gain in F1-score of 6%/8%. Again, the F1-score improvement of TiFi over HyperVec and HEAD on the two fully annotated universes is statistically significant (p-values 7.1^{-9}, 0.01, 5.8^{-5} and 6.5^{-5}, respectively).

To explore the scalability of TiFi, we again perform cross-domain experiments using 100 labeled edges per universe. The results are shown in Table 5. In all universes but *World of Warcraft*, TiFi achieves more than 80% F1-score, and the performance is further highlighted by mean average precision (MAP) scores above 89%, meaning TiFi can effectively separate correct from incorrect edges.

In the ablation test, all three groups of features showed importance, each leading to a 1-4% drop in F1-score when being removed. The individually most important features were *Only Plural Parent, Headword Matching, Common Children Support* and *Page Type Matching*.

Step 3: Top-level Construction. The key step in top-level construction is the linking of categories to WordNet synsets (i.e. category disambiguation), hence we only evaluate this step. For this purpose, in each universe, we randomly selected 50 such links and evaluated their correctness, finding precisions between 84% and 92%. Overall, this step is able to link 30-72% of top-level classes from Step 2, and adds between 22 to 373 WordNet classes and 76 to 3387 subclass relationships to our universes.

Final Taxonomies. Table 6 summarizes the taxonomies constructed for our 6 universes, with the bottom 4 universes built using the models for GoT. Reported precisions refer to the weighted average of the precision of subclass edges from Step 2, and the precision of WordNet linking. The taxonomies are available at https://www.mpi-inf.mpg.de/yago-naga/tifi.

Other Inputs. We also evaluated TiFi on the real-world Wikipedia dataset, and on the noisy WebIsALOD [21] hypernymy dataset. We find that TiFi performs comparable to a state-of-the-art Wikipedia baseline [37] on Wikipedia, and that it significantly outperforms [37] and [33] on the noisier WebIsALOD data. More details are in the extended version.

8 USE CASE: ENTITY SEARCH

To highlight the usefulness of our taxonomies, we provide an extrinsic evaluation based on the use case of entity search. Entity search is a standard problem in information retrieval, where often, textual queries shall return lists of matching entities. In the following, we focus on the retrieval of correct entities only, and disregard the ranking aspect. The number of answers and their precision@10 is shown in Table 7. As one can see, entity search using TiFi yields significantly higher precision than Google and Wikia text search.

Table 7: Avg. #Answers and precision of entity search.

	Text		Structured Sources	
Query	Google	Wikia	Wikia-categories	TiFi
t	2 (52%)	7 (65%)	10 (62%)	8 (87%)
$t_1 \cap t_2$	1 (23%)	2 (11%)	8 (40%)	3 (70%)
$t_1 \setminus t_2$	1 (20%)	4 (36%)	8 (63%)	6 (79%)
Average	1 (32%)	4 (37%)	9 (55%)	6 (79%)

9 CONCLUSION

In this paper we have introduced TiFi, a system for taxonomy induction for fictional domains. TiFi uses a three-step architecture with category cleaning, edge cleaning, and top-level construction, thus building holistic domain specific taxonomies that are consistently of higher quality than what the Wikipedia-oriented state-of-the-art could produce.

ABSTRACT

Bandit algorithms have gained increased attention in recommender systems, as they provide effective and scalable recommendations. These algorithms use *reward functions*, usually based on a numeric variable such as click-through rates, as the basis for optimization. On a popular music streaming service, a contextual bandit algorithm is used to decide which content to recommend to users, where the reward function is a binarization of a numeric variable that defines success based on a static threshold of user streaming time: 1 if the user streamed for at least 30 seconds and 0 otherwise. We explore alternative methods to provide a more informed reward function, based on the assumptions that streaming time distribution heavily depends on the type of user and the type of content being streamed. To automatically extract user and content groups from streaming data, we employ "co-clustering", an unsupervised learning technique to simultaneously extract clusters of rows and columns from a co-occurrence matrix. The streaming distributions within the co-clusters are then used to define rewards specific to each co-cluster. Our proposed co-clustered based reward functions lead to improvement of over 25% in expected stream rate, compared to the standard binarized rewards.

1 INTRODUCTION

Given the overwhelming choices faced by users on what to watch, read and listen to online, recommender systems play a pivotal role in helping users navigate the myriad of choices. Most modern recommender systems are powered by interactive machine learning algorithms such as bandits [14, 17, 23], which learn to adapt their recommendations by estimating a model of the user satisfaction metric from the users feedback.

A key component of such bandit based recommender systems is the choice of *reward function*. A proper reward function should correlate well with user satisfaction, to allow the model to learn to serve good recommendations. Most prior work on quantifying satisfaction has relied on leveraging implicit signals derived from user interactions, mostly clicks [12, 19, 21, 25]. Often, click based signals are not informative enough and fail to differentiate between satisfying and dissatisfying experiences of users [11, 28]. Consequently, there has been a pressing need to move beyond clicks and investigate *post-click* behavior of users. These focus on the engagement of users with the served recommendations and have shown promising results in other areas [1, 11, 15].

Considering the specific use case of music streaming, quantifying such a notion of satisfaction from implicit signals involves understanding the diverse needs of users and their expectations of what is a successful streaming session. Such needs often include how users feel, and the expectations that music recommended to them align with their mood or their intent of the moment [8]. To fulfill these, music streaming services provide users with curated playlists, ranging from "sleep" to "run". In addition, and to account for the diverse user interests and plethora of musics, genre playlists have been made available to users, ranging from rap, pop, jazz, to niche ones. As a results, millions of playlists are available to users to listen to based on their intent and needs. Given such a heterogeneity in user needs, and the different intents of content (playlists), it becomes important to consider both user and content behavior to formalize the notion of satisfaction, and in turn design the appropriate reward models to capture these.

A major portion of work done on specifying reward functions rely on manually crafted functions, including rewards based on click-through behavior of users and other positive and negative feedback signals [29]. Some efforts have looked at strategies to improve the reward estimation in dynamic recommendation environments [2]. Overall, most bandit models powering recommendation system employ a rather simple threshold based reward function, mostly determined through click-through behavior of the user: *if user clicks on X, a payout of 1 is incurred and 0 otherwise* [17].

In this work, we go beyond such simple threshold-based formulation. We consider the case of a music streaming service, Spotify, powered by a contextual bandit model [20], and aim at defining appropriate reward functions to optimize the bandit model. We revisit how success is quantified, based on how users *consume* playlists and how playlists *are consumed* by users. Our approach moves from a simple user- and content-agnostic, binary reward model to a more sophisticated reward model, which is aware of the distribution of listening behavior. We highlight the need for jointly

considering user and content interaction to define rewards, and leverage insights from co-clustering of users and contents together to define rewards. We obtain a substantial improvement of over 25% in expected stream rate with our proposed co-clustering-based calculation of the reward functions.

2 BACKGROUND AND MOTIVATIONS

Our work aims to improve on a current bandit algorithm used to select which playlists to display to users on the home of Spotify, a popular streaming service [20].

Rewards for playlist recommendation. Playlist recommendation in music streaming services is often cast as a contextual bandit problem. Given a set of playlists $\mathcal{Y}$, a contextual bandit algorithm has to decide which playlists to recommend to a user $u \in \mathcal{U}$ at a certain time iteration $t \in 1, \ldots, \infty$. At each iteration t, the algorithm has access to a "context", i.e. a feature vector $x_{t,y}$ for each playlist $y \in \mathcal{Y}$. For each recommended playlist y_t, the algorithm receives a reward $\hat{r}_t$ based on the metric being optimized and the behavior of the user. In playlist recommendation, the most frequently employed metric is the *stream rate*, i.e. a binary reward indicating whether the user has streamed the playlist y_t or not. When optimizing for stream rate, the reward signal with which the algorithm is trained is a function of the streaming time the user has listened a recommended playlist for, $\hat{r}_t = \hat{r}(s_t)$. This is a binary reward function that assigns a value of 1 to recommendations y_t for which the streaming time s_t exceeds a given threshold of 30 seconds:[1]

$$\hat{r}(s) = \begin{cases} 0 & \text{if } s \leq 30 \text{ seconds} \\ 1 & \text{if } s \geq 30 \text{ seconds} \end{cases} \tag{1}$$

As the users preferences, and thus their behavior, are unknown and non-deterministic, the contextual bandit algorithm has to trade-off *exploration* for gathering information about the user preferences over the playlist domain and *exploitation* for maximizing the expected reward. The expected reward $\mathbb{E}[r_{t,y}]$, in our case the expected stream rate, of a playlist y in context $x_{t,y}$ is unknown and has to be estimated from data collected in the recommendation process. Thus, the expected reward is modeled as a parametrized function of the type:

$$\mathbb{E}[r_{t,y}] = h(x_{t,y}; \theta_t) \tag{2}$$

The above function can then be learned from some hypothesis class $h \in \mathcal{H}$ (e.g. as a linear model or a neural network), and the previously recommended playlists and the resulting users behaviors. New recommendations are selected at each iteration by sampling according to some policy, i.e. a probability distribution that accounts for some degree of exploration versus exploitation. Commonly used policies encompass an exploitation component that selects the best playlists according to the current model $y_t = \text{argmax}_{y \in \mathcal{Y}} \mathbb{E}[r_{t,y}]$, and an exploration component that selects novel recommendations according to some criteria (e.g. uniform random sampling). As this paper focuses on the definition of novel reward functions, we refer to the literature for details on the algorithmic framework [17].

The reward signal defined in Equation 1 is, effectively, a translation of the click-through rate, used in many other domains, to music recommendation. In this paper we explore the use of the streaming time as a metric of its own and not just as a static threshold. Next we discuss the limitations of the standard stream rate metric.

Stream rate. Using the stream rate as above defined as a reward signal, the algorithm learn an expected reward that models the probability of a user to stream a given content y for an undetermined amount of time (more than a fixed threshold):

$$\mathbb{E}[r_{t,y}] = p(\text{user streams } y) \tag{3}$$

This, however, fails to take into account how the user actually engaged with the recommended content *after* a successful recommendation. In a music recommendation system, we can use the streaming time s_{t,y_t} as a proxy for the user engagement: *the longer a user streams a playlist, the higher the user engagement.*

Even when a recommended playlist is streamed for more than 30 seconds, the user behavior, and thus the streaming time, can still vary substantially, and as such may imply different things. If a user clicks on and streams a playlist once, it does not necessarily mean he or she will do it again in the future. Many streams are "explorative", i.e. the user streams a playlist for a short period to evaluate its content. Other unsuccessful recommendations may also be one-time streams or even mistaken clicks [26].

By employing a stream rate reward signal, the algorithm will not learn to distinguish from genuinely successful recommendations, with which the user engages and is likely to engage in the future, and other kinds of uninformative feedback. This is due to the fact that the algorithm gets rewarded the same amount for any recommended playlist that gets streamed, despite eventual large differences in streaming time. Our objective is, instead, to maximize the engagement of the user with respect to the recommended content. To do so, we take into account the distribution of *streaming time* and define a success metric that rewards the algorithm only when it makes recommendations with which the users *truly* engage. This can be achieved by learning as expected reward modeling the probability of a user being engaged with the recommended playlist, assuming the user streams the playlist:

$$\mathbb{E}[r_{t,y}] = p(\text{user engages with } y \mid \text{user streams } y) \tag{4}$$

By learning this expected reward model, the algorithm is able to estimate which content is more likely to keep the user engaged and, hopefully, increase the chances for the user to stream (and engage with) the content in the future. We propose different reward signals that can be used to learn the above expected reward model.

Streaming time. While taking into account the streaming time distribution is a step forward in defining an engagement-aware reward signal for playlist recommendation, the reward is independent on the user and the content that generated it. This implies that the algorithm will learn to judge streams from any kind of users and playlists with the same criteria. This might be suboptimal because different users exhibit different listening behavior and different playlists get listened in vastly different ways.

Indeed, a study comparing streaming time distributions associated with specific groups of playlists and users to the global distribution (for playlists and users, respectively) highlighted these differences. For instance, the average streaming time across all playlists is 23.75 minutes, compared to 43.28 minutes for "sleep"

[1] The 30 seconds threshold is somewhat arbitrary, and it is often determined by unrelated factors.

playlists, i.e. playlists people listen to fall asleep. This is almost double the global average, demonstrating that this type of playlists is listened to in a drastically different way. Now focusing on user types, users who like Jazz music tend to listen to recommended playlists (all playlists, not just Jazz playlists) for longer than other users, with an average of 27.16 minutes, which is significantly higher than the global average of 20.43 minutes.

This data highlights differences between listening habits of users, as well as different attitudes towards certain types of playlists. This suggests that a reward signal based on a single aka "static" threshold is essentially averaging-out these peculiarities that are key to better generalization over a vastly diverse set of users and contents. For this reason, we also propose an approach to take into account user- and content-specific patterns.

User and content patterns. Ideally, we would have a reward function for each pair of user and content, defined on the streaming behaviour of the user with respect to that content. This method, however, would only work in an ideal situation in which we had plenty of data from each user and each playlist. In practice, we have extremely sparse data, in which each user listens to only a handful of the available playlists. Applying such a method on our data would result in poor generalization to similar users and contents. We propose, instead, to group together users and playlists, on the basis of their streaming time distribution, and to define reward functions for each pair of user group and playlist group.

To extract these groups of users and playlists automatically, we need to jointly cluster users on the basis of their streaming behavior and playlists on the basis of how they get streamed. This can be achieved using *co-clustering*, a technique that simultaneously extract clusters from two different variables based on a joint distribution. We then define reward functions specific to each pair of user cluster and playlist cluster, based on the streaming time distribution of the users and playlists of each co-cluster.

3 DISTRIBUTION-AWARE REWARDS

We motivated the need for rewarding the contextual bandit algorithm with a signal based on the engagement of the user with streamed content, as opposed to a standard reward based on stream rate only. Our approach consists in using the streaming time distribution of our data as a basis for defining reward functions for user engagement, with the assumption that the longer a user streams a playlist, the higher the chances of him or her being engaged with the content.

We present three different reward functions aiming to give a sensible notion of user engagement in the playlist recommendation setting.

Mean-based reward. The first reward function consists in a binary reward that determines whether a user is engaged or not. We define a user being engaged with a playlist when he or she streams it for at least as long as global mean $\hat{\mu}$ of streaming times in our dataset. We reward the algorithm with different values based on whether the user is engaged or not. In formula (where $0 \leq \lambda_1 \leq \lambda_2 \leq 1$):

$$\hat{r}_{\hat{\mu}}(s) = \begin{cases} \lambda_1 & \text{if } s \in [0, \hat{\mu}) \\ \lambda_2 & \text{if } s \geq \hat{\mu} \end{cases} \tag{5}$$

Additive reward. A more fine-grained solution is to define "engagement levels", each associated with a specific interval of streaming time. Given the streaming time s the user spent on listening to a recommended playlist, the algorithm will observe the reward amount associated with the proper interval. We define the engagement levels based on how different the streaming time is from the mean $\hat{\mu}$. The variability of the streaming time can be quantified with the standard deviation $\hat{\sigma}$ of the streaming times, which we can use to define engagement levels in the following way:

$$\hat{r}_{\hat{\mu},\hat{\sigma}}(s) = \begin{cases} \lambda_1 & \text{if } s \in [0, \hat{\mu} - \hat{\sigma}) \\ \lambda_2 & \text{if } s \in [\hat{\mu} - \hat{\sigma}, \hat{\mu}) \\ \lambda_3 & \text{if } s \in [\hat{\mu}, \hat{\mu} + \hat{\sigma}) \\ \lambda_4 & \text{if } s \geq \hat{\mu} + \hat{\sigma} \end{cases} \tag{6}$$

Here $0 \leq \lambda_j \leq \lambda_{j+1} \leq 1$, for $1 \leq j \leq 3$, are the reward amounts associated with each level. With the same approach one could define more engagement levels at any given granularity, by adding and subtracting multiples and submultiples of the standard deviation. In our experiments, however, we considered only these four intervals.

Cumulative reward. We can define *infinite* engagement levels as a *continuous* function of the streaming time, based on the underlying distribution. This function needs to be bounded between 0 and 1 and increases with the streaming time. We obtain this "cumulative" function by first fitting a model to the relative frequency distribution, and then using the associated cumulative distribution function to define the reward. As the streaming time distribution in our data follow a clear exponentially decreasing pattern, we fit the following exponential model to our data:

$$f(s; \gamma) = \gamma e^{-\gamma s} \tag{7}$$

The cumulative distribution function associated with the above is:

$$F(s; \gamma) = 1 - e^{-\gamma s} \tag{8}$$

Once fitted, wee obtain the best $\hat{\gamma}$ value to fit our data, which can be used to parametrize the cumulative distribution function. The cumulative reward function is then defined as follows:

$$\hat{r}_{\hat{\gamma}}(s) = \max\{F(s; \hat{\gamma}), \lambda\} \tag{9}$$

4 USER- AND CONTENT-AWARE REWARDS

We defined rewards that take into account the distribution of the streaming time of the users, thereby optimizing the probability of picking recommendations that would result in high streaming times when streamed. Streaming patterns across different groups users and different group of playlists are, however, very different from each other. In this section we introduce a technique that allows us to subdivide our data into smaller sets associated with closely related groups of users and playlists, on the basis of their streaming behavior. These subsets then help us defining reward functions that are specific to the different user and playlist groups.

Co-clustering. We want to subdivide the distribution into smaller sets based on similar streaming patterns across users and playlists. As the streaming time distribution is jointly dependent on both users and clusters, we should take into account these dependency in the clustering process. This can be achieved using *co-clustering*, a technique that simultaneously clusters two (or more) different

variables based on a joint underlying distribution [6, 7, 24, 27]. Co-clustering has been successfully employed in combination with several recommendation techniques [4, 9, 16]. Co-clustering has also been used to improve recommendation based contextual bandits algorithms [18]. The difference with our work is that [18] learns a co-clustering from the given reward, e.g. click-through rate, whereas we use co-clustering to define specific metrics to optimize for each user and playlist group.

We employ the information-theoretic co-clustering technique introduced by Dhillon et al. [7]. Given two random variables, in our case one variable $U \in \mathcal{U}$ representing the user and a variable $Y \in \mathcal{Y}$ representing the playlist, and an underlying joint probability distribution $p(U, Y)$, co-clustering will output two sets of clusters $\hat{\mathcal{U}}$ and $\hat{\mathcal{Y}}$, as well as two mappings $C_U : \mathcal{U} \to \hat{\mathcal{U}}$ and $C_Y : \mathcal{Y} \to \hat{\mathcal{Y}}$ from elements onto clusters. The number of k of row clusters and ℓ of column clusters, i.e. elements of $\hat{\mathcal{U}}$ and $\hat{\mathcal{Y}}$ respectively, is fixed a priori. The aforementioned technique computes a co-clustering by minimizing the loss in mutual information [5] between the original variables and the clustered variables. This in turn equates to finding an approximate distribution $q(U, Y)$ minimizing the KL-divergence with the original distribution:

$$I(U;Y) - I(\hat{U};\hat{Y}) = D\left(p(U,Y) \| q(U,Y)\right) \tag{10}$$

where $q(U=u, Y=y) = p(\hat{u},\hat{y})p(u|\hat{u})p(y|\hat{y})$, $C_U(u)=\hat{u}$, $C_Y(y)=\hat{y}$.

The algorithm minimizes the objective in a coordinate descent fashion: at each iteration the algorithm re-computes the row and column clusters separately by minimizing the marginal objectives:

$$C_U(u) = \operatorname*{argmin}_{\hat{u}} D(p(Y|u) \| q(Y|\hat{u})) \tag{11}$$

$$C_Y(y) = \operatorname*{argmin}_{\hat{y}} D(p(U|y) \| q(U|\hat{y})) \tag{12}$$

for each row u (users) and column y (playlists). The algorithm recomputes the distributions $q(\hat{U},\hat{Y})$, $q(U|\hat{U})$ and $q(Y|\hat{Y})$ with the new found clusters. Each iteration diminishes the joint objective $D(p(U,Y)\|q(U,Y))$. The algorithm keeps iterating through the data until the maximum number of iteration is met or the change in the objective between iterations is lower than a fixed threshold.

We chose this co-clustering technique because it scales better then others with the amount of data we were dealing with. In particular, given that our data is very sparse, this techniques scales as $O(nz \cdot \tau \cdot (k+l))$, where nz is the number of non-zero elements and τ is the number of iterations, which was fixed to 20 as recommended by [7]. We considered a maximum number of 15 clusters for both rows and columns, and leave for future work how to determine the optimal number of co-clusters.

Reward functions based on co-clusters. After co-clustering the users and the playlists, we are left with $k \times l$ co-clusters, each associated with a pair $(\hat{u},\hat{y}) \in [1,k] \times [1,\ell]$ of user cluster and playlist cluster. Each co-cluster is associated with a set of data points for all users belonging to cluster $\hat{u}$ who listened to playlists belonging to cluster $\hat{y}$. These data points define a co-cluster specific streaming time distribution, which is used to define co-cluster specific reward signals. We use the distribution-aware reward functions defined in Section 3, but with respect to each co-cluster distribution. For a given user u and playlist y belonging, respectively, to cluster $\hat{u}$ and $\hat{y}$, we define the co-cluster specific binary engagement reward:

$$\hat{r}_{\hat{\mu}_{\hat{u},\hat{y}}}(s_i) = \begin{cases} \lambda_1 & \text{if } s_i \in [0, \hat{\mu}_{\hat{u},\hat{y}}) \\ \lambda_2 & \text{if } s_i \geq \hat{\mu} \end{cases} \tag{13}$$

where $\hat{\mu}_{\hat{u},\hat{y}}$ is the average streaming time computed only on the data point contained in the co-cluster $(\hat{u},\hat{y})$. Similarly, we can also define the additive reward:

$$\hat{r}_{\hat{\mu}_{\hat{u},\hat{y}},\hat{\sigma}_{\hat{u},\hat{y}}}(s_i) = \begin{cases} \lambda_1 & \text{if } s_i \in [0, \hat{\mu}_{\hat{u},\hat{y}} - \hat{\sigma}_{\hat{u},\hat{y}}) \\ \lambda_2 & \text{if } s_i \in [\hat{\mu}_{\hat{u},\hat{y}} - \hat{\sigma}_{\hat{u},\hat{y}}, \hat{\mu}_{\hat{u},\hat{y}}) \\ \lambda_3 & \text{if } s_i \in [\hat{\mu}_{\hat{u},\hat{y}}, \hat{\mu}_{\hat{u},\hat{y}} + \hat{\sigma}_{\hat{u},\hat{y}}) \\ \lambda_4 & \text{if } s_i \geq \hat{\mu}_{\hat{u},\hat{y}} + \hat{\sigma}_{\hat{u},\hat{y}} \end{cases} \tag{14}$$

with $\hat{\sigma}_{\hat{u},\hat{y}}$ being the cluster specific standard deviation. For the cumulative reward, we can fit different exponential models to each co-cluster, thereby defining the co-cluster based reward as:

$$\hat{r}_{\hat{\gamma}_{\hat{u},\hat{y}}}(s_i) = \max\left\{F(s_i;\hat{\gamma}_{\hat{u},\hat{y}}), \lambda\right\} \tag{15}$$

where $\hat{\gamma}_{\hat{u},\hat{y}}$ is the parameter found by fitting the exponential model on the co-cluster data.

The procedure for getting the co-cluster specific rewards from the data is straightforward. First compute a co-clustering over the dataset and group examples (u_i, x_i, y_i, s_i) by their associated co-cluster $(\hat{u}_i, \hat{y}_i)$. For each co-cluster $(\hat{u},\hat{y})$ compute the parameters $\hat{\mu}_{\hat{u},\hat{y}}$, $\hat{\sigma}_{\hat{u},\hat{y}}$ and $\hat{\gamma}_{\hat{u},\hat{y}}$. Finally assign the co-cluster specific rewards to each data point employing the respective parameters.

5 EXPERIMENTS

Dataset. The dataset consists of a sample of logged feedback data from user interaction with the recommendation system of Spotify, a popular music streaming service. The datasets contains about 9M data points, each corresponding to an "impression". Each impression is associated with a user u_i, a recommended playlist y_i, a contextual feature vector x_i, and the streaming time s_i (equal to 0 if the playlist was not selected). The data included feedback from more than 800K users about over 900K playlists.

The feature vectors used in the contextual bandit algorithm are composed of more than 150K features, including: (i) features of the user, such as age range, gender, location, affinity to genres; (ii) features of the playlist such as its artist, its (micro and macro) genres, diversity of songs, popularity; (iii) affinity between the user and the playlist, taking into account past interactions, such as streams, skips, likes, and saves; and (iv) other contextual information, such as the day of the week and the time of day.

The data was collected over a period of four weeks from a small percentage of the live traffic of the production system. The first three weeks worth of data were used for the training set ($\approx$ 90%) and the last one for the test set ($\approx$ 10%).

Evaluation Setup. The trained model used in the production system is an ensemble of boosted regression trees, trained by XGBoost [3]. We replicate the same training setup as the production system, including the same hyper-parameters of the learning algorithm. We train a model using the *stream rate* (akin to click-through rates) as reward signal (Equation 1) and use it as a baseline. We also use a *random threshold* approach as a second baseline, which is a binary reward function akin to that in Equation 1, but whose

Table 1: Precision, recall and F_1 results (percentage over the baseline) for the different rewards over the global distribution.

Reward for global distribution	Prec@1	Prec@5	Rec@1	Rec@5	F_1@1	F_1@5
Mean-based reward	+19.30 %	+3.27 %	+22.68 %	+2.40 %	+20.94 %	+3.13 %
Additive reward	+15.33 %	-0.62 %	+15.81 %	-0.53 %	+15.57 %	-0.60 %
Cumulative reward	+6.91 %	-0.38 %	+8.92 %	-1.04 %	+7.89 %	-0.48 %

threshold was set to a randomly chosen value in the range [0, 10] minutes, instead of being fixed to 30 seconds.

We compare the two baselines against models trained with the proposed reward functions on the *global* distribution, i.e. using the same reward function (akin to post-click). We then compare the models trained on reward defined with the use of *co-clustering*, i.e. using the reward specific for its co-cluster (akin to per co-cluster post-click). The hyper-parameters of the reward functions were determined empirically. In addition, as there are no principled way to determine a proper number of clusters, a typical situation when employing unsupervised clustering techniques, the number of row (user) and column (playlist) clusters were also determined empirically. In Tables 1 and 2, we report standard precision, recall and F_1 measures, as improvement percentage over the first baseline (stream rate based reward), for global- and co-clustering-based rewards, respectively.

Evaluating a trained offline model on logged data from an online recommender systems is know to lead to biases in the estimation of the user satisfaction metric. This is because user feedback is collected only on the recommended items selected by the given collection policy, and no feedback is observed on every item that was not recommended. To avoid this problem and perform an *unbiased* evaluation of the models performance, we used a counterfactual evaluation methodology [22], which constitutes a reliable and much less expensive alternative to online A/B testing [10].

We follow the protocol laid out by [17]. We first collect testing data using a random shuffle policy, which assigns a uniform probability score to all recommendations presented to users. Upon evaluation of a new policy, we "re-run" the history of recommendations and keep only the recommendations that happen to be selected again by the policy being evaluated. We then compute the average evaluation metric (expected stream rate) on the retained data points. The evaluation policy used was a multinomial distribution defined on the learned expected reward function. Results comparing various reward strategies are shown (the difference in expected stream rate) in Figures 1 and 2.

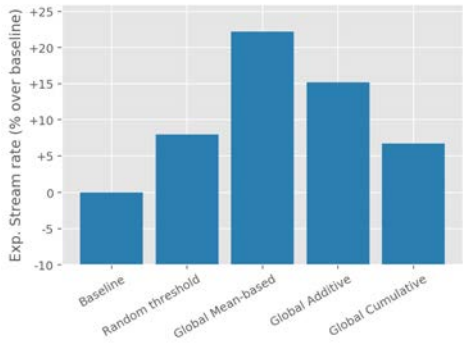

Figure 1: Expected stream rate improvement (in percentage over normalized baseline) of the random threshold method and all reward functions over the global distribution.

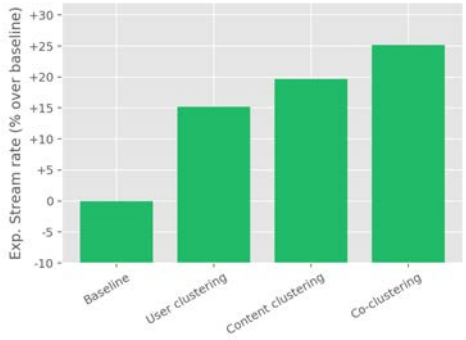

Figure 2: Expected stream rate improvement (in percentage over normalized baseline) of all mean-based reward functions over the distributions obtained by clustering users, clustering playlists and co-clustering.

6 RESULTS

Comparison of distribution aware rewards. Table 1 presents the precision and recall results comparing distribution aware reward functions with the static binary reward model. Overall, we observe that distribution aware models perform better than considering a fixed threshold. The mean based reward performs better than additive and cumulative reward, with over 19% gain in precision at the top and 22% gain in recall at the top. These results highlight that considering the distribution of user engagement is informative even without considering any user or content specific insights. Furthermore, upon randomly setting the threshold (see Figure 1), we observe an improvement in performance (expected stream rate), which further demonstrates the incompetence of the fixed threshold baseline strategy based on click-through rates.

Using co-clustering. Table 2 presents precision and recall results for the co-clustering method for all three distribution aware rewards. The co-clustering based reward model outperforms all other approaches, i.e. binary reward and global distribution aware reward. We observe a substantial improvement of over 25% in the unbiased

Table 2: Precision, recall and F_1 results (percentage over the baseline) for the different rewards over the co-cluster distributions. We experimented with several row x column numbers and we report those leading to the best performance.

Reward for co-cluster distribution	Row clusters	Column clusters	Prec@1	Prec@5	Rec@1	Rec@5	F_1@1	F_1@5
Mean-based reward	6	13	+24.74 %	+6.11 %	+26.40 %	+5.62 %	+25.56 %	+6.04 %
Additive reward	2	10	+13.34 %	+0.00 %	+12.83 %	+0.31 %	+13.09 %	+0.05 %
Cumulative reward	8	8	+13.34 %	+2.76 %	+14.76 %	+2.58 %	+14.04 %	+2.74 %

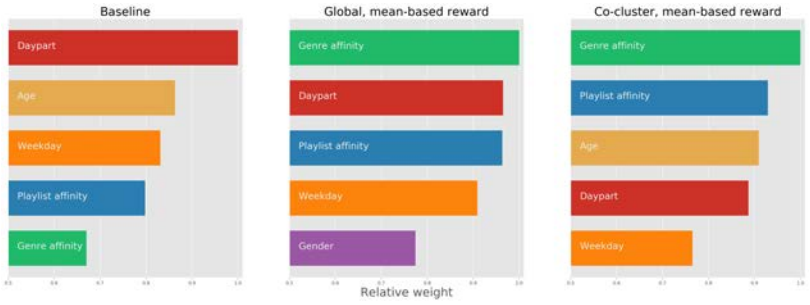

Figure 3: Relative weights of the model's features (by feature type) across the different trained models.

expected stream rate metric (see Figure 2). Similar to previously, the mean based function performs better than additive and cumulative even in the case of co-clustering of users and content.

While co-clustering of users and content allows us to jointly capture insights from both when defining the reward function, it may be hard to investigate the potential benefit offered by each. To disentangle the effect of user clusters from content clusters, we consider a special case of clustering, wherein we set the number of content clusters to 1, to give us a user-cluster, and vice-versa for content cluster. As shown in Figure 2, we observe that both the user- and content- aware reward models perform better than the static binary reward formulation, but both underperform the co-clustering based reward functions.

Comparison across metrics. The counterfactual method results indicate a consistent trend in performance across the unbiased counterfactual and offline evaluation metric, as we observe improvements in co-clustering based reward across all metrics. Furthermore, it is important to note that our estimate of expected stream rate metric is de-biased and corrected from position based bias, and as a result, provides a more reliable indicator of the benefit offered by the joint user- and content- aware reward model.

Quantifying the impact of contributing factors. We analyze how the trained models are different in terms of the features they give importance to. Figure 3 highlights the top 5 feature groups for the baseline binary reward model, the global distribution aware (mean) reward and the co-clustering reward model. As is expected, for the most important feature, the models give different weights to the different feature groups, with the baseline binary model method emphasizing the part of the day features more over others, whereas the distribution aware and user/content aware method focus on genre affinity feature group most. Indeed, the binary reward model is agnostic to user and content types, while the reward function in the co-clustering model is taking into account how users interact with content.

Looking beyond the most important feature group, among the top 5 most important features, user and content co-clustering values features that quantify user- and content- interactions: genre affinity and 7 day card affinity, whereas the baseline binary reward model values part of day and age group of users. Long term interactions like the 30 day affinity of users with content is weighted more in co-clustering than in others, which highlight the fact that training via co-clustering based reward signal allows the model to capture longer term interest and usage patterns.

Finally, we observe that as the reward signal becomes more sophisticated (binary → global mean → co-clustering), the focus moves from user-agnostic features (e.g. part of day), to user-only and content-only (e.g. user age and gender), to more sophisticated interaction based features (e.g. 30 day card affinity, genre affinity). These results highlight the importance of carefully defining reward signals that acknowledge the interaction between users and contents in our context (listening to music) by learning to weight the features appropriately.

7 CONCLUSIONS

We motivated this work by posting the hypothesis that distribution aware as well as user- and content-aware reward functions –capturing the "post-click" experience– are better than binary rewards –capturing only clicks. Extensive large-scale experiments on real world user data demonstrated the benefit of *personalizing* the definition of reward function according to how users listen to playlists **and** to how playlists are listened to.

Reward definitions lie at the forefront of systems that adopt reinforcement learning based methods to serve recommendations to users. As can be seen from our results, the reward function governs how the model is trained and has a major impact on the recommendations served. We contend that these results highlight the benefit of considering distribution and user/content aware functions to quantify the rewards, rather than creating hand-crafted reward functions. Setting fixed thresholds is very common. Indeed, a major portion of industrial search systems consider 30 seconds as the fixed threshold on dwell time to gauge user satisfaction with a clicked document [13].

Our findings reinforce the insight that when we optimize for a metric of user satisfaction, it is important to go beyond clicks. By focusing on the post-click experience, we can capture the "*intent*" of the content, as shown with "*genre*"-affinity being the most significant factor in impacting the bandit algorithm. We are also able to capture that users are different regarding how they consume content, as we see that "*playlist affinity*" is often the second most significant factor. Using clicks alone cannot surface these important components when measuring satisfaction.

Pcard: Personalized Restaurants Recommendation from Card Payment Transaction Records

ABSTRACT

Personalized Point of Interest (POI) recommendation that incorporates users' personal preferences is an important subject of research. However, challenges exist such as dealing with sparse rating data and spatial location factors. As one of the biggest card payment organizations in the United States, our company holds abundant card payment transaction records with numerous features.

In this paper, using restaurant recommendation as a demonstrating example, we present a *personalized* POI recommendation system (Pcard) that learns user preferences based on user transaction history and restaurants' locations. With a novel embedding approach that captures user embeddings and restaurant embeddings, we model pairwise restaurant preferences with respect to each user based on their locations and dining histories. Finally, a ranking list of restaurants within a spatial region is presented to the user. The evaluation results show that the proposed approach is able to achieve high accuracy and present effective recommendations.

1 INTRODUCTION

Personalized recommendation has greatly facilitated our daily life. For example, YouTube recommends a personalized video watch list based on each user's watching history as well as the reviews and ratings from the crowd [4, 5]. It is appealing to have such a personalized recommendation system for restaurant recommendations.

To recommend users with items particularly interesting to them, traditional personalized recommendation systems typically use collaborative filtering [20]. To provide recommendations to a user u, collaborative filtering first finds a group S of users that have similar tastes with u (e.g., they have rated similar items with a similar score for each), and then recommends user u with items that are liked by S but haven't been explored by u. An essential requirement of such an approach is the availability of user rating scores, such as Yelp ratings and reviews. However, such information is sparse and often hard to obtain. Furthermore, if a user never gives a rating or review, which is quite common, it is almost impossible to learn this user's preference to provide personalized recommendation. To make the matter worse, reviews and ratings are not always reliable as there are increasingly more artificially generated fake reviews.

To tackle this problem, implicit ratings have been proposed to replace explicit scores. For example, the YouTube [4] recommendation system considers a feedback as positive if a user watches a video until the end rather than aborting early. Yet similar features are not available for restaurant recommendations: knowing a person has visited a restaurant is relatively easy, but it is hard if not impossible to know whether this restaurant is being liked. Also, unexplored restaurants may be due to omission rather than being disliked. As such, simply assigning a visited restaurant with positive rating while unvisited ones with negative as in [12, 28] could make the results highly biased. A naïve idea to model user preferences is to use transaction frequencies made for different merchants as implicit ratings. However, for restaurant recommendation, this approach may not be effective due to the challenge introduced by location factor. User activities are greatly restricted by distance, especially when it comes to *where* to dine.

Our contributions. Our company holds one of the world's largest payments processing networks and handles hundreds of millions transactions every day. Most people in the US have transaction history in our network. Such scales of transaction data are invaluable towards learning users' purchasing behaviors for various recommendation purposes. This work shares our experience in mining the abundant payment card transaction history records to learn user preferences, with the particular focus of personalized restaurant recommendations as an example. Note that all user identity related attributes are processed as double hashing values, thus it is not able to identify a user based on a single transaction record. Further investigation on protecting user privacy while dealing with transaction data with advanced privacy-preserving techniques are also in place, which are not the focus of this work.

To the best of our knowledge, this is the first work that explicitly learns user preferences *based only on* card transaction records, without any rating or review data nor detailed metadata about the restaurants. Our contributions are summarized as follows.

(1) We adopt a novel embedding scheme to represent each user and each restaurant, where similar users/restaurants are represented by vector embeddings close in distance.
(2) We propose a novel approach to model user preferences over restaurants, which considers location effect while generating data samples to learn, but removes the influence of location information while modeling, for better generalization.
(3) We utilize user preferences learned from historical payment card transaction data to provide an effective ranked list of restaurants given any region.
(4) We evaluate our method on large-scale real transaction data to demonstrate its effectiveness, and a web demo was created to showcase the proposed approach.

2 PRELIMINARY

2.1 Dataset

For each card payment through our network, a *transaction record* is logged which contains numerous features: user id, merchant id, merchant location, transaction time, transaction amount, and etc..

2.2 Embeddings

To model the preference of any user to any restaurant, a major challenge is to find a meaningful and effective representation of each user and each restaurant. The number of users we have is comparable to the population in the United States, which makes it unrealistic to represent each user using a naïve method, say, one-hot encoding. Dimension reduction is necessary, while a question raised by which is how to find meaningful representations in low-dimensional space for hundreds of millions of users.

Specifically, for the time window between January 2016 and April 2016, we have around 30 billion transactions available in our database, among which there are around 220 million active cardholders (users) and 78 million active merchants (e.g., online shopping websites, local supermarkets, and restaurants). For each transaction, we extract a pair of user ids (i.e., cardholder account) and merchant ids, denoted as (uid_i, mid_i), which indicates that user uid_i has made a payment to merchant mid_i.

User embeddings. All (uid, mid) pairs are grouped by distinct merchants, i.e., by mids. Thus, each merchant group contains a sequence of all users who have made payments to this merchant, represented by mid_i: $[uid_{i,1}, \ldots, uid_{i,n_1}]$. Finally, each uid list is treated as a sentence and "sentences" from all merchants are treated as an article, and word2vec [16] is used to generate an embedding for each user uid.

Merchant embeddings. All (uid, mid) pairs are firstly grouped by distinct uids. A list of all merchants that have been attended by a user is treated as a sentence and all such "sentences" are treated as an article. Word2vec is used again to generate an embedding for each merchant mid.

Each user embedding is a 200 dimension float vector while each merchant embedding has 400 dimensions. The number of dimensions for each vector space are chosen to be both efficient and effective for different tasks.

All user embeddings and merchant embeddings are stored in two tables: *global_user_embeddings* and *global_merchant_embeddings*. Standard similarity measures such as k-nearest neighbors with euclidean distance or cosine similarity demonstrate that this embedding approach, as a representation method, is able to model intrinsic features of different entities. These embeddings have been shown effective in our other applications, e.g. fraud detection.

The embeddings are created in a way such that *similar* users have closer distance in the embedding space, e.g., if they live/work in the same area, or have similar shopping behaviors. Likewise, *similar* merchants also have closer distance in the embedding space if they are in the same category, in the same area or they accommodate similar users. Note that this property is essential towards building effective recommendation systems. Recall that the core idea of collaborative filtering is to provide a user with recommendations that are liked by other users who share *similar* tastes. Using this embedding approach, we are able to provide a user with effective restaurant recommendations even if this user has never been to a restaurant within our modeled time period. If this user has ever made any card payment through our network, e.g., shopping at a local grocery store, we could recommend to this user restaurants that are liked by other users who have similar purchasing behaviors.

3 METHODOLOGY

3.1 Overview

In this section, we will describe how Pcard works using the embeddings generated for each user and each restaurant. The objective is to provide a ranked list of restaurants for a given user u in a selected geographical region RG.

Pcard proceeds in two stages: 1) in an *offline learning stage*, a machine learning model is trained to learn different users' preferences over different restaurants, which we refer to as a *preference model*; 2) in an *online recommendation stage*, given a user u and a region RG, we rank all restaurants within RG based on u's preference over each restaurant in RG, provided by our preference model.

An intuition that we leverage is that a user's preference over a restaurant is typically a *relative ranking* compared to another restaurant, instead of an *absolute ranking*. Based on this observation, we learn user preferences by comparing pairs of restaurants for each user. Specifically, we extract data samples of $[u, r_1, r_2]$ from all transaction records within our learning time period, where r_1 and r_2 stand for two restaurants u has attended. The embeddings of u, r_1, r_2 are concatenated as the input vector for our machine learning model, and a label of 1 or 0 is given to indicate whether r_1 or r_2 is more preferred (by comparing the frequencies that u visited r_1 and r_2 respectively). Finally, given a user u and a region RG, we compare all pairs of restaurants within RG for u and output a ranked list, similar to ranking in a chess tournament.

However, for preference model learning, challenges exist for extracting data samples $[u, r_i, r_j]$ to learn. The major challenges are brought by location factors. First of all, location could be the major (or only) concern while considering *where* to dine, e.g., for work lunch, but it is not fair to say a company cafeteria is preferred over a fine restaurant that is far away. Thus, location information should be considered when generating data samples to learn. Secondly, a recommendation system that is built upon data from one location, should be generalized to provide recommendations for other locations. Therefore, location information should be removed while constructing the learning model. We address the two challenges at once by comparing restaurants that are close, and use visit frequencies as the preference measurements. For one, imagine if we are surrounded by multiple restaurants which are similar in distance, choosing which restaurant reveals our preference. For another, a pair of restaurants that are close have similar "location information" in their embedding space, which are automatically omitted in preference modeling since they do not provide a difference.

Another challenge is for a pair of restaurants (r_i, r_j) nearby, it is not certain to claim that a user u prefers r_i over r_j if, say, r_i was visited for 5 times but r_j for 4 times. As a result, we only assume that a restaurant r_i is preferred over r_j if r_i is visited many times but r_j few. We do not consider any restaurant that u has not visited during the learning period, since that could be simply due to that a user is unaware of this restaurant rather than he/she doesn't like the restaurant. Our embedding technique guarantees similar

users/restaurants would have similar embeddings, which enables the effective learning of user preferences on a subset of data.

To summarize, in the offline learning stage, from all transaction records within the learning period, we extract a data sample $[u,r_i,r_j]$ if: 1) r_i and r_j are within a distance threshold; 2) u attends r_i greater than or equal to f_u times while r_j less than or equal to f_ℓ times.

Finally, after the offline preference model is successfully trained, we could serve this model in the online recommendation stage for any user u and any region RG. The Pcard recommendation system, as shown in Figure 1, works as follows: 1) find all restaurants within region RG, denoted as *restSet*; 2) compare each pair of restaurants in *restSet* for u using our preference model; 3) compute a ranked list of all restaurants in RG based on the pairwise comparison results.

Next, we will explain each of the two stages in detail: 1) train a model that learns any user's preference on any pair of restaurants; 2) design a ranking method that is able to calculate an effective ranked list based on the pairwise comparison results.

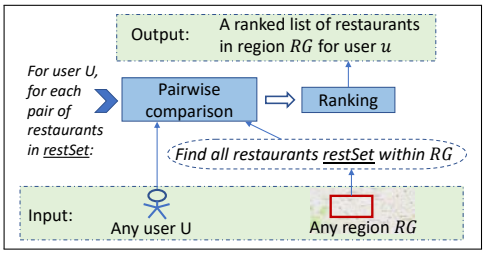

Figure 1: Recommendation system architecture

3.2 Learning a preference model

In this section, we train a preference model where given any user u and any pair of restaurants (r_i, r_j), it could output *how much* u prefers r_i compared to r_j. The resulting model serves as *Preference model* component in Figure 1.

Recall that each user is represented with an embedding such that users that are similar (e.g. have similar shopping preferences) have a smaller distance than users who are dissimilar. Such embeddings also exist for restaurants. Hence, although we're not able to cover all restaurants and all users for learning, the hope is if we have learned enough data, we are able to output meaningful results for similar users and restaurants that do not exist in training data.

To train a preference model, we take the following steps.

Step 1. Data extraction. In this step, we select all restaurant transaction records within the learning time period, and then group by user ids. For each user, we count the number of visits (i.e., visiting frequency f) to each distinct restaurant. The resulting data structure is: $\{u_1 : \{r_1: f_1, r_2: f_2, \ldots\}, u_2 : \{\ldots\}, \ldots\}$, which represents the frequency of visits to each restaurant by each user.

Step 2. Preference pair generation. With the data from step 1, we generate user preference pairs as data samples. Specifically, for all the restaurants a user u has visited, if restaurant r_i and restaurant r_j are within distance threshold D_{max}, and r_i's visiting frequency is higher than or equal to an upper threshold f_u, while r_j's visiting frequency is less than or equal to a lower threshold f_ℓ, we say u prefers r_i over r_j, and generate a preference sample $[u,r_i,r_j]$.

Step 3. Preference model training. After step 2, we have generated many preference pairs $[u,r_i,r_j]$ to learn. Since the goal is to learn a model which could output a preference over two restaurants for any user (i.e., whether u prefers the first restaurant or the second one), it is straightforward to use a binary classifier to learn this property and output "u prefers r_i" (label 1) or "u prefers r_j" (label 0). To generate training data for such model, for each preference pair $[u,r_i,r_j]$, we create two training samples: $[u,r_i,r_j]$ with label 1 to say u prefers the first restaurant, and $[u,r_j,r_i]$ with label 0 to indicate u prefers the second restaurant. For this task, we leverage a deep neural network (DNN) classifier provided by TensorFlow. As in Figure 2, for each data sample $[u,r_i,r_j]$, we first find embeddings for u, r_i and r_j in the embedding datasets and concatenate them to construct the input vector: [u embedding]+[r_i embedding]+[r_j embedding]. Optionally, we could also concatenate relevant statistics to the input vector to learn together. The output is a probability distribution of all possible classes, indicating which restaurant is more preferred. For example, ground truth label "1" is denoted with probability distribution of [1,0], indicating the first restaurant is more preferred. The process of training a DNN classifier is thus to adjust the parameters, in order to minimize the error between the actual output and the ground truth output.

After training, the preference model could be served in online recommendation stage to find a preference, for any given user u and any two restaurants. To do that, a concatenation of their embeddings is fed into the DNN classifier, the output of which is a pair of preference probabilities $[p_{j,i}, p_{i,j}]$, indicating u prefers r_i by a probability of $p_{j,i}$, and prefers r_j by $p_{i,j}$, where $p_{j,i} + p_{i,j} = 1$.

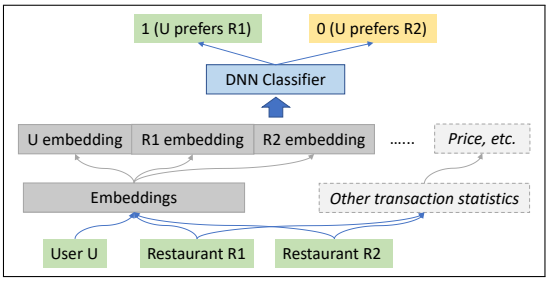

Figure 2: Preference model

3.3 Ranking from pairwise comparison

In online recommendation stage, for a given user u and a region RG, we find all pairs of restaurants within distance D_{max} and calculate their pairwise comparison results. With that, the next step is to output a meaningful ranking list for all distinct restaurants in RG. As discussed in Section 5, there are many previous works investigating the problem of ranking from pairwise comparisons.

3.3.1 Our approach. Recall that in Section 3.2, for a user u and a pair of restaurants (r_i, r_j) to compare, our preference model outputs a preference probability pair $[p_{j,i}, p_{i,j}]$. For all restaurants within region RG, i.e., $\{r_1, r_2, \ldots, r_n\}$, there are a total of $\binom{n}{2} = \frac{n(n-1)}{2}$ pairs of restaurants. For now, suppose the diameter of region RG is less than D_{max}, i.e., all pairs are comparable. Next, we need to find a meaningful way to rank all n restaurants from a total of $\binom{n}{2}$ pairwise comparison results. We use $\Pi(j)$ to denote the final ranking score for restaurant r_j, i.e., r_i ranks higher than r_j if and only if $\Pi(i) > \Pi(j)$. Since all the probability pairs are normalized in pairwise comparison results, it is reasonable to sum up all probabilities of each distinct restaurant, as the final ranking score Π for that restaurant. For instance, if the pairwise comparison results for 3

restaurants $\{r_1, r_2, r_3\}$ are $[p_{2,1}, p_{1,2}]$ (for (r_1, r_2)), $[p_{3,2}, p_{2,3}]$ (for (r_2, r_3)), $[p_{3,1}, p_{1,3}]$ (for (r_1, r_3)) respectively, there are $\Pi(1)=p_{2,1}+p_{3,1}$, $\Pi(2)=p_{1,2}+p_{3,2}$ and $\Pi(3)=p_{2,3}+p_{1,3}$. Finally, we could rank (r_1, r_2, r_3) by comparing $\Pi(1)$, $\Pi(2)$ and $\Pi(3)$. The extension to a larger region *RG* (i.e., not all pairs of restaurants within *RG* are comparable) is discussed later in Section 3.3.3. In evaluation we'll show this seemingly naïve method performs very good in practice, e.g., it is able to reduce the amount of noisy pairwise comparison results. What's more, it also has nice theoretical guarantees.

3.3.2 Theoretical property. Balanced Rank Estimation (BRE) is a ranking method proposed by Wauthier [24] to calculate the ranking score of each item from pairwise comparison results. Specifically, for the j-th item of a total of n items, its ranking score is:

$$\Pi(j) = \frac{\sum_{i \neq j} s_{i,j}(2\bar{c}_{i,j} - 1)}{2m(n)} \tag{1}$$

where $m(n)/n$ is the probability for each pairwise comparison being measured, $s_{i,j} = 1$ if a pair (i, j) is measured, and $\bar{c}_{i,j}$ is the (possibly noisy) measurement that is made.

In our case, each pairwise comparison is measured with a probability of 1, which has: 1) $m(n)/n = 1$, and hence $m(n) = n$; 2) $s_{i,j} = 1$; and 3) $\bar{c}_{i,j} = p_{i,j}$. Therefore, equation 1 reduces to: $\Pi(j) = \frac{\sum_{i \neq j}(2p_{i,j}-1)}{2n} \propto \sum_{i \neq j} p_{i,j}$. This means that BRE method is proportional to our proposed approach to calculate ranking score, which is, for each distinct restaurant, the sum of corresponding probabilities in all pairwise comparison results. Therefore, the theoretical properties proved for BRE method all proportionally hold for our approach. These include upper bound on number of inverts (cases where $p_{i,j} > p_{j,i}$ while $\Pi(j) < \Pi(i)$), and sample complexity (number of pairwise results needed to compute the final ranking), details of which could be found in [24].

3.3.3 Extension. The approach in Section 3.3.1 is based on pairwise comparison results for all pairs of restaurants in region *RG*. However, our initial assumption is that, two restaurants are only comparable if they are close (i.e., within a distance threshold D_{max}). Therefore, if two restaurants in region *RG* are further than D_{max}, it's neither valid nor accurate to compare them using our preference model, since there might be location information inscribed in their embeddings that may obfuscate the results. Hence, if *RG* is too large, we could only get incomplete pairwise comparison results, i.e., a set of pairwise results for pairs of restaurants that are within distance D_{max}, among a total of $\binom{n}{2}$ possibilities. Ranking from incomplete pairwise results is an important research topic in theory community [24]. However, the equations are not ready to use because they assume each pairwise comparison is *independently measured with the same probability*, which is often not the case in reality. Combined with the results from [24] (Equation 1), and our ranking approach in 3.3.1, we adopt another simple yet meaningful approach for ranking from incomplete pairwise results. In this approach, the ranking score of a restaurant is the sum of corresponding probabilities in all pairwise comparison results, normalized by the count of pairwise comparisons being made on that restaurant. For example, For three restaurants (r_1, r_2, r_3), if pairs (r_1, r_2) and (r_2, r_3) are close while r_1 and r_3 are far away, we have pairwise comparison results of $(p_{2,1}, p_{1,2})$, $(p_{3,2}, p_{2,3})$, then the ranking score for each restaurant is: $\Pi(1) = p_{2,1}$, $\Pi(2) = \frac{p_{1,2}+p_{3,2}}{2}$, $\Pi(3) = p_{2,3}$, based on which we could rank all three restaurants. Note that, by normalization we make sure each restaurant's measurements have the same weights in final ranking score (i.e., each restaurant is normalized to be measured once). Suppose restaurant r_j is measured by t_j times, the probability it is measured is $t_j/\binom{n}{2}$, i.e., $m_j(n)/n = t_j/\binom{n}{2}$ in Equation 1, which gives $m_j(n) = 2t_j/(n-1)$. Finally, Equation 1 becomes:

$$\Pi(j) = \frac{\sum_{i \neq j} s_{i,j}(2\bar{c}_{i,j} - 1)}{4t_j/(n-1)} \propto \frac{\sum_{i \neq j} p_{i,j}}{t_j} \tag{2}$$

which is exactly what we propose, to normalize the sum of corresponding probabilities for each restaurant by the number of times that restaurant is measured.

4 EVALUATION

This section evaluates the performance of Pcard. For all experiments we use the time period of January to February 2016 for training and validation, and March to April 2016 for testing. Note that *none* of the previous work has explored personalized restaurant recommendation in our setting, that is, without any explicit/implicit rating, and for a humongous volume of data. As a result, for baseline comparison, we simply adopt crowdsourcing approaches which are the only practical alternatives that could be evaluated on our data.

4.1 Pairwise comparison evaluation

4.1.1 Dataset. The evaluation dataset is extracted from transaction records stored in our database. For pairwise comparison evaluation, we first train a preference model on data samples generated from transaction records of a selected spatial area (e.g., Bay Area). After that, the accuracy of the preference model is tested not only on data samples of the same spatial region, but also for a different region, to test *the influence of location factors*.

Given an area, we first select all restaurant transaction records within this area. The rest of dataset generation follows the procedure described in Section 3.2. Recall that for each user u and each pair of restaurants (r_i, r_j), we generate a data sample $[u,r_i,r_j]$ if r_i, r_j are within distance threshold D_{max} and u has visited r_i more than or equal to f_u times while r_j fewer than or equal to f_ℓ times. The parameters used for all experiments are shown in Table 1a.

To validate our approach, we extract transaction records from areas ranging from smaller ones such as Bay Area, New York City, to larger ones such as California (CA) and the contiguous United States as our geographical regions to learn user preferences. Note that, if a preference pair $[u,r_i,r_j]$ appears in both training and testing datasets, we would eliminate that from testing data, to make sure that our model in fact learns preferences from embeddings instead of just memorizing training results. The number of data samples $[u, r_i, r_j]$ for each dataset is listed in Table 1b.

distance threshold	D_{max}	500 meters
visiting frequencies threshold	f_u	5
	f_ℓ	1

(a) Parameters used for all experiments

(BA: Bay Area; NYC: New York City; CA: California)

region	BA	NYC	BA & NYC	CA	US
#samples	1,951,413	2,720,745	4,679,721	24,955,210	211,519,990

(b) Number of preference pairs generated

Table 1: Datasets

4.1.2 Baseline. Our baseline mimics the default setting in current recommendation services (e.g., Yelp), which simply recommends a restaurant preferred by most users. Specifically, for each data sample $[u, r_i, r_j]$ in testing dataset, this baseline outputs a preference for r_i

if r_i has a higher visiting frequency by *all card holders* in training period, otherwise r_j.

4.1.3 Evaluation results. As discussed in Section 3.2 and Figure 2, for each extracted data sample [u,r_i,r_j], we create a concatenation of all their embeddings to train a DNN classifier using TensorFlow. The DNN classifier learns to output a pair of probabilities showing the preferences over two restaurants. For example, for an embedding concatenation [u embedding]+[r_i embedding]+[r_j embedding], the output of the classifier would be [$p_{j,i}$,$p_{i,j}$] where $p_{j,i} + p_{i,j} = 1$, showing the probabilities of liking r_i, r_j respectively. Note that, for a sample [u,r_i,r_j], there are two possible input embedding concatenations, one is [u embedding]+[r_i embedding]+[r_j embedding], and the other is [u embedding]+[r_j embedding]+[r_i embedding], which outputs [$p'_{i,j}$, $p'_{j,i}$]. In an ideal case, $p_{j,i} = p'_{j,i}$ and $p_{i,j} = p'_{i,j}$ should be true. However, due to the high dimension of input embeddings and the un-interpretable DNN classifier with millions of weights, it is not even true that [$p_{j,i}$, $p_{i,j}$] and [$p'_{i,j}$, $p'_{j,i}$] always have the same order (i.e., $p_{j,i} > p_{i,j}$ and $p'_{j,i} > p'_{i,j}$ or $p_{i,j} > p_{j,i}$ and $p'_{i,j} > p'_{j,i}$). To correct this, we test a sample [u,r_i,r_j] with the two different embedding concatenations as two separate inputs to the DNN classifier. Then, we output whether r_i or r_j is more preferred by comparing $p_{j,i} + p'_{j,i}$ and $p_{i,j} + p'_{i,j}$. The idea is that, although the order of [$p_{j,i}$, $p_{i,j}$] and [$p'_{j,i}$, $p'_{i,j}$] might not be the same, the case where the probability difference is higher means that the prediction label is more certain, where the other case might be because some part of the weights are not sufficiently trained. In our evaluation we found that this type of "two-way comparison" is more accurate than just using one type of embedding.

The prediction accuracy for each spatial area is shown in Table 2. Our method outperforms the baseline in all areas. We observe test accuracy decreases slightly when selected region size becomes larger, which could be caused by increased data varieties. Nevertheless, in the entire California state, the accuracy is still as high as 76.70%, and this accuracy does not drop further when the spatial area extends to the whole US region. Furthermore, to evaluate the influence of location information encoded in our embeddings, we use a classifier trained on New York City dataset to test preference accuracy in Bay Area, and the result is 80.77%, which is almost the same with the accuracy (81.33%) of using a classifier trained on Bay Area itself. It means that although restaurant embeddings may contain location information, by learning the preferences over pairs of restaurants within a region, DNN classifier is able to "ignore" that information which is similar between each pair of restaurants, and use other encoding information to learn a preference instead.

	BA	NYC	BA & NYC	CA	US
Pcard	81.33%	83.65%	80.64%	76.70%	76.66%
	Train on NYC and test on BA:		80.77%		
Baseline	64.27%	64.78%	64.53%	66.49%	68.38%

Table 2: Pairwise comparison evaluation results

4.2 Ranking from pairwise comparison results

In this section, we evaluate our ranking algorithm, which outputs a ranked list from pairwise preference probabilities provided by the preference model (see Figure 1 for detail).

To evaluate the correctness of ranking algorithm, previous works [19, 24] typically count the number of inverts. Given a set of n objects and binary pairwise comparisons between pairs of objects (e.g., object i > object j), an invert happens if the original pairwise order of object (i, j) is not preserved in the final ranked order. In previous work, the goal of ranking algorithm is to minimize the number of inverts.

However, in our work, there are two major differences. First, our pairwise comparison results are not the ground truth. To check final accuracy of ranking algorithm, we need to check with ground truth results from actual transaction history, instead of pairwise comparison probabilities output by the preference model. Second, it is very rare that a user u would have visited all restaurants within a region *RG*, which means that for ground truth data, we do not have all pairwise visiting frequency comparisons between any two restaurants within a region *RG* for a particular user u. Thus, we are not able to count the number of inverts in final ranking order compared to ground truth pairwise comparisons.

Instead, based on the data we have, we design a meaningful evaluation approach that could reveal the performance of our ranking algorithm. Specifically, in the testing dataset generated in Section 4.1, each sample [u,r_i,r_j] has a ground truth label of 1 or 0, meaning which restaurant between r_i and r_j is preferred. Using this dataset, the following procedures are applied to each data sample [u,r_i,r_j]: 1) find the smallest region RG_{ij} that could enclose both restaurants; 2) find all restaurants within region RG_{ij}; 3) compute pairwise preference probabilities for each pair of restaurants in region RG_{ij}; 4) rank all restaurants within region RG_{ij} based on pairwise probability results, through summing up all corresponding probabilities of each restaurant as its score; 5) check the ranking order of restaurants r_i and r_j, and see if it's the same with the ground truth label of data sample [u,r_i,r_j], i.e., whether the summed score of r_i in final ranking results is higher or lower than r_j, and whether the ground truth label of [u,r_i,r_j] is 1 or 0.

After above procedures, for all data samples in testing dataset, we get a *ranking order accuracy*, i.e., the percentage of the test samples that are correctly ordered in the *ranking results*. Then we compare this *ranking order accuracy* with the *pairwise comparison accuracy* in Section 4.1. If the *ranking order accuracy* is higher, it means that our ranking algorithm not only does not exacerbate previous step, but is even able to reduce noise in the pairwise comparison results.

The evaluation results show that the ranking algorithm has noticeably increased pairwise accuracy, from 79.95% (pairwise comparison accuracy) to 82.00% (ranking order accuracy) for Bay Area, which expresses the effectiveness of our ranking algorithm.

4.3 Overall recommendation performance

To test if our recommended restaurants are actually meaningful, for a given user, we use the whole end-to-end model shown in Figure 1 to output a ranked list of restaurants within a given region, and validate our results, by checking if this user actually attended the restaurants we recommended during the test period. We conducted this experiment for all users in Palo Alto area, and found that for over 80% of the cases, a restaurant the given user attended in test dataset is within top 30% of our ranked list. This means that if we recommend a list of 10 restaurants to a user, with large probability this user will go to one of our top 3 recommendations.

Baseline. For baseline, we adopt the crowdsourcing setting used by most services, where the recommendation list is sorted by visiting frequencies of all card holders. We found that, for over 80%

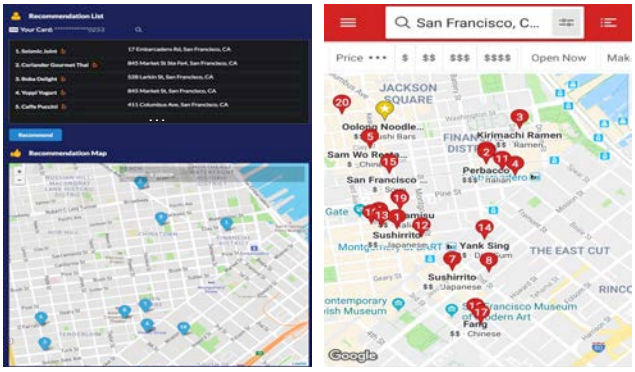

Figure 3: Screenshots of Pcard **(left) and Yelp (right) showing restaurant recommendations in downtown San Francisco**

of the cases, an attended restaurant in test dataset is only at top 46.15% of the recommendation list; while by only 65.12% of the cases could the attended restaurant appear within top 30% of the list. Apparently, Pcard provides more effective recommendations.

4.4 Interactive Demo

An interactive Pcard demo has been deployed at our company front desk to collect user feedbacks which continuously help to improve the system. A user interacts with the demo by sliding a payment card and selecting a location (range) for recommendations. The front-end submits a request for the restaurants in the area to be ranked by this user's preference. On the back-end, the system will look up all relevant embeddings, score all restaurants as described in Section 3, and finally return top k (e.g., k=10) restaurants.

A screenshot of the demo is shown on Figure 3 left. All restaurants' locations are shown with a link to each restaurant's Yelp page for more information. Compared with the Yelp recommendation result shown in Figure 3 right, which lists an overwhelming number of recommendations to be filtered further, Pcard saves user efforts to input additional information such as cuisine preference, which is already encoded in embeddings. Providing useful and interesting recommendations without using manual data labels is an important advantage of Pcard. The feedback from our demo is positive and is used to continue to improve the performance of Pcard.

4.5 Remarks

Pcard in its current state has certain limitations. First, two restaurants must be sufficiently close in order to be compared. The distance threshold of 500 meters in Table 1a is selected to be conservative. An alternative is to use restaurant density together with distance, in order to decide whether two restaurants are comparable. Second, Pcard may emphasize less expensive restaurants because of higher transaction frequency. To accommodate for this limitation, we could leverage the price range of restaurants and aggregated visiting frequencies to help with the preference model learning.

Despite the above limitations which we could address further, Pcard outperforms current POI recommendation systems in many aspects. First of all, with Pcard and our demo app as shown in Figure 3, users never have to explicitly label what they prefer or dislike in order to get useful recommendations. What's more, by only learning information from transaction records, Pcard addresses the cold start problem since we do not need any review or rating data to begin with. Also, our deployed model only contains information about double-hashed user ids and restaurant visiting frequencies, which protects user privacy. Last but not the least, Pcard could be further improved with user review data. A user could provide feedback through our app, after he/she tries a recommended restaurant.

5 RELATED WORK

Recommendation systems have been an important research topic for decades. Collaborative filtering, used by most traditional recommender systems [5, 13], recommends a user u with unexplored items that are liked by other users having similar tastes [6]. To achieve this, it needs sufficient rating scores to find *similar* users, e.g., Amazon rating scores [13], Yelp reviews [15], and Netflix's movie ratings [2]. However, explicit ratings or reviews are often not available, and could be highly biased. Implicit ratings [18] are proposed for the aforementioned problem. For instance, YouTube recommendation system treats a video as being liked by a user if the user finishes that video [4]. Similarly, if a webpage is being scrolled to the end, then it is likely that webpage is being liked [11].

However, everything is more complicated when it comes to point-of-interest (POI) recommendation [26, 27], especially restaurant recommendation, partly due to the complexity introduced by geographical location factors [1, 9, 14, 21, 26]. For restaurant recommendation, GeoMF [12] models geographical preferences of users using check-in data on location-based social networks (LBSNs), but they treat locations that users have been to as what users are likely to prefer. Zhang etc. [28] integrate implicit check-in data and explicit review data for more accurate recommendation, while analyzing user preferences based on their demographics information and restaurants attributes. In contrast, we aim to remove the influence of location factor while modeling user preferences, without any need of review data.

Deep learning has been gradually replacing many traditional algorithms in various tasks including recommendation systems [4, 8, 22, 23, 29]. Despite of the successful results, these methods still need either explicit ratings or implicit ones to begin with.

In our approach, we propose a ranking method that is able to output a ranking list of restaurants based on pairwise comparison results. Ranking from pairwise comparison results is heavily used in tournaments like chess player games, e.g., ELO rating system [25]. Research efforts in this field include to rank more efficiently [10, 17, 19], rank from incomplete pairwise results [24], and to only select top-k candidates [3, 7, 19]. Our proposed method is easy to implement, and has the same theoretical bounds with [24].

6 CONCLUSION

In this paper, we address the problem of restaurant recommendation using payment card transaction records, without any review or rating data. The experiences learnt shed light on addressing the *cold start* problem in general recommendation systems, especially for POI recommendations. For future work, we plan to utilize extra information such as restaurant statistics mined from transaction records and data from other websites to improve the accuracy, and to learn time series visiting patterns of each user for better recommendation performance.

ABSTRACT

In this paper, we propose a method of improving accuracy of multiclass classification tasks in crowdsourcing. In crowdsourcing, it is important to assign appropriate workers to appropriate tasks. In multiclass classification, different workers are good at different subcategories. In our method, we reorganize a given flat classification task into a hierarchical classification task consisting of several subtasks, and assign each worker to an appropriate subtask. In this approach, it is important to choose a good hierarchy. In our method, we first post a flat classification task with a part of data and collect statistics on each worker's ability. Based on the obtained statistics, we simulate all candidate hierarchical schemes, estimate their expected accuracy, choose the best scheme, and post it with the rest of data. In our method, it is also important to allocate workers to appropriate subtasks. We designed several greedy worker allocation algorithms. The results of our experiments show that our method improves the accuracy of multiclass classification tasks.

1 INTRODUCTION

Classification task, such as image categorization, is one of the most common types of tasks in crowdsourcing. Classification into multiple categories are called multiclass classification. For multiclass classification, flat classification schemes, which show all choices of categories to workers at once, is commonly used. Many crowdsourcing platforms, such as Amazon Mechanical Turk (http://www.mturk.com), provide templates of flat classification scheme.

In crowdsourcing, it is important to assign workers to tasks that they are good at in order to improve the quality of the task outputs. In multiclass classification, some workers are good at some subcategories while other workers are good at other subcategories. In the ordinary flat classification scheme, however, all the workers are assigned to the same task including all subcategories.

We propose a new approach to multiclass classification tasks. Given a flat multiclass classification task, we reorganize it into a hierarchical classification task consisting of several subtasks. We can then assign each worker to a subtask that she is good at.

For example, a flat classification task of classifying images of Canis animals into 7 categories (Siberian Husky, Alaskan Malamute, Samoyed, German Shepherd, wolf, coyote and dhole) can be reorganized into a two-level hierarchical classification task shown in Figure 1. This task consists of the following three subtasks: (1) a root task of classifying images into two top-level subcategories: (Husky, Malamute, Samoyed, Shepherd) and (wolf, coyote and dhole), which intuitively correspond to subcategories "dogs" and "wild species", respectively, (2) a task of classifying images that have been classified into the dog category further into the four breeds, and (3) a task of classifying images that have been classified into the wild species category further into the three species.

In this hierarchical task, we can assign different workers to different subtasks. If we have workers who are good at distinguishing these four dog breeds but not familiar with the wild species, we can assign them to the subtask of classifying dogs. Similarly, if we have workers who are familiar with wild animals but not familiar with dog breeds, we can assign them to the subtask of classifying wild species. Some workers are assigned to the root task of distinguishing dogs and wild species, which is relatively easy. We expect this assignment would improve the overall classification accuracy.

Another advantage of hierarchical schemes is simplicity of tasks. We expect that each subtask with a fewer choices requires less cognitive load and less execution time than the original flat task.

On the other hand, a disadvantage of hierarchical schemes is its cost. In a two-level hierarchical classification scheme, each data goes through two subtasks, thus the total number of the required task instances are double of that of the flat scheme. However, when we have enough budget and enough time, a method that can improve the accuracy of the output by fully utilizing these resources is useful.

Another standard method of improving the quality of crowdsourcing tasks by using more resources is the majority voting: we assign multiple workers to one task, and take majority vote. Improvement by the use of votes by two workers can be bigger than the improvement by the use of two-level hierarchical scheme. However, the majority voting and hierarchical reorganization are not exclusive with each other. For example, we can assign five workers to each subtask in a two-level hierarchical scheme, and take their majority vote. It requires ten workers for each data, so we could instead assign ten workers in a flat classification scheme. We should compare the accuracy of these two schemes. In other words, we

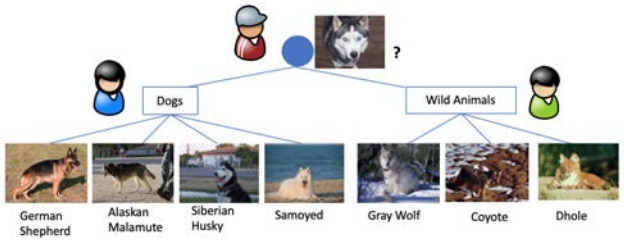

Figure 1: Example of a hierarchical classification scheme

should compare the benefit of two-level schemes with the benefit of doubling the number of workers in the majority voting scheme.

In the majority voting, we can assign as many workers to one task as we want, but the improvement is likely to stop after we reach some number of workers. For example, increasing the number of workers from five to ten is not likely to improve the accuracy significantly. We therefore expect that the benefit of the two-level schemes is bigger than the benefit of doubling the number of workers when we have already assigned enough number of workers.

In our hierarchical reorganization approach, there are many ways to reorganize a given flat classification task into a hierarchical one, and we need to choose an appropriate hierarchy. In this paper, we propose a method of selecting an appropriate hierarchy. We first post a flat classification task with a part of data as a worker qualification task, and collect statistics on each worker's ability. Based on the obtained statistics, we simulate all candidate hierarchical schemes and estimate their expected accuracy. We then choose the best scheme, and post it with the rest of data.

In our method, it is also important to allocate workers to appropriate subtasks in the simulation step, and when posting a hierarchical task. We designed several greedy worker allocation algorithms.

In order to evaluate our method, we ran several classification tasks on Amazon Mechanical Turk. The result shows that hierarchical schemes can improve the accuracy of multiclass classification if we choose appropriate hierarchies.

The contribution of this paper is summarized as follows:

- we propose a hierarchical reorganization approach for improving the accuracy of multiclass classification tasks,
- we propose a method of selecting appropriate hierarchy and a method of assigning workers to appropriate subtasks, and
- we experimentally confirmed that our method can improve the accuracy of multiclass classification tasks.

2 RELATED WORK

Hierarchical classification has been studied much in machine learning [4, 10, 14], but only in a few studies in crowdsourcing.

Vempaty et al. [15] proposed a method of transforming a flat multiclass classification (e.g., into multiple dog breeds) into a combination of many binary classifications (e.g., large/small dogs, and long/short tail dogs). They represent the results of the binary classifications of a data by a sequence of 0/1 and decode it into a class (e.g., a breed) based on coding theories. Their method uses a combination of binary classifications, not hierarchical one. In addition, appropriate binary classifications need to be specified manually.

Weng et al. [16] proposed a method of reorganizing a task of selecting data satisfying multiple conditions. Instead of asking all conditions at once, they reorganize a task into a hierarchical one where questions are asked one by one. In this scheme, they can reduce the number of tasks by narrowing down the candidates in earlier steps. Their goal is to reduce the workload in selection tasks while our goal is to improve the accuracy in classification tasks.

Otani et al. [12] proposed a method of aggregating multiple answers in flat multiclass classification tasks where classes have hierarchical relationships. For example, suppose two workers classify a given book into Society.Sociology category, two workers classify it into Science.Medical, and one worker classify it into Science.Others. In this case, Society.Sociology and Science.Medical have two votes, but they choose the latter because three of the five workers voted to Science category. The task shown to workers in their method is a flat multiclass classification task, and discovery of hierarchical relationship is not discussed.

Chilton et al. [2] and Bragg et al. [1] proposed a workflow for creating hierarchical taxonomy by crowdsourcing. In their methods, each worker classifies a small fraction of the data, and their methods create a globally consistent taxonomy based on the answers. Their purpose is to create a semantically meaningful hierarchy while our purpose is to select a hierarchy that best improve the accuracy of a classification task. As shown later in our experiment, the best hierarchy is not necessarily a semantically meaningful hierarchy.

There have also been many proposals of methods of assigning workers to appropriate tasks. The Hungarian algorithm [9] is a classical algorithm for the optimal task-worker assignment. However, we cannot simply use the Hungarian algorithm for assigning workers to hierarchical subtasks because the accuracy of subtasks in hierarchical classification tasks have inter-dependency: if the results of the upper subtasks are wrong, it cannot be corrected in the lower subtasks. In addition, the Hungarian algorithm is too slow when we have many workers. We develop new greedy algorithms for assigning workers to hierarchical classification subtasks.

Mavridis et al. [11] proposed a worker allocation method based on the hierarchical relationship between required skills. Their skill hierarchy, however, does not correspond to classification hierarchy, and we cannot use it for worker allocation in our method.

Our hierarchical schemes require more workers, and such resources can instead be used for repeated labeling as explained before. Sheng et al. [13] showed that repeated labeling does not always improve the output quality. For deciding whether we should assign more workers or not, Gao et al. [5] designed two models to estimate the profit of additional tasks. Kamar and Horvitz [7] also proposed a method of deciding whether to hire more workers or not. Karger et al. [8] has shown a theoretical result on the trade-off between the quality and the number of workers for each task in multiclass classification tasks. We can use these methods to determine whether we should introduce hierarchical schemes or should increase the number of workers for one data instead.

3 OUR METHOD

In this section, we explain the details of the four steps of our method: (1) posting qualification tasks, (2) generating candidate hierarchical schemes, (3) estimating ability of workers at subtasks in the

candidate schemes based on the statistics obtained in the qualification tasks, and (4) allocating workers to subtasks in the candidate schemes for estimating the expected accuracy of the schemes.

3.1 Qualification Task

As explained in Section 1, we first post an ordinary flat classification task with a part of data as a qualification task. Qualification tasks are popularly used in crowdsourcing for eliminating spammers. We use it also for calculating the accuracy of each worker for each category, and creating a confusion matrix of each worker.

For these purposes, we need the ground truth for the data used in the qualification task. In our experiment, we used data with the ground truth. When it is not available, we can estimate it by majority voting or more recent alternatives [3, 6, 17].

In our experiment, 20 to 30 items from each category was enough to obtain stable statistics. We use the same data set for all users.

3.2 Hierarchical Scheme Generation

We then generate candidate hierarchical schemes, and run simulations of them. There are, however, too many possible hierarchies to run simulation of. In this paper, we only consider two-level schemes because the number of levels corresponds to the number of subtasks each data goes through, and the cost of the whole classification task is proportional to the number of levels. The scheme in Figure 1 is an example of a two-level scheme with one root task, two top-level categories, two leaf tasks for them, and seven final leaf classes.

Because the number of two-level schemes is still large, we only consider schemes with at most $\lfloor n/2 \rfloor$ top-level categories when we have n leaf classes. Schemes with more top-level categories have at least one top-level category with only one leaf class, and are probably inefficient. With this restriction, the number of candidate schemes for n final classes is $\sum_{k=2}^{\lfloor n/2 \rfloor} S(n,k)$, where $S(n,k)$ is the Stirling numbers of the second kind.

3.3 Estimation of Worker Ability

Given a candidate scheme, we estimate two types of accuracy of each worker based on the results of the qualification task: (1) accuracy in the root task, and (2) accuracy in each leaf task.

When we estimate the root task accuracy of a worker, if the worker has classified an item of one class into another class within the same top-level category in the qualification task, it is regarded as a correct answer. For example, suppose we estimate the accuracy of a worker at the root subtask in the scheme in Figure 1. If she has classified a Husky image into the Samoyed class in the qualification task, it is regarded as correct. We calculate the ratio of the correct answers to the all answers in the qualification task.

On the other hand, when we calculate the accuracy of a worker at a leaf task corresponding to a top-level category A, we only consider items in the qualification task whose correct classes belong to A. In the qualification task, the worker sometimes classifies an item in A into some wrong leaf class c which does not belong to A. When the worker is really assigned to the leaf task for A, she cannot classify the item to c because c is not in the choices. In such cases, we determine which class she would choose based on the probability distribution of her answer in the qualification task.

For example, suppose we estimate the accuracy of a worker at the leaf task for the top-level category "dog" in the scheme in Figure 1. In the qualification task, the worker classified 6 images of Husky: 3 into the Husky class, 2 into Malamute, and 1 into wolf. When the worker is assigned to the leaf task for the dog category, she cannot classify an image into the wolf class, which is not in the choices. When calculating her accuracy in this subtask, we assume that she would classify the image she misclassified into wolf, either into Husky or Malamute in the probability 3/5 and 2/5, respectively.

We also collect statistics on task speed of workers. In order to minimize the response time of a task, the number of tasks assigned to workers should be proportional to their task speed.

3.4 Worker Allocation Algorithms

We have calculated the accuracy of workers at subtasks in the candidate scheme. In order to estimate the expected overall accuracy of the scheme, we also need to decide worker allocation to subtasks.

Notice that we cannot simply allocate each worker to a subtask for which she has her best accuracy. If we did it, we would have no worker for difficult subtasks. We need to assign appropriate number of workers to each subtask for minimizing response time.

We can assign a worker to more than one subtasks, but even if we do it, the worker would only work on a subtask with the best reward/time ratio until all the data at the subtask is processed. In this paper, we assume that each subtask has far more data than one worker can process. We, therefore, only consider simple worker allocation where each worker is allocated only to one subtask.

There are too many ways to allocate workers to subtasks, and we cannot calculate expected accuracy for all of them. Even with only three subtasks and 20 workers, we have $3^{20} > 3$ billion ways to allocate workers. To decide worker allocation without an exhaustive search, we designed four greedy worker allocation algorithms.

Algorithm 1 gives priority to workers whose accuracy largely changes depending on tasks. It is important to assign such workers to appropriate tasks. On the contrary, we give the least priority to workers who have the same accuracy for all tasks.

After calculating accuracy of workers for subtasks in the given scheme, we create a worker list l_r, which is sorted by the accuracy of workers at the root subtask in descending order. We also create worker lists $l_1, \ldots, l_k$, each of which is sorted by the accuracy of workers at the corresponding leaf subtask. Let $r_r^u, r_1^u, \ldots, r_k^u$ be u's ranks in $l_r, l_1, \ldots, l_k$. We calculate the variance of $r_r^u, r_1^u, \ldots, r_k^u$ for each worker. Here we measure the variance of u's ability by using her ranks instead of the accuracy values because the accuracy values for different subtasks are incomparable. We then produce a list of workers, W, sorted by the variance in descending order.

We also maintain variables $j_r, j_1, \ldots, j_k$ storing how many jobs are remaining at the root task and each leaf task. Suppose we have m data items, n leaf classes, and a hierarchical scheme with k top-level categories, which includes $n_1, \ldots, n_k$ leaf classes, respectively. We may not know the ratio of data in each leaf class, so we assume that each leaf class has m/n items. We initialize j_r to m and initialize each j_i $(i = 1, \ldots, k)$ to either $m * n_i/n$ if $n_i > 1$, or 0 if $n_i = 1$. We are also given w_u for each u, the relative task speed of u.

We scan W starting from its top, and for each u in W, we find the largest value among $r_r^u, r_1^u, \ldots, r_k^u$, i.e., the best subtask for u.

If it has remaining jobs, we assign u to that task and subtract the expected number of jobs the worker u will do, i.e., $2m * w_u/\Sigma_j w_j$, from the number of its remaining jobs. If it has no remaining job, we assign u to the next best task for u.

Algorithm 2 is same as Algorithm 1 except that we use the accuracy values instead of ranks. Because the accuracy values in different tasks are incomparable, we normalize them to the standard scores. Let a_i^u be the accuracy of worker u for the task i. For each task i ($i = r, 1, \ldots, k$), we calculate the mean of accuracy $\bar{a}_i = \sum_u a_i^u/|W|$ and the standard deviation $\sigma_i = \sqrt{\sum_u (a_i^u - \bar{a}_i)^2/|W|}$, where $|W|$ is the number of workers. We then calculate s_i^u, the standard score of the worker ability, by $s_i^u = (a_i^u - \bar{a}_i)/\sigma_i$. We use the variance of s_i^u instead of the variance of r_i^u when we sort W and when we select the best subtask for u.

Algorithm 3 is the opposite of Algorithm 1 and 2. It gives priority to tasks whose accuracy largely changes depending on the allocated workers. In this case, we do not need to use rankings or standard scores. For each task i, we calculate the average accuracy $\bar{a}_i = \sum_u a_i^u/|W|$ and the variance $\sigma_i^2 = \sum_u (a_i^u - \bar{a}_i)^2/|W|$. We then give priority to a task i with the largest σ_i^2, and assign it a remaining worker with the highest accuracy for i.

Algorithm 4 gives priority to a task with the largest ratio of remaining jobs. It repeatedly selects a task corresponding to the largest value among $j_r/j_r^0, j_1/j_1^0, \ldots, j_k/j_k^0$, where $j_r^0, j_1^0, \ldots, j_k^0$ are the initial values of $j_r, j_1, \ldots, j_k$ explained before, and allocates a remaining worker with the highest accuracy for that task. We repeat it until all the workers are assigned.

For all combinations of candidate schemes and our four allocation algorithms, we compute worker allocation, and compute the expected overall accuracy of the task under that worker allocation. We then choose the combination that achieved the highest accuracy, post the classification task using that hierarchical scheme, and assign workers to subtasks by using that worker allocation.

4 EXPERIMENTS

We ran experiments on two data sets on Amazon Mechanical Turk (AMT). The results are explained in this section.

4.1 Experiment of classifying Canis Animals

In the first experiment, we compare the accuracy of flat and hierarchical classification tasks classifying images of 7 kinds of Canis animals explained in Section 1. In this experiment, we only consider hierarchical schemes with two top-level categories, which we call A and B. We have $2^7 - 1 = 63$ such schemes (excluding one scheme that is equivalent to the flat classification).

We collected over 100 images of each of these seven kinds of Canis animals, and obtained 800 images in total. We posted a flat classification task with randomly chosen 200 images on AMT as a qualification task. The remaining 600 images are used in the main task later. One task instance consists of 20 images. We obtained information on 153 workers, and removed 11 workers as spammers.

We then estimated overall accuracy of 63 hierarchical schemes by allocating workers with Algorithm 1 and 4. For all 63 schemes, both Algorithm 1 and 4 achieved better expected accuracy than the accuracy observed in the flat classification task posted as the qualification task, which was 0.746. In addition, for all 63 schemes, Algorithm 1 achieved better accuracy than Algorithm 4. Table 1 lists schemes that achieved the three best and the three worst accuracies with Algorithm 1. The columns A and B show the leaf classes allocated to the two top-level categories.

Table 1: Best/Worst Hierarchical Schemes with Algorithm 1

rank	accuracy	A	B
1	0.866	(Samoyed, wolf, coyote)	others
2	0.862	(Malamute, Husky, dhole)	others
3	0.862	(Shepherd, Malamute, Husky)	others
⋮	⋮	⋮	⋮
61	0.807	(Shepherd)	others
62	0.800	(Malamute, wolf, dhole)	others
63	0.776	(Malamute, coyote)	others
flat	0.746		

Table 2: Confusion Matrix for All Users (bold fonts: > 0.1)

	Malamute	coyote	dhole	wolf	Shepherd	Samoyed	Husky
Malamute	0.611	0.002	0.009	0.016	0.024	0.038	**0.300**
coyote	0.018	0.618	**0.134**	**0.182**	0.016	0.018	0.015
dhole	0.010	**0.209**	0.698	0.030	0.012	0.018	0.015
wolf	0.053	**0.118**	0.026	0.674	0.022	0.029	0.077
Shepherd	0.009	0.009	0.022	0.008	0.917	0.018	0.017
Samoyed	**0.104**	0.006	0.045	0.020	0.015	0.755	0.055
Husky	**0.218**	0.010	0.008	0.040	0.028	0.023	0.674

Table 3: Accuracy of Real Tasks on AMT

Scheme	Total	Root	Sub-A	Sub-B
best scheme in Table 1 (3 to 4)	0.875	0.970	0.853	0.850
A: (wolf) B: others (1 to 6)	0.765	0.900	0.880	0.749
worst scheme in Table 1 (2 to 5)	0.590	0.610	0.444	0.644
flat (majority voting)	0.833	-	-	-
flat (weighted majority voting)	0.767	-	-	-

Table 2 shows the confusion matrix calculated from the answers by the workers in the qualification task. For example, it shows that 0.2% of Malamute images were classified as coyote. Misclassification with a probability higher than 0.1 is shown in bold fonts. This table shows that Malamute and Husky are most difficult to distinguish, coyote and dhole are the next, and coyote and wolf follow.

In all the top three schemes shown in Table 1, the most difficult pair, Malamute and Husky, are in the same top-level category, while they are in different top-level categories in the two worst schemes. It suggests that we can improve overall accuracy by allocating these two kinds to the same top-level category, and assigning workers who are good at distinguishing them to the leaf task corresponding to that top-level category. Another confusing pair, wolf and coyote, are also in the same top-level category in all the top three schemes.

We then posted three hierarchical classification tasks on AMT to know their real accuracy (i.e., not the estimation by our simulation). We chose the best scheme and the worst scheme in Table 1, and also the best 1-to-6 scheme (i.e., one class in A and 6 classes in B) as a medium-level scheme. Because the best scheme is 3-to-4 scheme and the worst scheme is 2-to-5 scheme, these three schemes include all n-to-m cases. Table 3 lists the three schemes and their results.

We have 600 images excluding 200 images used in the qualification task. We randomly divide them into three sets of 200 images and allocate them to the three hierarchical tasks. All 142 workers are invited to the three tasks, which were posted at the same time. We also posted a flat classification task with the same 600 images.

In all the tasks, five workers are assigned to each image. We used two methods to aggregate the five answers: majority voting and the standard EM-based weighted voting method [3]. When we have a tie in majority voting (e.g., 2 votes to wolf, 2 to coyote, and 1 to dhole), we randomly choose one of the classes involved in the tie.

We show the result in Table 3. Because the accuracy of the flat classification with the weighted voting is lower than that with the simple majority voting, we only used the simple majority voting in the hierarchical tasks. The hierarchical scheme which was best in the simulation achieved higher accuracy than the flat scheme. It confirms that we can improve the accuracy of a multiclass classification task by reorganizing it into a hierarchical task.

However, the accuracy of the other two hierarchical schemes are worse than that of the flat scheme although their expected accuracy was higher than it. This result suggests that the choice of hierarchical schemes significantly influence workers' performance, and if you choose an inappropriate scheme, it can result in the accuracy that is worse than the expected accuracy estimated from the workers' performance in the flat classification task.

Also note that none of the best three schemes in Table 1 is the semantically meaningful one shown in Figure 1. It shows that it is not easy to manually determine the good hierarchy, and we should compute it based on the ability of currently available workers.

To confirm that good hierarchies depend on the workers available at the time, we run the experiment of classifying Canis animals twice. In the previous run, the most confusing pair, Malamute and Husky, are allocated to one top-level category, and another confusing pair, wolf and coyote, are allocated to the other top-level category, in the three best schemes. In the second run, these two pairs are assigned to the same top-level category in the two best schemes. This happened because the set of workers who are good at distinguishing Malamute and Husky, and the set of workers who are good at distinguishing wolf and coyote, were relatively disjoint in the previous run, but have more overlaps in the second run. As a result, allocating both pairs to the same top-level category becomes a better strategy. As shown in this result, the best hierarchical schemes depends on the set of workers currently available.

4.2 Experiment with Reptiles and Amphibians

Next, we compare flat and hierarchical tasks classifying images of the following 10 kinds of reptiles and amphibians: Komodo dragon, frilled agama, chameleon, gecko, iguana, skink, giant salamander, tuatara, and basilisk. In the previous experiment, we only generated hierarchical schemes with two top-level categories, but in this experiment, we use 2 to 5 top-level categories.

We collected over 100 images for each class and obtained over 1000 images in total. We then published a qualification task on AMT with 200 images, collected answers from 307 workers, and we eliminated 44 workers as spammers, which result in 263 workers.

We computed the confusion matrix from their answers. We omit the details, but the most frequent misclassification was 21.7% of tuatara images classified into the iguana class, which look similar and better known. Compared with Canis animals, the distinction between confusing pairs and the others are not clear, and the confusion matrix is less symmetric. This is because the 10 classes in this task include both well-known classes and less-known classes.

We then generated all the hierarchical schemes with 2 to 5 top-level categories, and ran Algorithm 1 to 4. We obtain the best accuracy with Algorithm 2, which uses the standard score of the accuracy of workers. Table 4 shows some results obtained with Algorithm 2. It lists the best scheme, which has four top-level categories, the best one among those with five top-level categories (202nd), the best one among those with three top-level categories (6422nd), and the worst scheme. The worst scheme has five top-level categories, four of which include only one leaf class. The best to the 201th schemes all have four top-level categories.

In the best scheme shown in Table 4, basilisk is allocated to the same top-level category as frilled agama and chameleon, to which basilisk images are often misclassified. In this scheme, newt and giant salamander, which are often misclassified to each other, are also allocated to the same top-level category. Newt and giant salamander are allocated to the same top-level categories in most schemes with high accuracy (although it is not shown in Table 4). This is similar to what happened in the previous experiment.

We posted hierarchical classification tasks on AMT with the four schemes shown in Table 4, and assigned 263 qualified workers to the subtasks by Algorithm 2. We divide 800 images that were not used in the qualification task to four tasks so that each of them has 200 images. In each subtask, each image is classified by five workers, and we take the majority votes.

In this experiment, we calculate the accuracy of the flat scheme by using the answers in the qualification task. In the hierarchical tasks, we take majority votes by 5 workers, but in the flat task, we take majority votes by 10 workers because our two-level schemes require twice as many workers as the flat scheme. We randomly choose 10 users who participated in the hierarchical classification tasks, take the majority votes of their answers in the flat qualification task, and calculate the overall accuracy. We repeat the random selection of 10 users five times and took the average of the accuracy. We only choose users who also participated in the hierarchical tasks in order to be fair. If we include workers who did not participate in the hierarchical tasks, the accuracy of the flat scheme was lower.

Table 5 shows the results. It also shows the result we would have if we take majority votes by 3 workers for hierarchical schemes and 6 workers for the flat scheme. When we calculate the accuracy in these cases, we randomly choose 3 (or 6) workers from 5 (or 10) workers and take their majority votes. We repeat it five times and calculate the average of the accuracy.

When we take majority votes by 5 and 10 workers, our top and the 202th schemes achieved higher accuracy than the flat scheme. The 202th scheme achieved better accuracy than the top scheme. However, the 6422th scheme shows lower accuracy than the flat scheme, so it is again important to choose a good hierarchy.

On the other hand, when we take majority votes by 3 and 6 workers, the flat scheme achieved higher accuracy. The results in these two settings shows that the improvement we obtain by increasing the number of workers from 6 to 10 in the flat scheme is not as big as the improvement we obtain by increasing it from 3 to

Table 4: Part of Hierarchical Schemes and their Expected Accuracy Obtained with Algorithm 2

rank	accuracy	*A*	*B*	*C*	*D*	*E*
1	0.918	skink, tuatara	Komodo dragon, gecko	agama, chameleon, basilisk	others	-
202	0.903	basilisk	Komodo dragon, gecko	skink, agama, iguana	newt	others
6422	0.878	iguana, gecko, tuatara	skink, Komodo dragon, newt, basilisk	agama, chameleon, giant salamander	-	-
last	0.626	Komodo dragon	chameleon	skink	iguana	others

Table 5: Result with Majority Votes by 5 Workers (10 for Flat Scheme) and 3 Workers (6 for Flat Scheme)

Scheme	by 5 (10)	by 3 (6)
1st	0.885	0.855
202th	**0.890**	0.845
6422th	0.830	0.820
last	0.860	0.755
flat (majority voting)	0.863	**0.860**
flat (weighted majority voting)	0.730	-

Table 6: Average Task Execution Time (in second) for Reptile and Amphibian Images

	flat task			hierarchical task	
	all u	u at root	u at leaf	root	leaf
best	916.798	2372.66	578.958	2311.78	278.880

5 in the hierarchical schemes, and as a result, the accuracy of some hierarchical schemes become higher than that of the flat scheme when we have 5 (or 10) workers. This result suggests that our hierarchical scheme is useful when we have a budget to hire more workers, but we have already allocated enough number of workers to each task, and the benefit of doubling the number of workers is likely to be smaller than the benefit of hierarchical schemes.

4.3 Temporal Factors

When we take majority voting by the half number of workers in a hierarchical task, the number of required task instances is the same as in the flat task. We should also compare the workload of one task instance. Subtasks in hierarchical tasks have a fewer choices, so it may require lighter cognitive load than the tasks in the flat scheme.

To confirm it, we measured the average task execution time for a task instance including 20 reptile and amphibian images in the following cases: the average over flat tasks by all workers, the average over flat tasks done by workers who are allocated to the root task when they worked in the best hierarchical scheme, the average over flat tasks done by workers who are allocated to the leaf tasks when they worked in the best hierarchical scheme, the average over the root task in the best scheme, and the average over the leaf tasks in the best scheme. Table 6 shows the results.

The average execution time of flat tasks is 916.798, but the average over flat tasks done by workers who were allocated to the root task in the best hierarchical scheme is 2372.66. It means that our algorithm tend to allocate slow workers to the root task in this scheme. The average execution time of the root task in the best hierarchical scheme is almost the same. This is reasonable because both of them show workers all the leaf classes as the choices. The average execution time of the leaf tasks in the best hierarchical scheme is shorter than that of the flat task done by the same workers. This is also reasonable because the leaf tasks of the hierarchical scheme shows fewer choices to workers. The sum of the average execution time of the root tasks and the leaf tasks is bigger than the double of that of the flat task. Therefore, when we have a time constraint, hierarchical schemes have a disadvantage.

We also measured the time required by the worker allocation algorithms. In the experiment with images of Canis animals, it processed 63 schemes in a few minutes. In the experiment with images of reptiles and amphibians, we have a huge number of schemes because we generate schemes with 2 to 5 top-level categories, but our algorithms processed all of them within a day. This cost is not impractical when we classify a large number of data in crowdsourcing because such a task usually takes far longer. If we have more classes, and want to generate schemes including a larger number of top-categories, the time required in this step can be prohibitive. In that case, we should limit the number of top-categories. On the other hand, the time complexity of the Hungarian algorithm is in $O(n^3)$, and it is also infeasible when n is large.

5 CONCLUSION AND FUTURE WORK

In this paper, we propose a new approach to multiclass classification tasks in crowdsourcing. By reorganizing a task into a hierarchical classification task consisting of multiple subtasks, we can allocate workers with different expertise more appropriately to subtasks.

In our method, we generate all reasonable schemes, and estimate their expected accuracy by virtually assigning workers to its subtasks. For this step and also for the real execution of hierarchical tasks, we developed four greedy worker allocation algorithms. They give priority either to workers whose ability largely changes depending on tasks, to tasks whose accuracy largely changes depending on workers, or to tasks with higher remaining job ratio.

We posted hierarchical tasks on AMT with two data sets. We confirmed that we can achieve higher accuracy than the flat tasks if we choose appropriate hierarchical schemes, and also confirmed that our method can choose appropriate schemes. Because the best algorithm among our four algorithms depends on the data set, the best strategy is to use all of them to run simulation for all candidate schemes, and choose the one that achieved the best accuracy.

Our worker allocation algorithms have large room for improvement. We also need a method for efficiently enumerating promising candidate schemes because we cannot enumerate all schemes when we have many classes. They are remaining issues for future work.

Modeling the Factors of User Success in Online Debate

Abstract

Debate is a process that gives individuals the opportunity to express, and to be exposed to, diverging viewpoints on controversial issues; and the existence of online debating platforms makes it easier for individuals to participate in debates and obtain feedback on their debating skills. But understanding the factors that contribute to a user's success in debate is complicated: while success depends, in part, on the characteristics of the language they employ, it is also important to account for the degree to which their beliefs and personal traits are compatible with that of the audience. Friendships and previous interactions among users on the platform may further influence success.

In this work, we aim to better understand the mechanisms behind success in online debates. In particular, we study the relative effects of debaters' language, their prior beliefs and personal traits, and their social interactions with other users. We find, perhaps surprisingly, that characteristics of users' social interactions play the most important role in determining their success in debates although the best predictive performance is achieved by combining social interaction features with features that encode information on language use during the debate.

1 Introduction

Previous work from Natural Language Processing (NLP) and Computational Social Science (CSS) that studies argumentative text and its persuasive effects has mainly focused on identifying linguistic features that are indicative of effective argumentation strategies [13, 16, 17, 33, 37, 41, 43]. For example [43] has shown that language characteristics such as conversational flow, are predictive of the success of a debater in persuading an audience member to change their stance *during a debate.* [10] has further shown that the prior beliefs of the audience with respect to the topic of discussion and the stance/beliefs of the debaters are at least as important as the linguistic characteristics of the debate in predicting the successful debater. At the same time, it has been shown that there is a strong relationship between users' social interactions and their influence on social media. For example, [35] and [7] and have shown that individuals with more activity and personal engagement are more influential on Twitter. We **hypothesize** that success in persuasion might also depend on an individual's social interactions and engagement with other users (on the debate platform) **over time**. For example, being more engaged with others over time may expose an individual to more diverse ideas and people, which in turn could foster argumentation skills that are more applicable to convincing a more diverse audience. Focusing on only individual debates and discussion threads, prior work has not investigated the relative effect of individuals' social interactions, personal traits and language use on their success in persuasion. To understand the relative effect of these factors on users' success in persuasion, we focus on online debates and study success over a user's lifetime by looking at interactions and engagement with the community over time, rather than focusing on success in individual debates.

Our study employs the DDO (debate.org) dataset [10]. Its extensive user information and multiple well-structured debates/interactions per user provides a unique opportunity to study users' success over time while accounting for the effect of individuals' social interactions, personal traits and language use. Users provide demographic information as well as their stance on controversial topics. They interact with one another in many ways: 1) debating 2) evaluating the performance of other debaters, 3) commenting on debates, 4) asking/answering opinion questions, 5) voting in polls, 6) creating polls 7) becoming friends. Ultimately, we find that the characteristics of individuals' social interactions (e.g. their friendships and voter network) are an important component in predicting their success in debates. The best predictive performance is achieved by combining social interaction features with language use features (e.g. vocabulary diversity and the extent to which their language use matches that of their opponent). **Contributions.** To the best of our knowledge, this is the first work to study computationally 1) the factors of an individual's overall success in online debating **over time** 2) by considering the combined effect of **social interactions**, personal traits and language use on success[1].

2 Dataset

Available User Information. The DDO (debate.org) dataset contains personal trait information for 45, 348 users including demographics such as gender and ethnicity as well as users' beliefs, such as their political ideology, religious ideology and stance on

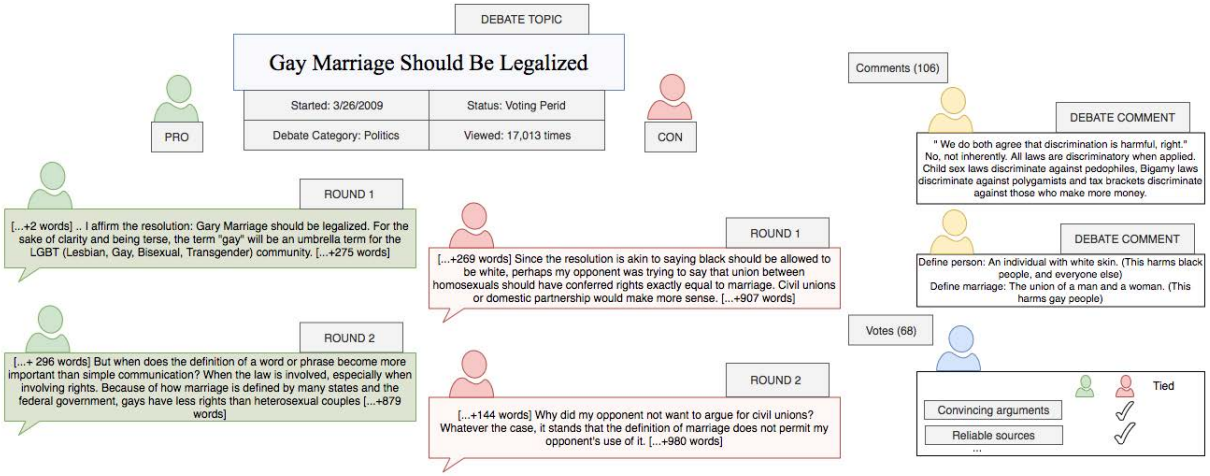

Figure 1: Example debate for the claim "*Gay Marriage Should Be Legalized*". In each round, opposing sides (PRO and CON) present their argument. Users on the platform give feedback and evaluate each debater's performance by providing comments and votes.

controversial issues. For this work, we augment DDO with social interaction data associated with each user: the debates that they participated in, voted on, and commented on; opinion questions asked, opinion arguments, poll votes and poll topics of the users[2]. Users can interact with others in more ways than simply participating in debates on DDO. For example, they can post poll and opinion questions/arguments. This allows users to exchange opinions, and to be exposed to new perspectives without engaging in a formal, structured argument. Opinion questions and arguments are more open-ended whereas polls require users to pick from a set of predefined options. An example opinion question and opinion argument are provided below:

Example Opinion Question. "Does God exist?"[3]

Example Opinion Argument. "He probably does not exist. I don't think that it's possible to say yes or no either way. We can only conclude that there is more logical evidence to say that a God probably does not exist, ..."

Debate structure. Each debate consists of multiple rounds, in which each of the two opposing debaters provides their argument. Debaters have a single opportunity to present their argument in any given round. The majority of debates have three or more rounds. There are 23 distinct debate categories. The most common debate categories are *Politics*, *Religion*, and *Society*. Figure 1 shows an example debate on GAY MARRIAGE as well as some of the comments and votes provided for this debate by other users. We see from the example that unlike monological argumentation, the debaters' arguments are shaped not only by their own opinions, but also by the way their opponents' express their opinions: debaters tend to refer to points made by their opponents throughout the debate. Voters evaluate debaters according to the quality and persuasiveness of their arguments and also provide an overall score for each debater. The winner of the debate is determined according to the total score from the voters.

3 METHODOLOGY

In this section we describe the methods used to investigate the underlying dynamics of success in online debate.

3.1 User Success

We compute the overall *success* in debate for user u as:

$$success_u = \frac{\#\text{ of debates } u \text{ won}}{\#\text{ of total debates } u \text{ participated in as a debater}}$$

We treat users with $success_u \geq 70\%$ as *successful*, $success_u \leq 30\%$ as *unsuccessful* and $30\% < success_u < 70\%$ as *mediocre*.

3.2 Prediction Task

To understand the relative effect of users' personal traits, social interactions and language on their *success*, we study the following prediction task: **given a pair of debaters where one of them is *successful* and other is *unsuccessful* over the second and third stage of their lifetime, predict the *successful* one**. Note that while determining our label for success, we consider only the debates in the second and third stage of the a user's lifetime, to be able to study the relative effect of *success* in their first life stage (*success prior*) vs. other factors in a controlled way. We experiment with two settings where we control for the effect of *debate experience* and *success prior* respectively.

SETTING 1. To **control the effect of debate experience** in *success*, we create the pairs by **matching the users according to the number of debates** that they participated in (i.e. users within a pair have the same number of debates[4].

[2]The dataset includes 77,655 debates, 592,390 comments, 197,231 debate votes, 262,222 poll votes, 20,300 poll topics, 10,045 opinion questions, and 61,183 opinion arguments.
[3]Full discussion on the topic can be found at https://www.debate.org/opinions/does-god-exist.
[4]There are 2154 such pairs in our dataset.

Aspect	Features
Personal traits	1) **match of the personal traits (e.g. gender, political ideology, religious ideology and ethnicity) with friends and voters**. 2) **opinion similarity with friends and voters**.
Social Interactions	1) **participation features** : # of comments, # of votes, # of friends, # of opinion questions and arguments, # of voted debates, # of poll votes and topics. 2) **friendship network features** : degree, degree centrality, page rank scores. 3) **voter network features**: in-degree, out-degree, in-degree centrality, out-degree centrality, page rank, hub and authority scores.
Language	1) **features of debaters' own language** : # of words, # of definite articles, # of indefinite articles, # of person pronouns, # of positive words, # of negative words, # of hedges, # of swear words, # of punctuation, # of links, average sentiment, type-token ratio, # of quotes, distribution of POS tags, distribution of named entities, BOW. 2) **features to encode the interplay** : exact content word match, exact stop word match, content word match with synonyms.

Table 1: Features

SETTING 2. Given that we're interested in understanding the factors that correlate with *success*, we **control for the *success prior*** in a very specific way – we only consider users that were *unsuccessful* in their initial life stage (**success prior**$\leq 30\%$[5]). This allows us to directly study the factors that are correlated with users that were initially *unsuccessful*, but later went on to become *successful* debaters.

3.2.1 Personal Traits It has been shown that characteristics of the audience's personality [22], and the degree to which the debaters' beliefs match with that of the audience [10], are important to consider in persuasion studies. We further investigate this effect in debaters' *success* over their lifetime. We also extend this study by considering additional personal traits, such as the degree to which debaters' demographics (e.g. gender and ethnicity) matches with those of their friends and the voters participating in the debates. We extract features to encode the similarity for a user's opinion, political ideology, religious ideology, gender, and ethnicity with that of her friends and voters. To compute opinion similarity, we used the information about users' opinions on 48 different controversial topics which they share on their user profiles and we measure the match of the opinions for these controversial topics[6].

3.2.2 Social Interactions The users interact with each other on the platform in following ways: 1) debating 2) evaluating the performance of other debaters, 3) commenting on debates, 4) asking/answering opinion questions, 5) voting in polls, 6) creating polls, 7) becoming friends.

We hypothesize that modeling these interactions is important to understand the differences between how *successful* and *unsuccessful* users interact on this platform, and whether or not these are important factors for success. The ability to interact with others in a myriad of different ways, provides users with ample opportunity to learn interesting new strategies and improve their skills over time, as they are exposed to a diverse set of perspectives.

[5]There are 957 such pairs in our dataset.

[6]We consider issues where users identified their side as either PRO or CON and measure the similarity of their opinion for these issues with their friends and voters.

Friendship network. We represent the friendship network as an **undirected** graph $G = (V, E)$ where V represents the set of users, and E represents the set of edges where $(x, y) \in E$ if $x \in V$ and $y \in V$ are friends.

Voter network. We represent the voter network as a weighted **directed** graph $G = (V, E)$ where V represents the set of users, and E represents the set of edges where $(x, y) \in E$ if $x \in V$ voted in a debate in which $y \in V$ participated as a debater. The weight of the graph represents how many times x voted in debates y was a debater. Note having (x, y) edge in the graph **does not** imply that x voted for y in a debate.

Using HITS algorithm [19], we compute hub and authority scores for each node (user) in the voter network graph. We find that *successful* users have, on average, a significantly higher hub score than *unsuccessful* users ($p < 0.001$).

3.2.3 Language To capture the linguistic style of the debaters' language and its relationship to their *success*, we use textual features that encode 1) users' own language and 2) the interplay between users' and their opponents' language.

Modeling users' own language. We extract features from the text of users' debates, opinion questions, opinion arguments, poll votes and poll topics. These features includes # of words, word category features (e.g. # of personal pronouns, # of positive and negative words), structural features (e.g. distribution of POS tags and named entities) and features to encode the characteristics of the entire language (e.g. type-token ratio)

Modeling the interplay between the debaters' and opponents'. We measure the interplay between debaters and their opponents by measuring how similar a debater's language is to the previous statement made by her opponent. To measure the similarity of a debater's language (D) to that of the opponent's (O) in a round, we look at # of content words that are in both D and O, # of stop words that are in both D and O and # of content words that are in D and have synonyms in O.

The *content word match with synonyms* feature aims to capture the cases where the opponent refers to similar concepts but doesn't necessarily use the exact same words as the debater.

		SETTING 1			SETTING 2		
	Feature	Precision(%)	Recall(%)	F1(%)	Precision(%)	Recall(%)	F1(%)
	(1) Majority	$26.47_{\pm 1.11}$	$51.44_{\pm 1.08}$	$34.95_{\pm 1.22}$	$26.67_{\pm 1.61}$	$51.62_{\pm 1.56}$	$35.16_{\pm 1.76}$

Table 2: Prediction Task Results for SETTING 1 and SETTING 2. For both SETTING 1 and SETTING 2, voter network features are the most predictive social interaction features. Combining interaction and language features achieves the best predictive performance.

The full list of features modeling the aspects of personal traits, social interactions and language features is shown in Table 1.

3.3 Prediction Results

We use weighted logistic regression and choose the amount and type of regularization ($\ell 1$ or $\ell 2$) by grid search over 5 cross-validation folds. We compute **weighted** precision, recall and F1 scores.

In SETTING 1, we create user pairs (u_1,u_2) where:

- u_1 and u_2 have an equal number of debates they participated in as debaters.
- One of u_1 or u_2 is *successful* and the other one is *unsuccessful* over the second and third stage of their lifetime [7].

In SETTING 2, in addition to the requirements of SETTING 1, we also require u_1 and u_2 to both have *success prior* ≤ 0.3.

Task. For both SETTING 1 and SETTING 2, we aim to predict whether u_1 or u_2 is *successful* over the second and third stage of her lifetime.

In SETTING 2, by only studying user pairs with low *success priors*, we aim to understand the factors that are important for a user to improve as a debater over time.

3.3.1 Results for SETTING 1 Table 2 shows the results for SETTING 1 and SETTING 2. We compare our model with three simple baselines – majority, debating experience, and success prior. For the majority baseline, for each example, we predict the most common label in the training data. For debating experience baseline, we use # of debates as the only feature to predict the *successful* debater. For success prior baseline, we pick the user with the higher *success prior* as successful.

In SETTING 1, since we do not control for the *success* in the first life stage, we see that the *success prior* information alone can achieve 63.63% F1 score. This implies that there is a correlation between users' *success* in their early life stage and later life stages. This factor may be related to users' prior debating skills. We observe that the features that encode debaters' overall similarity with voters and friends achieves significantly better F1 score than majority and debating experience baselines. However, these features do not have as high a predictive power as the *success prior*. We perform an ablation study for participation features, friendship network features and voter network features. We find that voter network features are significantly more predictive than the baselines, personal trait features and other social interaction features. We also perform an ablation study for the language features and find that # of words is a very predictive feature of *success*. When we combine the language features with the interaction features, we get the best predictive performance (81.61% F1 score) for this task which is significantly better than the baselines. This indicates that it is important to account for both social interaction and language factors to determine the *successful* debater since these two components encode different kinds of information about the users.

3.3.2 Results for SETTING 2 In this task, by controlling for *prior success*, we aim to understand the factors that are correlated with *success* by reducing the effect of prior debating skills of the users. As shown in Table 2, the F1 score for the *success prior* baseline is not as quite as high as in SETTING 1, since we control for this aspect by ensuring both users in the pair are *unsuccessful* in their initial life stage. However, this does not necessarily mean that the two paired users will have the exact same success prior, which explains why success prior still performs better than the other baselines. We do not observe any significant difference between the performance of the features encoding personal traits, participation, and the baseline. However, consistent with the SETTING 1, we see that features of the voter network are significantly better (69.65%) in predicting *success*. Although language features achieve significantly better F1 score than the baseline, they perform significantly worse than

[7] We consider success only over the second and third stage of users' lifetime in our prediction task, in order to study the effect of *success prior* vs. the other aspects. We use the success in the first life stage as *success prior*.

the voter network features. Similar to SETTING 1, combining these language features with the social interaction features improves the performance significantly (78.05% F1 score).

3.3.3 Feature Analysis To understand the important social interaction and language features, we 1) compute the correlation coefficients for the feature values and the labels, 2) analyze the coefficients of the logistic regression classifier and 3) apply recursive feature elimination method [15] to rank the features according to their importance. In this section, we present the features that are consistently important with respect to each of these methods.

Analysis of Social Interaction Features. We find that the **most important** social interaction features for SETTING 1 are authority score, hub score, in and out-degree centrality and the page rank of the voter network. Note that all these important features are **positively correlated** with *success*. Although participation and friendship network features (e.g. # of voted debates, degree of the user node in friendship network) are also positively correlated with *success*, the correlation values for these are not as high as the ones of the voter network features. We also find high correlation between some of the user activities. For example, users with more # of comments are more active in making friends, voting, providing poll votes and they have higher centrality value in the friendship network. Perhaps surprisingly, we do not observe any correlation between # of voted debates and hub/authority scores in voter network. However, we see a highly positive correlation between hub scores, authority scores, in-degree centrality, out-degree centrality and page rank values of voter network. This implies that *success* is not only about the quantity of voted debates but also about the characteristics of the debaters that are involved in these debates, because the hub score of a user is influenced by the authority scores of the debaters they vote for. Similarly, the authority score of a user is influenced by the hub scores of the voters that participate in her debates. Therefore, besides the frequency of interactions, type of interactions and characteristics of users involved in the interactions are important to take into account. Consistent with SETTING 1, in SETTING 2, the most important features (positively correlated with *success*) are authority score, hub score, in and out-degree centrality and the page rank of the voter network. We observe the same patterns of user activities and authority and hub scores as in SETTING 1.

Analysis of Language Features. We find that # of words is positively correlated with *success*. It may be the case that longer text may convey more information and explain the points more explicitly [29, 30]. Bag of words features are not as predictive as the # of words feature. For both SETTING 1 and SETTING 2, we observe that the value of average sentiment is negatively correlated with *success*. The reason for this may be that negative information is more attention grabbing than positive information [9, 18, 34] since people are more used to seeing arguments that are phrased in a more positive way [25]. We also find that *type-token ratio* (diversity of language) is negatively correlated with *success* for both settings. It may be the case that people who talk about a smaller set of topics gain expertise on these topics over time; therefore, they may be more *successful*. We observe that other textual features are positively correlated with *success* for both of these settings. However, the degree of correlation is not as high as it is for type-token ratio and sentiment.

4 UNDERSTANDING THE LOSS OF *SUCCESS*

In the previous section, we show that social interaction and language features are important to predict *successful* debaters. Our findings are consistent for the case when 1) we only control for users' debating experience and 2) we also control for users' *success prior*. Users' participation, the types of interactions they have on the platform, and the characteristics of the users they interact with are predictive of their *success*, regardless of a their prior expertise in debating (encoded by the *success prior*).

In SETTING 1, since we did not control for the *success prior*, we studied the factors that are important for a user to become *successful* in their second and third life stages, regardless of their *success* in the beginning. In SETTING 2, we studied the factors that are important for an *unsuccessful* users to improve their performance and become *successful* over time. As a natural follow-up, we would also like to understand what factors are correlated with users who are initially *successful*, but later become *unsuccessful* in their lifetime. To do that, in SETTING 3, in addition to the requirements of SETTING 1, we have an additional criterion for all user pairs (u_1,u_2):

- u_1 and u_2 both have *success prior* ≥ 0.7 [8].

4.1 Results

As shown in Table 3, features of personality traits, social interactions and language perform significantly better than the baselines. For this task, *success prior* baseline performs relatively worse than in the previous two settings. Upon closer examination, we observed that the variance of success priors for this task is an order of magnitude smaller than in SETTING 2, and therefore, as a possible explanation, the *success priors* may not be as predictive for this task.

In social interaction features, similarity with friends is the most predictive feature. However, participation features perform significantly better than the features of personal traits. For this task, contrary to SETTING 1 and SETTING 2, we see that participation features are the most predictive in the set of social interaction features. This implies users' participation is important for them to remain *successful*. Lower participation could be a contributing factor for these users to eventually become unsuccessful. Although friendship and voter network features are still significantly more predictive than the baselines, they are not as highly predictive as the participation features. For users with high *success priors*, continued participation may be the most important aspect of their social interaction. We observe that language features alone achieves a similar performance as the social interaction features. Consistent with the SETTING 1 and SETTING 2, combining social interaction and language features gives the best predictive performance (73.43% F1 score).

Analysis of Social Interaction Features. The **most important** social interaction features include # of voted debates, degree of the user node in the friendship network, in-degree, out-degree, in-degree centrality and out of the user node in the voter network. All these features are indicative of a higher participation on the platform and they are positively correlated with staying *successful*.

[8] We have 700 user pairs with these criteria.

	Feature	Precision(%)	Recall(%)	F1(%)
	(1) Majority	$26.97_{\pm 2.69}$	$51.86_{\pm 2.62}$	$35.46_{\pm 2.95}$
	(2) Debating experience	$53.77_{\pm 2.95}$	$52.43_{\pm 2.91}$	$43.02_{\pm 6.19}$
	(3) Success prior	$39.94_{\pm 7.63}$	$51.00_{\pm 2.23}$	$36.04_{\pm 2.35}$
Personal Traits	(4) Overall similarity with voters	$55.17_{\pm 1.58}$	$55.00_{\pm 2.36}$	$53.94_{\pm 2.99}$
	(5) Overall similarity with friends	$66.38_{\pm 4.11}$	$63.43_{\pm 2.77}$	$60.87_{\pm 3.33}$
Social Interactions	(6) Participation features	$68.88_{\pm 3.57}$	$68.00_{\pm 2.86}$	$67.88_{\pm 2.96}$
	(7) Friendship network features	$65.60_{\pm 4.83}$	$64.00_{\pm 3.81}$	$62.81_{\pm 3.73}$
	(8) voter network features	$64.36_{\pm 1.57}$	$62.72_{\pm 2.37}$	$61.44_{\pm 2.87}$
	(6) + (7) + (8)	$67.80_{\pm 1.86}$	$67.14_{\pm 1.43}$	$66.97_{\pm 1.42}$
Language	(9) # of words	$67.63_{\pm 3.90}$	$66.57_{\pm 2.70}$	$66.29_{\pm 2.39}$
	(10) Features of debaters' interplay	$58.76_{\pm 2.03}$	$57.43_{\pm 0.86}$	$56.60_{\pm 0.93}$
	(11) Features of debaters' own language	$68.47_{\pm 0.21}$	$68.14_{\pm 0.14}$	$68.10_{\pm 0.17}$
Combinations	(6) + (7) + (8) + (11)	$69.32_{\pm 2.48}$	$69.00_{\pm 2.42}$	$69.00_{\pm 2.41}$
	(6) + (7) + (8) + (10) + (11)	$\mathbf{73.60_{\pm 0.80}}$	$\mathbf{73.43_{\pm 0.70}}$	$\mathbf{73.43_{\pm 0.72}}$

Table 3: Prediction Task Results for loss of *success*. Participation features are the most important social interaction features. Combining the social interaction features with the language features gives the best prediction performance.

Although the other social interaction features, such as authority and hub scores of the voter network are also positively correlated with *success*, the value of correlation for these is not as high as the previously mentioned features. For users who are initially *unsuccessful*, participation alone may not be enough for them to become *successful* debaters – the type of interactions and the characteristics of people with whom they interact are crucially important for their *success*. On the other hand, users who are initially *successful* may already be experienced debaters, and staying active and participating may be sufficient for them to remain *successful*.

Analysis of Language Features. As in SETTING 1 and SETTING 2, # of words is positively correlated with staying *successful*. We find that the # of first person pronouns is the language feature with the highest positive correlation with staying *successful*. We observe that users who refer to their personal experiences and opinions use first person pronouns more often. It may be the case that debaters may try to appeal to logos by citing personal experience [8]. Consistent with SETTING 1 and SETTING 2, the value of average sentiment is negatively correlated with staying *successful*.

5 Related Work

5.1 Modeling Social Interactions

There has been a tremendous amount of research on understanding user interactions and behaviour on social media [2, 4, 5, 14, 20, 21, 23, 24, 27, 42]. For example, [42] analyze the interaction graphs of Facebook user traces and show that interaction activity on Facebook is significantly skewed towards a small portion of each user's social links. [21] investigates how people interact in multiple online social networks. Although there is a lot of work on understanding user behavior on social media sites such Facebook and Twitter, the work on understanding user behaviour on online debate platforms has been limited. [35] is the most similar to our work, in that the authors study the effect of interaction dynamics, such as participant entry order and degree of back-and-forth exchange in the discussion, on success in changing an opinion holder's stance in a thread. Note that unlike our study, this work does not consider the effect of social interaction features (such as friendship network or voter network) on users' *success*. Moreover, in our work, we study the overall *success* of users over their lifetime, rather than a single debate or discussion thread.

5.2 Language in Persuasion

Previous work in psychology and linguistics has studied the effect of language on people's perception of the arguments and persuasion [3, 12, 25, 39]. These studies explore the effects of *framing*, – whether presenting different formulations of the same problem (e.g. presenting something as a gain or loss) would result in different effects on people. Besides the effects of framing, researchers investigate the effects of structural and lexical characteristics of language on success. For example, [36] found that using concrete words yields more positive outcomes than using abstract words, in terms of convincing customers to have a positive attitude towards a product.

NLP (Natural Language Processing) studies in argumentation mining focus on 1) identifying the structure of the persuasive aspects of text and relationships between them [1, 26, 28, 31, 32, 38, 40] and 2) the characteristics of persuasive text [6, 13, 16, 17, 33, 37, 41, 43]. There is very limited work in NLP that considers the factors of the individuals who are involved in the argumentation [11, 22]. [22] analyzes the effect of people's personality traits on their perceptions of the monologic arguments. However, in their work, they do not have any information about the source of the arguments. Moreover, in their setting, there is no notion of social interactions. [10] considers the effect of prior beliefs of the audience members and debaters on success in an individual debate. However, unlike this study, it does not consider the effect of social interactions on a user's success in online debate over time.

ABSTRACT

This paper introduces HopRank, an algorithm for modeling human navigation on semantic networks. HopRank leverages the assumption that users know or can see the whole structure of the network. Therefore, besides following links, they also follow nodes at *certain distances* (i.e., k-hop neighborhoods), and not at random as suggested by PageRank, which assumes only links are known or visible. We observe such preference towards k-hop neighborhoods on BioPortal, one of the leading repositories of biomedical ontologies on the Web. In general, users navigate within the vicinity of a concept. But they also "jump" to distant concepts less frequently. We fit our model on 11 ontologies using the transition matrix of clickstreams, and show that semantic structure can influence teleportation in PageRank. This suggests that users—to some extent—utilize knowledge about the underlying structure of ontologies, and leverage it to reach certain pieces of information. Our results help the development and improvement of user interfaces for ontology exploration.

1 INTRODUCTION

Ontology Engineering and Ontology Learning are two branches of the Semantic Web whose aim is to accurately build and curate ontologies. The former studies new techniques to improve collaboration among humans while editing ontologies [26, 29], and the latter introduces new methodologies and algorithms to automatically create ontologies by crawling the Web [5, 25]. These efforts represent significant advances in the development of knowledge bases, which represent facts about the real world (e.g., people, diseases). However, there is little knowledge about how users consume such ontologies on the Web. To this end, Walk et al. studied how users browse BioPortal [28]. Their findings suggest that some ontologies influence the way users interact with the website. However, how users navigate through the ontology structure (i.e., from one concept to another) remains unclear.

Problem Statement: In this paper, we study the influence of semantic structure on *teleportation* (i.e., jumping to any node chosen at random) in PageRank. For example, consider the ontology shown in Figure 1(a), where nodes represent *classes* (a.k.a. concepts) and edges *isASubClassOf* relationships. On BioPortal, ontologies are shown vertically as hierarchical trees, and concepts can be explored using the *expand-on-demand* principle. This means that only top level concepts are shown first, and then users are able to expand and collapse as many concepts as they need at any level of the ontology. In other words, users can use and therefore are potentially aware of a *virtually fully connected network* in all stages of navigation. Previous studies [21, 31] have modeled user navigation using PageRank. However, these assume that navigation paths are constrained by links and random teleportation. In our scenario, where the whole structure of an ontology can be visualized at any time, we believe that teleportation is not fully random, but rather biased towards k-hop neighborhoods.

Approach: Motivated by previous studies on information foraging [8–10, 22], decentralized search [16, 18], and PageRank [4, 14, 15, 21, 31], we propose HopRank, a method for modeling transitions across k-hop neighborhoods on semantic networks. The key idea of this work relies on the HopPortation vector $\vec{\beta}$, which defines the probabilities of transitioning to each k-hop neighborhood. From the PageRank point of view, we can say that teleportation is not fully random, and the probability of following the structure of a page is not based only on one parameter (i.e., probability of following links), but on k parameters, representing all k-hop neighborhoods *reached from the current page*. Technically, we pass the HopPortation vector to a random walker to make biased decisions on which neighborhood to go next. Once this decision is made, the random walker uniformly chooses a concept within that neighborhood.

(c) Transition Probabilities

Figure 1: HopRank on semantic networks. This example illustrates an instance of navigation on an ontology. (a) Shows the underlying network composed by seven concepts (a-g) and six *isASubClassOf* relationships (straight-thin grey arrows). Transitions (curved-thick black arrows) are labeled by the actual number of transitions between concepts, as well as the [k-hop] distance (i.e., shortest path) between them. (b) Illustrates how the HopPortation vector $\vec{\beta}$ is built using transition counts per k-hop. (c) Shows the transition probabilities inferred by HopRank, see Equation (1).

Contributions: The contributions of this paper are:

(1) We empirically show how users leverage the structure of the ontologies on BioPortal by quantifying the proportion of transitions per k-hop neighborhood.
(2) We propose HopRank, an algorithm for modeling human navigation on semantic networks.
(3) We demonstrate that HopRank outperforms traditional navigation and popularity-based models on BioPortal, especially when users browse ontologies directly without search.
(4) We make an implementation of this approach openly available on the Web [11].

2 RELATED WORK

BioPortal provides users with a *tree-like explorer* and a *local search* engine to navigate ontologies. In addition, concepts can be *expanded on demand* to see their children nodes. Although these functionalities are exploited differently across ontologies [28], it is unclear how users navigate through the ontology structure. Thus, this section covers previous work on search and navigation on networks.

Search. *Information Foraging* [22] assumes that people, when possible, modify their strategies or the structure of the environment to maximize their gain of valuable information. These patterns are also found in the way humans recall information from memory [17]. Similarly, *berrypicking* [6], a model of online searching, states that queries are not static, but rather evolve, and users commonly gather information in pieces instead of in one large set.

Navigation. *PageRank* [21] is the most popular method to measure the importance of web pages based on their incoming and outgoing links. It relies on an imaginary surfer who is randomly *clicking on links*, and eventually *jumps* to any node in the network. The probability of following links is given by a *damping factor*. Multiple variations have been proposed for improving information retrieval systems, e.g., a biased PageRank [15] to capture the importance of a page more accurately by taken topics into account or a weighted PageRank [31] to assign larger rank values to more popular pages (i.e., preferential attachment) instead of distributing the rank value of a page uniformly to all outgoing pages. Geigl et al. suggest that the behavior of a *random surfer* is almost similar to real users, as long as they do not use search engines [13]. They also find that classical navigation structures, such as navigation hierarchies or breadcrumbs, only exercise limited influence on navigation. Experiments in [24] reveal that memory-less *Markov chains* represent a quite practical model for human navigation on a page level. However, this assumption is violated when the analysis is expanded to a topical level. Helic et al. identify certain configurations of *decentralized search* that are capable of modeling human navigation in information networks [16]. Their findings suggest that navigation on such networks is a two phase process combined with the *exploitation of the known* (i.e., goal-seeking) and the *exploration of the unknown* (i.e., orientation).

User Interfaces. Human navigation has also been studied for enhancing interfaces. For instance, [12] explores *fisheye* views to display large information structures such as programs and databases. The intuition behind this paradigm is that users often explore their neighborhood, and distant major landmarks in more detail. Similarly, Van Ham and Perer studied the *search, show context, expand on demand* browsing model in [27], and proposed techniques to design better graph visualization tools.

We propose HopRank—a biased random walker—to model navigation on semantic networks. HopRank builds upon insights from information foraging [17, 22], decentralized search [16, 18] and PageRank [21]. More precisely, we replace the *damping factor* by a HopPortation vector to encode the probabilities of visiting each k-hop neighborhood. The intuition here is that users browse semantically close terms more often than semantically distant ones.

3 BIOPORTAL

There exist a large number of ontologies in the biomedical domain. They are highly specialized and therefore expensive to develop. To enable ontology adoption and reuse, effective support for browsing and exploring existing ontologies is required. Towards that goal, the National Center for Biomedical Ontology (NCBO) [3, 19] features BioPortal [1, 20, 30]—one of the leading repositories of biomedical ontologies on the Web—containing currently more than 700 ontologies with more than 9 million ontology classes. On BioPortal, practitioners and experts can access ontologies via Web services and Web browsers. The latter allows users to navigate ontologies

by searching specific classes, or by directly browsing their concept hierarchies within a tree-like explorer [28].

Ontologies. We propose to model human navigation on semantic networks using the structure of the underlying ontology. On BioPortal, ontologies are defined as directed networks, where nodes represent *concepts* and edges *isASubClassOf* relationships. Since such edges are usually non-cyclic and have a common root, these ontologies often form trees. Table 1 shows 11 of the most visited ontologies in 2015[1]. For instance, LOINC the largest ontology with $175K$ nodes, $153K$ edges, and $74K$ connected components.

Transitions. We analyzed all HTTP requests made in 2015 and extracted $336K$ valid sessions (i.e., after filtering out sessions with less than 2 requests, and requests to ontologies or concepts which do not exist). Each session contains transitions (i.e., a sequence of visited concept pages) triggered by a single user (i.e., IP address) without breaks (i.e., pauses of at least 60 minutes). For simplicity, we only consider transitions within the largest connected component (LCC) of each ontology, and discard ontologies with less than 1000 transitions[2]. Overall, we found 11 ontologies and $133K$ transitions between their concepts[3], see Table 1 for some key properties.

Navigation Types. Based on the HTTP request headers, we inferred 7 navigation types: Details (DE), Direct Click (DC), Direct URL (DU), Expand (EX), External Link (EL), External Search (ES), and Local Search (LS). **DE**: are all clicks made within the *Details* tab of a selected concept. **DC**: are all clicks made on concepts within the tree-like explorer. **DU**: refers to all concept requests without HTTP referrer (e.g., direct URL in the browser). **EX**: considers all clicks on the (+) symbol of a concept, which triggers the expansion of the concept to show all its children nodes. Notice that this request is called only once, even if the symbol is clicked multiple times. The opposite behavior (collapse) is not considered[4]. **EL**: captures all requests coming from external websites that are not search engines. **ES**: are all requests coming from the top 10 most popular external search engines such as Google and Yahoo. **LS**: are all requests made via the local search functionality of each ontology. Notice that this search is a 3-step process. First users type a keyword, then the system shows auto-suggestions and finally users click on one of the concepts shown in the auto-suggestion list. We only consider the final step a local search transition. **ALL**: includes all the above-mentioned types. Figure 2 shows the distribution of transitions across navigation types for each ontology. In general, most traffic comes from expanding a concept (EX, 44%), followed by local search (LS, 17%), direct URL (DU, 16%) and details (DE, 14%). Surprisingly, direct clicks on concepts (DC) only represent 7% of all transitions. This suggests that users spend substantial time expanding concepts before they find a concept of interest.

[1]As ontologies can be edited over time, we work with their latest snapshots from 2015.
[2]Transitions within the LCCs of these ontologies represent 80% of all transitions.
[3]We left out the popular SNOMEDCT ontology due to computational limitations.

Table 1: Datasets. This table illustrates network properties of 11 of the most popular ontologies on BioPortal in 2015. Ontologies represent networks whose nodes refer to *concepts* and edges *isASubClassOf* relationships. Original number of nodes, edges, and connected components of ontologies are shown under N, E and cc, respectively. Properties of the largest connected component (LCC) of each ontology are shown under N', E', d' and T', where d' refers to the diameter and T' to the number of transitions.

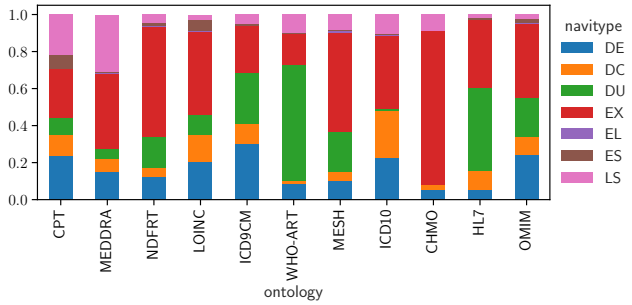

Figure 2: Navigation Types. Each bar shows the fraction of transitions within the LCC of each ontology. Stacked bars differentiate types of navigation: details (DE, blue), direct click (DC, orange), direct URL (DU, green), expand (EX, red), external link (EL, purple), external search (ES, brown) and local search (LS, pink). Most ontologies are mainly navigated by *expanding* nodes within the tree-like explorer.

4 HOPRANK: A BIASED RANDOM WALKER

HopRank models human navigation on semantic networks. Imagine a random walker whose decisions on where to go next are biased towards specific k-hop neighborhoods. This bias is what we call *HopPortation*, which encodes the probabilities of transitioning to each k-hop neighborhood. In our model, navigation on networks can be explained as a 2-step process. First, a k-hop neighborhood of the current node i is drawn from a categorical distribution. Second, a node j is randomly chosen within that k-hop neighborhood. Note that this process holds only if the walker is fully or partially aware of the structure of the network (i.e., knows or can see it). Without this prerequisite, and if links are not preferred, then random jumps to random pages will be more plausible. In comparison to the classic random walker with teleportation (e.g., PageRank [21]), where its movements are constrained by the damping factor α (i.e., probability of following links), HopRank is constrained by a vector $\vec{\beta}$ containing

[4]Collapse is a client-side functionality, and thus, it is not recorded in the log files.

k different factors, which define the probabilities of going to each k-hop neighborhood from the current location.

Visited k-hop Neighborhoods on BioPortal. We aggregate ALL transitions by the shortest distance between two sequentially visited nodes. This distance is referred to as k-hop neighborhood. In Figure 3(a) we see that target nodes at large distances are less likely to be visited next. This is expected, since—to some extent—larger distances enclose more branches, therefore more target candidates. Note that ontologies are sorted by diameter in descendant order from MESH to WHO-ART. Interestingly, users tend to hop as far as the ontology's diameter, for $d' \leq 12$. For instance, OMIM's diameter is 6 (see Table 1), and 6 is the maximum hop done by users. Otherwise, users (roughly) hop up to two-thirds of the ontology's diameter, for $d' > 12$. For example, MESH's diameter is 31, and the largest hop reached is 19.

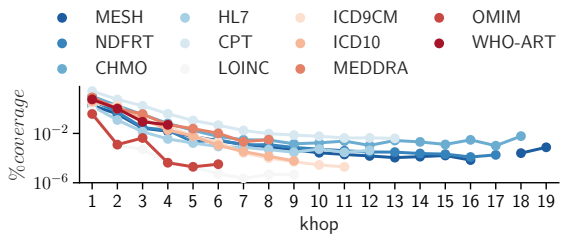
Transitions per k-hop Neighborhood on BioPortal. Figure 3(b) shows the average percentage of transitions across k-hop neighborhoods per navigation type. We see that users on average (ALL, grey) prefer to navigate through 2-hop (41%) and 1-hop (23%) neighbors. In particular, when navigation is triggered by direct clicks (DC, orange) and expand (EX, red). Notice their fast decay when $khop > 8$. Other types of navigation such as external link (EL, purple), and direct URL (DU, green)—which do not leverage the tree-like explorer—tend to reach concepts at larger distances more frequently. Notice their peaks at $khop = \{5, 11\}$, respectively. Interestingly, when users opt for external search (ES, brown), they often click on 2-hop concepts, but also on 12-hop and 15-hop neighbors. Intuitively, the details tab (DE, blue) helps users to click on nearby concepts at $khop \leq 2$, more often than local search (LS, pink), which is more likely to reach concepts at $khop \geq 2$.

5 MODELS OF HUMAN TRANSITIONS

In this section, we formally introduce our HopRank model, and recap popular navigation models for comparison. We denote the transition probabilities, and # of parameters according to HopRank and 7 other models that we will use later on for model selection.

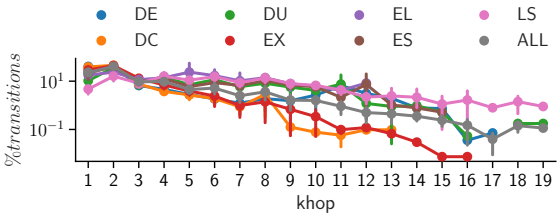
We formally represent an ontology[5] as a graph $G = (V, E)$, with $V = (v_1, \ldots v_n)$ being a set of N nodes, and $E = \{(v_i, v_j)\} \in V \times V$ a set of undirected edges[6]. The ontology structure is captured by the adjacency matrix $A_{N\times N} = a_{ij}$, where a_{ij} is 1 if the link exists, 0 otherwise. Transitions are represented by the transition matrix $T_{N\times N} = t_{ij}$, where t_{ij} represents the number of transitions between source node i and target node j.

HopRank (HR). Given the HopPortation vector $\vec{\beta}$, the probability of reaching a k-hop neighborhood is denoted by factor $\beta_k \in \vec{\beta}$. The stochastic k-hop matrix M_k encodes all nodes j with a shortest distance k from i. HopRank uniformly distributes β_k across all nodes j at distance k. The limits of k-hop neighborhoods go from 1 (direct edges), to d', the diameter of the ontology G. Noise $\beta_0 = 1 - \sum_{k=1}^{d'} \beta_k$ is added to allow for random jumps and self-loops. Figure 1(b) illustrates how the HopPortation vector is computed from the transition counts. *Number of model parameters:* $d' + 1$.



$$P_{HR} = \beta_1 \boldsymbol{M}_1 + \beta_2 \boldsymbol{M}_2 + \cdots + \beta_k \boldsymbol{M}_k + \frac{\beta_0}{N} \tag{1}$$

Preferential Attachment (PA). Given the degree matrix $D_{N\times N} = d_{ij} = d_j$, where d_j represents the degree of the target node j. The probability of moving from i to j is proportional to the degree of j. *Number of model parameters:* 0.



$$P_{PA} = \boldsymbol{D} \tag{2}$$

Gravitational (Gr). Given the matrix $S_{N\times N} = (sp(i,j) + \epsilon)^2$, where $sp(i,j)$ denotes the shortest path between nodes i and j. The probability of navigating from i to j is proportional to the degree of node j and inversely proportional to the square distance between i and j. We add a smoothing factor ϵ to avoid overflows when dyads are disconnected. In such cases, we set ϵ to the diameter d' of G plus 1, to consider these jumps with a very low probability. Similarly, we set the diagonal (i.e., self-loops) to $\epsilon = d' + 2$. *Number of model parameters:* 0.

$$P_{Gr} = \frac{\boldsymbol{D}}{S} \tag{3}$$

(a) % of dyads traversed per ontology

(b) Mean % of transitions per navigation type

Figure 3: Popularity of k-hops. (a) Shows the percentage of dyads that are traversed per k-hop neighborhood. Lines represent ontologies and are sorted by their LCC diameter: In descendent order from MESH (dark blue) to WHO-ART (dark red). (b) Shows the distribution of transitions across k-hop neighborhoods per navigation type. Percentages are averages across ontologies, and error bars the respective standard deviation. While several k-hop distances are being traversed non-uniformly, most transitions happen across nearby nodes, especially when browsing (DE, DC, EX, ES) 2-hop neighbors. In contrast, non-browsing types (EL, LS, DU) tend to reach more distant nodes more frequently.

[5]We focus on its largest connected component (LCC)
[6]Directionality of edges is omitted to calculate shortest paths between all pair of nodes.

Random Walker (RW). Given the damping factor α (i.e., probability of following links), the probability of visiting a node j is proportional to α divided by the degree of the source node i, plus a random choice equally distributed among all nodes. Depending on the α value, a random walker can model four different behaviors: **(i)** $\alpha = 0.0$: random jumps only, **(ii)** $\alpha \approx 1.0$: navigation over links only, **(iii)** $\alpha = 0.85$: PageRank using the commonly used damping factor for navigating the Web [7], and **(iv)** the empirical PageRank which learns the parameter α from the transitions data. *Number of model parameters:* 1 *if empirical,* 0 *otherwise.*

$$P_{RW} = \alpha \boldsymbol{A} + \frac{(1-\alpha)}{N} \tag{4}$$

Markov Chain (MC). We assume that moving to the next node follows a Markov process. Therefore, the probability of moving to a node j only depends on the current node i. These probabilities represent the maximum likelihood, learned from the transition matrix T. Thus, the probability of visiting node j from node i is proportional to the number of transitions t_{ij}. *Number of model parameters:* $N \times (N-2)$.

$$P_{MC} = \boldsymbol{T} \tag{5}$$

Note that $\boldsymbol{M}$, $\boldsymbol{A}$, and all P_* from Equations (1) to (5) are right stochastic matrices (i.e., each row must sum to 1).

6 EXPERIMENTS

In this section, we compare the performance of HopRank to the baselines on synthetic and real-world networks.

6.1 Model Selection

For comparing the models, we employ the Bayesian Information Criterion (BIC) [23] to select the best, i.e., lowest BIC score. BIC evaluates *log-likelihoods LL* (i.e., how likely our transitions are for a given model) and takes into account the *number of model parameters* and *observations* (i.e., # of transitions) to avoid over-fitting.

$$BIC = -2 \cdot LL + nparams \cdot log(nobservations), \tag{6}$$

$$LL = \sum_{i=1}^{N} \sum_{j=1}^{N} t_{ij} \cdot log(p_{ij}), \tag{7}$$

where t_{ij} represents the actual number of transitions from node i to node j, and p_{ij} the probability of transitioning from node i to node j for a given model.

6.2 Synthetic Network

Setup. The underlying network (structure) is a binary tree composed by $N = 7$ nodes and $|E| = 6$ edges as shown in Figure 1(a). Transitions (curved-thick edges) are biased towards 2-hop and 4-hop neighborhoods. These biases are reflected in the HopPortation vector shown in Figure 1(b).

Results. Probabilities inferred using Equation (1) are depicted in Figure 1(c). Figure 4 (left) shows the number of parameters inferred by each model. While the Markov chain model (MC) requires 35 parameters, HopRank only needs 5. The empirical PageRank (RW E.) learned a damping factor of $\alpha = 0.01$. This means that users are 1% likely to follow links. In Figure 4 (right) we see the comparison of models using BIC scores. In this synthetic network, transitions

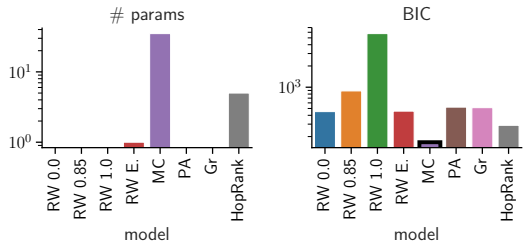


Figure 4: Results on Synthetic Network from Figure 1. X-axis maps the models at interest. (Left) Number of parameters inferred by each model. (Right) BIC scores: the lower the better at explaining the data. In this example, navigation is best described by Markov chain followed by HopRank.

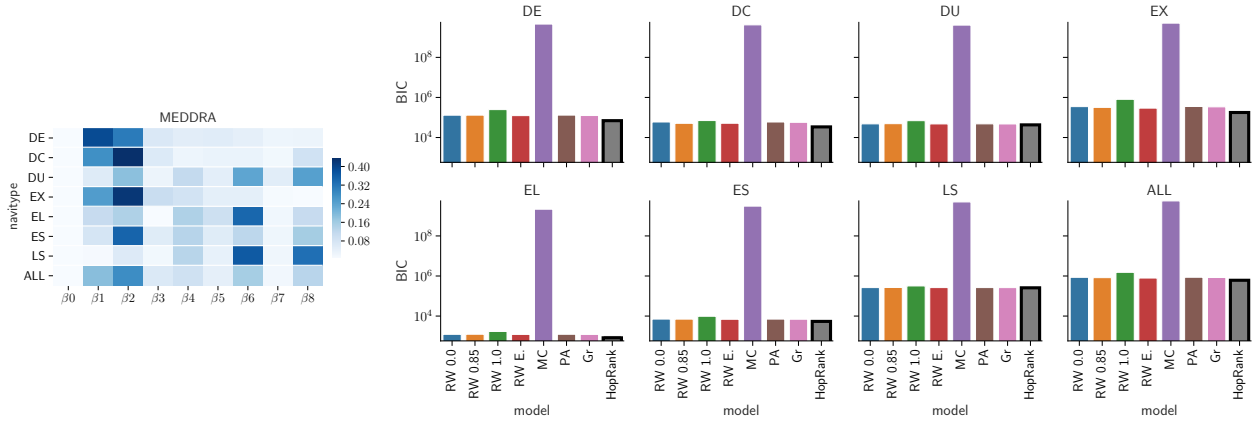
are best described by the Markov chain model because model parameters (i.e., maximum likelihood) are proportional to the actual transition counts per dyad, and the data structure is very small[7]. In spite of that, HopRank is the second best model and describes navigation better than random (RW 0.0).

6.3 Medical Dictionary for Regulatory Activities Terminology (MEDDRA)

Setup. MEDDRA[2] is one of the the largest ontologies in our dataset (see Table 1). After pre-processing, its largest connected component (LCC) consists of $23K$ nodes and $43K$ transitions.



Results. Figure 5(a) shows the HopPortation vectors learned for each type of navigation in MEDDRA. We see that users mainly navigate through 1, 2, 6, and 8-hop neighbors. For instance, transitions through direct clicks—on a concept (DC), its details (DE) or expand (EX)—mainly follow 1-hop and 2-hop neighbors. However, when transitions are triggered by direct URLs (DU), local search (LS) or external links (EL), users tend to reach distant target nodes (i.e., 6-hop and 8-hop neighbors). Figure 5(b) shows the ranking of models according to BIC scores (lower is better). We see that in MEDDRA all types of navigation are best explained by HopRank.

6.4 Top11 Ontologies in BioPortal

Setup. We fit HopRank and the baseline models to all transitions by ontology and navigation type. These represent $133K$ transitions coming from the 11 ontologies described in Table 1.

Results. In Figure 6 we highlight the model that explains the number of transitions per ontology and navigation type best (i.e., the model with lowest BIC score). Ontologies are sorted by their number of transitions from CPT (largest) to OMIM (smallest). HopRank outperforms the other models 89% of the time, especially when users browse directly—regardless of the ontology—the tree-like explorer via clicks (DC), details (DE) and expand (EX). When there are not enough observations (i.e., the number of transitions is small), the other models tend to outperform HopRank due to the fact that the other models require fewer parameters and/or it is less likely to find transitions across different k-hop neighborhoods. This is the case for 6 ontologies in certain navigation types. For instance, we found

[7]Therefore, number of parameters does not play a very important role in BIC.

(a) HopPortation vectors

(b) Model selection

Figure 5: Results on MEDDRA. (a) This heatmap shows the HopPortation vectors learned from the transitions in MEDDRA. Cells represent the probabilities of visiting a certain k-hop neighborhood (column) by a given navigation type (row). In general, 2-hop and 1-hop neighborhoods are more likely to be visited next, regardless of navigation type (ALL). However, distant hops are preferred through *direct URLs* (DU), *external links* (EL), and *local search* (LS). (b) This figure shows the comparison of models across navigation types using BIC scores. We see that HopRank outperforms all baseline models.

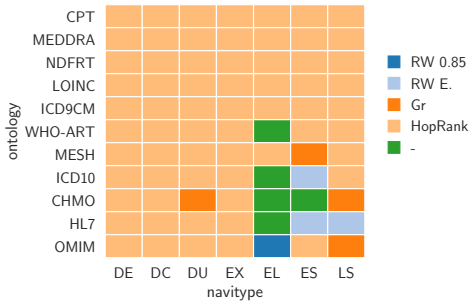


Figure 6: Model Selection on BioPortal. This heatmap highlights the model—with lowest BIC score—that best describes the # of transitions per ontology and navigation type. HopRank outperforms the other models 89% of the time, especially when browsing concepts via details (DE), direct click (DC) and expand (EX). When transitions are scarce (i.e., the other 11%), BIC penalizes HopRank since it has more parameters than the other models (except Markov chain).

5 external search (ES) transitions in MESH which are best described by the Gravitational model (Gr). Even though HopRank was a better candidate (i.e., higher log-likelihood), BIC penalized it for having more parameters ($nparams_{HopRank} = 32 > nparams_{Gr} = 0$). Notice that we model navigation in ontologies with at least 2 transitions. Ontologies that do not fulfil this condition per navigation type are marked as green cells "-".

7 DISCUSSION AND FUTURE WORK

In this section, we discuss decisions made for data processing, and future directions that can be pursued to improve our results.

Largest Connected Component (LCC). Surprisingly, ontologies on BioPortal may have multiple connected components. In those cases, only the branch connected to the root *owl:Thing* is shown at first in the tree-like explorer. Disconnected (and hidden) nodes or branches need to be accessed from external pages or local search. For simplicity, we opted to work with the LCC of each ontology with the cost of removing 20% of all transitions. Future work should consider the whole network to study the tradeoffs between number of transitions and random teleportation.

HopRank Extensions. More extensions based on network properties or similarity measures between nodes could improve our results. For instance, considering ontologies as directed graphs, and assuming that navigation is not only constrained by distance but also directionality: top-down or bottom-up.

Other Types of Networks. Even though this paper targets semantic networks, we believe that HopRank can be utilized to model human navigation in other networks, such as the Web or cities. The only assumption required is that users must have background knowledge of the underlying network they are surfing/traveling in.

8 CONCLUSIONS

In this paper, we introduced the concept of *HopPortation* which states that users—navigating a known or visible network—are biased towards certain k-hop neighborhoods. This is a variation of PageRank, where we assume that teleportation is not fully random but rather distributed non-uniformly across different neighborhoods. We proposed *HopRank*—a biased random walker—to model navigation on semantic networks. Our findings on BioPortal suggest that semantic structure (i.e., shortest path) influences navigation on networks. In particular, users tend to be biased towards certain k-hop neighborhoods depending on the type of navigation. For instance, when manually browsing the tree-like explorer, users tend to hop to nearby concepts, whereas far-away concepts are more

likely to be reached by non-browsing types such as external links. These results advance our understanding of how ontologies are actually navigated and consumed, and help to develop and improve user interfaces for ontology exploration.

ABSTRACT

Helpful reviews are essential for e-commerce and review websites, as they can help customers make quick purchase decisions and merchants to increase profits. Due to a great number of online reviews with unknown helpfulness, it recently leads to promising research on building automatic mechanisms to assess review helpfulness. The mainstream methods generally extract various linguistic and embedding features solely from the text of a review as the evidence for helpfulness prediction. We, however, consider that the helpfulness of a review should be fully aware of the metadata (such as the title, the brand, the category, and the description) of its target product, besides the textual content of the review itself. Hence, in this paper we propose an end-to-end deep neural architecture directly fed by both the metadata of a product and the raw text of its reviews to acquire product-aware review representations for helpfulness prediction. The learned representations do not require tedious labor on feature engineering and are expected to be more informative as the *target-aware* evidence to assess the helpfulness of online reviews. We also construct two large-scale datasets which are a portion of the real-world web data in Amazon and Yelp, respectively, to train and test our approach. Experiments are conducted on two different tasks: helpfulness identification and regression of online reviews, and results demonstrate that our approach can achieve state-of-the-art performance with substantial improvements.

1 INTRODUCTION

The e-commerce and review websites dramatically facilitate our daily lives as they provide a massive number of products and businesses available online and allow us to access to the comments made by experienced consumers. In order to find a desirable product, we prefer to browsing the online reviews of a product in addition to its descriptions, as we believe that the online reviews can provide more subjective and informative opinions from various perspectives on the product besides the objective descriptions given by its merchant. With the explosive growth of the transaction volume of the e-commerce market in recent years, it is common for an online product commented and rated by thousands of purchasers as illustrated by Figure 1. As a result, it is quite time-consuming for potential consumers to sift through all the online reviews with uneven qualities to make purchase decisions.

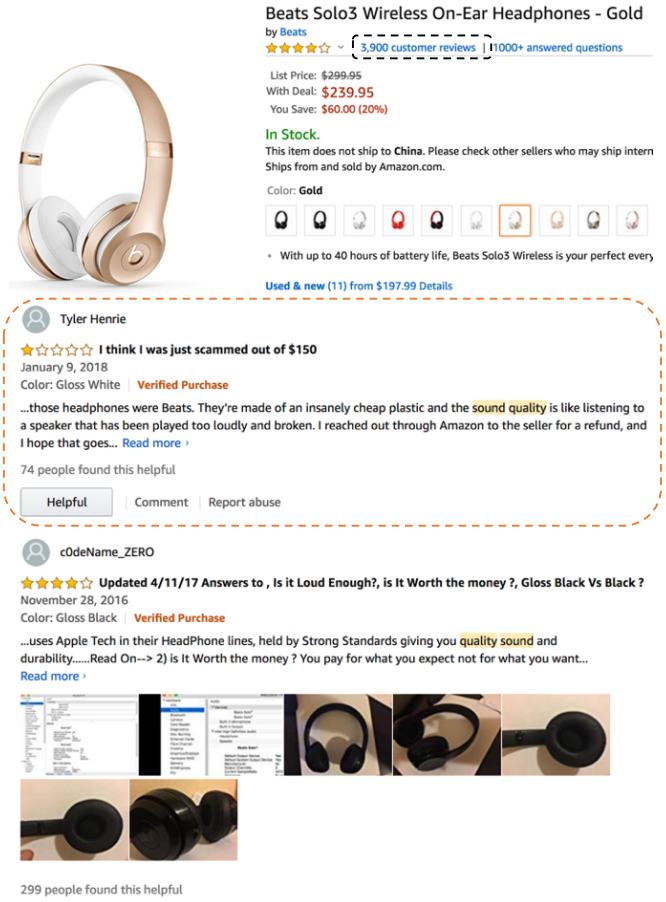

Figure 1: A screenshot of an online product sold on Amazon.com: *Beats Solo3 Wireless On-Ear Headphones - Gold* which receives 3,900 customer reviews. However, we have no ideas on the helpfulness of most reviews.

Therefore, helpful reviews are essential for e-commerce services, as they are able to bridge the gap between customers and merchants in a *win-win* manner, where customers tend to make quick purchase decisions once catching sight of helpful reviews and merchants can increase profits by surfacing the helpful reviews. To discover the helpful reviews, some platforms such as Amazon and Yelp have launched a module (see the "Helpful" buttons beneath each customer review shown by Figure 1) which allows users to

give feedbacks on the helpfulness of online reviews. This featured module proved by a recent study[1] increases the revenue of Amazon with an estimated 27 billion U.S. dollars annually. Although the crowd-sourcing module could help find a fraction of helpful reviews, roughly 60% online reviews in Amazon.com and Yelp.com did NOT receiving any vote of helpfulness or unhelpfulness. This phenomenon on unknown helpfulness is even more common in low-traffic items including those less popular and new arrival products.

It leads to a promising research direction on building an automatic helpfulness prediction system for online reviews, which we believe could be as useful as a product recommendation engine in e-commerce. So far as we know, a series of work on review helpfulness prediction has been proposed from two perspectives: 1) some work leverages domain-specific knowledge to extract a wide range of hand-crafted features (including structural, lexical, syntactic, emotional, semantic and argument features) from the text of reviews as the evidence for off-the-shelf learning tools; and 2) recent studies modify the convolutional neural network [9, 10] to acquire low-dimensional features from the raw text of online reviews. Generally speaking, these mainstream approaches extract various linguistic and embedding features solely from the text of a review as the evidence for helpfulness prediction.

We, however, suggest that the helpfulness of a review should be fully aware of the meta-data (e.g., title, brand, category, description) of the target product besides the textual content of the review itself. Take the online customer review (circled by the orange dashed box) shown by Figure 1 as an example. The effective features to indicate that it is a helpful review on the product: *Beats Solo3* are probably the phrase "*sound quality*" and word "*headphone*". But the same textual features are hardly considered to be *helpful* when appearing in a comment on a *Nikon Digital Camera*.

In this paper, we propose an end-to-end deep neural architecture to capture the intrinsic relationship between the meta-data of a product and its numerous comments that could be beneficial to discover the helpful reviews. Our model is directly fed by both the title of a product and the raw text of its reviews, and then acquire product-aware review representations from the supervision of helpfulness scores given by the crowd-sourcing module. The learned neural representations do not require tedious labor on feature engineering and are expected to be more informative as the product-aware evidence to assess the helpfulness of online reviews. Given the drawbacks that prior systems have been evaluated by different datasets and not built on the successes of each other, we also construct two large-scale datasets, i.e. *Amazon-9* and *Yelp-5*, which are a portion of the real-world web data in Amazon.com and Yelp.com, respectively, for the successive assessment on the helpfulness prediction of online reviews. The mainstream approaches mentioned in this paper are re-implemented in addition to our model, for fair comparison. Extensive experiments are conducted on two different application scenarios: helpfulness identification and regression of online reviews using the two benchmark datasets. Experimental results demonstrate that our model can achieve state-of-the-art performance on the two tasks with significant absolute improvements (**4.25%** AUROC in the identification of helpful reviews and **4.40%** R^2-score in the regression of helpfulness voting).

2 RELATED WORK

An up-to-date and comprehensive survey on various approaches on helpfulness prediction of online reviews was recently conducted by Ocampo Diaz and Ng [17]. According to their survey, these mainstream methods generally extract various linguistic and embedding features solely from the text of an online review as the evidence for helpfulness prediction. We go further and categorize those approaches into two classes in terms of the way of acquiring supportive features for helpfulness prediction, i.e., learning with hand-crafted features (see Section 2.1) and from deep neural networks (see Section 2.2), respectively.

2.1 Learning with Hand-crafted Features

So far as we know, a series of conventional approaches on review helpfulness prediction leverage domain-specific knowledge to extract a wide range of hand-crafted features from the text of customer reviews as the evidence fed into off-the-shelf classifiers or regressors such as SVM [1, 5] or Random Forest [12, 23]. According to [13] and [26], these hand-crafted features involve:

- *Structural features* (STR) [16, 25]: The structural evidence refers to the number of tokens, the number of sentences, the average length of sentences, and even the star rating of an online review. These important features indicate the attitude of the buyers when they write down their comments.
- *Lexical features* (LEX) [8, 24]: Inspired by the idea of text classification, the bag-of-words (BOW) features are essential to helpfulness prediction of online reviews. Explicitly, we usually remove the stop words and non-frequent words, extract unigrams (UGR) and bigrams (BGR) and weight these terms by the measurement of *tf-idf* as the lexical features.
- *Syntactic features* [8]: We can also obtain the part-of-speech (POS) tag of each token in a review. The syntactic features are composed of the percentages of tokens that are nouns, verbs, adjectives, and adverbs, respectively.
- *Emotional features*: Martin and Pu [14] used the Geneva Affect Label Coder (GALC) dictionary [20] to define 36 emotion states of a review. The emotional features include the number of occurrences of each emotional state plus one additional dimension for the number of non-emotional words.
- *Semantic features*: Yang et al. [26] leveraged the General Inquirer (INQUIRER) dictionary [22] to map each word in a review into a semantic tag. This is similar to the way of obtaining emotional features. The semantic features are formulated by a vector where each entry records the number of the occurrences of each semantic tag.
- *Argument features*: Liu et al. [13] explored more intricate linguistic features such as evidence-conclusion discourse relations, also known as arguments, to study the helpfulness of an online review. To be exact, they adopted different granularities of argument features, e.g., the number of arguments, the number of words in arguments, etc.

2.2 Learning from Deep Neural Nets

The emergence of Deep Learning [11] brings in a good insight that we do not have to manually design heuristic rules to extract domain-specific features for learning tasks. To avoid the tedious

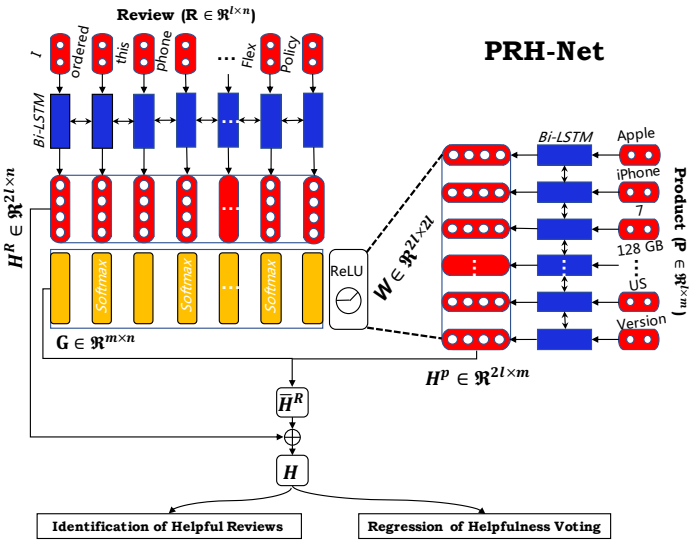

Figure 2: Framework of our neural architecture for product-aware review helpfulness prediction: PRH-Net. $\mathbf{H}^P \in \mathbb{R}^{2l\times m}$ and $\mathbf{H}^R \in \mathbb{R}^{2l\times n}$ are the contextual embeddings of the words in the review R and the product P, respectively. $\mathbf{G} \in \mathbb{R}^{m\times n}$ is the semantic matching matrix between R and P. $\overline{\mathbf{H}}^R \in \mathbb{R}^{2l\times n}$ is the product-aware review repesentation attended by G.

labor on feature engineering for helpfulness prediction of online reviews, the research community recently made several attempts:

- *Embedding-gated CNN* (EG-CNN) [2, 3]: This work adopts a convolutional neural network model [9] that is able to extract multi-granularity text features from reviews. As different words may contribute to the meaning of a review diversely, Chen et al. [2] suggest using word-level embedding-gates to control the word embeddings fed into the CNN model.
- *Multi-task Neural Learning* (MTNL) [4]: Fan et al. [4] introduce a multi-task neural learning (MTNL) paradigm for identifying helpful reviews. The main task, i.e. identifying helpful reviews, leverages the convoluted neural representations from the textual content of reviews. In order to make more accurate predictions on review helpfulness, the convoluted embeddings are also used to fit the star ratings of reviews as an auxiliary task.

Though MTNL [4] and EG-CNN [2, 3] are two newly proposed neural approaches which perform higher on review helpfulness prediction than the hand-crafted methods, these mainstream approaches generally acquire various embedding features solely from the textual content of a review as the evidence without considering the corresponding product, which we believe is inadequate for building a feasible system to discover helpful online reviews.

3 PROPOSED MODEL

In this section, we elaborate our neural model, abbr. PRH-Net, for product-aware review helpfulness prediction. PRH-Net is devised by the motivation that the helpfulness of an online review should be fully aware of the title of its target product besides the textual content of the review itself. As shown by Figure 2, it is composed of two components: 1) the local contextual embeddings of a review and 2) the product-aware distributed representations of the review. We will then explain how to model the two components.

Suppose that we have a product title P and one of its online reviews R. We use m and n to denote the number of tokens/words in the product title P and the review R, respectively. Firstly, we align each token with the embedding dictionary acquired by the word embedding approaches such as Word2Vec [15], Glove [18] or Elmo [19] to initialize the distributed representations of the product title $\mathbf{P} \in \mathbb{R}^{l\times m}$ and the review $\mathbf{R} \in \mathbb{R}^{l\times n}$.

To achieve the local contextual embeddings of the review R, we use a Bi-LSTM network [21] which takes the word embeddings of the review $\mathbf{R}$ as input:

$$\mathbf{H}^R = \text{Bi-LSTM}(\mathbf{R}). \tag{1}$$

$\mathbf{H}^R \in \mathbb{R}^{2l\times n}$ stands for the contextual embeddings where each word can obtain two hidden units with the length of $2l$ encoding both the backward and the forward contextual information of the review locally.

Similarly, we can re-fine the word embeddings of the product title $\mathbf{P}$ via another Bi-LSTM network:

$$\mathbf{H}^P = \text{Bi-LSTM}(\mathbf{P}), \tag{2}$$

and achieve the contextual embeddings of the product title $\mathbf{H}^P \in \mathbb{R}^{2l\times m}$. To make the contextual embeddings of the review fully aware of the product title, we devise a word-level matching mechanism as follows,

$$\mathbf{Q} = \text{ReLU}(\mathbf{W}^P\mathbf{H}^P + \mathbf{b}^P \otimes \mathbf{e}_P)^{\mathrm{T}}\mathbf{H}^R \tag{3}$$

where $\mathbf{W}^P \in \mathbb{R}^{2l\times 2l}$ is the weight matrix and $\mathbf{b}^P \in \mathbb{R}^{2l}$ is the bias vector for the Rectifier Linear Unit (ReLU). The outer product $\otimes$ copys the bias vector $\mathbf{b}^P$ m times to generate a $2l \times m$ matrix. Then $\mathbf{Q} \in \mathbb{R}^{m\times n}$ is the sparse matrix that holds the word-level matching information between the product title P and the review R. If we further apply the softmax function to each column of $\mathbf{Q}$, we will obtain $\mathbf{G} \in \mathbb{R}^{m\times n}$, the i-th column of which represents the normalized attention weights over all the words in product title P for the i-th word in the review R:

$$\mathbf{G} = \text{softmax}(\mathbf{Q}). \tag{4}$$

Then we can use the attention matrix $\mathbf{G} \in \mathbb{R}^{m\times n}$ and the contextual embeddings of the product $\mathbf{H}^P \in \mathbb{R}^{2l\times m}$ to re-form the product-aware review representation $\overline{\mathbf{H}}^R \in \mathbb{R}^{2l\times n}$:

$$\overline{\mathbf{H}}^R = \mathbf{H}^P\mathbf{G}. \tag{5}$$

Driven by original motivation, we need to join the local contextual embeddings of the review ($\mathbf{H}^R$) and the product-aware distributed representations of the review ($\overline{\mathbf{H}}^R$) together for predicting its helpfulness with the feature matrix $\mathbf{H} \in \mathbb{R}^{2l\times n}$:

$$\mathbf{H} = \mathbf{H}^R + \overline{\mathbf{H}}^R. \tag{6}$$

$\mathbf{H}$ can also benefit from the idea of ResNet [6] that efficiently acquires the residual between $\mathbf{H}^R$ and $\overline{\mathbf{H}}^R$, and provides a highway to update $\mathbf{H}^R$ if the residual is tiny.

Table 1: The statistics of the Amazon-9 dataset for helpfulness prediction of online reviews in Amazon.com. #(P.): the number of products; #(R.): the number of reviews; #(R. ≥ 1v.): the number of the reviews, each receiving at least 1 vote regardless of helpfulness/unhelpfulness; #(R. ≥ 0.75h.r.): the number of the reviews, each regarded as helpful by at least 75% votes.

4 EXPERIMENTS

4.1 Benchmark Datasets

We find two well-formatted JSON resources online which contain plenty of meta-data (including titles, brands, categories, and descriptions) of products and numerous customer reviews. One is the data collection[2] of Amazon.com crawled by He and McAuley [7] up to July 2014. The other one is the dump file[3] directly provided by Yelp.com for academic purposes.

We use the product ids ("*asin*" in Amazon and "*business_id*" in Yelp) as the foreign keys to align the meta-data of products with corresponding online reviews. 80% products with reviews are randomly picked as the training set, leaving the rest as the test set. In this way, two benchmark datasets, i.e. *Amazon-9* and *Yelp-5*, are prepared, and the statistics of the two datasets are shown by Table 1 and Table 2, respectively.

In line with Table 1, *Amazon-9* covers more than 3 million products spreading over nine different categories in Amazon.com. About 50 million online reviews are included, but less than 48% (roughly 24 million reviews) of them receive at least 1 vote regardless of helpfulness/unhelpfulness by crowd-sourcing. As for *Yelp-5* shown by Table 2, it contains about 130 thousand businesses which fall into five categories in Yelp.com. The proportion of voted reviews in *Yelp-5* is also lower, i.e., roughly 52% (about 2.5 million reviews).

In this work, we regard the reviews which receive at least 1 vote, i.e. the column named after # (R. ≥ 1v.) in Table 1 and Table 2, as the experimental samples. In Amazon.com, the crowd-sourcing module for voting helpful reviews provides an "X of Y" score of helpfulness where "Y" stands for the total number of users who participate in voting and "X" denotes the number of users who think the review is helpful. Yelp.com offers more options: *useful*: X,*cool*: Y, and *funny*: Z, to the users who are willing to give feedbacks. Regardless of the difference, we generally regard the reviews which receive at least 0.75 ratio of helpfulness/usefulness, i.e. # (R. ≥ 0.75h.r.), as positive samples, leaving the others as the negative samples.

4.2 Comparison Methods

We compare our model (PRH-Net) with a wide range of prior arts mentioned in Section 2. Specifically, we re-implement the methods learning with hand-crafted features and from deep neural networks. The up-to-date neural approaches involve the embedding-gated CNN (EG-CNN) [2, 3] and the multi-task neural learning (MTNL) architecture [4] for review helpfulness prediction. The hand-crafted

[2]The data collection is available at http://jmcauley.ucsd.edu/data/amazon/links.html
[3]The dump file can be downloaded from https://www.yelp.com/dataset

features include the structural features (STR) [16, 25], the lexical features (LEX) [8, 24], the emotional features (GALC) [14] and the semantic features (INQUIRER) [26]. We also add two more experiments on integrating all the hand-crafted features via the Support Vector Machines (SVM) and the Random Forest (R.F.) model for review helpfulness prediction.

4.3 Application Scenarios

Most previous studies just reported their performance on either the task of review helpfulness identification or regression. In this part, we assess the performance of PRH-Net by comparing our model with all the other approaches on both tasks.

4.3.1 Identification of Helpful Reviews. We use the data shown by the column named #(R. $\geq$ 1v.) in Table 1 and Table 2 to conduct this task. Within the data for binary classification, the reviews belonging to the column #(R. $\geq$ 0.75h.r.) are regarded as positive samples. As both the training and test sets are imbalanced, we adopt the Area under Receiver Operating Characteristic (AUROC) as the metric to evaluate the performance of all the approaches on helpful review identification. As shown by Table 3 and Table 4, MTNL [4] achieves the up-to-date performance on this classification task among the baseline approaches as it shows the best performance on 12 of 14 categories in *Amazon-9* and *Yelp-5* datasets. Our model (PRH-Net) surpasses MTNL on both datasets and obtains state-of-the-art (micro-averaged) results of 65.1% AUROC (*Amazon-9*) and 66.3% AUROC (*Yelp-5*) with absolute improvements of **2.6%** AUROC and **5.9%** AUROC, respectively.

4.3.2 Regression of Helpfulness Voting. In this task, all the approaches are required to predict the fraction of helpful votes that each review receives. We still use the data in the column named of #(R. $\geq$ 1v.) in Table 1 and Table 2 as the training and test sets. The Squared Correlation Coefficient (R^2-score) is adopted as the metric to evaluate the performance of all the approaches on helpfulness score regression. Table 5 and Table 6 show that MTNL [4] achieves the up-to-date performance on this regression task among the baselines. Our model (PRH-Net) outperforms MTNL on both datasets and obtains state-of-the-art (micro-averaged) results of 55.2% R^2-score (*Amazon-9*) and 58.2% R^2-score (*Yelp-5*) with absolute improvements of **3.5%** R^2-score and **5.3%** R^2-score, respectively.

Table 5: Comparison of the performance (R^2-score) of mainstream approaches on helpfulness voting regression evaluated by the test sets of Amazon-9. (*italic fonts: the best performance among the baseline approaches; bold fonts: the state-of-the-art performance of all the approaches)**

5 CONCLUSION AND FUTURE WORK

This paper engages in the emerging research on helpfulness prediction of online reviews. Our idea is driven by the motivations that 1) the helpfulness of an online review should be fully aware of the meta-data of its target product besides the textual content of the review itself; 2) the hand-crafted features requiring tedious labor are domain-specific and prone to high generation error; and 3) there is no widely-used benchmark dataset for constantly improving intelligent systems to precisely assess the helpfulness of online reviews.

To address the problems above, we contribute an end-to-end neural architecture which can automatically acquire product-aware review representations besides the textual embeddings of reviews as more informative evidence for review helpfulness prediction. We also construct two large-scale and real-world benchmark datasets, i.e. *Amazon-9* and *Yelp-5*, for the sake of 1) fairly conducting the performance comparison of all the approaches on review helpfulness prediction, and 2) leaving the datasets available for successive studies. Specifically, we run extensive experiments on our newly constructed datasets under the application scenarios of helpfulness identification and regression. Experimental results demonstrate that our model surpasses all the mainstream approaches and achieves state-of-the-art performance with substantial improvements.

For future work, we might consider to study the following topics related to helpfulness prediction of online reviews:

- User-specific and explainable recommendation of helpful reviews: As different users may concern about various aspects of the products online, helpful review recommendation needs to be more user-specific and self-explainable.
- Cross-domain helpfulness prediction of online reviews [3]: Given that it costs a lot on manually annotating plenty of helpful reviews in a new domain, we should explore effective approaches on transferring useful knowledge from limited labeled samples in another domain.
- Enhancing the prediction of helpful reviews with unlabeled data: As a small proportion of reviews could be heuristically regarded as helpful or unhelpful, it, therefore, becomes a promising study to automatically predict the helpfulness of online reviews based on the small amount of labeled data and a huge amount of unlabeled data.

ABSTRACT

As emojis become prevalent in personal communications, people are always looking for new, interesting emojis to express emotions, show attitudes, or simply visualize texts. In this study, we collected more than thirty million tweets mentioning the word "emoji" in a one-year period to study emoji requests on Twitter. First, we filtered out bot-generated tweets and extracted emoji requests from the raw tweets using a comprehensive list of linguistic patterns. Then, we examined patterns of new emoji requests by exploring their time, locations, and context. Finally, we summarized users' advocacy behaviors and identified expressions of equity, diversity, and fairness issues due to unreleased but expected emojis, and concluded the significance of new emojis on society. To the best of our knowledge, this paper is the first to conduct a systematic, large-scale study on new emoji requests.

1 INTRODUCTION

The word emoji comes from the Japanese words e ("picture") and moji ("character") and has a history of nearly 30 years since it originated on Japanese mobile phones in the late 1990s. In 2009, a set of 722 emojis were first officially added into Unicode Standard 5.2 [30]. After Apple introduced the iOS emoji keyboard in 2011, the use of emojis grew rapidly [44]. By 2018, more than 2700 emojis had been added into Unicode Standard 11.0. According to a recent survey [44], almost everyone online (92% of the online population) was using emojis. With the popularity of social networks, nowadays, emojis are used extensively on various social networking platforms, such as Twitter, Facebook, WhatsApp, and Instagram. In particular, nearly half of comments and captions on Instagram have emojis [11].

As the usage of emojis (and social media in general) evolves, new emojis are being continuously requested. The Unicode Consortium[1] updates the official list of Unicode emojis by judging and accepting proposals for new emojis annually. For each candidate emoji, its evidence of frequency from Google Search, Bing Search, Youtube Search and Google Trends must be submitted, and evidence from NGram Viewer and Wikipedia Search are optional. Besides substantial efforts to collect such evidence, this method has several additional drawbacks. First, not all objects with a higher frequency in search engines are more likely to be emojilized. For example, although the "mascot" is heavily searched, it is unlikely to be an emoji because there exists no specific image representing all mascots for different teams, events, and organizations. Second, it completely ignores emoji petitions directly generated by users who have first-hand information regarding the valuable usage context.

However, a systematic study on which new emojis are wanted, when, where and why these emojis are requested, and how to call for these emojis still remains unexplored. Few studies attempted to offer even partial answers to these questions. The emoji satisfaction survey [45] reported mobile message app users always desired more emoji choices, but provided no further detailed answers to the above specific emoji questions. Thomas Dimson [11] showed the emoji usage trend on Instagram from 2010 to 2015 during which a large number of new emojis were proposed, but those new emojis were not studied. Yonatan Zunger [52] analyzed the animal emoji requests of one day (August 3, 2017) using Twitter's Search APIs, and demonstrated the world wanted raccoon and lobster emojis. However, it only studied emojis in a single category on a small-scale in terms of both the number of tweets and the tweeting time span.

To more comprehensively study the emoji requests, this paper investigated more than thirty million tweets mentioning the word "emoji," and proposed a new framework to answer the above questions. Specifically, the framework consisted of the following analyses on the thirty million emoji-mentioned tweets. First, we extracted

the requested emoji descriptions and calculated their corresponding frequencies. After filtering out emojis that already existed (i.e., extant emoji requests) and explaining why they were still being requested, we proposed a WordNet [33] based emoji classifier to cluster requested emojis. Then, we studied spatiotemporal patterns of these requests and explored possible reasons why new emojis were requested. Moreover, we presented the common characteristics of requested emojis and advocacy behaviors. Finally, we illustrated the existing relatedness, fairness, and equality problems reflected through emojis, and discussed the positive impacts of new emojis on society.

As the first step to conduct a systematic, large-scale study on new emoji requests, our contributions can be summarized as follows:

- We revealed new and strong evidence of frequency, i.e., the explicit and accurate evidence like "why is there no *foo* emoji", for the Unicode emoji community to evaluate emoji petitions.
- Our study explained why extant emojis were still requested by users, and provided multiple suggestions to enable the timely availability of newly released emojis to users.
- A comprehensive understanding of new emoji requests was offered by profiling spatiotemporal distributions, summarizing advocacy behaviors, and exploring factors that inspire requests.
- We discussed the equality, fairness and diversity in emojis, and presented the potential significance of new emojis in many aspects like business promotion and violence control.

2 RELATED WORK

There is a great deal of work that investigates how people use emojis to facilitate communication and social interactions. Expressing and strengthening emotions [24, 43, 47], and conveying humor [10, 22] and sarcasm [16, 48] are major functions of emojis in interpersonal communication. Emojis are also used to manage conversations, such as maintaining a conversational connection, and ending a thread [9, 51]. In addition, emojis show more diverse functions in close relationships. Kelly et al. [27] reported that emojis encouraged playful interactions, and created shared and secret uniqueness between people in mediated close personal relationships. Similarly, Wiseman et al. [50] examined the repurposing emojis for personalized communication between close partners, friends and family members. An example is using the shared love of the pizza 🍕 to represent romantic love between partners.

Emojis are also having the significant influence on relevant life domains of business, politics, religion, entertainment and food, etc. Various companies used emojis to enrich their promotions, create awareness and attract attention from consumers [21, 28, 32]. Political leaders from the United States [3], Australia [42], and Argentina [20] used emojis in official speech, during interviews, or on social networks. For religions, some users embedded emojis like the folded hands (the prayer hands) emoji 🙏 into their usernames. Another example is the recycling symbol emoji ♻️, which was taking over on Twitter due to its extensive usage by Arabic speakers to represent a shared Islamic *Dua* (supplication or invocation) [40]. In the entertainment field, *The Emoji Movie*, an animated film based on emoji graphics, was released in 2017. Recently, many researchers [18, 25, 26, 47] associated foods with emojis, and suggested emojis to be an easy and non-verbal way to measure food-related emotions, especially for children [18].

As emojis are impacting various aspects of real life, problems of equity, diversity, and fairness caused by emojis are drawing more attention. To promote gender equality through emojis, researchers from Google proposed a set of emojis reflecting a wide range of professions for women (as well as men) with a goal of highlighting the diversity of women's careers [4]. The *person* emoji 👱, an adult with no gender specified, had become available as a gender-inclusive alternative to the man 👱‍♂️ or the woman 👱‍♀️ since Unicode Standard 10.0 in 2017. A recent study revealed that 0.13% of all emojis send by Americans were either a rainbow flag 🏳️‍🌈 (commonly known as the lesbian, gay, bisexual and transgender pride flag), men holding hands 👬 or women holding hands 👭 emojis [23]. Since *"people all over the world want to have emoji that reflect more human diversity, especially for skin tone"* [7], the Unicode Consortium released five different skin tone modifiers, which was based on the six tones of the Fitzpatrick scale [17, 49], to enrich human diversity in Unicode Standard 8.0 in 2015. When a human emoji is immediately followed by one skin tone modifier character, the person(s) or body part will be rendered using the specified skin tone. For example, 👶 + {🏻,🏼,🏽,🏾,🏿} → {👶🏻,👶🏼,👶🏽,👶🏾,👶🏿}. To depict diverse hair colors and styles, Unicode Standard 11.0 introduced hair components including red-haired, curly-haired, white-haired, and bald components in 2018 [8]. Besides, some emojis enable multi-person groupings, which enhances family-related emojis diversity significantly, such as single-parent families 👩‍👦 👨‍👧 , and homoparental families 👨‍👨‍👦 👩‍👩‍👧.

3 IDENTIFYING NEW EMOJI REQUESTS

3.1 Data Curation

We used Twitter's Streaming APIs, which enable developers to filter and collect real-time tweets, to crawl all the English tweets containing the word "emoji". In our study, more than thirty million tweets of interest were crawled in total from Oct. 2017 to Oct. 2018. The collected tweets were formatted in JavaScript Object Notation (JSON) files with named attributes and associated values [46].

To eliminate the side effects of bots on Twitter, we followed approaches proposed by Ljubesic et al. [29] to filter out those bot-generated tweets. More specifically, we removed eleven users who produced on average more than 10 "emoji" tagged tweets per day. For each of users having more than 100 collected postings, we calculated the time (in minutes) between her/his two successive tweets and removed those users whose three most frequent time spans between postings covered more than 90% of their overall production. This method deleted overall 131 users and 43,461 tweets.

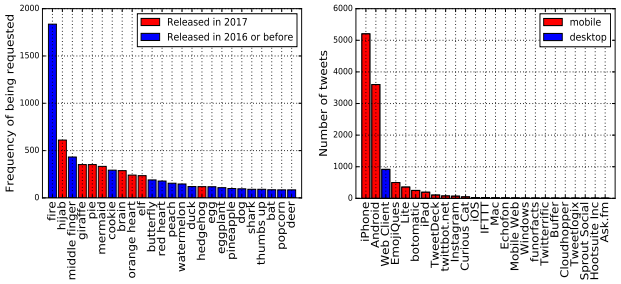
We then extracted information of interest such as user profiles, tweet contents, timestamps, and geo tags, from JSON files, and built the *complete dataset* and the *unique dataset* for emoji analysis subtasks in Section 4 and Section 5 respectively. The *complete dataset* consisted of four types of tweets including general tweets, retweets, quoted tweets and replies. The *unique dataset* only contained the original tweets and excluded duplicated tweets like retweets. As tweets are usually composed of incomplete, noisy and poorly structured sentences due to the frequent presence of abbreviations, irregular expressions, ill-formed words and non-dictionary terms, a series of preprocessing steps were applied to reduce noise in tweets.

For example, we removed URLs and non-ASCII characters except Unicode characters reserved for emojis.

3.2 Emoji Extraction Using Linguistic Patterns

Note that not all collected tweets were petitions for new emojis, e.g., the tweet like "I love this emoji!" was crawled as well since it contained the keyword "emoji". Therefore, we needed to identify emoji-requested tweets and extracted wanted emojis. However, Twitter users could choose different words and sentence patterns to express their expectations of new emojis, which made the emoji extraction challenging. Yonatan Zunger [52] assumed that mentions of phrases like "*foo* emoji" were positive statements about desiring such an emoji. Although this hypothesis was claimed to hold true when validating with spot-checks of the matching tweets, it suffered from false positives, e.g., a tweet like "I hate a *foo* emoji!" was incorrectly recognized as desiring the *foo* emoji.

Inspired by [52], we proposed fine-tuned linguistic patterns to detect desired emojis more precisely. Based on our observations, we summarized 49 frequent linguistic patterns and their 2620 variations to match emoji-requested tweets and extract emojis. Ten linguistic patterns are illustrated as follows, and the whole linguistic pattern list and corresponding tweet screenshots are available through http://yunhefeng.me/linguistic_patterns.html.



- why is there no *foo* emoji
- where is the *foo* emoji
- need a *foo* emoji
- look for a *foo* emoji
- demand a *foo* emoji
- have no *foo* emoji
- invent a *foo* emoji
- a *foo* emoji is overdue
- still no *foo* emoji
- give us a *foo* emoji

To broaden the matching scopes, we first adopted natural language processing techniques, including part-of-speech (POS) tagging, stemming and lemmatization, before checking tweet contents. For example, "look for a *foo* emoji" would match "looked for an *foo* emoji", "looks for the *foo* emoji", etc. We also considered characteristics of casual English on social networks [6] and fixed common problems, such as the punctuation omission/error (e.g., theres → there's), the wordplay (e.g., neeeeeed → need), and the censor avoidance (e.g., shlt, fck, f***). In addition, we took possible variations on sentence structures of linguistic patterns into account. For example, our linguistic patterns covered not only "need a *foo* emoji" but also "need an emoji of/with/for *foo*".

3.3 Requesting Extant Emojis

When examining extracted emojis, to our surprise, we found hundreds of emojis that had already been released by the Unicode Consortium were still requested extensively. Figure 1(a) demonstrates the top 25 most requested extant emojis. Seven out of the top 10 extant emojis came from the recent Emoji Version 5.0, which was released in May 2017 [13], while we started to crawl the data in Oct. 2017. It is also interesting to note that the percentage of Twitter users on mobile was about 80% [35], but they contributed more than 91.8% extant emoji requests, as shown in Figure 1(b).

We compared Twitter's post-a-tweet interfaces on different platforms to explore why users could not find extant emojis, especially on mobile. On Twitter's desktop site, the post-a-tweet interface offers an emoji picker which contains all latest official emojis. By contrast, on mobile devices, post-a-tweet interfaces of both the

(a) Extant emoji requests (b) Platform distribution

Figure 1: Requesting extant emojis

mobile site and mobile apps have no such emoji pickers. Instead, users have to rely on on-screen keyboards to type emojis, which may cause potential poor user experiences. First, keyboards may not incorporate the latest emojis promptly so that new emojis are unavailable for users. Second, users may not update keyboards to the latest versions to access the recently added emojis, or their mobile operating systems are too out-of-date to be compatible with the latest versions of keyboards. Third, bad emoji keyboard layouts make it difficult for users to find and type intended emojis even if these emojis have been included.

Accordingly, we have the following suggestions and recommendations to improve the user experience of inputting emojis. Mobile users should update installed keyboard software frequently and select the high-quality keyboard with proper emoji arrangements. It is keyboard developers' responsibility to merge newly released emojis into their products as soon as possible and highlight it in "What's New" descriptions of their keyboard apps to remind users that new emojis are available. For app developers, they can add the emoji picker or the search bar to enable users to input emojis without entirely relying on third-party keyboards.

3.4 Emojis Categorization

The emoji categorization plays a big role in facilitating emoji inputs for both mobile and desktop users. Almost all mobile emoji keyboards arrange emojis into categories to alleviate the problems of large lists. Most emoji pickers on social networks also group emojis to help users select wanted emojis quickly and effortlessly. When new emojis come, knowing the number of emojis in each category guides emoji input interface designers to adjust the emoji arrangement, such as increasing the number of emojis per screen. Especially when a large number of new emojis are requested, an automatic emoji classifier is necessary and helpful.

The Unicode Consortium officially categorizes emojis into eight groups, i.e., Smileys & People, Animals & Nature, Food & Drink, Activity, Travel & Places, Objects, Symbols, and Flags. The category of Flags is the easiest one to be detected, since each emoji belonging to this category contains the keyword of "flag". Therefore, we could simply search this keyword in descriptions of each requested emoji to determine whether it should be classified into the flag group.

However, for the rest categories, the method of searching keywords is obviously ineffective because of the difficulty in summarizing a set of keywords representing a particular category. We instead trained a semantic classifier based on WordNet [33], which is a widely-used lexical database for English. A critical concept in WordNet is the synset, namely a set of synonyms sharing a common meaning. In our study, we focused on noun synsets to which words in emoji descriptions belonged. For example, the similarity between two emojis e_1 and e_2 was calculated as the highest similarity score between the two noun synsets containing words in e_1 and e_2. For the similarity score between two synsets, we took the *path_similarity* score, a similarity metric based on the shortest path that connected the senses in the is-a taxonomy, to denote how similar two word senses were. For a testing emoji e_{te}, we calculated its *path_similarity* with each training emoji e_{tr} in each category c. Then, for each category c, we sorted its similarity score list and summed up the top k similarity scores to represent the similarity of the unlabeled emoji e_{te} and the category c. Finally, we set the category with the largest summed similarity as the label for e_{te}.

We performed the 5-fold cross validation on the category dataset collected from Emojipedia[2] for 50 times and achieved an average accuracy of 71.1% with the top k set as 9. One may argue that the accuracy is too low. However, even the official category labels of some emojis are indeed ambiguous. For example, the monkey face (U+1F435) is categorized as animals & nature, but the see-no-evil monkey (U+1F648), hear-no-evil monkey (U+1F649), and speak-no-evil monkey (U+1F64A) are classified as smileys & people. In addition, prior research studies [34, 37] revealed that ambiguities in emoji categorization were common. So, we think the achieved accuracy is acceptable with the messy data.

4 PATTERNS OF NEW EMOJI REQUESTS

4.1 Requested Emojis by Category

We used the proposed keyword matching method and the WordNet-based classifier to categorize requested emojis. Considering requested emojis were too diverse, we only counted emoji requests greater than 10 times. As shown in Table 1, more than 31.8% of wanted emojis were from the Smileys & People category, which might indicate people's great passions for new emojis to express emotions. The public also desired many emojis, including kangaroos and mangoes, from the Animals & Nature and Food & Drink categories. Surprisingly, the number of tweets requesting symbol emojis was very large. After digging into related tweets, we found one tweet petitioning the anarchy symbol emoji, had been retweeted for over 6,000 times, which accounted for more than 27% of the total tweets in the Symbols category.

It is reasonable that categories of the Activity, Travel & Places, and Flags had relative fewer requests, since most emojis in these categories have been released. In addition, it takes a long time to evolve a new activity like a sports game, a new place like electric vehicle charging stations, or flags for new-born countries or influential social movements. The different demands of emojis per category may inspire emoji input interface designers to optimize emoji layouts, such as reserving spaces for new coming emojis, and displaying more emojis per screen. They can even regroup emojis, as suggested by Na'aman et al [34], to enhance user experience.

[2]https://emojipedia.org/

Table 1: Emoji requests by category

Category	# emojis	# tweets	examples
Smileys & People	385	36,790	redhead, ass shaking
Animals & Nature	185	18,059	kangaroo, flamingo
Food & Drink	164	12,067	mango, waffle
Activity	42	2,421	slide, softball
Travel & Places	56	1,946	compass, brick
Objects	161	12,229	broom, red carpet
Symbols	170	21,443	anarchy, infinity
Flags	44	3,156	trans flag, Texas flag

4.2 Temporal Distributions

We aggregated tweets petitioning the same emoji together by month. Figure 2 demonstrates emojis that were requested more than 1000 times throughout one year (Oct. 2017 - Oct. 2018). The circle diameter represents the number of requests made. Although the overall requested number was not very large, emojis of brooms, flamingos and kangaroos appeared consistently in all months. In contrast, heavily requested emojis like the lookout and the red carpet mainly appeared in one or two months. The fact that the broom, flamingo and kangaroo emojis were selected as part of Unicode 11.0 in 2018 or Unicode 12.0 in 2019 implied those emojis that were requested continuously and by multiple users were more likely to be approved by the Unicode Consortium as they reflected the real needs of the majority of online users. We also found the extensive but relatively concentrated emoji requests were usually triggered by celebrities or their followers. For example, petitions of the red carpet emoji were retweeted more than one thousand times by fans of BTS, a South Korean boy band, within 24 hours. After that, there was nearly no petition for the red carpet emoji any more.

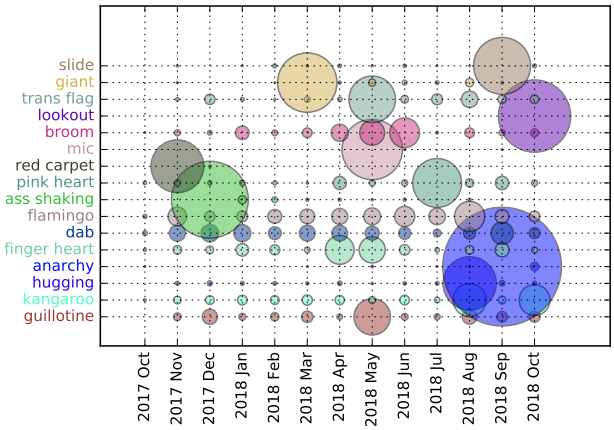


Figure 2: The number of requests per emoji per month. The circle diameter represents the number of requests.

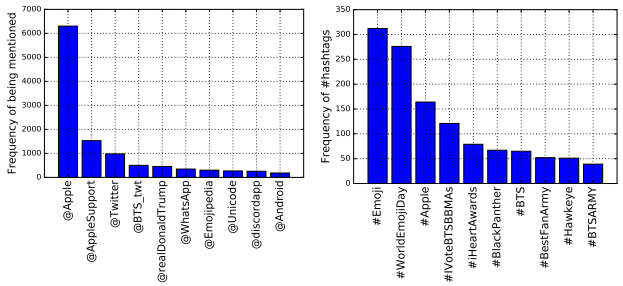
4.3 Geographic Distributions

We utilized geotagged tweets (2.8% of tweets in the *complete dataset*) to profile geographic distributions of new emoji requests at both worldwide and national levels. We observed that people in as many as 110 different countries petitioned for new emojis. As we collected tweets written in English, English-speaking countries, such as United States (73.6%), United Kingdom (10.9%), and Canada (3.2%), contributed the most of emoji requests. It is interesting that non-native English-speaking countries, such as China, Japan, Brazil and Mexico, also expressed their desire for new emojis even in English, which might be one evidence of the world's passion for emojis.

Since most requests were made in the United States, we then focused on the United States to explore the geographic distribution of emoji requests at the national level. As expected, states like California, Texas, and New York made a large number of requests, whereas those states lying at the heartland had low requesting percentages. We think this uneven distribution is caused mainly by the different populations in these regions. After normalizing by state population [39], the geographical distribution was relatively smooth and even across the country, which indicated that people in different states had a similar level of desire for new emojis.

5 BEHAVIORS OF NEW EMOJI REQUESTS

5.1 Context of Emoji Requests



5.1.1 Time-Related Events & Activities. During holidays and festivals, people requested time-sensitive and content-related emojis very frequently, such as the candy cane emoji on Candy Holidays, the carnation emoji on Mother's Day, and the waffle emoji on National Waffle Day. We also found emoji requests were related to popular entertainment products or events. Especially when trends of these popular elements emerged, related emojis were requested extensively by many participants such as movie audiences, music enthusiasts and game players. For example, shortly after Black Panther, a superhero film, was released in early 2018, hundreds of panther emoji requests occurred on Twitter. In addition, periodic reoccurring events like sports games might promote the expectation of new emojis. For example, during 2018 Winter Olympics, many users asked for the Olympic Rings. The yellow card (a serious warning sign in soccer) and red card (a sending-off sign) were petitioned widely in 2018 FIFA World Cup.

5.1.2 Place-Related Interests. Places of interests at different levels, like a single landmark, tourist attractions and even regions or countries, might encourage users to seek new place-related emojis. Many Twitter users visiting Paris claimed for an Eiffel Tower emoji, like "Paris first though!! why's there no Eiffel Tower emoji?!". Similarly, the Mickey and Minnie emoji was requested at Walt Disney World (WDW) Resort like "Guess where I am?!!! WDW (why is there no Mickey and Minnie emoji?!)". Note that the Unicode Consortium does not adopt emojis covered by trademarked logos or copyrighted designs [15, 19]. Residents in Hawaii and Texas looked for their state flag emojis respectively.

5.1.3 Twitter Influencer-Related Behaviors. Emoji requests made by prominent people on Twitter might trigger a widespread discussion of the requested emojis through a massive number of followers. In other words, people were more likely to interact with tweets created by Twitter influencers than those tweeted by unknown Twitter accounts. For example, Enya Umanzor, a famous YouTuber with over 800,000 subscribers to her makeup channel, tweeted "why is there no ass shaking emoji" and garnered 13,000 likes, 2,600 retweets and 34 replies. However, four non-prominent people tweeting for the same ass shaking emoji before Enya Umanzor only got three retweets, no like or reply in total.

5.2 Advocacy Behaviors

When wanted emojis were unavailable, nearly one in three Twitter users would use the symbol of '@' to mention some people or organizations for their attention. Figure 3(a) shows the top 10 Twitter accounts being mentioned by users, where eight of them (except BTS_twt and realDonaldTrump) are specific apps or mobile operating system related Twitter accounts. It is reasonable for ordinary users to seek help from the apps or operating systems, because users thought it was these service providers' responsibility for the nonexistent emojis. The fact that people switched to Twitter to petition new emojis for other apps, e.g., WhatsApp and Discord, could be viewed as a justification for choosing tweet data to study the emoji request.

(a) '@' Mentioning (b) #hashtags Mentioning

Figure 3: Frequency of '@' accounts and #hashtags

In addition to '@' other Twitter accounts, more than 12% of users inserted #hashtags in their tweets when wanted emojis were inaccessible. As we can see from Figure 3(b), the #Emoji is the most frequently created by users, which indicates that the primary concern of these tweets is about emojis. There are also some hashtagged words similar to those '@' mentioned words, such as the #Apple. According to Twitter, the #hashtags are mainly used for indexing keywords or topics, and popular hashtagged words are often trending topics. In our case, users attempted to advocate their desire for more emoji options with the aid of #hashtags.

5.3 Relatedness, Fairness, and Equality

An interesting scenario for the emoji request rose when users complained that there existed an emoji for A but no emoji for B in the same tweets. They thought it was unfair or unreasonable because A and B were usually very similar or related to each other. As emojis are ubiquitous in our lives, such concerns appear in diverse domains as shown in Table 2.

The gender, color, similar function and similar looking can cause a sense of unfairness and inequality. Gender equality and diversity

in emojis are expected by both women and men. Women claimed for the female skier and the woman in tuxedo emojis, while men wanted male-holding-baby and pregnant man emojis. Also, the transgender flag was requested widely. The color is another factor leading to emoji inequalities. Since the blond hair, purple grape, and red ribbon emojis were released, people thought the red hair, green grape, and pink ribbon emojis should be available as well. The similar function can also be an excuse to request new emojis, like mobile phone emojis versus iPad/tablet emojis, guitar emojis versus ukulele emojis, alembic emojis versus test tube emojis, and trophy emojis versus Oscar emojis. Besides, the similarity in looks between two distinct objects can cause unfairness if one of them is unavailable. For example, people reluctant to use the tortoise emoji to represent the turtle believed it was unfair to the turtle.

Emerging technologies, recent social movements, and the equality of political symbols motivate people to petition for new emojis. The bitcoin sign was approved in 2017 as a Unicode character, but not as an emoji. Twitter users wanted an emoji version of the bitcoin to be added. When #MeToo movement reached 1.7 million, Twitter gave it a custom emoji (three raising hands of different skin shades). However, this #MeToo emoji has not been officially supported by the Unicode Consortium and cannot be displayed across multiple platforms. In politics, the equality of both symbols and flags was considered. For example, as there existed the elephant emoji which could be used to represent GOP (the Republican Party), a donkey emoji representing the Democratic Party was requested.

6 SIGNIFICANCE OF NEW EMOJIS

New emojis contain both the unreleased emojis and the emojis needed to be re-designed by tech vendors, like Apple, Google, and Twitter. Identifying and introducing new emojis benefits the society a lot from many aspects, which explains why the Unicode Consortium and vendors update emojis continuously. The newly added hijab (woman with headscarf) emoji through the Hijab Emoji Project campaign led by 15-year-old Saudi Rayouf Alhumedhi promotes inclusivity for about 550 million Muslim women on this earth [2, 12]. Researchers from the Johns Hopkins Bloomberg School of Public Health and the Bill & Melinda Gates Foundation proposed a mosquito emoji to better explain mosquito-borne illnesses like malaria, Zika, dengue and yellow fever in 2017 [31]. Prior work also suggested creating a set of nursing emojis might facilitate health communications for patients and allow them to better understand their health data [41]. As branded emojis helped improve the amount of ads receive by almost 10% [38], brands like furniture company IKEA and fast food restaurant Tim Hortons have released app-specific branded emoji to iconize their products [1].

New appearances of emojis are always desired along with fixing design flaws, considering social influence, etc. When people found the original official lobster emoji and the one designed by Twitter were missing a set of legs, a new anatomically accurate lobster emoji was requested strongly and the four-legged lobster emoji was available soon. The misplaced cheese in Google's burger emoji sparked wide controversy online and was addressed soon by putting the cheese in its correct place [36]. A more recent example is the Apple's bagel emoji released in iOS 12.1 beta 2. Its lackluster appearance caused overwhelming complaints from bagel lovers and birthed the #SadBagel movement for a more appetizing design on Twitter. Apple added cream cheese to its forthcoming bagel emoji after the social media outcry [5]. To curb visual representations of gun violence, all major vendors switched the realistic-looking pistol emoji to a toy water gun in 2018, e.g., Apple (→), Google (→), Microsoft (→), Facebook (→) and Twitter (→) [1, 14].

Table 2: Requesting related emojis in the same tweets

Domain	Available Emoji (A)	Unavailable Emoji (B)
Human Diversity	breast-feeding	male-holding-baby
	man in tuxedo	woman in tuxedo
	blond hair	red hair
Life	pancakes	waffle
	bed	pillow
	wine glass	white wine
Science & Tech	antenna bars	Wi-Fi
	microscope	DNA
	mobile phone	ipad/tablet
Nature	honeybee	fly
	tortoise	turtle
	crab	lobster
Business	Unicode (U+20BF)	Bitcoin
	TOP arrow	bottom arrow
	bar chart	pie chart
Society	#MeToo hashtag	#MeToo in Unicode
	Greenland flag	transgender flag
	water pistol	real gun (AR15)
Politics	elephant for GOP	donkey for Dems.
	Guyana/Ghana flag	pan African flag
	United States flag	Confederate flag
Entmt. & Arts	trophy	Oscar
	videocassette/DVD	cassette tape
	guitar	ukulele

7 CONCLUDING REMARKS

In this paper, we proposed a framework for crawling and analyzing emoji requests on Twitter. We collected more than thirty million English tweets containing the keyword "emoji" throughout a year from Oct. 2017 to Oct. 2018. After filtering out bot-generated tweets, we extracted emoji descriptions using fine-tuned linguistic patterns. Surprisingly, some extant emojis were still frequently requested by many users, which were probably caused by out-of-date emoji keyboards or poor emoji keyboard layouts. For non-existing requested emojis, we categorized them into eight groups using a combination of keyword matching and WordNet-based classifiers. We then profiled temporal and geographic distributions of new emojis at different scales. Emojis requested consistently in every month and by multiple users were more likely to be approved by the Unicode

Consortium. We next summarized three typical contexts of emoji requests, i.e., time-related events & activities, place-related interests, and Twitter influencer-related behaviors. Finally, we presented the equity, diversity, and fairness issues due to unreleased but expected emojis, and discussed the significance of new emojis on society. To the best of our knowledge, this paper is the first to conduct a systematic, large-scale study on new emoji requests.

ACKNOWLEDGMENT

The work reported in this paper was supported in part by the grant USDA NIFA 2017-67007-26150 and the Roy & Audry Fancher Summer Research Award.

ABSTRACT

In this paper we investigate the problem of measuring end-to-end Incentive Compatibility (IC) regret given black-box access to an auction mechanism. Our goal is to 1) compute an estimate for IC regret in an auction, 2) provide a measure of certainty around the estimate of IC regret, and 3) minimize the time it takes to arrive at an accurate estimate. We consider two main problems, with different informational assumptions: In the *advertiser problem* the goal is to measure IC regret for some known valuation v, while in the more general *demand-side platform (DSP) problem* we wish to determine the worst-case IC regret over all possible valuations. The problems are naturally phrased in an online learning model and we design Regret-UCB algorithms for both problems. We give an online learning algorithm where for the advertiser problem the error of determining IC shrinks as $O\left(\frac{|B|}{T}\cdot\left(\frac{\ln T}{n}+\sqrt{\frac{\ln T}{n}}\right)\right)$ (where B is the finite set of bids, T is the number of time steps, and n is number of auctions per time step), and for the DSP problem it shrinks as $O\left(\frac{|B|}{T}\cdot\left(\frac{|B|\ln T}{n}+\sqrt{\frac{|B|\ln T}{n}}\right)\right)$. For the DSP problem, we also consider stronger IC regret estimation and extend our Regret-UCB algorithm to achieve better IC regret error. We validate the theoretical results using simulations with Generalized Second Price (GSP) auctions, which are known to not be incentive compatible and thus have strictly positive IC regret.

1 INTRODUCTION

Online advertising has grown into a massive industry, both in terms of ads volume as well as the complexity of the ecosystem. Most inventory is sold through auctions, and demand-side platforms (DSPs)—such as AppNexus, Quantcast, Google's DoubleClick and Facebook's Audience Network—offer advertisers the opportunity buy inventory from many different publishers. In turn, publishers themselves may run their own auctions to determine which ad to show and what price to charge, resulting in a complicated sequence of auction systems. While auction theory has influenced the design of online ad auctions, in practice not all auctions are incentive compatible. Practices such as sequential auctions (where the winners of an auction on a DSP compete in further auctions on the publisher website) and "dynamic reserve prices" (where publishers use a reserve price of e.g. 50% of the highest bid in the auction) both violate incentive compatibility, even when individual auctions are otherwise designed to be incentive compatible.

A lack of incentive compatibility in the ecosystem is problematic both for advertisers and DSPs. Advertisers have to spend time and energy in figuring out the optimal bidding strategy for different placements, a process which can be quite costly especially when incentives differ across different publishers. For DSPs this is problematic because common budget management techniques, such as multiplicative pacing, are only optimal when the individual auctions are incentive compatible [10].

Since (the lack of) incentive compatibility impacts bidding strategies for advertisers and the quality of the product that a DSP offers, it's important to understand the end-to-end incentive compatibility of an ad system. But how should we think of quantifying incentive compatibility? IC is a binary property: either a buyer maximizes their utility by bidding truthfully or she doesn't. However, this fails to capture that a first-price auction is "worse," in some sense, than a second-price auction with a dynamic reserve price of 50% of the highest bid. To capture these differences, we focus on dynamically measuring *IC regret*:

$$\text{IC regret}(v_i) = \max_{b_i} \mathbb{E}_{b_{-i}}\left[u_i(b_i, b_{-i}) - u_i(v_i, b_{-i})\right], \qquad (1)$$

where v_i is the true value of advertiser i, b_i the bid of i, b_{-i} the bids of other advertisers, and $u_i(\cdot)$ the (expected) utility of i. IC regret captures the difference in utility between bidding truthfully, and the maximum utility achievable. By definition, incentive compatible mechanisms have IC regret 0, while higher IC regret indicates a stronger incentive to misreport.

In this paper we focus on measuring IC regret assuming only black-box access to the auction mechanism. That is, for a given advertiser bid b_i we observe whether this yielded an impression x_i, and what price p_i was paid if any. While it seems restrictive to only focus on black box access, this setting allows one to deal with the fact that auction logic is spread out over different participants in the ecosystem (e.g. a DSP and publisher may each run an auction using proprietary code), and it even allows an advertiser who has no access to any auction code to verify the end-to-end incentives in the system.

Given black-box access to the auction mechanism, our goal is to 1) compute an estimate for IC regret in an auction, 2) provide a measure of certainty around the estimate of IC regret, and 3) minimize the time it takes to arrive at an accurate estimate.

We approach this problem using tools from the combinatorial (semi-)bandit literature: to measure the IC regret in an auction system, a bidder may enter different bids in different auctions[1]. By judiciously choosing these bids, we give bounds on the difference between the measured IC regret, and the true IC regret of the system as a function of the number of auctions the bidder participated in. This provides a trade-off between the accuracy of the IC regret measurement, and the the amount of time (and thus money) spend on obtaining the insight.

We consider the problem from two perspectives. The first, which we call the "Advertiser Problem," consists of determining the IC regret in the system for some *known* true value v. This is the problem the advertiser faces when they are participating in an online ad auction. In Section 3 we give an algorithm to select bids that determine IC regret with an error that shrinks as $O\left(\frac{|B|}{T}\cdot\left(\frac{\ln T}{n}+\sqrt{\frac{\ln T}{n}}\right)\right)$, where B is the (finite) bid space, n is the number of auctions at each time step and T is the total number of time steps. The second problem, which we call the "DSP Problem" consists of determining IC regret for the worst-case valuation v, i.e. the value v that yields the *highest* IC regret. This is the problem that a DSP faces if they want to ensure that IC regret is low for *all* advertisers that may use their services. In Section 4 we give an algorithm to select bids and (hypothetical) values that determine worst-case IC regret over all possible values where the error term shrinks as $O\left(\frac{|B|}{T}\cdot\left(\frac{|B|\ln T}{n}+\sqrt{\frac{|B|\ln T}{n}}\right)\right)$ as the number of time steps T grows.

1.1 Related Work

Structurally, designing incentive compatible (IC) mechanisms is well-understood: if the corresponding optimization problem can be solved exactly then the VCG mechanism [9, 13, 19] is IC. In cases where computing the optimal allocation is prohibitively expensive, and some approximation algorithm is used, VCG is no longer incentive compatible [17]. At the same time, the structure of IC mechanisms beyond optimal allocation is known, and tied to some monotonicity property of the allocation function for single-parameter settings [16] and more generally [18]. A weakness in these approaches is that determining if some given mechanism M is IC, one needs to know both the allocation *function* and the pricing *function*. Without access to the code that computes the allocation and pricing, the best an advertiser (or a DSP who depends on a third party auction that's run by a publisher) can hope to have access to is samples from the allocation and pricing functions, not the functions themselves.

Lahaie et al. [15] are the first to study the problem of testing incentive compatibility assuming only black box access. They design an A/B experiment to determine whether an auction is incentive compatible in both single-shot and dynamic settings (the latter concerns cases where an advertiser's bid is used to set their reserve price in later auctions). The work of Lahaie et al. [15] provides a valuable tool for validation of incentive compatibility, but leaves open the question of how to design an experiment that minimizes the time required to get results with high confidence. The present paper complements [15] by giving an algorithm to select alternative bids that minimize the error in the estimate for IC regret.

Our work is also related with *No regret learning in Game Theory and Mechanism Design* [6]. However, in Game Theory and Mechanism Design, most of the existing literature focuses on maximizing revenue for the auctioneer without knowing a priori the valuations of the bidders, e.g. [1, 2, 4], as well as optimizing the bidding strategy from the bidder side, e.g. [3, 11, 20]. To the best of our knowledge, this is the first paper on testing IC through online learning approach.

1.2 Contributions

There are three main contributions of this paper.

(1) We build an online learning model to measure IC regret with only black-box access to the auction mechanism. We present algorithms that find IC regret with an error that shrinks as $O\left(\frac{|B|}{T}\cdot\left(\frac{\ln T}{n}+\sqrt{\frac{\ln T}{n}}\right)\right)$ for a known valuation v, and an error that shrinks as $O\left(\frac{|B|}{T}\cdot\left(\frac{|B|\ln T}{n}+\sqrt{\frac{|B|\ln T}{n}}\right)\right)$ for all possible valuations v. In the above, B is the (finite) bid space, n is the number of auctions at each time step and T is the total number of time steps. We also extend our Regret-UCB algorithm to handle stronger IC regret estimation and shrink the error as $O\left(\frac{|B|^2(\ln T)^{2/3}}{n^{2/3}T}\right)$.

(2) We present a combinatorial semi-bandit algorithm for the setting where the "observed reward" is the max over several arms selected at each time while the benchmark is the standard optimal arm with highest expected reward. To understand this mismatch between the benchmark and observed reward, we analyze the *Pseudo-Regret* of the algorithm and uncover its trade-off with the number of arms selected at each time. This analysis may be of independent interest to the combinatorial (Semi-)Bandits literature.

(3) Simulations suggest that, (1) there is a trade-off between *Pseudo-Regret* and the number of blocks to partition auctions, i.e. we would like to choose the number of blocks to be neither very small nor very large, (2) the *Pseudo-Regret* (near linearly) decays when the number of auctions accessed at each time grows, and (3) our designed algorithm performs better than naive Random-Bids algorithm and ϵ-Greedy algorithm.

[1] In this paper, we consider the model that a bidder participates in many auctions and partitions them into several blocks. For every auction in each block, the bidder enters a bid and only observes the allocation and payment of the bid he enters from each block. For more formal definition, see Section 2.2.

2 MODEL AND PRELIMINARIES

In this section, we formally define the model we considered in this paper and present some important preliminaries. For simplifying description, we introduce "test bidder" to model both the advertiser and DSP.

2.1 Auctions for a Test Bidder

Consider a test bidder i who is eligible for n auctions every day. In each auction, they submit a bid b_i, the auction is run and the outcome is determined by the allocation rule $g_i : b_i \to [0, 1]$ and the payment rule $p_i : b \to \mathbb{R}_{\geq 0}$ (where g_i and p_i are conditioned on the competition in the auction). We assume a single-parameter quasilinear utility model $u_i(v_i, b_i) = g_i(b_i) \cdot v_i - p_i(b_i)$ for some true value $v_i \in \mathbb{R}_{\geq 0}$. Let U be a bound on the utility of a buyer, i.e. the utility function is bounded by $[-U, U]$.

Since there is a large number of auctions and other bidders in the ecosystem, we model the randomness in the system using a stationarity assumption where the conditional allocation and pricing functions are drawn from the same underlying distribution for each auction k:

Assumption 2.1 (Stochastic Assumption). *For each auction k, the allocation rule g_i and payment rule p_i of the test bidder i are drawn from an unknown distribution $\mathcal{F}$, i.e. $(g_i, p_i)_k \overset{i.i.d.}{\sim} \mathcal{F}$.*

2.2 Online Learning Model

At every time step $t \in [T]$, the test bidder participates n auctions and randomly partitions them into $m + 1$ blocks of equal size.[2] For $j \in [m + 1]$, let $\mathcal{A}_j$ be the set of auctions in block j.[3] For every auction in each block j, the test bidder submits a bid $b_t^j \in B$, where B is a finite set of bids.[4]

At the end of time t, in each block $j \in [m]$, the test bidder observes the average allocation probability $\widetilde{g}_t^j(b_t^j)$ and average payment $\widetilde{p}_t^j(b_t^j)$ over all auctions in block j. Let $\vec{b}_t = \{b_t^1, b_t^2, \cdots, b_t^m\}$ be the bids of the test bidder at time t. For block $m + 1$, the test bidder bids their true value v and observes the average allocation $\widetilde{g}_t^{m+1}(v)$ and payment $\widetilde{p}_t^{m+1}(v)$. Without loss of generality, we also assume $v \in B$. The average utility of the test bidder in each block $j \in [m + 1]$ is $\widetilde{u}_t^j(v, b_t^j) \equiv \widetilde{g}_t^j(b_t^j) \cdot v - \widetilde{p}_t^j(b_t^j)$.

With the setting defined, we can instantiate an empirical version of the IC regret from Equation (1) for a given true value v and bids $\vec{b}_t$:

Definition 2.2 (empirical IC regret).

$$\widetilde{rgt}_t(v, \vec{b}_t) = \max_{j \in [m]} \left\{ \widetilde{u}_t^j(v, b_t^j) - \widetilde{u}_t^{m+1}(v, v) \right\}. \tag{2}$$

For notational simplicity, we restate $g^* \triangleq \mathbb{E}[\widetilde{g}_t^j]$ and $p^* \triangleq \mathbb{E}[\widetilde{p}_t^j]$ for each block j at time t.[5] Similarly, define $u^*(v, b) \triangleq \mathbb{E}[\widetilde{u}_t^j(v, b)] \equiv g^*(b) \cdot v - p^*(b)$. Given these definitions, *IC-regret* for a particular true value v and bid b is:

Definition 2.3 (IC-regret). $rgt(v, b) = u^*(v, b) - u^*(v, v)$.

Thus far, in Definitions 2.2 and 2.3 we've considered the regret that a buyer has for bidding their true value v compared to a particular alternative bid b. The quantity that we're really interested in (cf. Equation (1)) is the worst-case IC regret with respect to different possible bids. For the Advertiser Problem (which we treat in Section 3) this is with respect to some known true value v, whereas for the DSP Problem (which we treat in Section 4) we consider the worst-case IC regret over all possible true values v. To summarize, the learning task of the test bidder is to design an efficient learning algorithm to generate v_t and b_t in order to minimize the following *Pseudo-Regret*, the difference between cumulative empirical regret and benchmark.[6]

Definition 2.4 (Pseudo-Regret [5]).

$$\mathbb{E}[R(T)] = \max_{v, b \in B} \sum_{t=1}^{T} rgt(v, b) - \mathbb{E}\left[\sum_{t=1}^{T} \widetilde{rgt}_t(v_t, \vec{b}_t) \right] \tag{3}$$

Given the above *Pseudo-Regret* definition, we can define the error of determining IC regret, which is to measure the distance between the optimal IC regret and the average empirical IC regret over time.

Definition 2.5 (IC Regret Error). $\mathcal{E}(T) = \frac{\mathbb{E}[R(T)]}{T}$

2.3 More Related work

The online learning model in our work is also related to Combinatorial (Semi)-bandits literature [8, 12, 14]. Chen et al. [8] first proposed the general framework and Combinatorial Multi-Armed Bandit problem, and our model lies in this general framework (i.e. the bids are generated from a super arm at each time step). However, in our model the test bidder can observe feedback from multiple blocks at each time step, which is similar to the combinatorial semi-bandits feedback model. Gai et al. [12] analyze the combinatorial semi-bandits problem with linear rewards, and Kveton et al. [14] provides the tight regret bound for the same setting. The Regret-UCB algorithm in our paper is similar and inspired by the algorithm in [12, 14]. However, in our model, the reward function is not linear and has a "max", which needs more work to address it. Chen et al. [7] firstly consider the general reward function in Combinatorial Bandits problem and can handle "max" in reward function, however, there is a mismatch between the benchmark and observed reward in our model (see more in "Contribution").

3 THE ADVERTISER PROBLEM

In this section, we focus on the special case of measuring the IC regret for a known true value v. The learning problem in this setting is to select, for each timestep t, a bid profile $\vec{b}_t$ of m bids to be used in the m auction blocks at that time. The bids $\vec{b}_t$ should be selected to minimize the *Pseudo-Regret* defined in Equation 3.

We propose the Regret-UCB algorithm, given in Algorithm 1, which is inspired by the CombUCB1 algorithm [12, 14]. Regret-UCB works as follows: at each timestep t, the algorithm performs three operations. First, it computes the *upper confidence bound* (UCB) on

[2] The number of blocks m is a variable that will be fixed later. The choice of which m to use will trade off the number of different bids we get information on and the accuracy of the outputs for each bid. Throughout the paper, we assume $m < |B|$.

[3] We let $[n] = \{1, 2, 3, \ldots, n\}$ be the set of positive integers up to and including n.

[4] While in theory the bid space is continuous, in practice outcomes for different bids are relatively smooth, see e.g. the plots in [15], so discretizing the bid space is a reasonable simplification.

[5] Throughout this paper, the expectation $\mathbb{E}$ is over all the randomness (e.g., randomization over payment and allocation distribution and randomization over algorithm).

[6] Where in the case of the Advertiser Problem, we define Pseudo-Regret with respect to a given value v analogously.

the expected utility of each bid $b \in B$ given v,

$$\text{UCB}_t^{\text{u}}(v,b) = \widehat{g}_{t-1}(b)\cdot v - \widehat{p}_{t-1}(b) + 2U\sqrt{\frac{2(m+1)\ln t}{n_{t-1}(b)\cdot n}}, \quad (4)$$

where $\widehat{g}_s(b)$ is the average allocation probability of bid b up to time s, $n_s(b)$ is the number of times that bid b has been submitted in s steps and U is the bound of utility (i.e. utility is bounded by $[-U, U]$). Second, the algorithm chooses the m bids that correspond to the largest UCB_t^{u} values; call this bid vector $\vec{b}_t$. The algorithm uses the m bids $\vec{b}_t$ in the first m blocks of auctions, and in the final block of auctions, it uses the bidder's true value v. Finally, for each of the blocks, the algorithm observes the average allocation probability and payment, and it uses that to update the estimates of allocation $\widehat{g}$ and payment $\widehat{p}$.

Algorithm 1 Regret-UCB Algorithm for a known valuation v.

Input: A finite set of bids B, parameter m, n. $\forall b \in B, n_0(b) = 1$
Initialize: Run Init(B, m, n) algorithm to get $\widehat{g}_0$ and $\widehat{p}_0$.
for $t = 1, \cdots, T$ **do**
  Update UCB^u terms (Eq. (4)) of each bid b.
  Generate a sequence of different m bids $\vec{b}_t \in B^m$ to maximize

$$\sum_{b\in\vec{b}_t} \text{UCB}_t^{\text{u}}(v,b) \quad (5)$$

  for $j = 1, \cdots, m$ **do**
    $n_t(b_t^j) \leftarrow n_{t-1}(b_t^j) + 1$
    Observe $\tilde{g}_t^j(b_t^j)$ and $\tilde{p}_t^j(b_t^j)$
    $\widehat{g}_t(b_t^j) \leftarrow \left[\widehat{g}_{t-1}(b_t^j)\cdot n_{t-1}(b_t^j) + \tilde{g}_t^j(b_t^j)\right] \big/ n_t(b_t^j)$
    $\widehat{p}_t(b_t^j) \leftarrow \left[\widehat{p}_{t-1}(b_t^j)\cdot n_{t-1}(b_t^j) + \tilde{p}_t^j(b_t^j)\right] \big/ n_t(b_t^j)$
  for $b \notin \vec{b}_t$ **do**
    $n_t(b) \leftarrow n_{t-1}(b), \widehat{g}_t(b) \leftarrow \widehat{g}_{t-1}(b), \widehat{p}_t(b) \leftarrow \widehat{p}_{t-1}(b)$

Algorithm 2 Init algorithm to get $\widehat{g}_0$ and $\widehat{p}_0$.

Input: A finite set of bids B, parameter m and n
for b in B **do**
  Randomly participate in $\frac{n}{m+1}$ auctions and submit bid b for each auction.
  Observe the average allocation $\widetilde{g}(b)$ and payment $\widetilde{p}(b)$.
  $\widehat{g}_0(b) \leftarrow \widetilde{g}(b), \widehat{p}_0(b) \leftarrow \widetilde{p}(b)$.

Given a fixed valuation v, define b^* to be the best-response bid:

$$b^* \triangleq \arg\max_{b\in B} rgt(v,b) = \arg\max_{b\in B} u^*(v,b).$$

and denote $\Delta(b) \triangleq u^*(v,b^*) - u^*(v,b)$. The following theorem bounds the worst case *Pseudo-Regret* of the Regret-UCB algorithm for known valuation v.

Theorem 3.1. *Regret-UCB achieves pseudo-regret at most*

$$\sum_{b\in B: u^*(v,b)<u^*(v,b^*)} \frac{32(m+1)U^2\ln T}{n\Delta(b)} + \frac{\pi^2}{3}\cdot\frac{\Delta(b)}{m}$$

To prove the theorem, we rely on the following lemma, which is widely used in stochastic bandit literature. We refer the reader to check [5] for more material.

Lemma 3.2 ([5]). *Fix a valuation v and an iteration $t-1$ (where $t \geq 2$). If a bid $b \neq b^*$ (i.e. $u^*(v,b) < u^*(v,b^*)$) has been observed $n_{t-1}(b) \geq \frac{8(m+1)(2U)^2\ln t}{n\Delta(b)^2}$ times, then with probability of at least $1-\frac{2}{t^2}$, $\text{UCB}_t^u(v,b) \leq \text{UCB}_t^u(v,b^*)$.*

3.1 Discussion

The Regret-UCB algorithm can also be used to implement a low-regret bidding agent: Consider an advertiser who knows the valuation v and wants to maximize the expected utility $u^*(v,b)$ by seeking for a best response bid b. Indeed, the advertiser can adopt the exact same algorithm – Regret-UCB to maximize the utility. The analysis for regret bound in Theorem 3.1 also works when we change the reward function from IC regret to utility.

The term m appears in both terms in Theorem 3.1, hence we can pick it to minimize the asymptotic *Pseudo-Regret*:

Corollary 3.3. *Let $\overline{\Delta} \triangleq \max_{b\in B}\Delta(b)$ and $\underline{\Delta} \triangleq \min_{b\in B}\Delta(b)$. Choosing $m = \frac{\pi}{4U}\sqrt{\frac{n\overline{\Delta}\underline{\Delta}}{6\ln T}}$, the error of determining IC regret achieved by Regret-UCB algorithm for known valuation setting is upper bounded by*

$$\mathcal{E}(T) \leq O\left(\frac{|B|}{T}\cdot\left(\frac{\ln T}{n} + \sqrt{\frac{\ln T}{n}}\right)\right).$$

The big-Oh notation assumes $\overline{\Delta}$ and $\underline{\Delta}$ to be constants.

4 THE DSP PROBLEM

In this section, we consider the problem of determining the worst-case IC regret over all possible valuations v. Let v^* and b^* be the value and bid combination that yields the highest *IC regret*,[7] i.e. $(v^*, b^*) = \arg\max_{v,b\in B} rgt(v,b)$, We modify our previous Regret-UCB algorithm in this setting and show the pseudocode in Algorithm 3.

At each time t, the algorithm first computes the UCBs on the expected *IC regret* of each valuation and bid pair (v,b).

$$\text{UCB}_t^{\text{rgt}}(v,b) = \widehat{rgt}_t(v,b) + 4U\sqrt{\frac{3(m+1)\ln t}{n\cdot\left(n_{t-1}(v)\wedge n_{t-1}(b)\right)}} \quad (6)$$

where $\widehat{rgt}_t(v,b) = \widehat{g}_t(b)\cdot v - \widehat{p}_t(b) - \left(\widehat{g}_t(v)\cdot v - \widehat{p}_t(v)\right)$, "$\wedge$" is the min function, and the other notations $\widehat{g}_t$, $\widehat{p}_t$, $n_{t-1}(b)$, $n_{t-1}(v)$, and U are identical to Section 3. Then the algorithm selects (v_t, b_t^1) to maximize the $\text{UCB}_t^{\text{rgt}}$ term. Given the valuation v_t, the algorithm chooses other $m-1$ bids to achieve the $(m-1)-$largest $\text{UCB}_t^{\text{u}}(v_t,\cdot)$ terms defined in Equation (4). The rest of update steps in the algorithm are exactly the same as in Algorithm 1.

We denote $\Delta(v,b) \triangleq rgt(v^*,b^*) - rgt(v,b)$ and start with the following lemma that gives the concentration property of the UCB^{rgt} terms.

[7] We assume, without loss of generality, that this optimal combination is unique throughout the paper.
[8] We choose the remaining $m-1$ bids be different with each other and b_t^1.

Algorithm 3 REGRET-UCB Algorithm for unknown valuation.

Input: A finite set of bids B, parameter m, n. $\forall b \in B, n_0(b) = 1$
Initialize: Run INIT(B, m, n) algorithm to get $\widehat{g}_0$ and $\widehat{p}_0$.
for $t = 1, \cdots, T$ **do**
  Update UCB^{rgt} terms (Eq. (6)) of every (v, b) pair
  Choose $(v_t, b_t^1) \in B \times B$ to maximize $\text{UCB}_t^{\text{rgt}}(v, b)$
  if $m \geq 2$ **then**
    Choose remaining $m-1$ bids $\{b_t^2, \cdots, b_t^m\}$ to maximize[8]

$$\sum_{b \in \vec{b}_t \setminus b_t^1} \text{UCB}^{\text{u}}(v_t, b)$$

  for $b \in \vec{b}_t \cup v_t$ **do**
    $n_t(b) \leftarrow n_{t-1}(b) + 1$
    Observe $\tilde{g}_t(b)$ and $\tilde{p}_t(b)$ (omit subscript j for each block),

$$\widehat{g}_t(b) \leftarrow \left[\widehat{g}_{t-1}(b) \cdot n_{t-1}(b) + \widetilde{g}_t^j(b)\right] \Big/ n_t(b)$$

$$\widehat{p}_t(b) \leftarrow \left[\widehat{p}_{t-1}(b) \cdot n_{t-1}(b) + \widetilde{p}_t^j(b)\right] \Big/ n_t(b)$$

  for $b \notin \vec{b}_t$ **do**
    $n_t(b) \leftarrow n_{t-1}(b)$

LEMMA 4.1. *At iteration $t-1, (t \geq 2)$, for a (value, bid) pair $(v, b) \neq (v^*, b^*)$, where v and b are both observed at least $\frac{48(m+1)(2U)^2 \ln t}{n\Delta(v,b)^2}$ times, then with probability at least $1 - \frac{4}{t^2}$, $\text{UCB}_t^{rgt}(v, b) \leq \text{UCB}_t^{rgt}(v^*, b^*)$.*

Utilizing Lemma 4.1, we show the worst case *Pseudo-Regret* bound for IC-testing in non-fixed valuation setting in Theorem 4.2.

THEOREM 4.2. *REGRET-UCB algorithm for unknown valuation setting (DSP problem) achieves pseudo-regret at most*

$$\sum_{\substack{v,b \in B, \\ (v,b) \neq (v^*, b^*)}} \frac{384(m+1)U^2 \ln T}{n\Delta(v,b)} + \frac{2\pi^2 \Delta(v,b)}{3} \cdot \left(\mathbb{1}\left\{v \neq v^*\right\} + \frac{\mathbb{1}\left\{v = v^*\right\}}{m} \right)$$

Following the same argument in Section 3, if we choose m appropriately, we will get the following asymptotic bound.

COROLLARY 4.3. *Let $\overline{\Delta} \triangleq \max_{v,b \in B} \Delta(v, b)$ and $\underline{\Delta} \triangleq \min_{v,b \in B} \Delta(v, b)$. Choosing $m = \frac{\pi}{24U} \sqrt{\frac{n\overline{\Delta}\underline{\Delta}}{|B| \ln T}}$, the asymptotic error of determining IC regret achieved by REGRET-UCB algorithm is upper bounded by*

$$\mathcal{E}(T) \leq O\left(\frac{|B|}{T} \cdot \left(\sqrt{\frac{|B| \ln T}{n}} + \frac{|B| \ln T}{n} \right) \right).$$

The big-Oh notation assumes $\overline{\Delta}$ and $\underline{\Delta}$ to be constants.

Note in the DSP problem, since we consider determining the worst-case IC regret over all possible valuations v, our asymptotic error bound quadratically grows as $|B|$, while for the advertiser problem the error linearly grows as $|B|$ since the benchmark we consider there is weaker than it in the DSP problem.

5 EXTENSION: STRONGER IC REGRET

In Section 4, we assume the test bidder (DSP) only chooses one valuation v_t at every time step t to empirically estimate IC regret. However, in practice, for each (value, bid) pair, the test bidder can switch the roles of bid and value to better estimate the IC regret.

Since there is no conceptual difference between bid and value in this setting, at time step t, the test bidder also submits a "bid" b_t^{m+1} for every auction in block $m+1$. We still denote the bids submitted at time t be $\vec{b}_t = \left\{b_t^1, b_t^2, \cdots, b_t^{m+1}\right\}$. The only difference between this case and our standard model is from the definition of *empirical IC regret*, we define the modified *empirical IC regret* in this setting as below,

Definition 5.1 (modified empirical IC regret).

$$\widetilde{rgt}_t(\vec{b}_t) = \max_{i,j \in [m+1], i \neq j} \left\{ \widetilde{u}_t^j(b_t^i, b_t^j) - \widetilde{u}_t^i(b_t^i, b_t^i) \right\}$$

The learning task in this setting is to design an efficient algorithm to generate $m+1$ bids at every time step to minimize *Pseudo-Regret*,

$$\mathbb{E}\left[R(T)\right] \triangleq \max_{v,b \in B} \sum_{t=1}^{T} rgt(v, b) - \mathbb{E}\left[\sum_{t=1}^{T} \widetilde{rgt}_t(\vec{b}_t) \right]$$

We extend our REGRET-UCB algorithm for unknown valuation (Algorithm 3) for this setting.

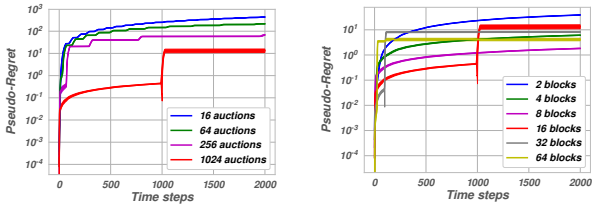
At each time step t, we update the UCB^{rgt} terms defined in Equation (6) for every (b_1, b_2) bids pair. Given these UCB^{rgt} terms, we run GENERATE-BIDS algorithm proposed in Algorithm 4 to generate $m+1$ bids and update $\hat{p}_t(b)$ and $\hat{g}_t(b)$ for any chosen b at time t.

Algorithm 4 GENERATE-BIDS Algorithm for generating bids given UCB^{rgt} terms.

Input: A finite set of bids B, UCB^{rgt} terms for every (b_1, b_2) bids pair, where $b_1, b_2 \in B$. Initialize a set $B_0 = \{\}$.
while $|B_0| < m+1$ **do**
  Choose the largest $\text{UCB}^{\text{rgt}}(b_1, b_2)$ such at $b_1 \notin B_0$ or $b_2 \notin B_0$.
  Update $B_0 \leftarrow B_0 \cup \{b_1, b_2\}$. [9]

We call the above algorithm for stronger IC regret estimation REGRET-UCB*, of which the *Pseudo-Regret* is shown in Theorem 5.2.

THEOREM 5.2. *REGRET-UCB* algorithm for DSP problem using stronger IC regret estimation achieves pseudo-regret at most*



$$\sum_{\substack{b_1, b_2 \in B, \\ (b_1, b_2) \neq (v^*, b^*)}} \frac{192(m+1)U^2 \ln T}{n\Delta(b_1, b_2)} + \frac{2\pi^2 \Delta(b_1, b_2)}{3(m+1)^2}$$

Note the *Pseudo-Regret* bound achieved by REGRET-UCB* algorithm is always better than it achieved by Algorithm 3 for any m. Then we can always get a better asymptotic error bound by REGRET-UCB* algorithm for the DSP problem.

COROLLARY 5.3. *Choosing $m = O\left(\frac{n}{\ln T}\right)^{1/3}$ the asymptotic error of determining IC regret achieved by REGRET-UCB algorithm is upper bounded by*[10]

$$\mathcal{E}(T) \leq O\left(\frac{|B|^2 (\ln T)^{2/3}}{n^{2/3} T} \right)$$

[9] If the two bids chosen in the last round are both not in B_0, we randomly choose one to add it in B_0.
[10] This asymptotic error bound can be achieved if the optimal m can be chosen to satisfy the constraint that $m < |B|$.

(a) (b)

Figure 1: *Pseudo-Regret* of Regret-UCB algorithm for known valuation $v = 9.5$ (Algorithm 1).

6 SIMULATIONS

In this section, we run some simulations with Generalized Second Price (GSP) auctions to validate our theoretical results. Every experiment is repeated for 10 times and the dash area represents the 95% confidence intervals of *Pseudo-Regret* at each time step.

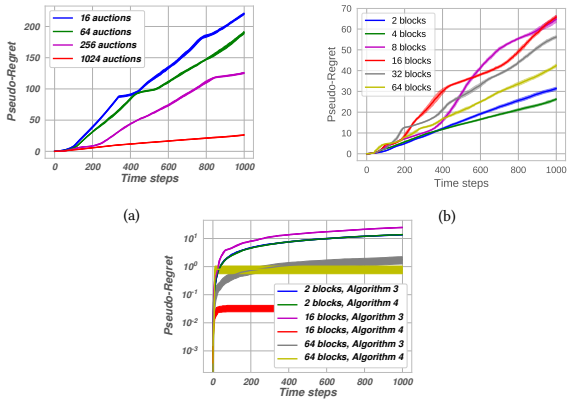
6.1 Settings

At each time t, the test bidder randomly participates n GSP auctions. Each auction has 5 slots and 20 bidders, each bidder's bid is i.i.d generated from $U[0, 10]$. The *click-through-rate* sequence of each auction is generated from descending ordered $Beta(2, 5)$ distribution[11]. We consider a finite bids space $B \triangleq \{0.01, 0.02, \cdots, 10\}$.

6.2 The advertiser problem

We test the performance of Regret-UCB algorithm for known valuation $v = 9.5$. First, we fix the number of blocks be 16 (i.e. $m = 15$) and plot the *Pseudo-Regret* achieved by Regret-UCB with different $n = 16, 64, 256, 1024$ (Figure 1(a)). We observe that the *Pseudo-Regret* decays linearly with n which is consistent with our analysis. Second, we fix $n = 1024$ and test the performance of the algorithm with different number of blocks, such as $m = 1, 3, 7, 15, 31, 63$ (Figure 1(a)). We find $m = 7$ (8 blocks) achieves the lowest *Pseudo-Regret*. When m is too large, the *Pseudo-Regret* curve incurs some shocks and suffers high variance because of the noisy observed information at each time.

6.3 The DSP problem

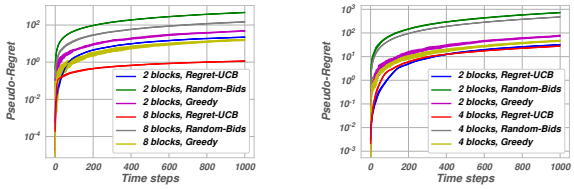


We test the performance of Regret-UCB for unknown valuation case (i.e., the DSP problem). Similarly, we show the *Pseudo-Regret* curve for different n given $m = 15$ and different m given $n = 1024$ in Figure 2. Figure 2(a) validates that *Pseudo-Regret* decays when n grows and we observe $m = 3$ (4 blocks) gives the best *Pseudo-Regret*. This corresponds to our theory that the optimal m in the DSP problem should be smaller than the optimal m in the advertiser problem for the same auction setting when $|B|$ is large (see Corollary (3.3) and (4.3)).

6.4 Efficiency of Regret-UCB algorithm

We first introduce two standard baselines, Random-Bids algorithm and ϵ-Greedy algorithm.

Random-Bids. At each time step t, the advertiser uniformly randomly choose m bids b_t, while the DSP uniformly randomly choose m bids b_t and a valuation v_t from B.



[11] *Click-through-rate* of each slot is first i.i.d generated from $Beta(2, 5)$ and then arranged by descending order.

(a) (b)

(c)

Figure 2: *Pseudo-Regret* plot of Regret-UCB algorithm for unknown valuation. (a): Algorithm 3 for different n, (b): Algorithm 3 for different m and (c): a semi-logarithmic *Pseudo-Regret* to compare Algorithm 3 and Regret-UCB*.

(a) (b)

Figure 3: *Pseudo-Regret* with Random-Bids, ϵ-Greedy and Regret-UCB for the advertiser problem (a) and DSP problem (b).

ϵ-Greedy. For the advertiser problem with known valuation v, at each time step, the advertiser uniformly randomly chooses m bids from B with probability ϵ, otherwise, chooses the m bids that correspond to the largest average utility $\hat{u}(v, \cdot)$ terms.[12] For the DSP problem, at each time step t, the DSP uniformly randomly choose m bids b_t and a valuation v_t with probability ϵ. Otherwise, the DSP chooses the (v_t, b_t^1) pair corresponds to the largest $\widehat{rgt}$ terms and the rest $m - 1$ bids associated with the largest $\hat{u}(v_t, \cdot)$ terms.

We compare the performance of our Regret-UCB algorithm with the above two baselines for the advertiser problem and the DSP problem. For the both settings, Regret-UCB algorithm performs better than two baselines for different number of blocks.

6.5 Regret-UCB for stronger IC regret

Moreover, we compare the performance of Algorithm 3 and Regret-UCB* algorithm for different m given $n = 1024$ in Figure 2(c) to validate the theory that allowing switching value and bid leads to lower Pseudo-Regret.[13] In addition, we also observe the tradeoff between Pseudo-Regret and m of Regret-UCB* algorithm. Among $m = 1, 15, 63$, the optimal m is 15 (16 blocks) for Regret-UCB*

[12] In the experiments, we fix $\epsilon = 0.1$

[13] Based on our observation in the experiments, sometimes switching value and bid may "over-estimate" the IC regret, i.e. the empirical estimation of IC regret is sometimes larger than worst case IC regret.

algorithm. If we choose m too large, like $m = 63$, Pseudo-Regret is worse than the $m = 1$ case and incurs high variance.

ABSTRACT

We focus on the problem of interlinking Wikipedia tables with fine-grained table relations: `equivalent` and `subPartOf`. Such relations allow us to harness semantically related information by accessing related tables or facts therein. Determining the type of a relation is not trivial. Relations are dependent on the schemas, the cell-values, and the semantic overlap of the cell values in tables.

We propose *TableNet*, an approach for interlinking tables with `subPartOf` and `equivalent` relations. *TableNet* consists of two main steps: (i) for any *source* table we provide an *efficient* algorithm to find *candidate* related tables with *high coverage*, and (ii) a neural based approach that based on the table schemas and data, determines with *high accuracy* the fine-grained relation.

Based on an extensive evaluation with more than 3.2M tables, we show that TableNet retains more than 88% of relevant tables pairs, and assigns table relations with an accuracy of 90%.

1 INTRODUCTION

One of the most notable uses of Wikipedia is on knowledge base construction like DBpedia [2] or YAGO [14], built almost exclusively built with information coming from Wikipedia's infoboxes. Infoboxes have several advantages as they adhere to pre-defined templates and contain factual information (e.g. *bornIn* facts). However, they are sparse and the information they cover is very narrow. In most use cases of Wikipedia, availability of factual information is a fundamental requirement.

Wikipedia tables on the other hand are in abundance, and are rich in factual information for a wide range of topics. Wikipedia contains more than 3.23M tables from more than 520k articles. Thus far, their use has been limited, despite them covering a broad domain of information that can be used to answer complex queries, e.g., *"Award winning movies of horror Genre?"* the answer can be found from facts in *multiple tables*. However, question answering systems [1] built upon knowledge base facts, in most cases will provide *incomplete* answers or fail altogether. The sparsity or lack of factual information from infoboxes can be easily remedied by additionally considering facts from tables.

A rough estimate shows that from the 3.23M tables we can generate hundreds of millions of additional facts that can be converted into knowledge base triples [10]. This amount in reality is much higher, when tables are aligned. That is, currently, tables are seen in isolation, and *semantically* related tables are not interlinked. Table alignments allow us to access related tables as *supersets or subsets* (i.e. `subPartOf` relations) or `equivalent` tables, which in turn we can use to infer new knowledge and facts that can be used in QA systems or other use cases.

Determining the fine-grained table relations is not a trivial task. The relations are dependent on the semantics of the columns (e.g. a column with values of type `Country`), the context in which the column appears (e.g. *"Name"* is ambiguous and it can only be disambiguated through other columns in a table schema), cell values etc. Furthermore, not all columns are important for determining the table relation [13]. Finally, to establish relations amongst all relevant table pairs, we need to ensure the efficiency by avoiding exhaustive computations between all table pairs that can be cumbersome given the extent of tables in Wikipedia.

We propose *TableNet*, an approach with the goal of aligning tables with `equivalent` and `subPartOf` fine-grained relations. Our goal is to ensure that for any table, we can find with high coverage candidate tables for alignment, and accurately determine the relation type for a given pair. We distinguish between two main steps: (i) efficient and high coverage table candidate generation for alignment, and (ii) relation type prediction by leveraging table schemas and values therein. An extensive evaluation of *TableNet* over the entire English Wikipedia with more than 3.2 million tables, shows that we are able to retain table pairs with a high coverage of 88%, and predict the fine-grained relation with an accuracy of 90%.

2 RELATED WORK

Google Fusion Tables [5, 6, 13, 15] are the most significant efforts in providing additional semantics over tables, and to the best of our knowledge, only some of the works carried in this project are most related to our work, against which we provide fair comparisons [13].

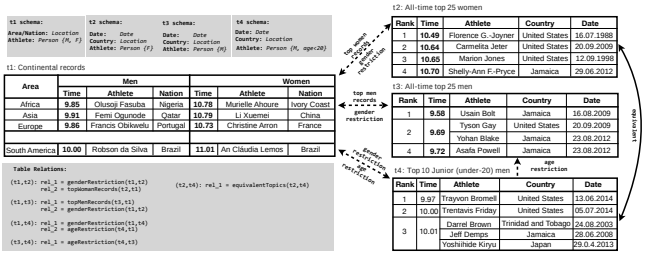

Figure 1: Table alignment example with `subPartOf` (dashed line), and `equivalent` relations (full line).

Carafella et al. [5] propose an approach for table extraction from Web pages and also provide a ranking mechanism for table retrieval. An additional aspect they consider is the schema auto-completion, specifically column recommendation for some input column to generate a "complete" schema. Our goals are different, while, we aim at providing more fine-grained representations of columns in a table schema, our goal is to use this information for table alignment.

Das Sarma et al. [13] propose an approach for finding related tables for two scenarios: (i) *entity complement* and (ii) *schema complement*. For (i), the task is to align tables with similar table schemas, however, with complementary instances. In (ii), the columns of a target table are used to complement the schema of a source table, with the precondition that the instances (from *subject* columns) are the same in both tables.

Our work is related to the first case. In the entity complement case [13] the *schema similarity* between two tables is computed in order to decide if a table can be considered for complementing the instances in another table. The similarity of the schemas is considered as a max-weight bipartite matching approach. The edges are weighted and are established between the columns in the disparate schemas. The weights correspond to the *string similarity* between column names and jaccard similarity between the column types (established from the values in a column through the `WebIsA` database). Despite the fact that this approach is unsupervised, we adapt it such that we find the best threshold of the max-weight matching, and consider tables to be either *aligned* or *not-aligned*.

3 PRELIMINARIES AND OVERVIEW

3.1 Terminology

We consider Wikipedia articles $A = \{a_1, \ldots, a_n\}$; each article a is associated with a set of Wikipedia categories $\Psi_a = \{\psi_1, \ldots, \psi_n\}$. From all the categories we induce the category graph Ψ, which consists of *parent* and *child* relations between categories ψ_i `childOf` ψ^p. The parent/child relations allow us to establish a hierarchical graph in Ψ. The level of a category is denoted by λ_ψ.

Next, we define the tables from an article a as $T_a = \{t_1, \ldots, t_n\}$. A table t has a *table schema* consisting of columns $C(t) = \{c_1, \ldots c_n\}$, where each column consists of a *textual description* and the set of all values $c_i = \langle desc, \{v_i^1, \ldots, v_i^n\}\rangle$ assigned to the corresponding column cells in the table rows $t_i(r) = \{r_i^1, \ldots, r_i^n\}$. More specifically, the cell value is indicated by v_i^k, where k is the row r^k and i is the column c_i. Cell values can point to existing articles in Wikipedia, that is $v_i^k = \langle a_k \rangle$, which we will refer to as *instance values*, or *primitive values* in cases of text, numbers, dates etc.

For the tables $T = \{t_1, \ldots, t_n\}$ from A, we define two fine-grained types of relations for a table pair $\langle t_i, t_j \rangle$: (i) $t_i \vDash t_j$ where t_j is considered to be *semantically* a `subPartOf` of t_i, and (ii) $t_i \equiv t_j$ where t_i and t_j are *semantically* `equivalent`. We indicate a relation with $r(t_i, t_j) \neq \emptyset$, and define in the next section the table relations.

3.2 Table Alignment Task Definition

Table Alignment. Our task is to determine the *fine-grained relation* for a table pair $r(t_i, t_j)$ from the articles $\langle a_i, a_j \rangle$. The relations can be either `subPartOf`, `equivalent` or `none` (in case $r(t_i, t_j) = \emptyset$).

Definition 1 (subPartOf). *For $r(t_i, t_j) = \{$`subPartOf`$\}$ holds if the schema $C(t_i)$ can subsume either at the **data value** (i.e. **cell-value**) or **semantically** the columns from $C(t_j)$, i.e., $C(t_i) \supseteq C(t_j)$.*

Definition 2 (equivalent). *For a pair $r(t_i, t_j) = \{$`equivalent`$\}$ holds if both table schemas have **semantically similar** column representation, that is, $C(t_i) \approx C(t_j)$.*

3.3 TableNet Overview

In TableNet, for any *source* article $a_i \in A$, we first generate candidate pairs $\langle a_i, a_j \rangle$, such that the likelihood of the corresponding tables to have a relation is high. We describe the two main steps: (1) article candidate pair generation, and (2) table alignment.

4 ARTICLE CANDIDATE PAIR GENERATION

Table 1: Article candidate pair features.

	feature	*description*	*group*
f_1	*tfidf*	*tfidf* similarity between abstracts	*abstract*
f_2	*d2v*	*doc2vec* similarity between abstracts	
f_3	*w2v*	*avg.* word2vec abstract vectors similarity	
f_4	$sim(\Psi_{a_i}, \Psi_{a_j})$	similarity in embedding space between Ψ_a and Ψ_a^p categories for the article pair	*Ψ & KB*
f_5	$\bigcap_{a \in \langle a_i, a_j \rangle} \Psi_a$	direct and parent categories overlap	
f_6	$sim(a_i, a_j)$	embedding similarity of the article pair	
f_7	*type*	type overlap	
f_8	$sim(\psi_i, \psi_j)$	column title similarity (f_8^l) and column distance (f_8^d) between the schemas in a table pair	*tables*
f_9	$\lVert\gamma(\psi_i) - \gamma(\psi_j)\rVert$	category representation similarity γ	

In this step, we address the problem of determining article pairs, whose tables will result in a relation. Here, we are interested in two main properties: (1) minimize the amount of *irrelevant article pairs*, whose tables do not have a relation, and (2) filtering out of article pairs should not affect the coverage of relevant pairs (i.e. whose tables in a table relation.

With these properties in mind, we define features and use them in two ways: (i) filter out irrelevant article pairs, and (ii) employ the features in a supervised manner to further filter out such pairs.

4.1 Features

Table 1 shows all the features. We omit the description of features that are obvious from the table.

Article Abstract. Abstracts contain a summary of the most important information of an article. This feature ensures *topical/semantic* similarities between a pair of articles, through contextual similarities like *doc2vec* [9], word based similarity in the embedding space [11], or through *tf-idf* which captures the salience of tokens.

Categories & Knowledge Bases. Wikipedia categories are indicators that two articles are semantically similar. Categories are associated *manually* to articles, and thus are prone to noise. We circumvent this problem by computing *graph embeddings* based on the category graph Ψ, and use node2vec embedding [7] to elevate the category comparisons from the link based structure in Ψ into the embedding space. The features represent the cosine similarity in the embedding space for an article pair, specifically between the *directly associated* and *parent* categories, the articles themselves.

Tables. Article pair features capture only coarse grained similarity. Thus, we compute light-weight features between the columns of a table pair. The features correspond to the maximal similarity w.r.t the *average word embedding* of the column descriptions, and additionally we compute the *positional index difference* between the matching columns in the respective tables.

Column-Representation. For a column c_i with instance-values, we compute a representation based on the attributes associated with the instances $\{v_i\}$ in a target KB, e.g. v_i^1 = *"George Lucas'* ***bornIn*** *"Modesto, California, U.S."*. Since usually there are multiple instances $|v_i| > 1$ for c_i, we find the *lowest common ancestor* ψ_L category from $\{v_i\}$ in the category graph Ψ, which can be seen as a the common *type* of instances in $\{v_i\}$. The representations allow us to compute the semantic similarity between columns.

The representation of c_i is computed as in Equation 1. We weigh the importance of *attributes* based on how discriminative they are for ψ_L, e.g. an attribute associated with articles directly belonging to category ψ_L are exclusive for ψ_L, and thus are weighted high. For an attribute p, the weight for ψ_L is computed as following:

$$\gamma(p, \psi_L) = \frac{\lambda_{\psi_L}}{\max \lambda_{\psi}} * \left(-\log \frac{|\bigcup o| : \forall \langle a, p, o \rangle \wedge a \in \psi_L}{|o| : \forall \langle a, p, o \rangle \wedge a \in \psi_L} \right) \quad (1)$$

where, the first part of the fraction weighs p by taking into account the level of λ_{ψ_L} and the deepest category where p is present in a target KB. $|\bigcup o|$ represents the number of distinct values assigned to attribute p in ψ_L, whereas $|o|$ is the total number of assignments.

Through $\gamma(\psi_L)$ we capture the most *important* and *descriptive* attributes for a column. For columns whose representations yield a high cosine similarity is an indicator of high semantic similarity.

4.2 Filtering & Classification

We use the computed features in two ways: (i) filter out irrelevant article pairs (i.e. *unlikely* to have a table relation), and (ii) train a supervised model to classify article pairs as *relevant* or *irrelevant*.

Filtering. We consider a *conjunction* of filtering criteria based on empirically evaluated thresholds for the individual features. Our main goal is to retain a high coverage of *relevant article pairs*, and at the same time filter out drastically *irrelevant pairs*. For thresholds we consider the *mean* value of a particular feature. This is an indicator that the pair is unlikely to yield any table relation based on a given feature. Section 7 shows that we are able to drastically reduce the number of pairs by simply applying such thresholds.

Classification. From the remaining pairs we train a classification model and classify pairs as either *relevant* or *irrelevant*. We consider as positive instances all table pairs from the article pair $\langle a_i, a_j \rangle$ which have *at least one* table relation, i.e, $r(t_i, t_j) \neq \texttt{none}$, where $\exists(t_i \in a_i \wedge t_j \in a_j)$.

We use Random Forests (RF) [4] for classification, as they allow to set *minimal amount of samples* that are allowed for a node in the tree to be split. This directly impacts the accuracy of the classifier, however, it allows us to retain high coverage. Setting this number high makes the leafs of the different trees to be impure containing relevant and irrelevant article pairs. Our classifier will classify such impure leafs as relevant. Section 7 shows that we can maintain high coverage of relevant pairs and at the same drastically reduce the amount of irrelevant pairs.

5 TABLE ALIGNMENT

TableNet is a bidirectional recurrent neural network (RNN) with LSTM cells, which classifies a table pair $r(t_i, t_j)$ into one of the relations `equivalent`, `subPartOf`, or `none`. For a model to accurately align table, the *order* of columns in their schemas needs to be taken into account. Additionally, the matching columns in the two schemas need to fulfill two main criteria: (i) the *context* in which the columns occur needs to be semantically similar, and (ii) the *positions* of the columns needs to be comparably similar [13].

5.1 Table Representation

How we represent columns is key towards an accurate alignment model. A column in a table schema consists of the following information $c_i = \langle desc, \{v_i^1, \ldots v_1^n\} \rangle$ (see Section 3).

Column Description. The column description is a strong indicator of the cell-values v_i. We represent the description based on GloVe pre-trained word embeddings [11]. In the case of multiple tokens, we average the word embeddings. One disadvantage of this representation is that the description can be ambiguous, e.g., *"Title"* can refer to various different value types, e.g. `Movies, Books` etc.

Instance–Values. In case c_i contains *instance values*, we represent c_i through the average embeddings of the values v_i based on pre-computed graph embeddings. We use *node2vec* embeddings [7] trained on the Wikipedia *anchor graph*[1]. The combination of *description* and *instance values* improves the representation of a column and reduces its ambiguity.

Column–Type. Representing the columns based solely on instance values poses a risk of biasing the column representation towards articles that are often linked together in the Wikipedia anchor graph, and thus it may ignore the topic information that is present in such articles based on their category associations.

For columns that contain instance values, we additionally represent it through its *type* or *category*. From the instances v_i of c_i, we extract their LCA category from Ψ (a similar idea was employed by Das Sarma et al. [13]). We represent the LCA category through graph embeddings. In cases we have multiple LCA categories, then we average their corresponding representations.

[1]The anchor graph consists of nodes (Wikipedia articles and categories), while the edges correspond to the anchor text and the category-article associations.

5.2 Table Alignment Architecture

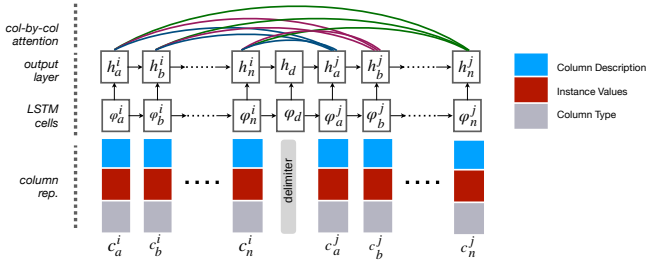

Figure 2: TableNet uses *BiLSTMs* to encode the tables as a sequence of columns. The *column-by-column* captures alignments between columns.

TableNet adopts the model from [12], and for a table pair $r(t_i, t_j)$ it predicts the relation as `equivalent`, `subPartOf`, or `none`. The alignment model is a bidirectional LSTM [8]. We compute a *column-by-column* attention, which helps us generate soft-alignments between columns in the table schemas, and thus further improve the alignment accuracy. Below we describe the encoding of table columns, and the intuition behind the attention mechanism.

Table Encoding. Since we have two separate tables, a precondition for accurate alignment is the encoding of the sequence of columns. Our model provides a *conditional encoding*, in that it first reads the columns from $C(t_i)$, then the cell state c_d (the table separator) is initialized with the last state of t_i (in this case c_n^i) and is used to conditionally encode the sequence of columns in $C(t_j)$.

The advantage of the conditional encoding is that by encoding table t_j with initial cell state that corresponds to the last column cell state of t_i, we bias the model to learn encodings that are optimal for the task of table alignment. That is instead of trying to encode all columns, it will learn to encode the columns of t_j such that it can best predict the relation for the table pair. Since we have a bidirectional LSTM, we encode in a similar fashion the table t_i by conditioning it on the last state of t_j.

Attention Mechanism. For a table pair to be aligned with either `equivalent` or `subPartOf` relation, we expect that the most important columns in each of the tables to have their corresponding matches. This is inline with the intuition that not all columns in a table are equally important [13].

The classification of the table pair $r(t_i, t_j)$ through a standard RNN model, is done by using the last cell state of the encoded table pair. This additionally forces the model to consider columns as being equally important. A common workaround is to use attention mechanism [3] or *global attention*, which is able to capture the importance of certain sequences. However, global attention is geared for language generation tasks, and as such is not suitable for the classification of $r(t_i, t_j)$.

Column-by-Column Attention. In TableNet, we employ the *column-by-column* attention mechanism, which works as following. After having encoded the last column from t_i, we process the columns in t_j individually and generate the attention weights w.r.t the columns in t_i. As a consequence, for each column in t_j we generate soft alignments to highest matching columns in t_j. After having processed all the columns in t_j and computing the corresponding attention weights (the upper part in Figure 2), for classification of the table pair $r(t_i, t_j)$ we will use a non-linear combination of the weighted representation of the last column c_n^j in t_j. We use *softmax* classification function for determining the label for $r(t_i, t_j)$.

6 EXPERIMENTAL SETUP

Here we describe the experimental setup. The entire evaluation setup and code of TableNet are available for download.[2]

6.1 Wikpedida Tables Dataset

We extract tables from the HTML content of Wikipedia articles. From the entire snapshot of Wikipedia, only 529,170 Wikipedia articles contain tables, resulting in a total of 3,238,201 tables. On average there are **6 tables per article** with an average of **6.6 columns**, and with an average of **10 rows** per table.

Additionally, more than 20% of columns in total are instance-values based (see Section 3), and additionally more than 85% of tables contain such columns. This shows that in the vast majority of cases, we can represent tables, specifically the columns with highly rich semantic representations.

6.2 Table Alignment Ground-Truth

Our ground-truth consists of a sample of 50 source Wikipedia articles from which we construct article candidate pairs. Since the *naive* approach would generate 26.5M pairs, we apply a set of *filtering keywords* to filter out irrelevant pairs. We filter articles by checking if a keyword appears *anywhere* in the article's content[3].

We manually inspect a random sample of pairs that are filtered out, and assess if we remove pairs that should be considered relevant, and consequentially refine the keywords. For article pairs that remain after filtering, we check if they can be seen as *false positives* and similarly refine our filtering keywords to remove such cases. We iteratively apply the refine and filtering steps, until we are left with an initial set of article pairs that we deploy for evaluation through crowdsourcing.

For the 50 source articles, we are left with 3.7k pairs after three rounds of filtering refinements, which result in a set of 17k table pairs that we evaluate by means of crowdsourcing.

6.2.1 Ground-Truth Statistics. From **17,047 table pairs**, after labeling our ground-truth consists of 52% table pairs marked with `noalignment` relation, 24% marked with as having `equivalent` alignment, and the remaining 23% with `subPartOf` relation. The 47% portion of table pairs with a relation, result from **876 article pairs**. The average agreement rate amongst crowdworkers is 0.91.

6.3 Baselines and TableNet setup

We compare *TableNet* in two main aspects: (i) efficiency in candidate pair generation, and (ii) table alignment.

6.3.1 ***Candidate Generation Baselines.***

Greedy – G. For each article we consider all other articles as pairs. This has maximal coverage, however, the amount of irrelevant pairs is extremely high.

[2] https://github.com/bfetahu/wiki_tables/

[3] A detailed description on the ground-truth generation is provided in the paper URL.

Direct Categories – C1. We consider as pairs articles that are associated with the same *directly connected* categories. Due to the noisy article-category associations, there is no guarantee that we will have maximal coverage of relevant pairs.
Deepest Category – C2. We consider as pairs all those articles that belong to the same *deepest associated category* in Ψ. Articles are associated with multiple categories across different levels in Ψ.
Parent Categories – PC. To increase the coverage of relevant pairs, we consider as pairs, articles that have the same *parent categories* based on the directly associated categories.

6.3.2 *Table Alignment Baselines.*

Google Fusion. The work in [13] finds related tables for a given table by computing a set relatedness scores against all possible table candidates. Two tables are related if their schemas are related based on max-weight bipartite graph matching score (see Section 2 for a detailed discussion). Google Fusion is unsupervised, thus, we use a threshold τ (we fine tune τ s.t we find the best F1 score) to classify table pairs as either having a relation or not.

BiLSTM. We train a BiLSTMs as a baseline for table alignment and use the different column representations from Section 5.

Setup: BiLSTM & TableNet. We use 100 dimensions for the *hidden layer* for the LSTM cells, and train for 50 epochs. We split the data with 60% for training, 10% for validation, and the remaining 30% for testing.

We represent columns based on the three representations (see Section 5). The simplest representation is the column description, TableNet^{d}, and then incrementally add the more complex representations, TableNet^{+v} and TableNet^{+t}, respectively.

6.4 Evaluation Metrics

Candidate Generation. The aim is to *minimize* the amount of *irrelevant article pairs* $\langle a_i, a_j \rangle = \emptyset$, and at the same time retain pairs whose tables have an alignment. We compute Δ to measure the amount of reduction we achieve w.r.t the *greedy* approach in generating article pairs:

$$\Delta = 1 - \frac{\langle a_i, a_j \rangle}{k * |A|} \text{ where } a_i \neq a_j \wedge a_i, a_j \in A \quad (2)$$

where, k is the number of source articles.

Coverage we measure through *micro* and *macro* recall indicated with R_μ and R, respectively. R_μ represents the recall in terms of all table pairs from all the source articles, whereas macro recall measures the average recall scores from all source articles.

Table Alignment. We measure the accuracy of the models for determining the table relation based on standard evaluation metrics, such as *precision* (P), *recall* (R), and *F1 score* (F1).

7 EVALUATION RESULTS

7.1 Candidate Generation Results

Table 2 shows the efficiency and coverage results for the baseline strategies. From the baselines we notice that the use of the Wikipedia category graph Ψ reduces the amount of irrelevant pairs drastically. In terms of recall, baseline **PC** maintains high recall with $R = 0.83$, and at the same time reduces by $\Delta = 87\%$ the amount of irrelevant pairs when compared to *greedy* approach. **C2** achieve the highest reduction rate Δ. Despite, the high reduction rates, we still face the issue of either having a highly imbalanced ratio of relevant and irrelevant pairs, or in some cases like **C2** where the reduction rate is the highest, the recall is low $R = 0.49$.

Table 2: Reduction rate for the baseline strategies.

	$\lvert\langle a_i, a_j \rangle\rvert$	Δ	*rel. pairs*	R
G	26,500,000	-	876	1.0
PC	3,486,031	0.87	724	0.83
C1	792,701	0.97	571	0.65
C2	6,738	0.99	440	0.50

TableNet: Filtering. The filtering step uses the features in Table 1 to remove irrelevant article pairs. Figure 3 shows the impact of the different features in reducing the amount of article pairs w.r.t *greedy* approach. For instance, the f_2 feature, which computes the similarity of article abstracts based on their *doc2vec* representation, provides a high reduction with $\Delta = 0.91$. This feature follows our intuition on generating the article pairs for the ground-truth (see Section 6), where the *topic* and other semantic similarities for an article pair can be extracted from the article's content.

Since different features capture different notions of similarity, we apply them in *conjunction*, resulting in very high reduction rate of article pairs with $\Delta > 0.99$, and at the same time retaining a relatively high coverage with $R = 0.68$. The reduction compared to the greedy approach is more than ▼255 times less pairs.

We believe that this high reduction rate and at the same time the relatively high recall of relevant pairs, when compared to the baseline approaches can be attributed to the fact that we consider the similarities of articles, and their corresponding categories and articles' content in the embedding space. This allows us to capture implicit semantics that cannot be captured through the simple link-based structure in the category graph Ψ.

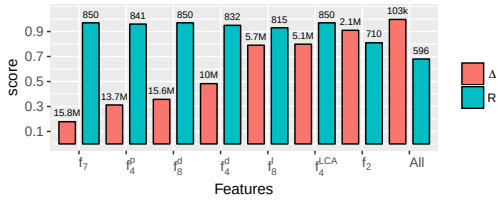

Figure 3: Feature impact in terms of reducing the amount of irrelevant pairs and the coverage of $\langle a_i, a_j \rangle_r$ pairs.

TableNet: Classification. Determining which article pairs, specifically, their tables will have a table relation is a difficult.

Despite the high reduction of irrelevant pairs from 26M pairs to 103k pairs, the amount of irrelevant pairs is still too high for any supervised approach to be able to learn models that predict with great accuracy the table relations. Thus, based on the configured RF model for high coverage (see Section 6), we train it on the feature set in Table 1 to further classify irrelevant pairs and filter them out.

Figure 4 shows the evaluation results for varying thresholds τ for the RF model. The increase of τ is directly proportional with the decrease in the amount of relevant pairs. This is intuitive as

from the 103k pairs, only 876 pairs are actually relevant. Based on the configuration of the RF (see Section 6), we retain relevant pairs with high coverage. We choose $\tau = 0.5$, as it shows the best trade-off between the coverage of relevant pairs, and the amount of irrelevant pairs that are passed onto the table alignment step. We achieve a high reduction rate of $\Delta = 0.982$ leaving us with only 1.8k pairs, and with a recall of $R_\mu = 0.81$.

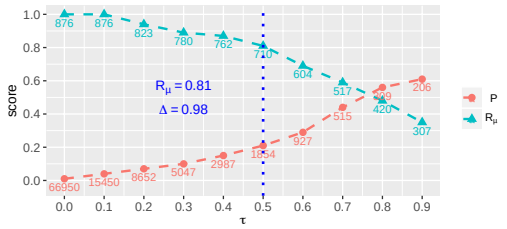

Figure 4: τ (x-axis) shows the scores for R_μ and P, and the corresponding amount of relevant pairs we retain.

Dependent on the scenario, higher τ can be used to have a higher ratio of relevant pairs, making the alignment task more efficient.

7.2 Table Alignment Results

Performance. Table 3 shows the table alignment evaluation results. In the case of *Google Fusion*, we consider a table pair to be *aligned* if their matching score is above some threshold that we determine empirically for which we achieve the highest F1 score.

Google Fusion. This baseline has a reasonably high accuracy in determining whether a $r(t_i, t_j) \neq \emptyset$. Here we cannot distinguish between the different classes as the approach is unsupervised. In terms of recall it has the lowest score. This is due to the fact that the matching is performed by considering only the *column type* and the *column title*similarity. Additionally, the *bipartite* matching algorithm cannot retain the order of the columns, which is highly important for determining the alignment relation.

BiLSTM. One key motivation in this work is the hypothesis that through sequence based models, we can retain the order of columns in their respective schemas, an important aspect in determining the table alignment relation. The BiLSTM approach represent a very competitive baseline. An additional advantage which addresses a deficiency in the standard supervised models, is that we jointly encode the different representations of a column for the classification task. Representing the columns as a combination of their description through word embeddings, and the type and instance values through graph embeddings, we can capture complex relationship between the column description and the underlying cell-values.

For `equivalent` relations, BiLSTM^{+d} achieves a very high F1 score with $F1 = 0.887$, which is close to the best result we achieve with TableNet^{+v}. For `subPartOf` relations, BiLSTM^{+v} the representation based on the column description and instance values achieves the highest F1 scores. The introduction of the column type in BiLSTM^{+t} provides a further boost in the accuracy of determining `subPartOf` relations. One conclusion we draw from the comparison between the two relations and two models, is that for `subPartOf` relations the *column type* provides additional power on determining the table alignment relation, whereas for `equivalent` it does not provide an additional advantage. These findings are inline with [13], where column type can provide important information in finding related tables. Comparing BiLSTM against *Google Fusion* we have a 64% improvement for `equivalent` relation.

TableNet. In our approach, we addressed several deficiencies from the related work. Through our *column-by-column* attention mechanism, we can compute soft alignments between columns in the respective table schemas and thus take into account the position of the matching columns in the corresponding schemas. Additionally, the column representations allow us to capture the similarity between columns and the schema context in which they appear, and additionally the representation context based on their description, type and its instance values.

The evaluation results reflect this intuition. Comparing our best performing setup, TableNet^{+t} achieves an overall $F1 = 0.840$ across all three classes, which presents also the highest F1 score across all competitors. We achieve a relative improvement of 64% when comparing F1 scores for the `equivalent` class against *Google Fusion*, or 56% if we compare the average F1 score for both alignment relations (`equivalent` and `subPartOf`). Furthermore, TableNet^{+t} outperforms the BiLSTM approach on average F1 score across all classes. For the individual classes, we note a variations amongst the different configurations of TableNet that perform best (marked in bold). This confirms the usefulness of the attention mechanism for the alignment task, where we achieve an overall better performance in terms of F1 score.

8 CONCLUSIONS AND FUTURE WORK

We presented TableNet, an approach for table alignment that ensures *high coverage* of retained table relations, and provides highly accurate *fine-grained* table alignments.

We constructed an exhaustive ground truth for a random sample of 50 Wikipedia articles for which we labeled all possible table pairs, providing a dataset against which we can measure the coverage and accuracy of approaches in determining table relations for more than 17k table pairs in our ground-truth.

In terms of *efficiency*, we show that from a naive approach which produces 26.5M pairs, we can guarantee a high coverage of retaining relevant article pairs with more than 68%, while, at the same time reducing the amount of irrelevant pairs by ▼255 times. In terms of *table alignment*, we show that we can improve over strong baselines and provide high improvement over strong baselines and other competitors like *Google Fusion*.

ABSTRACT

With the development of graph convolutional networks (GCN), deep learning methods have started to be used on graph data. In additional to convolutional layers, pooling layers are another important components of deep learning. However, no effective pooling methods have been developed for graphs currently. In this work, we propose the graph pooling (gPool) layer, which employs a trainable projection vector to measure the importance of nodes in graphs. By selecting the k-most important nodes to form the new graph, gPool achieves the same objective as regular max pooling layers operation on images and texts. Another limitation of GCN when used on graph-based text representation tasks is that, GCNs do not consider the order information of nodes in graph. To address this limitation, we propose the hybrid convolutional (hConv) layer that combines GCN and regular convolutional operations. The hConv layer is capable of increasing receptive fields quickly and computing features automatically. Based on the proposed gPool and hConv layers, we develop new deep networks for text categorization tasks. Our experimental results show that the networks based on gPool and hConv layers achieves new state-of-the-art performance as compared to baseline methods.

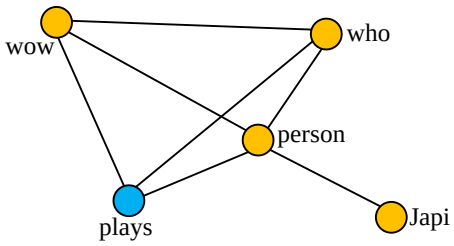
1 INTRODUCTION

Convolutional neural networks (CNNs) [11] have shown great capability of solving challenging tasks in various fields such as computer vision and natural language processing (NLP). A variety of CNN networks have been proposed to continuously set new performance records [4, 6, 10, 28]. In addition to image-related tasks, CNNs are also successfully applied to NLP tasks such as text classification [38] and neural machine translation [1, 31]. The power of CNNs lies in trainable local filters for automatic feature extraction. The networks can decide which kind of features to extract with the help of these trainable local filters, thereby avoiding hand-crafted feature extractors [33].

One common characteristic behind the above tasks is that both images and texts can be represented in grid-like structures, thereby enabling the application of convolutional operations. However, some data in real-world can be naturally represented as graphs such as social networks. There are primarily two types of tasks on graph data; those are, node classification [9, 32] and graph classification [21, 34]. Graph convolutional networks (GCNs) [9] and graph attention networks (GATs) [32] have been proposed for node classification tasks under both transductive and inductive learning settings. However, GCNs lack the capability of automatic high-level feature extraction, since no trainable local filters are used.



In addition to convolutional layers, pooling layers are another important components in CNNs by helping to enlarge receptive fields and reduce the risk of over-fitting. However, there are still no effective pooling operations that can operate on graph data and extract sub-graphs. Meanwhile, GCNs have been applied on text data by converting texts into graphs [15, 27]. Although GCNs can operate on graphs converted from texts, they ignore the ordering information between nodes, which correspond to words in texts.

In this work, we propose a novel pooling layer, known as the graph pooling (gPool) layer, that acts on graph data. Our method employs a trainable projection vector to measure the importance of nodes in a graph. Based on measurement scores, we rank and select k-largest nodes to form a new sub-graph, thereby achieving pooling operation on graph data. When working on graphs converted from text data, the words are treated as nodes in the graphs. By maintaining the order information in nodes' feature matrices, we can apply convolutional operations to feature matrices. Based on this observation, we develop a new graph convolutional layer, known as the hybrid convolutional (hConv) layer. Based on gPool and hConv layers, we develop a shallow but effective architecture for text modeling tasks [16]. Results on text classification tasks demonstrate the effectiveness of our proposed methods as compared to previous CNN models.

2 RELATED WORK

Before applying graph-based methods on text data, we need to convert texts to graphs. In this section, we discuss related literatures on converting texts to graphs and use of GCNs on text data.

"Japi is a person who plays wow."

Figure 1: Example of converting text to a graph using the graph-of-words method. For this text, we use noun, adjective, and verb as terms for node selection. The words of "Japi", "person", "who", "plays", and "wow" are selected as nodes in the graph. We employ a sliding window size of 4 for edge building. For instance, there is an undirected edge between "Japi" and "person", since they can be covered in the same sliding window in the original text.

2.1 Text to Graph Conversion

Many graph representations of texts have been explored to capture the inherent topology and dependence information between words. Bronselaer and Pasi [3] employed a rule-based classifier to map each tag onto graph nodes and edges. The tags are acquired by the part-of-speech (POS) tagging techniques. In [15] a concept interaction graph representation is proposed for capturing complex interactions among sentences and concepts in documents. The graph-of-word representation (GoW) [19] attempts to capture co-occurrence relationships between words known as terms. It was initially applied to text ranking task and has been widely used in many NLP tasks such as information retrieval [25], text classification [17, 24], keyword extraction [26, 30] and document similarity measurement [22].

Before applying graph-based text modeling methods, we need to convert texts to graphs. In this work, we employ the graph-of-words [19] method for its effectiveness and simplicity. The conversion starts with the phase preprocessing such as tokenization and text cleaning. After preprocessing, each text is encoded into an unweighted and undirected graph in which nodes represent selected terms and edges represent co-occurrences between terms within a fixed sliding window. A term is a group of words clustered based on their part-of-speech tags such as noun and adjective. The choice of sliding window size depends on the average lengths of processed texts. Figure 1 provides an example of this method.

2.2 GCN and its Applications on Text Modeling

Recently, many studies [9, 32] have attempted to apply convolutional operations on graph data. Graph convolutional networks (GCNs) [9] were proposed and have achieved the state-of-the-art performance on inductive and transductive node classification tasks. The spectral graph convolution operation is defined such that a convolution-like operation can be applied on graph data. Basically, each GCN layer updates the feature representation of each node by aggregating the features of its neighboring nodes. To be specific, the layer-wise propagation rule of GCNs can be defined as $\text{gcn}(\hat{A}, X_\ell) = \sigma(\hat{D}^{-\frac{1}{2}}\hat{A}\hat{D}^{-\frac{1}{2}}X_\ell W_\ell)$, where X_ℓ and $X_{\ell+1}$ are input and output matrices of layer ℓ, respectively. The numbers of rows of two matrices are the same, which indicates that the number of nodes in graph does not change in GCN layers. We use $\hat{A} = A + I$ to include self-loop edges to the graph. The diagonal node degree matrix $\hat{D}$ is generated to normalize $\hat{A}$ such that the scale of feature vectors remains the same after aggregation. W^ℓ is the trainable weight matrix, which plays the role of linear transformation of each node's feature vector. Finally, $\sigma(\cdot)$ denotes the nonlinear activation function such as ReLU [20]. Later, graph attention networks (GAT) [32] are proposed to solve node classification tasks by using the attention mechanism [35].

In addition to graph data, some studies attempted to apply graph-based methods to grid-like data such as texts. Compared to traditional recurrent neural networks such as LSTM [5], GCNs have the advantage of considering long-term dependencies by edges in graphs. Marcheggiani and Titov [18] applied a variant of GCNs to the task of sentence encoding and achieved better performance than LSTM. GCNs have also been used in neural machine translation tasks [2]. Although graph convolutional operations have been extensively developed and explored, pooling operations on graphs are not well studied currently.

3 GRAPH POOLING AND HYBRID CONVOLUTIONAL OPERATIONS

In this section, we describe our proposed graph pooling (gPool) and hybrid convolutional (hConv) operations. Based on these two new layers, we develop FCN-like graph convolutional networks for text modeling tasks.

3.1 Graph Pooling Layer

Pooling layers are very important for CNNs on grid-like data such as images, as they can help quickly enlarge receptive fields and reduce feature map size, thereby resulting in better generalization and performance [36]. In pooling layers, input feature maps are partitioned into a set of non-overlapping rectangles on which non-linear down-sampling functions, such as maximum, are applied. Obviously, the partition scheme depends on the local adjacency on grid-like data like images. For instance in a max-pooling layer with a kernel size of 2×2, 4 spatially adjacent units form a partition. However, such kind of spatial adjacency information is not available for nodes on graphs. We cannot directly apply regular pooling layers to graph data.

To enable pooling operations on graph data, we propose the graph pooling layer (gPool), which adaptively selects a subset of important nodes to form a smaller new graph. Suppose a graph has N nodes and each node contains C features. We can represent the graph with two matrices; those are the adjacency matrix $A^\ell \in \mathbb{R}^{N\times N}$ and the feature matrix $X^\ell \in \mathbb{R}^{N\times C}$. Each row in X^ℓ corresponds to a node in the graph. We propose the layer-wise propagation rule of gPool to be defined as

$$\begin{aligned} \mathbf{y} &= |X^\ell \mathbf{p}^\ell|, & \text{idx} &= \text{rank}(\mathbf{y}, k), \\ A^{\ell+1} &= A^\ell(\text{idx}, \text{idx}), & \tilde{X}^\ell &= X^\ell(\text{idx}, :), \\ \tilde{\mathbf{y}} &= \tanh(\mathbf{y}(\text{idx})), & X^{\ell+1} &= \tilde{X}^\ell \odot \left(\tilde{\mathbf{y}}\mathbf{1}_C^T\right), \end{aligned} \tag{1}$$

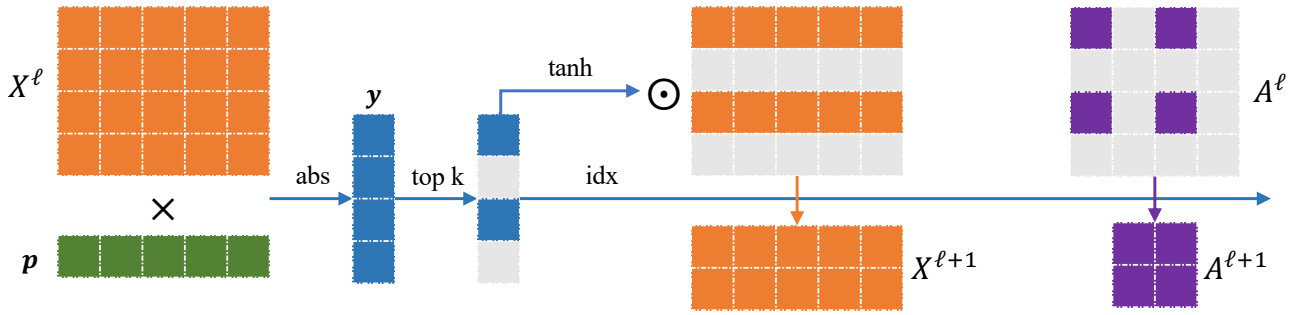

Figure 2: An illustration of the proposed graph pooling layer which samples $k = 2$ nodes. $\times$ and $\odot$ represent matrix and element-wise multiplication, respectively. This example graph has four nodes, each of which contains 5 features. We have the adjacency matrix $A^\ell \in \mathbb{R}^{4\times4}$ and the input feature matrix $X^\ell \in \mathbb{R}^{4\times5}$ of layer ℓ representing this graph. $\mathbf{p} \in \mathbb{R}^5$ is a trainable projection vector in this layer. By matrix multiplication and abs$(\cdot)$, we have scores $\mathbf{y}$ which estimate the closeness of each node to the projection vector. Using $k = 2$, we select two nodes with the highest scores and record their indices in idx, which represents indices of selected nodes. With indices idx, we extract corresponding nodes to form the new graph, which results in a new pooled feature map $\tilde{X}^\ell$ and adjacency matrix $A^{\ell+1}$. To control information flow, we create a gate vector by applying element-wise tanh$(\cdot)$ **to score vector $\mathbf{y}$. By element-wise multiplication between gate vector and $\tilde{X}^\ell$, we obtain the $X^{\ell+1}$. Outputs of this graph pooling layer are $A^{\ell+1}$ and $X^{\ell+1}$.**

where k is the number of nodes to be selected from the graph, $\mathbf{p}^\ell \in \mathbb{R}^C$ is a trainable projection vector of layer ℓ, rank$(\mathbf{y})$ is an operation that returns the indices corresponding to the k-largest values in $\mathbf{y}$, A^ℓ(idx, idx) extracts the rows and columns with indices idx, X^ℓ(idx, :) selects the rows with indices idx using all column values, $\mathbf{y}$(idx) returns the corresponding values in $\mathbf{y}$ with indices idx, $\mathbf{1}_C \in \mathbb{R}^C$ is a vector of size C with all components being 1, and $\odot$ denotes the element-wise matrix multiplication operation.

Suppose X^ℓ is a matrix with row vectors $\mathbf{x}_1^\ell, \mathbf{x}_2^\ell, \cdots, \mathbf{x}_N^\ell$. We first perform a matrix multiplication between X^ℓ and $\mathbf{p}^\ell$ followed by an element-wise abs$(\cdot)$ operation, resulting in $\mathbf{y} = [y_1, y_2, \cdots, y_N]^T$ with each y_i measuring the closeness between the node feature vector $\mathbf{x}_i^\ell$ and the projection vector $\mathbf{p}^\ell$.

The rank$(\cdot)$ operation ranks the N values in $\mathbf{y}$ and returns the indices of the k-largest values. Suppose the indices of the k selected values are $i_1, i_2, \cdots, i_k$ with $i_m < i_n$ if $1 \le m < n \le k$. These indices correspond to nodes in the graph. Note that the selection process retains the order information of selected nodes in the original feature matrix. With indices, the k-node selection is conducted on the feature matrix X^l, the adjacency matrix A^ℓ, and the score vector $\mathbf{y}$. We concatenate the corresponding feature vectors $\mathbf{x}_{i_1}^\ell, \mathbf{x}_{i_2}^\ell, \cdots, \mathbf{x}_{i_k}^\ell$ and output a matrix $\tilde{X}^\ell \in \mathbb{R}^{k\times C}$. Similarly, we use scores $\tanh(y_{i_1}), \tanh(y_{i_2}), \cdots, \tanh(y_{i_k})$ as elements of the vector $\tilde{\mathbf{y}} \in \mathbb{R}^k$. For the adjacency matrix A^ℓ, we extract rows and columns based on the selected indices and output the adjacency matrix $A^{\ell+1} \in \mathbb{R}^{k\times k}$ for the new graph.

Finally, we perform a gate operation to control the information flow in this layer. Using element-wise product of $\tilde{X}^\ell$ and $\tilde{\mathbf{y}}\mathbf{1}_C^T$, features of selected nodes are filtered through their corresponding scores and form the output $X^{\ell+1} \in \mathbb{R}^{k\times C}$. The ith row vector in $X^{\ell+1}$ is the product of the corresponding row vector in $\tilde{X}^\ell$ and the i^{th} scalar number in $\tilde{\mathbf{y}}$. In addition to information control, the gate operation also makes the projection vector $\mathbf{p}^\ell$ trainable with back-propagation [12]. Without the gate operation, the projection vector $\mathbf{p}^\ell$ only contributes discrete indices to outputs and thus is not trainable. Figure 2 provides an illustration of the gPool layer.

Compared to regular pooling layers used on grid-like data, our gPool layer involves extra parameters in the trainable projection vector $\mathbf{p}^\ell$. In Section 4.6, we show that the number of extra parameters is negligible and would not increase the risk of over-fitting.

3.2 Hybrid Convolutional Layer

It follows from the analysis in Section 2.2 that GCN layers only perform convolutional operations on each node. There is no trainable spatial filters as in regular convolution layers. GCNs do not have the power of automatic feature extraction as achieved by CNNs. This limits the capability of GCNs, especially in the field of graph modeling. In traditional graph data, there is no ordering information among nodes. In addition, the different numbers of neighbors for each node in the graph prohibit convolutional operations with a kernel size larger than 1. Although we attempt to modeling texts as graph data, they are essentially grid-like data with order information among nodes, thereby enabling the application of regular convolutional operations.

To take advantage of convolutional operations with trainable filters, we propose the hybrid convolutional layer (hConv), which combines GCN operations and regular 1-D convolutional operations to achieve the capability of automatic feature extraction. Formally, we propose the hConv layer to be defined as

$$\begin{aligned} X_1^{\ell+1} &= \text{conv}(X^\ell), \qquad X_2^{\ell+1} = \text{gcn}(A^\ell, X^\ell), \\ X^{\ell+1} &= \left[X_1^{\ell+1}, X_2^{\ell+1}\right], \end{aligned} \tag{2}$$

where conv$(\cdot)$ denotes a regular 1-D convolutional operation, and the gcn$(\cdot,\cdot)$ operation is defined in Eq. **??**. For the feature matrix X^ℓ, we treat the column dimension as the channel dimension, such that the 1-D convolutional operation can be applied along the row dimension. Using the 1-D convolutional operation and the GCN operation, we obtain two intermediate outputs; those are $X_1^{\ell+1}$ and

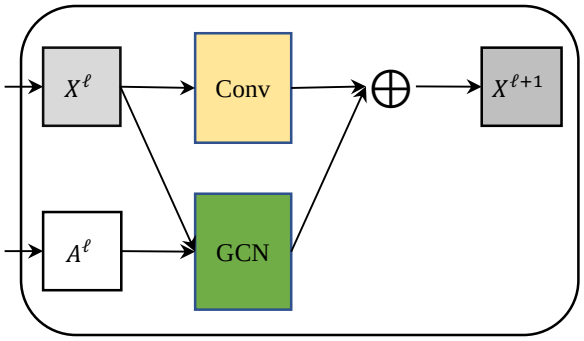

Figure 3: An illustration of the hybrid convolutional layer. $\oplus$ denotes matrix concatenation along the row dimension. In this layer, A^ℓ and X^ℓ are the adjacency matrix and the node feature matrix, respectively. A regular 1-D convolutional operation is used to extract high-level features from sentence texts. The GCN operation is applied at the graph level for feature extraction. The two intermediate outputs are concatenated together to form the final output $X^{\ell+1}$.

$X_2^{\ell+1}$. These two matrices are concatenated together as the layer output $X^{\ell+1}$. Figure 3 illustrates an example of the hConv layer.

We argue that the integration of GCN operations and 1-D convolutional operations in the hConv layer is especially applicable to graph data obtained from texts. By representing texts as an adjacency matrix A^ℓ and a node feature matrix X^ℓ of layer ℓ, each node in the graph is essentially a word in the text. We retain the order information of nodes from their original relative positions in texts. This indicates that the feature matrix X^ℓ is organized as traditional grid-like data with order information retained. From this point, we can apply an 1-D convolutional operation with kernel sizes larger than 1 on the feature matrix X^ℓ for high-level feature extraction.

The combination of the GCN operation and the convolutional operation in the hConv layer can take the advantages of both of them and overcome their respective limitations. In convolutional layers, the receptive fields of units on feature maps increase very slow since small kernel sizes are usually used to avoid massive number of parameters. In contrast, GCN operations can help to increase the receptive fields quickly by means of edges between terms in sentences corresponding to nodes in graphs. At the same time, GCN operations are not able to automatically extract high-level features as they do not have trainable spatial filters as used in convolutional operations. From this point, the hConv layer is especially useful when working on text-based graph data such as sentences and documents.

3.3 Network Architectures

Based on our proposed gPool and hConv layers, we design four network architectures, including our baseline with a FCN-like [16] architecture. FCN has been shown to be very effective for image semantic segmentation. It allows final linear classifiers to make use of features from different layers. Here, we design four architectures based on our proposed gPool and hConv layers.

Datasets	#Training	#Testing	#Classes	#Words
AG's News	120,000	7,600	4	45
DBPedia	560,000	70,000	14	55
Yelp Polarity	560,000	38,000	2	153
Yelp Full	650,000	50,000	5	155

Table 1: Summary of datasets used in our experiments. The #words denotes the average number of words of the data samples for each dataset. These numbers help the selection of the sliding window size used in converting texts to graphs.

- **GCN-Net:** We establish a baseline method by using GCN layers to build a network without any hConv or gPool layers. In this network, we stack 4 standard GCN layers as feature extractors. Starting from the second layer, a global max-pooling layer [14] is applied to each layer's output. The outputs of these pooling layers are concatenated together and fed into a fully-connected layer for final predictions. This network serves as a baseline model in this work for experimental studies.
- **GCN-gPool-Net:** In this network, we add our proposed gPool layers to GCN-Net. Starting from the second layer, we add a gPool layer after each GCN layer except for the last one. In each gPool layer, we select the hyper-parameter k to reduce the number of nodes in the graph by a factor of two. All other parts of the network remain the same as those of GCN-Net.
- **hConv-Net:** For this network, we replace all GCN layers in GCN-Net by our proposed hConv layers. To ensure the fairness of comparison among these networks, the hConv layers output the same number of feature maps as the corresponding GCN layers. Suppose the original ith GCN layer outputs n_{out} feature maps. In the corresponding hConv layer, both the GCN operation and the convolutional operation output $n_{out}/2$ feature maps. By concatenating those intermediate outputs, the ith hConv layer also outputs n_{out} feature maps. The remaining parts of the network remain the same as those in GCN-Net.
- **hConv-gPool-Net:** Based on the hConv-Net network, we add gPool layers after each hConv layer except for the first and the last layers. We employ the same principle for the selection of hyper-parameter k as that in GCN-gPool-Net. The remaining parts of the network remain the same. Note that gPool layers maintain the order information of nodes in the new graph, thus enabling the application of 1-D convolutional operations in hConv layers afterwards. Figure 4 provides an illustration of the hConv-gPool-Net network.

4 EXPERIMENTAL STUDY

In this section, we evaluate our gPool layer and hConv layer based on the four networks proposed in Section 3.3. We compare the performances of our networks with that of previous state-of-the-art models. The experimental results show that our methods yield improved performance in terms of classification accuracy. We also perform some ablation studies to examine the contributions of the gPool layer and the hConv layer to the performance. The number of extra parameters in gPool layers is shown to be negligible and will not increase the risk of over-fitting.

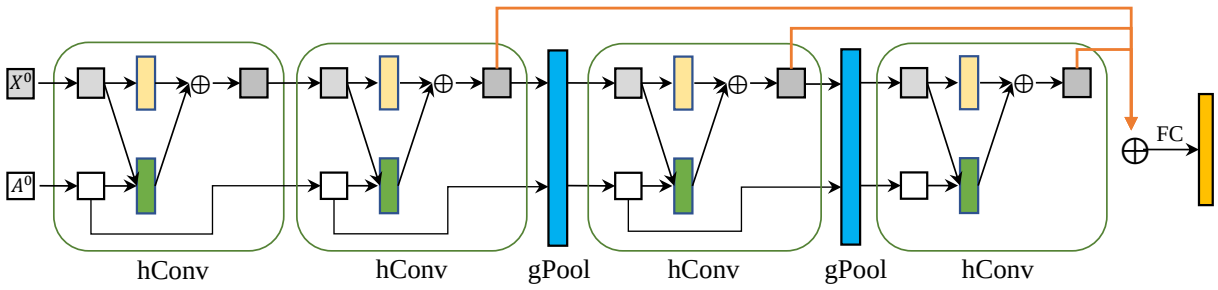

Figure 4: The architecture of the hConv-gPool-Net. $\oplus$ denotes the concatenation operation of feature maps. The inputs of the network are an adjacency matrix A^0 and a feature matrix X^0. We stack four hConv layers for feature extraction. In the second and the third hConv layers, we employ the gPool layers to reduce the number of nodes in graphs by half. Starting from the second hConv layer, a global max-pooling layer is applied to the output feature maps of each hConv layer. The outputs of these pooling layers are concatenated together. Finally, we employ a fully-connected layer for predictions. To obtain the other three networks discussed in Section 3.3, we can simply replace the hConv layers with GCN layers or remove gPool layers based on this network architecture.

Models	AG's News	DBPedia	Yelp Polarity	Yelp Full

Table 2: Results of text classification experiments in terms of classification error rate on the AG's News, DBPedia, Yelp Review Polarity, and Yelp Review Full datasets. The first two methods are the state-of-the-art models without using any unsupervised data. The last four networks are proposed in this work.

4.1 Datasets

In this work, we evaluate our methods on four datasets, including the AG's News, Dbpedia, Yelp Polarity, and Yelp Full [38] datasets. **AG's News** is a news dataset containing four topics: World, Sports, Business and Sci/Tech. The task is to classify each news into one of the topics. **Dbpedia** ontology dataset contains 14 ontology classes. It is constructed by choosing 14 non-overlapping classes from the DBPedia 2014 dataset [13]. Each sample contains a title and an abstract corresponding to a Wikipedia article. **Yelp Polarity** dataset is obtained from the Yelp Dataset Challenge in 2015 [38]. Each sample is a piece of review text with a binary label (negative or positive). **Yelp Full** dataset is obtained from the Yelp Dataset Challenge in 2015, which is for sentiment classification [38]. It contains five classes corresponding to the movie review star ranging from 1 to 5. The summary of these datasets are provided in Table 1. For all datasets, we tokenize the textual document and convert words to lower case. We remove stop-words and all punctuation in texts. Based on cleaned texts, we build the graph-of-word representations for texts.

4.2 Text to Graph Conversion

We use the graph-of-words method to convert texts into graph representations that include an adjacency matrix and a feature matrix. We select nouns, adjective, and verb as terms, meaning a word appears in the graph if it belongs to one of the above categories. We use a sliding window to decide if two terms have an edge between them. If the distance between two terms is less than the window size, an undirected edge between these two terms is added. In the generated graph, nodes are the terms appear in texts, and edges are added using the sliding window. We use a window size of 4 for the AG's News and DBpedia datasets and 10 for the other two datasets, depending on their average words in training samples. The maximum numbers of nodes in graphs for the AG's News, DBPedia, Yelp Polarity, Yelp Full datasets are 100, 100, 300, and 256, respectively.

To produce the feature matrix, we use word embedding and position embedding features. For word embedding features, the pre-trained fastText word embedding vectors [7] are used, and it contains more than 2 million pre-trained words vectors. Compared to other pre-trained word embedding vectors such as GloVe [23], using the fastText helps us to avoid massive unknown words. On the AG's News dataset, the number of unknown words with the fastText is only several hundred, which is significantly smaller than the number using GloVe. In addition to word embedding features, we also employ position embedding method proposed in Zeng et al. [37]. We encode the positions of words in texts into one-hot vectors and concatenate them with word embedding vectors. We obtain the feature matrix by stacking word vectors of nodes in the row dimension.

Models	Depth	Error Rate
Word-level CNN	9	8.55%
Character-level CNN	9	9.51%
GCN-Net	5	8.64%
GCN-gPool-Net	5	8.09%
hConv-Net	5	7.49%
hConv-gPool-Net	5	**7.09%**

Table 3: Comparison in terms of the network depth and the text classification error rate on the AG's News dataset. The depth listed here is calculated by counting the number of convolutional and fully-connected layers in networks.

Models	Error rate	# Params	Ratio of increase
GCN-Net	8.64%	1,554,820	0.00%
GCN-gPool-Net	**8.09%**	1,555,719	0.06%

Table 4: Comparison between the GCN-Net and GCN-gPool-Net in term of parameter numbers and text classification error rates on the AG's News dataset.

4.3 Experimental Setup

For our proposed networks, we employ the same settings with minor adjustments to accommodate the different datasets. As discussed in Section 3.3, we stack four GCN or hConv layers for GCN-based networks or hConv-based networks. For the networks using gPool layers, we add gPool layers after the second and the third GCN or hConv layers. Four GCN or hConv layers output 1024, 1024, 512, and 256 feature maps, respectively. We use this decreasing number of feature maps, since GCNs help to enlarge the receptive fields very quickly. We do not need more high-level features in deeper layers. The kernel sizes used by convolutional operations in hConv layers are all 3×1. For all layers, we use the ReLU [20] for nonlinearity. For all experiments, the following settings are shared. For training, the Adam optimizer [8] is used for 60 epochs. The learning rate starts at 0.001 and decays by 0.1 at the $30^t h$ and the $50^t h$ epoch. We employ the dropout with a keep rate of 0.55 [29] and batch size of 256. These hyper-parameters are tuned on the AG's News dataset, and then ported to other datasets.

4.4 Performance Study

We compare our proposed methods with other state-of-the-art models, and the experimental results are summarized in Table 2. We can see from the results that our hConv-gPool-Net outperforms both word-level CNN and character-level CNN by at least a margin of 1.46%, 0.45%, 0.23%, and 3.31% on the AG's News, DBPedia, Yelp Polarity, and Yelp Full datasets, respectively. The performance of GCN-Net with only GCN layers cannot compete with that of word-level CNN and char-level CNN primarily due to the lack of automatic high-level feature extraction. By replacing GCN layers using our proposed hConv layers, hConv-Net achieves better performance than the two CNN models across four datasets. This demonstrates the promising performance of our hConv layer by employing regular convolutional operations for automatic feature extraction. By comparing the GCN-Net with GCN-gPool-Net, and hConv-Net with hConv-gPool-Net, we observe that our proposed gPool layers promote both models' performance by at least a margin of 0.4%, 0.1%, 0.08%, and 1.54% on the AG's News, DBPedia, Yelp Polarity, and Yelp Full datasets. The margins tend to be larger on harder tasks. This observation demonstrates that our gPool layer helps to enlarge receptive fields and reduce spatial dimensions of graphs, resulting in better generalization and performance.

4.5 Network Depth Study

In addition to performance study, we also conduct experiments to evaluate the relationship between performance and network depth in terms of the number of convolutional and fully-connected layers in models. The results are summarized in Table 3. We can observe from the results that our models only require 5 layers, including 4 convolutional layers and 1 fully-connected layer. Both word-level CNN and character-level CNN models need 9 layers in their networks, which are much deeper than ours. Our hConv-gPool-Net achieves the new state-of-the-art performance with fewer layers, demonstrating the effectiveness of gPool and hConv layers. Since GCN and gPool layers enlarge receptive fields quickly, advanced features are learned in shallow layers, leading to shallow networks but better performance.

4.6 Parameter Study of gPool Layer

Since gPool layers involve extra trainable parameters in projection vectors, we study the number of parameters in gPool layers in the GCN-gPool-Net that contains two gPool layers. The results are summarized in Table 4. We can see from the results that gPool layers only needs 0.06% additional parameters compared to GCN-Net. We believe that this negligible increase of parameters will not increase the risk of over-fitting. With negligible additional parameters, gPool layers can yield a performance improvement of 0.54%.

5 CONCLUSION

In this work, we propose the gPool and hConv layers in FCN-like graph convolutional networks for text modeling. The gPool layer achieves the effect of regular pooling operations on graph data to extract important nodes in graphs. By learning a projection vector, all nodes are measured through cosine similarity with the projection vector. The nodes with the k-largest scores are extracted to form a new graph. The scores are then applied to the feature matrix for information control, leading to the additional benefit of making the projection vector trainable. Since graphs are extracted from texts, we maintain the node orders as in the original texts. We propose the hConv layer that combines GCN and regular convolutional operations to enable automatic high-level feature extraction. Based on our gPool and hConv layers, we propose four networks for the task of text categorization. Our results show that the model based on gPool and hConv layers achieves new state-of-the-art performance compared to CNN-based models. gPool layers involve negligible number of parameters but bring significant performance boosts, demonstrating its contributions to model performance.

ABSTRACT

An important task in Location based Social Network applications is to predict mobility – specifically, user's next point-of-interest (POI) – challenging due to the implicit feedback of footprints, sparsity of generated check-ins, and the joint impact of historical periodicity and recent check-ins. Motivated by recent success of deep variational inference, we propose VANext (Variational Attention based Next) POI prediction: a latent variable model for inferring user's next footprint, with historical mobility attention. The variational encoding captures latent features of recent mobility, followed by searching the similar historical trajectories for periodical patterns. A trajectory convolutional network is then used to learn historical mobility, significantly improving the efficiency over often used recurrent networks. A novel variational attention mechanism is proposed to exploit the periodicity of historical mobility patterns, combined with recent check-in preference to predict next POIs. We also implement a semi-supervised variant – VANext-S, which relies on variational encoding for pre-training all current trajectories in an unsupervised manner, and uses the latent variables to initialize the current trajectory learning. Experiments conducted on real-world datasets demonstrate that VANext and VANext-S outperform the state-of-the-art human mobility prediction models.

1 INTRODUCTION

Many users of Location-Based Social Networks (LBSNs) such as Foursquare and Twitter leave and/or share their footprints with friends. This has enabled new research in learning human mobility and using it in various settings – e.g., social relation inference [1], friendship prediction [24], trajectory-user linking [11, 34], etc. A critical task in understanding human mobility patterns is the next Point-of-Interest (POI) prediction – extensively studied in recent years [6, 7, 17, 27] and becomes of interest in many application domains – e.g., location sharing or recommendation for users of enterprises in social media [16]; route planing for taxi driver to maximize potential passenger pickups [27]; forecasting criminals/terrorists next location for public safety [11]; etc.

Many methods exploiting human recent mobility and their historical visits have been proposed for next POI prediction, including Matrix Factorization (MF) [16], Markov Chain (MC) [9], Factorizing Personalized Markov Chains (FPMC) [8] and Tensor Factorization (TF) [32], all incorporating human visit preferences and investigating sequential patterns. Deep learning techniques have also been applied in learning users' mobility – ST-RNN [17], POI2Vec [7], and DeepMove [6] – employing recurrent neural networks (RNN – e.g., LSTM [21] and GRU [4]) to capture the sequential patterns of users' mobility preferences. Given historical trajectories, these works train a RNN module to predict the next POI, together with corresponding contextual (e.g., spatial and temporal) features.

However, there are certain challenges for the existing works: (1) *Sparsity of recent mobility* – within a given period, a user may generate only a few check-ins (different from GPS data that is passively/continuously sampled), making the prediction difficult. (2) *Density of historical mobility* – LBSNs often collect user's check-ins for months and even years. In comparison with recent mobility, it is more difficult to represent and exploit the whole historical trajectory effectively and efficiently in a training model. (3) *Complex data* – user's historical moving patterns affect the subsequent footprints [3, 17], whereas individual check-in behaviors are complex and personalized.

To address the above challenges, we propose a novel model – Variational Attention based Next (VANext) POI prediction, leveraging the recent advances in variational Bayesian techniques [14] to encode recent mobility into a latent variable and use it to query

one's historical mobility. We also introduce a historical trajectory-based learning module implemented by a convolutional neural network (CNN) kernel – capturing individual's long-term moving patterns in a more efficient way, compared to widely used RNNs. Specifically, a variational attention on historical trajectory is combined with the latent representation learned from a recent trajectory to capture the similar check-in sequence (not necessarily continuous) which reflects user long-term visit intention. Finally, we concatenate representations of recent mobility and historical trajectory features to predict user's next POI. We also propose VANext-S – a semi-supervised variant, to better capture the latent variables by pre-training all current trajectories in an unsupervised manner within the framework of Variational Auto-Encoder (VAE) [14]. It samples from latent variables to generate and reconstruct each current trajectory, and utilizes the encoder to initialize VANext. In summary, our main contributions are:

• We frame the mobility prediction task using a generative probabilistic model together with neural networks, and propose VANext that can simultaneously learn implicit relationships between users and POIs and capture sequential patterns of user check-in behavior for next POI prediction.

• We introduce a novel variational attention mechanism to learn the attention on the historical trajectories, from which the latent representation of a recent trajectory is leveraged to match user's most similar moving patterns in the past.

• We conduct experiments on real-world datasets consisting of users' check-in behavior in four cities, demonstrating that VANext outperforms existing models in terms of both prediction accuracy and training efficiency.

To our knowledge, VANext is the first attempt to incorporate CNN to capture long term and structural dependency among user check-ins, achieving comparable learning ability with the state-of-the-art RNN based methods, while significantly improving the learning efficiency. For the rest of this paper, we first review the related work, then formalize the problem and present our main results, followed by experimental evaluations and concluding remarks.

2 RELATED WORK

POI recommendation and prediction are two different but related and extensively studied topics in LBSN: the former usually learns users' preferences over POIs while the latter is more interested in mobility pattern recognition. Collaborative filtering (CF)-based models, such as Matrix Factorization (MF) [2, 15, 16] and tensor factorization (TF) [32], are widely used in POI recommendation for learning users latent preferences. Geographical information [15, 16, 31], as well as time-aware influence and content-aware influence [10, 26, 30] are most effective features incorporated in enhancing recommendation performance [18]. However, these model-based methods are not suitable to predict user's next behavior/visits, due to the lack of taking sequential and periodical patterns into account. Markov Chains (MC)-based methods are widely used for modeling sequential influence. For example, FPMC [20] and FPMC-LR [3] aim to predict the user's next visit based on factorization of the probability transition matrix. In addition, embedding has also been applied for addressing next POI prediction [7, 8] – e.g., a Personalized Ranking Metric Embedding (PRME) [8], attempting to capture user preference with the latent space. Inspired by the word2vec [19] technique in NLP, POI2Vec [7] was proposed for next POI prediction with geographical influence included. However, both MC and embedding based methods are not capable of learning long term dependency of POIs and the periodicity of individual's historical moving.

Recently, deep learning techniques – especially recurrent neural networks (RNNs) such as LSTM [21] and GRU [4] – have been widely used to capture the long term sequential influence and mobility patterns. Spatial Temporal Recurrent Neural Networks (ST-RNN) [17] extend the RNN model by incorporating temporal and spatial context in each time unit for predicting next POIs. A unified RNN-based framework jointly learning the embeddings of multiple factors (e.g., user identity, location and time, etc.), was presented in [29]. However, these methods do not explicitly model user's historical visit patterns and personal preferences, but greatly focusing on current locations and short term dependencies among POIs. More recently, [6] propose an attentional recurrent network for mobility prediction from lengthy and sparse trajectories, where two RNN models – learning the current and the historical trajectory, respectively – together exploit user's mobility and location preference with attention on multi-level periodicity of historical trajectories. However, it is complicated to train due to the relative high density of historical trajectories.

CNNs have been widely applied in image classification and video tagging, but are less common for sequence embedding. A CNN-based architecture successfully improving the machine translation performance was recently proposed in [12]. Compared to RNN-based model, CNNs can easily capture hierarchical representations of the underlying context, and, most importantly, are faster to be trained due to parallelization with GPU. Variational Auto-Encoder (VAE) [14] has been applied in many NLP tasks, such as text classification [25] and dialogue generation [22], and has shown promising performance in exploiting underlying patterns of trajectories [34]. In addition, these models neither consider the contextual information associated with POIs, nor capture periodical mobility patterns, thereby cannot be directly employed for POI prediction.

Our proposed model VANext differs from these VAE-based methods in terms of its periodical pattern learning and the variational attention mechanism.

3 PRELIMINARIES

We now proceed with introducing the basic terminology and formalizing the problem, followed by the details of the proposed model – including causal POI embedding, variational current trajectory learning, historical trajectory attention module and the classifier.

A POI is defined as a location of relevance obtained, for example, as a GPS point; a centroid of a region; an address of an object, etc. – which can be uniquely identified in a suitable coordinate system. It is represented as a triplet $l = <id,lo,la>$, where id, lo and la denote the POI id, longitude and latitude. T^u denotes a trajectory generated by a user u, represented as a sequence $\mathrm{T}^u = (l^u_{t_1}, l^u_{t_2}, \cdots, l^u_{t_n})$, where $l^u_{t_i}$ is i-th POI visited by user u at time t_i. When there is no ambiguity, we will omit the superscript ^{u}. A trajectory T can be segmented as $\mathrm{T} = (\mathrm{T}^1, \mathrm{T}^2, \cdots, \mathrm{T}^m)$, meaning that there are m

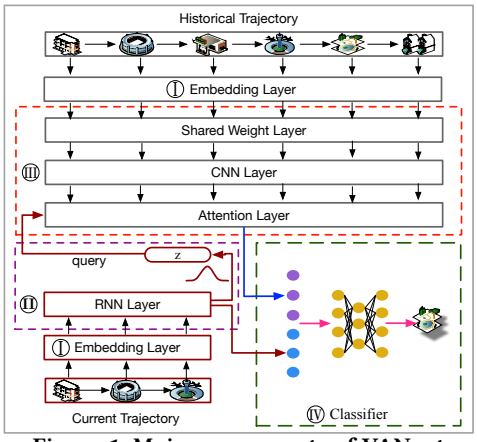

Figure 1: Main components of VANext

sub-trajectories within the time interval $[t_1, t_n]$, ordered along the temporal dimension. The trajectories are separated from each other by application dependent thresholds δ_{T}^{j} $(1 \le j \le m)$, which could indicate, for example: – the time span of each T^j is no more than δ_{T}^{j}; – the last time-stamp of T^j is at least δ_{T}^{j} time units smaller than the time-stamp of the first location in T^{j+1}; etc.

Let $\mathrm{T}_h = (\mathrm{T}^1, \cdots, \mathrm{T}^m)$ denote the entire historical trajectory of the user u (note that its time span may vary, from weeks, to months or even years for different users) and let $\mathrm{T}_c = \mathrm{T}^{m+1} = (l_{t_{n+1}}, l_{t_{n+2}}, \cdots, l_{t_{n+k-1}})$ denote the current/most recent sub-trajectory.

Problem formulation: We consider next POI prediction as a multi-classification problem, which is formulated as: given a user u with the historical trajectory T_h, and the recently visited sequence of POIs $\mathrm{T}_c = (l_{t_{n+1}}, l_{t_{n+2}}, \cdots, l_{t_{n+k-1}})$, train a model M to predict the next POI $\gamma = l_{t_{n+k}}$ for user u – i.e., $M(\mathrm{T}_h, \mathrm{T}_c) \mapsto \gamma$.

VAE [14] is a generative model that learns the probability $p(X|\mathbf{z})$ of the data X (e.g., a trajectory) given a latent variable $\mathbf{z}$, and a recognition model $q(\mathbf{z}|X)$ simultaneously. The lower bound of the true marginal log likelihood is:

$$\log p_\theta(X) \ge \mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|X)}[\log p_\theta(X|\mathbf{z})] - \mathcal{KL}(q_\phi(\mathbf{z}|X)||p(\mathbf{z}))$$

where both $q_\phi(\cdot)$ and $p_\theta(\cdot)$ are learned with deep neural networks, parameterized by ϕ and θ, respectively. $\mathcal{KL}$ is the KL-divergence.

4 METHODOLOGY

4.1 Basic Framework

Figure 1 shows the four main modules of our proposed model VANext:

(I) *Causal POI embedding*: To better present the semantic relationships among different POIs, we first embed POIs, from both current trajectory and historical trajectory, into a low dimensional representation using a causal embedding method.

(II) *Current Trajectory Learning Module*: We apply a recurrent neural network (RNN) – in this paper, we choose the GRU cell – to encode the current trajectory T_c, and use the last hidden state to represent it , and further learns the distribution of a latent variable $\mathbf{z}$ using variational encoding as $q_\phi(\mathbf{z}|\mathrm{T}_c)$.

(III) *Historic Trajectory Learning Module*: VANext utilizes a shared weight matrix and a convolutional layer to encode the historical trajectory T_h. The attention mechanism with latent variable $\mathbf{z}$ is considered as a query to exploit users' (historical) mobility patterns. It seeks the most similar mobility to the current trajectory T_c by searching the historical trajectory T_h, and aggregates its hidden state from T_h to form the representation. The formalized representation of aggregated result is $\tilde{\mathrm{T}}_h$. In other words, attention module will force the historical trajectory representation $\tilde{\mathrm{T}}_h$ to automatically match T_c.

(IV) *Classifier*: This is the final component which unifies the last hidden state from current trajectory and the aggregated attention from historical trajectory into a feature representation, and predicts the next POI γ.

4.2 Trajectory Generative Model

Before presenting the details of each component, we first adapt our VANext into a trajectory generative model. The primary task of VANext is to predict γ from T_c. Hence, the likelihood can be specified as:

$$\begin{aligned}\log p_\theta(\gamma|\mathrm{T}_c) &= \log \int_{\mathbf{z}} p_\theta(\gamma|\mathrm{T}_c, \mathbf{z}) p(\mathbf{z}) d\mathbf{z} \\ &= \log \int_{\mathbf{z}} q_\phi(\mathbf{z}|\mathrm{T}_c, \gamma) \frac{p_\theta(\gamma|\mathrm{T}_c, \mathbf{z})}{q_\phi(\mathbf{z}|\mathrm{T}_c, \gamma)} p(\mathbf{z}) d\mathbf{z},\end{aligned}$$

With Jensen's inequality, we have

$$\begin{aligned}&\log p_\theta(\gamma|\mathrm{T}_c) \ge \mathbb{E}_{q_\phi(\mathbf{z})}[\log p_\theta(\gamma|\mathrm{T}_c, \mathbf{z}) + \log \frac{p(\mathbf{z})}{q_\phi(\mathbf{z}|\gamma, \mathrm{T}_c)}] \\ &= \mathbb{E}_{q_\phi(\mathbf{z})} p_\theta(\gamma|\mathrm{T}_c, \mathbf{z}) - \mathcal{KL}(q_\phi(\mathbf{z}|\gamma, \mathrm{T}_c)||p(\mathbf{z})). \quad (1)\end{aligned}$$

Since γ is a function of input T_c, we can absorb γ into T_c following [33] and therefore obtain the following variant of Eq.(1):

$$\log p_\theta(\gamma|\mathrm{T}_c) \ge \mathbb{E}_{q_\phi(\mathbf{z})} p_\theta(\gamma|\mathrm{T}_c, \mathbf{z}) - \mathcal{KL}(q_\phi(\mathbf{z}|\mathrm{T}_c)||p(\mathbf{z})). \quad (2)$$

In VaNext, we propose a variational attention mechanism to obtain an attentional representation $\tilde{\mathrm{T}}_h$. In detail, we use the latent variable $\mathbf{z}$ as a query vector to find the most similar mobility $\tilde{\mathrm{T}}_h$ from T_h. Since $\mathbf{z}$ determines $\tilde{\mathrm{T}}_h$, hence we obtain our training objective that is to maximize the lower bound of likelihood $L(\theta, \phi)$:

$$L(\theta, \phi) = \mathbb{E}_{q_\phi(\mathbf{z})}[\log p_\theta(\gamma|\mathrm{T}_c, \tilde{\mathrm{T}}_h)] - \lambda \mathcal{KL}[q_\phi(\mathbf{z}|\mathrm{T}_c)||p(\mathbf{z})], \quad (3)$$

where λ is harmonious factor.

4.3 Causal POI Embeddings

Inspired by word2vec [19], previous works [6, 11, 34] embed POIs with the context information using CBOW or Skip-Gram models. However, for the next POI prediction problem, we are more interested in embedding the proceeding part of a trajectory instead of the surrounding context – the rationale behind is that the current POI is determined by its previous footprint rather than the ones behind it, which is very similar to the idea of high-order Markov Process. That is, there can be no leakage from the future into the past when embedding the POIs. This can be accomplished with a *causal* embedding where the probability of check-in l_τ is maximized only with the given elements from earlier footprints $l_{\tau-\omega} : l_{\tau-1}$, where ω is the fixed size of the sliding window.

Specifically, the check-in representations $\mathbf{v} \in \mathbb{R}^{|\mathcal{L}| \times d}$ – $|\mathcal{L}|$ is the number of check-ins in the dataset and d is the dimensionality – are obtained by predicting each current location l_τ in both T_h

and T_c given the proceeding context locations $l_{\tau-\omega} : l_{\tau-1}$. The probability $p(l_\tau|C(l_\tau))$ is defined by the *softmax* function as:

$$p(l_\tau|C(l_\tau)) = \prod_{l' \in C(l_\tau)} \frac{\exp(\mathbf{v}(l_\tau) \cdot \mathbf{v}(l'))}{\sum_{l'' \in \mathcal{L}} \exp(\mathbf{v}(l'') \cdot \mathbf{v}(l'))}$$

where we adopt the *Negative Sampling* technique to avoid the enumeration of all check-ins $l'' \in \mathcal{L}$ for the efficiency purpose.

4.4 Current Trajectory Learning Module

This module processes the current trajectory T_c with a recurrent network and meanwhile learns a distribution of a latent variable $\mathbf{z}$.

4.4.1 – Current trajectory with GRU:. To capture users' current sequential check-in pattern, we use a vanilla GRU to exploit the mobility of T_c. Note that user's recent trajectories are usually shorter sequence compared to the extremely long historical trajectory, i.e., $|T_c| \ll |T_h|$. Therefore, we use a recurrent network instead of convolutional operation that would be employed in the historical module introduced in next section. Moreover, to make a well-targeted comparison with previous work [6], we also select GRU kernel as the neural network unit:

$$h_\tau = (1 - g_\tau)h_{\tau-1} + g_\tau \tilde{h}_\tau \tag{4}$$

where g_τ is the update gate in time τ which decides how much the unit updates its activation by

$$g_\tau = \sigma(W_g \mathbf{v}(l_\tau) + U_g h_{\tau-1}), \tag{5}$$

where σ denotes the sigmoid activation function. The candidate state $\tilde{h}_t$ is computed similarly to traditional RNN unit

$$\tilde{h}_\tau = \tanh(W_{\tilde{h}} \mathbf{v}(l_\tau) + U_{\tilde{h}}(s_\tau \odot h_{\tau-1})) \tag{6}$$

where $\odot$ is element-pair product, s_τ is a set of reset gates and is computed similarly to update the gate

$$s_\tau = \sigma(W_s \mathbf{v}(l_\tau) + U_s h_{\tau-1}) \tag{7}$$

where W_* and U_* are both parameterized matrices.

4.4.2 – Latent variable learning: Variational auto-encoding provides an efficient way to approximate the posterior distribution of latent variables. In our trajectory generative model, we sample the empirical posterior $q_\phi(\mathbf{z}|T_c)$ of latent variables $\mathbf{z}$ from the last hidden state of current trajectories. The objective is to minimize the KL-divergence between posterior and prior as shown in Eq.(3). Typically, we assume the prior distribution of latent variable $\mathbf{z}$ following a standard Gaussian: $p(\mathbf{z}) \sim N(0, I)$.

4.5 Historical Trajectory Learning Module

This module involves the convolutions on historical trajectories and the variational attention layer.

4.5.1 – Historical trajectory convolution: Before applying the convolution operation over the historical trajectories, we first use a shared weight layer (e.g, a MLP) to incorporate each POI representation vector into a hidden state:

$$c_{t_i} = \text{ReLU}(W_h(\mathbf{v}(l_{t_i})) + b_h), i \in [1, 2, \cdots, n] \tag{8}$$

where ReLU is the activation function. Then, we obtain all hidden states of embedded POIs as: $c_t = (c_{t_1}, c_{t_2}, \cdots, c_{t_n})$.

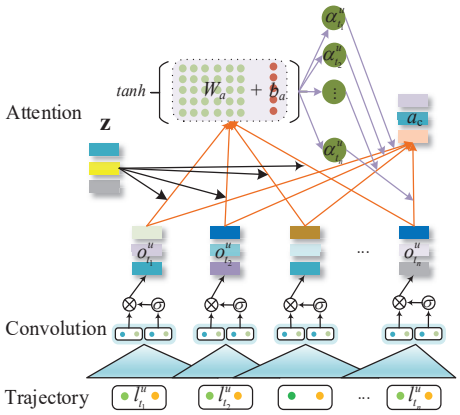

Figure 2: Attention mechanism in Historical Trajectory Module.

Subsequently, a 1×D convolution with non-linearity neural network is involved to exploit the hidden state patterns. The convolution kernel is parameterized with matrix $W_c \in \mathbb{R}^{2d \times nd}$ and bias $b_c \in \mathbb{R}^{2d}$, where n is the number of the hidden states. Therefore, each input hidden state $c_{t_i} \in \mathbb{R}^d$ will generate an output $O_i \in \mathbb{R}^{2d}$ by a CNN. By splitting each element O_i into O_{i_1} and O_{i_2} (both $\in \mathbb{R}^d$), the final output o_{t_i} will be obtained by activating O_{i_1} and O_{i_2} to a non-linearity with gated linear units, as follows:

$$o_{t_i} = O_{i_1} \odot \sigma(O_{i_2}) \tag{9}$$

Thus, the convolutional state $o_t = (o_{t_1}, o_{t_2}, \cdots, o_{t_n})$ is obtained as the input of the next attention layer.

4.5.2 – Variational attention. As the Figure 2 shows, we present a variational attention method to learn the weight of convolutional states in historical trajectories. We first use a MLP to obtain the query vector $\mathbf{q}$ from $\mathbf{z}$:

$$\mathbf{q} = \text{ReLU}(\mathbf{z}W_z + b_z) \tag{10}$$

which is then used as a query to calculate the similarity score between $\mathbf{q}$ and o_t as

$$u_{t_i} = \tanh(\mathbf{q}(W_u o_{t_i} + b_u)) \tag{11}$$

We next get a normalized importance weight α_i with a softmax function.

$$\alpha_i = \frac{\exp(u_{t_i}^\top u_w)}{\sum_{i=1}^n \exp(u_{t_i}^\top u_w)} \tag{12}$$

where u_w is a vector variable learned during the training process.

Now we obtain the representation of historical trajectory as a weighted sum of the POIs.

$$\tilde{a} = \sum \alpha_i o_{t_i} \tag{13}$$

Note that above attention method is different from traditional attention methods in that the learned mobility pattern representation not only depends on the check-ins of historical trajectory but also considers the variational query variable $\mathbf{z}$ from current trajectory. This variational attention technique allows us to sample from a continuous distribution $q_\phi(\mathbf{z}|T_c)$ rather than from discrete/sparse current trajectory T_c, and thus is able to better match the historical trajectory. As we will show in experiments, this novel variational attention method introduces significant performance

improvement compared to the traditional vanilla attention used in previous work [6].

Next POI prediction To predict the next POI of T_c, we first concatenate the last hidden state of current trajectory and the attentional historical trajectory to obtain Φ as follows:

$$\Phi = W_e * \begin{bmatrix} h_{n+k-1} \\ \tilde{a} \end{bmatrix} + b_e \tag{14}$$

Then, we feed Φ into a softmax function to calculate the probability of each POI $p(l)$ in the dataset. During the training of VANext, we are interested in minimizing the empirical risk of predicting the next POI γ.

Semi-supervised VANext: VANext-S We propose a variant of VANext, called VANext-S, which utilizes VAE to pretrain all current trajectories in an unsupervised manner, and uses the encoder and latent variables to initiate the current trajectory learning.

5 EXPERIMENTS

In this section, we conduct experiments on two real-world datasets to compare the performance of the proposed models against several baselines.

Datasets. To ease reproducing the results, we conduct all experiments on the publicly available datasets including Foursquare and Gowalla [7, 28, 30]. We select two cities (New York, Singapore) from Foursquare, and two cities (Houston, California) from Gowalla. For each dataset, we remove the POIs which have been visited by fewer than 5 users. For each user, we concatenate all check-in locations to form a single trajectory – subsequently, we divide it into sub-trajectories with the time interval of 6 hours each, as it was done in previous related works [7, 11, 17]. Further, we filter out the users who have fewer than 5 sub-trajectories. For all datasets, we choose each user's first 80% sub-trajectories as the training set, and the remaining 20% as testing data. Table 1 summarizes the statistics of the datasets after pre-processing.

Table 1: Descriptive statistics of Datasets.

City	Users	POIs	Check-ins	Sub-trajectories
New York	1,083	9,815	120,007	36,182
Singapore	2,321	5,596	194,108	34,713
Houston	4,627	15,234	362,783	18,501
California	3,987	21,354	239,493	66,612

Table 2: Experimental settings of VANext and VANext-S.

Parameter	Values	Model Setting	Chooses
window size	5	embedding size	256
HS/NS	NS	hidden size	300
learning rate	1e-3	attention size	300
dropout rate	0.5	$\|\mathbf{z}\|$ size	128
λ	0.01	batch size	16

Settings. Table 2 characterizes the specific settings and hyper-parameters when implementing our VANext and VANext-S models. In particular, we use negative sampling (NS) instead of Hierarchical Softmax (HS) for our causal POI embedding. We implement two models, as well as all deep neural network-based models, on the Tensorflow platform and speed up using a GTX1080ti GPU.

Metrics. To make fair comparisons, we use the standard evaluation performance metrics, such as **Top@k**, Area under the ROC curve (**AUC**) and Mean Average Precision (**MAP**) used in [6, 17].

Baselines. We compare our models with several classical methods and the most recently proposed methods regarding next POI prediction, including:

• **Markov chain** [9] – Markov chain is one of the classical methods which predict the POIs using the estimated transition probability.

• **PRME** [8] – Personalized ranking metric embedding is a pairwise metric embedding method embedding every POI into a latent Euclidean space and computing the location transition in a Markov chain model.

• **ST-RNN** [17] – It is a deep learning model that incorporates spatial and temporal context and predicts user's next visit within the framework of RNN.

• **Bi-LSTM** [26] – It is a method extending ST-RNN with a more sophisticated Bidirectional-LSTM model that has been used in [26] for learning individual trajectory patterns and predicting POIs.

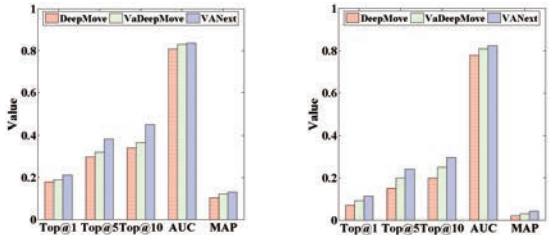
• **POI2vec**[7] – It is an embedding method which incorporates the geographical influence for next POI prediction based on word2vec technique.

• **DeepMove**[6] – The first historical attention method for learning human mobility, consists of a sequential encoding module with RNN for learning motion patterns from both recent and historical trajectories.

Experimental Results

Overall performance comparison. Table 3 shows the **Top@k** performance comparison on four citywide datasets. As we can see, overall, the proposed VANext and VANext-S yield the best performance among all methods in terms of prediction precision. Specifically, VANext and VANext-S outperform the second-best method DeepMove by 31.52%, 36.81% and 32.68%, in terms of *Top@1*, *Top@5* and *Top@10* respectively on Singapore dataset.

As for the performance of baselines, deep neural network-based methods (i.e., ST-RNN, Bi-LSTM, POI2vec and DeepMove) exhibit higher prediction accuracy than traditional feature-based embedding method and Markov-based methods. Furthermore, DeepMove generally gives better performance than other baselines due to its ability of exploiting historical trajectories while others can only learn the sequential patterns in (short) current trajectories during training. Although all of these methods have employed recurrent networks in order to capture long term POI dependency, even LSTM and GRU cannot work well on very long historical trajectories due to the gradient vanishing problem inherent in recurrent networks. This result is in accordance with the limitations of applying RNN in natural language processing [5, 13]. Therefore, the main advantage of DeepMove lies in its attention on historical trajectories, which also confirms the superiority of attention mechanism in processing sequential data, e.g., attention mechanism along achieves comparable results on machine translation with CNN or RNN based seq2seq methods [23].



On the other hand, our methods outperform DeepMove mainly because the introduced trajectory generative model which not only captures short-term human mobility patterns more effectively but also yields better historical trajectory attention with the novel variational attention method.

Additionally, VANext-S outperforms VANext because of its pre-training on the current trajectories in an unsupervised manner. Although autoencoder based pretraining is a well-known training

Table 3: Comparison of overall prediction accuracy on four datasets. The best method is shown in bold, and the second best is shown as underlined

Method	New York			Singapore			Houston			California		
	Top@1	Top@5	Top@10	Top@1	Top@5	Top@10	Top@1	Top@5	Top@10	Top@1	Top@5	Top@10

trick in NLP, we are the first to adapt it in a variational autoencoder framework for learning human mobility. Since this is not core part of this paper, we focus on the VANext in following experiments for further explanations.

(a) New York. (b) Singapore.

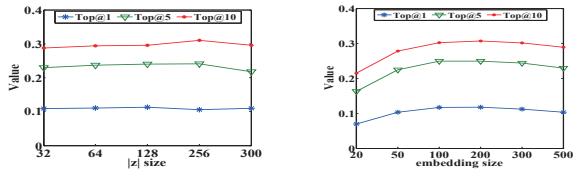

Figure 3: Module performance comparison.

Individual Module Performance. To investigate the effectiveness of various components in VANext, we conduct experiments by manipulating modules in different ways. Specifically, we replace the attention mechanism of *DeepMove* with our proposed variational attention module, yielding a new method *VaDeepMove*. Thus, VaDeepMove is similar to VANext only except the historical trajectory learning – VANext uses CNN while GRU units are employed in VaDeepMove. We compare our VANext with VaDeepMove and DeepMove upon New York and Singapore datasets, as illustrated in Figure 3(a) and 3(b). The result clearly indicates the superiority of CNN and variational attention used in VANext. Further, it proves that CNN exhibits better structural learning than RNN in the case of extremely long history trajectories which encodes more structural and periodical patterns of human mobility. The results of VaDeepMove and DeepMove reflect the advantage of variational attention which is also their difference.

Efficiency. We now investigate the efficiency of the proposed methods. Table 4 shows the time consumed when training VANext (CNN units) and VaDeepMove (RNN units). Note that both VANext and (Va)DeepMove use RNN for training current trajectory T_c. However, it is negligible due to few POIs in most current trajectory. Obviously, CNN based historical trajectory learning significantly reduces the training time. Combined with above results on learning structural/periodical patterns of historical trajectories, we conclude that, arguably, CNN is the most suitable method for learning human mobility, at least for long term motion patterns.

Table 4: Comparison of time consumption during the model training. $|T_c|$: average length of the current trajectories; $|T_h|$: average length of the historical trajectories.

City in Dataset	$\|T_c\|$	$\|T_h\|$	Cell	Time Cost(min)
New York	3.23	207.70	RNN CNN	≈487 ≈277
Singapore	2.92	119.80	RNN CNN	≈267 ≈117
Houston	9.53	1027.94	RNN CNN	≈1810 ≈463
California	3.64	129.66	RNN CNN	≈790 ≈247

(a) Sensitivity of $|\mathbf{z}|$ size. (b) Sensitivity of embedding.

Figure 4: Sensitivity of parameters in Singapore data.

Parameter sensitivity. Finally, Figure 4(a) evaluates impact of latent variable size $|\mathbf{z}|$ and causal POI embedding size d on the performance of VANext. Simply speaking, VANext demonstrates robust performance to the two parameters and achieves stable results when both are small. We observe similar robust results for other parameters and omit to report due to the space limitation.

6 CONCLUSIONS AND FUTURE WORK

We propose a novel model VANext and its variant VANext-S to learn human mobility patterns for next POI prediction. It introduces an attention mechanism affected by the latent variable learned from current mobility to capture the moving pattern and hierarchical semantics of historical trajectories. We also apply convolutional operations on trajectory to greatly improve efficiency over the existing RNN-based methods. Part of our future work will focus on incorporating other contextual POIs attributes (e.g., "museum"; "restaurant") to further improve VANext effectiveness. Another possible extension is to include transportation modes (e.g., "walk"; "bus"; "taxi") of users trajectories for performance boosting.

ABSTRACT

Understanding the economic nature of consumer decisions in e-Commerce is important to personalized recommendation systems. Established economic theories claim that informed consumers always attempt to maximize their utility by choosing the items of the largest *marginal utility per dollar* (MUD) within their budgets. For example, gaining 5 dollars of extra benefit by spending 10 dollars makes a consumer much more satisfied than having the same amount of extra benefit by spending 20 dollars, although the second product may have higher absolute utility value. Meanwhile, making purchases online may be risky decisions that could cause dissatisfaction. For example, people may give low ratings towards purchased items that they thought they would like when placing the order. Therefore, the design of recommender systems should also take users' risk attitudes into consideration to better learn consumer behaviors.

Motivated by the first consideration, in this paper, we propose a learning algorithm to maximize marginal utility per dollar for recommendations. With the second, economic theory shows that rational people can be arbitrarily close to risk neutral when stakes are arbitrarily small, and this is generally applicable to consumer online purchase behaviors because most people spend a small portion of their total wealth for a single purchase. To integrate this theory with machine learning, we propose to augment MUD optimization with approximate risk-neural constraint to generate personalized recommendations. Experiments on real-world e-Commerce datasets show that our approach is able to achieve better performance than many classical recommendation methods, in terms of both traditional recommendation measures such as precision and recall, as well as economic measures such as MUD.

1 INTRODUCTION

Due to the significant information overload in the Web environment, designing personalized recommendation systems is important to help users find relevant items efficiently. On one hand, it helps to save the exploration time for consumers, and on the other hand, it helps to improve the revenue of various online economic platforms. Traditional recommendation algorithms mostly focus on optimizing rating- or ranking-oriented measures. For example, rating prediction algorithms such as matrix factorization [10, 12, 23] or neural approaches [27] devise models to optimize for the prediction accuracy in terms of RMSE, while top-N recommendation algorithms such as pair-wise learning to rank [7, 20, 28] propose models to optimize for ranking performance in terms of Precision, Recall, F1 and NDCG, etc.

However, previous recommendation algorithms seldom consider users' economic incentives when modeling user behaviors and generating recommendations. Actually, consumers' economic incentives play an important role when making decisions in online economic systems such as e-Commerce. By integrating well-established behavioral economic principles and machine learning algorithms, it is possible to develop economics-driven recommender systems so as to make informed recommendations. Therefore, in this paper, we propose to maximize the marginal utility per dollar for economic recommendation. According to behavioral economic theories, rational consumers would always attempt to maximize their utility out of the purchased products by choosing the items that have the largest Marginal Utility per Dollar within their budget. The underlying intuition is that consumers would like to spend their money in an efficient way so that every spent dollar should bring the maximum marginal utility. Meanwhile, making purchasing decisions online involves potential risks of dissatisfaction. A common observation in practical systems is that people may spend money to purchase an item that they think will match their preference when placing the order, but they may eventually find themselves unsatisfied with

the decision when the item is received, and will thus make lower ratings towards the item. As a result, an informed recommendation system should be able to incorporate risk attitude into the model. Fortunately, when integrated with machine learning, established economic principles can help to model the risk attitudes of user decisions based on large-scale user transaction logs.

In this work, we introduce users' risk attitudes into the economic modeling of recommendation systems. In particular, we simulate the risk distribution of each item based on its rating distribution, and by jointly optimizing the marginal utility per dollar under approximate risk neutral constraint, our model learns to predict the consumer decisions with risk-awareness. Experiments based on real-world e-Commerce datasets verify that our approach not only achieves better recommendation performance in terms of precision and recall than both shallow and deep baselines, but also achieves better economic performance in terms of the marginal utility per dollar, which means that our recommendation results would help consumers to spend their money in a more efficient way.

The key contributions of the paper can be summarized as follows:

- We propose to conduct marginal utility per dollar maximization for economic recommendation, which is consistent with established behavioral economic principles, and helps users to spend their money more efficiently.
- We take consumers' risk-attitude into consideration for economic recommendation, which better simulates the real-world online economic environment, where users have to make decisions under potential risks of dissatisfaction.
- We design a joint learning framework to maximize the utility per dollar under risk constraints. Experimental results on several real-world e-commerce datasets show that our approach not only achieves better performance than both shallow and neural recommendation baselines, but also improves the economic measures in terms of money efficiency.

The following parts of the paper will be organized as follows: we review the related work in section 2, and then introduce the necessary economics preliminary knowledge in section 3 to help readers better understand the background. The proposed model and recommendation strategy are introduced in section 4, followed by the experimental results in section 5. We finally conclude the work with possible future research directions in section 6.

2 RELATED WORK

2.1 Collaborative Filtering

Collaborative Filtering (CF) has been an important approach to recommender systems. Early approaches to CF consider the user-item rating matrix and conduct rating prediction with user-based [9, 21] or item-based [14, 24] collaborative filtering methods. With the development of dimension reduction methods, latent factor models such as matrix factorization are later widely adopted in recommender systems, such as singular value decomposition [11], non-negative matrix factorization [13], probabilistic matrix factorization [16], localized matrix factorization [29], etc. In these approaches, each user and item is learned as a latent factor representation to calculate the matching score of the user-item pairs.

Recently, the development of deep learning and neural networks has further extended collaborative filtering methods for recommendation. The relevant methods can be broadly classified into two sub-categories: similarity learning approach, and representation learning approach. The similarity learning approach adopts simple user/item representations (such as one-hot) and learns a complex prediction network as the similarity function to calculate user-item matching scores [8], while the representation learning approach learns rich user/item representations and adopts a simple similarity function (e.g., inner product) for matching score calculation [28].

Another important research direction is learning to rank for recommendation, which learns the relative ordering of items instead of the absolute preference scores. The most representative method on this direction is perhaps Bayesian personalized ranking [20], which is a pair-wise learning to rank method. It is also further generalized to take other information sources such as images [7].

2.2 Economic Recommendation

For a long time, recommendation system research has been working on the above mentioned rating- or ranking-related tasks such as rating prediction and top-N recommendation. However, the related methods seldom consider the economic value that a recommendation list brings to the user or the system, although this is one of the most important goals for real-world recommendation systems. Some recent research on economic recommendation has begun to take care of the economic value of personalized recommendation. For example, [26] studied user's sense of value in terms of utility in recommender systems, and [31] conducted large-scale experiments with real-world users to validate the consumer sense of utility for personalized promotion. [30] further bridged economic principles and machine learning to maximize the social surplus for recommendation, [32] proposed to learn the substitutive and complementary relations between products for utility maximization, and [18] proposed value-aware recommendation for profit maximization based on reinforcement learning. Although current economic recommendation approaches may improve the economic value, their basic motivation is to maximize a total utility function for each user to generate recommendations. However, established behavioral economic principles show that consumers tend to rely on the marginal utility per dollar to make purchasing decisions so as to improve their money efficiency [4, 22], which motivates us to estimate and maximize the marginal utility per dollar for economics-driven recommender systems.

3 PRELIMINARIES

3.1 Utility and Marginal Utility

Utility is an economic measure to quantify consumer's pleasure or satisfaction towards some items. Basically, it is widely used to analyze human behavior in rational choice theory [3]. Utility is usually a function of the consumption quantity Q, which measures the total utility of consuming Q services of a certain product. Among the many different forms of utility functions, the most fundamental and frequently used one is the King-Plosser-Rebelo (KPR) Utility:

$$U_{KPR}(x) = a_x \ln(1 + Q_x), \tag{1}$$

where Q_x is the consumption quantity of item x, and a_x is a scale

parameter that could be different for diffident users, which means that people may have different utility even for the same amount of the same product, because of their different personalized preference.

Marginal Utility (MU) is the increment of utility gained from purchasing one extra unit of a product. It can be defined as the first derivative of the utility function, which is

$$MU_{KPR}(x) = \frac{a_x}{1 + Q_x}. \tag{2}$$

3.2 Expected Utility and Utility of Expectation

Expected utility, also known as the Von Neumann-Morgenstern (VNM) utility, is a basic concept in economics, game theory and decision theory to measure user preference in uncertain circumstances. When an individual has to make a decision under uncertainty, it is rational to make a choice with the highest expected utility [5, 25].

Assuming that U is the utility function for random variable X, then the expected utility (EU) is $EU(X) = \sum_{x \in X} U(x)P(x)$. Meanwhile, the utility of expectation is the utility of the expected value of random variable X, which is $U(EX) = U\Big(\sum_{x \in X} xP(x)\Big)$. In this paper, we use the rating distribution of an item to estimate the probability distribution $P(x)$ for the item.

3.3 Marginal Utility per Dollar (MUD)

In rational choice theory, the condition where a consumer's total utility reaches its maximum is called the *consumer equilibrium*, which means that the consumer would not purchase either more or less products. The equilibrium condition can be defined as follows,

$$\Big\{ p_1 Q_1 + p_2 Q_2 + \cdots + p_n Q_n = I \tag{3}$$

$$\begin{cases} \frac{MU_1}{p_1} = \frac{MU_2}{p_2} = \cdots = \frac{MU_n}{p_n} = \lambda \end{cases} \tag{4}$$

where Q_i is the purchasing quantity of product i; p_i is the price of i; I is the budget (or 'income' in economics); MU_i is the marginal utility of i; λ is called the *marginal utility of money*, which is a constant value at the equilibrium [17, 22]. Based on the above KPR utility function, we can also get the functional form of marginal utility per dollar (MUD) as follows,

$$MUD_{KPR}(x) = \frac{a_x}{(1 + Q_x)p_x} \tag{5}$$

Intuitively, rational choice and consumer equilibrium mean that when deciding which item to buy, users will always choose the one that makes the best use of their money. However, after an item is purchased, its marginal utility (and thus MUD) will diminish, which means that the next optimal choice could be another item. This process will iterate until equilibrium, where MUDs of all items are at the same level that equals the marginal utility of money λ. More intuitively, at the consumer equilibrium condition, the marginal utility of purchasing any product with the remaining money will be less than the marginal utility of the remaining money itself, so the consumer will stop buying any product. In this work, we use sigmoid-normalized price $\sigma(p_x)$ in Eq.(5) for easier optimization.

3.4 Risk Attitude

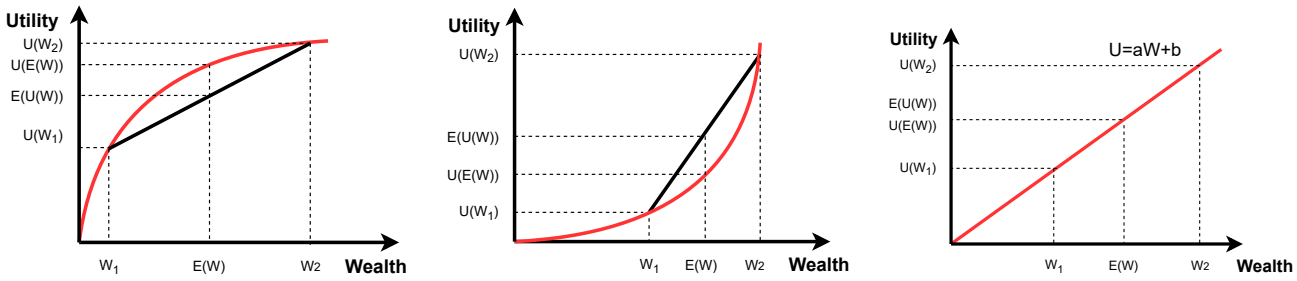
Risk usually exists when people make decisions under uncertainty, for example, in recommender systems, consumers never know for sure if they will satisfy with a product or not. Different people have different attitudes toward risk. Generally, risk attitudes can be divided into three categories, which are risk aversion, risk appetite, and risk neutral. Take buying lottery as an instance, let $p : Z \to [0, 1]$ describe a lottery that has uncertain incomes, and let lottery X be a random variable, whose expected value is $EX = \sum_{x \in Z} xp(x)$ (or $EX = \int xp(x)dx$ for continuous cases), then,

Risk Aversion implies that, for a given lottery, its expected utility is less than its utility of expectation, as in Figure 1(a), $EU(X) < U(EX)$. A risk aversion person always tries to avoid risks.

Risk Appetite means that, for a given lottery, its expected utility is greater than its utility of expectation, as in Figure 1(b), $EU(X) > U(EX)$. A risk appetite person prefers to maximize the profits even with considerable risks.

Risk Neutral implies that, for a given lottery, its expected utility is equal to its utility of expectation, as in Figure 1(c), which means that a person keeps neutral in face of risks, $EU(X) = U(EX)$.

For example, suppose there are two choices in a gamble, one is to win either \$100 or \$0 with 50% probability each, and the other choice is to get \$50 with 100% probability. Though the expected utility of both choices is the same (\$50), the user's utility of expectation can be different because of their different risk preferences.



In this paper, our model is based on an economic assumption that the risk attitudes of all the consumers are approximately risk-neutral, which means that the optimization algorithm attempts to minimize the difference between $EU(X)$ and $U(EX)$. The theoretical basis of this assumption comes from classical economic theorem on expected utility [1, 2, 19], which shows that a rational person with a differentiable utility function will always prefer to take a sufficiently small stake in any positive-expected-value bet. In other words, rational persons can be (almost everywhere) arbitrarily close to risk neutral when stakes are sufficiently small. Since most people only spend a small part of their assets purchasing an item online, this theorem is suitable for e-Commerce recommendation scenarios.

4 THE FRAMEWORK

4.1 The Personalized MUD Function

Different users may have different marginal utility functions, which represent their personalized preferences towards different items. In order to leverage MUD optimization for personalized recommendation, we need to adapt the (non-personalized) MUD function in Eq.(5) to personalized settings. First, the parameter a_x in Eq.(5) only depends on the product x instead of a particular user-item pair. To solve the problem, we substitute a_x with a_{ij}, where i indicates the i-th user, and j indicates the j-th item. Besides, a piece of important information in recommendation systems is the user-item rating, which contains rich signals about the consumer preference on targeted items. Usually, higher rating scores for a user-item pair imply higher consumer satisfaction, thus brings higher MUD. As a result, we introduce the rating scores into the MUD function. Finally, the personalized MUD function is defined as:

$$\mathcal{M}_{ij}(\hat{r}_{ij}, Q_{ij}) = \frac{\tanh(\hat{r}_{ij})a_{ij}}{(1 + Q_{ij})\sigma(p_j)} \tag{6}$$

(a) Risk Aversion (b) Risk Appetite (c) Risk Neutral

Figure 1: Three different risk attitudes based on the relationship between the expected utility and the utility of expectation. Here, x-axis represents the uncertain income, which depends on the specific scenario, e.g. it can be the reward money in a lottery. y-axis is the utility of the corresponding value. Intuitively, W can be considered as the objective (monetary) utility of an item or action, and U can be considered as the consumer's subjective utility (feeling) over the item. The relative relationship between U and W reflects the risk attitude of the consumer.

where Q_{ij} is the consumption quantity of item j by consumer i; $\sigma(p_j)$ is the sigmoid price of item j, which can be seen as a normalization of item prices; a_{ij} is the personalized shape parameter that determines the scale of MUD; and $\hat{r}_{ij}$ is the predicted rating score of item j by consumer i. For easy optimization, we adopt hyperbolic tangent $\tanh(\cdot)$ to map the ratings in to the range of (0,1).

There are many different ways to predict the user-item rating scores $\hat{r}_{ij}$, including user/item-based collaborative filtering, matrix factorization, or deep neural networks. For simplicity, we take the most commonly used matrix factorization (MF) approach [11] for rating prediction.

4.2 Multinomial Logistic Modeling (MLM)

Discrete choice problem describes a situation when a consumer chooses an option between two or more discrete alternatives. There are many forms of different discrete choice models and they share some similarities. More formally, suppose that at time point t, consumer i chooses item j over a set of some other alternative products $\Omega_{it}(j)$. We define the total choice set as $\Pi_{it} = \{j, \Omega_{it}(j)\}$ and its k-th element is Π^k_{it} ($\Pi^1_{it} = j$). The probability that consumer i chooses alternative j is expressed as P_{ij}.

Researchers in economics have utilized Random Utility Models (RUM) to deal with this problem [32]. Different from traditional RUMs, in this paper, we adapt the idea of choosing the alternative item that provides the highest utility into choosing the alternative item with the highest MUD, so as to maximize the utility without violating the budget constraint. In this way, we have $\hat{\mathcal{M}}_i(\Pi^k_{it}) = \mathcal{M}_i(\Pi^k_{it}) + \epsilon_k$, where $\mathcal{M}_i(\Pi^k_{it})$ represents the true MUD of a product combination, and $\hat{\mathcal{M}}_i(\Pi^k_{it})$ represent the observed MUD. ϵ_k is a random variable capturing the impact of all unknown factors. Thus, the probability a customer chooses Π^1_{it} (item j) over other alternatives is:

$$P_{ij}(\hat{\mathcal{M}}_i(\Pi^1_{it}) > \hat{\mathcal{M}}_i(\Pi^k_{it})) = P_{ij}(\epsilon_k - \epsilon_1 < \mathcal{M}_i(\Pi^1_{it}) - \mathcal{M}_i(\Pi^k_{it})) \quad (7)$$

where $k = 2, \dots, |\Pi_{it}|$. If ϵ_1 and ϵ_k obey an i.i.d. extreme value distribution, then we have,

$$P_{ij}(y_{it} = 1) = P_{ij}(\hat{\mathcal{M}}_i(\Pi^1_{it}) > \hat{\mathcal{M}}_i(\Pi^k_{it})) = \frac{exp(\mathcal{M}_i(\Pi^1_{it}))}{\sum_{k=1}^{|\Pi_{it}|} exp(\mathcal{M}_i(\Pi^k_{it}))} \quad (8)$$

where y_{it} is an indication function that,

$$y_{it} = \begin{cases} 1 & \mathcal{M}_i(\Pi^1_{it}) > \mathcal{M}_i(\Pi^k_{it}) \quad \forall k \neq 1 \\ 0 & Otherwise \end{cases} \quad (9)$$

4.3 Estimated Risk Distribution

Shopping online is risky because consumers may be unsatisfactory with the purchased items. In order to better understand consumer behaviors, we take risk into consideration based on classical expected utility theory. To calculate the expected utility of a product, we have to know the probability distribution function $P(x)$ of its utility. In this work, we simulate the distribution function for each specific user-item pair as $\mathcal{N}(\hat{r}_{ij}, \sigma^2_{MF})$, where $\hat{r}_{ij}$ is the predicted rating score from matrix factorization (MF), and $\sigma_{MF} = \sqrt{\frac{1}{N-1}\sum(r_{ij} - \hat{r}_{ij})^2}$ is the unbiased estimation of prediction RMSE. Since the objective function of MF minimizes RMSE, this distribution naturally applies a higher probability to those frequent ratings. As a result, the intuition of the setting is that if the predicted rating $\hat{r}_{ij}$ is close to the true rating r_{ij} (i.e., easy to predict), then we should have a higher probability to observe this rating.

4.4 Risk-based Optimization of MUD (ROM)

We introduce our optimization framework based on approximate risk neutral constraint as follows:

$$\begin{cases} \max \sum_{(i,j)\in\mathcal{R}} log(P(y_{ij} = 1)) - \lambda\|\Phi\|^2 \end{cases} \quad (10)$$

$$\begin{cases} s.t. \ \min \sum_{(i,j)\in\mathcal{R}} (\bar{U}_{ij} - U_{ij}(\bar{r}))^2 + \lambda\|\Phi\|^2 \end{cases} \quad (11)$$

where $\mathcal{R}$ is the set of all the observed user-to-item rating pairs; $P(y_{it} = 1)$ is the multinomial logistic model described in Eq.(8); $\bar{U}_{ij}$ is the expected utility, and $U_{ij}(\bar{r})$ is the utility of expectation, which will be introduced in detail in the next section; and finally, Φ is the parameter set to be learned in the corresponding loss function, which will also be crystallized in the next section. The model involves two optimization functions Eq.(10) and Eq.(11), showing that

Table 1: Parameters setting for each datasets and method where K is the latent factor size, lr is learning rate, #i is the number of iterations and λ is the regularization parameter.

Dataset	Baby				Electronics				Games			
Methods	K	lr	λ	#i	K	lr	λ	#i	K	lr	λ	#i
CF	50	1e-4	1.5	3	100	1e-4	0.5	2	100	1e-5	1	3
BPR	100	1e-4	1	3	50	1e-4	1	3	100	1e-4	1	3
NCF	100	1e-4	1	5	70	1e-4	1	5	100	1e-4	1	5
MPUM	100	1e-4	1	3	70	5e-4	1	3	100	5e-4	1.5	3
ROM	100	5e-4	1	3	70	1e-4	0.5	3	100	1e-4	1.5	3

we maximize the log-likelihood of a multinomial logistic model, so as to optimize the probability of purchasing positive items based on marginal utility per dollar under risk neutral constraint.

4.5 Model Specification

We provide details of the above framework to explain how to learn the parameters. In particular, ratings are predicted based on MF:

$$\hat{r}_{ij} = \alpha^r + \beta_i^r + \gamma_j^r + (\mathbf{p}_i^r)^T \mathbf{q}_j^r \tag{12}$$

where α^r is the global bias, β_i^r is the user bias, γ_j^r is the item bias, $\mathbf{p}_i^r$ and $\mathbf{q}_j^r$ are K-dimensional latent factors of user i and item j. Then we use $\hat{r}_{ij}$ as an input to calculate MUD, as shown in Eq.(6). To reduce the parameter space, a_{ij} is also re-parameterized based on the idea of latent factor modeling,

$$a_{ij} = \alpha^a + \beta_i^a + \gamma_i^a + (\mathbf{p}_i^a)^T \mathbf{q}_j^a \tag{13}$$

In this way, the optimization problem in Eq.(10) and Eq.(11) can be specialized as follow:

$$\max \sum_{(i,j)\in\mathcal{R}} \log\left(\frac{exp(\mathcal{M}_i(\Pi_{it}^1))}{\sum_{k=1}^{|\Pi_{it}|} exp(\mathcal{M}_i(\Pi_{it}^k))}\right) - \lambda\|\Phi\|^2, \tag{14}$$

$$\min \sum_{(i,j)\in\mathcal{R}} \left\{\sum_{n=1}^{5} P_n \tanh(n) - \tanh\left(\sum_{n=1}^{5} nP_n\right)\right\}^2 a_{ij}^2 \ln^2(1+Q_{ij}) + \lambda\|\Phi\|^2, \tag{15}$$

where $P_n = Pr(r_{ij} = n) = \int_{n-0.5}^{n+0.5} \mathcal{N}(\hat{r}_{ij}, \sigma_{MF}^2)\mathrm{d}r$ is the probability that the rating score of item j is n (n = 1, 2, 3, 4 or 5, representing five different rating scores, for $n = 1$, integral lower bound is $-\infty$, and for $n = 5$, upper bound is $+\infty$). We use SGD optimization algorithm to learn the model parameters.

4.6 Top-K Recommendation

Once we learned the model parameters a_{ij} and $\hat{r}_{ij}$ according to ROM, we can then calculate the marginal utility per dollar $\mathcal{M}_{ij}$ for each user-item pair. We rank all products for a user according to their MUD values, and select the top items whose price is within the user's budget to generate the top-K recommendation list, wherein this work, a consumer's budget is considered as the highest price that the consumer had ever spent in his/her purchasing history.

5 EXPERIMENTS

5.1 Dataset Description

We use the consumer transaction data from Amazon[1] [6, 15] in our experiments. The dataset includes user transaction (user id, item id, rating, etc.) and item metadata (item id, price, related item, etc.) on 24 product categories lasting from May 1996 to July 2014. We take three categories (Baby, Electronics and Video Games) that have different size and data sparsity for experiments.

Table 2: Basic statistics of the experimental data sets.

Dataset	#users	#items	#interactions	sparsity
Baby	23,894	39,767	200,170	0.0211%
Electronics	58,248	45,777	477,074	0.0179%
Video Games	24,735	23,669	236,530	0.0404%

Basic statistics of the experimental datasets as shown in Table 2. For each dataset, we sort the transactions of each consumer according to the purchase timestamp, and then split the records into training, validation and testing sets chronologically by 3:1:1 [2].

5.2 Experimental Setup

We compare our model with the following baselines, including both economic and non-economic methods. For non-economic methods, we involve both shallow and deep learning baselines.

CF: Collaborative Filtering based on matrix factorization is a representative method for rating prediction. In this experiment, we use CF based on latent factor modeling [11].

BPR: Bayesian Personalized Ranking [20] is one of the most representative ranking-based methods for the top-N recommendation.

NCF: Neural Collaborative Filtering is a state-of-the-art recommendation algorithm based on deep neural networks. We choose Neural Matrix Factorization to conduct the experiments, which fuses Generalized Matrix Factorization and Multiple Layer Perceptron under the NCF framework.

MPUM: Multi-Product Utility Maximization for recommendation [32], which is an economic recommendation approach that maximizes the utility of product combinations for recommendation.

For each dataset, we use the validation set to find the best parameters of each method, which are shown in Table 1.

5.3 Evaluation Measure

To compare the performance of our model with the baselines, we use both traditional measures such as Precision, Recall, and F_1, and the economic measure MUD. Assuming Γ_i is the recommendation list for consumer i, and N is the total number of consumers, the average marginal utility per dollar over all users is,

$$\mathcal{M}@|\Gamma_i| = \frac{1}{N}\sum_{i=1}^{N}\sum_{j\in\Gamma_i} \frac{a_{ij}\tanh(r_{ij})}{(1+Q_{ij})\sigma(p_j)} \tag{16}$$

[1] http://jmcauley.ucsd.edu/data/amazon/

[2] code of the paper is released at https://github.com/TobyGE/Maximizing-Marginal-Utility-per-Dollar-for-Economic-Recommendation

Table 3: Summary of the performance. We evaluate for ranking (P, R, F_1, NDCG) and economic value (MUD), and K is the length of recommendation list. When ROM is the best, its improvements against the best baseline are significant at p=0.01.

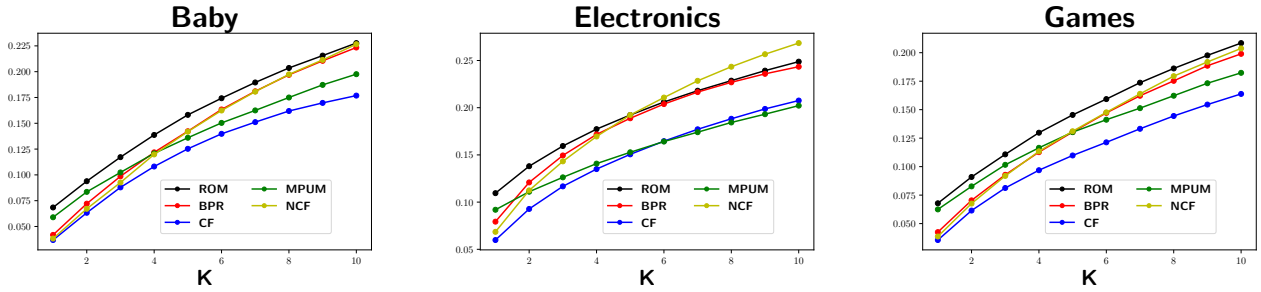

Figure 2: Conversion rate on three datasets. x-axis is the length of the recommendation list and y-axis is the conversion rate.

5.4 Experimental Results

Key experimental results are shown in Table 3, and we also plot the conversion rate in Figure 2 under different recommendation length K (from 1 to 10). We analyze and discuss the results in terms of the following three perspectives.

5.4.1 **Recommendation Performance:** According to Table 3, among the shallow baseline models (CF, BPR, and MPUM), all pair-wise learning methods (BPR and MPUM) are better than the point-wise CF method, which shows the superiority of pair-wise methods on top-K ranking tasks. By learning deep structures for user-item matching, NCF achieves the best baseline performance in many cases. Furthermore, our ROM approach achieves the best top-K performance against all baselines in most cases. For example, when averaged across all datasets and recommendation lengths, we get 27.97% improvement than NCF. In particular, the improvement is 83.18% for Precision@1 on the *Baby* dataset against NCF. For NDCG, we get 112.54% improvement in average than NCF baseline, especially the largest improvement (407.75%) is achieved on the *Electronics* when $K = 1$. For conversion rate, we get 15.66% improvement than the BPR baseline when averaged across K on the *Baby* dataset, and the largest improvement (63.5%) is achieved when $K = 1$. Compared with NCF, we got 19.01% improvement for top 1 to 10 conversion rate on *Baby* and the largest improvement (78.69%) is achieved when $K = 1$.

The observations imply that by modeling user behaviors based on established economic principles, our model is able to better capture the user preferences for the top-K recommendation.

5.4.2 **Economic Performance:** It is not surprising that our method achieves significantly higher MUD scores than non-economic methods, because we try to optimize for economic values directly. Therefore, we only compare ROM with another economic baseline (i.e., MPUM). We see that our model gets much higher MUD than MPUM, which means that higher utility values do not necessarily imply higher marginal utility per dollar. The higher MUD values produced by our model mean that our recommendations could help users to spend their money more efficiently (i.e., more utility gain per dollar), and thus help to provide more informed recommendations.

5.4.3 **Shallow vs. Deep Models:** According to Table 3 and Figure 2, our model is better than NCF in most cases. Nevertheless, NCF got 6.43% improvement from ROM when $K = 10$ on *Electronics*, and according to Fig.2, NCF grows faster when the length of the recommendation list increases. Neural network is good at learning complex user-item interactions, so it is not surprising that deep models are able to achieve better performance when K is sufficiently large. However, in practical recommender systems, the top-5 or 10 results are much more important than later items. Our model is better than NCF from top-1 to top-10 in most cases, and the improvement is especially significant on top-1, which is also reasonable because marginal utility measures the incremental benefit for each extra unit of an item.

6 CONCLUSIONS AND FUTURE WORK

In this paper, we bridge economic principles and machine learning for personalized recommendation together. In particular, we propose to maximize marginal utility per dollar under approximate risk-neutral constraint for recommendation. Experimental results verified the effectiveness of our model on top-K recommendation and economic values. In the future, we will relax the risk-neural constraint to other risk attitude functions for more diverse user modelings. We will also consider other economic principles and/or learning methods to benefit recommendation systems both effectively and economically.

ABSTRACT

Ranking algorithms play a crucial role in online platforms ranging from search engines to recommender systems. In this paper, we identify a surprising consequence of popularity-based rankings: the fewer the items reporting a given signal, the higher the share of the overall traffic they collectively attract. This few-get-richer effect emerges in settings where there are few distinct classes of items (e.g., left-leaning news sources versus right-leaning news sources), and items are ranked based on their popularity. We demonstrate analytically that the few-get-richer effect emerges when people tend to click on top-ranked items and have heterogeneous preferences for the classes of items. Using simulations, we analyze how the strength of the effect changes with assumptions about the setting and human behavior. We also test our predictions experimentally in an online experiment with human participants. Our findings have important implications to understand the spread of misinformation.

1 INTRODUCTION

Ranking systems are at the core of many online services, including search engines, recommender systems, or news feeds in social media. Recent research suggests that the underlying ranking algorithms may impact society, playing an active role in the spread of misinformation [29], political polarization [11], or trustworthiness [14]. They might also reinforce existing judgment biases [2].

Rankings systematically affect the information people access about products, services, events, or ideas, because users are more likely to click on top-ranked items [19, 24, 30]. When items are ranked based on popularity, this leads to a self-reinforcing dynamics according to which popular items become increasingly more popular [28].

In this paper, we identify a surprising effect of popularity-based rankings. Consider a setting with two distinct classes of news sources that differ in their political orientations, e.g., left-leaning or right-leaning. We show that, under a fairly broad set of conditions, *the total share* of web traffic (proportion of clicks) attracted by a given class of news sources *decreases* with the number of news sources in that class. We call this phenomenon the 'few-get-richer' effect. For example, if there are 20 news sources, the total number of clicks on left-leaning sources will be larger when there are just 3 of these sources than when there are 17 of them.

Intuition suggests that popular items should be more relevant and trustworthy than unpopular ones. Yet, extensive research indicates that popularity is often not very informative about quality, especially in settings characterized by 'rich-get-richer' dynamics (sometimes called the 'Matthew effect') [13, 22, 25, 28], or information cascades [3, 5]. In these settings, the randomness inherent to the dynamics of the system implies that items that become the most popular are not always those with the best quality. The 'few-get-richer' effect adds to research on the 'rich-get-richer' dynamics by showing that popularity-based rankings do not only create 'noise' in the ranking, but can also lead to a systematic ranking bias: when there are two distinct classes of items, items from the smaller class become better ranked than similar items from the larger class.

The few-get-richer effect emerges in settings characterized by two design features. The first feature consists in the ranking of items in terms of popularity (i.e., items with more clicks are higher ranked). The second feature is a partition of the available items in two (or more) distinct classes.

We make two reasonable behavioral assumptions. The first assumption is users' tendency to click on top-ranked items. The second assumption is that users have heterogeneous preferences for the item classes. Some users have a preference for items of a particular class, while others have a preference for items of other classes. Still other users are indifferent to the item class.

Returning to our news search example, suppose there are few left-leaning and many right-leaning news sources. We assume there are three types of users: left-leaning, right-leaning, and indifferent. The heterogeneous preference assumption means that left-leaning users are more likely to click on left-leaning news sources, right-leaning users are more likely to click on right-leaning news sources, and indifferent users click exclusively based on rank. Even if the left-leaning news sources are unpopular, left-leaning individuals will seek them out. Because there are few such news sources, the clicks of these left-leaning individuals will be concentrated on a few news sources, and these sources will tend to 'shoot up to the top'.

Once a news source has gotten close to the top, it will attract not only the clicks from the left-leaning individuals, but also the clicks of indifferent users, simply because of the rich-get-richer dynamics. This is the few-get-richer effect.

2 RELATED WORK

Our results contribute to the understanding of the limitations of recommender systems [8, 10, 18, 21, 23, 24], with direct applications to the design of fair, transparent and efficient ranking systems [4, 6, 32], as well as methods to reduce the spread of misinformation [20, 29] or uncivil behavior [9, 26].

An extensive literature on modeling (click) user behavior is weakly related to our work [7, 15, 27, 33]. Closer to our work, several papers have proposed models of the dynamics of interactions between individual searches and ranking algorithms, e.g., for understanding the feedback loop between ranking system and user queries [12], explaining the observed mitigation of search engines' popularity bias [16], or the competition of memes using limited attention [31]. The paper closest to ours is [17], which also obtains a few-get-richer effect in a model where individuals get multiple signals and where (news) items are ranked via a probabilistic popularity-based ranking. Besides being simpler, our model works with a discrete and deterministic ranking of the websites rather than a continuous and probabilistic one. Among other things, this allows for a tighter connection with the experiment of Section 5.

3 THE MODEL

We present a stylized model of a search environment where individuals use a search engine to look for information on a binary issue. At the center of the model is the ranking algorithm, which ranks and directs individuals to the different websites, based on the popularity of individuals' choices.

3.1 Model of the Search Environment

There are M items, each of which belongs to exactly one of two classes. For example, the items can be news articles and the class of an article can be whether the source is known to be left-leaning or right-leaning. A different, visual, example can comprise images about animals, some of which are cats while the others are dogs. In general, each of the M items is characterized by a binary signal $\{0, 1\}$ that defines its class; let M_k denote the set and number of items of class k, $k \in \{0, 1\}$.

There is a single popularity-based ranking algorithm which, starting with a given initial ranking (r_1), ranks all the items in M according to the number of clicks received. Let $r_n \in \{1, \dots, M\}^M$ denote the ranking seen by individual n, where $r_{n,m} \in \{1, \dots, M\}$ denotes the rank of item m observed by individual n.

There are N individuals, each of which is characterized by a parameter γ_n, which can be of one of three types. The three types are denoted by Type 0, Type 1 and Type 2, and their proportions in the population are p_0, p_1 and $p_2 = 1 - p_0 - p_1$, respectively. Type 0 (resp. Type 1) individuals have a preference for clicking on items of class 0 (resp. class 1). Type 2 individuals are indifferent between clicking on items of class 0 or of class 1 *absent ranking*. We represent the set of possible types by $\Gamma = \{\Gamma_0, \Gamma_1, \Gamma_2\}$, where Γ_i denotes the probability that an individual of Type i (i.e., with $\gamma_n = \Gamma_i$) clicks on an item of class 0 *absent ranking*. Our assumptions about the preferences of the individuals in the three types imply $\Gamma_0 > \frac{1}{2}$, $\Gamma_1 < \frac{1}{2}$ and $\Gamma_2 = \frac{1}{2}$.

We summarize these preferences in terms of propensities $\varphi_{n,m}$ with which individual n with $\gamma_n \in \Gamma$ clicks on item m, defined by:

$$\varphi_{n,m} = \begin{cases} \frac{\gamma_n}{M_0} & \text{if } m \in M_0 \\ \frac{1-\gamma_n}{M_1} & \text{if } m \in M_1. \end{cases} \tag{1}$$

For simplicity, in this section, we consider the extreme and symmetric case, where $\Gamma_0 = 1$, $\Gamma_1 = 0$ and $p_0 = p_1 = p > 0$.

3.2 Model of Stochastic Choices

Individuals enter one after the other and observe the ranked list of items, and based on the ranking and on their preference for the signals given by $\varphi_{n,m}$, they click on one of the M items according to a probabilistic choice function obtained as follows. We use the function $\beta^{(M-r_{n,m})}$ to weigh the propensities $\varphi_{n,m}$, whereby $\beta > 1$ calibrates an individual's search cost or attention bias, so that an item ranked exactly one position higher has β times as much probability of being clicked. The probability individual n clicks on website m is given by:

$$\rho_{n,m} = \frac{\beta^{(M-r_{n,m})}\varphi_{n,m}}{\sum_{m' \in M} \beta^{(M-r_{n,m'})}\varphi_{n,m'}}. \tag{2}$$

Thus, individual n observes $r_{n,m}$ and clicks on a website according to $\rho_{n,m}$. His click gets recorded by the ranking algorithm, which updates its ranking to r_{n+1}. This affects the ranking of the websites observed by the next individual, who clicks on a website according to $\rho_{n+1,m}$ and so on. We denote the total clicking probability on items of class k (M_k) by $\rho_{n,M_k} = \sum_{m \in M_k} \rho_{n,m}$.

Overall, this defines a search environment $\mathcal{E}$ with parameters $(M, M_1); (N, \beta, \Gamma, p); r_1$. We assume $\beta > 1$ and $0 < p < \frac{1}{2}$ so that individuals are subject to an attention bias and are heterogeneous in the sense that there are nonzero shares of Types 0, 1 and 2.

3.3 The Few-Get-Richer Effect

The following result shows how few items of a given class can attract more traffic than many more items of the same class taken together. In particular, it implies that if there is just one item of a given class, then it will attract more traffic by itself than $M - 1$ such items taken together in a corresponding environment where there are $M - 1$ such items.

Proposition 1. *Fix two popularity-based search environments $\mathcal{E}$ and $\mathcal{E}'$ that differ only in the number of items of class 1 (M_1 and M_1' respectively). Suppose $M_1 < \frac{M}{1+\beta} < \frac{\beta M}{1+\beta} < M_1'$, then there exists $\overline{N}$ such that, for any $N \geq \overline{N}$, the total clicking probability (ρ_{N,M_1}) by individual N on an item in M_1 in environment $\mathcal{E}$ is strictly greater than the total clicking probability ($\rho_{N,M_1'}$) by individual N on an item in M_1' in environment $\mathcal{E}'$, provided $p > 0$ is sufficiently small.*

The proof is in three steps. First, we characterize a limit ranking (r_∞) of the process ρ_n defined by Eq. (2) and show it constitutes a (stable) limit. Second, we show it is the unique such limit ranking. Finally, we compute total traffic on all items in M_1 at the limit and

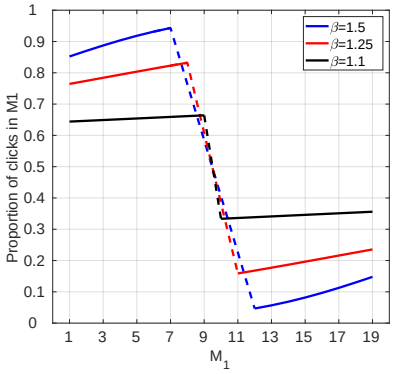

Figure 1: Total traffic on all M_1 items of class 1 as a function of M_1 for the limit distribution of the process ρ_n of Eq. (2) for different values of β, with $M = 20$, $\Gamma = \{0.8, 0.2, 0.5\}$ and $p = p_0 = p_1 = 0.4$.

show it is over half of total traffic when $M_1 < \frac{M}{1+\beta}$, and hence greater than total traffic on all items in M_1' for $M_1' > \frac{\beta M}{1+\beta}$.

Step 1. Consider M items and a ranking $r_\infty \in \{1, \ldots, M\}$ defined by $r_{\infty,k} = k$, for $k = 1, \ldots, M$. Then, by popularity ranking, r_∞ is a (stable) limit ranking of the process ρ_n if and only if at r_∞:

$$\rho_{n,1}(r_\infty) > \rho_{n,2}(r_\infty) > \ldots > \rho_{n,M}(r_\infty) \tag{3}$$

holds for the expected individual n. Suppose r_∞ is such that the M items are ranked in two blocks of items of the same class where, if $M_1 < \frac{M}{1+\beta}$, the first ranked M_1 items are all in M_1 and the remaining ones (bottom ranked) are all in M_0; and symmetrically if $M_1 > \frac{\beta M}{1+\beta}$, the bottom ranked M_1 items are all in M_1 and the remaining ones (top ranked) are all in M_0. To see that these constitute limit rankings, suppose $M_1 < \frac{M}{1+\beta}$, and consider the ranking r_∞, where the first M_1 items are ranked on top. In this case, the corresponding clicking probabilities for $k \in M_1$ (i.e., $k \in \{1, \ldots, M_1\}$) are given by:

$$\rho_{n,k}(r_\infty) = \frac{\beta^{(M-k)}(1-\gamma_n)/M_1}{\sum_{k=1}^{M_1} \beta^{(M-k)}(1-\gamma_n)/M_1 + \sum_{k=M_1+1}^{M} \beta^{(M-k)}\gamma_n/M_0},$$

and for $k \in M_0$ (i.e., $k \in \{M_1 + 1, \ldots, M\}$) satisfy:

$$\rho_{n,k}(r_\infty) = \frac{\beta^{(M-k)}\gamma_n/M_0}{\sum_{k=1}^{M_1} \beta^{(M-k)}(1-\gamma_n)/M_1 + \sum_{k=M_1+1}^{M} \beta^{(M-k)}\gamma_n/M_0}.$$

Clearly, $\rho_{n,k}(r_\infty) > \rho_{n,k+1}(r_\infty)$ holds within the classes M_1 and M_0, that is, for $k = 1, \ldots, M_1 - 1$ and for $k = M_1 + 1, \ldots, M - 1$ Hence it suffices to show that $\rho_{n,k=M_1}(r_\infty) > \rho_{n,k=M_1+1}(r_\infty)$. This is easily checked for the expected individual n (whose value of γ_n is drawn from $\Gamma = \{1, 0, \frac{1}{2}\}$ according to the probabilities, respectively, $p_0 = p, p_1 = p < \frac{1}{2}$ and $p_2 = 1 - 2p > 0$).

Step 2: To see that the above ranking constitutes a unique limit, we show that no other ranking satisfies Eq. (3) and that, for any other ranking, whenever an item is in the less numerous class (say M_1 when $M_1 < \frac{M}{1+\beta}$), it will always get strictly more clicks in expectation than the item of the other more numerous class ranked just above. Assume $M_1 < \frac{M}{1+\beta}$, then it can be checked that the two strongest constraints to be satisfied are the ones comparing the clicking probability on the lowest-ranked item of class M_1 when (i) it is ranked in the Mth position while all remaining $M_1 - 1$ items are ranked in the first $M_1 - 1$ positions, and when (ii) it is ranked in position $M_1 + 2$ while all remaining $M_1 - 1$ items are ranked in the first $M_1 - 1$ positions. Both are easily seen to be satisfied whenever $p = 0$ and $M_1 < \frac{M}{1+\beta}$. By continuity they continue to hold for sufficiently small $p > 0$. The case $M_1 > \frac{\beta M}{1+\beta}$, which implies $M_0 < \frac{M}{1+\beta}$ and which has the M_0 items ranked on top holds by symmetry.

Step 3. It suffices to show that whenever $M_1 < \frac{M}{1+\beta}$, then the first ranked items in M_1 always get strictly more that half the share of the total clicks. Since the share of traffic on the individual items is given by the probabilities $\rho_{n,k}(r_\infty)$ defined above, it suffices to show that for any $M_1 < \frac{M}{1+\beta}$, $\rho_{n,M_1}(r_\infty) = \sum_{k=1}^{M_1} \rho_{n,k}(r_\infty) > \frac{1}{2}$. Given our assumptions on p and Γ, this is easily checked for the expected individual n (using the fact that, for any $1 \le K < K' \le M$, $\sum_{k=1}^{K} \beta^{M-K}/K > \sum_{k=1}^{K'} \beta^{M-K'}/K'$). It also implies that when $M_1' > \frac{\beta M}{1+\beta}$ all items in M_1' will (be bottom-ranked) and will obtain less than half the total traffic. □

When the share of items in M_1 is close to one half ($\frac{M}{1+\beta} < M_1 < \frac{M}{2}$), then there may be multiple limit rankings and the above proof no longer applies. We believe that the few-get-richer result may still go through in these cases, but it is necessary to evaluate the likelihood of the different limit rankings and guarantee that limit rankings are more likely to give classes with fewer items a higher probability of being higher ranked. This proof goes beyond the scope of this paper.

Similarly, for interior types ($\Gamma_0 < 1, \Gamma_1 > 0$). As Figure 1 shows for different values of β (see also the simulations in the next section), the effect continues to hold: when M_1 has few items (minority case $M_1 < \frac{M}{1+\beta}$) it obtains a larger proportion of clicks than when M_1 has many items (majority case $M_1 > \frac{\beta M}{1+\beta}$).

4 SIMULATIONS OF THE MODEL

We now analyze through simulations the presence of the few-get-richer effect in different settings. Our focus is on analyzing the click-through rate (CTR), defined as the the ratio of the probability of clicking on an item in M_1 to the total number of clicks N (which we fix at $N = 100$ users), as a function of M_1 for different settings. We mainly consider stochastic choices with $\Gamma = \{0.9, 0.1, 0.5\}$, which means that non-indifferent users do not exclusively click on one of the two classes. We assume that the ranking r_n is proportional to the number of clicks that the item received at time n. As before, we consider a ranking of $M = 20$ items with the M_1 items initially at the bottom. In this case, instead of the limit ranking, we characterize the dynamic transient during which the minority class may reach the top of the ranking. This makes our analysis dependent on the initial conditions. For an item m initially at position $r_{1,m}$, we assume a *uniform* initialization, with all items having one click.

4.1 Dependence on β

We first consider the dependence on the ranking effect, parametrized by β. Larger values of β correspond to a stronger relative ranking

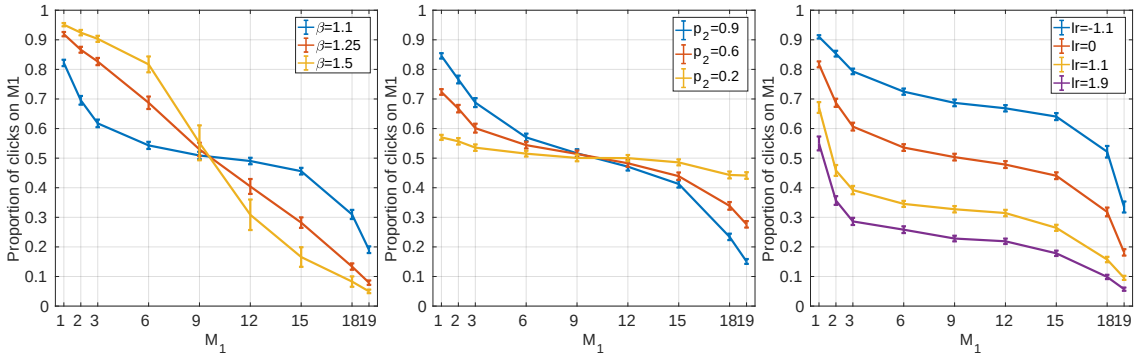

Figure 2: Proportion of clicks on all M_1 items of class 1 as a function of M_1 for runs of $N = 100$, and assuming $M = 20$, $\beta = 1.1, \Gamma = \{0.9, 0.1, 0.5\}, p_0 = p_1 = 0.4$ and uniform initialization, as baseline, and varying β (left plot), $p_2 = 1 - p_0 - p_1$ (middle plot), and the log-ratio $\log \frac{p_0}{p_1}$ (right plot). Error bars indicate confidence intervals for 100 different random realizations.

effect compared to the propensities. Here, we consider a symmetric case with $p_0 = p_1 = p = 0.4$.

Figure 2 (left) shows the CTR for different values of β. The resulting CTR is almost symmetric. We observe a monotonic decrease as a function of M_1 in all cases, showing, in particular, that the minority class *always* receives more clicks than the majority one.

We can differentiate between three cases, corresponding to small, intermediate and large values of β, respectively. In general, larger values of β lead to a relatively larger CTR for the minority class, due to relatively larger probability of clicking on top ranked items. For small values of β, the CTR is the smallest, but even here the effect as a function of M_1 is particularly pronounced for small (and large) M_1. For intermediate values of β, the flat region for intermediate values of M_1 disappears and the CTR decreases monotonically with constant slope, indicating a decrease independent of M_1. Finally, for larger values of β, the CTR is largest, and the effect as a function of M_1 is smallest for small (and large) M_1. In this extreme case, for $M_1 = 1$, the single item at the bottom quickly reaches the top and attracts almost all the traffic, leaving almost no traffic to the remaining $M - 1$ items of the other class.

From these simulations, we can conclude that the few-get-richer effect is robust to varying β.

4.2 Dependence on p_2

We now analyze the CTR as a function of the proportion of indifferent users $p_2 = 1 - p_0 - p_1$. For this, we choose $\beta = 1.1$ and vary the proportion of indifferent users while keeping $p_0 = p_1$. To better analyze this dependence, we consider extreme preferences, so that only indifferent users can really click on both items, that is, we assume $\Gamma = \{1, 0, 0.5\}$.

Figure 2(middle) shows the results. We observe that, in this case, the few-get-richer effect is more pronounced as p_2 increases. Having a larger proportion of indifferent users results in relatively more clicks per item, and hence a larger amplification of ranking effect, which is a key ingredient for the few-get-richer effect to emerge. With less extreme preferences, e.g., $\Gamma = \{0.9, 0.1, 0.5\}$, the effect in p_2 is still present, but less pronounced (data not shown).

We conclude that the indifferent users play a key role in amplifying the effect of the ranking, and that in general, having a larger proportion of them contributes importantly towards the few-get-richer effect.

4.3 Dependence on the ratio $\frac{p_0}{p_1}$

So far we have considered cases where the distribution of user types was symmetric, $p_0 = p_1 = p$. In practice this need not be the case since, e.g., the minority class might also be preferred by a minority of users. We analyze the effect as a function of $lr = \log \frac{p_0}{p_1}$.

Figure 2(right) shows the results for different values of lr. As expected, the few-get-richer effect is more pronounced when there is a larger relative proportion of users that prefer the minority item. To see this, compare the blue line, where $p_1 = 0.6 > p_0 = 0.2$ (there are three times more users who prefer the 'minority' item), and the purple line, where $p_1 = 0.1 < p_0 = 0.7$. We see that the effect is still present for this choice of parameters, even when there are seven times more users who prefer the majority item. Here, the proportion of indifferent users is set to $p_2 = 0.2$. Consistent with the results of the previous subsection, if we increase p_2 and keep the same ratios, the effect becomes more pronounced. We conclude that the effect is also robust to different ratios of proportions lr.

4.4 Ranking evolution

Finally, we illustrate the typical behavior of the ranking evolution for different values of M_1, assuming our usual baseline parameter values for β, Γ, and p and uniform initialization. Figure 3 shows the results, which confirm the idea that minority items tend to move towards the top.

5 ONLINE EXPERIMENT WITH HUMAN PARTICIPANTS

To test the predictions of the model, we executed an online experiment in which participants clicked on one out of 20 possible options (pictures).[1] The options belonged to two classes, M_0 and M_1, just as in the model. As in the simulations reported above, we measure the effect of the popularity-based ranking of options as the total number of clicks attracted by items of type M_1. To this end,

[1]Data from the experiment are available at https://osf.io/nwjyf/.

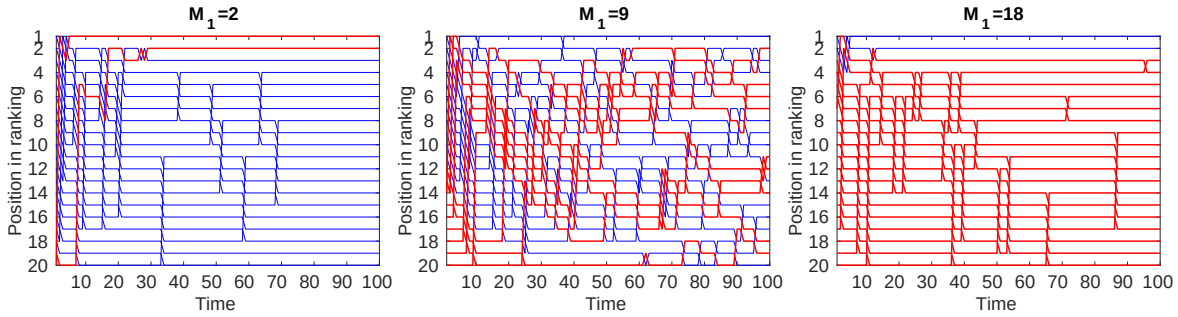

Figure 3: Examples of ranking evolution for different values of M_1. The items in M_1 always start at the bottom of the ranking. With $M_1 = 2$ (left plot), the two items quickly move to the top. With $M_1 = 9$ (middle plot), the items in M_1 are spread through the different ranking positions. Finally, with $M_1 = 18$ (or $M_0 = 2$) (right plot), the items M_1 eventually stay at the bottom.

we created 8 independent conditions. In conditions D1 to D4, the ordering of the options changed dynamically as a function of the number of clicks received by each option, with the most popular option (in terms of cumulative number of clicks) at the top of the screen and the least popular option at the bottom of the screen. The conditions differed in terms of the number of options in M_0 and M_1, as summarized in Table 1. The number of options in M_1 was 17, 12, 8, or 3 in conditions D1, D2, D3 and D4, respectively.

These four 'dynamic' conditions were matched to four 'static' conditions with the same sets of options M_0 and M_1. In the static conditions, the ranking of options did not change over time and was set to the initial ranking in the matching dynamic condition. We denote these static conditions by S1, S2, S3, and S4.

Comparisons of matched pairs of conditions allows us to establish the causal effect of the ranking algorithm on the total traffic attracted by each option. Comparisons of the 4 dynamic conditions allows us to test the prediction that the total traffic attracted by options in M_1 decreases with the number of options in M_1.

To keep the experimental setup as simple as possible, the options in our experiment were not news sources, but pictures of dogs and cats. In order to activate their preferences for cat or dog pictures, participants were first asked whether they were a 'cat person', a 'dog person', or 'neither a cat person nor a dog person.' Answers to this identity question allowed us to compute the proportion of participants in each of the 3 types discussed in the model section. Then participants were shown a set of 20 pictures in a vertical list. In this setup, M_0 is the set of cat pictures (initially at the top of the screen) and M_1 is the set of dog pictures (initially at the bottom). The initial popularity of all pictures was set to 1, consistent with the uniform initialization of the previous section.

5.1 Methodological Details

We recruited 786 participants on Amazon Mechanical Turk. It was administered via a Qualtrics survey embedded in the Amazon Mechanical Turk webpage as an iframe. After signing up for the task, participants read the informed-consent form. Then they were randomly assigned to one of 8 conditions. They first answered a question about their type: "Are you more of a cat person or a dog person?" with three possible choices "I am a cat person" / "I am neither a cat person nor a dog person" / "I am a dog person." On the next screen they were shown 20 buttons with "Please click on a photo from the following list of photos of cats and dogs and rate it according to your liking." The buttons were displayed in a vertical list. Participants could initially see 3 to 4 buttons and had to scroll down to access the other buttons. After clicking a button, participants were shown the corresponding picture and gave it a rating of 1 to 5 stars. The rating task was presented as a reason to ask participants to select an item according to their preferences. The collected ratings are not discussed because our interest is only in the clicking behavior of the participant. Participants were paid $0.15 for their time.

5.2 Results

5.2.1 Participant Types. 30% indicated they were 'Cat persons' ($p_0 = 0.30$), 55% 'Dog persons' ($p_1 = 0.55$), 15% neither ($p_2 = 0.15$).

5.2.2 Total Traffic Attracted by M_1 (Dog pictures). Dog pictures were initially ranked at the bottom the screen. First we discuss the effect of popularity-based ranking of options on the total traffic attracted by Dog pictures. In the 4 dynamic conditions, Dog pictures attracted substantially more traffic than in the corresponding static condition (compare the two rows 'Experiment' in the top and bottom panels of Table 1). In other words, ordering the options in terms of popularity had a systematic effect on the share of traffic attracted by options that started at the bottom of the choice screen.

Unsurprisingly, in all static conditions, the total traffic attracted by Dog pictures was lower than 50%. The set of Dog pictures attracted more traffic when there were relatively more Dog pictures. For example, while 17 Dog pictures attracted 44% of the traffic, 3 Dog pictures attracted 27%.

The pattern is completely different in the dynamic conditions. First, in all dynamic conditions, the total traffic attracted by Dog pictures was higher than 50%. The most important finding is that the total traffic attracted by Dog pictures was *larger* with just 3 Dog pictures (and 17 Cat pictures) than with 17 Dog pictures (and 3 Cat pictures)! Similarly, the total traffic attracted by Dog pictures was *larger* with 8 Dog pictures (and 12 Cat pictures) than with 12 Dog pictures (and 8 Cat pictures). These results are consistent with the predictions of our model. The total traffic attracted by Dog pictures did not decrease monotonically with the size of the set of Dog pictures (it is larger with 8 Dog pictures than with 3 Dog pictures). This pattern is seemingly inconsistent with the predictions of the

Table 1: Experiment results. The 'Sim1' rows report the average traffic attracted by Dog pictures (M_1) over 1000 simulations of the choice model with a setting matching the exact number of participants of each identity type in each condition. The 'Sim2' rows report the average traffic attracted by Dog pictures (M_1) over 1000 simulations of the choice model with 100 users in each condition where the numbers of users who are a 'dog person', 'neither a dog person nor a cat person' and a 'cat person' are 55, 15 and 30, respectively (same frequencies for all conditions).

# Cats (M_0)		3	8	12	17
# Dogs (M_1)		17	12	8	3
Dynamic Button Ordering					
Condition		D1	D2	D3	D4
# participants		96	102	99	101
# participants in each type	Cat person	34	30	24	29
	Neither	9	21	11	16
	Dog person	53	51	64	56
Dog traffic share	Experiment	.53	.69	.76	.71
	Sim1	.46	.56	.73	.76
	Sim2	.47	.60	.67	.75
Static Button Ordering					
Condition		S1	S2	S3	S4
# participants		96	101	95	96
# participants in each type	Cat person	34	30	25	33
	Neither	13	19	9	15
	Dog person	49	52	61	48
Dog traffic share	Experiment	.44	.37	.40	.27
	Sim1	.41	.37	.39	.28
	Sim2	.44	.39	.35	.30

simulations (Fig. 2). Yet, this lack of monotonicity can be explained by the fact that the conditions were not perfectly balanced with respect to the distribution of identity types of the participants. In condition D3 (8 Dog pictures) there were substantially more Dog lovers (64/99) than in condition D4 (3 Dog pictures, 56/101). This is a chance event resulting from the fact that we elicited the identity type of the participants after the random assignment into conditions, thus we could not balance types within conditions.

5.2.3 Estimated Parameters of the Choice Model. We estimated the parameters of the stochastic choice model, Eq. (2), using maximum likelihood on the whole dataset. Our parameter estimates are $\beta = 1.22$, $\Gamma_C = .74$ for Cat persons (Γ_0 in the model), and $\Gamma_D = .08$ for Dog persons (Γ_1 in the model). Cat and Dog persons had strong tendencies to choose pictures from the class consistent with their identity type.

We used these estimated parameters to simulate choices and the dynamics of picture ranks in the 8 experimental conditions. Simulations reported in rows 'Sim1' in Table 1 indicate a close match between the simulated data and the actual traffic proportions attracted by Dog pictures (both in static and dynamics conditions).

We also used the estimated parameters to simulate what would happen if there were 100 participants in each condition and if the distributions of identity types were the same in all conditions ('Sim2' rows). We find a decreasing monotonous relation between the number of Dog pictures and the share of traffic attracted by Dog pictures. This pattern is consistent with the qualitative prediction of our model.

5.2.4 Summary. Overall, the results indicate that the experimental setting falls within the boundary condition of application of our theory. They provide a proof-of-concept that popularity-based ordering of options can lead to the counter-intuitive phenomenon that when there are fewer options of one class, the total share of traffic attracted by this class of options becomes larger.

6 DISCUSSION & CONCLUSION

The few-get-richer effect can have both positive and negative effects on the quality of the information people obtain from search results. On the positive side, when there are few relevant items, the few-get-richer effect may help them become top-ranked, making them more accessible. At the same time, the few-get-richer effect can contribute to the spread of misinformation. It may help few irrelevant or 'fake news' items become top-ranked, especially if there is a strong preference for such items and only few websites report them.

Our analyses highlight a potential unintended effect of regulations that 'ban' particular 'alternative' news sources known for spreading 'fake news'. When a sizeable proportion of users have a preference for identifiable 'alternative' news sources, the removal of some of these news sources might lead to an increase in the total traffic attracted by the remaining 'alternative' news sources. This could result in more overall exposure to 'fake news'!

To neutralize the few-get-richer effect, our theory suggests that it may be advisable to keep track of the number of items in each class when incorporating clicks in the search engine algorithm. Ideally, the ranking algorithm should use the popularity of the different items in a way that is neutral to the number of items in each class.

The few-get-richer effect also has implications for the design of recommender systems. The learning efficiency of these systems is impeded by the *presentation bias* problem: items shown to the user can get clicks whereas items not shown get no clicks. The recommender system thus cannot learn about the relevance of the latter items. A popular solution to this challenge is the *explore-and-exploit* approach, in which some items from a minority class are randomly inserted in the search results [1]. This purportedly increases the amount of exploration (clicks on the minority class), and thus increases the learning opportunities of the system at the cost of slightly hurting the user experience [18, 23]. The few-get-richer effect suggests precisely the opposite. Adding more of those items might reduce, rather than increase, the total amount of exploration.

Context-Sensitive Malicious Spelling Error Correction

Hongyu Gong, Yuchen Li, Suma Bhat, Pramod Viswanath
University of Illinois at Urbana-Champaign
{hgong6,li215,spbhat2,pramodv}@illinois.edu

ABSTRACT

Misspelled words of the malicious kind work by changing specific keywords and are intended to thwart existing automated applications for cyber-environment control such as harassing content detection on the Internet and email spam detection. In this paper, we focus on malicious spelling correction, which requires an approach that relies on the context and the surface forms of targeted keywords. In the context of two applications–profanity detection and email spam detection–we show that malicious misspellings seriously degrade their performance. We then propose a context-sensitive approach for malicious spelling correction using word embeddings and demonstrate its superior performance compared to state-of-the-art spell checkers.

1 INTRODUCTION

Automatic spelling correction has been an important natural language processing component of any input text interface of today [17]. While spelling errors in common writing could be regarded as innocuous omissions, affecting opinions about the writer's competence at worst, those of the malicious kind can potentially be highly offensive, since they are intended to deceive an automated mechanism–be it a spam filter for emails or a profanity detector for social media. For those applications that rely on automatic detection of specific keywords to enable real-time control of the cyber-environment, detecting and correcting spelling errors is of primary importance.

Perspective [11], is one such application that helps reduce abusive content online by detecting profane language. It has been pointed out that Perspective's otherwise good performance in detecting toxic comments is not robust to spelling errors [15]. Consider the sentence, "My thoughts are that people should stop being stupid." which was assigned a perceived toxicity score of 86% by Perspective. When the word "stupid" was misspelled as "stup*d" in the same sentence, its toxicity score reduces to 8%. This marked reduction induced by the deceptive spelling error on the keyword 'stupid' reflects the importance of accurate spelling correction for optimal toxicity detection. Had the spelling error been detected and corrected *before* scoring for toxicity, the score would not have lowered.

Likewise, deliberate typographic errors are common in phishing scams and spam emails. For instance, "Please pya any fees you may owe to our company" where *pya* is clearly a spelling error, included to deceive spam filters that are sensitive to keywords. In both these instances, spelling correction as a preprocessing step of the messages are critical for a robust performance of the target system. Spelling correction in the preprocessing stage in malicious settings constitutes the focus of this study.

In this paper, we empirically demonstrate the effect of spelling errors in a malicious setting by adding synthetic misspellings to sensitive words in the context of two applications–profanity detection and spam detection. We propose an *unsupervised* embedding-based algorithm to correct the targeted misspelled words. Earlier approaches to spelling correction primarily depend on edit distances to find words morphologically similar to corrections. More recently, improved spell checkers with the addition of contextual information (e.g., n-gram modeling in [37]), often with intensive computation and memory requirements (to obtain and store N-gram statistics). A recently studied neural network-based spell checker learns the misspelling pattern from annotated train data in a supervised way, and was found to be sensitive to data domains and dependent on human annotations [9]. Our approach to make the correction procedure context-aware involves harnessing the geometric properties of word embeddings. It is light-weight in comparison, unsupervised, and can be adapted to a variety of data domains including Twitter data and spam data, since domain information can be well captured by tuning embeddings on domain-specific data [33].

We first demonstrate the effect of spelling errors in a malicious setting in two applications–profanity detection and spam detection. Then we propose an unsupervised algorithm to correct the targeted spelling errors. Besides performing well on the correction of synthetic spelling errors, the algorithm also performs well on spell checking of real data, and shows that it can improve hate speech detection using Twitter data.

2 RELATED WORK

Spelling correction. Automatic spelling correction in non-malicious settings has had a long research track as an important component of text processing and normalization. Early works have used edit

distance to find morphologically similar corrections [29], noisy channel model for misspellings [17], and iterative search to improve corrections of distant spelling errors [12]. Word contexts have been shown to be improve the robustness of spell checkers with n-gram language model as one approach to incorporate contextual information [8, 14]. Other ways of incorporating contextual information include n-gram statistics capturing the cohesiveness of a candidate word with the given context [37].

Effect of malicious misspellings. Misspellings are commonly seen in online social platforms such as Twitter and Facebook, and recent studies have drawn attention to the fact that online users deliberately introduce spelling errors to thwart bullying detection [27] or to challenge to moderators of online communities [26]. This is because simple ways of filtering terms of profanity are rendered inadequate in the presence of spelling errors. Likewise, email spam filters are often obfuscated by misspelled sensitive words [38] because word-based spam filters tend to make false decisions in the presence of misspellings [32], and so are word-based cyberbullying detection systems [3]. Misspelling is also seen in web attacks where a phishing site has a domain name as a misspelling of a legitimate website [16].

Approaches to correct malicious misspellings. Given the malicious intent of misspellings in the context of the Internet, recent studies have proposed correction strategies specifically for malicious misspellings. Levenshtein edit distance is commonly used in spell checking of detection systems. Spam filters [38] and cyberbullying detection systems [36] rely on the idea of edit distance to recognize camouflaged words by capturing the pattern of misspellings. For example, [30] studied an edit distance function designed to reveal instances where spammers had interspersed black-listed words with non-alphabetic symbols. Lexical and context statistics, such as word frequency, have also been used to make corrections in social texts [5, 18]. Existing approaches have the problem of domain specificity, since their lexical statistics are obtained from a certain domain which might differ from the domain of target applications.

Our study considers the spelling correction in a malicious setting where errors are not random, but are carefully introduced. Our context-aware approach to spelling correction relies on the geometry of word embeddings, which has the advantage of efficient domain adaptation. As we will show in Section 4.2, the embedding can be easily tuned on a small corpus from the target domain to capture domain knowledge.

3 METHODS

Spelling errors include non-word errors and real-word errors [28]. Non-word misspelling is not a valid word in standard dictionaries, while real-word misspelling is. For example, *piecce* is a non-word error of *piece*, and *peace* is its real-word misspelling. In this work, we focus on non-word misspellings. We study malicious spelling correction for three target applications–toxicity detection using the Perspective API, email spam detection, and hate speech detection on Twitter data. We work with synthetic spelling errors in the first two applications, and study the real misspellings in the third.

For the toxicity detection task, we use the Perspective dataset [11], which provides a set of comments collected from the Internet with human annotated scores of toxicity. Using the Perspective API we obtained the toxicity score for 2767 comments in the dataset.

The spam dataset consists of 960 emails from the Ling-Spam dataset [1]. We randomly split the data into 700 train emails and 260 test emails. Both the train and test sets were balanced with respect to the positive and negative classes. The most frequent 2500 words in the training data were selected, and we counted the occurrence of each word in the emails. The number of occurrences of these frequent words were used as a 2500-dimension feature vector for each email. We first used these features to train a Naive Bayes classifier. It achieved an accuracy of 98% in spam detection.

As for the Twitter data, a total of 16K user posts were collected from Twitter, a social communication platform and used in used in [34]. Of these tweets, 1937 were labeled as being racist, 3117 were labeled as being sexist, and the rest were neither racist nor sexist. The task of hate speech detection is to classify these tweets into one of the three categories *racist, sexist, neither*. We randomly split the tweets into train and test data, and trained a neural-network based hate speech detection system on the training data (described later in Section 5.3).

3.1 Characterization

Here we summarize our assumptions on the characteristics of the malicious spelling errors.

(1) Malicious errors are usually made on the sensitive keywords in order to obfuscate the true intentions and deceive detection systems that rely on keywords [35].

(2) The error yields a word that is similar to the original word in surface form. The misspelled words would be words that humans can easily understand (thus the erroneous words still convey the intended meaning, while being in disguise). Their similarity is reflected in the small edit distance between the erroneous and the correct word [24]. The errors often involve character-level operations as shown in Table 1 [21].

(3) With edit distance as the similarity criterion, it is often the case that the word with an error is similar to multiple valid words, making correction a challenge in real applications. For example, both *stud* and *stupid* can be thought of as the correct form of the erroneous word *stupd*. In such cases, spelling correction relies on the context in which the word occurs.

3.2 Effect of malicious spelling errors

We quantify the effect of spelling errors by showing that a simple mechanism of injecting malicious spelling errors greatly degrades the performance of toxicity detection and spam detection. Toward this, we first describe the general mechanism to generate synthetic errors and then study their impact on toxicity and spam detection. We point out that owing to the absence of a dataset with intended malicious errors, we had to generate them synthetically.

Spelling error generation. We first choose the "sensitive" words that the detection algorithm relies (the mechanism will be discussed separately for each application we consider). We then replace these words with their erroneous forms (which may not be real words). Given the characteristics of malicious errors mentioned in Section 3.1, our assumption is that as a result of these errors the altered

[1] http://csmining.org/index.php/ling-spam-datasets.html

words will appear similar to the original ones. As illustrated in Table 1, we consider four basic character-level operations to change the sensitive words: insertion, permutation, replacement, and removal. In our experiments we perform these operations on randomly picked characters of the sensitive word. For permutation, we exchange this character with the next one. Each operation in Table 1 increases the edit distance by 1, and we generate malicious misspellings of the sensitive word that are at most 2 edit distance from the correct word.

Table 1: Common Spelling Errors

Type	insertion	permutation	replacement	removal
Error	idio.t	moeny	chanse	stupd
Correction	idiot	money	chance	stupid

Finally, we obtain revised sentences by replacing the sensitive words in the original sentences with their erroneous counterparts. Next, we introduce our mechanism for selecting the "sensitive" words for each application.

Perspective toxicity detection. We select 2767 clean comments from a total of 2969 comments in the Perspective data, with the selection criteria given below.

- The most toxic word in a comment should contain more than two characters. A word that is too short is not likely to be a meaningful toxic word, and can have too many candidate corrections in the dictionary.
- The most toxic word in a comment should appear at least 100 times in the dataset, since rare words tend to be misspellings.
- The most toxic word in a comment should be a content word, i.e., it should not belong in the list of function words such as "must", "ought", "shall" and"should". Function words are not toxic and so were excluded from our experiments.

For each comment, its predicted toxicity score lies in the range of $[0, 1]$. The higher the score, the more toxic the sentence is. For each sentence, we chose the most toxic word to be that word, without which the toxicity score reduced the most. We then added malicious errors, as described above, to this word. We note that for 2380 toxic comments with toxicity scores higher than 0.5, spelling errors brought down their predicted toxicity by 32%. Section 5 provides the details of the degradation in toxicity detection.

Spam detection. A Naive Bayes spam detection model provides the likelihood of each word given the spam and non-spam classes. For a given word, the difference between these probabilities reflects how important that word is in spam detection. We sorted all the words in decreasing order of this difference in probabilities, and picked the most spam-indicative words. We then added malicious errors to these words in test spam emails. For a spam filtering system which relies heavily on the counts of spam-indicative words, the errors can easily disguise spams as non-spams. This is seen in the test accuracy dropping from 98% on the original test data to 72% on the revised test data.

We note that for the Perspective data, we added errors to only one word per sentence, but did not have such limits for the spam data. Also, we do not limit the number of corrections during the spell check process.

4 SPELLING CORRECTION

We have shown that malicious errors degrade the performance of toxicity and spam detection. We next introduce our unsupervised algorithm on non-word error correction based on the relevant context. Our correction method proceeds in two stages. In the first stage of **candidate enumeration**, the algorithm detects the spelling error and proposes candidates that are valid words and similar in surface form to the misspelled word. In the next stage, **correction via context**, the best candidate is chosen based on its context.

4.1 Candidate Enumeration

As in the case of non-word spelling correction [17], we check whether an erroneous word is valid or not using a vocabulary of valid words. For toxicity detection and spam detection, the vocabulary consists of words that occur more than 100 times in English Wikipedia corpus [2] For hate speech detection, the vocabulary consists of standard words from Wikipedia and the list of internet slang words as detailed in Section 5.3, since slang words frequently occur in tweets. For an invalid word, we find candidate words with the smallest Damerau-Levenshtein edit distance [7, 20]. This distance between two strings is defined as the minimum number of unit operations required to transform a string into another, where the unit operations include character addition, deletion, transposition and replacement. We note that because there are potentially multiple candidates having the smallest distance to the misspelled word, the output of this stage is a set of candidate corrected words.

4.2 Correction via Context

After enumerating all possible candidates, we choose the one that fits the best in the context. We propose a word-embedding-based method to match the context with the candidate.

Pretrained embedding. We use the word2vec CBOW model to train word embeddings on the training data of the three applications [22]. The Perspective and Twitter data have an informal style, while email data consists of relatively formal expressions. Word embeddings are known to be domain-specific [25] and naturally domain-specific corpora are used to train word embeddings for use in a given domain. We note that in the absence of a large enough representative corpus to train domain-specific high-quality embeddings for this study, we reconcile with word embeddings trained on a large WikiCorpus [4] to capture the general lexical semantics and further tuned on a domain-specific corpus, such as that of the Perspective dataset, the spam emails data and the Twitter data. This step allows us to combine domain information in trained embeddings.

Error Correction. Word vectors permit us to decide the fit of a word in a given context by considering the geometry of the context words in relation to the given word. Firstly, the embedding of the compositional semantics of phrases or sentences can be approximated by a linear combination of the embeddings of their constituent words [31]. Let v_w be the embedding of the token w. Take the phrase "hate group" as an example, it holds that

$$v_{\text{hate_group}} \approx \alpha v_{\text{hate}} + \beta v_{\text{group}},$$

where α and β are real-valued coefficients.

[2] available at: http://www.cs.upc.edu/~nlp/wikicorpus/

Table 2: Correction Accuracy on Perspective and Spam

Dataset	Our system	PyEnchant	Ekphrasis	Google
Perspective	**0.840**	0.476	0.713	0.323
Spam	**0.786**	0.618	0.639	0.526

This enables us to represent the context as a linear space of the component words. Another property is that semantically relevant words lie close in the embedding space. If a word fits the the context, it should be close to the context space, i.e., the normalized Euclidean distance from the word embedding to the context space should be small [10]. We quantify the inconsistency between the word and its context by the distance between the word embedding and the span of the context words.

For a misspelled word in a sentence, all words occurring within a window of size p are considered to be its context words. Let the context T_p be the set of words within distance p from w_0:

$$T_p = \{w_{-p}, w_{-p+1}, \ldots, w_0, \ldots, w_{p-1}, w_p\},$$

where w_0 is the misspelled word. Let C be the set of candidate replacements of w_0. Let v_i be the word embedding of context word w_i. We denote by $\text{dist}(c, T_p)$, the distance between a candidate c and the linear span of the words in its context T_p, termed as the candidate-context distance of a candidate, defined as the normalized distance between the word embedding of the candidate, v_c and its linear approximation obtained by the context vectors:

$$\text{dist}(c, T_p) = \min_{\{a_i\}} \frac{1}{\|v_c\|_2} \| \sum_{\substack{i=-p, \\ i\neq 0}}^{p} a_i v_i - v_c \|_2^2. \quad (1)$$

This is a quadratic minimization problem for which we can find a closed-form solution.

Instead of fixing one context window size, we consider multiple window sizes and weigh the distances obtained using different window sizes. The context words that are closer to the misspelled word are more informative in candidate selection. In the sentence "the stu*pid and stubborn administrators", the word *stubborn* suggests that the misspelled word should be a negative personality adjective, and the word *administrator* that it should be an adjective for people. Thus, the closest context word *stubborn* provides more relevant information than the distant word *administrator*.

We thus weigh the distance by the inverse of the context window size, i.e., the weight $\frac{1}{p}$ for the window size p. Suppose that T is the full context, and the candidate-context distance is defined below:

$$\text{dist}(c, T) = \sum_{p=1}^{P} \frac{1}{p} \cdot \text{dist}(c, T_p), \quad (2)$$

where $P = 4$ in our experiments.

Given the context T, the suggested correction c^* is the candidate with the smallest distance to the linear space of context words, i.e.,

$$c^* = \arg\min_{c \in C} \text{dist}(c, T). \quad (3)$$

5 EXPERIMENTS

We evaluated our spelling correction approach in three settings: toxicity and spam detection with synthetic misspellings, and hate speech detection with real errors. Even though some recent works using neural networks [9] are available, they require ground truth corrections for supervised training. For our unsupervised approach, we compare its performance with that of three strong unsupervised baselines below, which are generic off-the-shelf tools used in many NLP systems such as AbiWord [1] and Google search engine [2].
(1) Pyenchant: a generic spell checking library of multiple correction algorithms [19]. We use the MySpell library in this work.
(2) Ekphrasis: a spelling correction and text normalization tool for texts from social networks [5].
(3) Google spell checker: a Google search engine-based spell check [6]. We chose it for its ability to undertake context-sensitive correction on the basis of user search history.

Table 3: Correction on Perspective Data

Original	**stupid** and stubborn administrators	anti American **hate** groups
Revised	**stu*pid** and stubborn administrators	anti American **ahte** groups
Our result	**stupid** and stubborn administrators	anti American **hate** groups
PyEnchant	**sch*pid** and stubborn administrators	anti American **hate** groups
Ekphrasis	**stupid** and stubborn administrators	anti American **ate** groups
Google	**stupid** and stubborn administrators	anti American **ahte** groups

5.1 Toxicity Detection

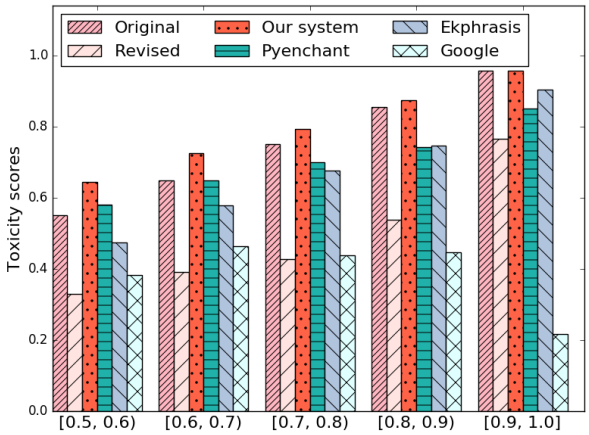

Figure 1: Toxicity scores by different approaches.

We took 2380 sentences from Perspective dataset whose toxicity scores were higher than 0.5 and added synthetic errors maliciously to these sentences as described in Section 3. Some example Perspective sentences, revised sentences and corrections given by different algorithms are shown in Table 3. The correction accuracy achieved by different approaches is reported in Table 2.

We divided toxic sentences into 5 bins according to their original toxicities. In Fig. 1, we report the average toxicity of the original, revised and corrected sentences in each bin. We see that the malicious errors drastically reduce the sentences' toxicities. The original average toxicity in the first bin is 0.55, whereas the revised toxicity is only 0.33 (a drop by 40%). This shows that toxicity detection is very sensitive to spelling errors.

Table 4: Correction Examples on Spam Data

Original sentence	it really be a **great** oppotunity to make relatively easy **money** , with little **cost** to you .	we have quit our **jobs** , and will soon buy a home on the beach and live off the interest on our **money** .
Revised sentence	it really be a **grfat** opportunity to make relatively easy **fmoney**, with little **cosgt** to you.	we have quit our **tobs**, and will soon buy a home on the beach and live off the interest on our **jmoney**.
Our correction	it really be a **great** opportunity to make relatively easy **money**, with little **cost** to you.	we have quit our **jobs**, and will soon buy a home on the beach and live off the interest on our **money**.
PyEnchant	it really be a **graft** opportunity to make relatively easy **fmoney**, with little **cost** to you.	we have quit our **bots**, and will soon buy a home on the beach and live off the interest on our **money**.
Ekphrasis	it really be a **great** opportunity to make relatively easy **money**, with little **cost** to you.	we have quit our **tobs**, and will soon buy a home on the beach and live off the interest on our **money**.
Google	it really be a **great** opportunity to make relatively easy **fmoney**, with little **cosgt** to you.	we have quit our **jobs**, and will soon buy a home on the beach and live off the interest on our **jmoney**.

From the same figure we see that our proposed error correction results in toxicity scores closer to the original ones when compared with the baselines, validating the effectiveness of our approach. We note that in some cases our approach might result in a slightly higher toxicity score than the original one, because of the pre-existing misspellings in the original sentences. For example, original sentences "you are a *fagget*", "*fukkin* goof's track record" and "I suspect that closedmouth is *g*y*" have crude misspellings, which are used as Internet slang. Our approach corrects these pre-existing misspellings in addition to the errors we add later, resulting in higher toxicity scores of corrected sentences. We perform corrections of all spelling errors, recovering more toxic words than we added maliciously.

5.2 Spam Detection

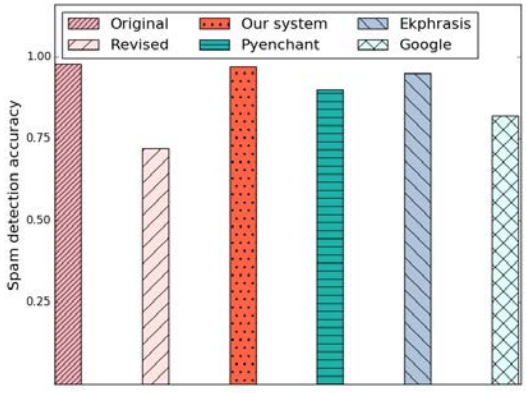

Figure 2: Spam detection accuracy on test emails.

We next evaluate our spelling correction on the spam data. Synthetic malicious errors were added to spam-indicative words in spam mails based on our misspelling generation mechanism.

Some example spams are shown in Table 4. Sensitive words such as "money" which are indicative of spams are highlighted, and the corrections given by different approaches are shown. Table 2 shows the spelling correction accuracy achieved by our algorithm and the baselines for the spam data.

Fig. 2 shows the spam detection accuracy on the original, revised and corrected test emails. Again we see that malicious errors resulted in a large accuracy drop, the accuracy was restored after spelling correction, and the increase in accuracy using our approach was the maximal among those compared.

5.3 Real Misspellings in Tweet Hate Speech Detection

We have shown that synthetic misspellings are able to deceive the toxicity detector and the spam detector, and reported the performance of spell checkers on the synthetic data. We also experimented with data containing real spelling errors collected from Twitter, where instances of hate speech contain user-generated spelling errors. The correction performance of spell checkers are now compared on the real misspellings.

Table 5: Example of Tweets and Hate Speech Categories

Category	Example sentence
Racism	#isis #islam pc puzzle: converting to a religion of peace leading to violence? http://t.co/tbjusaemuh
Sexism	Real question is do feminist liberal bigots understand that different rules for men/women is sexism
Neither	The mother and son team are sooooo nice !!!

Tweet normalization. Some example tweets of racist and sexist nature are shown in Table 5. Tweets are notoriously noisy and unstructured given the frequent occurrences of hashtags, URLs, reserved words and emojis. These non-standard tokens greatly increase the vocabulary size of tweets while also injecting noise to classification tasks. We use Tweet Preprocessor, a tweet preprocessing tool which can replace aforementioned tokens with a special set of tokens. For example, one tweet is "#isis #islam pc puzzle: converting to a religion of peace leading to violence ?,http://t.co/tbjusaemuh", which becomes "$HASHTAG$ $HASHTAG$ pc puzzle: converting to a religion of peace leading to violence? URL" after preprocessing. This preprocessing stage can clean texts without dealing with misspellings. Tweets are preprocessed right before they are fed into the neural network.

Hate speech detection. The state-of-the-art system for hate speech detection is a Bidirectional Long Short Term Memory (BLSTM) network with attention mechanism [3]. The model takes a sequence of words in a tweet, obtains word embeddings in the embedding layer, and passes them to bidirectional recurrent layers to generate

Table 6: Hate Speech Detection Results with Different Spelling Corrections

Category	Metric	Original	Our system	PyEnchant	Ekphrasis	Google
racist	Precision	0.630	**0.640**	0.630	0.630	0.569
	Recall	0.617	0.681	0.617	0.617	**0.702**
	F1 score	0.623	**0.660**	0.623	0.623	0.628
sexist	Precision	0.641	0.630	0.629	0.629	**0.649**
	Recall	0.775	0.767	**0.790**	0.790	0.759
	F1 score	0.701	0.692	**0.701**	**0.701**	0.700
Macro average over all categories	Precision	0.721	**0.721**	0.718	0.718	0.703
	Recall	0.741	0.757	0.743	0.743	**0.759**
	F1 score	0.727	**0.737**	0.727	0.727	0.727

a dense representation of the input tweet. The feedforward layer takes the tweet vector and predicts its probability distribution over all three classes. The class with the highest likelihood is chosen as the category of the input tweet. In our experiment, we use a BLSTM model for the hate speech detection task.

Vocabulary construction. Firstly we build a vocabulary list using both a standard dictionary and the frequent words (frequency higher than 5) in the training data. This list will serve as a reference for spelling correction; words outside the list will be taken as spelling errors and replaced with legal words from the vocabulary. The reason for collecting words from the training data is to include the Internet slangs in tweets which may not exist in the standard dictionary. Some examples are "tmr" (for *tomorrow*), "fwd" (for *forward*) and "lol" (for *laughing out loudly*). Some previous works proposed to replace these slang terms with their standard forms [13, 23], which require either expert knowledge or human annotations. We argue that because these Internet slangs change rapidly we should understand them in a data-driven manner instead of standardizing them based on human knowledge. Since the representation of these slangs and their use in hate speech will be learned by the neural network from the train data, we add these slangs to our vocabulary as legal words.

Spelling correction. Misspellings are another source of noise which cannot be handled in the tweet normalization stage. Some misspellings are user-created to deceive the online detection system. For example, the swear word "fucking" has a lot of variants in tweets such as "fckn", "f*ckin", "f**king", "fckin", and "fuckin". When a new variant of a swear word arises in the test data, the model takes it as an out-of-vocabulary word, and is unable to match it with any learned pattern. The purpose of spelling correction is to map these new variants to words that are known to the model. As discussed in Section 4, we enumerate the candidates of a misspelled word, and choose the candidate which best fits with the context as its correction.

Results. We do a random 80:20 train-test split of the Twitter dataset. A detection system was trained on the normalized train data (without spelling correction) using the state-of-the-art BLSTM model. There were 3218 test tweets, 571 of which had misspellings. We applied the different spelling correction approaches to these 571 tweets, and the corrected tweets were then cleaned as described in the tweet normalization stage. Processed tweets were input to the trained detection system. We compared the hate speech detection results on the 571 test tweets to evaluate the effect of spelling correction on this downstream application. As shown in Table 6, We report results on the original test data, and also on the test data which are corrected by our approach, PyEnchant, Ekphrasis, and google spell checker. We report precision, recall and F1-score of racist and sexist classification respectively and the macro-averages (to evaluate the overall performance).

The best performance of each metric is highlighted in the table. Compared with the classification performance on the test data with spelling errors for the racist category, our approach improves the precision by 1%, the recall by 6.4%, and the F1 score by 3.7% absolute points. Both PyEnchant and Ekphrasis spell checkers improve the recall of sexist category, but decrease the precision, so their corrected forms achieve F1 scores similar to the original test data. Google spell checker also gives similar F1 score on both racist and sexist classes. Our approach outperforms the other baselines in terms of F1 score for the racist class and the macro F1 score.

For sexism-related tweets, our approach does not improve the results compared to the original test data. Taking a closer look at these tweets we notice that they often contain some abbreviations which might be taken as misspellings, and that their contextual information is insufficient to decide the appropriate corrections. For example, in the sexist tweet "I'm sorry but if you watch women ufc fights kys". Our approach replaces *kys* with *keys*, and the trained neural network misclassified the corrected tweet. Another instance is "these nsw promo girls think way too highly of themselves", where *nsw* is incorrectly replaced with *new* by our approach.

6 CONCLUSION

In this study, we showed how malicious spelling errors can deceive profanity- and spam detectors. To deal with these malicious misspellings, we proposed a context-sensitive spelling corrector based on word embeddings. Our spell checker is light-weight, unsupervised and can be easily incorporated into downstream applications. It achieved a favorable spelling correction performance when compared with general purpose spell-checking tools such as PyEnchant, Ekphrasis and Google spell checkers on both synthetic and real misspellings from different datasets.

ABSTRACT

Social recommendations have been a very intriguing domain for researchers in the past decade. The main premise is that the social network of a user can be leveraged to enhance the rating-based recommendation process. This has been achieved in various ways, and under different assumptions about the network characteristics, structure, and availability of other information (such as trust, content, etc.) In this work, we create neighborhoods of influence leveraging only the social graph structure. These are in turn introduced in the recommendation process both as a pre-processing step and as a social regularization factor of the matrix factorization algorithm. Our experimental evaluation using real-life datasets demonstrates the effectiveness of the proposed technique.

1 INTRODUCTION

Humans form opinions and make multiple decisions, small or big, on any given day. For many of those, such as deciding which movie to watch, or which new restaurant to try, or even which graduate school to attend, we tend to rely not only on our own personal judgment, knowledge and intution, but also that of others, especially those whose opinion we value and trust. This type of influence is what social recommender systems attempt to simulate. Social recommender systems leverage social relations to improve the rating-based recommendation process [1], based on the assumption that a user's preferences are likely to be similar to, or influenced by these of their friends [11].

Most of existing related work is making the assumption that the users are mostly influenced by their direct neighbors. However, studies have shown that humans tend to form opinions not only through their direct connections, but also via acquaintances [8, 9]. This concept aligns with the study of influence propagation in social networks. This line of work is drawing inspiration from social correlation theories such as homophily and social influence [18, 19]. Most of the existing approaches regard this as a long-term, network diffusion process, and follow a graph-theoretic approach to solve the problem of identification of influentials in a social network [2, 6, 13].

In this work, we introduce a social recommendation algorithm that leverages the influence propagation beyond direct neighbors in a social graph. In particular, we explore the integration of the social graph as input to the recommendation process. We employ our threshold-bounded influence propagation algorithm [10] to generate social graph-based neighborhoods for each user. This neighborhood of influence is used as a pre-processing step. The outcome of this algorithm is also integrated as a social regularization factor in the matrix factorization process. Our experimental results using real-life datasets demonstrate the effectiveness of such an approach. The proposed high-level methodology is depicted in Figure 1.

The rest of the paper is organized as follows: we review the related work in Section 2. We then present the influence propagation algorithm in Section 3. The proposed recommendation algorithm with social regularization is presented in Section 4. Finally, in Section 5 we discuss the results of our experimental evaluation and conclude with our observations and our plans for future work in Section 6.

2 RELATED WORK

Social recommender systems have gained a lot of attention from the research in an effort to leverage social relationships to improve the recommendation process. Rooted in the sociology concepts of homophily and social influence [18], this line of work is based on the assumption that users' preferences are influenced more by these of their connected friends than these of unknown users [26]. Tang et al. [22] give a narrow definition of social recommendation as "any recommendation with online social relations as an additional

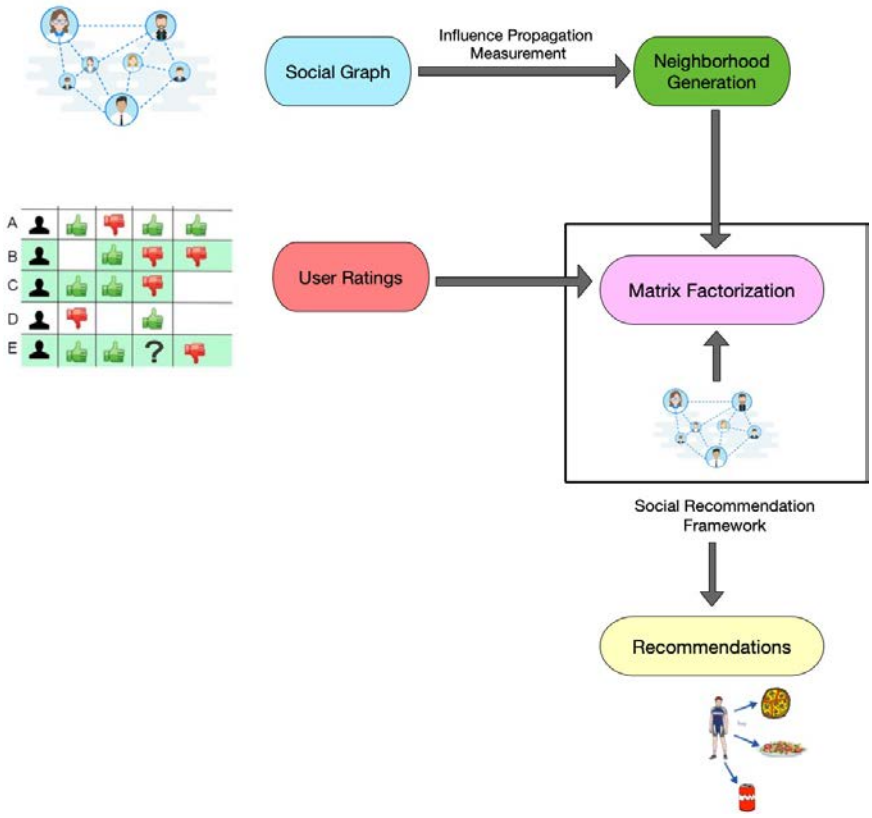

Figure 1: Social Recommendation Framework incorporating influence propagation approach for neighborhood generation in Matrix Factorization for generating effective recommendations for users.

input, i.e., augmenting an existing recommendation engine with additional social signals" (a broader definition, not applicable to this work, refers to recommender systems targeting social media domains [11]).

The various proposed approaches can be categorized depending on the type of social relationship (trust, friendship etc.), the type of the underlying recommendation algorithm (model-based, memory-based, etc.), and the level of integration of the social information in the recommendation process. A common approach is to enhance model-based recommender systems with social connections, again most often expressed as trust. This can be done through co-factorization, where the assumption is that the users share the same preference vector in both the rating and the social spaces (e.g. [20]), ensemble methods, where the resulting recommendation is derived by the linear combination of two systems (e.g. [15, 21]), or regularization, where priority is given to the social-based ratings (e.g. [12, 16]).

An alternative line of work involves ways to enhance the memory-based collaborative filtering process by forming the user's neighborhood using similarities deriving from the users' ratings and/or their social relationships, focusing on trust [5, 7, 17, 23–25]. One of the most recent works [4] introduces a Deep Learning Matrix Factorization (DLMF) approach to address the issues related to the initialization of latent feature vectors in Matrix Factorization (MF). The authors use the user's trust on other users who belong to his/her clique as the basis of neighborhood formation, and integrate it with Matrix Factorization as a trust regularization factor to predict ratings.

Ma et al. [16] introduced social regularization constraints in the recommendation framework. They used the social information to effectively predict the missing user-item matrix. Experimental results on real world data showed that their algorithm outperformed the traditional Matrix Factorization methodology. In this work we follow a similar approach, however we focus on influence as derived from the social graph connections, rather than metadata related to the users. We leverage our proposed influence propagation algorithm [10] and create social graph-based personalized neighborhoods that are subsequently used as input to the recommendation process. Moreover, we combine the social information of the users gained from influence propagation algorithm to Matrix Factorization forming a unified social recommendation framework.

3 NEIGHBORHOOD FORMATION USING INFLUENCE PROPAGATION

In this section we briefly present our Threshold-Bounded Influence Propagation algorithm (TB-IP) [10]. While this algorithm was introduced to solve the *min-max* problem of maximizing influence coverage on a social network with the minimum number of "seed" nodes, in this work we utilize it as a means to integrate social graph data to the recommendation process[1].

A social network can be modeled as a weighted-edge graph $G = (V, E, W)$, where V is the set of all the vertices in the graph (i.e. people), E is the set of edges (i.e. their connections), and W is the set of edge weights. An edge from node u to node v ($u \rightarrow v$) signifies that user u "follows" v in the social network, and the edge weight $w(u_v)$ represents the influence of v on u. Our objective is to identify the influential nodes $v \in M, M \subset V$ that influence the remaining nodes $u \in D, D \subset V$, $D \cap M = \emptyset$ such that $|M|$ is minimized and $|D|$ is maximized. The *Threshold-Bounded Influence Propagation in Digraph (TB-IP)* algorithm takes as input a graph G and outputs sets M and D.

The algorithm accepts the following as parameters: a) a threshold thr that is defined according to the selected threshold condition and is used to determine whether a node u is influenced by v, b) a maximum number of *"hops"* (i.e. the maximum allowed depth of influence propagation), c) a *decay factor* for the influence propagation, and d) a ranking strategy for initializing the nodes (e.g. PageRank, Out-degree centrality, Upper-bound PageRank etc.). We consider three alternatives as threshold conditions:

- *Condition I: No Threshold (NoThr):* The first condition is considered for two-hops in the graph considering no threshold for influence propagation.
- *Condition II: Average Threshold (AvgThr):* The second condition takes threshold as the average of edge-weights of the entire network. This would mean that the threshold is constant for all the nodes, depending on the characteristics of the network as a whole.
- *Condition III: Edge-Weight dependent Threshold (EWThr):* The third condition determines the threshold by taking average of edge-weights of all the outgoing-edges from the node in the graphically represented social network. Thus, this threshold condition is vertex-specific but constant for every node.

The algorithm begins by sorting all nodes in descending order based on their assigned rank $r(v)$. Then, beginning with the highest ranked node, it examines whether its direct connections should be added to its neighborhood and therefore be considered influenced or not. This is determined by examining whether the edge-weight $w(u_v)$ of a connected node u is above the set threshold thr or not. If at least one connected node qualifies, node v is being added to the "influencer" set M and the qualifying nodes are being added to the "influenced" set D. If the algorithm is set to examine nodes that are indirectly connected to v (depth is defined by the *maxhop* parameter), each of the nodes that were added to $N_G(v)$ in the previous step are used to find their directly connected nodes. However, in this case, the respective edge-weights are updated by the *hopping factor* before being evaluated against the threshold thr as follows:

$$w(p_u) * (1 + hop * decay) \geq threshold \quad (1)$$

where *hop* is an integer value 0 for immediate neighbors (i.e. adjacent nodes) and it increments by 1 for each subsequent hop, and *decay* is a constant equal to 0.1[2].

When a node satisfies the threshold condition and has not been previously added to the "influenced" set D, then it is being added to both this set, and the neighborhood of v, $N_G(v)$. The algorithm stops this loop when either the maximum depth (i.e. number of hops) has been reached, or no nodes are qualifying as "influenced" in the current level. This process is being repeated for each of the nodes, as selected from the ranked list, and as long as they have not already been added in the "influenced" set D. The above process is described in detail in Algorithm 1.

Algorithm 1 Threshold-Bounded Influence Propagation in Digraph (TB-IP)

Require: A weighted and directed social network $G = (V, E, W)$
Ensure: Influenced Vertices $D \subset V$ and Influential Vertices $M \subset V$a

```
Initialize: thr, maxhop, visit = 0, hop = 0, decay = 0.1, D = ∅, M = ∅
∀v ∈ V, r(v) = compute_rank(v)

for each v ∈ S do
    if w(u_v) > thr and ∃ u ∈ V \ D then
        N_G(v) = N_G(v) ∪ u
        D = D ∪ u
        M = M ∪ v
        visit = 1
    end if
    while hop ≤ maxhop and visit = 1 do
        hop = hop + 1
        visit = 0
        for each u ∈ N_G(v) do
            w(p_u) = w(p_u) * (1 + hop * decay)
            if w(p_u) > thr and ∃ p ∈ V \ D then
                N_G(v) = N_G(v) ∪ p
                D = D ∪ p
                visit = 1
            end if
        end for
    end while
end for
output D, M
```

4 SOCIAL REGULARIZATION IN MATRIX FACTORIZATION

A lot of techniques have been used in the past to generate effective recommendations for users. Perhaps the most popular methodology in terms of both effectiveness and efficiency is matrix factorization [14]. This collaborative filtering technique takes as input the

[1] More details as well as the experimental evaluation of this algorithm can be found in [10].

[2] Value set after experimentation.

matrix containing user ratings for items and applies dimensionality reduction to identify latent features of correlated user-item interactions. Mathematically, the sparse user-item (or *utility*) matrix ($R \in \mathbb{R}^{m \times n}$) can be decomposed into two matrices, representing the users ($P \in \mathbb{R}^{k \times m}$) and items ($Q \in \mathbb{R}^{k \times n}$). The low-ranked matrix factorization approach approximates the utility matrix R by multiplication of k-rank factors (where $k < min(m, n)$):

$$\mathrm{R} \approx \mathrm{P}^{\mathsf{T}} \times \mathrm{Q} \tag{2}$$

Singular Value Decomposition (SVD) is traditionally used to factorize the observed ratings from the utility matrix to obtain the latent factors by minimizing the following objective function:

$$\min_{P,Q} \frac{1}{2} \sum_{u=1}^{m} \sum_{i=1}^{n} I_{ui}(R_{ui} - P_u^T \cdot Q_i)^2 + \lambda_1(\|P\|^2) + \lambda_2(\|Q\|^2), \tag{3}$$

where $\lambda_1 > 0$ and $\lambda_2 > 0$ are the regularization factors added to avoid overfitting. I_{ui} is an indicator function which is 1 when user u has rated item i and it is equal to 0 if the user has not rated the item. Several optimization approaches can be used to find local minimum of Equation 3, such as Alternating Least Squares (ALS) or Stochastic Gradient Descent (SGD).

In this work, we integrate the social graph data in the recommendation process following a similar approach to that of Ma et al. [16], who introduced a social regularization term in the objective function, incorporating the preferences of a user's friends, i.e. the directly connected nodes of a node in the social graph. We employ the TB-IP algorithm discussed in section 3 in two ways, as shown in Figure 1.

First, we apply the algorithm as a pre-processing step to define a social graph-based neighborhood of influence in the graph. This process removes some of the nodes that do not belong to the circle of influence of any other users, and thus are expected to contribute less to the rating prediction. Secondly and most importantly, we define a new social similarity function that integrates the edge-weights derived from the TB-IP algorithm as social relation weights between users.

The problem of estimating the utility matrix R is therefore reduced to minimizing the following objective function and regularization terms:

$$\begin{aligned} \min_{P,Q} \mathcal{L}_2(R, P, Q) = \frac{1}{2} \sum_{u=1}^{m} \sum_{i=1}^{n} I_{ui}(R_{ui} - P_u^T \cdot Q_i) + \\ \frac{\beta}{2} \sum_{v \in N_G^{+(u)}} SocSim(u, v)(\|P_u - P_v\|^2) + \\ \lambda_1(\|P\|^2) + \lambda_2(\|Q\|^2), \end{aligned} \tag{4}$$

where $\beta > 0$, and ${N_G}^{+(u)}$ denotes u's out-link connections belonging to its neighborhood N_G^u as derived by the TB-IP algorithm.

We further augment this social regularization term by introducing a social similarity to weigh how much each neighbor's preference affects the user's predictions. We define the social similarity $SocSim(u, v)$ between two users u and v as follows:

$$SocSim\,(u, v) = \frac{1}{2}(Sim\,(u, v) + w(u_v)). \tag{5}$$

$Sim(u, v)$ stands for any vector similarity metric that can be employed to calculate how similar the two user vectors u and v are (in terms of similar ratings). In this work, we use the Pearson correlation coefficient [3] formulated as:

$$Pearson\,(u, v) = \frac{\sum_{i \in P_u \bigcap P_v} (R_{ui} - \bar{R}_u)(R_{vi} - \bar{R}_v)}{\sqrt{\sum_{i \in P_u \bigcap P_v} (R_{ui} - \bar{R}_u)^2} \sqrt{\sum_{i \in P_u \bigcap P_v} (R_{vi} - \bar{R}_v)^2}}. \tag{6}$$

Here, i is the subset of total items user u and user v have both rated. R_{ui} is the rating given by user u to item i. $\bar{R}_u$ and $\bar{R}_v$ are the average ratings of users u or v respectively and R_{ui}, R_{vi} are the ratings of users u and v respectively for item i.

The second term, $w(u_v)$, is the edge weight derived by Algorithm 1. This weight measures the extend to which user v influences user u, and is based on the social graph's structure. Therefore, this social similarity metric leverages both the social graph and the rating preferences of the users.

A local minimum of Equation 4 can be obtained by applying SGD on the P_u and Q_i feature vectors, solving the partial derivatives on both the feature vectors as shown in Equations 7 and 8:

$$\begin{aligned} \frac{\partial \mathcal{L}_2}{\partial P_u} = \sum_{i=1}^{n} I_{ui}(P_u^T \cdot Q_i - R_{ui})Q_i + \lambda_1 P_u \\ +\beta \sum_{v \in N_G^{+(u)}} SocSim(u, v)(P_u - P_v) \end{aligned} \tag{7}$$

$$\frac{\partial \mathcal{L}_2}{\partial Q_i} = \sum_{u=1}^{m} I_{ui}(P_u^T \cdot Q_i - R_{ui})P_u + \lambda_2 Q_i \tag{8}$$

5 EXPERIMENTAL EVALUATION

The need for datasets that combine both user-item-rating triplets and social graph data for the users limits our choices to a big extend. One of the most known and broadly used datasets that combines both sources of information is the Yelp Challenge dataset[3]. We also employ the Epinions dataset[4]. Epinions is a trust-based rating dataset - in essence users have denoted whether they trust other users in their reviews and ratings or not. For our work we have translated "trust" endorsements to directed edges. While the resulting graph is not representing social relationships (of friendship), it encapsulates some social characteristics (users trusting other users in some context), and in the absence of other publicly available datasets, we follow the example of related research approaches and use this as a second real-life data source.

For the Yelp dataset we select the Las Vegas subset, including only the users who had rated at least one business in the city of Las Vegas. This is because the Yelp social subset (i.e. friends's network) is very sparse, with the Las Vegas dataset containing the most dense social graph subset. Hence, we only considered those connections who rate restaurants and reside in the same area. The details of the social graph of each dataset are included in Table 1, while the user-item-rating characteristics are included in the first row of Tables 2 and 3.

[3] https://www.yelp.com/dataset/challenge
[4] www.epinions.com

For each dataset, we generate recommendations using two baselines and several variations of our proposed methodology. We employ the optimal parameters for the TB-IP algorithm, as experimentally identified in [10], running the algorithm using the *EWThr* threshold selection strategy for two *hops* (named *TwoD EWThr*).

Table 1: Social graph dataset characteristics

Dataset	Yelp (Las Vegas)	Epinions (Trust)
# Nodes	247,111	18,089
# Edges	5,340,568	355,217
Avg. Degree	21.612	19.6372
Type	Directed	Directed

Table 2: Yelp input datasets

Dataset	# Users	# Businesses	# Ratings
BaseAll	247,111	26,304	1,104,768
TwoD EWThr	96,900	24,632	733,408

Table 3: Epinions input datasets

Dataset	# Users	# Items	# Ratings
BaseAll	22,164	296,277	922,267
TwoD EWThr	7,615	222,281	539,963

We evaluate the effect of the neighborhood formation in two levels: i) as the input (i.e. as a pre-processing step) to the recommendation process, and ii) as an integral part of the recommendation algorithm.

To evaluate the first objective, we apply TB-IP to the entire dataset. We therefore create two different input sets, as shown in Tables 2 and 3:

Dataset 1: BaseAll. This dataset has the entire user-item-rating data.

Dataset 2: TwoD EWThr. This dataset has the rating data only for users obtained after applying the TB-IP Algorithm with *EWThr* threshold condition. We use the *Outdeg* ranking methodology for initial ranking of nodes.

We consider two baseline methodologies to evaluate our proposed Social Recommendation Framework. The first baseline evaluates the traditional Matrix Factorization (*SimpleMF*) explained in equation 3. As the second baseline we consider the Social Regularization in Matrix Factorization (*Simple SoReg*) developed by Ma et al. [16]. In that work, the similarity function does not incorporate the social graph weight (in essence reflects a normalized Pearson correlation coefficient). We compare these baselines against several variations of our method, employing the TB-IP algorithm and the new similarity metric function (*SocSim*) that we defined in Equation 5. The different setups are explained in what follows.

Experiment 1: SimpleMF (First Baseline). Using as input the entire dataset (*BaseAll*) and implemented *Basic MF*, i.e. traditional Matrix Factorization [14].

Experiment 2: TB-IP SimpleMF. In this experiment, we considered the social-graph induced dataset (*TwoD EWThr*) and generated recommendations using *Basic MF*.

Experiment 3: Simple SoReg (Second Baseline). Here, we evaluated *SoReg* methodology with *Sim* for *BaseAll* dataset, as discussed in [16].

Experiment 4: TB-IP SoReg. We use as input the social-graph induced dataset *TwoD EWThr* and generate recommendations using *SoReg* technique using the normalized Pearson similarity metric.

Experiment 5: SocSim Simple SoReg. Here, we apply our proposed *SoReg* algorithm incorporating the *SocSim* similarity metric over the entire (*BaseAll*) dataset.

Experiment 6: SocSim TB-IP SoReg. In this experiment, the preprocessing step is applied to create the input dataset *TwoD EWThr* and the recommendations are generated by using the *SoReg* technique with *SocSim* similarity metric.

We performed 5-fold cross validation for all the experimental setups.[5] We evaluated all combinations of the following Matrix Factorization parameters: *rank (f)* = $\{10, 20\}$, *regularization* (λ) = $\{0.1, 0.01, 0.001\}$, *maximum iterations (max_iter)* = $\{10, 20\}$. For the Social Regularization technique we also used another metric, called *social regularization* (β) = $\{0.1, 0.01\}$.

We use RMSE and MAE evaluation metrics. The results, along with the optimal parameters for each setup, are presented with the corresponding experiment in Tables 4 and 6 (RMSE) and Tables 5 and 7 (MAE) for the Epinions and Yelp dataset respectively.

Table 4: RMSE and optimal parameter settings for different experiments performed for Epinions

Experiment	RMSE	f	λ	β	max iter
SimpleMF	1.063	20	0.001	0	10
TB-IP SimpleMF	1.046	20	0.001	0	10
Simple SoReg	1.046	20	0.01	0.1	20
TB-IP SoReg	**1.030**	20	0.01	0.1	20
SocSim Simple SoReg	1.061	20	0.01	0.1	10
SocSim TB-IP SoReg	1.043	20	0.01	0.1	10

Table 5: MAE and optimal parameter settings for different experiments performed for Epinions

Experiment	MAE	f	λ	β	max iter
SimpleMF	0.812	20	0.001	0	10

SocSim TB-IP SoReg	0.899	20	0.01	0.01	10

influential neighborhoods within the original dataset, outperform the others in both datasets. For the Epinions dataset we observe that the *TB-IP SoReg* approach outperforms the others, giving the best results both in terms of RMSE and MAE, with second best our *SocSim TB-IP SoReg* approach. On the other hand, we observe that for the much larger Yelp dataset, our approach (*SocSim TB-IP SoReg*) gives better results than the other approaches in terms of RMSE while having very comparable MAE results with the *TB-IP SoReg*. In fact, we observe a big improvement over the baselines, ranging from 6.3% to 8.6% for RMSE and 5.8% to 7.7% for MAE.

As previously mentioned, the Yelp social graph represents a real social network (in that the edges reflect friendships between users), compared to the one of Epinions that signifies trust relationships ("I trust someone's opinions/reviews") but not necessarily real-life friendships or social relationships. Therefore we can conclude that the difference in our algorithm's effectiveness lies in the fact that it works better when real-life relationships are represented in the social graph and therefore better reflected in the social weights $w(u_v)$ and the derived *SocSim* similarity.

Tables 8 and 9 show the running time for neighborhood formation (where applicable) and recommendation for the Epinions dataset. The times reported reflect the optimal parameters for each setup. As expected, the proposed approaches introduce an overhead for the neighborhood formation phase, resulting in higher total times. However, this pre-processing step is performed offline and is not expected to affect real-time recommendations. On the contrary, we observe that both approaches integrating our social regularization factor with the *SocSim* similarity are faster than their simple Pearson similarity counterparts during recommendation time. This is due to the fact that the algorithm took less iterations to converge in the former case. We hypothesize that this is due to the fact that the social graph weights $w(u_v)$ introduced in the user similarity (*SocSim*) act as a form of better initialization for the matrix factorization process, helping the algorithm to converge in fewer steps.

Overall our results confirm our claim that combining neighborhood formation with influence propagation and social regularization produces better recommendations than the traditional social recommendation approaches.

6 CONCLUSIONS

In this work, the problem of generating social recommendations is explored in the context of influence propagation. We employ an influence propagation algorithm to create social graph-based neighborhoods of influence. This neighborhood is then used as input to the recommendation algorithm, both as a pre-processing step and as an integral part of the recommendation algorithm in the form of a similarity metric. Our experiments show that the integration of social graph-derived information improves the traditional rating-based recommendation process. Moreover, we observe that in the case of real-life relationships reflected in the input social graph, our proposed similarity metric greatly improves the results and accelerates the recommendation algorithm.

Part of our ongoing work includes improving further on the social regularization component and social similarity metric. We are also exploring employing deep learning to initialize the latent vectors, and want to study how other influence propagation algorithms and centrality metrics can be employed as a means to create user influence neighborhoods. Finally, we believe that the introduction of a social component in the recommendation process not only improves the accuracy of recommendations, but can also be leveraged to generate explainable recommendations. This is an interesting extension of this work that we plan to explore in the near future.

ABSTRACT

Spell correction is a must-have feature for any modern search engine in applications such as web or e-commerce search. Typical spell correction solutions used in production systems consist of large indexed lookup tables based on a global model trained across many users over a large scale web corpus or a query log.

For search over personal corpora, such as email, this global solution is not sufficient, as it ignores the user's personal lexicon. Without personalization, global spelling fails to correct tail queries drawn from a user's own, often idiosyncratic, lexicon. Personalization using existing algorithms is difficult due to resource constraints and unavailability of sufficient data to build per-user models.

In this work, we propose a simple and effective personalized spell correction solution that augments existing global solutions for search over private corpora. Our event driven spell correction candidate generation method is specifically designed with personalization as the key construct. Our novel spell correction and query completion algorithms do not require complex model training and is highly efficient. The proposed solution has shown over 30% click-through rate gain on affected queries when evaluated against a range of strong commercial personal search baselines - Google's Gmail, Drive, and Calendar search production systems.

1 INTRODUCTION

Misspelling is common in real-world information retrieval systems. More than 10% of search engine queries are misspelled [8]. This rate is even higher for tail queries, for which there is more than a 20% misspelling rate [3]. Misspellings are not just limited to unintentional typing errors, but are often a result of the challenges imposed by the spelling itself. For example, due to factors such as ambiguous word breaks, phonetically similar words, introduction of new words (e.g. project names), and inconsistent spelling rules [1], remembering the correct spelling can be surprisingly difficult even for native speakers.

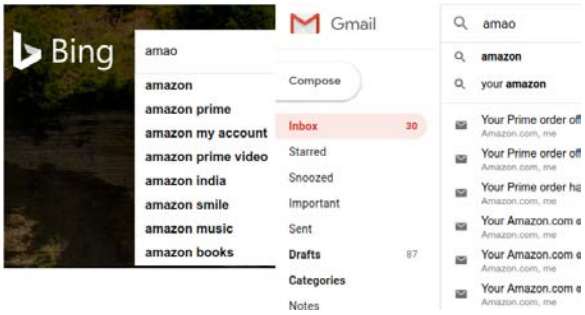

Figure 1: Online spell correction and query completion while the user types on-the-fly (Left) provides suggestions only, (Right) provides as suggestions as well as results.

For these reasons, spelling correction is essential in modern information retrieval systems today. By providing high quality spell correction capabilities, search engines can significantly reduce the amount of effort required for users to find their desired results.

The traditional spell correction approach, referred to as *offline spell correction*, is provided only after the entire query is typed and passed to the search engine (e.g. after a user presses "Enter"). Such a system assumes that any query sent to the search engine has been completely typed by the user. The modern approach, referred to as *online spell correction* [10], provides spell correction and query completion as the user is typing. It is enabled for almost all popular web search services nowadays. In this case, most of the queries under consideration are incomplete. See Fig. 1 for an illustration.

The algorithm presented in this paper is particularly designed for online spell correction systems, and specifically for personal search scenarios. Providing online spell corrections for personal search is remarkably complicated primarily due to the large and diverse vocabulary of private corpora. Furthermore, the stringent latency requirements for online spell correction systems adds to the complexity and renders most of the alternative algorithms impractical for large-scale use.

Personal search, including email search [2, 5, 24], desktop search [11], and most recently on-device search [18], has recently attracted a considerable amount of attention from the information retrieval community. The key difference between personal and public search (e.g. web search) is that users, in the personal search scenario, have access only to their own private document corpora (e.g. emails,

files, or mobile application data). This poses several new challenges for existing spell correction approaches: (1) A global lexicon may not work well or even hurt performance as each user may have a very unique private corpus. (2) Traditional machine learning-based models are difficult to train for personalization due to relatively small-sized personal corpus, sparse user interactions, and resource constraints. In many real-world cases, training a model directly from private data may not even be allowed due to privacy restrictions. (3) Tail-queries, which are difficult to handle using traditional spell correction systems, become even more problematic, since for personal search many frequently used private terms for a particular user are tail-queries from a global perspective. (4) Due to the lack of quality control, there could be more misspellings in private data itself (e.g. a typo in an email title). This is contrary to the rationale behind existing spell correction systems which build models over correctly spelled words.

This paper introduces an effective and efficient training-free spell correction solution for personal search. It can either be used independently or to complement existing global spell correction systems. We describe the spell correction candidate generation algorithm that provides a personalized lexicon created from a user's recent activities. We provide some details on how to realize such a system under real-world constraints (e.g. privacy and computing resources). We then describe a novel and simple algorithm augmenting the Levenshtein distance based approach for unified spell correction and query completion that allows serving millions of users in a real-time online spell correction system. We build and test our system using real-world online experiments conducted on millions of users for three of the world's largest commercial private corpora (Google's GMail, Drive, and Calendar), and show unanimously positive performance for each corpus across several languages, compared against strong production baselines with spell corrections learned using public web search data.

The remainder of the paper is organized as follows. We start with related works in Section 2. An overview of our system is presented in Section 3. Section 4 outlines candidate generation setup followed by detailed discussion on the spell correction and query completion algorithms in Section 5. Finally, evaluations from our experiments are presented in Section 6.

2 RELATED WORK

Most recent work on spell correction generally focuses on public search queries. Related methods usually produce a global model for all users. Also, a large amount of historical user interactions are normally needed for learning-based approaches. Such approaches typically cannot be applied to personal search settings, as the private data (e.g. search queries, corpora) available is often many orders of magnitude smaller.

For traditional offline spell correction (e.g. "did you mean"), Cucerzan and Brill [8] proposed an iterative approach that transforms unlikely queries into more likely variants based on web query logs. Chen *et al.*[7] explored web search results (queries and their top-ranked candidates) to improve existing spell correction models. Some methods [15] depend on user feedback using an existing spell correction system, which can have cold-start problems and bias concerns (e.g. position bias by the existing system). Sun *et al.*[23] learned phrase-based spell correction models from clickthrough data. Hasan *et al.*[16] collected similar user queries using user session and time information in which users "correct themselves," and uses Levenshtein distance [19] as the similarity criterion. Recently, approaches based on deep learning have become popular, such as those using sequence-to-sequence learning [13]. All of these approaches, especially deep models, typically require large amounts of user interactions or labeled data which does not scale to fully personalized spell correction and personal search scenarios.

A special less data intensive case is word embedding [21] based methods where pre-trained embeddings can be used. However, existing methods primarily use embeddings trained on a large public corpus in a user agnostic manner (e.g. Word2Vec [20] is trained over news articles). Some methods are designed in an *ad hoc* manner for specific language pairs [13, 14]. Our simple approach works well across several languages.

Online spell correction has drawn more interest in the research community [6, 9, 10] and real-world applications (e.g. Google and Bing web search engines). These systems may provide search results, but the incoming queries are often incomplete. Hence, spell correction and query completion are essential components. Chaudhuri and Kaushik [6] made use of edit distance for spell correction followed by a fuzzy search over database records to find completions. Our work unifies spell correction and query completion in an efficient augmented edit distance method. Huizhong and Bo-June [10] trained a Markov n-gram transformation model and adapted A^* search with pruning for efficiency. However, their method is specific to data-intense public corpora since it can only be applied to previously observed queries and requires a large amount of training data. Our approach does not require historical queries (which could be sparse) and complex model training.

More broadly, personalized search, including personalized query completion, has also been extensively explored [4, 22] on public corpora. Existing approaches are typically segment-based (e.g. using gender as a feature) while our work is specifically focusing on individual-level private corpora search. Some works utilize user's past search activities (e.g. queries) as signals, which could be sparse for many users. We are not aware of any prior work that focuses on individual-level spell correction in personal search, where personal lexicon is ubiquitous and user search activities are sparse, both of which pose challenges to existing personalized search methods.

3 OVERVIEW

A high level overview of our online spell correction system is present in Fig. 2, depicting the *candidate generation* and the *spell correction and query completion* components. Each user has their own personal lexicon constructed only from their set of private corpora. The lexicon can be updated periodically or in real-time (e.g. when a new document is created). The private user lexicon is small and highly relevant, and does not need any sophisticated data structure, language model or error model trained for that user.

4 CANDIDATE GENERATION

The candidate generation component is responsible for creating a personalized lexicon for every user represented as a set of contextually relevant n-grams. Generating these n-grams consists of

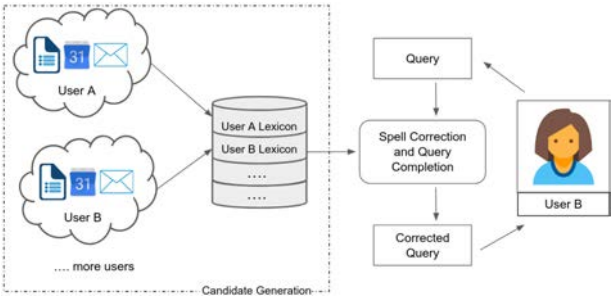

Figure 2: System Overview: Candidates from the personalized lexicon generator passed to spell correction and query completion component.

the following steps: 1) data ingestion, 2) candidate extraction, and 3) candidate update under constraints. Below, we discuss each of these steps in more detail providing general guidelines that can be useful for other applications.

4.1 Data Ingestion

We limit the input data for users to their private corpus. There are a couple of reasons for this design choice: 1) Users will only have access to their private data in personal search, so information from other users decreases the signal-to-noise ratio. 2) Privacy is critical in real-world systems, and non-aggregated data from other users can leak information. 3) By limiting candidates to the user's own set of corpora, the candidate space of n-grams for evaluation is trimmed to a significantly smaller (but highly relevant) set. Note that the user does not need to be the owner of a document, shared documents are taken into account as well.

4.2 Candidate Extraction

The lexicon of a user is composed of n-grams. We use three sources of data that are combined to form a single lexicon per user: 1) Email subjects and the email addresses of senders and recipients, 2) Drive document titles and the email addresses of the owners, and 3) Calendar event titles and the email addresses of the event participants. We found that titles (ignoring bodies) are simpler to manage and have high signal-to-noise ratio for spelling. Note that users can still search document bodies. Also, we keep email addresses as they are frequent query terms.

The snippets collected in the previous step are decomposed into candidate n-grams by standard techniques including tokenization and stopword removal. Additionally, we apply normalization techniques including lowercasing and lemmatization. Note that if documents are retrieved for a spell corrected query (see Fig. 1 right), these normalizations must be consistent with the normalization used when indexing the documents.

4.3 Candidate Update Under Constraints

Maintaining a personal lexicon for every user has many real-world constraints. For example, due to data retention policies, the system may be required to delete any candidate derived from deleted documents. Also, the system is bounded by space constraints as it stores a personal lexicon for every user. This is especially critical for real-world search engines that serve many millions of users. Additionally, a small but high-quality lexicon allows fast online spell correction by iterating over candidates without designing sophisticated index-based data structures for each user. We propose to use an event driven model that addresses these constraints in a unified manner.

The high-level idea of candidates update is to construct a small lexicon that is contextually relevant to the user when they issue a query. For this work, the model ranks snippets generated from the user's recent events based on the recency. The set of events used in our experiments are:

- GMail: Search interactions with emails.
- Drive: Interactions with documents including creation, view, edit, and comment events that are relevant to the user.
- Calendar: Ongoing and upcoming calendar events.

For example, when a user edits a document, n-grams from the document title are prioritized high in the lexicon. When space constraints are reached, the lowest ranked candidates are removed from the lexicon to accommodate new candidates. Prioritization of n-grams may not be necessary in some applications. For instance, in mobile apps search, it might be feasible to retain all of the currently installed app names.

4.4 Properties

There are several interesting properties of our event driven candidate generation method.

- Previous *search* activity and clicks are helpful but not required, unlike in most prior work. For example, n-grams from Drive documents can be from an edit event, or even initiated by another user (e.g. comment events where this user is tagged, share events, etc).
- Prioritization of n-grams based on recency provides a simple approach to address privacy and resource constraints.
- n-grams from multiple corpora (GMail, Drive, Calendar) are merged into a single lexicon and are used in search for each corpus. This is intuitively useful for our scenario. If someone has been working on a `TheWebConference` paper, it's possible that she gets emails and calendar invites discussing `TheWebConference` and has related documents about the `TheWebConference` paper. We advocate that applications should take into account such a unified representation whenever sensible, since (1) shared knowledge across corpora mitigates the data sparsity problem and (2) a single lexicon for each user is much easier to manage in practice.

5 EFFICIENT SPELL CORRECTION AND QUERY COMPLETION

We describe an efficient spell correction and query completion algorithm using a modified Levenshtein distance based approach. Given each candidate from a user's lexicon and an input query (which may be incomplete and have spelling mistakes), the algorithm calculates a modified edit distance between them, which will be used for spelling correction candidate selection or ranking. We also describe several improvements to further speed up the calculation in practice.

5.1 Levenshtein Distance

Edit distance is defined in terms of the minimum number of operations (insertions, deletions, or substitutions) required to convert the user input string to a candidate spell correction. Levenshtein Distance is a special case of edit distance with three allowed operation: insertion, deletion, and substitution with unit cost for each of them. See an example in Fig. 3. The algorithm is $O(m * n)$ where m is the length of the input string and n is the length of the candidate string.

		E	L	E	P	H	A	N	T
	0	1	2	3	4	5	6	7	8
R	1	1	2	3	4	5	6	7	8
E	2	1	2	2	3	4	5	6	7
L	3	2	1	2	3	4	5	6	7
E	4	3	2	1	2	3	4	5	6
V	5	4	3	2	2	3	4	5	6
A	6	5	4	3	3	3	3	4	5
N	7	6	5	4	4	4	4	3	4
T	8	7	6	5	5	5	5	4	3

Figure 3: Levenshtein Distance algorithm example between user input string RELEVANT and candidate string ELEPHANT.

5.2 Extending Levenshtein Distance For Query Completion

The main novelty of our algorithm lies in extending the Levenshtein distance algorithm for low-cost query completions that makes it feasible for use in online spell correction scenarios. Fig. 4 shows the edit distance matrix M for the evaluation of Levenshtein distance.

The entry *M[i][j]* denotes the minimum cost to transform i characters of the input string to j characters of output string. For example, *M[3][5]* in Fig. 4 denotes the cost of transforming ELE to ELIZA.

The most important row for extending the algorithm for query completion is the last row. If *input_length* denotes the length of the input string, the *jth* column of this row, denoted by *M[input_length][j]*, represents the cost of transforming the complete input string into the first j characters of the output string. In other words, this row represents the cost of transforming the input string to each prefix of the output string. Hence, in Fig. 4, each column in the last row represents the cost of transforming ELEZA into the corresponding prefix of ELIZABETH.

In order to support query completions, we define a new parameter *prefix_completion_cost*. In the edit distance algorithm above, each of the substitution, insertion, and deletion operations have unit cost. This new parameter allows insertion of characters at a different cost, which should be much lower than the unit cost. We take the entries in the last row and count the number of additional characters required to convert the corresponding prefix string to the complete candidate string. For the prefix corresponding to column j, we need to insert $output_length - j$ characters, where *output_length* is the length of the output string. Let *R'* be a new row denoting the overall cost after allowing prefix completion. Hence, *R'[j]* denotes the cost after transforming the input string to a prefix of length j of the output string, followed by using low cost prefix completion operations to complete it to the output string.

$$R'[j] = M[input_length][j] + prefix_completion_cost * (output_length - j). \quad (1)$$

In Fig. 4, the input string is ELEZA and the candidate string is ELIZABETH. The edit distance produced by Levenshtein distance is 5. But since *prefix_completion_cost* is 0.2, one possible sequence of operations is to replace the second "E" in the input string with an "I", which has unit cost, following by completing the obtained prefix by adding BETH at the end. This will incur a cost of $0.2 * 4 = 0.8$ resulting in a total cost of 1.8 as the minimum cost.

5.3 Further Speed-up techniques

Take the case of an input string ELEPHANT and the candidate string RELEVANT. The Levenshtein Distance between the two strings is 3 but we had to calculate all the entries in the matrix.

Suppose that the max distance for candidates that we are interested in is *max_allowed_distance* (i.e., any candidate with a higher edit distance from the query will be filtered out). For Levenshtein Distance, it can be proved that if we calculate a strip of $2 * max_allowed_distance + 1$ along the diagonal, any element outside this strip must be greater than *max_allowed_distance*. For example, for $max_allowed_distance = 3$, Fig. 3 highlights the strip of interest along the diagonal.

This reduces the complexity of the algorithm from $O(m * n)$ to $O(m * max_allowed_distance)$, which is linear in the length of the input string. In practice, we found a *max_allowed_distance* of 2 is sufficient for our use cases.

Another speed-up technique we use is to reject a candidate if its first or second characters do not match the first character of the input string. The first character of an input query is rarely found to contain any error [12]. But it was observed that due to lag in web browsers, the first character is often missing in the input query. Therefore, we relaxed our check to also allow candidates with the second character same as the first character of the input string.

6 EXPERIMENTS

Due to privacy concerns and counterfactual effects (e.g. enabling our algorithm will generate very different search results that are not available in search logs), it is difficult to perform thorough offline analysis except for limited qualitative check (e.g. Fig. 5). We thus directly conduct real-world online experiments against three of the world's largest private corpora search systems: Google's GMail, Drive, and Calendar. These systems use the sophisticated spell correction and query completion mechanisms of Google's web search, thereby providing strong baselines [17].

We demonstrate consistent and significant improvements in effectiveness over these strong production baselines. Since these are online experiments within live systems used by millions of users, we were required to meet the rigorous latency requirements of these systems. The algorithm proposed here easily achieves these requirements. More details about the performance of the proposed algorithm are described in section 6.4.

		E	L	I	Z	A	B	E	T	H
	0	1	2	3	4	5	6	7	8	9
E	1	0	1	2	3	4	5	6	7	8
L	2	1	0	1	2	3	4	5	6	7
E	3	2	1	1	2	3	4	4	5	6
Z	4	3	2	2	1	2	3	4	5	6
A	5	4	3	3	2	1	2	3	4	5
perfix completion cost = (0.2 * (9 - column_index))	1.8	1.6	1.4	1.2	1	0.8	0.6	0.4	0.2	0
R' = original cost + prefix completion cost	6.8	5.6	4.4	4.2	3	1.8	2.6	3.4	4.2	5

Figure 4: Illustration of our augmented Levenshtein Distance algorithm that unifies spell correction and query completion. Column *j* for row *R'* represents the cost of prefix completion after converting input string (ELEZA) to a prefix of length *j* of candidate string (ELIZABETH).

query_length	1	2	3	4+
Prefix Completion	X	✓	✓	✓
Spell Correction(dist = 1)	X	X	✓	✓
Spell Correction(dist = 2)	X	X	X	✓

Table 1: Desirable behavior of prefix completion and spell correction for different length of queries.

6.1 Setup

Our application scenario is "instant" search, which performs "search as you type" (e.g. see Fig. 1 right). This type of search has stringent latency requirements to ensure a high quality user experience. The spell corrected and prefix completed query is used to retrieve the final list of relevance ranked search results.

We conduct three A/B live experiments, one on each of the above mentioned corpora (GMail, Google Drive, Google Calendar) that augments their existing approaches to spell correction that use global models trained on web data. These experiments are run on millions of users for a month, resulting in many millions of queries being included in the experiment (the exact number being proprietary).

6.2 Hyperparameters

Real-world experiments that affect millions of users forbids trying many hyperparameter combinations. Thus we first define the "desirable behavior" in Tbl. 1 and tune the hyperparameters offline.

We proposed this setting because it has clear and intuitive semantics. For very short queries, neither spell correction nor prefix completion is enabled. But as the query length increases, prefix completion gets enabled followed by both spell correction and prefix completion getting enabled.

In order to achieve the above behavior, we introduce a new parameter *max_cost* which can be used to control *max_allowed_distance* based on the *query_length* as follows:

$$max_allowed_distance = max_cost - \frac{\alpha}{query_length^2} \quad (2)$$

Since Levenshtein distance has unit cost for every operation, the number of spelling errors allowed are decided by the integer part of *max_allowed_distance*. We set *max_cost* to 2.7, α to 7, and *prefix_completion_cost* to 0.08. These parameters allow us to realize the desirable behavior (compare Tbl. 1 and Tbl. 2).

query_length	1	2	3	4+
$max_allowed_distance$ $(max_cost - \frac{\alpha}{query_length^2})$	-4.3	0.95	1.92	2.26
$\lfloor max_allowed_distance \rfloor$	-5	0	1	2
Prefix Completion $(max_allowed_distance > 0)$	X	✓	✓	✓
Spell correction(dist = 1) $(\lfloor max_allowed_distance \rfloor \geq 1)$	X	X	✓	✓
Spell correction(dist = 2) $(\lfloor max_allowed_distance \rfloor \geq 2)$	X	X	X	✓

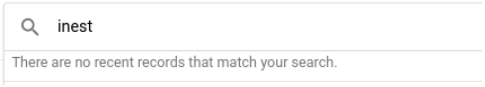
Table 2: Behavior of the algorithm after setting *max_cost* to *2.7* , α to 7 and *prefix_completion_cost* to *0.08.*

6.3 Metrics

Through the above mentioned algorithms, we measure the impact on the following search quality metrics:

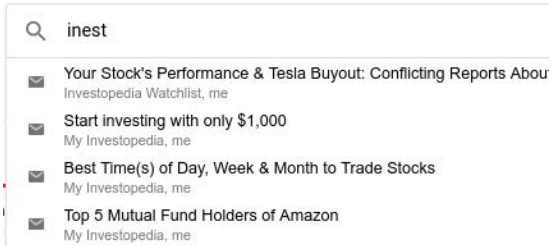
- **Click-Through Rate (CTR)**: represents the fraction of queries for which a result was clicked.
- **Mean Reciprocal Rank (MRR)**: The reciprocal rank is the multiplicative inverse of the rank of the clicked result: 1 for first place, $\frac{1}{2}$ for second place and so on, and 0 for queries without click. MRR is the mean of reciprocal ranks of all query responses.
- **Has Result Rate**: represents the fraction of queries for which we have at least one result.
- **Number of Results**: represents the mean of the number of results that were shown to the user for a given query. GMail, Drive, and Calendar search engines show a maximum of 6, 5, and 4 results respectively.

For all metrics, larger numbers are better. *CTR* and *MRR* are traditional search quality metrics. *Has result rate* and *Number of Results* are particularly interesting for spell correction, because misspelled queries tend to produce either a low number of results, or no result at all. These metrics signify improved recall while CTR and MRR signify precision improvements.



6.4 Runtime

Our per-user lexicon has at most 50 n-grams and 25 email addresses. We consider up to 7-grams. The average number of characters in the input query and candidate unigrams (from lexicon n-grams) was observed to be 5 and 8 respectively. The average number of characters in email addresses was observed to be 23.



Under this configuration, the algorithm takes 0.2ms on single-thread modern hardware to produce corrections. Hence, the time taken by the spell correction component is insignificant and is well-suited for our latency-sensitive system.

6.5 Illustrative Example

We show an illustrative example in Fig. 5 to demonstrate the quality improvements. As shown, our personalized online spell correction solution is able to successfully correct the query and provide relevant search results, while the baseline system without personalized spell correction produces bad quality results.

(a) Performance without our algorithm.

(b) Performance with our algorithm enabled.

Figure 5: A qualitative illustration of our solution in GMail. "investopedia", with its prefix misspelled as "inest", is a word only relevant to certain users. (a) The production system with web spelling is unable to find any relevant email. (b) Since the user interacts frequently with documents containing the word "investopedia", it is used to spell correct "inest" and show relevant emails.

6.6 Online Experiment Results

We report search quality metrics for affected queries for each of the three corpora under consideration. Affected queries in the experiment group are those rewritten by our component (i.e. a spell correction and query completion is applied, and the corrected word is used for search). Affected queries in the control group are those that would be affected if our component were deployed (i.e. we only detect that a spell correction is possible). Our current setup results in 3% of affected queries across all corpora, which (in absolute terms) is a non-trivial amount of search queries. We summarize the results to show relative improvements in Tbl. 3.

We observe consistently positive improvements in search quality metrics across each of the three corpora. These improvements are significant and highly meaningful in the production setting.

Metrics	Email	Drive	Calendar
CTR	+31.55%	+16.04%	+38.27%
MRR	+26.00%	+10.17%	+30.41%
Has Result Rate	+15.55%	+8.51%	+43.34%
Number of Results	+31.13%	+14.53%	+76.61%

Table 3: Search quality improvements on affected queries in our online experiment. All numbers in the table are statistically significant at the $p < 0.05$ level.

Language	Email CTR	Drive CTR	Calendar CTR
English	+28.78%	+14.04%	+38.57%
Spanish	+44.58%	+11.24%	+21.51%
French	+21.02%	+9.60%	+220.93%
Japanese	+12.48%	+1.72%	+32.33%
Portuguese	+25.44%	+65.88%	+50.29%
Italian	+27.19%	+33.04%	+68.05%
Chinese	+41.86%	+28.94%	NA

Table 4: CTR improvements on affected queries in different languages across corpora.

Furthermore, these metrics are quite intuitive. In personal search, a misspelled query without good spell correction is unlikely to locate any meaningful result due to the small personal corpora, leading to low CTR and result count based metrics such as Has Result Rate.

6.7 Cross-Language Performance

We further show that our simple approach works well across different languages in Tbl. 4 in terms of CTR (we omit other metrics with similar trends due to space constraints). These languages are the top languages in terms of query count and cover more than 90% of all queries in our experiments.

Overall we get positive CTR (and other metrics) on a diverse set of languages including languages without natural delimiters like Chinese, Japanese, and Korean. There is variance in terms of quality improvements and further adapting our approach for different languages (e.g. through simple parameter tuning) could yield additional improvements as part of future work.

7 CONCLUSION

In this paper, we introduced a practical solution for personalized spell correction in personal search. We discussed our approach to generate a personal lexicon for users that ensures high quality by extracting them from the user's context derived from recent activities. We then used it in our novel spell correction and query completion algorithm that performs well under the resource constraints and latency requirements.

We further evaluated it on some of the world's largest private corpora (GMail, Google Drive, and Calendar) on hundreds of millions of users and saw highly significant improvements in search quality metrics for each corpus. Even though more sophisticated approaches are needed for global models, restricting our corrections to a small highly relevant lexicon helped us achieve great results with a simple and elegant approach. While many spell correction algorithms need sophisticated mechanisms to support different languages, our improvements are agnostic of the language.

ABSTRACT

We study the problem of search query inference from web documents, where a short, comprehensive natural language query is inferred from a long article. Search query generation or inference is of great value to search engines and recommenders in terms of locating potential target users and ranking content. Despite being closely related to other NLP tasks like abstract generation and keyword extraction, we point out that search query inference is, in fact, a new problem, in that the generated natural language query, which consists of a few words, is expected to be comprehensive enough to lead to the click-through of the corresponding document. Therefore, query generation requires an accurate inference of query words, as well as a deeper level of understanding on document semantic structures. Toward this end, we propose a novel generative model called the Graph-augmented Sequence to Attention (G-S2A) network. Adopting an Encoder-Decoder architecture, G-S2A incorporates a sentence-level Graph Convolutional Network (GCN), a keyword-level GCN, as well as a hierarchical recurrent neural network (RNN) into the encoder to generate structural document representations. An attentional Transformer decoder is then applied to combine different types of encoded features to generate a target query. On a query-document dataset from a real-world search engine, our model outperforms several neural generative models on a wide range of metrics.

1 INTRODUCTION

Search engines handle a massive amount of natural language queries every second. Although a search query is commonly made up of only a few words, it can reflect the user's intent as well as the theme of the retrieved documents on a conceptual level. In this paper, we consider a reverse problem of web search, which is to infer the natural language query that leads to the click-through of a web document. Automatically reverse-engineering search queries from documents is of great values to personalization in search and news feed apps for a number of reasons. First, a search query usually reveals the conceptual theme of the article retrieved by the query and thus can assist information retrieval and personalized recommendation. Second, we can discover trending topics broadly discussed on the Internet by looking at search queries. Natural language search queries, such as "best SUVs under 50k" and "jobs with least competitions", are more fine-grained than keywords and topics. As a result, concepts represented by these queries provide a unique angle to reveal user interests, as compared to pre-defined topics or key phrases. In the meantime, a query is still less specific than a headline or abstract of the document—a query covers a number of matching articles. Thus, generated queries also serve as excellent labels for fine-grained text classification and clustering.

A natural, conventional method to tag documents with search queries is to check query-document pairs in the click-through logs of a search engine. The first document a user clicks and spends some time reading can be viewed as a positive match to the query, while the remaining documents retrieved by the query may or may not be a match, depending on the search engine. As a result, the positive query-document pairs generated this way would only cover a small portion of all available documents. This fact motivates the need to reverse-engineer the best query for a given document via a generative machine learning model, such that documents can be automatically tagged with the matching search queries, which can in turn enhance personalized search experience and recommender performance.

In this work, we first formally define the problem of search query generation from web documents and show that it is unique as compared to other similar Natural Language Processing (NLP) tasks. We propose a deep learning model called **G**raph-augmented **S**equence to **A**ttention network (G-S2A) to solve this problem. To better capture the most important concepts and semantic attentions within a document, in G-S2A, we extend the existing hierarchical Recurrent Neural Network (RNN) based encoder [38] by novelly incorporating two Graph Convolutional Networks (GCN) [16], namely, a sentence-level GCN that produces a condensed graphical representation of a document, and a keyword-level GCN, which emphasizes on the interactions among critical keywords in a document. Subsequently, an attentional Transformer-based [44] decoder, which is more efficient to train, is adopted to attend over different types of the document representations to generate a natural language query.

We evaluate the proposed generative model on a real-world query-document dataset collected from the Tencent news engine in the QQ mobile browser. Extensive evaluation results suggest that by adopting a number of innovations in the encoding and decoding processes, G-S2A outperforms a number of generative baselines, including the widely popular Seq2Seq model with copying and attention mechanisms and a hierarchical RNN-based generative model [38], on all variants of ROUGE [18] and BLEU [33] scores as well as the Exact Match (EM) ratio.

Content: Heihe City, located in the northwestern part of Heilongjiang Province, has the reputation of the doors of Europe and Asia, the window of China and Russia, and is the first batch of open cities along the border. The only border city in the Heihe Sino-Russian # km border that corresponds to the Russian capital. It is also the largest and highest-profile border city. Famous attractions include Wudalianchi, Sino-Russian National Customs Park, Shaoguan East Film and Television Base, Jinhe Grand Canyon, and Ancient City. Wudalianchi Scenic Area, located in Wudalianchi City, Heihe City, Heilongjiang Province, is composed of the Wushan Lake area of Helong Lake, Heilongjiang Lake, Bailong Lake, Heilongjiang Lake, and is a national AAAAA scenic spot global geological park.

Topics: Heihe city, attractions, parks

Keywords: Wudalianchi, city, world, reputation, Jinhe, national, lake, park, attractions

1-Sentence Summary: Famous attractions include Wudalianchi, Sino-Russian National Customs Park, Shaoguan East Film and Television Base, Jinhe Grand Canyon, and Ancient City.

Query: Tourist attractions worth visiting in Heihe

Figure 1: An example illustrating the differences between topics, keywords, summaries and queries. Note that the keyword "attractions" appears in the content and all outputs, whereas the rest of the query words are inferred.

2 PROBLEM DEFINITION

The goal of search query generation is to reverse-engineer *appropriate* queries from a given piece of text. The term *appropriate* means that the generated query should be similar to what a human user would type into a search engine, and then he/she would click on the input text. By doing this, the user implicitly creates an input-query pair. In this paper, the input is a long document. We also limit the scope of this work to generate a single best query only and leave multi-query generation as future work. We model the search query generation task as a sequence-to-sequence learning problem [40], where given an input text sequence T with n tokens $\{t_1, t_2, ..., t_n\}$, the objective is to maximize the conditional probability of generating query sequence Q with m tokens $\{q_1, q_2, ..., q_m\}$.

We argue that the problem of search query generation is different from existing NLP tasks such as summarization, keyword extraction and topic detection. Fig. 1 is an example from our training data that best illustrates the differences. We use TextRank [29] to extract the keywords and the 1-sentence summary. We manually determine the topics and translate the article content from Chinese to English. We discuss the differences from other tasks separately.

Summarization: We believe search query generation and automatic summarization share the same starting point—both tasks attempt to gain a deeper semantic understanding on the document context. The key difference between them lies in the output length. Summarization consolidates a document into a shorter summary of one or several sentences. Each summary is unique to the document itself and captures its most salient information. In contrast, a query crafted in our problem is much more concise, usually consisting of only a few words. A query does not need to summarize a document accurately, but rather, should match the document on a higher conceptual level. Consider the summary and query in Fig. 1. Here the query does not contain any details about tourist attractions in Heihe, but the document is still a good match to this query because they matched on the concept of "Heihe tourist attractions".

Keyword & key-phrase extraction: The key distinguishing factor here is that query generation relies on semantic understanding while keyword extraction does not. If a word in a search query also appears in the matching document, then it is likely to be a keyword. However, the reverse is not true, as shown in Fig. 1. A document could have many keywords or key-phrases. Yet, simply assembling some of them would not produce an appropriate query. The reason is that a generated query needs to properly and semantically "grasp" the central concept discussed in a document, whereas in keyword & key-phrase extraction we only need to determine whether a word or a phrase is important.

Topic detection: The boundary between topic detection and search query generation lies in their granularities. A traditionally perceived topic is usually predefined, such as "signs of pregnancy", "baby foods", "in-door plants", while a good fraction of queries are very specific, such as "early pregnancy signs", "recipes for three-year-old babies", "best in-door plants for lazy people", which automatically discovers finer-grained topics that people pay more attention to.

In essence, the problem of search query generation is different from yet is related to all previously compared tasks. Therefore, a good model for our problem should first develop a strong semantic understanding of the article context. Then, it should be able to accurately extract critical query terms from the content as well as infer the corresponding higher-level conceptual terms to produce a concise natural language query. In Sec. 4, we design our generative query inference model taking these challenges into consideration.

3 RELATED WORK

In this section, we review the literature in closely related tasks including text summarization, keyword extraction, query-document matching, and topic models.

Summarization: Traditional approaches [7, 29] are extractive based, where salient summary sentences are discovered from a document. Deep extractive models like [4, 30, 34] are able to learn more useful latent semantic features and easily outperform traditional methods. Generative summarization models are attracting increased attention due to their potential in generating diverse summaries. [31] is the first to apply an RNN-based Encoder-Decoder setup with an attention mechanism. [37] further refines this framework by adding a pointer network to permit direct copy from the input. More recently, [41] introduces a hierarchical Encoder-Decoder with a graph attention mechanism to better capture multi-granularity features in a document. Other studies [9, 22, 23] improve summary quality from the perspectives of semantic relations, bottoms-up key-phrase selection and multi-document clustering.

Keyword & Key-phrase Extraction: As another classic NLP task, unsupervised keyword & key-phrase extraction methods like [20, 24, 29, 36] rank all the words in a document and select the top candidates as keywords. Supervised approaches such as [8, 42] initially model this task as a binary classification problem, where key-phrases are distinguished from non-key-phrases. Then, statistical machine learning methods like Naive Bayes [43], Conditional Random Fields (CRFs) [46] and Support Vector Machines (SVMs) [47] have been applied to learn from more useful input features like TF-IDF scores, Part-of-Speech (POS) tags and syntactical functions.

We would also like to point out that many extraction techniques [6, 20, 29] propose that a document should be represented as a graph, in order to discover key dependencies among words. In the query generation problem, if a query word appears in the document, then it is likely to be a keyword of the document. This motivates us to also consider graphical representations in our model.

Query-Doc Matching & Query Generation: Another relevant field is query-document matching, where the best document for a query is selected. Trivial approaches compute an aggregated similarity score between query and document word embeddings. Metrics like cosine and TF-IDF similarities, or Okapi BM25 [35] are often considered. Many deep matching models have also been proposed [14, 15, 21, 25, 32, 39], which are either representation-based that focus on semantic feature extraction, or interaction-based that emphasize pair-wise matching. The MGAN [48] is a more recent framework for query to long document matching. It models a long document as a keyword distance graph, where each vertex is a keyword and edge weights are the inverses of distances between keyword pairs. The only related work on search query generation, to the best of our knowledge, is [45]. It proposes a multi-tasking sequence-to-sequence model that simultaneously perform title compression and query generation on E-commerce product titles.

Topic Models: Conventional methods for topic modelling take either probabilistic, Singular Value Decomposition (SVD) based, or matrix factorization based approaches [1, 2, 13]. Deep learning based methods have also been proposed, [27] applies Deep Belief Nets (DBN) to discover topics from digital media content. [17] applies deep neural networks to bag-of-words document representations and achieve state-of-the-art topic modelling performance. [49] further extends the model to multimodal data. A common characteristic of these approaches is that the generated topic is always a single word or phrase.

4 MODEL

In this section, we present a detailed description of the proposed G-S2A network. Fig. 2 is a complete illustration of the model.

4.1 Hierarchical Bi-directional RNN

To reveal the sequential structure of a document, we first utilize a hierarchical RNN-based encoder [38, 41] to model the document, where the lower-level RNN encodes each sentence word-by-word into a single vector, while the higher-level RNN aggregates all sentence vectors to create a paragraph representation. We believe the hierarchical RNN is an effective approach for learning crucial sequential dependencies among the sentences. In our work, we generate a single vector representation for each sentence S_i using a Bi-directional Gated Recurrent Unit (GRU) [5] network. Next, we join sentence vectors on the first axis to form a 2-D document representation, which is then fed into another sentence-level Bi-GRU to yield sequential sentence embeddings.

4.2 Sentence-Level GCN

In order to capture more complex semantic structures beyond sequential dependencies, we further represent a document as a graph $G_s = \{V_s, E_s\}$, where the vertices V_s correspond to sentences and the edges E_s represent some connections between sentences. Our sentence-level Graph Convolutional Network (GCN) [16] is partially established on top of the word-level Bi-GRU from Sec. 4.1. Specifically, the feature of a vertex input to the GCN is the sentence vector produced by the word-level Bi-GRU.

Each edge weight in our sentence-level document graph reflects the percentage of word overlaps between a pair of sentences, which is determined by dividing the number of unique overlapping words against the total number of unique words in both sentences. The intuition here is that similar sentences have more overlapping words and thus a higher edge weight between them. At this point, we have created a new feature map that captures the pair-wise sentence similarities within a document. Next, a multi-layer GCN learns from such sentence interactions by iteratively convolving on the features of a node and its neighbors. This operation is defined by the following update rule:

$$H^{l+1} = \sigma(\hat{D}^{-\frac{1}{2}}\hat{A}\hat{D}^{-\frac{1}{2}}H^l W^l), \tag{1}$$

where H^l is the output of the previous GCN layer. For the first layer, H^0 is simply the input vertex features, i.e., the sentence vectors produced by the word-level Bi-GRU. $\hat{A}$ is the adjacency matrix constructed based on edge weights, which is symmetrical. $\hat{D}$ is a diagonal degree matrix where $D_{ii} = \sum_j A_{ij}$. σ is the sigmoid activation function. W^l is the set of trainable weights in layer l. We refer interested readers to [16] for more GCN-related details.

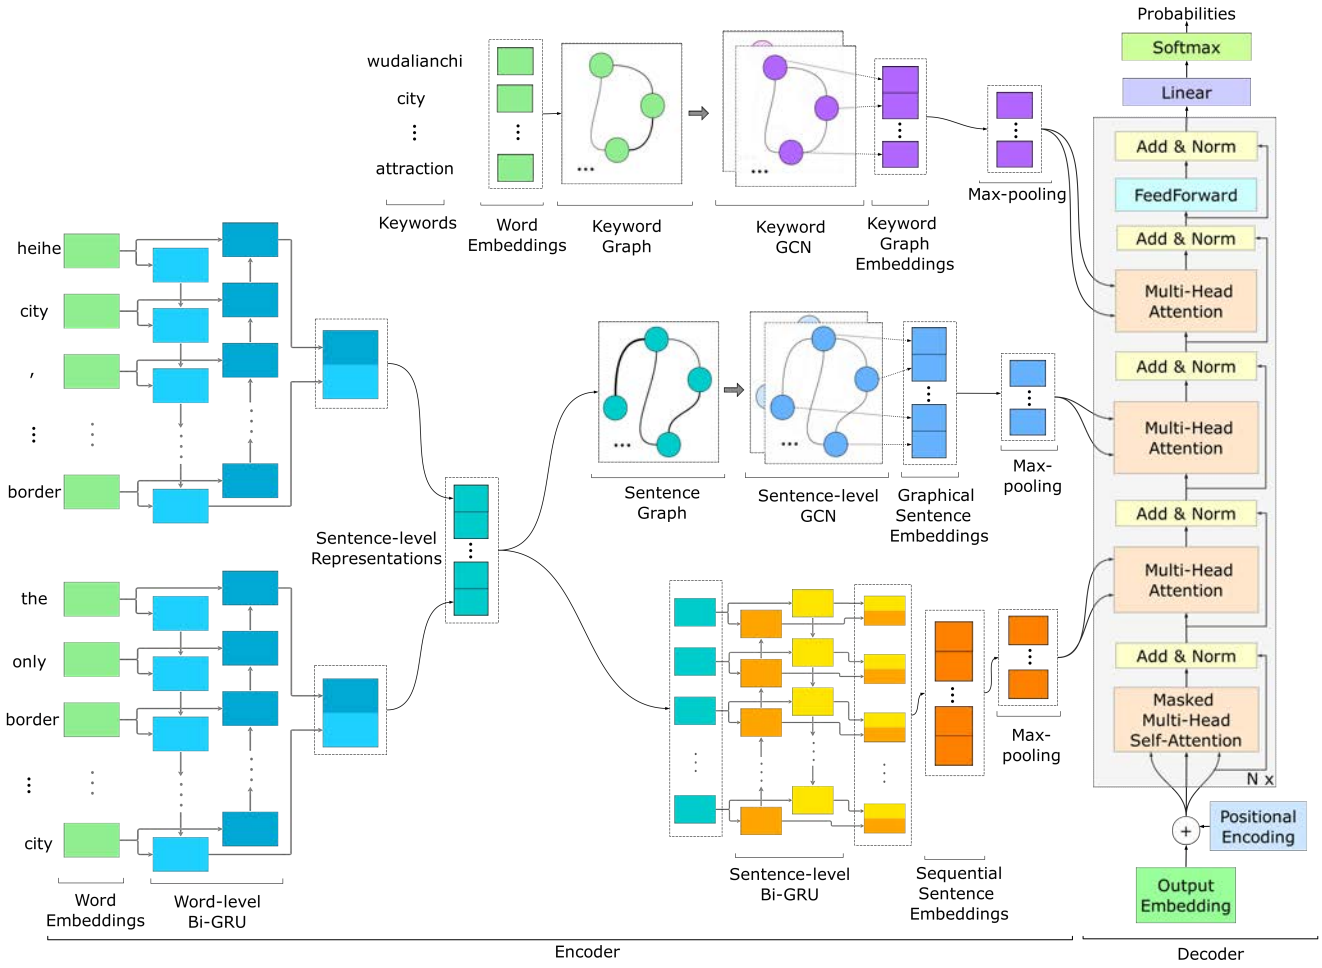

Figure 2: Full view of our proposed model.

4.3 Keyword-Level GCN

As has been mentioned in Sec. 2, if a query word appears in a document, it is usually also a keyword for that document. Therefore, in addition to the sentence-level abstractions, we should permit the decoder to learn from keyword-related information directly. To this end, we further augment our model with a document keyword distance graph similar to [48]. In the keyword distance graph $G_{kw} = \{V_{kw}, E_{kw}\}$, each vertex feature is the embedding vector of a keyword, and the edge weight between two vertices is the inverse average distance among the keywords. Specifically, for unique keywords k_i and k_j, we first locate all of their occurrences in the document. Next, we calculate the pair-wise distance between each pair of occurrences by counting the number of words between them. In other words, if there is no word between two occurrences, the distance is 1; if there is one word in-between, then the distance is 2, and so forth. We take the inverse of the average pair-wise distance. The intuition here is that keywords that are closer to each other are more closely related. Thus, their edge weight is higher in the keyword distance graph. Mathematically, this is expressed as

$$w_{ij} = \frac{1}{d_{ij}^{\text{avg}}} = \frac{m}{\sum_{j=1}^{m} d_{ij}}, \tag{2}$$

where w_{ij} is the edge weight between keywords k_i and k_j, and m is the total number of pair-wise keyword occurrences in the document. After the graph construction, we feed the node and edge features to a keyword-level GCN. The output is an enhanced keyword-level representation, which embodies the graphical keyword interactions within a document.

4.4 Transformer Decoder

Our decoder is a uni-directional Transformer [44] with two additional Multi-Head Attention modules for the GCN outputs. We choose the Transformer decoder over RNN decoders mainly because the Transformer decoder offers a more modularized internal structure, which permits us to readily incorporate more features into the decoding process. Also, the Multi-Head Attention mechanism is more efficient to train due to its easily parallelizable design.

The Multi-Head Attention module is the core component of the Transformer and it is made up of parallel layers of the Scaled Dot-Product Attention. On 2-D feature maps Q, K, and V, the Scaled Dot-Product Attention defines the operation of query Q attending on value V through keys K as follows:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}})V, \tag{3}$$

where d_k is the feature dimension of K. For the masked self-attention block in Fig. 2, Q, K, V all correspond to the partially generated search query vector. For the remaining attention modules, Q is the partially generated search query vector, while K and V are the output representations from the encoder. The Multi-Head Attention module equally divides the feature dimension of Q, K and V into h heads, producing a set of $\{Q_i, K_i, V_i\}$ with i ranging from 1 to h. Then, a feed-forward layer is added before Q_i, K_i and V_i, which allows the network to learn and adjust these inputs. Finally, the output from each head is concatenated to restore the original shape and fed through another feed-forward network. Interested readers are referred to [44] for more details on the Transformer.

4.5 The Complete Model

We connect the components as depicted by Fig. 2. The word-level Bi-GRU first encodes each sentence in a document. Then, the aggregated sentence vectors propagate to the sentence-level Bi-GRU and sentence-level GCN for further learning. We believe this hierarchical encoding scheme combined with the additional sentence-level graphical embedding allow our model to better understand the semantic interactions within a document. On the other hand, the graphical embedding produced by the keyword-level GCN lets the decoder directly attend on potential query words while maintaining awareness of the document context at the same time, which aids the query term selection and generation process.

In addition to the aforementioned components, we also apply a single *Max-Pooling* layer onto all encoder outputs, since empirically, we find that the Multi-Head Attention mechanism in the decoder performs poorly when attending on long target sequences. Although we have already condensed document representations at the sentence and keyword levels, in reality, a query can be inferred from an even more compact representation—Max-Pooling serves as another stage of significance filtration before decoding.

5 EXPERIMENTATION

In this section, we present the experimental setup and compare results of our model on a real-world Chinese query document dataset against a number of generative baselines.

5.1 Dataset

A suitable dataset for our problem should contain the content of documents and the matching queries. Unfortunately, we cannot locate a publicly available dataset that meets this criteria. Summarization datasets like CNN or DailyMail [11] are not suitable because their summaries are too long to be considered queries. Query-document matching datasets like Ohsumed [12] contains too few queries, whereas datasets with enough unique user queries, such as the NFCorpus [3], have too few unique documents. The lack of a suitable dataset is another evidence that the search query generation problem is new and is less studied.

Therefore, we work with our industry partners at Tencent to create a Chinese query-document dataset, which includes real search queries collected anonymously from the QQ mobile browser. The documents in this dataset mainly consist of news articles or blog posts provided by the Tencent news engine. We construct the query-document pairs using the passive method from Sec. 1, where the first article the user clicks and spends some time reading is considered a matching document. Train, development, and test sets are randomly divided. Table 1 lists the important statistical information about our dataset.

Table 1: Dataset information

Train size	120773
Dev size	10000
Test size	10000
Average document length	286.8
Number of unique queries	10420
Min query length	2
Max query length	11
Average query length	3.2
Document vocabulary	479K
Query vocabulary	9.2K
Average doc-query word overlap	1.85

5.2 Experimental Setup

We adopt the word-overlap based ROUGE [19] and BLEU [33] metrics, which are widely used in summarization and machine translation tasks. In our work, we report the macro-averaged ROUGE-1, 2, L, BLEU-1 to 4 scores. Each metric variant cumulatively considers n-gram (1 to 4) or longest common sub-sequence (L) overlaps. ROUGE-1 is also the metric used to select the best performing model on the development set. ROUGE and BLEU scores reflect how well a generated sequence captures the truth sequence, with higher scores indicating better performance. Additionally, we report the Exact Match (EM) percentages. Because the search queries are a lot more concise, we are interested in how many generated queries match the truth exactly.

We tokenize documents and queries with the Stanford CoreNLP tool [28]. We limit the document word length at 300, All characters are lower-cased. All numbers are replaced with a # symbol. We construct the vocabulary by first combining the document and query vocabularies, then take the top 40000 most frequent words. In every experiment, we train a word embedding layer from scratch, and share it among the encoder and decoder.

For our model, we set the hidden layers of GCNs, the hidden layers of Bi-GRUs, as well as the attention dimension of the decoder to the same value. The position-wise feed-forward dimension is set to be 4 times this value. We also set a global dropout probability for all components. We fix the number of GCN and Transformer layers to 2, and the number of Bi-GRU layers to 1. The word embedding dimension is set to 300. The Max-Pooling window is set to 2. The number of Transformer attention heads is set to 8. We tune the global hidden size and dropout probability on the development set.

Table 2: Performance of various models on the test set

Models	#Weights	ROUGE-1	ROUGE-2	ROUGE-L	BLEU-1	BLEU-2	BLEU-3	BLEU-4	EM
TextRank-kw	-	12.94	0.49	7.97	8.33	2.75	1.92	1.60	0.0
TextRank-kw-cheat	-	15.38	1.11	14.75	15.38	6.94	5.17	4.43	0.0186
TextRank-kp	-	11.85	3.73	11.26	10.73	6.63	4.18	3.32	0.0276
Seq2Seq-Attn	35.7M	72.82	58.15	72.41	71.78	63.17	37.60	25.27	0.6220
Seq2Seq-Attn-Copy	35.7M	72.38	57.24	71.97	71.30	62.46	37.15	24.96	0.6147
HRED	23.7M	73.83	58.45	73.42	72.70	63.69	37.55	25.14	0.6381
Transformer	33.5M	68.87	52.51	68.36	67.51	58.14	34.66	23.31	0.5650
G-S2A	25.8M	**75.18**	**60.21**	**74.73**	**73.98**	**65.32**	**38.67**	**25.94**	**0.6426**

We use the Noam Optimizer [44] with a warm-up steps of 2000 and a label-smoothing constant of 0.1 for training. Our model converges in 100 epochs, where each epoch takes approximately 10 minutes with a mini-batch size of 128 on a GTX1070 GPU. Finally, We compare our model with the following baselines.

TextRank-kw is a simple keyword extractor based on the TextRank [29] method. We include three keyword & key-phrase extraction baselines to prove that search query generation is a more challenging task. We set the number of target keywords to 8.

TextRank-kw-cheat is also a TextRank-based keyword extractor. However, for this baseline we provide the number of words in the truth queries as additional clues.

TextRank-kp is a TextRank-based key-phrase extractor. We extract the most salient key-phrase from the document and use it as the generated query. TextRank baselines do not require training.

Seq2Seq-Attn is the classic encoder-decoder model [40] with the *general* attention mechanism [26]. We feed the entire document as one sequence into the model. We implement this baseline with a Bi-GRU encoder and a Uni-GRU attentional decoder.

Seq2Seq-Attn-Copy further incorporates the copy mechanism [10], which allows the model to directly copy important words from the input. Consider the fact that many query words also appears in the document, as indicated in Table 1. We believe this baseline is a strong competitor.

HRED is a RNN-based hierarchical encoder-decoder model proposed by [38]. Our implementation uses a hierarchical Bi-GRU as the encoder, which is essentially, the same hierarchical sequential encoder in our model. The decoder is a Uni-GRU.

Transformer is the new generative model proposed by [44]. We fix the number of encoder and decoder layers to 6 and the number of attention heads to 8. We tune the attention dimension and dropout probability. The position-wise feed-forward dimension is set to be 4 times of the attention dimension.

5.3 Results & Discussion

In addition to the metrics mentioned in Sec. 5.2, we report the number of trainable weights (#Weights) in every supervised model. We believe the number of trainable weights is critical factor to consider in real-world applications, because a large model often implies a higher cost of training.

The best hidden size for G-S2A is 128. As we can observe in Table 2, G-S2A outperforms all baselines on all metrics, which proves the effectiveness of the proposed additional components. We also note that the performance for keyword extractors are far worse than other models, which indicates that they are not suitable for our problem. Therefore, search query generation and keyword & key-phrase extraction are different problems.

Another interesting conclusion we could draw from Table 2 is that hierarchical models like HRED and G-S2A achieve better performance, but have less trainable weights. We believe this is because the hierarchical encoders break down long documents at an intuitive sentence-level, which effectively exposes its structural information. Other models without the hierarchical design would need to learn such information with more trainable weights.

Table 3: Ablation study results

Model variants	ROUGE-1	ROUGE-L
S2A	73.98	73.55
S2A+sGCN	74.15	73.72
S2A+sGCN+kwGCN	74.30	73.85
G-S2A	75.18	74.73

5.4 Ablation Study

We further evaluate G-S2A through an ablation study and report the changes in ROUGE-1 and ROUGE-L scores.

S2A only contains the hierarchical Bi-GRU encoder and the attentional Transformer decoder. We remove the two GCNs and the Max-Pooling layer from G-S2A to create this model.

S2A+sGCN incorporates the sentence-level GCN.

S2A+sGCN+kwGCN further includes the keyword-level GCN, yet without the Max-Pooling layer.

From Table 3, we observe that S2A initially outperforms the HRED model. We believe this is attributed to the Multi-Head Attention mechanism, which the HRED lacks. With the addition of more components, the performance of the model consistently improves. This proves our initial claim that exploring sentence-level and keyword-level graphical representations for long documents is extremely helpful in the search query generation task.

6 CONCLUSION AND FUTURE WORK

In this paper, we investigate the new problem of search query generation from long documents. We propose that graphical document representations help build a deeper semantic understanding of context and improve query term selection & inference. We introduce the G-S2A model, which incorporates a sentence-level GCN and keyword-level GCN to learn from the corresponding document

graphs. G-S2A outperforms a number of generative baselines, at the same time it is more light-weight. We believe the effective learning of graph features, combined with a modularized decoder, makes G-S2A a superior model for the problem of search query generation. For future work, we plan to extend our model toward multi-query generation and explore other forms of document representations.

ABSTRACT

Result ranking diversification has become an important issue for web search, summarization, and question answering. For more complex questions with multiple aspects, such as those in community-based question answering (CQA) sites, a retrieval system should provide a *diversified* set of *relevant* results, addressing the different aspects of the query, while minimizing redundancy or repetition. We present a new method, *DRN* , which learns novelty-related features from unlabeled data with minimal social signals, to emphasize diversity in ranking. Specifically, *DRN* parameterizes question-answer interactions via an LSTM representation, coupled with an extension of neural tensor network, which in turn is combined with a novelty-driven sampling approach to automatically generate training data. *DRN* provides a novel and general approach to complex question answering diversification and suggests promising directions for search improvements.

1 INTRODUCTION

Search engines and conversational assistants are expected to answer increasingly complex questions, such as requests for advise or opinions. Perhaps the most important source are Community Question Answering (CQA) sites, which offer an opportunity for millions of online users to contribute, share, and discover knowledge. The number of answers for community questions can range from a few, to dozens, but it is not realistic to expect a user to read them all. At the same time, a user might be interested in several aspects of the answers, and would benefit from being exposed to several relevant answer aspects. For example, when looking for recommendations of a movie or a restaurant, one could be interested in several viewpoints, and not just a single answer.

An ideal ranking of answers to such a question should combine relevance to the asked question, as well as novelty – by addressing different aspects of the question instead of repeating already seen information in previous answers.

So far, the best performing state-of-the-art systems addressing the CQA novelty problem have been supervised, requiring extensive training datasets [20]. For these methods, two types of training labels are required – relevance labels, and explicit aspects diversity judgments. Relevance judgments datasets are more common, and can be inferred based on implied ranking of users on social sites (e.g., through clicks or user ratings of answers) and indeed have been used in a form of a distant supervision for training learning-to-rank systems. In contrast, diversity-labeled datasets in large amounts need to be obtained for each new domain to enable supervised learning. Additionally, supervised learning-to-rank systems typically apply statistical models to features, engineered for a specific domain. The required feature engineering for each problem leads to complex and brittle systems with many steps and dependencies. In contrast, we present an approach that avoids feature engineering, yet reaches high ranking performance for multiple types of questions, by introducing a novel deep learning algorithm leveraging large unlabeled data sets with minimal distant supervision based on social signals, and does not require direct diversity judgments.

In this work, we introduce *DRN* (Diversity Ranking Network), which, to the best of our knowledge, is the first neural network approach for community-question-answering ranking that addresses both relevance of the answers, and their marginal novelty. Specifically, our model captures relationships between questions and their corresponding answers with a non-linear tensor layer, which promotes answers that are both relevant to the question, and diversified with respect to other answers. Our method combines the trained neural network scores with an iterative algorithm for efficiently ranking the community answers with respect to previously chosen answers. Our system reaches state-of-the-art results, compared to previous novelty-ranking unsupervised approaches, and shows comparable results to the supervised methods that use extensive feature engineering and labeled datasets. Specifically, our contributions are:

- A novelty-driven sampling approach (Section 3.3), for leveraging unlabeled data and minimal social signals as distant supervision to optimize a novelty-driven loss function.
- A novel end-to-end deep-learning approach, modeling interactions of question and answers for identifying novelty and relevance of answers without manual feature engineering.

Question	How can I lose weight I'm 73 lbs I need to exercise but I'm fat and lazy so can you please help me does someone have tips to lose weight?
Answer 1	Exercise, Nutrient dense foods. If you lose weight very quickly you will be a lot less likely to keep it off. The first thing I would suggest is to believe in you.
Answer 2	The more you feel good about yourself the easier and faster it is to lose weight. Exercise, exercise, exercise! Please consult your doctor before beginning an exercise or weight loss program. Safest way is to lose 2-3 lbs a week.
Answer 3	diet always trumps exercise. Add or lose muscle. Too much body fat is not good for your health. Your lifestyle habits can influence . You have to diet and exercise.
Answer 4	I've gone down from 103 kg to 89 kg in three months by reducing my caloric intake and walking at least 10 kms a day and sometimes I even up to 20 km
Answer 5	trust me it wont be healthy why are people seriously giving you tips on losing weight? even if it is through healthy means, you don't need tips on losing weight.
Answer 6	If indeed some infections contribute to obesity in people , we could have a potentially very simple and effective prevention strategy vaccination...

Figure 1: An example question with candidate answers from the TREC LiveQA dataset, with relevant answers partitioned into propositions corresponding to aspects. Each aspect is color-coded according to human annotation.

- A new method for novelty-aware scoring of answers for complex questions over social media (Section 3) using a neural architecture, and an iterative algorithm for ranking answers, reaching state-of-the-art results.

We report results of an extensive experimental evaluation of different variations of our *DRN* method, showing significant improvements over state-of-the-art approaches (Section 5) on two benchmark datasets, one of which we created and will share with the research community.

Our *DRN* model lays the foundation for deep learning for answer diversification, that is aware of both relevance and novelty. Making it a promising approach for many other ranking tasks.

2 RELATED WORK

Ranking social media content, and specifically CQA content, has been an active area of research [18, 19]. CQA content in particular has a number of distinct characteristics, such as the duality of questions and answers, and social signals, that have been explored for improving retrieval performance. For example, Xue et al. [35] experimented with variations of language models for retrieving question-answer pairs from CQA archives, while Wang et al. [31] demonstrated improvements by modeling question-answer relationships. It has also been shown that additional features for CQA ranking can be more naturally incorporated using a supervised Learning-to-Rank (LTR) approach (e.g., see Bian et al. [3], Cao et al. [5], Surdeanu et al. [27]), with the added benefit that LTR systems can be optimized for the measure of interest, such as result diversity, in addition to relevance. However, supervised LTR approaches require extensive training data, a shortcoming that we address in the next section by introducing an deep learning method trained in a distant supervised manner. While numerous studies on document novelty and diversification for Web Search and IR have been done in the past [17, 23, 33] the CQA setting exhibits significant differences. First, the answers provided to a specific question are mostly relevant, as opposed to document ranking where many documents are irrelevant to the query. Therefore, common methods in IR, such as MMR perform significantly worse on this task (see Section 4.1). Additionally, many of those methods [33] are supervised and require significant labeling per domain, which is impractical for CQA. Second, CQA answers are shorter than most documents and therefore pose additional challenges to diversification. Finally, the length of the queries in Web search is significantly shorter compared to the length of the CQA questions. Specifically in the CQA domain, Szpektor et al. [28] presented a recommendation algorithm for suggesting questions to potential answerers in CQA sites. They showed that ignoring diversity degrades recommendation performance. Recently, deep learning techniques have been applied to many variants of LTR and Question Answering [13, 30, 32, 34] and specifically for Learning To Rank in CQA, e.g., [6, 21, 33, 36, 37]. While building on these previous works, our effort is distinct in that we develop an end-to-end method for automatically learning to diversify CQA ranking with only minimal distant supervision based on social signals.

3 *DRN*: DEEP NETWORK ANSWER DIVERSIFICATION MODEL

Our goal is to train a ranking function for CQA that emphasizes both relevance and marginal novelty. Consider an example CQA question in Figure 1, which shows the first six out of eleven answers to the question. The first three answers contain a wide range of aspects, with some shared across answers, and others specific to a certain answer. Answer 4 is relevant to the question, but does not add novelty with respect to former answers. Answer 5 is not highly relevant to the question, and does not address many aspects. Finally, Answer 6 is irrelevant and should be ranked last.

We model the problem as a supervised-learning problem, optimizing to rank a triplet consisting a question and two possible answers, where a positive example is one consisting of both relevant and diverse answers. We learn a fixed-size vector representation of question and candidate answers using a LSTM layer. Then, triplets of question and two answers are combined with a neural tensor layer, and combined score for each triplet is computed. Figure 2 presents *DRN* architecture at high level. The key innovation of our

work is a novel, novelty-driven sampling process, which emphasizes relevance and novelty simultaneously for training the model. A greedy algorithm selects at each round an answer that is both relevant to the question and introduces most novelty with respect to former ranked answers.

3.1 Low-Dimensional Embedding of Question and Answer Text

To be able to perform the neural network matrix operations over question and answer, we need to represent them as a fixed-length vector. In this work, we use a deep recurrent neural network architecture (RNN) to process sequentially each word in the question and the answers, and to produce a low dimensional vector at each step. Intuitively, the output vector at each step represents the information given in the sentence, until the current word. We use an LSTM model [11, 12] and obtain the last word in the sentence embedding as the semantic vector representation for the sentence.

3.2 Modeling Question and Answer Context

An answer to a question can be a good candidate or a bad candidate depending on the context where it is given, in our case, within the context of the question asked. Modeling the interactions between the answer and the question is a key aspect in being able to judge its relevance and usefulness. One could try to model these interactions by designing hand-crafted features, which is not an easy task. Our approach is to discover such features automatically. In the past, the use of tensors to model interactions was shown to be successful [21, 26]. While those models were required to model a single interaction, to capture *novelty*, it must capture the interaction of the question with several answers. To address *novelty*, we argue that one should consider interactions between *all entries* in a triplet ($question, answerA, answerB$). With these interactions, we can model both relevance of an answer to a question, and the novelty that the answer introduces with respect to previous chosen answer. Intuitively, we want this score to be high if the first answer is relevant to the question, and diverse with respect to the second answer. Modeling such a score function can be done by linearly combining two score functions, each trained for different desired property, e.g., relevance and novelty. Using a more general non-linear function, allows the algorithm to learn to optimize both relevance and diversity simultaneously. To accomplish this, we present an extension to [26] for modeling triplets, denoted $TNTN$, the parameters of the network will be shared across the triplet, thus able to encode features representing semantic interactions between *all entries* in the triplet. This is done by firstly introducing the question into the parametrization, $W = M^{[1:n\cdot r]}v_q$, and then multiplying the answers with a bilinear tensor product. $TNTN$ can be described as follows:

$$s(q, a, a') = u^T f\left(v_a^T W^{[1:r]} v_{a'} + V\begin{bmatrix} v_a \\ v_q \\ v_{a'} \end{bmatrix} + b\right) \quad (1)$$

where $M^{[1:n\cdot r]} \in R^{n\times n\times n\times r}$, $V \in R^{r\times 3n}$,$b \in R^r$ and $u \in R^r$ $v_q, v_a \in R^n$.

v_q, v_a and v'_a are the question and two answer vector representations from LSTM layer, f is a nonlinearity applied element-wise,

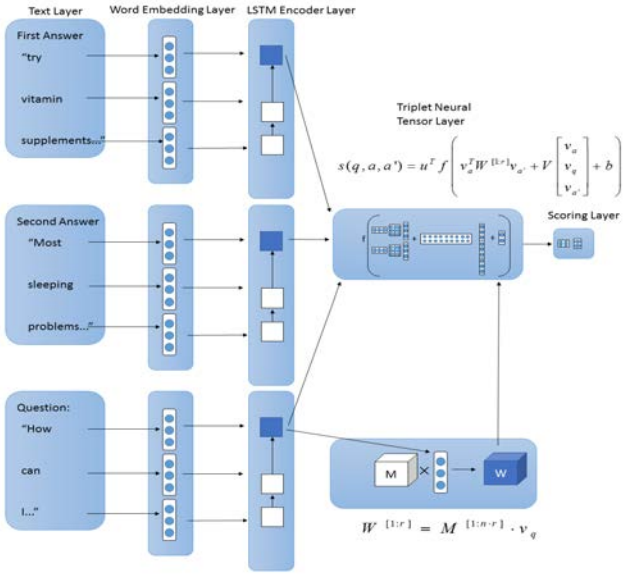

Figure 2: Visualization of the *DRN* network

The tensor product $M^{[1:n\cdot r]}v_q$ is done by multiplying $n \cdot r$ matrices of $n \times n$ by v_q, thus results at r matrices of size $n \times n$, or in other words a tensor $W^{[1:r]} \in R^{n\times n\times r}$. The bilinear tensor product $v_a^T W^{[1:r]} v'_a$ results in a vector $h \in R^r$, where each entry is computed by one slice i = $1, \ldots, r$ of the tensor. The other parameters to be learned are $V \in R^{r\times 3n}$, $b \in R^r$ and $u \in R^r$.

3.3 Novelty Driven Sampling

Intuitively, our scoring function should learn to address both relevance and novelty. To tackle this, we introduce a novel sampling approach, which presents three types of examples to our network, one positive and two types of negative examples. To guide the sampling, we introduce a $Novelty$ function that is able to measure the amount of diversity between two given answers.

To construct the positive example for a given question – $(q, Ba, BaDiv)$ for both high relevance and novelty, we select the best answer Ba in a distant supervised manner to be the most voted answer by Yahoo! users, which is commonly assumed to be highly relevant to the question. To address novelty with respect to Ba, we construct $BaDiv = argmax_{a\in A(q)} Novelty(Ba, a)$ via the $Novelty$ function.

We construct two types of negative examples – one expressing low novelty of a relevant answer, and the second representing low relevance. The first negative example is constructed by selecting an answer Ba as before, and $BaSim = argmin_{a\in A(q)} Novelty(Ba, a)$ is an answer the $Novelty$ function suggests to be similar to Ba and therefore not Novel.

The second type of a negative example, $(q, Ra, RaDiv)$ is constructed by selecting a random answer Ra to a random question, and therefore assumed to have poor relevance to the question q of the triplet. Such a triplet is used as a negative example, even though the answer $RaDiv = argmax_{a\in A(Random(q))} Novelty(Ra, a)$ is *novel* with respect to Ra by the $Novelty$ function.

Several *Novelty* function families can be used for the sampling process without any significant alternations to *DRN* . We experimented with cosine distance over topic representation of the text, e.g. LDA [4], and over embedding space, e.g. doc2vec [16]. On validation dataset, we found that the LDA function performed better for the diversification task. Thus, we represent each answer with its corresponding LDA topic probabilities vectors and their level of diversity is measured with the cosine distance.

Loss function for training *DRN* : Our loss function is inspired by the MMR [7] framework. Our approach generalizes the idea of combining relevance and diversity functions by encoding them both into a loss function. We train the network with max-margin criterion, which provides an alternative to probabilistic, likelihood-based estimation methods by concentrating directly on the robustness of the decision boundary of a model [29]. Intuitively, a good example will be separated in space by some margin from the sampled corrupted examples. Our loss function for diversification is defined as:

$$\begin{aligned} L = \sum_{C,C'} & - [s(q, Ba, Ba_{Div}) - s(q, Ba, Ba_{Sim})] \\ & - [s(q, Ba, Ba_{Div}) - s(q, Ra, Ra_{Div})] \\ & + \gamma + \lambda \left\|\Theta\right\|_2^2 \end{aligned} \tag{2}$$

where $\gamma > 0$ is the margin hyper-parameter, C is the training collection of good examples $(q, Ba, BaDiv)$ triplets from the data and C' denotes the collection of all corrupted triplet examples $(q, Ba, BaSim)$ and $(q, Ra, RaDiv)$. To minimize our objective function we used the Adam Optimizer [14].

Algorithm 1 Ranking for Diversification Algorithm

1: NN Inference: Compute s(q,a,a') - $n \times n$ scores matrix for question q
2: R $\leftarrow$ *SelectFirstAnswer*
3: for $j = 1$ to $|A(q)| - 1$ do
4: R $\leftarrow argmax_a \Sigma_{a' \in R} s(q, a, a')$
5: end

3.4 Ranking Algorithm

In the previous sections we described the construction of an embedding of questions and answers (section 3.1), which is then used in a neural tensor network to assign relevance and novelty scores. In this Section we leverage these scores into a novelty-driven ranking Algorithm (1). The algorithm greedily selects answers to maximize scores learned by the neural network. For each question and the set of its n corresponding answers, we perform $n \times n$ forward inference steps, thus producing a score for every combination of the question and two of its answer. This step results in an $n \times n$ scores matrix for each question and its answers. We then select the first answer and add it to the ranked answers list. We note that in this work, we focus on the diversification aspect, i.e., given a selected first answer, we wish to select relevant answers that introduce new aspects. To initialize our ranking algorithm, we must choose the first answer. Selecting the best answer to a question is a well researched task in the literature [2, 25]. Inspired by prior work, we choose the first answer using a classifier optimized to select answer with high number of aspects.

Going back to our ranking algorithm, in line 4 we iteratively choose the next answer as the one with the highest sum of scores with respect to the question and the answers chosen so far. Intuitively, the answer that maximize this step, is the one with high relevance to the question, and simultaneously a high level of novelty with respect to the answers chosen in earlier steps, where all these answers are taken into account.

4 EXPERIMENTAL SETTING

In this section we describe the state of the art baselines that we compare to our method, *DRN* , as well as the evaluation metric and the CQA datasets used in the experiments. All the methods, including baselines, first used basic pre-processing, including: tokenization, stop-words removal, and spell checking, which is an important step in CQA domain due to its noisy nature.

Tuning and Final Configuration Based on a validation set, we tuned our network hyper-parameters, with final values of r = 5, learning rate = 0.001, batch size = 100, negative examples = one of each type, regularization λ = 0.0001, LSTM state size = 50.

4.1 Evaluation Metrics

One of the most prominent metrics for diversification measurement in QA and IR systems is $\alpha NDCG$ [9]. To compute $\alpha NDCG$ we first define $r_k^i = 1$ as an indicator function for the event where the i-th answer contain proposition related to the k-th aspect. The complete $\alpha NDCG$ formulation is:

$$\alpha NDCG = \sum_k \frac{1}{\log_2(k+1)} \sum_i r_k^i (1-\alpha)^{s_{i,k-1}} \tag{3}$$

where $s_{i,k-1} = \sum_{j=1}^{k-1} r_j^i$.

Intuitively, $\alpha NDCG$ rewards answers with the highest discounted cumulative gain, where gain is measured by the novelty the answer aspects introduce with respect to previously ranked answers.

Additionally, we present results with an additional common IR metric for diversification – ERR-IA [8]. ERR-IA is defined as the expectation of ERR over the different aspects, where R_i is the probability that the user will be satisfied with the i-th document (or in our case, the i-th answer) and n is the number of answers retrieved. Specifically, *ERR* is defined as:

$$ERR = \sum_{r=1}^{n} \frac{1}{r} \prod_{i=1}^{r-1} (1 - R_i) R_r \tag{4}$$

Together, $\alpha NDCG$ and ERR-IA comprise the two main metrics recommended to use for evaluating search result diversity, as surveyed in reference [24].

4.2 Baseline Methods

BM25 [22]: Originally proposed for ad-hoc information retrieval, BM25 ranks documents according to term frequencies.

MMR [7]: The maximal marginal relevance is a traditional method promoting diversity by combining two standalone similarity and diversity functions.

LDARanker [15]: This is an unsupervised algorithm that aims to diversify ranking by selecting answers with good coverage over the set of all answers to a question.

SimRanker [20]: Serves as our state-of-the-art *supervised* baseline method. This algorithm use the notion of propositions and leverage on data with diversity labels for training parameters to

predict whether two propositions are diverse, then a greedy procedure selects iteratively answer that best combines a set of relevant propositions that are both diverse, and important.

SimRanker-ESA [20]: Serves as our state-of-the-art *unsupervised* baseline method. *SimRanker − ESA* only differs from the supervised version in the similarity function between propositions, as it uses a cosine similarity of the "Explicit Semantic Similarity", or CQA-ESA[10] representations of each proposition.

Due to lack of access to a proprietary method described in [20], our method *DRN* is compared to *SimRanker* and *SimRanker − ESA* only on the first benchmark with results given by the authors, for calibration of our method to the state of the art. On the second benchmark, we compare *DRN* with *BM*25, *MMR* and *LDARanker*.

4.3 Datasets

In 2009, Yahoo published a dataset with questions and their corresponding answers from Yahoo Answers web site. The corpus contains 4,483,032 questions and their answers. In addition to question and answer text, the corpus contains a small amount of metadata, (e.g. most voted answer). We use a subset of this dataset with randomly chosen 250k questions and their corresponding answers for generating training data with our novel sampling approach.

Yahoo-Novelty Dataset: Recently, [20] developed a dataset specifically for diversification, the dataset consist a random sample from Health category in Yahoo answers. The data consist of questions and answers, with their relevant propositions clustered into aspects.

LiveQA-Novelty Dataset: To be able to test our system on larger scale, and on questions from a variety of categories, we have developed an additional larger dataset designed specifically for diversification, following the methodology presented by Omari et al. [20]. The questions were sampled from three categories of the LiveQA 2015 dataset [1]: Health, Pets, and Arts & Humanities. We then selected the subset of the questions with at least 7 answers. First, each answer is partitioned into propositions, and each proposition is then manually judged for its relevance to the question. Propositions found to be relevant to a question from all of its answers are then grouped into aspects.

Specifically, annotation of the LiveQA-Novelty data was done in 3 phases: (1) Identifying relevant propositions in answers[1] - We have used Amazon Mechanical Turk for the annotations. Each HIT* (A Human Intelligence Task) contained a question and an answer partitioned automatically into propositions, and the MTurk workers were given the instruction to mark each proposition as relevant or not to the question. (2) Filtering questions [2] - Second step of relevant propositions filtering was done manually by the authors. During this phase we removed all the questions with fewer than 5 total relevant propositions in their answers. (3) Aspects clustering - the authors manually grouped relevant propositions for each of the test question into clusters representing aspects. We computed the answer/aspect-cluster agreement of two annotators using Cohen's kappa statistic. The score $kappa = 0.72$ suggests moderate to high agreement indicating the labeling is reliable. As a result of this labeling, our LiveQA-Novelty dataset contains 207 questions, with 2,488 answers in total, with at least 7 answers for each question. We make our labeled LiveQA-Novelty Dataset available for the research community [1].

Model	α NDCG (Yahoo)	α NDCG (LiveQA)	ERR-IA (Yahoo)	ERR-IA (LiveQA)
LDARanker	0.62	0.58	0.6	0.51
BM25	0.67	0.52	0.53	0.43
MMR	0.66	0.56	0.57	0.46
SimRanker-ESA	0.75	-	-	-
SimRanker	**0.80***	-	-	-
DRN	**0.81***	**0.68***	**0.65***	**0.56***

Table 1: $\alpha NDCG$ for all methods over Yahoo-Novelty dataset (Left) and LiveQA-Novelty dataset (Right); significant improvements are marked with *.

5 EXPERIMENTAL RESULTS

In this section we present our experimental results, and analyze the performance of *DRN* . Then, we take deeper look at *DRN* internal latent space behavior.

5.1 Main Results

Table 1 report the performance of *DRN* and the baseline algorithms on Yahoo-Novelty and LiveQA-Novelty datasets respectively. Statistically significant ($p < 0.05$) improvements are marked with "*"s. The results show that on both datasets, *DRN* outperforms the baselines *BM*25, *MMR*, *LDARanker* and *SimRanker − ESA*. We hypothesize that our algorithm is able to automatically learn novelty-driven features defined over interactions of questions and answers, while *BM*25 and *SimRanker − ESA* are mostly dependent on semantic similarity between questions and answers. One might consider *LDARanker* comparable to our method, as both are based on a topic models (i.e., *DRN* utlizes it during the sampling phase). However, *LDARanker* does not consider the interactions with the question when considering the novelty-driven answers ranking, thereby ignoring essential information. The only method directly comparable to ours is the *SimRanker*-Supervised. However, this is a supervised approach, which requires data with diversity labels for training. In contrast, our method *DRN* is trained in a distant supervised manner, which requires only minimal social signals and does not require any human-annotated diversity labels.

We can observe a significant difference between the performances measured by αNDCG in the Tables 1. The reason for that, is the rate of relevant answers in Yahoo Answers Novelty Based Answer Ranking dataset compared to liveQA Answers Novelty Based Answer Ranking dataset. The former holds a relevant answer rate of 0.8 which means, 80% of the answers contain 1 relevant aspect or more, while the latter holds a rate of 0.45, which makes it a more realistic and difficult environment for all discussed algorithms. Also liveQA Answers contains questions from various categories and therefore complicates the ranking.

5.2 Performance Analysis

In the example in Figure 3, eight relevant aspects appear in ten answers that were provided for the question. *DRN* is able to cover three of them in the first answer, adds another four in the following one where two of them are novel aspects. The third answer the algorithm choose has no relevant aspects – presenting an example where our approach might fail. This failure can be explained by the topic-driven nature of our *Novelty* function (Section 3). The third answer contains a lot of seemingly new topics (e.g., "meditation" and "house plant"). Since our algorithm rewards diverse topics, it

Question	How can I sleep longer? Ok, so it may seem like a silly question, but how do I sleep longer? No matter how tired I am at night, it's impossible for me to sleep more than 5 or 6 hours...
Answer 1; Aspects: 2,4,7	try vitamin supplements. . At night be sure to turn off all electronics that receive radio waves! . Make sure your diet and exercise are at a standard level.
Answer 2; Aspects: 0, 1, 2, 4	Most sleeping problems are probably caused by stress, depression, anxiety and worry. To sleep better just relax and switch off. some light exercise. Common OTC sleep aids include Chamomile tea, 5-HTP, Melatonin.
Answer 3; Aspects: ∅	When it comes to sleep, if I don't get enough, my day gets all out of wack.got a house plant for my bedroom, tried meditation before bed.started drinking chamomile tea.In aggregate, all those things really just moved the needle...
Answer 4; Aspects: 3, 4, 5, 6, 7	Nice shower before bed helps. make sure no disturbance from any noise. Good nutrition and vitamins everyday helps too who knows maybe the cellular radiation has effect on your sleep rhythm. Dont watch tv too late. Make sure room is dark enough so no disruption in the morning.

Figure 3: Example question with its top four answers ranked by *DRN*. The aspects are numbered in the left column and colored in different colors across answers according to human gold-standard annotation.

BM25 Ranking
Answer 1 - Aspects: 2, 4, 7
Answer 2 - Aspects: 2
Answer 3 - Aspects: ∅
Answer 4 - Aspects: 0, 1, 2, 4

Table 2: BM25 ranking by aspects over the same example as in figure 3.

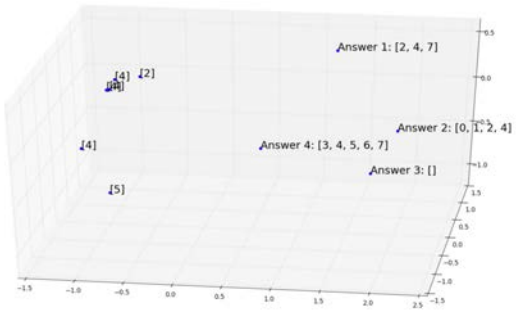

Figure 4: *DRN* LSTM answers vector space for the same question as in figure 3.

might fail if the answer topics are diverse and have a disambiguation in relevance. This issue can be addressed by introducing the network with other types of negative examples which are not based on topic modeling. Another possible explanation is that this answer is controversially annotated as having no relevant aspects to the question. Going back to the ranking, we observe that the 4th ranked answer contains five relevant aspects, of which four are novel aspects. For comparison, table 2 reports the BM25 ranking over the same example from figure 3. This example illustrates the capability of *DRN* to emphasize relevance and novelty simultaneously, by selecting answers that are both relevant to the question and novel with respect to the previously chosen answers.

As discussed earlier, our sampling process and objective function are aimed at learning novelty-driven features automatically, thus we expect the LSTM representation for the answers to express these novel features. Figure 4 gives some intuition of *DRN* behavior and latent features for the example answers from 3. Using the PCA method, we project the answer LSTM vector representations into three most informative dimensions. Each dot in space is an answer, annotated with the list of the aspects it contains. Answers presented in Figure 3 are also labeled with the answer number. We can see a large gap between answers contain low number of aspects (left side), and the answers containing many of the aspects (right side). Moreover, observing the aspects' behavior across answers, we can see that answers with similar aspects tend to be nearby in space, for example, all four answers which contain only the aspect 4 are close, while answers with only the aspects 2 or 5 are further. On the right side of the figure, the answers are far from each other because of the large number of novel aspects they introduce with respect to each other. One exception is Answer 3, analyzed previously.

6 CONCLUSIONS

Modeling both relevance and novelty for ranking answers is a key requirement for effective and user-friendly complex question answering and result presentation, especially with increasing adaption of conversational interfaces and small-screen mobile devices. Previous state of the art approaches have been supervised, requiring extensive manual annotations to obtain both relevance and diversity labels. To address this problem, we presented *DRN*, a novel method which reaches state-of-the-art results using distant supervision for relevance, and no labeled data for diversity. Our method automatically learns a novelty-aware answer scoring function from CQA archives, based on the Neural Tensor Network representations of the interactions between questions and answers, and a novel sampling approach for training, which emphasizes relevance and novelty. We present a new answer ranking algorithm utilizing our model, which iteratively ranks answers by their diversity and relevance with respect to the formerly chosen answers. Experimental results based on two data sets demonstrated that our algorithm outperformed the state of the art baselines that required significant feature engineering and labeled datasets. In future work, we plan to address multiple forms of diversity, by extending our sampling phase to emphasize multiple types of *Novelty* functions and novelty-driven negative examples. Our method could be extended to other settings of complex question answering over social media, and more broadly to complex question answering and web search tasks that require retrieving relevant, useful, and novel answers.

ABSTRACT

As an alternative means of convenient and smart transportation, mobility-on-demand (MOD), typified by online ride-sharing and connected taxicabs, has been rapidly growing and spreading worldwide. The large volume of complex traffic and the uncertainty of market supplies/demands have made it essential for many MOD service providers to *proactively* dispatch vehicles towards ride-seekers.

To meet this need effectively, we propose STRide, an MOD coordination-learning mechanism reinforced spatio-temporally with capsules. We formalize the adaptive coordination of vehicles into a reinforcement learning framework. STRide incorporates spatial and temporal distributions of supplies (vehicles) and demands (ride requests), customers' preferences and other external factors. A novel spatio-temporal capsule neural network is designed to predict the provider's rewards based on MOD network states, vehicles and their dispatch actions. This way, the MOD platform adapts itself to the supply-demand dynamics with the best potential rewards. We have conducted extensive data analytics and experimental evaluation with three large-scale datasets (~21 million rides from Uber, Yellow Taxis and Didi). STRide is shown to outperform state-of-the-arts, substantially reducing request-rejection rate and passenger waiting time, and also increasing the service provider's profits, often making 30% improvement over state-of-the-arts.

CCS CONCEPTS

1 INTRODUCTION

By integrating online information of rides demands and supplies, transit network operation and communication, cooperative mobility-on-demand (MOD) systems, such as Uber, Lyft, Didi and connected taxicabs, have provided unprecedented transportation alternatives.

Given its significant economic and social values, we should coordinate the MOD operations, *i.e.,* dispatching (matching) supplies (i.e., available vehicles/drivers) towards demands (*i.e.,* passengers/requesters/riders). A coordination policy/strategy usually uses current observations to determine where and when to relocate vehicles for maximization of MOD service providers' profit and satisfaction of riders' desire/requirement. During each phase of coordination, the idle/vacant MOD vehicles are dispatched towards different service zones (a discretized city map), and matched with their nearest requesters. The resultant rides also "connect" the zones, forming an MOD network.

However, increasingly complex urban traffic networks and miscoordination of demand-supply dynamics often under/over-serve many service zones, thus degrading the providers' profitability, service quality, passenger satisfaction and drivers' enthusiasm. The problem is particularly severe during rush hours when people travel in similar directions between home and work. Despite numerous efforts and enormous historical ride data available, designing an MOD coordination mechanism remains to be difficult for the following reasons.

First, due to urbanization and MOD market expansion, the *static* coordination based upon old data in some zones cannot be applied and scaled throughout the dynamically-changing MOD network, thus calling for an adaptive mechanism. Second, coordination of complex MOD supplies and demands makes sequential and long-term effects. A single vehicle dispatching action may introduce profound consequences to the environment and other vehicles, that cannot be easily foreseen by a heuristic coordination mechanism. Third, there usually exists *multi-level periodicity* within traffic routines, commute patterns, annual festival events, and ride preferences. Weather can also affect the ride requests, which will, for example, surge during rainy hours. Without comprehensive modeling of these factors, the conventional coordination methods cannot easily and accurately capture the repeating patterns.

We meet these challenges by proposing STRide, deep reinforcement learning (RL) based on spatio-temporal capsules for coordinating the MOD network. Specifically, we design an RL framework with a data-driven emulator, adjusting the coordination policy with an online *self-adapting* mechanism. A state in this RL represents the spatial MOD demand, supply and external temporal factors, and each action there represents the zones that vehicle can be relocated to. The multi-objective reward function characterizes the platform profitability, cost and service coverage, whose long-term values are maximized by STRide. The framework also takes into account the

contextual scopes of vehicles and travel time estimation to emulate a fine-grained learning environment.

Since it is difficult to specify the long-term coordination effects on future demands and supplies, we design a novel capsule-based neural network to comprehensively learn the relationship between observed states, coordination actions and potential rewards. This way, STRide foresees an upcoming demand–supply imbalance and proactively provides optimal decisions, achieving fine-grained coordination. STRide incorporates the spatial demand-supply dynamics, temporal external influence factors and ride preferences to capture the complex periodicity in MOD ride demands. The optimized coordination policy is stored in the capsule network for efficient online use by service providers.

This paper makes the following three major contributions:

- *Comprehensive Learning Framework for Proactive & Efficient MOD Coordination*: We have formalized the dynamic vehicle dispatching and rides matching into a spatio-temporal RL framework. STRide accounts for spatial and temporal distributions of supplies and demands, ride preferences and other external factors. Using double deep Q-network (DQN) learning and contextual scope processing, STRide learns how to dispatch each participating vehicle effectively and efficiently.
- *Spatio-Temporal Capsule-based Policy Learning*: Within the RL framework, we integrate a novel spatio-temporal capsule neural network, accurately and efficiently mapping the observed MOD network states, vehicles and dispatch actions to the provider's rewards. This way, STRide finds the spatio-temporally adaptive coordination policy with the best platform profitability, service quality, passenger satisfaction and driver incentivization.
- *Extensive Data-driven Analytics & Evaluation*: Based on above, we have conducted large-scale (a total of 21,150,163 rides) data analytics and comprehensive experimental evaluation of STRide. Our results based on data of Uber/Yellow Taxi, New York City and Didi, Chengdu, China show STRide to outperform other state-of-the-arts, lowering request reject rate, and passenger waiting time, and also enhancing the platform's profits (often making more than 30% improvement over the state-of-the-arts).

2 PROBLEM FORMULATION & SYSTEM OVERVIEW

2.1 Preliminary

Zones, Rides & MOD Network: A large-area city map is discretized into R zones, $\mathbf{Z} = \{z_1, \ldots, z_R\}$, while balancing between coordination granularity and computation efficiency. The shape and size of a zone can be subject to the performance goal and platform customization. In our prototype, the entire map is discretized into $L_{\text{lon}} \times L_{\text{lat}}$ rectangular "zones", the shape of each of which may be altered to reflect the existence of buildings, rivers, roads, etc.

Let $\mathbf{T}(i, j)$ be the set of directed MOD rides from z_i to z_j, and $\mathbf{T} = \{\mathbf{T}(i, j);\ i, j = 1, \ldots, z_R\}$. The MOD network is then a directed graph $\mathbb{G}(\mathbf{Z}, \mathbf{T})$ and formed by the end-to-end (e2e) MOD rides $\mathbf{T}$ across R different zones. The thus-formed $\mathbb{G}(\mathbf{Z}, \mathbf{T})$ serves as the *environment* of our coordination learning.

Discretization of Time Domain: The data structure for STRide's training is prepared by following the practice in RL framework [29] and slicing ride records $\mathbf{T}$ (sorted by their pick-up timestamps) into N_{epi} identical non-overlapping chunks. Each chunk, or *episode*, is a time period within a day, during which the MOD platform maximizes the financial returns. Similarly to the map discretization, the time domain of each trip chunk is discretized into N_{step} equal intervals (30 min each in our prototype). Each interval k ($k \in \{1, \ldots, K\}$) corresponds to a *learning step*. Then, for each z_i in a step k, we let $D_i^{(k)}$ be the number of aggregated pick-ups (requests).

Vehicles: Considering the connectivity of the MOD network, the service provider monitors the status of $M^{(k)}$ participating vehicles in step k. Each of these vehicles, denoted as v_m ($m \in \left\{1, \ldots, M^{(k)}\right\}$), contains its unique identifier, the current location (longitude and latitude *loc*; zone z_i), availability (vacant or not), and destination of ride/dispatch, if any. Each vehicle is in one of the following 4 states: *dispatching* (relocating to another zone for potential pick-ups), *matching* (heading to the pick-up location after accept), *occupied* (between pick-up and drop-off), and *vacant* (staying in the same zone after "dispatching" or "occupied" is over). Besides, each v_m is associated with estimated time of arrival, ETA_m.

2.2 Problem Formulation

Coordination Problem: Given the spatio-temporal distributions of MOD ride pick-ups and drop-offs, we would like to proactively decide on *where and when* each available vehicle should be coordinated to serve ride requests so as to maximize the service provider's profitability and passenger-perceived service quality.

This problem is characterized with the following five major components: $\{\boldsymbol{\mathcal{S}}, \boldsymbol{\mathcal{U}}, \tau, \pi, Q\}$.

a) **State $\boldsymbol{\mathcal{S}}$**: We consider that an MOD network or environment is coordinated by a web-based/online coordination center, or an *agent*, connecting a large group of spatially-distributed vehicles and passengers with mobile apps. The state space $\boldsymbol{\mathcal{S}}^{(k)}$ that the agent observed at the learning step k consists of:

- *MOD vehicles* $\mathbf{V}$: the 2-D (an $L_{\text{lon}} \times L_{\text{lat}}$ matrix) distribution of all vehicles v_m's. From $\mathbf{V}$, we derive the 2-D distribution of vacant/available vehicles, denoted as $\mathbf{A}$. Both $\mathbf{V}$ and $\mathbf{A}$ capture the participating vehicles.
- *Departures/demands/pick-ups* $\mathbf{D}$: the 2-D distribution ($L_{\text{lon}} \times L_{\text{lat}}$) of requests or departures of passengers.
- *External factors* $\mathbf{E}$: Since the different events (e.g., holidays or not), meteorological metrics (e.g., wind speed) and weather conditions (e.g., rainy or snowy) affect the demand/supply [38] as well as the resultant coordination performance, we form them into an L_{ext}-D vector as the additional hints for model training.

We model distributions of $\mathbf{D}$, $\mathbf{A}$ and $\mathbf{V}$ into frames of *heatmaps* (each is an $L_{\text{lon}} \times L_{\text{lat}}$ matrix; warmer colors indicate more passenger requests or vehicles) such that they can be processed by our spatio-temporal learning algorithm as *input features*. At each step k, we find the comprehensive state or observation $\boldsymbol{\mathcal{S}}^{(k)}$ as the important spatial features characterizing the MOD environment, *i.e.,*

$$\boldsymbol{\mathcal{S}}^{(k)} = \left\{\mathbf{D}^{(k)}, \mathbf{A}^{(k)}, \mathbf{V}^{(k)}, \mathbf{E}^{(k)}\right\}. \tag{1}$$

b) **Action $\boldsymbol{\mathcal{U}}$**: An action is a coordination solution. The action space $\boldsymbol{\mathcal{U}}_m$ for each vehicle v_m is defined as a set of discrete transits to any of its neighboring rectangle zones, plus staying where it is. Let L ($\leq R$) be the number of neighboring zones that a vehicle can relocate to. For each v_m, we consider $\boldsymbol{\mathcal{U}}_m$ of size $(L+1)$ is centered

at her/his current zone, and d_{ml} represents a destination zone l relative to the current center. Then, the dispatch *action space* for v_m is $\mathcal{U}_m = \{d_{m0}, d_{m1}, \ldots, d_{ml}, \ldots, d_{mL}\}$, where d_{m0} represents the action of staying where it resides.

c) **Reward** τ: Given the settings of states $\mathcal{S}$ and actions $\mathcal{U}$, each of $M^{(k)}$ available vehicles dispatched by the agent, arrives at the next state, and is returned with an immediate *reward, i.e.,* $\mathcal{S} \times \mathcal{U} \times \mathcal{S} \rightarrow \tau$. Specifically, each vehicle (driver) m at learning step k is associated with an instant reward function $\tau_m^{(k)}$. $\tau_m^{(k)}$ takes into account the platform revenues and coordination cost (often subsidized by MOD service providers [11]), such that maximizing individual rewards can also maximize the platform profitability (Sec. 3.2). Driver incentivization and passenger satisfaction are also figured in the fine-grained multi-objective formulation.

d) **Policy** π & **Long-term Value** Q: Intuitively, the MOD coordination actions have long-term effects upon the vehicle distributions. STRide aims at maximizing the expected reward in each episode, and mitigating the demand-supply imbalance. From the platform's perspectives, this coordination policy, as a joint mapping function, not only predicts gaps between future demands and supplies based on current market status, but also yields the highest reward by relocating idle vehicles. Specifically, at each step k, we find the subsequent cumulative returns based on a certain policy of coordination $\mathcal{S} \times \mathcal{U} \rightarrow \pi$, with a weight parameter $\gamma \in (0, 1)$ that differentiates rewards in terms of temporal proximity. For each v_m, at step k STRide expects the long-term values in the remaining steps of the episode as

$$Q_m^{(k)} = \tau_m^{(k)} + \gamma \tau_m^{(k+1)} + \cdots + \gamma^{K-k} \tau_m^{(K)}. \tag{2}$$

Then, the optimal value function $Q_m^*(\cdot)$ is the maximum expected long-term reward of all candidate dispatch decisions, *i.e.,*

$$Q_m^*\left(\mathcal{S}^{(k)}, \mathcal{U}^{(k)}\right) \triangleq \max_{\pi} \mathbb{E}\left[Q_m^{(k)} \middle| \mathcal{S}^{(k)}, \mathcal{U}^{(k)}, \pi\right], \tag{3}$$

which fulfills the Bellman equation [29] for iterative learning as

$$Q_m^*\left(\mathcal{S}^{(k)}, \mathcal{U}^{(k)}\right) = \mathbb{E}_{\mathcal{S}'}\left[\tau_m^{(k)} + \gamma \max_{\mathcal{U}'} Q_m\left(\mathcal{S}', \mathcal{U}'\right) \middle| \mathcal{S}^{(k)}, \mathcal{U}^{(k)}\right], \tag{4}$$

where $\mathcal{S}'$ and $\mathcal{U}'$ represent the given state and action of subsequent step $(k+1)$. Note that vehicles with the same spatio-temporal states are considered homogeneous. In other words, vehicles in the same zone and step (time interval) share the same coordination policy and value function. Due to the difficulty of specifying the sophisticated long-term value Q, we design a spatio-temporal deep capsule network as the Q-*network* (Sec. 4) to store policy π.

2.3 System Framework & Flow

Fig. 1 overviews the STRide's system design with two phases, *offline learning* and *online coordination*. The entire system consists of following 3 major components:

1) **Feature Extraction & Processing**: Given the MOD data of rides from mobile apps and other external factors from the MOD (online) environment (Sec. 3.1), STRide first extracts features, structuring the batched data into states $\mathcal{S}$ as Eq. (1) for ease of the following offline emulation and model learning. The historical (offline learning) and real-time (online coordination) external knowledge can be obtained via weather station records or Internet [38].

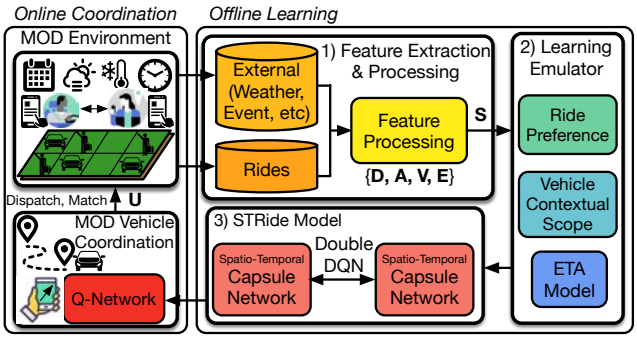

Fig. 1: The system framework of STRide.

2) **Learning Emulator**: In our RL design, the emulator [29, 31] provides the offline and emulated environment derived from real-world ride data and the city map for model training. Its design (Sec. 3.2) accounts for the ride preferences, the contextual scope for each individual vehicle. Meanwhile, STRide finds the estimated time of arrival (ETA) for each matching or dispatching transit. Note that the emulator can be cold-started by several episodes of rides without STRide's coordination. Historical ride data can also be used for offline learning to train an initial model of STRide, .

3) **STRide Model**: The environment states, the agent's coordination actions and resultant rewards at each step are used to train our deep capsule network model for policy learning, minimizing the Q estimation loss. During model training, the emulator is reset given each episode of ride data, while the model is updated *w.r.t.* each learning step k. After taking multiple steps, the double DQN mechanism learns the coordination policy, and the STRide model is returned for next episode. The offline learning ends when all episodes of data are examined. The learned capsule network returns the optimal policy (subject to ϵ-greedy mechanism) and actions for online coordination, e.g., routing vacant vehicles to destinations via mobile apps [19].

3 DATA-DRIVEN LEARNING EMULATOR

3.1 Data Sets for Analytics & Evaluation

Our emulator is built for data analytics and performance evaluation based on the following three large-scale MOD datasets:

- *Uber, NYC* [5]: The ride sharing data of Uber in New York City (NYC), June 2015, contains a total of 2,816,895 rides.
- *Yellow Taxis, NYC* [4]: The ride data of Yellow Taxis in May 2016 contains 11,588,760 rides, their pick-up/drop-off locations and timestamps. Taxis share many similar characteristics with ride-sharing/hailing vehicles (e.g., driving distance and time), making this experimental study feasible [27].
- *Didi, Chengdu* [6]: The ride-sharing data provided by Didi Chuxing [6], contains a total of 6,744,508 rides (with pick-up/drop-off locations and timestamps) from the city of Chengdu, Sichuan Province, China in November 2016.

For each of these datasets, we also include local weather [2], weekday/weekend and festivals/events as the external factors (**E**) in the model, as summarized in Fig. 3. We also obtain the road network from OpenStreetMap (OSM) [3].

3.2 Design of Comprehensive Learning Emulator

We design and implement a *data-driven* learning platform that emulates a real-world MOD platform with the following considerations.

a) **Contextual setting**: A driver usually focuses on her/his neighborhood observations or *contexts* for (re)location. The relocation policy for each vehicle is made fine-grained by cropping and padding (zeros) [13] in the heatmap frames in $\boldsymbol{\mathcal{S}}$ such that the *local* scope $\boldsymbol{\mathcal{S}}_m$ of each v_m (*i.e.,* the observed contexts in its neighborhood) is centered around its current zone. This way, STRide can learn the coordination policy based on each vehicle's neighborhood observations. This also reflects the drivers' tendency in (re)locating to nearby zones for less time/fuel consumption. STRide will also pay less computation overhead. At step k, we find the contextual scopes of $M^{(k)}$ available vehicles from the global state $\boldsymbol{\mathcal{S}}^{(k)}$. The state of each vehicle m to be dispatched is $\boldsymbol{\mathcal{S}}_m^{(k)} = \left\{\mathbf{D}_m^{(k)}, \mathbf{A}_m^{(k)}, \mathbf{V}_m^{(k)}, \mathbf{E}_m^{(k)}\right\}$. Each of $\mathbf{D}_m^{(k)}$, $\mathbf{A}_m^{(k)}$ and $\mathbf{V}_m^{(k)}$ is cropped from $\boldsymbol{\mathcal{S}}^{(k)}$ into a sub-frame of smaller size $L'_{\text{lon}} \times L'_{\text{lat}}$ ($L'_{\text{lon}} < L_{\text{lon}}$ and $L'_{\text{lat}} < L_{\text{lat}}$), and centered at m's current zone like $\boldsymbol{\mathcal{U}}_m$. $\mathbf{E}_m^{(k)}$ is an $(L_{\text{ext}} + 2)$-D vector consisting of L_{ext} external factors and v_m's current 2-D location.

In a sequential-learning setting [29], we consider all idle vehicles sequentially determine where to relocate to. Each vehicle considers all other peers' present status, while its dispatch decision is independent of the peers' next moves/actions [37]. In state $\boldsymbol{\mathcal{S}}_m^{(k)}$, v_m's relocation to a neighboring zone $d_{ml}^{(k)}$ at step k leads to a subsequent $\boldsymbol{\mathcal{S}}_m^{(k+1)}$ observation and an instant reward $\tau_m^{(k)}$. Then, a *transition sample* $\mathbf{H}^{(k)}$ of consecutive states at k and $(k+1)$ is given by

$$\mathbf{H}^{(k)} = \left\{\boldsymbol{\mathcal{S}}_m^{(k)}, d_{ml}^{(k)}, \boldsymbol{\mathcal{S}}_m^{(k+1)}, \tau_m^{(k)}\right\}, \tag{5}$$

which is stored in the *experience replay* $\mathbf{O}$ and resampled for further training of STRide model in Sec. 4.

b) **Multi-objective ride reward function**: For each vehicle, STRide accounts for the platform profitability (in proportion to the vehicle's earning), service coverage and configuration cost in characterizing the agent's reward function. Intuitively, more rewards are expected if more ride fares are earned and less time of dispatching/idle driving is consumed. To accommodate this, we consider for each v_m in the k-th step two critical perspectives: *earning score* $P_m^{(k)}$ in terms of fulfilled rides and revenues, and the *relocation cost* $F_m^{(k)}$ related to dispatching and idle driving time (and fuel consumption). Then, v_m's reward at step k is defined as the sum of earning scores minus the relocation costs in a window of w steps, *i.e.,*

$$\tau_m^{(k)} \triangleq \sum\nolimits_{\widetilde{k}=k-w}^{k} \left(\alpha P_m^{(\widetilde{k})} - F_m^{(\widetilde{k})}\right), \tag{6}$$

where $\alpha > 0$ is an adjustable parameter. In our prototype, we empirically set $w = 15$. In other words, the more pick-up revenues and the less relocation time and fuel consumption, the higher reward a vehicle could achieve. The earning score $P_m^{(k)}$ is defined as the weighted sum of serviced ride fares among the zones based on the historical ride preferences $\omega(i,j)$'s, *i.e.,*

$$P_m^{(k)} \triangleq \sum\nolimits_{i=1}^{R} \sum\nolimits_{j=1}^{R} \left|\mathbf{T}_m^{(k)}(i,j)\right| \cdot e_{ij}, \tag{7}$$

where $\left|\mathbf{T}_m^{(k)}(i,j)\right|$ represents the number of actual rides from zones i to j provided by v_m, and e_{ij} is the resultant earning. In our emulator prototype, the driver revenue or ride fare is set as

$$e_{ij} = a \cdot \delta_{ij} + b, \quad a > 0, \quad b > 0, \tag{8}$$

where a is the unit price *w.r.t.* distance δ_{ij} and b is the base price (our prototype uses the local ride rates [5, 6]).

c) **Ride preference & zone-to-zone connectivity**: The drivers and passengers usually have frequent travel patterns among zones due to their commute routes and ride preferences. Considering the MOD network $\mathbb{G}$ connecting the zones $\mathbf{Z}$ with rides $\mathbf{T}$, inspired by the *first-order proximity* in network embedding [30], we design a ride preference metric $\omega(i,j)$ for rides $\mathbf{T}(i,j)$ between z_i and z_j as

$$\omega(i,j) \triangleq \left(1 + \exp\left(-\vec{c}_{ij} \cdot \vec{c}_{ji}\right)\right)^{-1} \tag{9}$$

where the relative proportion of rides $\vec{c}_{ij}$ is defined as a vector of

$$\vec{c}_{ij} \triangleq \left[\frac{|\mathbf{T}(i,j)|}{\sum_{k=1,k\neq i}^{R} |\mathbf{T}(i,k)|}, \quad 1 - \frac{|\mathbf{T}(i,j)|}{\sum_{k=1,k\neq i}^{R} |\mathbf{T}(i,k)|}\right]. \tag{10}$$

That is, the more rides recorded between z_i and z_j, the higher $\omega(i,j)$, indicating a stronger connectivity between the two zones.

We incorporate the above ride tendency of zones into STRide's formulation, not relying only upon individually-aggregated demand values. Our prototype discretizes each day into four 6-hour periods, and aggregates rides of the same period for different sets of $\omega(i,j)$'s. Then, to calculate $F_m^{(k)}$, we consider in Eq. (6) the relocation travel time $\Gamma(i,j)$, and the recent weight $\omega(i,j)$ between z_i and z_j belonging to the same historical periods (say, 06:00 – 12:00 of the same weekday in its preceding week), and find the weighted sum of

$$F_m^{(k)} \triangleq \sum\nolimits_{i=1}^{R} \sum\nolimits_{j=1}^{R} \frac{\beta \Gamma(i,j)}{\omega(i,j)}, \tag{11}$$

where $\beta > 0$ is the unit cost related to the relocation time or petrol prices [1] (say, a subsidy rate by the MOD platform for dispatching [10]). Rides starting and ending within the same zone, *i.e.,* when $i = j$, are also considered within Eq. (9).

d) **Estimated time of arrivals**: For fine-grained evaluation, the learning emulator also calculates the estimated travel time between two locations for characterizing: (1) the time of travel from current location to destination when passengers are served; (2) the time of passenger wait if vehicles and certain passengers are matched; and (3) the time of idle driving if vehicles are dispatched to another location for potential requests. Specifically, we implement a random forest regression [14] (other more advanced models [18, 33, 34] may apply) to estimate the travel time ETA_m between one location to another given the input vector of start/end coordinates, length of the shortest path between them, day of a week and hour/minute of a day belonging to the start time. The length of interim road segments during the vehicle's travel are derived from OSM [3].

4 CAPSULE-BASED COORDINATION LEARNING

Characterizing Q, the relationship between states, actions and long-term values, is essential for STRide to decide on the best coordination policy π while adapting to the environment. We propose the use of capsule-based Q-network for more comprehensive MOD coordination learning, dynamically capturing and learning $Q_m(\mathcal{S}_m, \mathcal{U}_m)$. A *capsule* is a structured group of neurons [28], and many capsules can be grouped together in one layer. A link between two capsules in consecutive layers becomes a vector. Such vectorized (instead of scalar) representation of data is propagated between layers. Hence, more comprehensive ride patterns, including spatial co-existence

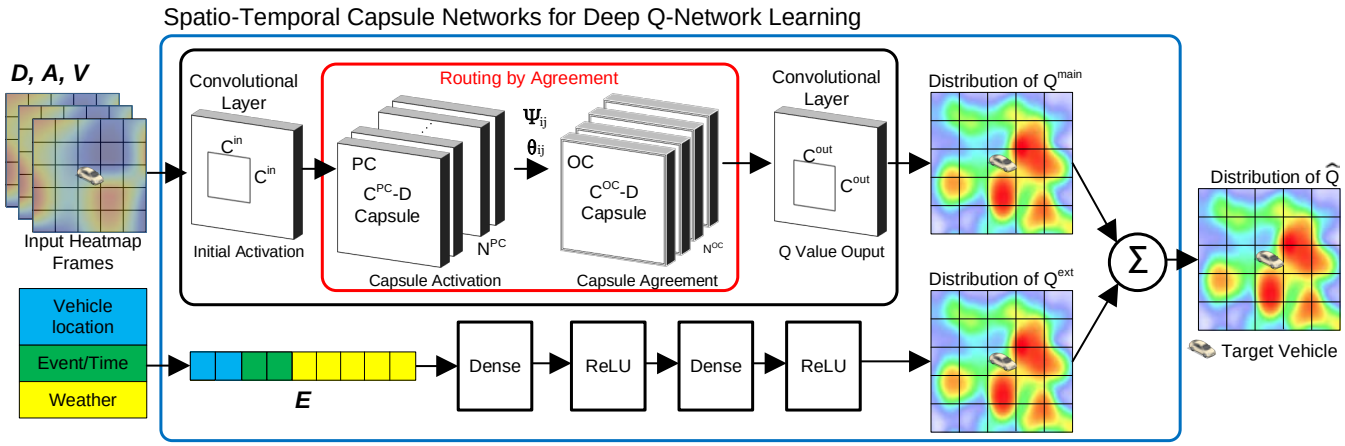

Fig. 2: Core module of spatio-temporal capsule-based Q-network.

of multiple demand surges during rush hours or rainy days, are captured with the vector representation as *instantiated entities* [16].

Fig. 2 illustrates the processing structures of the main and external state features, as detailed below.

a) **Main spatial features** $\{\mathbf{D}, \mathbf{A}, \mathbf{V}\}$: Given the input heatmap frames, $\left\{\mathbf{D}_m^{(k)}, \mathbf{A}_m^{(k)}, \mathbf{V}_m^{(k)}\right\}$, the core deep neural network in STRide captures the *spatial* relationship between states, actions and rewards. In particular, a fine-grained capsule network takes in the vehicle's 2-D state representation, and returns the estimated Q-values, denoted as $\boldsymbol{Q}^{\text{main}}$, *w.r.t.* the 2-D action space $\mathcal{U}_m$.

We further illustrate the basic structures and learning process of capsule network in STRide. Specifically, given the input heatmap $\mathbf{X}^{\text{input}} = \left\{\mathbf{D}_m^{(k)}, \mathbf{A}_m^{(k)}, \mathbf{V}_m^{(k)}\right\}$ processed from state $\boldsymbol{\mathcal{S}}_m^{(k)}$, the capsule network consists of four sequential major components, *i.e.,*

$$\begin{aligned} \mathbf{X}_1 &= \mathsf{Conv}\left(\mathbf{X}^{\text{input}}\right), \quad \mathbf{X}_2 = \mathsf{PC}\left(\mathbf{X}_1\right), \\ \mathbf{X}_3 &= \mathsf{OC}\left(\mathbf{X}_2\right), \quad \boldsymbol{Q}^{\text{main}} = \mathsf{Conv}\left(\mathbf{X}_3\right), \end{aligned} \tag{12}$$

where the first and fourth two-dimensional convolutional layers (Conv) are used for transformation between the physical heatmap frames (scalar-based) and hidden capsule layers (vector-based), *Primary Capsule* (PC) and *Output Capsule* (OC).

In our implementation, each capsule contains a structured group of neurons reshaped and regrouped from convolutional layers [28]. Each cuboid in PC/OC of Fig. 2, as a capsule, corresponds to a group of convolutional units or neurons (each neuron as a dimension is with a 9×9 kernel and a stride of 2 in our prototype). Specifically, PC is comprised of N^{PC} C^{PC}-D capsules, while OC is made of N^{OC} C^{OC}-D capsules. The input Conv layer has N^{in} $C^{\mathsf{in}} \times C^{\mathsf{in}}$ convolutional kernel filters, while the output one has N^{out} $C^{\mathsf{out}} \times C^{\mathsf{out}}$ filters.

The learning process is presented as follows. In a nutshell, the parameters of STRide's capsules, consisting of traditional *neuron weights* and additional *capsule probabilities*, are propagated and refined between the layers of PC and OC. Specifically, let θ_{ij} be the logarithm prior probability captured by a preceding capsule i in PC and its succeeding peer j in OC. A softmax function [13] is then applied upon the θ_{ij}'s, returning the coupling coefficient f_{ij} as

$$f_{ij} = \exp(\theta_{ij}) \cdot \left(\sum\nolimits_l \exp(\theta_{il})\right)^{-1}. \tag{13}$$

θ_{ij}'s capture the strengths of vehicle distributions in the map.

Similarly to the traditional neuron structure, the capsule network also has the weight coefficient across capsules i and j, denoted as Ψ_{ij}, learned through the conventional back-propagation algorithm [13]. All coefficients thus form an $N^{\mathsf{PC}} \times N^{\mathsf{OC}}$ weight matrix $\boldsymbol{\Psi}$. For each succeeding capsule j, let $\mathbf{q}_i$ be the ride prediction vector returned from a preceding peer i in PC. The propagated vector from capsules i to j, denoted as $\mathbf{q}_{j|i}$, is given by the product of neural network weights Ψ_{ij} and prediction vectors $\mathbf{q}_i$, *i.e.,* $\mathbf{q}_{j|i} = \Psi_{ij}\mathbf{q}_i$, is then fed to capsule j as a weighted average by f_{ij}'s, *i.e.,*

$$\mathbf{e}_j = \sum\nolimits_i f_{ij}\mathbf{q}_{j|i}. \tag{14}$$

A *routing-by-agreement* between capsules [28] is used to differentiate the vectors by their strengths of mutual agreement. Capsule training can then be regarded as extracting and refining the active *routes* from a preceding capsule layer (PC) to a succeeding one (OC). An active route across layers means a specific coordination strategy with certain zones, as an entity, is "memorized", while a deactivated one represents that the unimportant connections can be "forgotten". Specifically, a *squash function* $\mathbf{o}_j(\cdot)$ is applied first upon $\mathbf{e}_j$ to characterize its length [28], which is given by

$$\mathbf{o}_j(\mathbf{e}_j) \triangleq \frac{\|\mathbf{e}_j\|^2}{1+\|\mathbf{e}_j\|^2} \cdot \frac{\mathbf{e}_j}{\|\mathbf{e}_j\|}. \tag{15}$$

In other words, an increase in the vector length of the spatial ride distribution saturates the output towards one, which is identified and captured by the capsule network. The logarithm prior probabilities θ_{ij} are updated with the product of prediction $\mathbf{q}_{j|i}$ and adjustment $\mathbf{o}_j(\mathbf{e}_j)$, *i.e.,*

$$\theta_{ij} \leftarrow \theta_{ij} + \mathbf{q}_{j|i} \cdot \mathbf{o}_j(\mathbf{e}_j). \tag{16}$$

The resultant θ_{ij} is returned to Eq. (13) for another routing iteration. Via routing-by-agreement, STRide finds the vectors with higher agreement, preserving the ride correlations across zones.

b) **External temporal features** $\mathbf{E}$: $\mathbf{E}$ is processed as in Fig. 3. Due to $\mathbf{E}$'s lower dimension than vehicle and passenger distributions, we form it into a vector of the external features, and design a fully-connected neural network (Dense) to learn the coordination. Specifically, the sequential model with two layers of dense/fully-connected networks (with respective output dimensions C_1^{Den} and

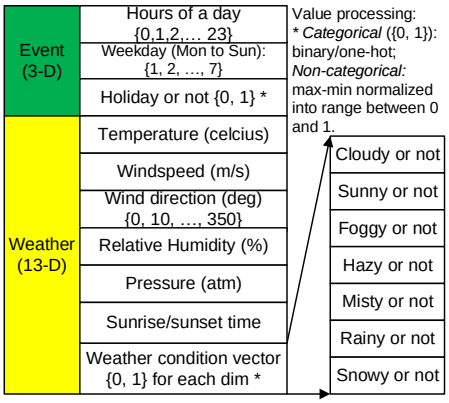

Fig. 3: External factors E.

C_2^{Den}) and subsequent ReLU activation functions [13] is given by

$$\mathbf{E}_1 = \texttt{Dense}\left(\mathbf{E}^{\text{input}}\right), \quad \mathbf{E}_2 = \texttt{ReLU}\left(\mathbf{E}_1\right), \\ \mathbf{E}_3 = \texttt{Dense}\left(\mathbf{E}_2\right), \quad \boldsymbol{Q}^{\text{ext}} = \texttt{Reshape}\left(\texttt{ReLU}(\mathbf{E}_3)\right). \tag{17}$$

where the final output $\boldsymbol{Q}^{\text{ext}}$ is reshaped from a vector back to 2-D matrix *w.r.t.* the vehicle's action space $\mathcal{U}_m$.

Finally, the estimated Q-value function *w.r.t.* each state and action is given by merging $\boldsymbol{Q}^{\text{main}}$ and $\boldsymbol{Q}^{\text{ext}}$, *i.e.,*

$$\widehat{\boldsymbol{Q}} = \boldsymbol{Q}^{\text{main}} + \boldsymbol{Q}^{\text{ext}}. \tag{18}$$

Then, in coordination STRide finds the zone with the maximum Q-value in $\widehat{\boldsymbol{Q}}$ for dispatching (subject to ϵ-greedy). The set of parameters to be trained, denoted as $\boldsymbol{\Omega}$, is hence made of those contributing to $\boldsymbol{Q}^{\text{main}}$ (including Ψ_{ij}'s and θ_{ij}'s) and those neuron weights for $\boldsymbol{Q}^{\text{ext}}$. We implement a double deep Q-network (DQN) learning mechanism [31] within STRide to train the core deep Q-network.

5 EXPERIMENTAL EVALUATION

Experimental settings: We compare STRide with the following typical algorithms: (1) *CRL*: an online learning framework [12] leveraging the conventional convolutional neural network (CNN) for coordination policy learning [25, 36]. (2) *CONT*: a conventional model-based approach, formulating a traffic control problem [7, 25] to find the dispatching and matching strategy based on the demand-supply balancing model. (3) *GD*: a heuristic vehicle dispatching without optimizing or learning the ride dynamics. MOD vehicles are greedily dispatched towards zones with the highest demand-supply imbalances [7, 27]. All evaluated schemes (the detailed parameter settings can be found in the corresponding references) use the same ride data, ETA module and learning emulator settings.

We comparatively evaluate the performance based on the following metrics: profits (platform; rides revenues minus relocation subsidies on fuel costs), idle driving time (the time when a vehicle is not occupied but still incurs the driving cost), reject rate (due to unavailability of vehicles nearby), (passenger's) waiting time, and coordination time (overhead of each online decision for MOD request matching and vehicle dispatching).

Unless stated otherwise, we use the following default parameters. In the learning emulator, we empirically set the total number of vehicles $M = 8,000$, $\alpha = 1.0$, $\beta = 0.3$, and $\epsilon = 0.1$. The total number of episodes is set to 12, while each of them is 30 hours long. Each step lasts for 30 min. A rejection happens if the distance between a request and the nearest vacant vehicle is greater than 5.0 km. For

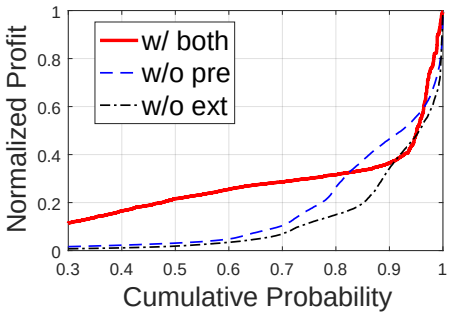

Fig. 4: Components (Uber).

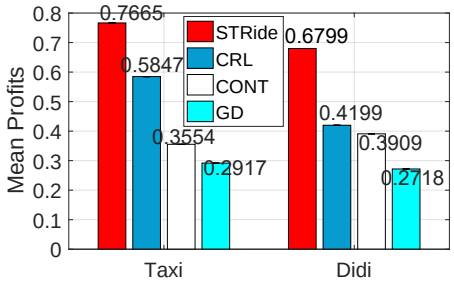

Fig. 5: Mean profit (Taxi&Didi).

Uber/Taxi, $a = 5$ and $b = 3$; for Didi, $a = 5$ and $b = 1$. The platform revenues are 20% of the ride fares, and the subsidies are 20% of the relocation costs based on studies in [10, 17, 27]. The city map is partitioned into $L_{\text{lon}} \times L_{\text{lat}} = 219 \times 219$ zones, while each vehicle is considered to move in its neighborhood of 15×15 zones ($\mathcal{U}_m$). Each vehicle's scope is set $L'_{\text{lon}} \times L'_{\text{lat}} = 23 \times 23$.

In the core Q-network, we set each layer of the spatio-temporal capsule network as follows: $\left(N^{\text{PC}}, C^{\text{PC}}\right) = (8, 8)$, $\left(N^{\text{OC}}, C^{\text{OC}}\right) = (8, 50)$, $\left(N^{\text{in}}, C^{\text{in}}\right) = (64, 9)$, $\left(N^{\text{out}}, C^{\text{out}}\right) = (64, 6)$ (each Conv has a stride of 1 and ReLU activation) for main feature components in Fig. 2; $\left(C_1^{\text{Den}}, C_2^{\text{Den}}\right) = (10, 15^2)$ for the rest components handling the 18 external features ($L_{\text{ext}} = 16$ and 2-D location in $\mathbf{E}$ as in Fig. 3). With the above settings, we obtained the following experimental results.

Experimental Results: *Profits & Efficiency*: Fig. 4 shows STRide's normalized profits without either ride preference (pre) or external factors (ext), and the complete model with both components. Introducing ride preferences helps STRide relocate vehicles across popular zones with strong connectivities, leading to more pick-ups and hence more profits. Inclusion of auxiliary factors related to MOD rides help STRide capture more intrinsic routines in the spatio-temporal ride distribution, hence achieving more profits.

Fig. 5 shows the mean profit (normalized *w.r.t.* each dataset) of all schemes. STRide is shown to achieve much higher profits than other schemes. Taking the large-scale NYC taxi dataset as an example, we show the CDFs of computation time in Fig. 6. Due to fast weight propagation across the layers, STRide achieves much better computational efficiency, which is essential for real-time coordination.

Idle driving time: Fig. 7 shows that shorter idle driving time for NYC Taxis. It is due mainly to the highly accurate Q-value approximation within STRide, capturing the spatio-temporal relations

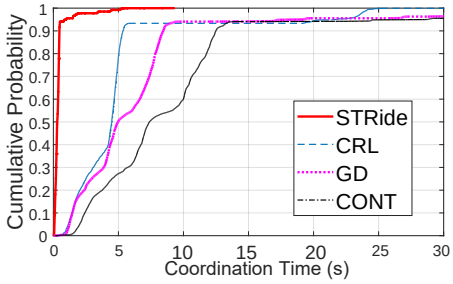

Fig. 6: Online overhead (Taxi).

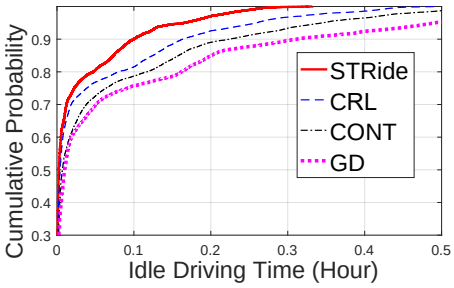

Fig. 7: Idle time (Taxi).

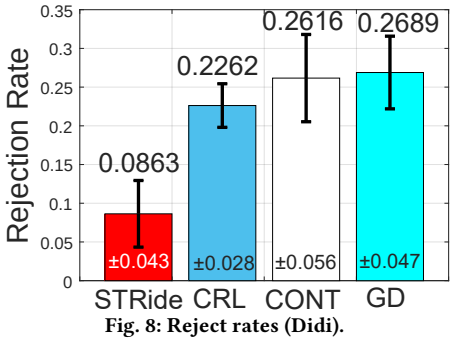

Fig. 8: Reject rates (Didi).

among states, actions and consequent rewards. Less idle driving may also lead to lower subsidies and costs from the MOD platform, thus enhancing its overall profitability.

Rejection rate: Fig. 8 shows the lower mean rejection rates of the schemes (with standard deviation) in the Didi dataset. Thanks to STRide's proactive relocation of MOD vehicles, ride requests are rejected less. On the other hand, STRide accurately learns the locations of potentially high demands, and determines proactive dispatch regions within the rejection distance threshold.

Waiting time: Fig. 9 shows the shorter passenger waiting time of STRide than other related algorithms. With more proactive dispatching, the supplies match demands in time and hence overall shorter waits are needed. This way, the MOD platforms can enhance service quality and passengers' satisfaction.

6 RELATED WORK

Numerous *optimization*-based schemes have been proposed for transportation management [7, 15, 32, 40], including control-based methodology [24], combinatorial optimization [37], and queueing theory [8]. Powered by exploding big data [23] and facilitating parallelism [9, 39], we have witnessed unprecedented advances in *learning*-based transportation management [20, 22, 26, 35]. Wen *et al.* [36] conducted preliminary studies upon learning-based MOD rebalancing. Lin *et al.* [21] studied an RL-based mechanism managing the fleet with a scalar-based neural network. Similarly, Xu *et al.* [37] explored the order dispatching, focusing on the sequential dispatch optimization problem. Oda *et al.* [25] proposed a fleet management system based on convolutional neural networks (CNNs), finding the optimal policy for relocating connected taxicabs.

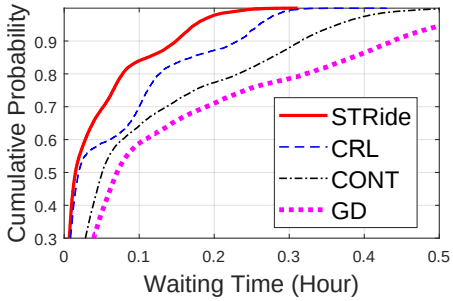

Fig. 9: Waiting time (Didi).

7 CONCLUSION & ACKNOWLEDGMENT

We have proposed STRide, a spatio-temporal reinforcement learning framework for MOD coordination. Given MOD ride data, STRide builds a learning emulator for coordination policy training. We have designed a spatio-temporal capsule network in STRide to map the states and dispatch actions towards the expected future rewards. Spatial distributions of demands and supplies, and temporal external factors like events and weather conditions, are considered together to learn the coordination policy. We have conducted extensive data analytics and experimental evaluation on three large-scale datasets. STRide is shown to outperform state-of-the-arts, with lower request rejection rates, shorter waiting times, and higher platform profitability, often by more than 30% improvement.

We would like to thank DiDi Chuxing GAIA Open Dataset Initiative for the shared ride data.

ABSTRACT

From a national security viewpoint, a higher degree of *cyber autonomy* is crucial to reduce the reliance on external, oftentimes untrustworthy entities, in order to achieve better resilience against adversaries. To probe into the concept of government cyber autonomy, this study examines the *external dependency of public-facing government websites* across the world's major industrialized, Group of Seven (G7) countries. Over a two-year period, we measured HTTPS adoption rates, the autonomy status of CAs, and the autonomy status of CPs on G7 government websites. We find that approximately 85% of web resources loaded by G7 government sites originate from the United States. By reviewing policy documents and surveying technicians who maintain government websites, we identify four significant forces that can influence the degree of a government's autonomy, including government mandates on HTTPS adoption, website development outsourcing, the citizens' fear of large-scale surveillance, and user confusion. Because a government websites are considered critical information infrastructures, we expect this study to raise awareness of their complex dependency, thereby reducing the risk of blindly trusting external entities when using critical government services.

CCS CONCEPTS

• **Security and privacy → Web application security**.

KEYWORDS

Cyber autonomy; government website security; HTTPS adoption

1 INTRODUCTION

A central guideline to cybersecurity is to reduce reliance on *external entities*, especially for those systems under different jurisdictions or governance. From a national security standpoint, it is critical to reduce the reliance on external entities in order to achieve *cyber autonomy*[1]. Recently, cyber autonomy has gained increased attention by worldwide governments due to the revelation of state-sponsored hacktivism [8, 13], including hardware/software shipped with spyware [23, 29], compelled certificates issued for Internet interception [53], and zero-day exploits developed by rival government agencies [26].

To understand how cyber autonomy is practiced by governments worldwide, we investigated a critical facet of a government's cyber autonomy: *external dependency of public-facing government websites*. Since public-facing government websites are the front line for delivering official information and accessing government services, attacks targeting these websites can not only cause widespread panic and social instabilities, e.g., spreading inaccurate information or falsifying alerts [11, 16, 25], but also steal citizens' credentials and sensitive information [17, 19, 22, 24, 30].

In our investigation, we examined the top 100[2] government websites for each of the world's major industrialized countries, known as Group of Seven (G7), in 2017 and 2018. We considered three crucial elements for the cyber autonomy of governments: HTTPS adoption status and dependency on two external entities, namely Certificate Authorities (CAs) and Content Providers (CPs).

HTTPS adoption on government websites can protect sensitive information of their citizens. Unfortunately, our findings reveal the uneven HTTPS adoption rates across G7 countries. In 2017, the US (97%) and the UK (81%) had the highest HTTPS adoption rates, followed by Germany (57%), Canada (53%), France (46%), Japan (40%), and Italy (25%). There has been a steady increase in the adoption rate (13.7% on average) in 2018; a notable increase is by Germany, whose adoption rate has jumped to 90% in 2018. However, among these G7 government websites supporting HTTPS, 91% (in 2017) and 77% (in 2018) are incorrectly configured and thus still vulnerable to attacks. The adoption rates of HSTS, a countermeasure to HTTPS downgrade attacks, remain low (below 50%) in most G7 counties (except the US, reaching 83% in 2018).

CAs are the roots of trust on the Web. With hundreds of eligible CAs to issue certificates, an identified challenge is preventing rogue CAs from spoofing certificates or issuing certificates for phishing domains. For example, CAs can be forced by local governments to issue compelled certificates for HTTPS interception [41]. Among the G7 government websites with valid certificates, approximately

[1] We use cyber autonomy to refer to "self-controlling and free from external influence" [1] in achieving security protection.
[2] Websites are ranked based on Alexa's statistics. See §2.1.1 for details.

https://doi.org/10.1145/3308558.3313645

10% are using the Extended Validation (EV) certificates, which are designed to mitigate phishing. France, Japan, and the US operate their own government root CAs (i.e., root CAs run by a government), but their root certificates are untrusted by Mozilla and Apple, causing multiple certificate errors.

CPs are servers that host web resources (e.g., images, JavaScript) for websites. When a website loads resources from untrusted servers, a variety of undesirable consequences can occur, such as including malicious content, executing malicious scripts that secretly steal credentials, mining cryptocurrencies, or sending denial-of-service traffic [44, 47]. Among the 660 websites that we crawled in 2018, 287 accessed resources from oversea countries, and each website made an average of 1.89 requests to load resources hosted on foreign servers. Among 2,160 external resources loaded by the G7 government websites, 912 (42%) were from 126 location-dependent URLs, which were served by different destination servers based on the source locations. Of the 1,248 location-independent resources, 1,063 (85%) of them originated from the US.

To understand the forces that influence the dependency level of government websites, we also reviewed policy documents and conducted a survey on technicians who maintain government websites. We highlight our findings below:

1. Government mandates help increase autonomy. The HTTPS adoption rates in the countries that have announced mandates over a year are significantly higher than the rest of the G7 countries.

2. Outsourcing undermines cyber autonomy. In our survey, 53 of 63 government websites are created and maintained by third-party contractors. While contractors are legally bound to provide services, they may be unable to respond immediately to attacks.

3. Fear of large-scale government surveillance hinders autonomy. Pinning government websites to government root certificates could eliminate the impact of rogue CAs spoofing government website certificates. However, because some countries have exploited government-issued certificates for Internet surveillance, the trustworthiness of government root CAs has been questioned, and few government root certificates are currently included in all major browsers' trust stores [14].

4. User confusion. Partial inclusion of government root CAs in the browsers' trust stores results in certificate warnings, confusing users whether the government websites in question are trustworthy. The lack of distinct government domain indication may result in users falling for attacks that could have been easily identifiable with government-specific domain names.

Contributions. This paper attempts to measure the current practice of building cyber autonomy on government websites. Over a two-year period, we measured HTTPS adoption rates and the autonomy status of CAs and CPs on G7 government websites. We also conducted a survey on technicians who maintain government websites. Our findings indicate the importance of having government mandates to enhance the overall security of government websites, as well as synchronizing autonomy-oriented government policies with corresponding entities (CAs and CPs) such that they can provide consistent, trustworthy services without errors.

Table 1: The weakness of eleven TLS attacks.

Type	Attack	Weakness
Weakness in cryptography	FREAK Attack [34]	Support RSA_EXPORT
	Logjam Attack [31]	Support DHE_EXPORT
	RC4 Attack [32, 56]	Support RC4 stream cipher
	Sweet32 Attack [35]	Support block ciphers with 64-bit block size and CBC mode
Oracle attacks	BEAST Attack [38]	Support TLS versions earlier than TLS 1.0 and CBC mode of block cipher
	CRIME Attack [39]	Support SSL/TLS compression
	DROWN Attack [33]	Use the same RSA keys in both SSL2.0 and newer versions of SSL/TLS
	POODLE Attack [46]	Support SSL3.0 without using TLS_FALLBACK_SCSV
Weakness in implementation	Heartbleed Attack [6, 40]	Support OpenSSL versions 1.0.1-1.0.1f
Weakness in protocol	ECDH-DH Cross-Protocol Attack [45]	Support ECDH and secp384r1 (ECC parameter) in server side and DH in client side
	Renegotiation Attack [51]	Support insecure renegotiation mechanism

2 HTTPS ADOPTION

HTTPS [3] runs HTTP over Transport Layer Security (TLS), which is a fundamental security protocol that enables end-to-end encryption and authentication for HTTP connections. Without HTTPS, traffic can be intercepted by any en-route adversary, as well as off-path adversaries who are capable of hijacking routes (e.g., malicious ISPs). TLS attacks can be categorized into four types based on the following weaknesses [37].

Weaknesses in cryptography: Websites supporting outdated cryptographic algorithms (e.g., RC4 and MD5) or weak key lengths (e.g., RSA_EXPORT and DHE_EXPORT) enables attackers to crack TLS.

Weaknesses in protocol design: attackers can replay, interleave, or manipulate protocol messages to deceive the client or server into an unintended state, such as deliberately downgrading the protocol version or a cipher suite.

Weaknesses in implementation: attackers can exploit vulnerabilities in the TLS software libraries (e.g., OpenSSL).

Oracle attacks: attackers can adaptively interact with a victim running TLS and derive secret information based on responses.

Table 1 summarizes 11 critical TLS attacks examined in our study. Most of the attacks can be prevented by changing TLS configuration or disabling outdated protocol versions. The last two attacks would require updating to the latest protocol version, TLS 1.3.

2.1 Methodology

In this section, we describe our approach of collecting the G7 governments' domain datasets and measuring their security.

2.1.1 URL Collection. Because there is no single source maintaining a list of up-to-date government websites, we combined multiple publicly-available datasets and systematically curated them. For each of the G7 countries, we first crawled the list of domains under the Regional/Continent Name/Country Name/Government category on Alexa [7].

Because the scope and number of websites vary by country,[3] we improved the data quality of the combination of Alexa and public datasets by heuristically restricting domain names to the corresponding country code's top-level domains (cc-TLD) or second-level domain (e.g., gov, go), assuming that the majority of the collected government domains in that country adhere to a naming convention. As we noticed that the Alexa datasets are often incomplete and

[3]The US dataset contains 1,078 federal domains, while the dataset for Japan has only 77 for "the Cabinet, Ministries and Agencies, the Diet, the Supreme Court, and other government agencies". The UK dataset contains 3,631 central and local domains; the Germany data contains 620 federal and 8,468 non-federal domains.

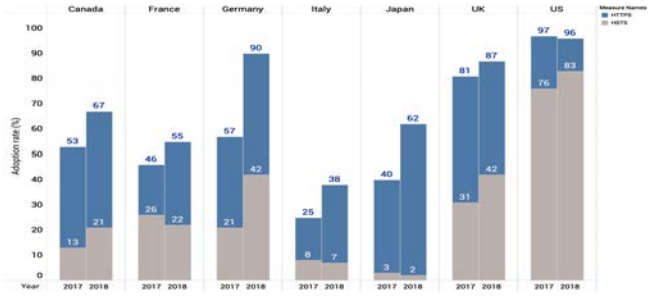

Figure 1: HTTPS and HSTS adoption rates of G7 top 100 government websites in 2017 and 2018

mixed with non-government sites (such as politicians' websites), we also searched for publicly-available datasets online. Another rationale to do so is to avoid the risk of using single evidence to generate our result [48]. We thus found official lists of government websites for the US, the UK, Canada, and Japan, but not the rest of G7. The list and final dataset we collect are available and can be accessed at the Open Science Framework project page [2].

2.1.2 Website Scanning. For each of the G7's government domains, we formed the request URL by adding four common prefixes: `http://`, `http://www`, `https://`, and `https://www`. Measurements were performed in September 2017 and August 2018. We further examined the resilience to the 11 TLS attacks (Table 1) if the domain supports HTTPS (i.e., at least one of the four requests gets redirected to an HTTPS page). Websites with certificate errors are not classified as HTTPS-supporting.

2.2 Findings

HTTPS adoption rate. Figure 1 shows the HTTPS and HSTS adoption rates of G7 government domains in 2017 and 2018. The colored bars stand for the HTTPS adoption rates, where the gray shade within each bar represents its HSTS adoption rates. The countries from the highest to the lowest HTTPS adoption rate in 2017 are as follows: the US (97%), the UK (81%), Germany (57%), Canada (53%), France (46%), Japan (40%) and Italy (25%). Both the US and UK remain equivalently high in 2018, while Germany increases from 53% to 90% within a year. The other countries show an average increase of 14.5% from 2017 to 2018, conforming to the global trend of HTTPS adoption.

HSTS adoption. HTTP Strict Transport Security (HSTS) [4] is a web security policy mechanism that allows a server to declare that it accepts only HTTPS (not HTTP) connections from browsers. HSTS is designed to prevent a man-in-the-middle (MitM) attack, which downgrades HTTPS to plain HTTP, or a *SSL stripping attack*. An HTTP request to an HSTS-enabled site will be automatically upgraded to HTTPS by supported browsers. As shown in Figure 1, the HSTS adoption rates of government websites in Japan (3%) and Italy (8%) are extremely low in 2017, and even decrease by 1% in 2018. France also has a 4% decrease in 2018. While HSTS adoption rates for the US, the UK, Germany and Canada have increased from 2017 to 2018, all except the US remain below 50%.

Resilience to critical TLS attacks. Among these G7 government websites supporting HTTPS, 91% (in 2017) and 77% (in 2018) are incorrectly configured and thus still vulnerable to attacks. Given the

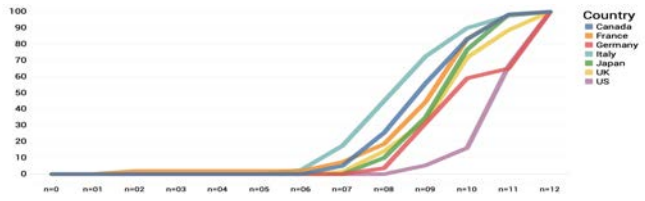

Figure 2: Resilience to 11 TLS attacks and SSL stripping in G7 in 2018

11 TLS attacks (Table 1) and the SSL stripping attack, we quantified a website's resilience level by the number of attacks against which the website can defend. Figure 2 shows the cumulative distribution of government websites resilience levels in each G7 country. More than 80% of US government websites can defend against at least 11 types of attacks. Germany makes significant progress in 2018: more than two-thirds of government websites can defend against more than 10 types, whereas it had 47% in 2017.

Autonomy implications. Increase in HTTPS and HSTS adoption rates on G7 government websites are promising, and as we discuss in §5.1, one catalyst to increase adoption rates is a government mandate. On the other hand, incorrect configurations may end up providing a false sense of security to users while leaving the door open for attackers. Hence, cross-validating implementations and keeping them up to date are crucial for secure cyber autonomy.

3 DEPENDENCY ON CA

Because HTTPS relies on digital certificates for entity authentication, trust in HTTPS is bootstrapped from certificate authorities, which issue certificates that bind a site's public key to the domain name after validating its identity. CAs are structured hierarchically for scalability: *intermediate* CAs can certify other CAs' identities, and users can determine which *root* CAs are trusted. Most users trust the root certificates in the default trust store distributed with the underlying operating systems (OS) or browsers.

Unfortunately, with hundreds of CAs eligible to issue certificates, rogue CAs can easily spoof certificates for phishing or HTTPS interception. In addition, issues in certificates and certificate chains undermine the trustworthiness of a website.

3.1 Methodology

Using the G7 governments' top 100 website lists as described in §2.1.1, we analyzed their certificates. For each website, we examined the *country* field of its root certificate to assess its dependency on foreign CAs , whether an Extended Validation (EV) certificate is used, and whether the certificate and its chain are valid.

We consider a certificate to be invalid if any of the following errors is detected: (1) a *name mismatch* error, which occurs when the hostname is inconsistent with the leaf certificate's common name; (2) an *untrusted root CA* error, which occurs when the root certificate's issuer is not in the trust store, potentially resulting in untrustworthy self-signed certificates or certificates signed by untrusted entities; (3) an *invalid time* error, which occurs when the current time is before or after the valid certificate lifetime; or (4) a *certificate issuer error*, which occurs when a leaf certificate's issuer is inconsistent with its parent's subject field.

3.2 Findings

Government root CAs. We analyzed the root certificates included in the trust stores of the major browsers and OS. 168, 359, and 149 trusted root certificates are pre-installed in the latest trust store of Apple macOS 10.13 (High Sierra) [9], Microsoft Windows [20], and Mozilla [21], respectively. Microsoft Windows's trust store contains 53 government root certificates[4] from 26 countries, including France, Japan, and the US. The Mozilla's trust store contains eight government root certificates from Hong Kong, the Netherlands, Spain, Taiwan, and Turkey. Apple macOS's trust store contains only two government root certificates, from Taiwan and Finland. As some government root certificates are not included in all trust stores, using these certificates will trigger warnings on some browsers. In the 2017 dataset, 11 Japanese government websites relied on ApplicationCA2 Root, a Japanese government root CA that is untrusted by Mozilla and Apple macOS.

Certificate type. Table 2 summarizes the number of websites with valid certificates, domestic root CAs, and EV certificates in 2018. The percentages in the last two columns are computed over websites with valid certificates. Among G7 government websites with valid certificates, about 10% are using Extended Validation (EV) certificates, which are designed to mitigate phishing. Interestingly, despite its great share of the CA market, Let's Encrypt (LE)[5] certificates are rarely used by government websites. As of November 2018, LE issues more than 60% of certificates on the Internet [10]. In our 2018 dataset, there are 8 from Germany and 2 from Italy, and each of the remaining G7 countries has only one government website using LE certificates.

Root CA dependency. Governments can reduce the root of trust and increase legal accountability by restricting CAs to those registered in the same country (e.g., via DNS-based Authentication of Named Entities). Hence, we examined the reliance of the government websites on domestic CAs. A root certificate's country is determined by the country field in its certificate information.

Figure 3 uses a circular layout for visualizing the relationship between the G7 countries' government websites and their root CAs' countries of origin as of August 2018. For instance, the clockwise curve from Country A to Country B represents higher dependency of A's government websites on B's root CAs. A larger circle area of a country indicates that more websites rely on the CAs in the country. Among all G7 government sites we analyzed, the most popular root CAs and their registered countries are GlobalSign Root CA in Belgium (accounting for 16% of 496 G7 sites with valid certificates), AddTrust External CA Root in Sweden (6%), DigiCert

[4]We consider that a certificate is issued by a government if it contains "government", "gov", or "federal" in the description.
[5]Let's Encrypt is a non-profit certificate authority that issues free certificates.

Table 2: Certificate analysis and Domestic CA of top 100 government sites in G7, 2018

Country	w/ HTTPS protocol	Valid Cert	Domestic CA	EV Cert
Canada	70	67	0 (0%)	7 (10.4%)
France	65	55	21 (38.1%)	6 (10.9%)
Germany	92	90	44 (48.8%)	6 (6.6%)
Italy	44	38	9 (23.7%)	4 (10.5%)
Japan	65	62	27 (43.5%)	7 (11.3%)
UK	91	87	9 (10.3%)	10 (11.5%)
US	96	96	89 (92.7%)	10 (10.4%)
Total/Average	523/74.7	495/70.7	200/28.6	51/7.3

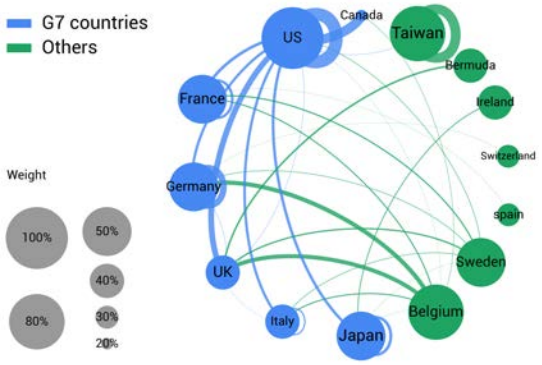

Figure 3: Dependency on root CAs by countries.

Global Root CA in the US (34%), and Entrust Root Certification Authority in the US (11%). Among G7, all but the US have more than 50% of government websites using root CAs registered in foreign countries in 2018. Ninety out of 96 US government sites adopt US-based root CAs, including one using Let's Encrypt and three using Entrust.net CA, the third most popular CA in G7.

The validity of certificates and certificate chains. Table 3 summarizes common misconfigurations. In 2017, 45% of France's Top 100 government sites suffered from name mismatch errors. Several certificates used `www.snakeoil.dom` or `ssl3.ovh.net` as their common name, which are used as examples in online tutorials. Japan has the highest percentage of untrusted root certificates: 11 (out of 12) use the same root certificate, ApplicationCA2 Root, a Japanese government root CA not trusted by all major browsers.

Autonomy implications. While governments are moving towards CA autonomy by restricting the usage of external CAs and promoting government root CAs, we observed inconsistencies across the trust stores of the browsers and OS. Although different browser and OS vendors have different policies, such inconsistencies imply some concerns about including the government root CAs to the trust store. Hence, further analysis must be conducted to resolve the conflicts, which may require cooperation among the browser and OS vendors. As we discuss in §5.3, skepticism about government surveillance activities on its citizens can be addressed by restricting the government root CAs' usage to government websites only, or by delegating the management of government root CAs to non-profit organizations within the same jurisdiction.

4 DEPENDENCY ON CP

Content Providers (CP) provide web resources (e.g., images and JavaScript) that can be included on websites. However, when a site loads resources from untrusted servers, it may include malicious content or even execute malicious scripts [44, 47].

Table 3: G7 certificate scanning result for the indicated issues. A lower percentage is better in terms of security.

Country	Domains w/ cert.		Name mismatch		Issuer error		Untrusted root		Invalid time	
	2017	2018	2017	2018	2017	2018	2017	2018	2017	2018
Canada	53	70	2%	4%	0%	0%	4%	0%	0%	0%
France	46	65	45%	15%	9%	0%	13%	6%	6%	3%
Germany	57	92	10%	2%	0%	0%	0%	0%	0%	0%
Italy	25	44	25%	13%	0%	0%	15%	0%	12%	4%
Japan	40	65	0%	4%	0%	0%	28%	28%	1%	1%
UK	81	91	2%	3%	0%	0%	1%	0%	0%	0%
US	97	96	0%	0%	0%	0%	0%	0%	0%	0%

Table 4: # websites loading resources from oversea servers.

country	ca	fr	de	it	jp	UK	US	total/Average
CP_ASIA	48	51	26	46	30	55	31	287/41
CP_NA	52	49	28	55	29	61	12	287/40.9

4.1 Methodology

We loaded each website from the top 100 government website dataset for each country using Google Chromium Version 68.0.3440.106 for 20 seconds, and extracted the request URLs logged by the browser's network panel. As some content may be served by nearby servers, we loaded these websites from servers located in Asia and North America in October 2018 to capture such location-dependent behaviors. We fetched the IP from the remote address field in each request header, and used pygeoip GeoIP API along with the Maxmind geolocation database[6] to identify its country of residence.

Since we are interested in external CPs that may provide untrusted resources, we removed URLs with the same domain name (and thus are considered local), and focused on URLs that retrieve the most common external resources such as image, JavaScript, and JSON files [43] from foreign servers, as these resources can be used to exploit the website [44, 47]. Our CP_ASIA and CP_NA datasets contain 2,160 and 2,185 URLs for crawling from Asia and North America, respectively. Among these total 4,345 URLs, 1,960 (45.2%), 2,151 (49.5%), and 231 (5.3%) are for JavaScript, image, and JSON files, respectively.

We say that a request URL is *location-aware* if it is routed to different destination servers when it is loaded from different source locations. A location-aware URL could have a negative impact on cyber autonomy because the user cannot be assured that the resource is always loaded from domestic servers. We identified 126 location-aware URLs that appear in both the CP_ASIA and CP_NA datasets, and in total 912 (of out 2,160; 42%) external resources were loaded from these location-aware URLs. Excluding the location-aware ones, the number of external JavaScript, image, and JSON files are 1,292 (51%), 1182 (46%), and 74 (3%), respectively.

4.2 Findings

Websites loading resources from foreign servers. Among the 660 websites that were successfully crawled, each website made an average of 1.89 requests to load resources hosted on foreign servers, with a median of 1. Table 4 summarizes the percentage of websites, among the top 100 government websites in each G7 country, that load resources from foreign servers. All G7 countries have a non-negligible degree of dependency, from 8% (US) to 23% (Japan, Germany) and more than 40% (the rest of G7), when users access government websites from Asia. The percentage reduces drastically for US government websites when accessed from North America. However, most G7 countries tend to have a high degree of dependency regardless of access location.

We found several government websites hosted in foreign countries. For example, the National Film Board of Canada (www.nfb.ca) is hosted in the US and loads resources from US-based servers.

CP dependency by country. The three most common destinations of external resources are the US (1,173), the Philippines (269), and Taiwan (225) in the CP_ASIA dataset, with a total of 2,160 external resources, and the US (1,915), Ireland (120), and the Netherlands (72) in the CP_NA dataset. These results align with common beliefs that the US hosts a large portion of web resources and that Content Distribution Network (CDN) servers are prevalent. Figure 4 shows the CP dependency by country, utilizing the similar circular layout as Figure 3. The orange lines represent the location-aware resources, whose IP addresses were different in the two datasets collected from different locations. Of the 1,248 location-independent resources, 1,063 (85%) of them originate from the United States.

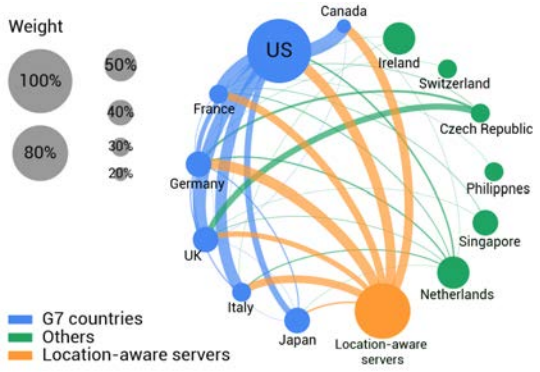

Figure 4: Dependency on external resources by countries.

Autonomy implications. In general, we observed greater reliance on US content providers for all G7 governments. Regarding location-aware URLs, a majority of the government websites may be loading content from foreign CPs, possibly to tolerate the latency. However, proving better usability with short delays have negative effects towards having cyber autonomy. Further investigation on the trade-offs between latency and autonomy may be needed to analyze the benefits of risking security for enhanced time delays.

5 DISCUSSION

5.1 Government Policies

Government policies play an important role in cyber autonomy. We found that at least four of the G7 countries have mandates that promote HTTPS adoption on government websites, and some have policies limiting the use of weak cryptographic algorithms and parameters for HTTPS and certificates. However, we did not find policies that restrict access to external resources. Considering the issuance or enforcement date of their security policies, we found that countries with established HTTPS adoption policies indeed exhibit a significantly higher level of security than others in terms of HTTPS deployment. The adoption rates of the US and UK were the highest in 2017, and Germany has improved in 2018. We briefly describe the findings on G7's HTTPS policies below.

The US. On June 8, 2015, the White House Office of Management and Budget memorandum M-15-13 was released to "Require Secure Connections across Federal Websites and Web Services" [5]. The memorandum provides a timeframe for compliance, requesting that all federal websites and services upgrade to HTTPS-only (with HSTS) by the end of 2016. Note that this memorandum applies to federal sites only, not to the state or local sites. On October 16, 2017, the Department of Homeland Security issued Binding Operational Directive 18-01, requiring federal agencies to remove

[6]The Maxmind database has 96-98% accuracy in the country level [49] and has been used to validate the IP geolocation information released by Regional Internet Registries(RIR) [57].

support for outdated cryptographic algorithms and protocols. There is no restriction on acceptable CAs for federal domains.

The UK. The Digital Service Standard and Service Manual in the UK requires all Government Digital Service (GDS) websites to be accessible only through HTTPS starting October 1, 2016 and provides guidelines to configure HTTPS and HSTS [18].

Germany. In January 2018, the Federal Office for Information Security (BSI) issued BSI-TR-02102-2 (TLS), a technical guideline providing recommendations for TLS usage, and stating that the "Federal Administration is obliged to encrypt all data traffic over unprotected networks using SSL/TLS" [27].

Japan. The Japanese government announced a standard security guideline [15] in July 2018, which explicitly states that servers should install legitimate certificates for supporting TLS protocol.

EU. Enforced on May 25 2018, the General Data Protection Regulation (GDPR) is a new regulation that aims to enhance personal privacy on the Internet. Adopting HTTPS is considered a baseline security measure for protecting the PII during transmission.

5.2 Outsourcing

To understand the factors that influence the dependency level of government websites, we conducted two online surveys aimed at web technicians who maintain government websites in Taiwan[7] in September 2017 and September 2018. To recruit more survey participants, we contacted 161 government agencies (not limited to the top 100). Among 73 websites with valid responses, only three (4%) are self-developed by the institutions themselves; the rest have been outsourced to third-party companies. Outsourcing the website to third-party contractors is reasonable for small government agencies, which often lack sufficient resources and budgets to hire dedicated staff specialized in network security and web development. Unfortunately, outsourcing development to third-party contractors may introduce an additional barrier in communicating required security features, thereby further complicating the security configuration and maintenance of government websites. When the majority of the websites are developed by third-party contractors, technical specification plays an important role in defining the requirements in website development. However, 8 of the 70 websites did not put HTTPS in their specification.

Our survey results also indicate that government website administrators consciously consider whether a relevant mandate exists when prioritizing their tasks. Six out of 23 participants (26%) reported that the main reason for not fully upgrading to HTTPS is beause there is "no mandate from the supervising agencies", possibly reducing the priority of HTTPS adoption given other tasks. This echoes our observation that government policies can expedite the deployment of security measures.

5.3 Fear of large-scale Surveillance

Although pinning government websites to government root CAs could eliminate reliance on hundreds of CAs in the browser's default trust store, governments root CAs may be abused for large-scale surveillance [12, 14, 28]. Due to this privacy concern, several government root certificates are excluded from trust stores. For example, the government root certificates of France, Japan, and the US are included in Microsoft Windows' trust store, but not in Apple macOS or Mozilla. However, such partial inclusion may confuse users who see inconsistent certificate warnings. Another complication is that certificate pinning mechanisms are not widely supported on the web. HTTP Public Key Pinning (HPKP) is rarely used by websites and has been deprecated by the latest version of Chrome. DNS-based Authentication of Named Entities (DANE) has not been fully supported by major browsers either.

[7]The HTTPS adoption rate among the top 100 gov websites in Taiwan is 87% in 2018, and among the 68 websites with valid certificates, 63 (92.6%) are using the domestic CAs, and 60 (88%) using the government root CAs. As for foreign resources, there were only one URL to Germany and four to US loaded by the top 100 government websites.

5.4 Usability Issues

For cyber autonomy, it is crucial that the citizens can distinguish government websites from potentially spoofed websites. Some countries use government-specific (top level) domains, such as .gov for the US and UK, and .go.jp for Japan; hence, users can easily recognize if the website in question belongs to the government of the representing country. Unfortunately, without such a domain requirement, users may fall for attacks that might have been easily identifiable with government-specific domain policies.

Another usability issue arises when governments support their own root CAs for cyber autonomy, but the CAs are not recognized as trustworthy by the browsers or OS. As reported in §3.2, Japan operates its government root CAs, GPKI ApplicationCA2 Root and Japanese Government ApplicationCA, but they are only included in Microsoft Windows' trust store, not Apple macOS or Mozilla. Consequently, users experience frequent certificate errors when they use Safari or Mozilla to access a Japanese government website whose certificate is endorsed by either of these two CAs. Such frequent errors may result in a user (1) ignoring certificate warnings [54], or (2) losing trust in the government websites.

6 RELATED WORK

To the best of our knowledge, this is the first study examining the external dependency of public-facing government websites; prior work focuses on one aspect of dependency of popular websites.

A large body of research investigates the current practices of HTTPS. These studies usually scan the IPv4 address space or popular domains, or analyze collected datasets to uncover statistical facts and correlations [36, 50]. Felt et al. [50] observed an increase of HTTPS support from 2016 to 2017. In addition to HTTPS adoption rates, we also investigated websites vulnerable to known TLS attacks and discuss the effectiveness of government policies on prompting HTTPS adoption. To identify HTTPS deployment challenges encountered by security experts, Krombholz et al. [42] performed a lab experiment with 28 technically-competent students and interviewed seven security auditors. Our survey targeted government website operators instead of developers, and the results suggest infrastructural and administrative challenges that government websites may encounter when using HTTPS.

Fadai et al. [41] analyzed the trust stores of multiple browsers and operating systems and identified CAs owned by companies and governmental institutions that might not be trustworthy. Vallina-Rodriguez et al. [55] compared the trust stores on Android devices

with different OS versions and manufacturers. We focused on analyzing government root certificates and the certificates used by government websites.

Simeonovski et al. [52] proposed to model web dependencies using a property graph, and applied the model to analyze Alexa's Top 100k domains. Kumar et al. [43] also investigated the dependencies on external services of Alexa's Top Million domains. They found that the median of external resources loaded by websites is 23, which is much higher than for government websites. Such differences suggest the importance of performing in-depth studies based on website types, because each type of website may have unique challenges and incentives for security deployment.

7 CONCLUSIONS AND FUTURE WORK

This paper attempts to measure the current practice of building cyber autonomy on government websites. Our findings indicate the importance of having government mandates, as well as synchronizing autonomy-oriented government policies with corresponding entities. An interesting future direction is to investigate dependency on software (e.g., web frameworks and libraries), hardware (e.g., servers and routers), and network (e.g., routing paths), as well as to assess a government's cyber autonomy from other complementary perspectives. We hope that our findings serve as a stepping stone towards building cyber autonomy.

ABSTRACT

Collaborative Filtering (CF) is the key technique for recommender systems. CF exploits user-item behavior interactions (e.g., clicks) only and hence suffers from the data sparsity issue. One research thread is to integrate auxiliary information such as product reviews and news titles, leading to hybrid filtering methods. Another thread is to transfer knowledge from source domains such as improving the movie recommendation with the knowledge from the book domain, leading to transfer learning methods. In real-world applications, a user registers for multiple services across websites. Thus it motivates us to exploit both auxiliary and source information for recommendation in this paper. To achieve this, we propose a Transfer Meeting Hybrid (TMH) model for cross-domain recommendation with unstructured text. The proposed TMH model attentively extracts useful content from unstructured text via a memory network and selectively transfers knowledge from a source domain via a transfer network. On two real-world datasets, TMH shows better performance in terms of three ranking metrics by comparing with various baselines. We conduct thorough analyses to understand how the text content and transferred knowledge help the proposed model.

1 INTRODUCTION

Recommender systems are widely used in various domains and e-commerce platforms, such as recommending products to buy at Amazon and videos to watch on Youtube. Collaborative Filtering (CF) is an effective approach based on an intuition that if users rated items similarly in the past then they are likely to rate items similarly in the future. Matrix Factorization (MF) techniques are its main cornerstone [26, 35] since they can learn latent factors for users and items. Recently, neural networks like multilayer perceptrons (MLP) are used to learn non-linear interaction functions from data [10, 17]. Both MF and neural CF suffer from the data sparsity and cold-start issues.

One solution is to integrate CF with the content information, leading to hybrid methods. Items are usually associated with unstructured text like the news articles and product reviews. Additional information alleviates the data sparsity issue and is essential for recommendation beyond user-item interactions. For application domains like recommending research papers and news articles, the unstructured text associated with an item is its text content [1, 47]. Other domains like recommending products, the unstructured text associated with the item is its user reviews which justify the rating behavior of consumers [21, 33, 56]. Recently, neural networks have been proposed to exploit the item content. For example, memory networks [43] are used to model item reviews [19], or to model a user's neighbors who rated the same items with this user [11].

Another solution is to transfer the knowledge from relevant domains and the cross-domain recommendation techniques address such problems [3, 27, 37]. In real-world applications, a user typically registers multiple service systems to acquire different information need. For example, a user installs applications in an app store and reads news from another website. It brings us an opportunity to improve the recommendation performance in the target service (or all services) by learning from across domains. In the above example, we can represent the app installation feedback using a binary matrix whose entries indicate whether a user has installed an app. Similarly, we use another binary matrix to indicate whether a user has read a news article. Typically these two matrices are highly sparse, and it is beneficial to learn them simultaneously. This idea is sharpened into the Collective Matrix Factorization (CMF) approach [42] which jointly factorizes these two matrices by sharing the user latent factors. It combines CF on a target domain and another CF on an auxiliary domain, enabling knowledge transfer [36, 54]. In terms of neural networks, given two activation maps from two tasks, cross-stitch network [34] and its sparse variant [22] learn linear combinations of both the input activations and feed these combinations as input to the successive layers, and hence enabling the knowledge transfer between two domains.

These two threads motivate us to exploit information from both the content and cross-domain information for recommendation in this paper. To capture text content and to transfer cross-domain

knowledge, we propose a novel neural model, TMH, for cross-domain recommendation with unstructured text. TMH can not only attentively extract useful content via a memory network but also selectively transfer knowledge across domains by a novel transfer network. A shared layer of feature interactions is stacked on the top to couple high-level representations learned from both networks. On real-world datasets, TMH shows the better performance in various settings. We conduct thorough analyses to understand how the content and transferred knowledge help the proposed model.

Our contributions are summarized as follows:

- The proposed model is a novel deep model that transfers cross-domain knowledge for recommendation with unstructured text by using an attention based neural network. (Sec. 4)
- We interpret the memory networks to attentively exploit the text content to match word semantics with user preferences.
- The transfer network can selectively transfer source items with the guidance of target user-item interactions by the attentive weights.
- Our model alleviates cold-user and cold-item start issues, and outperforms various baselines on real-world datasets. (Sec. 5)

2 RELATED WORKS

We review related works on three topics: collaborative filtering, hybrid methods, and cross-domain recommendation.

Collaborative Filtering Recommender systems aim at learning user preferences on unknown items from their past history. Content-based recommendations are based on the matching between user profiles and item descriptions. It is difficult to build the profile for each user when there is no/few content. CF alleviates this issue by predicting user preferences based on the user-item interaction behavior, agnostic to the content [9]. Latent factor models learn feature vectors for users and items mainly based on MF [26] which has probabilistic interpretations [35]. Factorization machines (FM) can mimic MF [40]. To address the data sparsity, an item-item matrix called Shifted Positive Pointiest Mutual Information (SPPMI) is constructed from the user-item interaction matrix in the CoFactor model [28]. It then simultaneously factorizes the interaction matrix and the SPPMI matrix in a shared item latent space, enabling the usage of co-click information to regularize the learning of the user-item matrix. In contrast, we use independent unstructured text and source domain information to alleviate the data sparsity issue in the user-item matrix. Neural networks are proposed to push the learning of feature vectors towards non-linear representations, including the Neural Network Matrix Factorization (NNMF) and MultiLayer Perceptron (MLP) [10, 17]. The basic MLP architecture is extended to regularize the factors of users and items via social and geographical information [51]. Other neural approaches learn from the explicit feedback for the rating prediction task [5, 56]. We focus on learning from the implicit feedback for top-N recommendation [50].

Hybrid Filtering Items are usually associated with the content information such as unstructured text (e.g., abstracts of articles and reviews of products). CF approaches can be extended to exploit the content information [1, 47, 48] and user reviews [16, 20, 33]. Combining matrix factorization and topic modelling technique (e.g., Topic MF) is an effective way to integrate ratings with item contents [2, 29, 33]. Item reviews justify the rating behavior of a user, and item ratings are associated with their attributes hidden in reviews [14]. Topic MF methods combine latent item factors in ratings with latent topics in reviews [2, 33]. The behavior factors and topic factors are aligned with a link function such as softmax transformation in the Hidden Factors and hidden Topics (HFT) model [33] or an offset deviation in the Collaborative Topic Regression (CTR) model [47]. The CTR model assumes the latent item vector learnt from the interaction data is close to the corresponding topic proportions learnt from the text content, but allows them to be divergent from each other if necessary. Additional sources of information are integrated into CF to alleviate the data sparsity issues including knowledge graph [49, 55]. Convolutional Networks (CNNs) have been used to extract features from audio signals for music recommendation [45] and from image for product and multimedia recommendation [6, 16]. Autoencoders are used to learn an intermediate representations from text [48, 53]. Recurrent networks [1] and convolutional networks [5, 24, 56] can exploit the word order when learning the text representations. Memory networks can reason with an external memory [43]. Due to the capability of neurally learnt word embeddings to address the problems of word sparseness and semantic gap, a memory module can be used to model item content [19] or the neighborhood of users [11]. Memory networks can learn to match word semantics with the specific user. We follow this thread by using neural networks to attentively extract important information from text content.

Cross-domain Recommendation Cross-domain recommendation [3] is an effective technique to alleviate the data sparsity issue. A class of MF-based methods has been applied to cross-domain recommendation. Typical methods include the CMF approach which jointly factorizes two rating matrices by sharing the latent user factors and hence it enables knowledge transfer. CMF has its heterogeneous variants [37], and codebook transfer [27]. The coordinate system transfer can exploit heterogeneous feedbacks [38, 52]. Multiple source domains [32] and multi-view learning [13] are also proposed for integrating information from several domains. Transfer Learning (TL) aims at improving the performance of the target domain by exploiting knowledge from source domains [36]. Similar to TL, Multitask Learning (MTL) is to leverage useful knowledge in multiple related tasks to help each other [4, 54]. The cross-stitch network [34] and its sparse variant [22] enable information sharing between two base networks for each domain in a deep way. Robust learning is also considered during knowledge transfer [15]. These methods treat knowledge transfer as a global process with shared global parameters and do not match source items with the specific target item given a user. We follow this research thread by using neural networks to selectively transfer knowledge from the source items. We introduce a transfer network to exploit the source domain knowledge.

3 A BASIC NEURAL CF NETWORK

We adopt a Feedforward Neural Network (FFNN) as the base neural CF model to parameterize the interaction function [7, 8, 17]:

$$f(\boldsymbol{x}_{ui}|\boldsymbol{P}, \boldsymbol{Q}, \theta_f) = \phi_o(...(\phi_1(\boldsymbol{x}_{ui}))...), \tag{1}$$

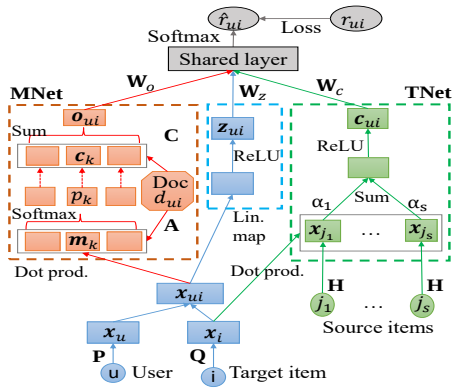

Figure 1: The architecture of TMH.

where input $\boldsymbol{x}_{ui} = [\boldsymbol{P}^T\boldsymbol{x}_u, \boldsymbol{Q}^T\boldsymbol{x}_i] \in \mathbb{R}^{2d}$ is concatenated from embeddings of user u and item i and is a projection of their one-hot encodings $\boldsymbol{x}_u \in \{0,1\}^m$ and $\boldsymbol{x}_i \in \{0,1\}^n$ via embedding matrices $\boldsymbol{P} \in \mathbb{R}^{m\times d}$ and $\boldsymbol{Q} \in \mathbb{R}^{n\times d}$, respectively. The output and hidden layers are computed by ϕ_o and $\{\phi_l\}$ in FFNN. The sizes of users and items are m and n, respectively. The rating r_{ui} is 1 if user u has an interaction with item i and 0 otherwise.

The base network consists of four modules with the information flow from the input (u, i) to the output $\hat{r}_{ui}$ as follows.

Input: $(u, i) \rightarrow \mathbb{1}_u, \mathbb{1}_i$ This module encodes user-item interaction indices. We adopt the one-hot encoding. It takes user u and item i, and maps them into one-hot encodings $\mathbb{1}_u \in \{0,1\}^m$ and $\mathbb{1}_i \in \{0,1\}^n$ where only the element corresponding to that index is 1 and all others are 0.

Embedding: $\mathbb{1}_u, \mathbb{1}_i \rightarrow \boldsymbol{x}_{ui}$ This module firstly embeds one-hot encodings into continuous representations $\boldsymbol{x}_u = \boldsymbol{P}^T\mathbb{1}_u$ and $\boldsymbol{x}_i = \boldsymbol{Q}^T\mathbb{1}_i$ by embedding matrices $\boldsymbol{P}$ and $\boldsymbol{Q}$ respectively, and then concatenates them as $\boldsymbol{x}_{ui} = [\boldsymbol{x}_u, \boldsymbol{x}_i]$, to be the input of following building blocks.

Hidden layers: $\boldsymbol{x}_{ui} \rightsquigarrow \boldsymbol{z}_{ui}$. This module takes the continuous representations from the embedding module and then transforms through several layers to a final latent representation $\boldsymbol{z}_{ui} = (\ldots(\phi_1(\boldsymbol{x}_{ui})\ldots)$. This module consists of hidden layers to learn nonlinear interaction between users and items.

Output : $\boldsymbol{z}_{ui} \rightarrow \hat{r}_{ui}$. This module predicts the score $\hat{r}_{ui}$ for the given user-item pair based on the representation $\boldsymbol{z}_{ui}$ from the last layer of multi-hop module. Since we focus on one-class collaborative filtering, the output is the probability that the input pair is a positive interaction. This can be achieved by a softmax layer: $\hat{r}_{ui} = \phi_o(z_{ui}) = \frac{1}{1+\exp(-\boldsymbol{h}^T\boldsymbol{z}_{ui})}$, where $\boldsymbol{h}$ is the parameter.

4 THE PROPOSED TMH MODEL

The architecture of the TMH model is illustrated in Fig. 1.

Matching Word Semantics with User Preferences We adapt a memory network (MNet) to integrate unstructured text since it can learn to match word semantics with user preferences [12, 19, 23, 44]. The MNet consists of one internal memory matrix $\mathbf{A} \in \mathbb{R}^{L\times 2d}$, where L is the vocabulary size (typically $L = 8,000$ after processing [47]) and $2d$ is the dimension of each memory slot, and one external memory matrix $\mathbf{C}$ with the same dimensions as $\mathbf{A}$. The function of the two memory matrices works as follows.

Given a document $d_{ui} = (w_1, w_2, \ldots, w_l)$ corresponding to the (u, i) interaction, we form the memory slots $\boldsymbol{m}_k \in \mathbb{R}^{2d}$ by mapping each word w_k into an embedding vector with matrix $\mathbf{A}$, where $k = 1, \ldots, l$ and the length of the longest document is equal to the memory size. We form a preference vector $\boldsymbol{q}^{(ui)}$ corresponding to the given document d_{ui} and the user-item interaction (u, i) where each element encodes the relevance of user u to these words given item i as: $q_k^{(ui)} = \boldsymbol{x}_u^T\boldsymbol{m}_k^{(u)} + \boldsymbol{x}_i^T\boldsymbol{m}_k^{(i)},\ k = 1, \ldots, l$, where we split the $\boldsymbol{m}_k = [\boldsymbol{m}_k^{(u)}, \boldsymbol{m}_k^{(i)}]$ into the user part $\boldsymbol{m}_k^{(u)}$ and the item part $\boldsymbol{m}_k^{(i)}$.

Then, we compute the attentive weights over words for a given user-item interaction to infer the importance of each word's unique contribution: $p_k^{(ui)} = \text{Softmax}(q_k^{(ui)}) = \frac{\exp(\beta q_k^{(ui)})}{\sum_{k'}\exp(\beta q_{k'}^{(ui)})}$, where parameter β is introduced to stabilize the numerical computation and can amplify or attenuate the precision of the attention like a temperature [18]. We set $\beta = d^{-\frac{1}{2}}$ by scaling along with the dimensionality [46].

We construct the high-level representations by interpolating the external memories with the attentive weights as the output:

$$\boldsymbol{o}_{ui} = \sum\nolimits_k p_k^{(ui)}\boldsymbol{c}_k, \tag{2}$$

where the external memory slot $\boldsymbol{c}_k \in \mathbb{R}^d$ is another embedding vector for word w_k by mapping it with matrix $\mathbf{C}$.

Selecting Source Items to Transfer We propose a novel transfer network (TNet) which can selectively transfer source knowledge for specific target item in a coarse-to-fine way. Given the source items $[j]^u = (j_1, j_2, \ldots, j_s)$ with which the user u has interacted in the source domain, TNet learns a transfer vector $\boldsymbol{c}_{ui} \in \mathbb{R}^d$ to capture the relations between the target item i and source items given the user u. The similarities between target item i and source items can be computed by their dot products: $a_j^{(i)} = \boldsymbol{x}_i^T\boldsymbol{x}_j,\ j = 1, \ldots, s$, where $\boldsymbol{x}_j \in \mathbb{R}^d$ is the embedding for the source item j by an embedding matrix $\boldsymbol{H} \in \mathbb{R}^{n_S\times d}$. This score computes the compatibility between the target item and the source items consumed by the user.

Then, we normalize similarity scores to be a probability distribution over source items: $\alpha_j^{(i)} = \text{Softmax}(a_j^{(i)})$. Finally the transfer vector is a weighted sum of the corresponding source item embeddings:

$$\boldsymbol{c}_{ui} = \text{ReLU}(\sum\nolimits_j \alpha_j^{(i)}\boldsymbol{x}_j), \tag{3}$$

where we introduce non-linearity on the transfer vector by the rectified linear unit $\text{ReLU}(x) = max(0, x)$.

Putting It All Together We firstly use a simple neural CF model (CFNet) which has one hidden layer to learn a nonlinear representation for the user-item interaction:

$$\boldsymbol{z}_{ui} = \text{ReLU}(\boldsymbol{W}\boldsymbol{x}_{ui} + \boldsymbol{b}), \tag{4}$$

where $\boldsymbol{W}$ and $\boldsymbol{b}$ are the weight and bias parameters in the hidden layer. Usually the dimension of $\boldsymbol{z}_{ui}$ is half of that $\boldsymbol{x}_{ui}$ in a typical tower-pattern architecture.

The outputs from the three individual networks can be viewed high-level features of the content text, source domain knowledge, and the user-item interaction. They come from different feature space learned by different networks. Thus, we use a shared layer on

the top of the all features: $\hat{r}_{ui} = \frac{1}{1+\exp(-\boldsymbol{h}^T \boldsymbol{y}_{ui})}$, where $\boldsymbol{h}$ is the parameter. The joint representation, $\boldsymbol{y}_{ui} = [\boldsymbol{W}_o \boldsymbol{o}_{ui}, \boldsymbol{W}_z \boldsymbol{z}_{ui}, \boldsymbol{W}_c \boldsymbol{c}_{ui}]$, is concatenated from the linear mapped outputs of individual networks where matrices $\boldsymbol{W}_o, \boldsymbol{W}_z, \boldsymbol{W}_c$ are the corresponding linear mapping transformations.

Learning Due to the nature of the implicit feedback and the task of item recommendation, the squared loss $(\hat{r}_{ui} - r_{ui})^2$ may be not suitable since it is usually for rating prediction. Instead, we adopt the binary cross-entropy loss: $\mathcal{L} = -\sum_{(u,i)\in\mathcal{S}} r_{ui} \log \hat{r}_{ui} + (1 - r_{ui}) \log(1 - \hat{r}_{ui})$, where the training samples $\mathcal{S} = \boldsymbol{R}_T^+ \cup \boldsymbol{R}_T^-$ are the union of observed target interaction matrix and randomly sampled negative pairs. Usually, $|\boldsymbol{R}_T^+| = |\boldsymbol{R}_T^-|$ and we do not perform a predefined negative sampling in advance since this can only generate a fixed training set of negative samples. Instead, we generate negative samples during each epoch, enabling diverse and augmented training sets of negative examples to be used. The objective function can be optimized by stochastic gradient descent (SGD) and its variants like adaptive moment(Adam) method [25].

Complexity In the model parameters Θ, the embedding matrices $\boldsymbol{P}$, $\boldsymbol{Q}$ and $\boldsymbol{H}$ contain a large number of parameters since they depend on the input size of users and (target and source) items, and their scale is hundreds of thousands. Typically, the number of words, i.e., the vocabulary size is $L = 8,000$ [47]. The dimension of embeddings is typically $d = 100$. Since the architecture follows a tower pattern, the dimension of the outputs of the three individual networks is also limited within hundreds. In total, the size of model parameters is linear with the input size and is close to the size of typical latent factors models [42] and neural CF approaches [17] with a hidden layer. During training, we compute the outputs of the three individual networks in parallel using mini-batch stochastic optimization which can be trained efficiently by back-propagation. TMH is scalable to the number of the training data. It can easily update when new data examples come by just feeding them into the training mini-batch. Thus, TMH can handle the scalability and dynamics of items and users similar to an online fashion. In contrast, topic modeling techniques have difficulty in benefitting from these advantages to some extent.

5 EXPERIMENTS

In this section, we conduct empirical study to answer the following questions: 1) how the proposed TMH model performs compared with state-of-the-art recommender systems; and 2) how the text content and the source domain information contributes to the proposed framework. We firstly introduce the evaluation protocols and experimental settings, and then compare the performance of different recommender systems. We further analyze the TMH model to understand the impact of the memory and transfer components. We also investigate that the improved performance comes from the cold-users and cold-items to some extent.

5.1 Experimental Settings

Dataset We evaluate on two real-world cross-domain datasets. The first dataset, **Mobile**, is provided by a large internet company, i.e., Cheetah Mobile (http://www.cmcm.com/en-us/) [30]. The information contains logs of user reading news, the history of app installation, and some metadata such as news publisher and user gender collected in one month in the US. We removed users with fewer than 10 feedbacks. For each item, we use the news title as its text content. Following [47], we filter stop words and use tf-idf to choose the top 8,000 distinct words as the vocabulary. This yields a corpus of 612K words. The average number of words per news is less than 10. The dataset we used contains 477K user-news reading records and 817K user-app installations. There are 15.8K shared users which enable the knowledge transfer between the two domains. We aim to improve the news recommendation by transferring knowledge from app domain. The data sparsity is over 99.6%.

Table 1: Datasets and statistics.

Dataset	Domain	Statistics	Amount
Mobile News	Shared	#Users	15,890
	Target	#News	84,802
		#Reads	477,685
		Density	0.035%
		#Words	612,839
		Avg. Words Per News	7.2
	Source	#Apps	14,340
		#Installations	817,120
		Density	0.359%
Amazon Product	Shared	#Users	8,514
	Target	#Clothes (Men)	28,262
		#Ratings/#Reviews	56,050
		Density	0.023%
		#Words	1,845,387
		Avg. Words Per Review	32.9
	Source	#Products (Sports)	41,317
		#Ratings/#Reviews	81,924
		Density	0.023%

The second dataset is a public **Amazon** dataset (http://snap.stanford.edu/data/web-Amazon.html), which has been widely used to evaluate the performance of collaborative filtering approaches [16]. We use two categories including Amazon Men and Amazon Sports as two domains [16, 20]. The original ratings are from 1 to 5 where five stars indicate that a user shows a positive preference on the item while the one star is not. We convert the ratings of 4-5 as positive samples. The dataset we used contains 56K positive ratings on Amazon Men and 81K positive ratings on Amazon Sports. There are 8.5K shared users, 28K Men products, and 41K Sports goods. We aim to improve the recommendation on the Men domain by transferring knowledge from relevant Sports domain. The data sparsity is over 99.7%. We filter stop words and use tf-idf to choose the top 8,000 distinct words as the vocabulary [47]. The average number of words per review is 32.9.

The statistics of the two datasets are summarized in Table 1. As we can see, both datasets are very sparse and hence we hope to improve performance by transferring knowledge from the auxiliary domain and exploiting the text content as well. Note that Amazon dataset are long text of product reviews (the number of average words per item is 32), while Cheetah Mobile contains short text of news titles (the number of average words per item is 7).

Evaluation Protocol For item recommendation task, the Leave-One-Out (LOO) evaluation is widely used and we follow the protocol in [17]. That is, we reserve one interaction as the test item for each user. We determine hyper-parameters by randomly sampling another interaction per user as the validation/development set. We follow the common strategy which randomly samples 99 (negative) items that are not interacted by the user and then evaluate how well the recommender system can rank the test item against these negative ones. Since we aim at top-K item recommendation, the typical evaluation metrics are hit ratio (HR), Normalized Discounted Cumulative Gain (NDCG), and Mean Reciprocal Rank (MRR), where the ranked list is cut off at $topK = \{5, 10, 20\}$. HR intuitively measures whether the reserved test item is present on the top-K list and is defined as: $HR = \frac{1}{|\mathcal{U}|}\sum_{u\in\mathcal{U}}\delta(p_u \leq topK)$, where p_u is the hit position for the test item of user u, and $\delta(\cdot)$ is the indicator function. NDCG and MRR also account for the rank of the hit position, respectively, and they are defined as: $NDCG = \frac{1}{|\mathcal{U}|}\sum_{u\in\mathcal{U}}\frac{\log 2}{\log(p_u+1)}$, and $MRR = \frac{1}{|\mathcal{U}|}\sum_{u\in\mathcal{U}}\frac{1}{p_u}$. A higher value with lower cutoff indicates better performance.

Baselines We compare with various baselines, categorized as shallow/deep, single/cross-domain, and hybrid methods. MLP++: We combine two MLPs by sharing user embeddings. CDCF++: We extend CDCF by augmenting the feature vector with words.

Baselines	Shallow method	Deep method
Single-domain	BPRMF [41]	MLP [17]
Cross-domain	CDCF [31], CMF [42]	MLP++, CSN [34]
Hybrid	HFT [33], TextBPR [16, 20]	LCMR [19]
Cross + Hybrid	CDCF++	TMH (ours)

Implementation For BPRMF, we use LightFM's implementation which is a popular CF library. For CDCF and CDCF++, we adapt the official libFM implementation. For CMF, we use a Python version reference to the original Matlab code. For HFT and TextBPR, we use the code released by their authors. The word embeddings used in the TextBPR are pre-trained by GloVe [39]. For latent factor models, we vary the number of factors from 10 to 100 with step size 10. For MLP, we use the code released by its authors. The MLP++ and CSN are implemented based on MLP. The LCMR model is similar to our MNet model. Our methods are implemented using TensorFlow. Parameters are randomly initialized from Gaussian $\mathcal{N}(0, 0.01^2)$. The optimizer is Adam with initial learning rate 0.001. The size of mini batch is 128. The ratio of negative sampling is 1. The MLP and MLP++ follows a tower pattern, halving the layer size for each successive higher layer. Specifically, the configuration of hidden layers in the base MLP network is $[64 \rightarrow 32 \rightarrow 16 \rightarrow 8]$ as in the original paper [17]. For CSN, it requires that the number of neurons in each hidden layer is the same and the configuration is $[64]*4$ (i.e., $[64 \rightarrow 64 \rightarrow 64 \rightarrow 64]$). We study several typical configurations $\{16, 32, 64, 80\} * 4$. The embedding dimension is $d = 75$.

5.2 Comparison Results

In this section, we report the recommendation performance of different methods. The comparison results are shown in Table 3 and Table 2 respectively on the Mobile and Amazon datasets where the last row is the relative improvement of TMH vs the best baseline. We have the following observations. Firstly, we can see that the proposed TMH model performs better than all baselines on the two datasets at each setting, including the MLP network, shallow cross-domain models (CMF and CDCF), deep cross-domain models (MLP++ and CSN), and hybrid methods (HFT and TextBPR, LCMR). These results demonstrate the effectiveness of the proposed neural model.

On the Mobile dataset, the differences between TMH and other methods are more pronounced for small numbers of recommended items including top-5 or top-10 where we achieve average 2.25% relative improvements over the best baseline. This is a desirable feature since we often recommend only a small number of top ranked items to consumers to alleviate the information overload issue.

Note that the relative improvement of the proposed model vs. the best baseline is more significant on the Amazon dataset than on the Mobile dataset, obtaining average 9.56% relative improvements over the best CSN baseline, though the Amazon data is sparser than the Mobile data (see Table 1). We show the benefit of combining text content by comparing with CSN. One explanation is that the relatedness of the Men and Sports domains is larger than that

Table 3: Results on Mobile data.

between the news and app domains. This will benefit all cross-domain methods including CMF, CDCF, MLP++, and CSN, since they exploit information from both two domains. Another reason is that the text content contains richer information on the Amazon dataset. As it is shown in Table 1, the average number of words in the product reviews is more than that in the news titles. This will benefit all hybrid methods including HFT, TextBPR, and LCMR. We show the benefit of transferring source items by comparing with LCMR.

The hybrid TextBPR model composes a document representation by averaging the words's embeddings. This can not distinguish the important words to match user preferences. This may explain that it has some difficulty in improving the recommendation performance when integrating text content. For example, it cannot consistently outperform the pure CF method, MLP. The CSN model transfers every representations from the source network with the same coefficient. This may have a risk in transferring the noise and harm the performance, as pointed out in its sparse variant [22]. On the Amazon dataset, it is inferior to the TMH model by a large margin (though TMH leverages content information). In contrast, the memory and transfer components are both selective to extract useful information based on the attention mechanism. This may explain that our model is consistently the best at all settings.

There is a possibility that the noise from auxiliary domain and some irrelevance information contained in the unstructured text pose a challenge for exploiting them. This shows that the proposed model is more effective since it can select useful representations from the source network and attentively focus on important words to match preferences of users. In summary, the empirical comparison results demonstrate the superiority of the proposed TMH model to exploit the text content and source domain knowledge for recommendation.

5.3 Impact of Text and Source Domain

We have shown the effectiveness of the two memory and transfer components together in the proposed framework. We now investigate the contribution of each network to the TMH by eliminating the impact of text content and source domain from it in turn. 1) **TMH\M\T**: Eliminating the impact of both content and source information from TMH. This is a collaborative filtering recommender. Actually, it is equivalent to a single hidden layer MLP model. 2) **TMH\M**: Eliminating the impact of content information (MNet) from TMH. This is a novel cross-domain recommender which can adaptively select source items to transfer via the attentive weights. 3) **TMH\T**: Eliminating the impact of source information (TNet) from TMH. This is a novel hybrid filtering recommender which can attentively match word semantics with user preferences.

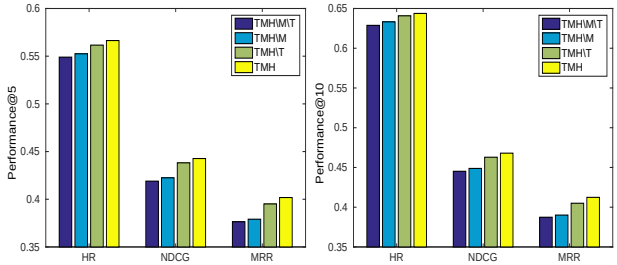

Figure 2: Contributions from unstructured text and cross-domain knowledge on Mobile Data.

The ablation analyses of TMH are shown in Figure 2 (Results on Amazon data are not shown due to space limit). The performance degrades when either memory or transfer modules is eliminated. This is understandable since we lose some information. In other words, the two components can extract useful knowledge to improve the recommendation performance. For example, TMH\T and TMH\M reduce 1.1% and 4.3% relative NDCG@10 performance, respectively, by comparing with TMH on the Mobile dataset (they are 8.5% and 16.1% on Amazon), suggesting that both memory and transfer networks learn essential knowledge for recommendation. On the two datasets, removing the memory component degrades the performance worse than removing the transfer component. This may be due to that the text content contains richer information or the source domain contains much more noise or both.

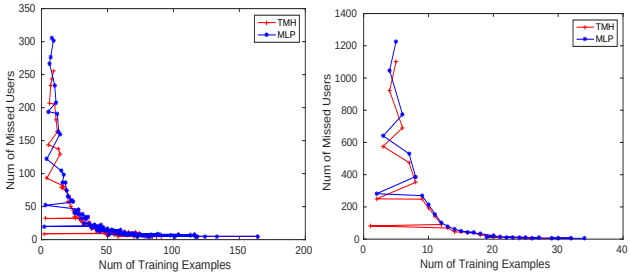

Figure 3: The Missed Hit Users (MHU) distribution (not normalized) over the number of training examples on the Mobile (left) and Amazon (right) datasets.

5.4 Improvement on Cold Users and Items

The cold-user and cold-item problems are common issues in recommender systems. When new users enter into a system, they have no history that can be exploited by the recommender system to learn their preferences, leading to the cold-user start problem. Similarly, when latest news are released on the Google News, there are no reading records that can be exploited by the recommender system to learn users' preferences on them, leading to the cold-item start problem. In general, it is very hard to train a reliable recommender system and make predictions for users and items that have few interactions. Intuitively, the proposed model can alleviate both the cold-user and cold-item start issues. TMH alleviates the cold-user start issue in the target domain by transferring his/her history from the related source domain. TMH alleviates the cold-item start issue by exploiting the associated text content to reveal its properties, semantics, and topics. We now investigate whether TMH indeed improves the performance over the cold users and items by comparing with the pure neural collaborative filtering method, MLP.

We analyse the distribution of Missed Hit Users (MHUs) of TMH and MLP (at cutoff 10). We expect that the cold users in MHUs can be reduced by using the TMH model. The more amount we can reduce, the more effective that TMH can alleviate the cold-user start issues. The results are shown in Figure 3 where the number of training examples can measure the "coldness" of a user. Naturally, the MHUs are most of the cold users who have few training examples. As we can see, the number of cold users in MHUs of MLP is higher than that of TMH. If the cold users are defined as those with less than seven training examples, then TMH reduces the number of cold users from 4,218 to 3,746 on the Amazon dataset, achieving relative 12.1% reduction. On the Mobile dataset, if the cold users are those with less than ten training examples (Mobile is denser than Amazon), then TMH reduces the number of cold users from 1,385 to 1,145 on the Mobile dataset, achieving relative 20.9% reduction. These results show that the proposed model is effective in alleviating the cold-user start issue. The results on cold items are similar and we omit them due to the page limit.

6 CONCLUSION

It is shown that the text content and the source domain knowledge can help improve the recommendation performance and they can be effectively integrated under a neural architecture. The sparse target user-item interaction matrix can be reconstructed with the knowledge from both kinds of information. The results demonstrate that our model outperforms the baseline that relies on the memory network only or relies on the transfer network only. In real-world services, data sources may belong to different providers. The data privacy is a big issue when we combine the multiple data sources. In our future work, it is worth developing new learning techniques to learn a combined model while protecting user privacy.

ABSTRACT

Recently a number of algorithms under the theme of 'unbiased learning-to-rank' have been proposed, which can reduce position bias, the major type of bias in click data, and train a high-performance ranker with click data. Most of the existing algorithms, based on the inverse propensity weighting (IPW) principle, first estimate the click bias at each position, and then train an unbiased ranker with the estimated biases using a learning-to-rank algorithm. However, there has not been a method for unbiased pairwise learning-to-rank that can simultaneously conduct debiasing of click data and training of a ranker using a pairwise loss function. In this paper, we propose a novel framework to accomplish the goal and apply this framework to the state-of-the-art pairwise learning-to-rank algorithm, LambdaMART. Our algorithm named Unbiased LambdaMART can jointly estimate the biases at click positions and the biases at unclick positions, and learn an unbiased ranker. Experiments on benchmark data show that Unbiased LambdaMART can significantly outperform existing algorithms by large margins. In addition, an online A/B Testing at a commercial search engine shows that Unbiased LambdaMART can effectively conduct debiasing of click data and enhance relevance ranking.

1 INTRODUCTION

Learning-to-rank, which refers to machine learning techniques on automatically constructing a model (ranker) from data for ranking in search, has been widely used in current search systems. Existing algorithms can be categorized into pointwise, pairwise, and listwise approaches according to the loss functions they utilize [11–13]. Among the proposed algorithms, LambdaMART is a state-of-the-art algorithm [3, 18]. The data for training in learning-to-rank is usually labeled by human assessors so far, and the labelling process is often strenuous and costly. This raises the question of whether it is possible to train a ranker by using click data collected from the same search system. Click data is indicative of individual users' relevance judgments and is relatively easy to collect with low cost. On the other hand, it is also noisy and biased [8, 19]. Notably, the orders of documents in the search results affect users' judgments. Users tend to more frequently click documents presented at higher positions, which is called position bias. This has been preventing practical use of click data in learning-to-rank.

Recently a new research direction, referred to as unbiased learning-to-rank, is arising and making progress. Unbiased learning-to-rank aims at eliminating bias in click data, particularly position bias, and making use of the debiased data to train a ranker. Wang et al. [16] and Joachims et al. [9] respectively propose employing the inverse propensity weighting (IPW) principle [15] to learn an 'unbiased ranker' from click data. It is proved that the objective function in learning using IPW is an unbiased estimate of the risk function defined on a relevance measure (a pointwise loss). The authors also develop methods for estimating position bias by randomization of search results online. Wang et al. [17] further develop a method for estimating position bias from click data offline. More recently Ai et al. [1] propose a method that can jointly estimate position bias and train a ranker from click data, again on the basis of IPW. In the previous work, the IPW principle is limited to the pointwise setting in the sense that position biases are only defined on click positions.

In this paper, we address the problem of jointly estimating position biases and training a ranker from click data for pairwise learning-to-rank, particularly using a pairwise algorithm, LambdaMART. To do so, we extend the inverse propensity weighting principle to the pairwise setting, and develop a new method for jointly conducting position bias estimation and ranker training.

Specifically, we give a formulation of unbiased learning-to-rank for the pairwise setting and extend the IPW principle. We define position biases as the ratio of the click probability to the relevance

probability at each position, as well as the ratio of the unclick probability to the irrelevance probability. This definition takes both the position biases at click positions and those at unclick positions into consideration. We prove that under the extended IPW principle, the objective function becomes an unbiased estimate of risk function defined on pairwise loss functions. In this way, we can learn an unbiased ranker using a pairwise ranking algorithm.

We then develop a method for jointly estimating position biases for both click and unclick positions and training a ranker for pairwise learning-to-rank, called Pairwise Debiasing. The position bias and the ranker can be iteratively learned through minimization of the same objective function. As an instance, we further develop Unbiased LambdaMART[1], an algorithm of learning an unbiased ranker using LambdaMART.

Experiments on the Yahoo learning-to-rank challenge benchmark dataset demonstrate that Unbiased LambdaMART can effectively conduct debiasing of click data and significantly outperform the baseline algorithms in terms of all measures, for example, 3-4% improvements in terms of NDCG@1. An online A/B Testing at a commercial news search engine, Jinri Toutiao, also demonstrates that Unbiased LambdaMART can enhance the performance of relevance ranking at the search engine.

The contribution of this paper includes the following proposals.

- A general framework on unbiased learning-to-rank in the pairwise setting, particularly, an extended IPW.
- Pairwise Debiasing, a method for jointly estimating position bias and training a pairwise ranker.
- Unbiased LambdaMART, an algorithm of unbiased pairwise learning-to-rank using LambdaMART.

2 RELATED WORK

Learning-to-rank is to automatically construct a ranking model from data, referred to as a ranker, for ranking in search. The algorithms of learning-to-rank can be categorized as pointwise approach, pairwise approach, and listwise approach, based on the loss functions in learning [11–13]. The pairwise and listwise algorithms usually work better than the pointwise algorithms [12], because the key issue of ranking in search is to determine the orders of documents but not to judge the relevance of documents, which is exactly the goal of the pairwise and listwise algorithms.

Recently, a new direction in learning-to-rank, referred to as unbiased learning-to-rank, is arising and making progress. The goal of unbiased learning-to-rank is to develop new techniques to conduct debiasing of click data and leverage the debiased click data in training of a ranker[2].

Wang et al. [16] apply unbiased learning-to-rank to personal search. They conduct randomization of search results to estimate query-level position bias and adjust click data for training of a ranker in personal search on the basis of inverse propensity weighting (IPW) [15]. Joachims et al. [9] theoretically prove that with the inverse propensity weighting (IPW) principle, one can obtain an unbiased estimate of a risk function on relevance in learning-to-rank. They also utilize online randomization to estimate position bias and perform training of a RankSVM model. Wang et al. [17] employ a regression-based EM algorithm to infer position bias by maximizing the likelihood of click data. The estimated position bias is then utilized in learning of LambdaMART. Recently, Ai et al. [1] design a dual learning algorithm which can jointly learn an unbiased propensity model for representing position bias and an unbiased ranker for relevance ranking, by optimizing two objective functions. Both models are implemented as neural networks. Their method is also based on IPW, while the loss function is a pointwise loss function.

Our work mainly differs from the previous work in that:

- In previous work, position bias is defined as the observation probability, and thus IPW is limited to the pointwise setting. In this work, we give a more general definition of position bias, and extend IPW to the pairwise setting, in which the loss function is pairwise and debiasing is carried out at both click positions and unclick positions.
- In previous work, estimation of position bias either relies on randomization of search results online, which can hurt user experiences [9, 16], or resorts to separate learning of a propensity model from click data offline, which can be suboptimal to relevance ranking [1, 17]. In this paper, we propose to jointly conduct estimation of position bias and learning of a ranker through minimizing one objective function.

3 FRAMEWORK

In this section, we give a general formulation of unbiased learning-to-rank, for both the pointwise and pairwise settings, and extend the inverse propensity weighting principle to the pairwise setting.

3.1 Pointwise Unbiased Learning-to-Rank

In learning-to-rank, given a query document pair denoted as x, the ranker f assigns a score to the document. The documents with respect to the query are then ranked in descending order of their scores. Traditionally, the ranker is learned with labeled data. In the pointwise setting, the loss function in learning is defined on a single data point x.

Let q denote the query and D_q the set of documents associated with q. Let d_i denote the i-th document in D_q and x_i the feature vector of q and d_i. Let r_i^+ and r_i^- represent that d_i is relevant and irrelevant respectively. The risk function in learning is defined as

$$R_{rel}(f) = \int L(f(x_i), r_i^+)\, dP(x_i, r_i^+) \tag{1}$$

where f denotes a ranker, $L(f(x_i), r_i^+)$ denotes a pointwise loss function based on an IR measure [9] and $P(x_i, r_i^+)$ denotes the probability distribution on x_i and r_i^+.

Suppose that there is a labeled dataset in which the relevance of documents with respect to queries is given. One can learn a ranker $\hat{f}_{rel}$ through the minimization of the empirical risk function (objective function) as follows.

$$\hat{f}_{rel} = \arg\min_f \sum_q \sum_{d_i \in D_q} L(f(x_i), r_i^+) \tag{2}$$

One can also consider using click data as relevance feedbacks from users, more specifically, viewing clicked documents as relevant documents and unclicked documents as irrelevant documents, and training a ranker with a click dataset. This is what we call 'biased learning-to-rank', because click data has position bias, presentation

[1]Code is available at https://github.com/acbull/Unbiased_LambdaMart

bias, etc. For convenience, let us assume that document d_i in D_q is exactly the document ranked at position i by the original ranker. Let c_i^+ and c_i^- represent that document d_i is clicked and unclicked in the click dataset respectively. The risk function and minimization of empirical risk function can be defined as follows.

$$R_{click}(f) = \int L(f(x_i), c_i^+)\, dP(x_i, c_i^+) \tag{3}$$

$$\hat{f}_{click} = \arg\min_f \sum_q \sum_{d_i \in D_q} L(f(x_i), c_i^+) \tag{4}$$

The loss function is defined on clicked documents with label c_i^+. The ranker $\hat{f}_{click}$ learned in this way is biased, however.

Unbiased learning-to-rank aims to eliminate the biases, for example position bias, in the click data and train a ranker with the debiased data. The training of ranker and debiasing of click data can be performed simultaneously or separately. The key question is how to fill the gap between click and relevance, that is, $P(c_i^+|x_i)$ and $P(r_i^+|x_i)$. Here we assume that the click probability is proportional to the relevance probability at each position, where the ratio $t_i^+ > 0$ is referred to as bias at a click position i.

$$P(c_i^+|x_i) = t_i^+ P(r_i^+|x_i) \tag{5}$$

There are k ratios corresponding to k positions. The ratios can be affected by different types of bias, but in this paper, we only consider position bias.

We can conduct learning of an unbiased ranker $\hat{f}_{unbiased}$, through minimization of the empirical risk function as follows.

$$R_{unbiased}(f) = \int \frac{L(f(x_i), c_i^+)}{t_i^+}\, dP(x_i, c_i^+) \tag{6}$$

$$= \int \frac{L(f(x_i), c_i^+)}{\frac{P(c_i^+|x_i)}{P(r_i^+|x_i)}}\, dP(x_i, c_i^+) \tag{7}$$

$$= \int L(f(x_i), c_i^+)\, dP(x_i, r_i^+) \tag{8}$$

$$= \int L(f(x_i), r_i^+)\, dP(x_i, r_i^+) = R_{rel}(f) \tag{9}$$

$$\hat{f}_{unbiased} = \arg\min_f \sum_q \sum_{d_i \in D_q} \frac{L(f(x_i), c_i^+)}{t_i^+} \tag{10}$$

In (9) click label c_i^+ in the loss function is replaced with relevance label r_i^+, because after debiasing click implies relevance.

One justification of this method is that $R_{unbiased}$ is in fact an unbiased estimate of R_{rel}. This is the so-called inverse propensity weighting (IPW) principle proposed in previous work. That is to say, if we can properly estimate position bias (ratio) t_i^+, then we can reliably train an unbiased ranker $\hat{f}_{unbiased}$.

3.2 Pairwise Unbiased Learning-to-Rank

In the pairwise setting, the ranker f is still defined on a query document pair x, and the loss function is defined on two data points x_i and x_j. Traditionally, the ranker is learned with labeled data.

Let q denote a query. Let d_i and d_j denote the i-th and j-th documents with respect to query q. Let x_i and x_j denote the feature vectors from d_i and d_j as well as q. Let r_i^+ and r_j^- represent that document d_i and document d_j are relevant and irrelevant respectively. Let I_q denote the set of document pairs (d_i, d_j) where d_i is relevant and d_j is irrelevant. For simplicity we only consider binary relevance here and one can easily extend it to the multi-level relevance case. The risk function and the minimization of empirical risk function are defined as

$$R_{rel}(f) = \int L(f(x_i), r_i^+, f(x_j), r_j^-)\, dP(x_i, r_i^+, x_j, r_j^-) \tag{11}$$

$$\hat{f}_{rel} = \arg\min_f \sum_q \sum_{(d_i, d_j) \in I_q} L(f(x_i), r_i^+, f(x_j), r_j^-) \tag{12}$$

where $L(f(x_i), r_i^+, f(x_j), r_j^-)$ denotes a pairwise loss function.

One can consider using click data to directly train a ranker, that is, to conduct 'biased learning-to-rank'. Let c_i^+ and c_j^- represent that document d_i and document d_j are clicked and unclicked respectively. Let I_q denote the set of document pairs (d_i, d_j) where d_i is clicked and d_j is unclicked. The risk function and minimization of empirical risk function can be defined as follows.

$$R_{click}(f) = \int L(f(x_i), c_i^+, f(x_j), c_j^-)\, dP(x_i, c_i^+, x_j, c_j^-) \tag{13}$$

$$\hat{f}_{click} = \arg\min_f \sum_q \sum_{(d_i, d_j) \in I_q} L(f(x_i), c_i^+, f(x_j), c_j^-) \tag{14}$$

The ranker $\hat{f}_{click}$ is however biased.

Similar to the pointwise setting, we consider dealing with position bias in the pairwise setting and assume that the click probability is proportional to the relevance probability at each position and the unclick probability is proportional to the irrelevance probability at each position. The ratios $t_i^+ > 0$ and $t_j^- > 0$ are referred to as position biases at a click position i and an unclick position j.

$$P(c_i^+|x_i) = t_i^+ P(r_i^+|x_i) \tag{15}$$

$$P(c_j^-|x_j) = t_j^- P(r_i^-|x_j) \tag{16}$$

There are $2k$ position biases (ratios) corresponding to k positions.

We can conduct learning of an unbiased ranker $\hat{f}_{unbiased}$, through minimization of the empirical risk function as follows.

$$R_{unbiased}(f) = \int \frac{L(f(x_i), c_i^+, f(x_j), c_j^-)}{t_i^+ \cdot t_j^-}\, dP(x_i, c_i^+, x_j, c_j^-) \tag{17}$$

$$= \int\int \frac{L(f(x_i), c_i^+, f(x_j), c_j^-) dP(c_i^+, x_i) dP(c_j^-, x_j)}{\frac{P(c_i^+|x_i)P(c_j^-|x_j)}{P(r_i^+|x_i)P(r_i^-|x_j)}} \tag{18}$$

$$= \int\int L(f(x_i), c_i^+, f(x_j), c_j^-) dP(r_i^+, x_i) dP(r_i^-, x_j) \tag{19}$$

$$= \int L(f(x_i), r_i^+, f(x_j), r_j^-) dP(x_i, r_i^+, x_j, r_j^-) \tag{20}$$

$$= R_{rel}(f) \tag{21}$$

$$\hat{f}_{unbiased} = \arg\min_f \sum_q \sum_{(d_i, d_j) \in I_q} \frac{L(f(x_i), c_i^+, f(x_j), c_j^-)}{t_i^+ \cdot t_j^-} \tag{22}$$

In (17) it is assumed that relevance and click at position i are independent from those at position j. In (20), click labels c_i^+ and c_j^-

are replaced with relevance labels r_i^+ and r_j^- because after debiasing click implies relevance and unclick implies irrelevance.

Similar to the pointwise setting, $R_{unbiased}$ is an unbiased estimate of R_{rel}. Therefore, if we can accurately estimate the position bias (ratios) t_i^+ and t_j^-, then we can reliably train an unbiased ranker $\hat{f}_{unbiased}$. This is an extension of the inverse propensity weighting (IPW) principle to the pairwise setting.

4 APPROACH

In this section, we present Pairwise Debiasing as a method of jointly estimating position bias and training a ranker for unbiased pairwise learning-to-rank. Furthermore, we apply Pairwise Debiasing on LambdaMart and describe the learning algorithm of Unbiased LambdaMART.

4.1 Learning Strategy

We first give a general strategy for pairwise unbiased learning-to-rank, named Pairwise Debiasing.

A key issue of unbiased learning-to-rank is to accurately estimate position bias. Previous work either relies on randomization of search results online, or resorts to a separate learning of position bias from click data offline. In this paper, we propose to simultaneously conduct estimation of position bias and learning of a ranker offline through minimizing the following regularized loss function.

$$\min_{f,t^+,t^-} \mathcal{L}(f, t^+, t^-) \tag{23}$$

$$= \min_{f,t^+,t^-} \sum_q \sum_{(d_i,d_j)\in I_q} \frac{L(f(x_i), c_i^+, f(x_j), c_j^-)}{t_i^+ \cdot t_j^-} + ||t^+||_p^p + ||t^-||_p^p \tag{24}$$

$$s.t.\ t_1^+ = 1,\ t_1^- = 1 \tag{25}$$

where f denotes a ranker, t^+ and t^- denote position biases (ratios) at all positions, L denotes a pairwise loss function, $||\cdot||_p^p$ denotes L_p regularization. Because the position biases are relative values with respect to positions, to simplify the optimization process we fix the position biases of the first position to 1 and only learn the (relative) position biases of the rest of the positions. Here $p \in [0, +\infty)$ is a hyper-parameter. The higher the value of p is, the more regularization we impose on the position biases.

In the objective function, the position biases t^+ and t^- are inversely proportional to the pairwise loss $L(f(x_i), c_i^+, f(x_j), c_j^-)$, and thus the estimated position biases will be high if the losses on those pairs of positions are high in the minimization. The position biases are regularized and constrained to avoid a trivial solution of infinity.

It would be difficult to directly optimize the objective function in (24). We adopt a greedy approach to perform the task. Specifically, for the three optimization variables f, t^+, t^-, we iteratively optimize the objective function $\mathcal{L}$ with respect to one of them with the others fixed; we repeat the process until convergence.

4.2 Estimation of position bias ratios

Given a fixed ranker, we can estimate the position biases at all positions. There are in fact closed form solutions for the estimation.

The partial derivative of objective function $\mathcal{L}$ with respect to position bias t^+ is

$$\frac{\partial \mathcal{L}(f^*, t^+, (t^-)^*)}{\partial t_i^+} = \sum_q \sum_{j:(d_i,d_j)\in I_q} \frac{L(f^*(x_i), c_i^+, f^*(x_j), c_j^-)}{-(t_i^+)^2 \cdot (t_j^-)^*} + p \cdot (t_i^+)^{p-1} \tag{26}$$

Thus, we have

$$\arg\min_{t_i^+} \mathcal{L}(f^*, t^+, (t^-)^*) = \left[\sum_q \sum_{j:(d_i,d_j)\in I_q} \frac{L(f^*(x_i), c_i^+, f^*(x_j), c_j^-)}{p \cdot (t_j^-)^*} \right]^{\frac{1}{p+1}} \tag{27}$$

$$t_i^+ = \left[\frac{\sum_q \sum_{j:(d_i,d_j)\in I_q} (L(f^*(x_i), c_i^+, f^*(x_j), c_j^-) \ / \ (t_j^-)^*)}{\sum_q \sum_{k:(d_1,d_k)\in I_q} (L(f^*(x_1), c_1^+, f^*(x_k), c_k^-) \ / \ (t_k^-)^*)} \right]^{\frac{1}{p+1}} \tag{28}$$

In (28) the result is normalized to make the position bias at the first position to be 1.

Similarly, we have

$$t_j^- = \left[\frac{\sum_q \sum_{i:(d_i,d_j)\in I_q} (L(f^*(x_i), c_i^+, f^*(x_j), c_j^-) \ / \ (t_i^+)^*)}{\sum_q \sum_{k:(d_k,d_1)\in I_q} (L(f^*(x_k), c_k^+, f^*(x_1), c_1^-) \ / \ (t_k^+)^*)} \right]^{\frac{1}{p+1}} \tag{29}$$

In this way, we can estimate the position biases (ratios) t^+ and t^- in one step given a fixed ranker f^*. Note that the method here, referred to as Pairwise Debiasing, can be applied to any pairwise loss function. In this paper, we choose to apply the pairwise learning-to-rank algorithm LambdaMART.

4.3 Learning of Ranker

Given fixed position biases, we can learn an unbiased ranker. The partial derivative of $\mathcal{L}$ with respect to f can be written in the following general form.

$$\frac{\partial \mathcal{L}(f, (t^+)^*, (t^-)^*)}{\partial f} = \sum_q \sum_{(d_i,d_j)\in I_q} \frac{1}{(t_i^+)^* \cdot (t_j^-)^*} \frac{\partial L(f(x_i), c_i^+, f(x_j), c_j^-)}{\partial f} \tag{30}$$

We employ LambdaMART to train a ranker. LambdaMART [4, 18] employs gradient boosting or MART [6] and the gradient function of the loss function called lambda function. Given training data, it performs minimization of the objective function using the lambda function.

In LambdaMART, the lambda gradient λ_i of document d_i is calculated using all pairs of the other documents with respect to the query.

$$\lambda_i = \sum_{j:(d_i,d_j)\in I_q} \lambda_{ij} - \sum_{j:(d_j,d_i)\in I_q} \lambda_{ji} \tag{31}$$

$$\lambda_{ij} = \frac{-\sigma}{1 + e^{\sigma(f(x_i) - f(x_j))}} \left| \Delta Z_{ij} \right| \tag{32}$$

where λ_{ij} is the lambda gradient defined on a pair of documents d_i and d_j, σ is a constant with a default value of 2, $f(x_i)$ and $f(x_j)$ are the scores of the two documents given by LambdaMART, ΔZ_{ij}

denotes the difference between NDCG[7] scores if documents d_i and d_j are swapped in the ranking list.

Following the discussion above, we can make an adjustment on the lambda gradient $\tilde{\lambda}_i$ with the estimated position biases:

$$\tilde{\lambda}_i = \sum_{j:(d_i,d_j)\in I_q} \frac{\lambda_{ij}}{(t_i^+)^* \cdot (t_j^-)^*} - \sum_{k:(d_k,d_i)\in I_q} \frac{\lambda_{ki}}{(t_k^+)^* \cdot (t_i^-)^*} \quad (33)$$

Thus, by simply replacing the lambda gradient λ_i in LambdaMART with the adjusted lambda gradient $\tilde{\lambda}_i$, we can reliably learn an unbiased ranker with the LambdaMART algorithm. We call the algorithm Unbiased LambdaMART.

4.4 Learning Algorithm

The learning algorithm of Unbiased LambdaMART is given in Algorithm 1. The input is a click dataset $\mathcal{D}$. The hyper-parameters are regularization parameter p and total number of boosting iterations M. The output is an unbiased ranker f and estimated position biases at all positions t^+, t^-. As is outlined in Algorithm 1, Unbiased LambdaMART iteratively calculates adjusted lambda gradient in line 4, re-trains a ranker with the gradients in line 6, and re-estimates position biases in line 7.

Algorithm 1 Unbiased LambdaMART

Require: click dataset $\mathcal{D} = \{(q, D_q, C_q)\}$; hyper-parameters p, M;
Ensure: unbiased ranker f; position biases (ratios) t^+ and t^-;
1: Initialize all position biases (ratios) as 1;
2: **for** $m = 1$ to M **do**
3: **for** each query q and each document d_i in D_q **do**
4: Calculate $\tilde{\lambda}_i$ with $(t^+)^*$ and $(t^-)^*$ using (33);
5: **end for**
6: Re-train ranker f with $\tilde{\lambda}$ using LambdaMART algorithm
7: Re-estimate position biases (ratios) t^+ and t^- using (28) and (29)
8: **end for**
9: **return** f, t^+, and t^-;

5 EXPERIMENTS

In this section, we present the results of two experiments on our proposed algorithm Unbiased LambdaMART. One is an offline experiment on a benchmark dataset. The other experiment is an online A/B testing at a commercial search engine.

5.1 Experiment on Benchmark Data

We made use of the Yahoo! learning-to-rank challenge dataset[1] to conduct an experiment. The Yahoo dataset is one of the largest benckmark dataset for learning-to-rank. It consists of 29921 queries and 710k documents. Each query document pair is represented by a 700-dimensional feature vector manually assigned with a label denoting relevance at 5 levels [5].

There is no click data associated with the Yahoo dataset. We followed the procedure in [1] to generate synthetically click data from the Yahoo dataset for offline evaluation.

[1] http://webscope.sandbox.yahoo.com

5.1.1 Click Data Generation. The click data generation process in [1] is as follows. First, one trains a Ranking SVM model using 1% of the training data with relevance labels, and uses the model to create an initial ranking list for each query. Next, one samples clicks from the ranking lists by simulating the browsing process of users. The position-based click model (PBM) [14] is utilized. It assumes that a user decides to click a document according to probability $P(c_i^+) = P(o_i^+)P(r_i^+)$. Here $P(o_i^+)$ and $P(r_i^+)$ are the observation probability and relevance probability respectively.

The probability of observation $P(o_i^+)$ is calculated by

$$P(o_i^+|x_i) = \rho_i^\theta$$

where ρ_i represents position bias at position i and $\theta \in [0, +\infty]$ is a parameter controlling the degree of position bias. The position bias ρ_i is obtained from an eye-tracking experiment in [8] and the parameter θ is set as 1 by default.

The probability of relevance $P(r_i^+)$ is calculated by

$$P(r_i^+) = \epsilon + (1-\epsilon)\frac{2^y - 1}{2^{y_{max}} - 1}$$

where $y \in [0, 4]$ represents a relevance level. The parameter ϵ represents click noise, which is set as 0.1 by default.

5.1.2 Baseline Methods. We made comprehensive comparisons between our method and the baselines. The baselines were created by combining the state-of-the-art debiasing methods and learning-to-rank algorithms. There were six debiasing methods. To make fair comparison, we used click model to generate 165660 query sessions as training dataset, and utilized the same dataset for all debiasing methods. All the hyper-parameters of the baseline models were the same as those in the original papers.

Randomization: The method, proposed by Joachims et al. [9], uses randomization to infer the observation probabilities as position biases. We randomly shuffled the rank lists and then estimated the position biases as in [1].

Regression-EM: The method, proposed by Wang et al. [17], directly estimates the position biases using a regression-EM model implemented by GBDT.

Dual Learning Algorithm: The method, proposed by Ai et al. [1], jointly learns a ranker and conducts debiasing of click data. The algorithm implements both the ranking model and the debiasing model as deep neural networks.

Pairwise Debiasing: Our proposed debiasing method, which is combined with LambdaMART. In this experiment, we set the hyper-parameter p as 0 by default. As explained below, a further experiment was conducted with different values of p.

Click Data: In this method, the raw click data without debiasing is used to train a ranker, whose performance is considered as a lower bound.

Labeled Data: In this method, human annotated relevance labels without any bias are used as data for training of ranker, whose performance is considered as an upper bound.

There were three learning-to-rank algorithms.

DNN: A deep neural network was implemented as a ranker, as in [1]. We directly used the code provided by Ai et al.[2].

Table 1: Comparison of different unbiased learning-to-rank methods.

Ranker	Debiasing Method	MAP	NDCG@1	NDCG@3	NDCG@5	NDCG@10
LambdaMART	Labeled Data (Upper Bound)	0.854	0.745	0.745	0.757	0.790
	Pairwise Debiasing	**0.836**	**0.717**	**0.716**	**0.728**	**0.764**
	Regression-EM [17]	0.830	0.685	0.684	0.700	0.743
	Randomization	0.827	0.669	0.678	0.690	0.728
	Click Data (Lower Bound)	0.820	0.658	0.669	0.672	0.716
DNN	Labeled Data (Upper Bound)	0.831	0.677	0.685	0.705	0.737
	Dual Learning Algorithm [1]	0.828	0.674	0.683	0.697	0.734
	Regression-EM	0.829	0.676	0.684	0.699	0.736
	Randomization	0.825	0.673	0.679	0.693	0.732
	Click Data (Lower Bound)	0.819	0.637	0.651	0.667	0.711
RankSVM	Labeled Data (Upper Bound)	0.815	0.631	0.649	0.675	0.707
	Regression-EM	0.815	0.629	0.648	0.674	0.705
	Randomization [9]	0.814	0.628	0.644	0.672	0.707
	Click Data (Lower Bound)	0.811	0.614	0.629	0.658	0.697

RankSVM: We directly used the Unbiased RankSVM Software provided by Joachims et al.[3], with hyper-parameter C being 200.

LambdaMART: We implemented Unbiased LambdaMART by modifying the LambdaMART tool in LightGBM [10]. We utilized the default hyper-parameters of the tool. The total number of trees was 300, learning rate was 0.05, number of leaves for one tree was 31, feature fraction was 0.9, and bagging fraction was 0.9.

In summary, there were 13 baselines to compare with our proposed Unbiased LambdaMART algorithm. Note that Dual Learning Algorithm and DNN are tightly coupled. We did not combine Pairwise Debiasing with RankSVM and DNN, as it is beyond the scope of this paper.

5.1.3 Experimental Results. Table 1 summarizes the results. We can see that our method of Unbiased LambdaMART (LambdaMART + Pairwise Debiasing) significantly outperforms all the other baseline methods. The results of Regression-EM and Dual Learning Algorithm are compariable with those reported in the original papers. In particular, we have the following findings.

- Our method of LambdaMART+Pairwise Debiasing (Unbiased LambdaMART) achieves better performances than all the state-of-the-art methods in terms of all measures. For example, in terms of NDCG@1, our method outperforms LambdaMART+Regression-EM by 3.2%, outperforms DNN+Dual Learning by 4.3%, and outperforms RankSVM+Randomization by 8.9%.
- Pairwise Debiasing works better than the other debiasing methods. When combined with LambdaMART, Pairwise Debiasing outperforms Regression-EM by 3.2%, outperforms Randomization by 4.8% in terms of NDCG@1.
- LambdaMART trained with human labeled data achieves the best performance (upper bound). An unbiased learning-to-rank algorithm can still not beat it. This indicates that there is still room for improvement in unbiased learning-to-rank.

Table 2: Relative increases of first click ratios by Unbiased LambdaMART in online A/B testing.

Measure	Click@1	Click@3	Click@5
Increase	2.64%	1.21%	0.80%
P-value	0.001	0.004	0.023

5.2 A/B Testing at Commercial Search Engine

We further evaluated the performance of Unbiased LambdaMART by deploying it at the search engine of Jinri Toutiao, a commercial news recommendation app in China with over 100 million daily active users. We trained two rankers with Unbiased LambdaMART and LambdaMART + Click Data using click data of approximately 19.6 million query sessions collected over two days at the search engine. Then we deployed the two rankers at the search system to conduct A/B testing. The A/B testing was carried out for 16 days. In each experiment group, the ranker was randomly assigned approximately 1.5 million queries per day.

In the online environment, we observed that different users have quite different click behaviors. It appeared to be necessary to have a tighter control on debiasing. We therefore set the hyper-parameter p as 1, i.e., we conducted L_1 regularization to impose a stronger regularization on the position biases. We validated the correctness of this hyper-parameter selection on a small set of relevance dataset.

We compared the results of the two rankers in terms of first click ratios, which are the percentages of sessions having first clicks at top 1,3,5 positions among all sessions. A ranker with higher first click ratios should have better performance.

As shown in Table 2, Unbiased LambdaMART can significantly outperform LambdaMART + Click Data in terms of first click ratios at the A/B Testing. It increases the first click ratios at positions 1,3,5 by 2.64%, 1.21% and 0.80%, respectively, which are all statistically significant (p-values < 0.05). It indicates that Unbiased LambdaMART can make significantly better relevance ranking.

6 CONCLUSION

In this paper, we have proposed a general framework for pairwise unbiased learning-to-rank, including the extended inverse propensity weighting (IPW) principle. We have also proposed a method called Pairwise Debiasing to jointly estimate position biases and train a ranker by directly optimizing a same objective function within the framework. We develop a new algorithm called Unbiased LambdaMART as application of the method. Experimental results show that Unbiased LambdaMART achieves significantly better results than the existing methods on a benchmark dataset, and is effective in relevance ranking at a real-world search system.

ABSTRACT

Recently, scholars have demonstrated empirical successes of deep learning in sequence labeling, and most of the prior works focused on the word representation inside the target sentence. Unfortunately, the global information, e.g., domain information of the target document, were ignored in the previous studies. In this paper, we propose an innovative joint learning neural network which can encapsulate the global domain knowledge and the local sentence/token information to enhance the sequence labeling model. Unlike existing studies, the proposed method employs domain labeling output as a latent evidence to facilitate tagging model and such joint embedding information is generated by an enhanced highway network. Meanwhile, a redesigned CRF layer is deployed to bridge the 'local output labels' and 'global domain information'. Various kinds of information can iteratively contribute to each other, and moreover, domain knowledge can be learnt in either supervised or unsupervised environment via the new model. Experiment with multiple data sets shows that the proposed algorithm outperforms classical and most recent state-of-the-art labeling methods.

1 INTRODUCTION

Sequence labeling, including tasks like segmentation, named entity recognition, chunking, etc., is an essential stage for a number of downstream nature language processing applications, e.g., natural language understanding and semantic role labeling. Recently, there have been huge improvements in sequence labeling tasks and these breakthroughs were largely fueled by recent advances in deep learning models. For NLP tasks, most of the newly explored methods focused on characterizing (local) word-level or character-level embedding representation, which uncover the important latent semantic information inside the document for sequence labeling. However, for all of those works [2, 15, 17, 29], the global information, e.g., domain/category information, was ignored for model generation. Meanwhile, experience from other NLP tasks, e.g., question answering and semantic search, tells that domain information, when combining with local features, can be potentially important to further enhance the algorithm performance.

Take the following sentences as an example [Domain: Travel] *Big Apple could be a good choice for all-inclusive vacations*, [Domain: Technology] *In the past black friday, a big Apple sale event was first accounted by...*, the word pair **big apple** plays different roles in these sentences, and domain information could be useful to discover such variation. From sequence labeling viewpoint, "*big apple*" could be labeled differently (e.g., named entity or not) in the different contexts, and the global domain knowledge may contribute to the target named entity recognition model.

In this paper, in order to address this problem, we propose a novel domain-aware sequence labeling neural model, which encapsulates both global and local information by learning an independent joint embedding in each possible domain. The domain features can be characterized in either supervised or unsupervised environment. Moreover, a redesigned CRF layer is utilized to estimate output labels probability based on the statistic distribution which is generated by the joint embeddings learned from the last iteration.

The contribution of this paper contains three aspects. Firstly, to the best of our knowledge, this study is the first attempt to explore the domain knowledge in the neural model for sequence labeling tasks, and unlike prior methods, the latent global information is used as a distributional component in a joint learning framework. Secondly, a two level Bi-LSTM with an innovative highway layer is proposed to enable communications between layers and to distinguish the joint embedding from the direct concatenation of contextual and domain representations. Last but not least, we have verified the proposed method on three open corpora with domain labels for the tasks named entity recognition (NER) and segmentation, and another standard dataset without domain labels associated with the chunking task. The experiments show the superiority of the new model compared with a number of classical and most recent state-of-the-art baselines. Meanwhile, experiment results support our initial hypothesis that domain information can be important for sequence labeling tasks.

2 RELATED WORK

For sequence labeling tasks, classic linear statistical methods aim to maximize the joint probability over the linguistic observation data for label generation by leveraging the Markov approach, such like hidden Markov models [22], maximum entropy Markov models [19] and conditional random fields [14]. These methods have been successfully applied in various kinds of NLP tasks. While these models rely heavily on the hand-crafted features, and the long-range

dependency restricts the algorithm performance. In order to break this boundary, in the past few years, neural network approach, e.g., convolutional neural networks (CNN) and recurrent neural network (RNN) approaches, along with the word embedding features were employed as an important alternative for sequence labeling. Collobert et al. [6], for instance, utilized feed-forward neural network to learn the word representations from unlabeled data instead of man-made features and used CNN to extract high-level features. In addition, several models based on RNN [7] and its variation long short-term memory (LSTM) [10] or gated recurrent unit (GRU) [3], were proposed to capture the long-range dependency of the sequential data. More recently, several RNN-like models were proposed for sequence tagging, e.g., deep RNN for speech recognition [8], encoder-decoder via LSTM cell for sequence-to-sequence learning [26], etc. Recent studies also showed the benefits of merging the neural networks and CRF because the representative features obtained by the RNNs exactly fit the need of CRF. For example, Huang et al. [11] combined bidirectional LSTM (Bi-LSTM) with CRF layer and Ma [17] added CNN on Bi-LSTM-CRF for tagging sentences. Furthermore, language models were introduced for calculating the probability of context [16, 21, 23], which produced promising results in the tasks like chunking, named entity recognition, part-of-speech tagging and so on. However, to the best of our knowledge, all the existing approaches only focused on the local information and the global domain potentials were ignored.

Experience from prior studies shows that global information, e.g., domain knowledge, can be potentially important for a number of text mining tasks, e.g., information extraction [1], information retrieval [27, 28], and information summarization [4]. However, most of the previous works employed global information as a kind of simple feature or side-information for model generation. More sophisticated investigations are quite sparse in the deep learning community.

To take advantage of the domain knowledge, in this paper, we propose an innovative domain-aware sequence labeling model. Unlike prior methods, the new model encapsulates both local contextual information and global domain knowledge into a joint learning framework. For each possible domain, the proposed algorithm extracts independent joint representations of context and domain information via a multi-channel highway layer which integrates the outputs of two-level Bi-LSTM, and then estimates output labels probability using a redesigned CRF layer based on the domain distribution.

3 JOINT LEARNING FOR SEQUENCE LABELING WITH DOMAIN KNOWLEDGE

3.1 Problem Definition

To introduce global domain features, we tailor the original linear-CRF by adding a new vertex d that represents the domain knowledge of input sequence X, which is illustrated as the new probabilistic graphical model as Fig.1. Based on the Bayesian chain-rule in DAG [18, 24] the expected output labels Y^* should has a maximum marginal probability as follow:

$$Y^* = \underset{Y}{\operatorname{argmax}} \sum_{i=1}^{k} P(Y|X, d_i)P(d_i|X) \tag{1}$$

$$Y = (y_1, y_2, \cdots y_m)$$

where d_i is the ith domain and $i \in \{1, 2, \cdots k\}$. Following this model and the latent variable d_i, the label sequence depends on both input data X (local features) and domain knowledge d (global features) as an integration of all the distributional components for k domains. Consequently, we build up a joint learning framework to estimate the first factor $P(Y|X, d_i)$ (the output label sequence probability given X in the target domain d_i) and the second $P(d_i|X)$ (the probability that input sequence X falls into the domain d_i) iteratively via extracting joint embedding information for each (X, d_i).

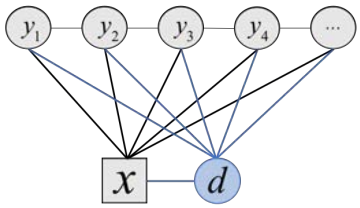

Figure 1: The new DAG for modeling sequence labeling problem based on CRF, in which the vertex d denotes the variant of domain label.

3.2 Proposed model

Based on the proposed model framework, the output label sequence is determined by both joint embedding information and domain distribution. The former factor heavily can be depend on the latter. Hence we propose a joint learning framework illustrated as Fig.2 that contains two parts. The sequence labeling part applies an innovative domain-aware CRF layer to estimate the output label probability via joint representations of domain and context through a joint representation extractor. The other, domain knowledge extractor, is a multi-class classifier for calculating domain distribution of the input sequence. Each token, in the input sequence, is represented as a concatenation of word embedding and character-level embedding, and then passed through two extractors respectively to obtain the joint representation and domain distribution. Finally, the domain-aware CRF layer calculates the probability of the label sequence by using both joint features and the domain knowledge. The two parts in the framework can be trained iteratively by forward pass and back-propagation through time (BPTT) while contributing to each other.

3.3 Joint representation extractor

In the proposed model, in order to learn the joint representation based on context and domain embedding information, a two-level depth bidirectional LSTM and an enhanced highway layer are implemented as shown in Fig.3, where x is the inputs and o denotes the outputs of LSTM cell with $\leftarrow$ or $\rightarrow$ as the forward or backward directions. v_i is the ith domain vector that is initialized randomly, and $s_!^i$ describes the joint representation for the token with the ith domain knowledge.

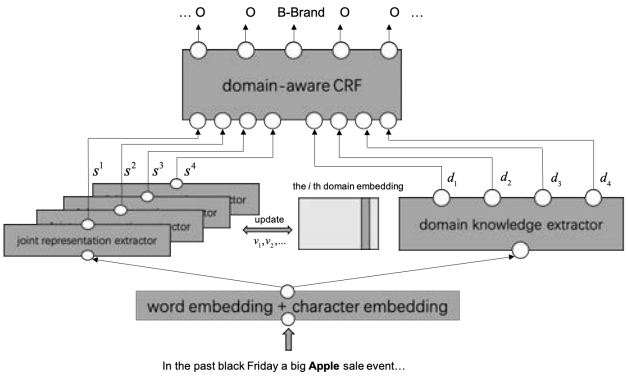

Figure 2: The overview of the proposed model. Domain knowledge extractor generates the global domain distribution and the joint representation extractor learns the joint embedding information. Domain-aware CRF layer calculates the output label probability based on the two modules.

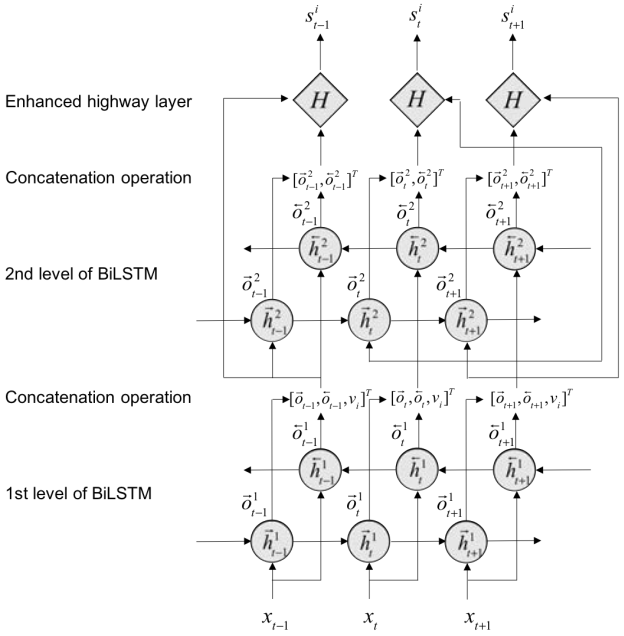

Figure 3: For the ith domain, we employ two-level Bi-LSTM to embed both context and domain features. The novel multi-channel highway layer balances the contextual and domain representations as the joint representation.

The deep Bi-LSTMs extract the contextual representation and domain embedding information respectively utilizing each level of Bi-LSTMs. Next, for adaptively learning a joint representation from context and domain embeddings, an enhanced highway layer is deployed whose cell has multiple gates to balance the effects of multi-channel inputs. Note that this highway design is quite different from the original one [25]. The multi-channel highway layer allows the networks rationally copy and transform multiple inputs and then output a joint embedding representation. The function of multi-channel highway cell can be formalized as follows:

$$
\begin{aligned}
s_t^i = &\sum_c \lambda_c (F_c(\alpha_{c,t}^i, W_c^F) \cdot T(\alpha_{c,t}^i, W_c^T) \\
&+ \alpha_{c,t}^i \cdot (1 - T(\alpha_{c,t}^i, W_c^T))) \\
\alpha_{c,t}^i &\in \{[\overrightarrow{o}_t, \overleftarrow{o}_t, v_i]^T, [\overrightarrow{o}_t^2, \overleftarrow{o}_t^2]^T\} \\
s.t. &\quad \sum_c \lambda_c = 1
\end{aligned}
\tag{2}
$$

where $\alpha_{c,t}^i$ is the output vector (hidden states) of cth layer of deep Bi-LSTMs at t-step in ith domain and $\cdot$ is element-wise product. $F_c(\cdot,\cdot)$ is the activation function of cth gate and $T(\cdot,\cdot)$ denotes the transition function that determines the proportion of transformed and original input vector α. $W_\cdot^\cdot$ is the weights for each function that can be learned automatically with the subscript for channel and superscript for function. Note that, for scale invariance, the transformation of the multi-channel highway cell subjects to the criterion that the summation of each weight λ_c equals to 1.

3.4 Domain knowledge extractor

Domain knowledge extractor is essentially a supervised multi-class classifier in this proposed framework. We build up bidirectional LSTM networks and concatenate the final states of the forward and backward networks to optimize and obtain the global features. A softmax layer is deployed to estimate the likelihood that the input sentence should be classified into the target domain. The detailed domain knowledge extractor is depicted in Fig.(4), where x is the input sequence with length n, and d denotes the domain distribution conditioned on input sequence x. For generality, this model could be estimated by MLE and the loss based on softmax function is formularized as follows:

$$
J(\theta) = -\frac{1}{m} \sum_{i=1,j=1}^{m,k} 1\{y_i = d_j\} \log \frac{e^{\theta_j^T f_i}}{\sum_{l=1}^{k} e^{\theta_l^T f_i}} \tag{3}
$$

where $1\{\cdot\}$ is indicator function equals to 1 when the ith output y_i matches the ground-truth label d_j. Note that f_i is the concatenation of final states $[\overrightarrow{f}_i, \overleftarrow{f}_i]$ for the ith sentence and θ is the parameters.

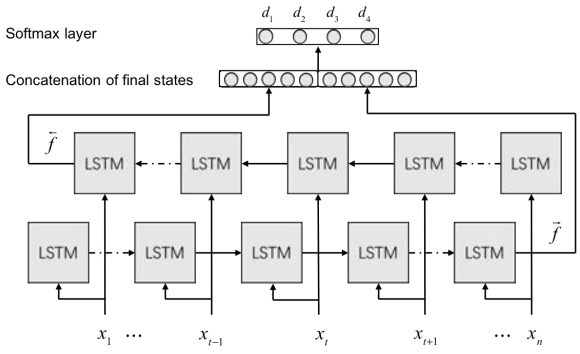

Figure 4: We use the final states of Bi-LSTM for generating the domain distribution.

To generalize the model, the proposed algorithm is able to work in two different scenarios: training samples with or without domain labels. For the latter one, unsupervised clustering algorithms, like K-means, can be cast as a pre-processing and then each training sample can be labeled with a cluster index (pseudo domain label). Finally, we train the model as a supervised learning process.

3.5 Domain-aware CRF

Based on equation (1) and fundamental theorem of random fields [9], the conditional probability can be rewritten as the joint distribution of the minimal cliques:

$$
\begin{aligned}
P(Y|X) &= \sum_{d} P(d|X) \frac{\exp(E(y,x,d))}{Z(X,d)} \\
E(y,x,d) &= \sum_{k} W_k \sum_{t} f_k(y_{t-1}, y_t, x_t, t, d) \\
Z(X,d) &= \sum_{y} \exp(\sum_{k} W_k F_k(y,x,d))
\end{aligned}
$$

where $f_k(\cdot)$ is the kth feature function within W_k as the parameter vector. x_t and y_t denote respectively the tth input token and output label subscripted with t as the position. d denotes domain distribution and $Z(\cdot)$ is the normalization which accumulates over all possible label sequences in the finite label set $\{y_l\}$. Note that the feature function $f_k(\cdot)$ consists of two parts: one is to calculate the transition probability from last state to the current and the other represents the correlation between labels and input tokens. Hence, the energy function $E_k(\cdot)$ has the form as the following:

$$
\begin{aligned}
E(y,x,d) = &\sum_{k} U_k \sum_{t} \lambda_k(y_{t-1}, y_t, x_t, t, d) \\
&+ \sum_{k} V_k \sum_{t} \mu_k(y_t, x_t, t, d)
\end{aligned}
$$

whose form is similar to recurrent neural networks. From this perspective, the redesigned domain-aware CRF block is depicted as Fig.5, in which the hidden state h_t is an integration of the probabilistic components in the different domains and d_i denotes the probability corresponding to the input sentence dropping in the ith domain. s_t^i is the jointly embedding vector in the ith domain produced by joint representation extractor. Note that each block C in domain-aware CRF layer is implemented based on forward-backward algorithm using RNN cell [5].

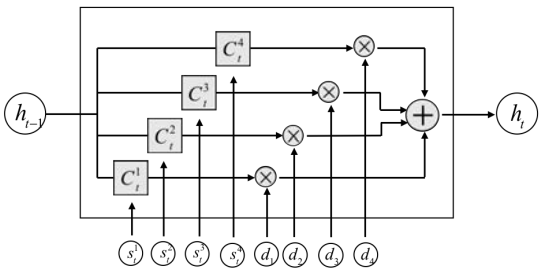

Figure 5: The domain-aware CRF block calculates the marginal probability based on equation (1).

As a discriminative model, the domain-aware CRF can be trained by maximum likelihood estimation (MLE), whose objective function $L(W)$ is a collection from all the domain channels as follows:

$$
\begin{aligned}
L(W) &= \sum_{d} L_d(W_d) \\
&= \sum_{d} \log(P(d|x) \prod_{x,y} P(y|x,d)^{\overline{P}(x,y)}) \\
&= \sum_{d} \overline{P}(x,y) \log P(d|x) \\
&+ \sum_{d} \sum_{x,y} \overline{P}(x,y) \sum_{k} W_K F_k(x,y,d) \\
&- \sum_{d} \sum_{x} \overline{P}(x) \log \sum_{y} e^{\sum_k W_k F_k(x,y,d)}
\end{aligned}
\tag{4}
$$

where $\overline{P}(x,y)$ is the empirical distribution that can be calculated from training samples. Hence, the gradient can be derived with feature vector $F(\cdot)$ as follows:

$$
\begin{aligned}
\frac{\partial L}{\partial W} &= \sum_{d} \sum_{x,y} \overline{P}(x,y) F(x,y,d) \\
&- \sum_{d} \sum_{x,y} \overline{P}(x) P(y|x,d) F(x,y,d)
\end{aligned}
\tag{5}
$$

3.6 Model training

Since the joint representations learning in the proposed model is determined by both global domain distribution of input data X and the local context features, multi-task learning is applied for training with two different but related tasks: domain label classifier (a sub-task), and the sequence labeling model generation (main-task). For each batch in an epoch, the two tasks are trained alternatively. We firstly train the multi-class classifier using forward pass to calculate the loss $J(\theta)$ as eq.(3) and apply backward propagation to update the parameters θ. After the domain distribution is obtained, the joint representation s_i can be computed, and then the objective $L(W)$ of labeling model can be computed via domain-aware CRF as eq.(4). Finally the gradient can be computed as eq.(5) and back-propagation is deployed to update the parameters W and domain embedding v_i of main-task. Note that training will be stopped if the performance on the development set is no longer improving for 15 epochs or the maximum number of iterations has been achieved. The iterative training process is clarified in Algo.1.

4 EXPERIMENTS

4.1 Dataset

In order to validate the proposed method for sequence labeling, we use two types of datasets: one is blended data crossing multiple domains, and the other is a single data set without domain labels. The former ones are generated by combining several independent data sets following the works of Kurata et al. [13] and Zhai et al. [30]. Three considerably large data sets, LARGE3, LARGE4, and LARGE5 are obtained for the tasks of *named entity recognition (NER)* and *segmentation*. LARGE*k* represents how many sub sets it contains. For the latter one, we use CoNLL 2000 shared task for *text chunking* to test the effectiveness of our model on the data without specific domain information. For comparison, several baselines are selected

including classic linear probabilistic models and neural networks. The details of datasets and baselines are depicted as follows.

LARGEs. The construction of this kind of data set is aiming for containing a large amount of data sequences from several domains, which is motivated by the fact that many practical applications of sequence tagging involve a large scale of documents crossing multiple domains. Specifically, five open data sets for NER and segmentation are included: ATIS, MIT Restaurant Corpus, MIT Movie Corpus, SemEval 2017 task 10 and SemEval 2018 task 8. LARGEk denotes the combination of k-headed sub sets, and we collect the training set, development set and test set from each subset respectively for constructing the corresponding samples of LARGEs. The detail of each involved dataset are shown as Tab.1 and all the subsets can be found online.

CoNLL 2000. To verify our model can be applied to the data without domain labels, we use CoNLL 2000 to test the effectiveness. This data set is extracted from Wall Street Journal corpus, containing 8,068 training, 868 development and 893 test sentences. 12 syntactic labels are defined for text chunking, e.g. NP, VP, ADJP, other, etc.

4.2 Baselines

For comparison, several baselines are selected including classic linear probabilistic models and neural networks. We first choose CRF [14] as the classical linear probabilistic model baseline for its broad applications. Then, three recent state-of-art neural models, BiLSTM-CRF [11], LMcost [23], and LM-LSTM-CRF [21], are selected as the deep learning baselines. All of those models are implemented using open-source code offered by authors and we test them on the LARGEs and CoNLL 2000 data sets to evaluate the algorithms' performance.

4.3 Preparation

The proposed model applies same settings of pre-trained word embeddings and optimization strategy as baseline models referred before. To initialize the word lookup table, we deploy GloVe [20], 300-dimension pre-trained word embeddings, and the character/domain embeddings are both 100-dimension. To avoid bias, each test is repeated 10 times for averaging the final score. In LARGEs, each sample has a specific field label because its original data source covers a certain field as shown in Tab.1. However, unlike LARGEs, samples in CoNLL 2000 do not associate with explicit domain labels, hence, we apply K-means clustering to explore the distributional distinctiveness among the data sequences and labeled them with the cluster index. After the label system has been defined, the domain knowledge extractor is trained as a multi-class classifier. Then the labeling model can work based on the domain distribution.

The novel approach in this paper is noted as DA-BiLSTM-CRF++ in the following sections. In order to validate the usefulness of the domain knowledge in the sequence labeling tasks, we launch another two experiment models, DA-BiLSTM-CRF and DA-BiLSTM-CRF+, which simplify the joint representation of the proposed model. The key difference between these models and the DA-BiLSTM-CRF++ is whether the second layer of Bi-LSTM and the enhanced highway layer participate the joint representation learning. For details, joint representation extractor in DA-BiLSTM-CRF directly connects the contextual representation with domain embedding, and feeds the domain-aware CRF with the vector $[\overrightarrow{o}_t^1, \overleftarrow{o}_t^1, v_i]^T$. While the joint representation extractor in DA-BiLSTM-CRF+ applies the second layer of Bi-LSTM to learn a joint representation $[\overrightarrow{o}_t^2, \overleftarrow{o}_t^2]^T$ from the direct concatenation $[\overrightarrow{o}_t^1, \overleftarrow{o}_t^1, v_i]^T$ to feed the top domain-aware CRF layer. Moreover, DA-BiLSTM-CRF++ uses a multi-channel highway layer to balance the embeddings of the first and the second Bi-LSTM layer.

4.4 Experimental results

To evaluate the performance of the novel approach on the datasets with domain discrimination, we perform named entity recognition (NER) and segmentation on the test sets of LARGE3, LARGE4 and LARGE5. The performance is measured in terms of F1-score, which is calculated by the public script *conlleval.pl*. After the named entity

Table 2: The results of NER and segmentation on LARGEs. Note that * denotes p-value < 0.05 and ** denotes p-value < 0.005.

	NER			segmentation			chunking
	LARGE3	LARGE4	LARGE5	LARGE3	LARGE4	LARGE5	CoNLL 2000
CRF	80.42	76.54	70.27	85.19	76.54	73.89	86.18
BiLSTM-CRF	85.79	77.81	75.04	88.85	81.32	78.65	94.25
LMcost	86.08	77.65	75.39	89.47	82.67	79.87	94.03
LM-LSTM-CRF	86.2	77.98	75.48	89.67	83.22	79.98	94.41
DA-BiLSTM-CRF	86.71	78.12	75.47	89.68	82.54	79.9	94.7
DA-BiLSTM-CRF+	86.67	**78.6****	75.68	**89.91***	83.38	80.18	94.89
DA-BiLSTM-CRF++	**86.89****	78.53	**75.72***	89.83	**83.43***	**80.35****	**94.95***

labels have been obtained, we reassign each word with IOB labels to assess the segmentation performance. Also, we report the F1-score of segmentation which is computed by *conlleval.pl* in the Tab.2. The results indicate the novel model produces significant improvements (p-value < 0.05) due to the effects of the domain knowledge. DA-BiLSTM-CRF++ and DA-BiLSTM-CRF+ perform better than the basic version DA-BiLSTM-CRF in most of cases, because the former two models learn the joint embedding information via contextual and domain representation rather than a direct concatenation of them. DA-BiLSTM-CRF+ is functionally equivalent to DA-BiLSTM-CRF++ and performs roughly the same.

The robustness of the proposed model has also been tested. Several experiments on CoNLL 2000 shared dataset are deployed for testing the chunking performance, which is a typical sequence labeling task as well as NER or segmentation. The best F1-score is achieved with the parameter $k = 2$ when K-means clustering has been applied as a pre-processing to obtain the scattering distinctiveness of unlabeled data. In the same way, we report the F1-score via *conlleval.pl*, and the chunking results are displayed in Tab.2. The evaluation results show the effectiveness of proposed model (p-value < 0.05). When the explicit training labels are not available, the proposed approach of obtaining (pseudo) domain knowledge is promising. However, the performance is vulnerable to the incorrect clustering labels.

4.5 Analysis.

The model is validated for three main sequence labeling tasks by the experiments aforementioned, and the essential reasons of the superiority against prior works should be further investigated. As Fig.1 illustrated, the fundamental distinction of the proposed approach is the contribution of both the sequence features and the domain knowledge, which contains two important factors. First, we employ the joint representation of the input sequence X and domain knowledge d; second, the marginal probability calculated by domain-aware CRF based on eq.(1) is utilized to enhance the labeling performance. The improvements produced by the first point can be observed through the comparisons between the basic model DA-BiLSTM-CRF and DA-BiLSTM-CRF+/DA-BiLSTM-CRF++ that deploy some extra neural networks to learn the joint representation from the direct connection of contextual and domain embeddings. The second factor can be proved via the advantages of the basic model DA-BiLSTM-CRF in the experiments using the redesigned CRF layer to integrate each domain component. Furthermore, we investigate the correlation between performance and the class divergence in each dataset using Silhouette Coefficient [12], which is widely deployed as a relocating measurement. Tab.3 reveals the positive relationship between Silhouette Coefficient and the model performance, which proves that our method maximizes its potential if the experiment corpus can be clearly divided into a number of independent partitions (as domain knowledge). Note that S.C. represents the Silhouette Coefficient and F1-gap is the gap between the best-performed and the second-performed F1-scores.

Table 3: The relationship between Silhouette Coefficient and F1-gap on each dataset.

	S.C.	F1-gap
LARGE3	0.2128	0.69
LARGE4	0.2042	0.62
LARGE5	0.1246	0.24
CoNLL 2000@$k = 2$	0.2671	0.54
CoNLL 2000@$k = 3$	0.1249	0.49
CoNLL 2000@$k = 4$	0.0807	0.31
CoNLL 2000@$k = 5$	0.0610	0.17

5 CONCLUSION AND FUTURE WORK

In this study, we propose a novel neural sequence labeling model in a joint learning framework. While the model takes the domain probability distribution into account, the global and local features are integrated via a novel multi-channel highway learning for efficient joint embedding optimization. Moreover, an innovative CRF layer integrates the joint representations that range over all the possible domains and calculates the probability of the output labels. The proposed method is trained in a multi-task learning framework. Three datasets (with or without explicit domain labels) associated with different sequence labeling tasks were employed for algorithm evaluation. Experiment result indicated that the proposed model significantly outperforms the previous classical and recent baselines in a number of different sequence labeling tasks, like NER, segmentation and chunking. In this work, clustering based approach was implemented to address the problem of domain label missing, and in the future, we will investigate more sophisticated end-to-end method to consider domain knowledge into sequence labeling task when explicit domain labels are not available.

ABSTRACT

Obfuscated language is created to avoid censorship in adversarial communication such as sensitive information conveying, strong sentiment expression, secret actions plan, and illegal trading. The obfuscated sentences are usually generated by replacing one word with another to conceal the textual content. Intelligence and security agencies identify such adversarial messages by scanning with a watch-list of red-flagged terms. Though semantic expansion techniques are adopted, the precision and recall of the identification is limited due to the ambiguity and the unbounded creation way. To this end, this paper frames the obfuscated language identification problem as a text matching task, where each message is checked whether matches a red-flagged term. We propose a multimodal text matching model which combining textual and visual features. The proposed model extends a Bi-directional Long Short Term Memory network with a visual-level representation component to achieve the given task. Comparative experiments on real-world dataset demonstrate that the proposed method could achieve a better performance than the previous methods.

1 INTRODUCTION

Motivation: Nowadays, online social networks have become more and more important in the diffusion of information by increasing the spread of live content and diverse opinions [2]. The development of online social networks provide convenience for people to get a very vast source of information on an unprecedented scale[9]. But at the same time, the security of cyberspace also faces enormous challenges. Some netizens have utilized online social networks to discuss sensitive information, plan for secret actions, trade illegal products, spread political rumours, or express strong sentiment. In order to detect such harmful communications, intelligence and security agencies would maintain a watch-list of red-flagged terms such as attack, bomb and heroin. The watch-list is used for keyword-spotting in online spread messages which are filtered as suspicious information [8].

However, netizens usually create and use obfuscated language to evade the censorship of intelligence and security agencies[13]. The original information is obfuscated by replacing the red-flagged term with an ordinary word or a brand new word (not a word before). Such substitution words are called *morphs* of the original red-flagged terms[11]. For example, "金太阳(Kim Sun)" is a morph generated from the original term "金日成(Kim Il-sung)" because the character "日" in the original term means "太阳(Sun)". The morph "火乍弓单" is generated from the original term "炸弹(Bomb)" by decomposing the Chinese characters. The morph "P0RN" of "PORN" is generated by substituting the letter "O" with the number "0" because they are visually similar. Such kind of obfuscated language can help to avoid the automatic detection since the watch-list of red-flagged terms is always manually maintained and impossible to cover all morphs.

Problem Statement: This paper addresses the problem of identifying obfuscated language that is created to evade censorship. The

raw input of this task is a watch-list of red-flagged terms and a set of documents to be scanned. The target is to find all documents that mention any of the red-flagged terms even the original terms are obfuscated. An intuitive solution is to expand the original terms by enumerating all possible morphs. However, morphs are created in unbounded way and evolve rapidly over time. Furthermore, some morphs are hardly identified even by human. So enumerating all morphs corresponding to the original terms is impossible. This opens an unexplored area of obfuscated language processing [13]. In detail, this task entails the following challenges:

- *Synonymy and Polysemy.* Due to the synonymy of natural language, many words or phrases can express similar meaning with the original terms. Some researchers have tried to apply an external knowledge base[1, 18], while existing knowledge bases can hardly cover a wide range of original terms and similar words referred by morphs. Meanwhile, considering the polysemy of natural language, a document might be innocuous even if the red-flagged terms or corresponding morphs are used. For example, *ice* and *skiing* refer to *Cocaine* in illegal drug dealing. But they refer to a kind of winter sports in more common situations.
- *Domain Knowledge.* Some morphs are generated based on domain knowledge. It is difficult to identify such obfuscations even for a man who is not familiar with this domain. For example, "薄熙来(Xilai Bo)" is a former Chinese politician. In Chinese social networks, Bo is morphed as "平西王(Conquer West King)" who was a historical figure four hundreds years ago. They have been linked together because they have similar experiences, both governed the same region and experienced a downfall and an arrest at the end of their career.
- *Unbounded candidates.* Obfuscated language effectively hides in plain sight because anything can be a candidate referred to the original term[25]. Netizens create morphs with a motley variety of functions. Some researchers have summarized the categories of obfuscated morphs [12, 24], such as phonetic substitution, spelling decomposition, translation and transliteration, semantic interpretation,etc. However, people's imagination is infinite and any connections can be utilized to create obfuscated language. So it is impractical to enumerate all obfuscation functions.

State of the Arts: With our observation, no matter how complicated rules are applied to create obfuscated language, the core features used can fall into two types, textual features and visual features. Previous researchers mainly focus on textual features to identify obfuscated language. Some methods [3, 4, 10] utilize the known morphs as seeds and find the patterns of the co-occurrence of the known morphs and the original terms, then find new morphs based on the acquired patterns. However, morphs are not used together with the original terms in most obfuscated language. Some methods pre-define rules to generate morphs [12, 24, 25]. The rules are all based on lexical relations, sematic relations or context relations between the original terms and morphs. Our method goes beyond the previous ones by targeting at identifying the adversarial passages obfuscated with various morphs rather than only finding morphs corresponding to the original terms.

Furthermore, we observe that some morphs are generated without any textual relations. But from the visual aspects, they are similar with the original terms. We name such relations as visual features. For example, the above mentioned morphs "火乍弓单" and "P0RN" belong to such type. The morphs based on visual features are created more casually than textual features based obfuscation. And it is impossible to summarize some generation rules since people can use any visually similar characters or symbols to replace the original terms. Thus makes previous methods fail to identify most content with visual features based obfuscation.

Our Solutions: To this end, we propose a multimodal text matching model to identify obfuscated language.

Firstly, we transfer this problem to a text matching task, where each document is checked whether matches a red-flagged term based on the matching degree of their relevance. Thus can help to overcome the first challenge since we mainly care about the relevance between documents and red-flagged terms no matter the original terms appears in the documents or not.

Besides, we adopt the Bi-directional Long Short Term Memory network(Bi-LSTM) to model textual features, which can help to extract the context information. This is useful to overcome the second challenge. When the original terms or morphs are used in a specific domain, their surrounding information (people, organizations, topics, events, etc) is always similar.

In order to overcome the third challenge, we propose to involve visual features to cover as many as possible candidates. We involve visual features by regarding each document as a source image and each red-flagged term as a template image in a template matching problem from computer vision area [6].

At last, we integrate both textual features and visual features in the neural network to achieve the final matching results. To evaluate the proposed method, we construct a large-scale dataset from Sina Weibo[1], which contains manually annotated labels. Experimental results show that our method outperforms previous methods.

Contributions: This paper presents a multimodal text matching model for identifying obfuscated language given a watch-list of red-flagged terms. To sum up, the contributions are as follows:

- the task of obfuscated language identification is novel and has not been carefully studied in previous methods. In this paper, we frame the problem as a text matching task and evaluate several methods suitable for this task.
- we introduce a multimodal text matching model that combines textual and visual features to identify obfuscated language.
- we conduct experiments on real-world dataset and validate the effectiveness of obfuscated language identification with multimodal features.

2 PROBLEM DEFINITION

The target of this paper is to identify obfuscated language in adversarial communication. The core problem of obfuscated language identification is to check whether a document is relevant to a red-flagged term in the given watch-list. To this end, we frame the given problem as a text matching task formalized as follows.

[1] http://weibo.com

Definition 2.1. Given a set of documents $D = \{d_1, d_2, ..., d_m\}$ and a watch-list of red-flagged term $Q = \{q_1, q_2, ..., q_n\}$. The matching task is to measure each pair of $< d_i, q_j >$ through a scoring function based on the representation:

$$match(d_i, q_j) = F_S(\Phi(d_i), \Phi(q_j))$$

where Φ is a function to map d_i and q_j to a representation vector, and F_S is the scoring function based on the relevance between them.

In this paper, we add a virtual term q_0 to the set Q which means none red-flagged. For each $d_i \in D$, if d_i have the highest matching score with $q_j (j \neq 0)$, then d_i is identified as an obfuscated document relevant to q_j. Note that the original terms or the substitution might appear, or both or neither appears in the obfuscated document.

3 THE PROPOSED MODEL

In this section, we describe our multimodal model for matching each document d_i to a given term q_j. The overall architecture of our proposed model is shown in Figure 1. For clarity, we describe our model in three parts: Textual-level Representation, Visual-level Representation, and Multimodal Fusion. The input of our model is a document d_i and a set of given terms Q. The output of our model is the selected term which gets the maximum probability that d_i belongs to. We will illustrate the details of the proposed framework in the following section.

3.1 Textual-level Representation

The textual-level representation tries to capture textual features of each document. The proposed method is based on the following hypothesis:

Hypothesis 1: When people talk about a subject, the textual context (entities, attributes or events) will be similar no matter whether the corresponding morphs are used or not.

For example, "Big Yao" is a morph of the NBA star "Ming Yao". When people use "Big Yao" to describe "Ming Yao", "Houston Rockets", "NBA", "Basketball" are mostly mentioned in the context, which is almost the same when talking about "Ming Yao".

According to hypothesis 1, the context around the terms and the corresponding morphs would not change much. Thus, we adopt word2vec[15] to generate the feature vector $V = \{v(x_1), ..., v(x_n)\}$ for each document, where $\{x_1, ..., x_n\}$ symbolizes the segments of the document.

To capture the context from both the past and the future, we adopt the Bidirectional LSTM(Bi-LSTM) network, which is a bidirectional formal model of LSTM [16]. Bi-LSTM can use the historical and future states data of input series simultaneously. It connects two recurrent neural networks with positive(forward state) and negative(backward state) time direction to a single output which has proved to be a good solution for expressing context information. With this structure, the output layer can obtain more tremendous information. Meanwhile, Bi-LSTM has the ability to solve the issue of learning long-term dependencies.

The structure of Bi-LSTM model is shown in Figure 2. Two directional neurons of Bi-LSTM do not interact. The general training process is with similar algorithms as LSTM. Forward and backward states are processed first in the forward pass, then do forward pass for output neurons. For the backward pass, output neurons are processed before forward and backward states are passed. Backward pass is similar to standard Back Propagation which involves reusing chain rules. Weights are updated only after the forward and backward passes are complete.

In a single LSTM unit, at the time slice t, the updating equations are as follows:

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \tag{1}$$

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \tag{2}$$

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \tag{3}$$

$$C_t = f_t \times C_{t-1} + i_t \times \tanh(W_C \cdot [h_{t-1}, x_t] + b_C) \tag{4}$$

$$h_t = o_t \times \tanh(C_t) \tag{5}$$

where f_t, i_t, o_t denote the forget gate's activation vector, the input gate's activation vector, and the output gate's activation vector respectively. σ and $tanh$ denote the sigmoid function and the $tanh$ function. C_t denotes the cell state vector and h_t denotes the output vector of the LSTM unit. $W_f, W_i, W_o, W_C, b_f, b_i, b_o, b_C$ denote the weight matrices and the bias vector parameters which need to be learned during training.

Bi-LSTM contains two separate LSTMs to extract both past and future information, where one encodes the sentence from the start to the end, and the other encodes the sentence with the reverse direction. Thus, we can obtain two representations $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$, then the two representations are concatenated to acquire the final output:

$$h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}] \tag{6}$$

After achieving the final hidden states $h_t (t = 1, 2, ..., n)$, the matching probability vector P_{text} corresponding to terms Q can be obtained using $Softmax$, which is the extracted feature of the textual-level representation.

$$P_{text} = Softmax(h_1, h_2, ..., h_n) \tag{7}$$

3.2 Visual-level Representation

The visual-level representation module captures the visual features based on template matching technique in computer vision. Template matching has proven to be a useful solution in digital image processing for finding small parts of a source image which matches a template image. This is similar to match documents with red-flagged terms. The red-flagged terms can be regarded as template images, and the documents to be checked can be regarded as source images. Then the matching process is like the template matching process to find the source images that match the template images. An example of a source image, a template image and the search area is shown in Figure 3. The arrow indicates the direction of the movement of the template.

Firstly, the red-flagged terms Q and documents D are all transferred to corresponding text images, where the font, size and color are unified. Given a document d_i and a red-flagged term q_j, the corresponding images are denoted as I and T. Then the template matching process is as follows.

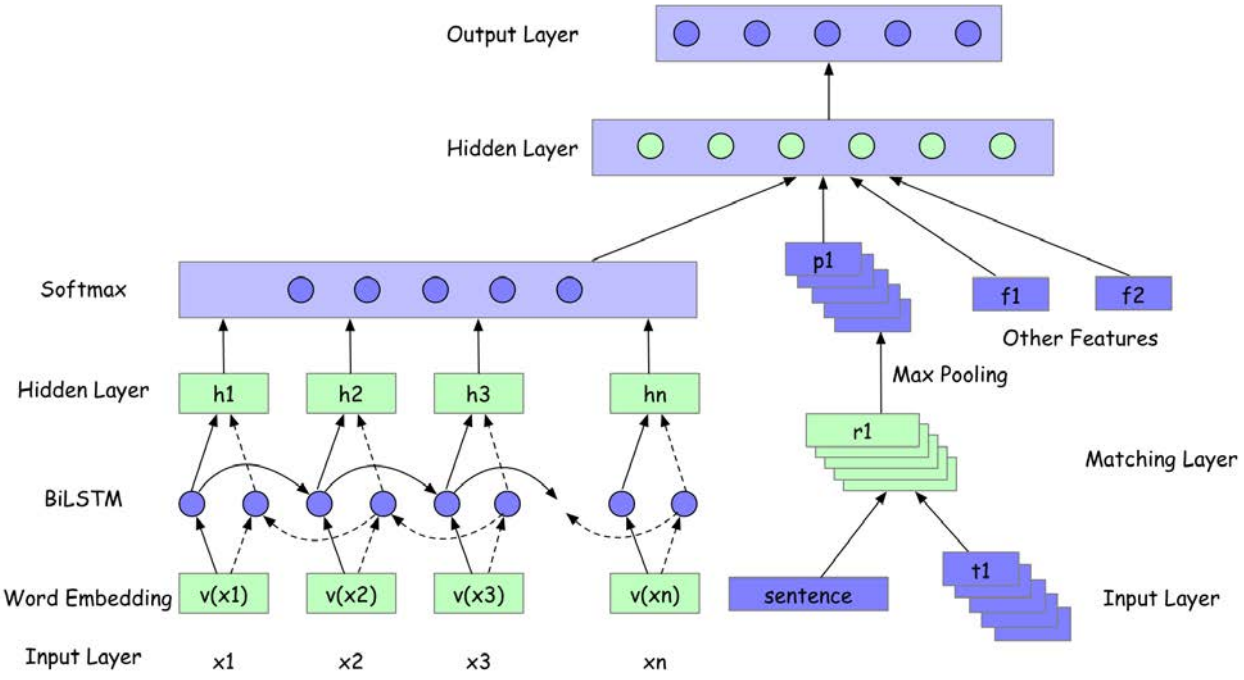

Figure 1: Architecture of the proposed multimodal model.

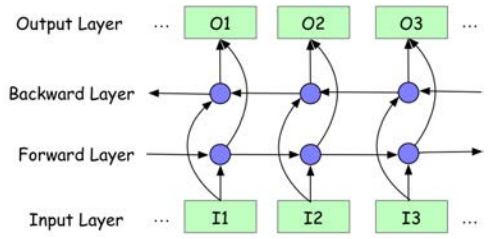

Figure 2: Structure of the Bi-LSTM model.

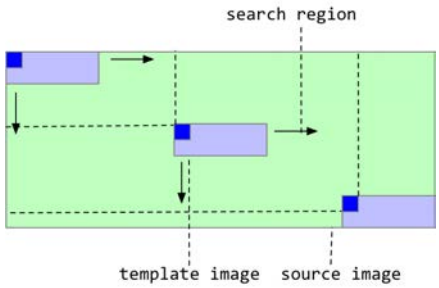

Figure 3: Source image, template image and search area.

(1) Position the template T over the image I at every possible location. In order to avoid phrases spanning multiple lines, I is generated with all content in only one line. That is, the height of I is identical to T. Then T is moved horizontally over I with one pixel each time.

(2) For each time T is positioned, we will compute the numeric metric of similarity between the template T and the image segment it currently overlaps with. The metric represents how similar the template T is to that segment of the source image I.

(3) For each location of T over I, the metric is stored in the result matrix R. Since the height of I is identical to T, R is an array in our experiment. Each location (x, y) in R contains the matching metric (normalized correlation matching):

$$R(x,y) = \frac{\sum_{x',y'} T(x',y') \cdot I(x+x', y+y')}{\sqrt{\sum_{x',y'} T(x',y')^2 \cdot I(x+x', y+y')^2}} \tag{8}$$

where (x, y) is the coordinate of the location T over I. (x', y') is the coordinate of the pixels in T. $T(x, y)$ and $I(x, y)$ is the RGB value of the pixel at the location.

(4) After T is slidden over the whole area of I and each $R(x, y)$ is calculated, the global max pooling is applied on the $R(x, y)$, which is done by applying a max filter to non-overlapping subregions of the initial representation. Then a vector P_{visual} is obtained:

$$P_{visual} = MaxPool(R) \tag{9}$$

Thus, P_{visual} is the output of the visual-level representation module. The highest value $Smax$ in P_{visual} corresponds to the matching position in R.

3.3 Multimodal Fusion

After achieving the outputs of the textual-level and the visual-level representations with the equations (7) and (9), we come to the multimodal fusion process. An existing work demonstrates that some non-linear interactions between the sentence vectors can help to learn good representations[17]. To achieve this, we include two common pair-wise vector operations: subtraction and multiplication. Then the integration process is as follows.

$$f_1 = P_{text} - P_{visual} \tag{10}$$

$$f_2 = P_{text} \times P_{visual} \tag{11}$$

$$F = P_{text} \oplus P_{visual} \oplus f_1 \oplus f_2 \tag{12}$$

where f_1 and f_2 denote two combining operations of P_{text} and P_{visual}. F denotes the final fusion features.

Finally, we utilize a Multi-Layer Perceptron (MLP) to serve as a matching model in which F is a input vector. Then F is considered to compute the probability distribution and the output layer presents the matching results.

4 EXPERIMENTS

4.1 Datasets

We crawl 1,245,812 tweets from Sina Weibo from October 1 to 31, 2017. We select 55 keywords as red-flagged terms and 186 morphs corresponding to the terms are found from the tweets. Some examples are shown in Table 1. Then we sample 43,206 non-redundant tweets as the experimental dataset and label them by three independent annotators. The annotated dataset is then randomly split into training set(27,642 tweets), development set(6,910 tweets) and test set(8,654 tweets). We tune parameters on the development set and apply them to get final results on test set.

All the 43,206 tweets are annotated by three Chinese native speakers. Each tweet is annotated with a red-flagged term or not. A tweet would be labeled with a given term as long as the tweet mentions the meaning of the term no matter the original term is used or not. Due to the polysemy of natural language, a tweet including a red-flagged term is possible to be annotated irrelevant with the given term.

4.2 Baselines

In this part, we will describe the methods in the comparative experiments. We mainly concern three groups of methods suitable for the given problem: classification methods, morph recognition methods and text matching methods. The methods are listed as follows:

- **Classification methods**: Such methods treat the problem in this paper as a classification problem. Each document will be classified into two categories (Relevant with the red-flagged terms or not). We select four popular models: **Naive Bayes (NB)**[20], **Logistic Regression (LR)**[21], **Decision Tree (DT)**[14] and **Support Vector Machine (SVM)**[22].
- **Morph Recognition methods**: Such methods are used to find all possible morphs to expand red-flagged terms for scanning. We select two state-of-art work on morph recognition **CEMD**[25] and **KIEM**[12]
- **Text Matching methods**: Such methods are used to match each document to the given terms, which is the same as our methods. We select one state-of-art work **MatchPyramid**[19], which takes text matching as image recognition.

4.3 Evaluation Metrics

To evaluate different methods mentioned above, we compare the outputs of different methods against the ground truth. The metrics for comparison are precision, recall and F1.

$$precision = \frac{|M_i \cap GT|}{|M_i|} \tag{13}$$

$$recall = \frac{|M_i \cap GT|}{|GT|} \tag{14}$$

$$F1 = \frac{2 \times precision \times recall}{precision + recall} \tag{15}$$

where M_i is the set of output tweets by the i-th method, GT is the set of tweets with red-flagged labels.

4.4 Parameter Setting

To initialize the word embeddings used in our method, we pre-train the word embeddings on 2 million documents from Sina Weibo and news websites. The sentence length is set to 20. The dimensions of the word embeddings and Bi-LSTM units are set 200. The model is trained using RMSprop optimizer with a learning rate 0.001.

4.5 Results Analysis

Overall Evaluation. Table 2 shows the comparison results on precision, recall and F-measure. From the results, we can observe that our approach performs better than the other methods. The morph recognition methods CEMD and KIEM perform better than the classification methods because they extend the original terms by finding more morphs. But they fail to generate all correct morphs so that the precision and recall are not as good as our proposed methods. Though MatchPyramid also solve this problem in a text matching way, the F1 of our approach is 12% better than it. This validates the benefit of involving visual features.

Zero-shot Evaluation. We now turn to the evaluation of generalization behavior with respect to some obfuscated morphs that have been never seen by the systems. We consider the zero-shot

Table 1: Some Examples in Datasets

Red-flagged Terms	Morphs	Tweets
炸弹(Bomb)	火(Fire)乍(Sudden)弓(Arrow)单(Single)	如何组装N2火乍弓单 How to assemble the bomb N2
赌博(Gamble)	堵(block)博(doctor)	我的梦想就是靠堵博发家致富 My dream is to become rich through gambling
裸体(Nude)	果(Fruit)体(Body)	电影中十大令人难忘的果体场面... Top-10 nude scenes in movies...

Table 2: Overall Evaluation Result

Methods	Precision	Recall	F1
NB	0.82	0.64	0.72
LR	0.83	0.66	0.74
DT	0.84	0.63	0.72
SVM	0.85	0.66	0.74
CEMD	0.86	0.81	0.83
KIEM	0.88	0.85	0.86
MatchPyramid	0.87	0.77	0.82
Our Approach	**0.93**	**0.91**	**0.92**

setting, i.e. some morphs for the original terms only appear in the test set and are not used during training. This is more similar with practical cases because morphs are not static and evolves rapidly over time. The evaluation results are summarized in Table 3. Our approach also performs best in comparison with the other methods. The drop ratio means the decrease compared with the overall evaluation. We can observe that our approach also achieves the lowest drop ratio. Previous methods fail to keep high precision and recall if they never see the morphs in training set since the context might also change when a new morph is created. The result also validates that our approach can cover more kinds of obfuscation by combining textual and visual features.

Table 3: Zero-Shot Evaluation Result

Methods	Precision	Recall	F1	Drop Ratio
NB	0.49	0.34	0.40	44.16%
LR	0.67	0.41	0.51	30.82%

Our Approach	**0.84**	**0.82**	**0.83**	**9.79%**

5 RELATED WORK

Obfuscated Language Identification has been recently proposed [13]. Several previous work on name alias detection, word obfuscation, and morph resolution can contribute to this task. The basic idea of detecting name alias is automatically finding the patterns between the real names and aliases, and then these patterns are utilized to search for candidates. In the end, various ranking scores are calculated to measure the associations between a name and its candidates [3, 4, 10]. Yin et al. introduce a system to extract and rank name aliases in emails [23]. However, the co-occurrence of the real names and aliases is not common in most adversarial communications. Brennan et al. summarize three types of approaches to create adversarial messages: obfuscation, imitation, and translation [5]. They find manual circumvention approaches work best, while automated translation approaches are not so effective. Other recent work detects word obfuscation in adversarial communication using existing commonsense Knowledge Bases such as ConceptNet to expand similar words for substitution [1, 7]. Morph resolution is another closely related work to this task which aims to resolve the morphs to the target entities. Encoding and decoding entity morph is a special case of coded name alias to hide the original entities for evading censorship[11, 12, 24, 25]. Recent works propose a number of novel methods to automatically encode implicit and relevant morphs[24], including Phonetic Substitution, Spelling Decomposition, Nickname Generation, Translation and Transliteration and Historical Figure Mapping, which can effectively avoid decoding detection. They also study on effective morph decoder methods, which can automatically recognize and resolve entity morphs to their real targets [11, 12, 25]. Such methods need to take the encoding rules into consideration.

Our model differs from these previous methods, and improves the model in two critical ways: (1) propose a multimodal text matching model which can overcome the challenges of Synonymy and Polysemy and Domain Knowledge. (2) incorporate visual features to cover as many as possible morphs in obfuscated language

6 CONCLUSIONS

In this work, we propose a multimodal text matching model for obfuscated language identification. We introduce a multimodal model by integrating a text-level module and a visual-level module. In textual level, we employ Bi-LSTM model to extract the matching probability feature. In visual level, we utilize template matching to get the visual matching feature. Finally, we evaluate our approach with a manually annotated dataset collected from Sina Weibo. Compared to other state-of-the-art models that use only textual features, the performance of the proposed method is much better. We will try to extend to other languages in the future.

ABSTRACT

The Web is a tangled mass of interconnected services, where websites import a range of external resources from various third-party domains. The latter can also load resources hosted on other domains. For each website, this creates a dependency chain underpinned by a form of implicit trust between the first-party and transitively connected third-parties. The chain can only be loosely controlled as first-party websites often have little, if any, visibility on where these resources are loaded from. This paper performs a large-scale study of dependency chains in the Web, to find that around 50% of first-party websites render content that they did not directly load. Although the majority (84.91%) of websites have short dependency chains (below 3 levels), we find websites with dependency chains exceeding 30. Using VirusTotal, we show that 1.2% of these third-parties are classified as suspicious — although seemingly small, this limited set of suspicious third-parties have remarkable reach into the wider ecosystem.

1 INTRODUCTION

In the modern web ecosystem, websites often load resources from a range of third-party domains such as ad providers, tracking services, content distribution networks (CDNs) and analytics services. This is a well known design decision that establishes an *explicit trust* between websites and the domains providing such services. However, often overlooked is the fact that these third-parties can further load resources from other domains, creating a *dependency chain*. This results in a form of *implicit trust* between first-party websites and any domains loaded further down the chain.

Consider the `bbc.com` webpage, which loads JavaScript from `widgets.com`, which, upon execution loads additional content from another third-party, say `ads.com`. Here, `bbc.com` as the first-party website, *explicitly* trusts `widgets.com`, but *implicitly* trusts `ads.com`. This can be represented as a simple dependency chain in which `widgets.com` is at level 1 and `ads.com` is at level 2. Past work tends to ignore this, instead, collapsing these levels into a single set of third-parties [4, 22]. Here, we argue that this overlooks a vital aspect of website design. For example, it raises a notable security challenge, as first-party websites lack visibility on the resources loaded further down their domain's dependency chain. This potential threat should not be underestimated as errant active content (*e.g.,* JavaScript) opens the way to a range of further exploits, *e.g.,* Layer-7 DDoS attacks [23] or massive ransomware campaigns [15].

This paper studies dependency chains in the web ecosystem. Although there has been extensive work looking at the presence of third-parties in general [4, 20, 22], little work has focused on how content is indirectly loaded. We start by inspecting how extensive dependency chains are across the Alexa's top-200K (Section 2). We confirm their prominence, finding that around 50% of websites *do* allow third-parties to form dependency chains (*i.e.,* they implicitly trust third-parties they do not directly load). The most commonly *implicitly* trusted third-parties are well known operators, *e.g.,* `google-analytics.com` and `doubleclick.net`: these are implicitly imported by 68.3% (134,510) and 46.4% (91,380) websites respectively. However, we also observe a wide range of more obtuse third-parties such as `pippio.com` and `51.la` imported by 0.52% (1,146) and 0.51% (1,009) of websites. Although the majority (84.91%) of websites have short chains (with levels of dependencies below 3), we find first-party websites with dependency chains exceeding 30 in length. This not only complicates page rendering, but also creates notable attack surface.

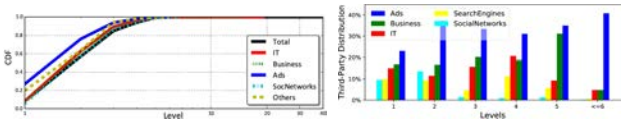
We then proceed to inspect if *suspicious* or even potentially *malicious* third-parties are loaded via these long dependency chains (Section 4). We do not limit this to just traditional malware, but also include third-parties that are known to mishandle user data and risk privacy leaks. Using the VirusTotal API [14], we classify third-party domains into innocuous *vs.* suspicious. When using a reasonable classification threshold, we find that 1.2% of third-parties are classified as suspicious. Although seemingly small, we find that this limited set of suspicious third-parties have remarkable reach. 73% of websites under-study load resources from suspicious third-parties,

and 24.8% of first-party webpages contain at least 3 third-parties classified as suspicious in their dependency chain. This, of course, is impacted by many considerations which we explore — most notably, the power-law distribution of third-party popularity, which sees a few major players on a large fraction of websites. We share our datasets, experimental testbed code and scripts used in this paper with the wider research community for further analysis of the consequences of implicit trust `https://wot19submission.github.io`.

2 DATASET AND DATA ENRICHMENT

2.1 Data Collection

We obtain the resource dependencies of the Alexa top-200K websites' main pages[1] using the method described in [18]. This Chromium-based Headless [6] crawler renders a given website and tracks resource dependencies by recording network requests sent to third-party domains. The requests are then used to reconstruct the dependency chains between each first-party website and its third-party URLs. Note that each first-party can trigger the creation of multiple dependency chains (to form a tree structure). To construct the dependency tree, we identify third-party requests by comparing the second level domain of the page (*e.g.,* `bbc.com`) to the domains of the requests (*e.g.,* `cdn.com` and `ads.com` via `widgets.com`). Those with different second level domains are considered third-party. We ignore the sub-domains so that a request to a domain such as `player.bbc.com` is not considered as third-party. Due to the lack of purely automated mechanism to disambiguate between site-specific sub-domains (*e.g.,* `player.bbc.com`) or country-specific sub-domains (*e.g.,* `bbc.co.uk`), we leverage Mozilla Public Suffix list [27] and `tldextract` [19] for this task. From the Alexa Top-200k websites, we collect 11,287,230 URLs which consist of 6,806,494 unique external resources that correspond to 68,828 and 196,940, respectively, unique second level domains of third- and first-parties.



Constructing the dependencies between objects in a webpage is a non-trivial task. In cases where third-party JavaScript gets loaded into a first-party context, and then makes an AJAX request, the HTTP(S) request appears to be from the first-party (i.e. the *referrer* will be the first-party). To overcome such cases and to preserve the information on relations between the nested resource dependencies, we allow the crawler to include the URL of the third-party from which the JavaScript was loaded by first-party.

To augment the dependency data, we use VirusTotal which is an online solution which aggregates the scanning capabilities provided by more than 68 AV tools, scanning engines and datasets. It has been commonly used in the academic literature to detect malicious apps, executables, software and domains [7, 11, 13, 16, 17]. We use the VirusTotal report APIs to obtain the VTscore for each third-party URL. This score represents the number of AV tools that flagged the website as malicious (max. 68). The reports also contain meta-information such as the first scan date, scan history, domain name resolution (DNS) history, website or domain category, reverse DNS, and whois information. We further supplement each domain with their WebSense [31] category provided by the VirusTotal's record API. During the augmentation, we eliminate repeating, unresponsive or invalid URLs in each dependency chain. Thus, we collect the above metadata for each second level domain in our dataset. This results in a final sample of 196,940 first-party websites, and 68,828 third-party domains.

[1]We select the top 200K as this gives us broad coverage of globally popular websites, whilst also remaining tractable for our subsequent data enrichment activities.

Table 1: Overview of the Dataset for different ranges of Alexa's ranking. The rows indicate the proportion of Alexa's Top-X websites that explicitly and implicitly trust at least one third-party (*i*) resource (of any type); and (*ii*) JavaScript.

	Alexa Rank					
	1-200K	1-10K	190-200K	10-50K	50-100K	100-200K
F.-Parties that trust:						
All Resources:						
Explicit (Lvl. 1)	95%	95%	95%	94%	95%	95%
Implicit (Lvl. ≥ 2)	49.7%	55.1%	47.9%	51.8%	50.23%	48%
JavaScript:						
Explicit	91%	92%	91%	91%	91%	90%
Implicit	49.5%	55%	47.8%	51.69%	50%	47.8%

(a) (b)

Figure 1: (a) CDF of dependency chain lengths (broken down into categories of first-party websites); and (b) distribution of third-party websites across various categories and levels.

3 EXPLORING THE CHAINS

We begin by exploring the presence and usage of implicit trust chains. We first confirm if websites do, indeed, rely on implicit trust and then explore how these chains are used.

3.1 Do websites rely on implicit trust?

Overall, the Top-200k dataset makes 11,287,230 calls to 6,806,494 unique external resources, with a median of 27 external resources per first-party website. To dissect this, Table 1 presents the percentage of webpages in each Alexa range that load explicitly and implicitly trusted third-parties. Confirming prior studies [4, 20], it shows that 95% of websites import external resources, with 91% importing externally hosted JavaScript. More important is that observation that around 50% of the websites *do* rely on implicit trust chains, *i.e.,* they allow third-parties to load further third-parties on their behalf. The propensity to form dependency chains is marginally higher in more popular websites; for example, 55% in the Alexa top 10K have dependency chains compared to 48% in the bottom 10K (*i.e.,* rank 190-200K). In other words, more popular websites tend to rely more on implicitly trusted third-parties.

These implicitly trusted third-parties appear at various positions in the dependency chain. Intuitively, long chains are undesirable as they typically have a deleterious impact on page load times [30] and increase attacks surface. Figure 1a presents the CDF of chain length for all first-party websites. For context, websites are separated into their sub-categories.[2] It shows that 80% of the first-party websites create chains of trust of length 3 or below. However, there is also a small minority that dramatically exceed this chain length:

[2]We only include the most popular categories.

Table 2: Breakdown of resource types requested by the Top-200K websites across each level in the dependency chain.

Lev.	Total	Image	JS	Data	Font/CSS	Uncat.
1	9,212,245	34.4%	30.6%	16.0%	7.8%	11.3%
2	1,566,841	48.8%	16.7%	11.7%	3.3%	19.4%
3	405,390	45.0%	12.3%	11.1%	1.3%	30.2%
4	78,107	41.8%	18.4%	8.0%	8.1%	23.6%
5	14,413	40.6%	18.0%	12.8%	2.0%	26.4%
≥6	10,208	36.6%	12.3%	13.0%	1.2%	36.8%

we find that all website categories import ≈2% of their external resources from level 3 and above. In the most extreme case, we see `rg.ru` (news) with a chain containing 38 levels, consisting of mutual calls between `adriver.ru` (ad provider) and `admelon.ru` (IT website). Other notable examples include `thecrimson.com.bg` (Harvard's student newspaper), `argumenti.ru` (news), `mundomax.com` (IT news), `lifestyle.bg` (entertainment), which have a maximum dependency level of 15. We argue that these complex configurations make it extremely difficult to reliably audit such websites, as a first-party cannot be assured of which objects are later loaded.

3.2 What objects exist in the chain?

The previous section has confirmed that a notable fraction of websites create dependency chains with (up to) tens of levels. We next inspect the types of resources imported within these dependency chains. We classify resources into four main types: Image, JavaScript, Data (consisting of HTML, JSON, XML, plain text files), and CSS/Fonts. Table 2 presents the volume of each resource type imported at each level in the trust chain. We observe that the make-up of resources varies dramatically based on the level in the dependency chain. For example, the fraction of images imported tend to increase — this is largely because third-parties are in-turn loading images (*e.g.,* for adverts). In contrast, the fraction of JavaScript decreases as the level in the dependency chain increases: 30.6% of resources at level 1 are JavaScript compared to just 12.3% at level 3. This trend is caused by the fact that new levels are typically created by JavaScript execution (thus, by definition, the fraction of JavaScript must deplete along the chain). However, it remains at a level that should be of concern to web engineers as this confirms a significant fraction of JavaScript code is loaded from potentially unknown implicitly trusted domains.

To build on this, we also inspect the *categories* of third-party domains hosting these resources. Figure 1b presents the make-up of third-party categories at each level in the chain. It is clear that, across all levels, advertisement domains make up the bulk of third-parties. We also notice other highly demanded third-party categories such as search engines, Business and IT. These are led by well known providers, *e.g.,* `google-analytics.com` (web-analytics[3]) is on 68.3% of pages. The figure also reveals that the distributions of categories vary across each dependency level. For example, 23.1% of all loaded resources at level 1 come from advertisement domains, 37.3% at level 2, 46.2% at level 3, *i.e.,* the proportion increases across dependency levels. In contrast, social network third-parties (*e.g.,* Facebook) are mostly presented at level 1 (9.58%) and 2 (13.57%) with a significant drop at level 3. The dominance of advertisements is not, however, caused by a plethora of ad domains: there are far fewer ad domains than business or IT (see Table 3). Instead, it is driven by the large number of requests to advertisements: Even though ad domains only make-up 1.5% of third-parties, they generate 25% of resource requests. Importantly, these popular providers can trigger further dependencies; for example, `doubleclick.com` imports 16% of its resources from further implicitly trusted third-party websites. This makes such domains an ideal propagator of malicious resources for any other domains having implicit trust in it.

4 FINDING SUSPICIOUS CHAINS

We next study the existence of *suspicious* third-parties, which could lead to abuse of the implicit trust. Within this section we use the term *suspicious* (to be more generic than malicious) because VirusTotal covers activities ranging from low-risk (*e.g.,* sharing private data over unencrypted channels) to high-risk (malware).

4.1 Do chains contain suspicious parties?

First, we inspect the fraction of third-party domains that trigger a warning by VirusTotal. From our third-party domains, 2.5% have a VTscore of 1 or above, *i.e.,* at least one virus checker classifies the domain as suspicious. If one treats the VTscore as a ground truth, this confirms that popular websites *do* load content from suspicious third-parties via their chains of trust. However, we are reticent to rely on VTscore ≥ 1, as this indicates the remaining 67 virus checkers did not flag the domain.[4] Thus, we start by inspecting the presence of suspicious third-parties using a range of thresholds.

Table 3 shows the fraction of third-parties that are classified as suspicious using several VTscore thresholds. For context, we separate third-parties into their respective categories (using WebSense). The table confirms that a noticeable subset of suspicious third-party domains exist; for example, if we classify any resource with a VTscore ≥ 10 as suspicious, we find that 1.2% of third-party domains are classified as suspicious with 6.2% of all resource calls in our dataset going to these third-parties. Notably this only drops marginally (to 5.7%) with a *very* conservative VTscore of ≥ 40. We observe similar results when considering thresholds in the [3..50] range. This confirms, with a high certainty, that approximately 6% of resource calls in the dependency chains are towards domains that engage in suspicious activity (further detailed in [12]). We will conservatively refer to domains with a VTscore ≥ 10 as suspicious in the rest of this analysis.

We also check if dependency chains contain suspicious JavaScript resources. We focus on JavaScript as active content poses greater threats, *e.g.,* cross-site scripting (XSS) and advanced phishing [20]. Table 4 shows the top first-party domains, ranked according to the number of unique suspicious third-parties in their chain of dependency. We note that the top ranked (most vulnerable) first-party domains belong to various categories such as Content Sharing, News, or IT. This indicates that there is no one category of domains that inherits suspicious JavaScript. However, we note that

[3]Grouped as in business category as per VirusTotal reports.

[4]Diversity is likely caused by the virus databases used by the different virus checkers [2]

Table 3: Overview of suspicious third-parties in each category. Col.2-4: number of third-party websites in different categories, the number of resource calls to resources, and the proportion of calls to suspicious JavaScript. Col.5-9: Fraction of third-party domains classified as suspicious (*Num.*), and fraction of resource calls classified as suspicious (*Vol.*), across various VTscores (i.e., ≥ 3 and ≥ 55).

				VTScore ≥ 3		VTScore ≥ 10		VTScore ≥ 20		VTScore ≥ 40		VTScore ≥ 55	
Category	Third-Parties	Total Calls	Suspicious JS	Num.	Vol.	Num.	Vol.	Num.	Vol.	Num.	Vol.	Num.	Vol.
All	68,828	11,287,204	270,758 (2.4%)	1.6%	6.4%	1.2%	6.2%	1.0%	6.1%	0.6%	5.7%	≤ 0.1%	≤ 0.1%
Business	6,786	1,924,591	184,360 (9.6%)	1.5%	21.5%	1.1%	21.5%	1.0%	21.4%	0.5%	20.6%	0%	0%

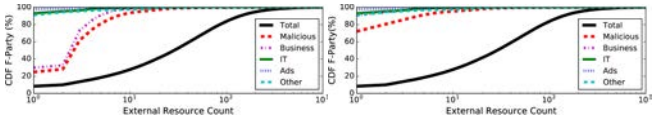
IT	8,619	1,646,287	10,547 (0.6%)	2.2%	3.8%	1.5%	3.6%	1.2%	3.5%	0.6%	3.0%	≤ 0.1%	≤ 0.1%
Other	52,406	4,845,844	67,927 (1.4%)	1.4%	4.6%	1.1	4.3%	0.9%	4.2%	0.6%	3.8%	≤ 0.1%	≤ 0.1%



first party websites categorized as "Business" represent the majority of most exposed domains at Level ≥2, with 16% of the total number of first-party domains implicitly trusting suspicious JavaScript belonging to the Business Category, with distant second being the "News & Media" Category and third the "Adult" category. The number of suspicious JavaScript codes loaded by these first-party domains ranges from 4 to 31. We note the extreme case of `amateur-fc2.com` website *implicitly* importing 31 unique suspicious JavaScript programs from 4 unique suspicious domains. Moreover, we observe at most 7 unique third-parties (combining both explicit and implicit level) that is a cause of suspicious JavaScripts in first-parties. This happens for `privet-rostov.ru` domain, having third-party domains such as `charter.com, vk.com. rambler.ru, doubleclick.net, dx.com, cdn.adlegend.com, syncsw.pool.datamind.ru`.

Table 4: Top 5 most exposed first-party domains (with VTscore ≥ 10) ranked by the number of unique suspicious domains.

	Unique Suspicious Domains at Level = 1					
#	First-party Domain	Alexa Rank	# Mal. JSes	Unique Susp. Doms.	Category	Chain Len.
1	theinscribermag.com	46,242	6	5	Blogs	5

2	radionetplus.ru	166,003	8	4	SW Download	6
3	studiofow.tumblr.com	85,483	11	4	Adult	4
4	amateur-fc2.com	52,556	31	4	Adult	5
5	fasttorrent.ru	24,250	9	4	File Sharing	7

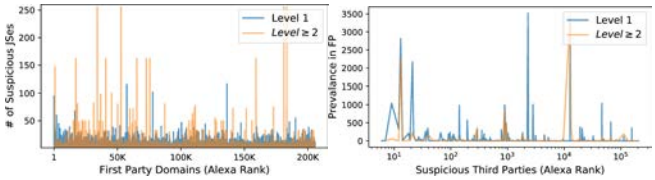
4.2 How widespread are suspicious parties?

We next inspect how widespread these suspicious third-parties are at each position in the dependency chain, by inspecting how many websites utilize them. Figure 2a displays the cumulative distribution (CDF) of resource calls to third-parties made by each first-party webpage in our dataset. Within the figure, we decompose the third-party resources into various groups (including total *vs.* suspicious). The figure reveals that suspicious parties within the dependency chains are commonplace: 24.8% of all first-party webpages contain at least 3 third-parties classified as suspicious in their dependency chain. Remarkably, 73% of first-party websites load resources from

(a) All websites (b) Without google-analytics

Figure 2: CDF of resources loaded per-website from various categories of third-parties.

third-parties at least once. Hence, even though only 1.6% of third-party domains are classified as suspicious, their reach covers nearly three quarters of websites (indirectly via implicit trust).



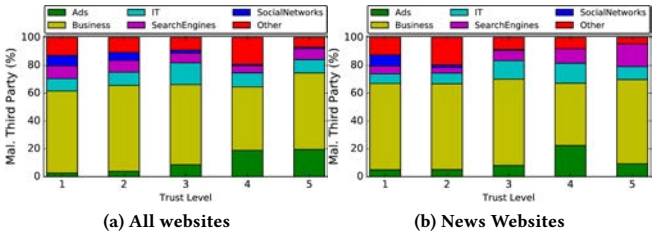
The above is demonstrated in Table 5, which presents the top 10 most frequently encountered suspicious third-party domains that are providing suspicious JavaScript. It can be seen that popular third-party domains exist across *many* first-party sites. The top 20% of third-party domains cover 86% (9,650,582) of all resource calls. Closer inspection shows that it is driven by one prominent third-party: `google-analytics.com`. At first, we thought that this was an error, however, during the measurement period `google-analytics.com` obtained a VTscore of 51, suggesting a high degree of certainty. This was actually caused by `google-analytics.com` loading another third-party, `sf-helper.net`, which is known to distribute adwares and spywares. It is unclear why Google was performing this. We therefore repeated these checks in October 2018, to confirm that this activity has ceased, and `sf-helper.net` is no longer loaded. To understand the impact its new de-classification has, Figure 2b shows the distribution of resource calls to third-party categories when `google-analytics.com` is benign. This reduces the number of first-party websites exposed to suspicious resources by 63%. This highlights effectively the impact of high centrality third-parties being permitted to load further resources: the infection of just one can immediately effect a significant fraction of websites.

4.3 How popular are suspicious third-parties?

We next test if widespread suspicious third-parties are also highly ranked within Alexa. We treat this as a proxy for global popularity. Beyond `google-analytics.com` we find several other suspicious third-party domains from the Top 100 Alexa ranking. For-instance, `vk.com`, a social network website mostly geared toward East European countries has been used by 3,094 first-parties and is ranked 13 by Alexa. This website is found to be one of the most prevalent suspicious third-party domains at both level 1 and levels ≥ 2. An obvious reason for this domain's presence is because of other infected (malware-based) apps that try to authenticate users from

Table 5: Top 5 most prevalent suspicious third-party domains (with VTscore ≥ 10) on level 1 (explicit trust) and beyond (implicit trust) providing resources to first-parties. #FP refers to the number of First-party domains having the corresponding suspicious third-party domain in their chain of dependency.

#	Third-party Domain	Alexa Rank	# FP	Category
Prevalence of Third-parties at Level = 1				
1	google-analytics.com	13,200	43,156	Business (Web Analytics)
2	gravater.com	2,292	3,520	IT
3	charter.com	12,714	3,425	Business
4	vk.com	13	2,815	Social Network
5	statcounter.com	2,265	2,327	Business (Web Analytics)
Prevalence of Third-parties at Level ≥ 2				
1	charter.com	12,714	3,452	Business
2	vk.com	13	2,290	Social Network
3	livechatinc.com	888	851	Web Chat
4	onesignal.com	950	467	Business
5	rambler.ru	291	370	SearchEngine



(a) (b)

Figure 3: Figure (a) depicts the number of suspicious JavaScript content imported (explicitly and implicitly) by first-party domains shown according to their Alexa ranking; and (b) shows the number of impacted first-party domains as function of the ranking of domains of Suspicious JavaScript.

such domains [24]. Other websites such as `statcounter.com` or `gravater.com` are also among the most prevalent third party domains in level 1. These websites were reported to contain malware in their Javascript codes [3]. For instance, users in statcounter forums reported it as malicious because a Javascript running its website redirects users to a malware website `gocloudly.com`, and forces users to click the button [5].

More generally, we observe the presence of a wide range of Alexa ranks in the list of most prevalent domains at levels ≥ 2. In Figure 3a, we show the number of suspicious JavaScripts imported by the first-party domains (Y-axis) according to their Alexa rank (X-axis). Overall, first-party domains import a larger number of suspicious third-party JavaScript codes at levels ≥ 2, however, the first-party domains seem to be equally vulnerable to the implicit import of suspicious content regardless of their rank. There are exceptions though, signified by the peaks in the number of suspicious JavaScripts — these are near exclusively driven by a large number of ≥level-2 scripts (implicit trust). We also encounter an interesting case, which we exclude from the graphs for readability purposes: The first-party domain `kikar.co.il` imports 2,592 JavaScript codes originating from the third-party `hwcdn.net`, a well-known browser hijacker that has been reported to force users to visit spam pages [29]. The VirusTotal API indicates a VTscore of 22 for this suspicious domain. We also note that 35 other first-party

(a) All websites (b) News Websites

Figure 4: Distribution of calls to suspicious third-party websites per category at each level, for all top-200K websites (Figure 4a) and most vulnerable first-party category (Figures 4b).

domains have this domain in their chain of dependency. Again, this highlights the risk of implicit trust.

In Figure 3b we show the number of impacted first-party domains as a function of the Alexa Rank of suspicious third-party domains (limited to a maximum Alexa Rank of 1 million) — note the log scale of X-axis. We observe that some very prevalent third-parties have a high Alexa ranking (even excluding `google-analytics.com`). For instance, note a spike around the 2000 rank, which reaches a prevalence of 3500 first-party domains at level 1. This spike is caused by `gravatar.com`, propagating suspicious Javascripts. This supports our statements earlier (from Table 5) where `gravatar.com` is ranked second top most suspicious domain. Similarly, a spike around 10K rank indicates the presence of `charter.com` both at level 1 and 2 respectively. These findings demonstrate the wide variety of third-party suspicious JavaScript content loaded from various, not necessarily "obscure", third-party domains.

4.4 At which level do suspicious third-parties occur?

Next, we inspect the location(s) in the dependency chain where these suspicious third-parties are situated. This is vital, as implicitly trusted (≥level 2) resources are far more difficult for a first-party administrator to remove. Table 6 presents the proportion of websites that import at least one resource with a VTscore ≥ 10. We separate resources into their level in the dependency chain. The majority of resources classified as suspicious are located at level 1 in the dependency chain (*i.e.,* they are explicitly trusted by the first-party). 73% of websites containing suspicious third-parties are "infected" via level 1. This suggests that these website operators are not entirely diligent in monitoring their third-party resources. This might include websites that purposefully utilize such third-parties [8]. Perhaps more important, the above leaves a significant minority of suspicious resources imported via *implicit* trust (*i.e.,* level ≥ 2). In these cases, the first-party is potentially unaware of their presence. The most vulnerable category is news: over 15% of news sites import *implicitly* trusted resources from level 2 with a VTscore ≥ 10. Notably, among the 56 news websites importing suspicious JavaScript resources from trust level 3 and deeper, we find 52 loading advertisements from `adadvisor.net`. One possible reason is that ad-networks could be infected or victimized with malware to perform malvertising [21, 28].

Table 6: Proportion of top-200K websites importing resources classified as suspicious (with VTscore ≥ 10) at each level.

Lv.	All		News		Sports		Entertainment		Forums	
	All	JS	All	JS	All	JS	All	JS	All	JS
1	61.30%	57.70%	75.40%	73.50%	75.70%	73.20%	69.30%	65.60%	67.40%	65.50%
2	5.20%	2.20%	13.40%	5.60%	11.10%	3.70%	8.60%	4.10%	9.10%	4.05%
3	1.30%	0.18%	2.90%	0.45%	3.60%	0.28%	2.70%	0.30%	3.20%	0.15%
4	0.22%	≤ 0.1%	0.64%	0.08%	0.80%	≤ 0.1%	0.70%	0.08%	0.60%	0.00%
≥ 5	≤ 0.1%	0	0.002	≤ 0.1%	0.001%	≤ 0.1%	0.002%	≤ 0.1%	≤0.001%	0.00%

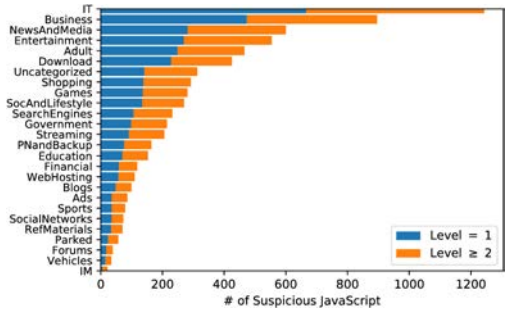


Figure 5: Breakdown of JavaScript resources based on category of domain. Uncategorized category includes domain such as `newmyvideolink.xyz` **and** `cooster.ru`

Similar, albeit less extreme, observations can be made across Sports, Entertainment, and Forum websites. Briefly, Figure 4 displays the categories of (suspicious) third-parties loaded at each level in the dependency chain — it can be seen that the majority are classified as business. This is, again, because of several major providers classified as suspicious such as `convexity.net` and `charter.com`. Furthermore, it can be seen that the fraction of advertisement resources also increases with the number of levels due to the loading of further resources (*e.g.,* images).

Figure 5 also presents the breakdown of the domain categories specifically for suspicious JavaScript resources. Clear trends can be seen, with IT (e.g., `dynaquestpc.com`), Business (*e.g.,*`vindale.com`), News and Media (e.g., `therealnews.com`), and Entertainment (*e.g.,*`youwatchfilm.net`) dominating. Clearly, suspicious JavaScript resources cover a broad spectrum of activities. Interestingly, we observed that 70% and 67%, respectively, of Business (Web analytics) and Ads JavaScripts are loaded from level ≥ 2 in contrast to 17% and 31% of JavaScripts of Government and Shopping loaded at level 1. We next strive to quantify the level of suspicion raised by each of these JavaScripts. Intuitively, those with higher VTscores represent a higher threat as defined by the 68 AV tools used by VirusTotal. Hence, Figure 6 presents the cumulative distribution of the VTscores for all JavaScript resources loaded with VTscore > 0. We separate the JavaScripts into their location in the dependency chain. Clear difference can be observed, with level 2 obtaining the highest VTscore (median 28). In fact, 78% of the suspicious JavaScript resources loaded on trust level 2 have a VTscore > 52 (indicating *very* high confidence). It is also worth noting that the VTscore for resources loaded further down the dependency chain is lower (*e.g.,* level 4). For example, 80% of level 4 resources receive a VTscore below 5. This suggests that the activity of these resources is more contentious, with a smaller number of AV tools reaching consensus. It is impossible to state the reason for this, hence in our extended work [12] we analyze the dynamic activities of these JavaScript content.

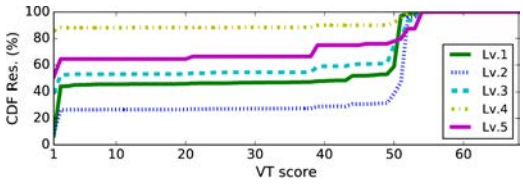

Figure 6: CDF of suspicious JavaScripts (VTscores ≥ 10) at different levels in the chain.

5 RELATED WORK

There has been a wealth of research into the utilisation and exploitation of third-parties and JavaScript libraries [9, 10, 20, 22, 25, 26]. Our work differs quite substantially from these in that we are not interested in the JavaScript code itself, nor the simple presence of third-party domains in a webpage. Instead, we are interested in *how* third-parties are loaded, and their use of "implicit" trust (*i.e.,* dependency chains). In contrast to our work, these prior studies ignore the presence of dependency chains and treat all third-parties as "equal", regardless of where they are loaded in the dependency chain. Closer to our own work is Bashir *et al.* [1], who studied websites' resource inclusion trees and analyzed retargeted ads using crowdsourcing. This allowed them to identify and classify ad domains, as well as predominant cookie matching partners in the ad exchange environment. Our study is far broader, and sheds light on dependency chains across many different types of websites rather than simply inspecting advertisements. More related is Kumar *et al.* [18], who recently characterized websites' resource dependencies on third-party services. In-line with our work, they found that dependency chains are widespread. This means, for example, that 55% of websites are prevented from fully migrating to HTTPS by their dependencies. Their focus was not, however, on identifying suspicious or malicious activities. To the best of our knowledge, this paper is the first study to analyze the role of implicit trust from a security perspective to better understand the role of dependency chains in loading suspicious third-party content.

6 CONCLUDING REMARKS

This paper has explored dependency chains in the web ecosystem. Inspired by the lack of prior work focusing on how resources are loaded, we found that over 40% of websites *do* rely on implicit trust. Although the majority (84.91%) of websites have short chains, we found first-party websites with chains exceeding 30 levels. Of course, the most commonly *implicitly* trusted third-parties are well known operators (*e.g.,* `doubleclick.net`), but we also observed various less known implicit third-parties. We hypothesized that this might create notable attack surfaces. To confirm this, we classified the third-parties using VirusTotal to find that 1.2% of third-parties are classified as potentially malicious. These resources have remarkable reach — largely driven by the presence of highly central third-parties, *e.g.,* `google-analytics.com`. With this in mind, in our extended work [12], we perform sandbox experiments on the

suspicious JavaScript to understand their actions. We witness extensive download activities, much of which consisted of *dropper* files and malware, which is installed on the machine. It was particularly worrying to see that JavaScript resources loaded at level ≥ 2 in the dependency chain tend to have more aggressive properties, particularly as exhibited by their higher VTscore. This is only the first step in our research agenda. We wish to perform longitudinal measurements to understand how these metrics of maliciousness evolve over time. We are particularly interested in understanding the (potentially) ephemeral nature of threats.

ABSTRACT

Interaction-based neural ranking has been shown to be effective for document search using distributed word representations. However the time or space required is very expensive for online query processing with neural ranking. This paper investigates fast approximation of three interaction-based neural ranking algorithms using Locality Sensitive Hashing (LSH). It accelerates query-document interaction computation by using a runtime cache with precomputed term vectors, and speeds up kernel calculation by taking advantages of limited integer similarity values. This paper presents the design choices with cost analysis, and an evaluation that assesses efficiency benefits and relevance tradeoffs for the tested datasets.

1 INTRODUCTION AND RELATED WORK

Neural networks have been applied in information retrieval and text mining tasks (e.g. [5, 9, 20, 23, 24, 33–36]). In general, exploiting neural representation of words adds significant rank scoring computation cost during query processing. While parallel computing with a large number of CPUs or GPUs can accelerate, this paper studies how to speed up neural rank scoring with an algorithmic approximation to reach a reasonable query response time without resorting to expensive hardware. This is important for a large online query processing website which needs to dedicate more hardware resource for handling high query traffic. Fast scoring also opens opportunities to integrate a more complex neural scheme.

The previous research on neural ranking falls into the following two categories: interaction-based or representation-based models [23]. The earlier work has focused on the representation based models [11, 27] where each document and a query are separately represented as vectors through a sequence of neural computations and the final ranking is based on the similarity of the two representative vectors. The recent studies have focused on interaction-based neural ranking models [5, 9, 34] where the word or term-level similarity of a query and a document is explored first based on their embedding vectors before applying an additional sequence of neural computation. These studies have shown their interaction based models outperform the earlier representation-based models and thus our paper is focused on the acceleration of the three interaction-based models, more specifically DRMM [9], KNRM [34], and CONV-KNRM [5]. We find that the query processing time cost in the above interaction-based models for computing query-document interaction and deriving kernel values is dominating. For CONV-KNRM, the time to prepare term vectors is very expensive.

The contribution of this paper is an LSH approximation of these three neural methods with fast histogram-based kernel calculation and term vector precomputing for a runtime cache. Another contribution is an analysis and experimental evaluation of design choices and a demonstration using more complex dual embeddings leveraging fast neural scoring. While our study is focused on the above three models, LSH approximation may be used for other interaction-based methods that employ cosine similarity (e.g. graph embedding [35, 36]) and this is a future work.

Our work is motivated by the rich history of research on approximation with hashing such as LSH [1–4, 7, 8, 13, 15, 37] and in various data-intensive applications [6, 10, 17, 18, 30]. The reason to choose the Random Hyperplane LSH [4] is that the computation with hashed embeddings can not only preserve the semantic similarity within a small error bound, but also allow us to take advantage of the binary nature of sketch vectors for designing a fast kernel calculation.

The acceleration of neural network computation has been studied for image classification with complex neural network structure (e.g. [12, 26, 28] for binarization). Their work is less applicable to our context where neural network involved is relatively simple and cost of forward neural computation in query processing is one or two orders of magnitudes smaller than interaction and kernel computation. To our knowledge, there is no research work on accelerating neural ranking models for fast online query processing.

2 INTERACTION-BASED NEURAL RANKING

Interaction-based neural ranking can be formalized as performing computation: RankingScore = $f(Ker(\vec{q} \otimes \vec{d}))$, where $\vec{q}$ and $\vec{d}$ are two sequences of embedding vectors for the query and the document respectively, $\otimes$ is the interaction operation, Ker is the operation for kernel computation, and f is the operation involving neural network computation. Embedding vectors in $\vec{q}$ and $\vec{d}$ can be term vectors for unigram/n-gram in query/document [5, 9, 34], or can be entity vectors for existing entities in query/document [35]. Those embedding vectors can be learned from one of many existing neural embedding models [19, 25] or generated by additional neural operations [5].

Table 1: Frequently used notations.

Notation	Definition
$\vec{q}$	Embedding vectors for query terms.
$\vec{d}$	Embedding vectors for document terms.
m	Number of words in the query.
n	Number of words in the document.
l	Dimension of pre-trained unigram word embedding vectors.
h	The largest span of n-gram considered in CONV-KNRM [5].
F	The number of filters in CONV-KNRM [5].
M	The interaction matrix between query and document.
V	Vocabulary size of unigrams in the corpus.
H	Vocabulary size of n-grams in the corpus where $n \leq h$.
N	Number of documents in the corpus.
R	Number of kernels in the neural ranking model.
μ_k	Mean of the k-th kernel in KNRM and CONV-KNRM.
σ_k	Standard deviation of the k-th kernel.
$K_k(M_i)$	The k-th kernel value for the i-th query term.
b	Number of bits in hashing footprint.

Interaction operator $\otimes$. This step outputs an interaction matrix M containing vector similarities for all pairs of one query term vector and one document term vector.

- **DRMM [9] and KNRM [34]** consider only the interaction between unigrams in the query and unigrams in the document. Each matrix element M_{ij} is the cosine similarity between the term vectors of the i-th query term and the j-th document term.
- **CONV-KNRM [5]** extends KNRM to incorporate n-grams in building a set of interaction matrices. Let h be the maximum n-gram length considered and there are h^2 interaction matrices. Each interaction matrix $M^{r,t}$ where $1 \leq r, t \leq h$ denotes a cosine similarity score matrix between query term vector modeled with r-gram embeddings and document term vectors modeled with t-gram embeddings. These n-gram embeddings are computed from convolution filters and pre-trained unigram embedding vectors. The dimension of n-gram embeddings depends on the number of filters involved (defined as F).

Since computing each interaction matrix requires a dot product computation for each matrix element, given a document with n terms, the time complexity to compute the similarities of this document for m-word query is $\Theta(nml)$ for DRMM and KNRM, and $\Theta(nmF)$ for CONV-KNRM.

Kernel computation operator Ker. Ker is used for extracting multi-level soft matching features and generating inputs for neural network computation.

- In DRMM, each interaction matrix element represents the similarity between a query term and a document term, varying from -1 to 1. The interval $[-1, 1]$ is divided into a set of non-overlapping ranges. Thus a histogram can be generated where each bucket represents one range, and the value of a bucket represents the number of similarities falling into that bucket. Different buckets contain soft matching signals of different levels, just like kernels in the Kernel Pooling [34]. Thus in this paper, for simplicity, we denote each bucket as a kernel. Calculating all kernel/bucket values requires $\Theta(nm)$ time complexity.
- In KNRM and CONV-KNRM, each kernel is defined using a distribution and computation involved is called kernel pooling. There are R kernels defined in advance and symbols μ_k and σ_k denote the mean and standard deviation of the k-th kernel respectively. Each element value of an interaction matrix contributes kernel computation. For KNRM with one interaction matrix M, the kernel value of the k-th kernel for the i-th query term is:

$$K_k(M_i) = \sum_{j=1}^{n} \exp(-\frac{(M_{ij} - \mu_k)^2}{2\sigma_k^2})$$

  where n is the number of terms in the document. The output of kernel computation is a vector of R size: $(\sum_{i=1}^{m} \log K_1(M_i), \cdots, \sum_{i=1}^{m} \log K_R(M_i))^T$. Building this kernel for each query term requires $\Theta(nmR)$ time given there are R kernels.
  In CONV-KNRM, there are h^2 interaction matrices and the total cost of this kernel computation is $\Theta(nmRh^2)$. This expression does not include the cost of preparing term vectors and we discuss this issue further in Section 3.3.

Forward neural network computation f. This step uses a forward neural network to compute the final ranking score based on a vector of kernel values computed in the previous step.

- In DRMM, a multilayer perception network with one hidden layer of a constant size is used and the logarithms of the kernel/bucket values of the similarity ranges for the i-th query terms form an input vector. The final ranking score is a weighted linear combination of the neural network outputs of all query terms. The time cost of computing is in $\Theta(mR)$.
- In KNRM, a simple single-layer network is used and the input vector is a vector of size R computed in the previous step. The time cost for neural network computation is in $\Theta(R)$.
- In CONV-KNRM that extends KNRM, the formula of forward neural computation in this step is about the same as KNRM except that the output of the previous step produces a vector of dimension Rh^2 given h^2 interaction matrices and this vector is the input of this step. Thus the time cost for forward neural network computation is in $\Theta(Rh^2)$.

3 NEURAL RANKING WITH LSH

We summarize the time cost of above interaction-based neural ranking steps for query processing in Table 2. This section proposes three techniques to bring down time cost of query processing: approximation of term vectors with LSH in Section 3.1, fast kernel computing in Section 3.2, and precomputing of term vectors for CONV-KNRM in Section 3.3. The query-processing time cost after using our three techniques is listed in Table 2 also.

3.1 LSH for fast interaction computation

We adopt a hyperplane LSH [4], motivated by the previous work in clustering and nearest neighbor search [17, 30] that adopts such a scheme also. In [17, 30], multiple LSH signatures are produced for each document and the probability of similar documents falls into the one of LSH buckets is computable. In our context, we only use one LSH signature to approximate one term vector.

Table 2: Time complexity in Θ notion for ranking one single document with and without LSH.

Models	DRMM		KNRM		CONV-KNRM without precomputing		CONV-KNRM with precomputing	
With LSH?	No	Yes	No	Yes	No	Yes	No	Yes
Vectors	-	-	-	-	$(n+m)h^2lF$	$(n+m)(hbF+h^2lF)$	h^2mlF	$(mhbF+h^2mlF)$
Interaction	nml	nm	nml	nm	h^2nmF	h^2nm	h^2nmF	h^2nm
Kernel	nm	nm	nmR	$nm+bmR$	h^2nmR	$h^2(nm+bmR)$	h^2nmR	$h^2(nm+bmR)$
Neural	mR	mR	R	R	Rh^2	Rh^2	Rh^2	Rh^2

Table 3: Dominating factor of storage space cost in bytes with and without LSH using a reference or value based method.

Models	DRMM		KNRM		CONV-KNRM without precomputing		CONV-KNRM with precomputing	
With LSH?	No	Yes	No	Yes	No	Yes	No	Yes
Reference	$4nN+4Vl$	$4nN+Vb/8$	$4nN+4Vl$	$4nN+Vb/8$	$4nN+4Vl$	$4nN+4Vl$	$4hnN+4HF$	$4hnN+Hb/8+4Vl$
Value	$4nNl$	$nNb/8$	$4nNl$	$nNb/8$	$4nNl+4Vl$	$4nNl+4Vl$	$4hnFN+4HF$	$hnbN/8+4Vl$

Formally, for each embedding vector, we generate b-bit footprint

$$\text{LSH}(v)[i] = \begin{cases} 1 & r_i \cdot v > 0, \\ 0 & r_i \cdot v \le 0. \end{cases}$$

Here $\text{LSH}(v)[i]$ denotes the i-th bit of the LSH footprint of the vector v, and each vector r_i is independently sampled by a multivariate normal distribution from the vector space of the embeddings. The time complexity to compute the above LSH for an embedding is $\Theta(bl)$, where l is the embedding length. In particular, for CONV-KNRM we need to compute LSH for the n-gram vectors in the query, which needs $\Theta(mhbF)$, since query of m words has mh n-grams (s.t. $n \le h$), and the length of each n-gram vector is F.

Then we estimate the angle between two embeddings by the Hamming distance between their LSH footprints. Formally, given any two embeddings x and y with angle θ between them, estimator $\hat{\theta}$ is defined as $\hat{\theta} = \frac{\pi}{b} D(\text{LSH}(x), \text{LSH}(y))$, where $D(\cdot,\cdot)$ denotes Hamming distance (Eq. (2) in [30]). Modern hardware is fast at finding Hamming distance between two words, or equivalently, counting the set bits of the XORed words. The time complexity of deriving the Hamming distance that approximates the cosine similarity is $\Theta(nm)$ for one n-word document and m-word query.

The above approximation error is estimated as follows. Given any two embedding vectors u, v with angle θ between them, the probability that both hyperplane LSH footprints have the identical i-th bit is $\Pr[\text{LSH}(u)[i] = \text{LSH}(v)[i]] = 1 - \theta/\pi$ (also in [4, 17, 30]). Since each bit in the footprint is sampled independently, the Hamming distance between the LSH footprints is a random variable of Binomial distribution with $p = \theta/\pi$. Let b be the number of bits in the LSH footprint. Then the mean and variance of the Hamming distance are $\mathbb{E}[D(\text{LSH}(u), \text{LSH}(v))] = b\frac{\theta}{\pi}$, $\text{Var}[D(\text{LSH}(u), \text{LSH}(v))] = b\frac{\theta}{\pi}\left(1 - \frac{\theta}{\pi}\right)$. For the above angle estimator between u and v, $\mathbb{E}[\hat{\theta}] = \frac{\pi}{b}\mathbb{E}[D(\text{LSH}(u), \text{LSH}(v))] = \theta$. Note that for an unbiased estimator, mean squared error (MSE) equals to its variance [31]. Then:

$$\begin{aligned} MSE = \text{Var}[\hat{\theta}] &= \frac{\pi^2}{b^2}\text{Var}[D(\text{LSH}(u), \text{LSH}(v))] \\ &= \pi\frac{\theta}{b}\left(1 - \frac{\theta}{\pi}\right) = \frac{\pi^2}{b}\frac{\theta}{\pi}\left(1 - \frac{\theta}{\pi}\right) \le \frac{\pi^2}{4b}. \end{aligned}$$

For a relatively large b value, the upper bound of MSE is fairly small. For example, when $b = 256$, $MSE \le 0.00963$.

There is a line of work to derive feature hashing [32] that can preserve cosine similarity with the same error variance. But each hashed value in [32] is a sequence of float point numbers and thus using such a method only accomplishes the dimensionality reduction, does not significantly decrease the time complexity.

3.2 Fast kernel computation

Once interaction matrices are derived, kernel computation still takes significant time compared to other steps in neural ranking. Our key idea for the second optimization technique is to take advantages that the distinct number of similarity values is limited after the use of Hamming distances as an approximation. With this in mind, we transform the kernel computation for a histogram-based formula with a significantly lower computational cost. With b-bit hyperplane LSH-based footprints, since there are at most $b+1$ values of Hamming distance, we first build a histogram on Hamming distances, and then compute kernels based on the histogram values.

For interaction matrix M in KNRM with R kernels, each kernel can be computed as

$$\begin{aligned} K_k(M_i) &= \sum_{j=1}^{n} \exp\left(-\frac{(\cos\hat{\theta}_{ij} - \mu_k)^2}{2\sigma_k^2}\right) \\ &= \sum_{j=1}^{n} \exp\left(-\frac{(\cos(\frac{\pi}{b}D_{ij}) - \mu_k)^2}{2\sigma_k^2}\right) \\ &= \sum_{d=0}^{b} \underbrace{|\{j : D_{ij} = d\}|}_{\textbf{online computed}} \cdot \underbrace{\exp\left(-\frac{(\cos(\frac{\pi}{b}d) - \mu_k)^2}{2\sigma_k^2}\right)}_{\textbf{offline computed}}, \end{aligned}$$

where D_{ij} denotes the Hamming distance between the i-th query term footprint $\text{LSH}(\mathbf{q}[i])$ and the j-th document term footprint $\text{LSH}(\mathbf{d}[j])$. Set $\{j : D_{ij} = d\}$ is the histogram on Hamming distances between query and document terms. The above formula marks the part of computation conducted in the offline time.

The above histogram-based method reduces time complexity of kernel computing from $\Theta(nmR)$ for the original algorithm to

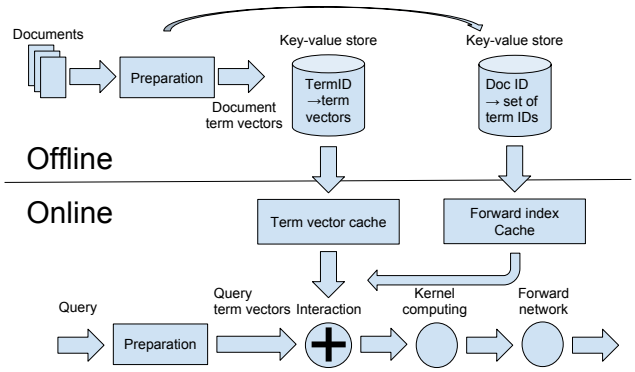

Figure 1: Architecture of interaction-based neural ranking.

$\Theta(nm+bmR)$. For web page ranking, a web page has 500 to 1K words on average, and neural ranking models usually take 20 to 50 kernels, there is a big cost difference. With $b = 256$, $n = 807$, and $R = 30$, the reduction ratio from above cost order expression $\Theta(nmR)$ to $\Theta(nm + bmR)$ is about 2.85. In our evaluation, we have observed around 417.38x speed improvement with the above histogram-based method. The reason for this large extra acceleration is partially because the original computation uses floating point arithmetic and our histogram-based method uses integer arithmetic. Another reason is that it allows us to re-arrange computation for better cache performance using a matrix notation and we will present more details on computation re-arrangement in an extended paper.

For CONV-KNRM with h^2 interaction matrices $M^{r,t}$ where $1 \le r, t \le h$, the above transformation is applied to each of R kernels for each of such matrices. Thus

$$K_k(M_i^{r,t}) = \sum_{d=0}^{b} \underbrace{|\{j : D_{ij}^{r,t} = d\}|}_{\textbf{online computed}} \cdot \underbrace{\exp(-\frac{(\cos(\frac{\pi}{b}d) - \mu_k)^2}{2\sigma_k^2})}_{\textbf{offline computed}}$$

where $D_{i,j}^{r,t}$ is the Hamming distance between the i-th LSH footprint of r-gram query term and the j-th LSH footprint of t-gram document term. The cost of kernel computation drops from the original complexity of $\Theta(h^2nmR)$ to $\Theta(h^2(nm + bmR))$.

3.3 Preparation of Term Vectors and Space Cost

For DRMM and KNRM, term vectors used for neural ranking directly adopt pretrained word embeddings (e.g. [19]), and thus there is no extra computation needed. In CONV-KNRM, a set of F convolution filters is applied to n-gram vectors based on word embeddings. The time complexity to prepare these document term vectors is $\Theta(nh^2lF)$ while deriving query term vectors costs $\Theta(mh^2lF)$.

Since $n >> m$, the time of this convolution computation for deriving document term vectors is dominating if it is conducted at the runtime when a query is handled. Our evaluation shows that without precomputing, CONV-KNRM spends too much time in preparing document term vectors. To reduce this cost, precomputation of these vectors can be employed to conduct such computation at the offline time. On the other hand, the disadvantage of precomputing is that it requires a substantial amount of space to store precomputed vectors, and LSH mapping can reduce this need significantly. The impact of incorporating LSH is described as follows.

- Without precomputing, following the original step of CONV-KNRM, we need to perform the convolution computation to derive all term vectors. Then we need extra $\Theta(mhbF)$ time to apply LSH to all unigram and n-gram term vectors for a query and documents to be ranked.
- With precomputing, the convolution computation and LSH mapping of all document term vectors are conducted in the offline time. The online query processing only needs to spend time to prepare query term vectors, which costs $\Theta(mhbF + h^2mlF)$.

Caching and space cost. Table 3 lists the dominating factors of disk space cost in bytes for the three algorithms with and without LSH or precomputing, assuming each term ID takes 32 bits and each floating number takes 32 bits. We describe two ways of storing document term representations as follows.

1) **Reference based method**.

Each term including a unigram or n-gram in the vocabulary is assigned an ID. Each term ID gives a reference to where the word embedding or term vector is stored. For each document, we need to store all the IDs of its necessary words or terms based on vector precomputing. Figure 1 illustrates the flow of neural ranking with two caches for runtime query processing. One cache is called the forward index cache which gives a mapping from a document ID to a set of term IDs this document owns. The second cache is called the term vector cache which is a mapping from a term ID to a term vector or its hash footprint. There is much higher access traffic to the second cache in ranking a document and thus the high hit ratio of the second cache is extremely important otherwise the cache miss would lead to a large number of random I/O operations to the disk.

2) **Value based method**. We store the values of embedding vectors or LSH footprints together with each document ID and they are directly accessible by a document ID. This method is useful when the memory cache demand is too high in the above reference method while it demands a larger amount of disk space.

For DRMM and KNRM with LSH, the main storage space cost for the reference method is about $4hnN$ to store the term IDs of documents and $Vb/8 + 4V$ bytes to store the map from term IDs to hash footprints where cost factor $4V$ is less significant. The second portion is the memory cache demand for fast access of hash footprints. The overall storage with LSH has a decent decrease compared to that without LSH. The size of the term-vector cache drops from about $4Vl$ without LSH to about $Vb/8$ with LSH. When $b = 256, l = 300$, the reduction ratio is about 32.8x.

For CONV-KNRM with LSH, if the reference based method is used with precomputing, the disk space needs $4hnN$ bytes for storing term IDs of N documents, and $Hb/8 + 4H$ bytes for hash footprints and index where $4H$ is less significant. Under precomputing, the size of the term-vector cache demand drops from about $4HF$ without LSH to about $Hb/8$ with LSH. When $F = 128, b = 256$, the cache space demand reduction ratio is about 6x.

To compare the storage cost of reference-based and value-based methods, using ClueWeb Category B dataset parameters with about 50 million documents, the dominating cost factor of storage space in CONV-KNRM with precomputing is $4hnN$ using the reference-based method and $hnbN/8$ using the value based method. The ratio of the value-based storage space cost over reference-based cost is approximately $\frac{b}{32}$, which is 8 when $b = 256$. With this size of the

database, the ratio of the value-based space cost over reference-based cost is also approximately $\frac{nNb/8}{4nN} = 8$ for DRMM with LSH and KNRM with LSH, respectively. With $b = 256$, the term vector disk space of the value-based method for CONV-KNRM is about 2.6TB for the ClueWeb dataset while the reference-based method costs about 351GB. Our evaluation uses the reference-based method.

4 EVALUATION

The objectives of our evaluation are to compare ranking relevance after applying LSH approximation with our design choices, demonstrate its time and space benefits, and assess the impact of using more complex embeddings on relevance and time cost.

Datasets and settings. We mainly report the performance using ClueWeb09 Category B with 50M webpages and 200 queries from the TREC Web Tracks 2009-2012 with 5-fold cross validation. We have also used two other smaller TREC datasets: TREC45 based on TREC Disks 4 and 5 with 0.5M news articles and AQUAINT with 1M news articles. Following the settings in [5, 9, 34], we first exclude spam webpages and rerank for top 1,000 documents of each query given by Galago initial ranking in the Lemur system [16]. For DRMM, the neural network has $R = 30$ kernels as input, and has a hidden layer of 5 neurons. For KNRM and CONV-KNRM, we do not update the embeddings during the training for simplicity, hence the accuracy scores may have a degradation compared with the results from the original papers. Other parameters used are: $l = 300$, $F = 128$, $h = 2$. We do not compare with the representation-based methods since the previous work shows that the interaction-based models perform better [23].

Word representation with dual embeddings. The previous work in DRMM, KNRM, CONV-KNRM typically used pretrained embeddings (e.g. word2vec) as a starting point. Nalisnick et al. firstly introduced Dual Embedding [21] for document ranking, given the fact that word2vec [19] with Negative Sampling actually trains two sets of word embedding vectors, defined as "input" (IN) and "output" (OUT) vector representations. Vector interactions between IN and IN are typically used in DRMM, KNRM, CONV-KNRM, and others for measuring term similarity. To leverage dual embedding interaction-based neural ranking models, we add a "dual" interaction matrix using IN vector representations and OUT vector representations and applying the same kernel computing techniques with the doubled time cost.

Ranking relevance and query processing time with hyperplane LSH. Table 4 shows the NDCG@20 scores [14] and average query time for different neural ranking models when using regular word embedding vectors or dual embeddings. The query processing C++ code for DRMM, KNRM, and CONV-KNRM is compiled with an optimization flag in a Linux machine which has Intel Xeon E5-2680v3 2.5 GHz dual socket and 128 GB DDR4 DRAM, and a local SSD with about 0.1 ms latency [29]. All the results are within confidence interval ±0.01 with p-value < 0.05. When increasing the number of bits for LSH, the NDCG score is getting closer to the original ones starting 64 bits, and the scores of 256 bits are fairly close to the original ones and we select this number as our choice in conducting other comparison. The competitiveness using LSH for NDCG@5 and @10 is similar. From Row 2, even time cost is roughly doubled, dual embeddings does yield a good improvement of relevance score compared to regular embeddings and LSH approximation can make it one or two orders of magnitude faster while retaining most of the relevance benefits from dual embeddings.

For average query time in Table 4, we use precomputing to derive the bigram and unigram embeddings for CONV-KNRM with and without LSH. The query response time in this table does not include the I/O cost to access document term embedding vectors. With 256 bits, DRMM with LSH is 4.12x faster than DRMM; KNRM with LSH 80.54x faster than KNRM; CONV-KNRM with LSH is 106.52x faster than CONV-KNRM. A similar speedup is accomplished when dual embeddings are used. Here we assume that term IDs of each document in processing a query are cached in memory. This forward index cache shown in Figure 1 does not need to be large and in the worst case with a cache miss, the I/O cost of accessing 1,000 such vectors is about 100ms from a local SSD. Thus we do not discuss the size demand of such a cache in this paper.

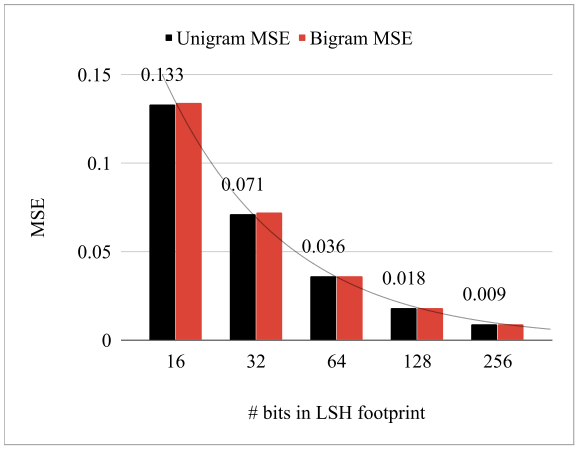

Figure 2: Errors of cosine similarity estimated with LSH.

To explain why the above three algorithms with LSH approximation can still be competitive in relevance when using a reasonable number of hash bits, Figure 2 shows that the mean squared errors of LSH-based cosine similarity approximation is relatively small for word2vec embeddings of unigrams and bigrams when increasing the number of hyperplane LSH bits. For example, when the number of LSH bits becomes 256, the actual approximation error is within 0.009, which corroborates that the relevance loss in Table 4 is reasonably small with such approximation.

Query time breakdown and impact of design optimization. With $b = 256$, Table 5 shows query time breakdown for different models in four steps discussed in Section 2 and Section 3 to re-rank 1,000 documents for a query for ClueWeb. Again document I/O cost is not included, which can be as high as 100ms per query. The underlined numbers are estimated since they require either too much time or too much space in experiments. For all methods, the time for forward neural computation step is relatively less significant compared with other steps. For DRMM, the interaction matrix computing time dominates and LSH produces a great reduction. For CONV-KNRM, the time cost for preparing term vectors corresponding word and n-gram embeddings is very expensive, and precomputing yields a significant advantage. For both KNRM and

CONV-KNRM, LSH reduces interaction matrix and kernel value computation significantly. The time for kernel computation is no longer dominating and our histogram-based kernel algorithm yields 417.38x reduction.

Table 6 compares the space requirements for three datasets with $b = 256$. The parameters of the datasets are listed blow. For the TREC45 data set, $N = 0.528$ million, average $n = 484$, $V = 0.67$ million, $H = 16.2$ million. For the AQUAINT data set, $N = 1.03$ million, $n = 440$, $V = 0.72$ million, $H = 17.3$ million. For the ClueWeb09 dataset, $N = 50.22$ million, $n = 807$, $V = 13.6$ million, $H = 328.43$ million [22]. The table lists two numbers in each entry. One is the total amount of disk storage space needed and another number inside a parenthesis is the size of the term-vector cache.

Our method using LSH reduces the size of term-vector cache significantly for DRMM/KNRM and CONV-KNRM with precomputing. For ClueWeb, the reference based method for CONV-KNRM without LSH needs about 492.4 GB in disk while memory size for term-vector cache is 169.5 GB. If such a memory cache is not available, the foot prints of each document need to be fetched with a random disk I/O. For ranking top 1000 documents matched for a query, the total I/O access cost can take about 100 seconds in our experiments. By integrating LSH, 351 GB disk space is still needed and the size of the term-vector cache is reduced by 6.01x to only 28.2 GB, which is fairly affordable.

5 CONCLUSION

This paper presents the design choices and algorithm optimization to improve the efficiency of three interaction-based neural ranking algorithms with LSH and a histogram-based kernel computing method. The evaluation shows that the proposed design choice yields 4.12x, 80.54x, and 106.52x time speedups for DRMM, KNRM, and CONV-KNRM respectively in the tested ClueWeb dataset with a reasonable response time and competitive relevance. Precomputing is used in our CONV-KNRM implementation for avoiding expensive document term vector preparation while it does carry extra space cost. Our LSH integration moderately decreases the overall storage space while making a major reduction for the term vector cache space demand, and the reduction ratio is 32.8x for DRMM and KNRM, and 6.01x for CONV-KNRM. This is critical to enable fast in-memory access of (hashed) embedding contents for a large dataset. More complex dual embeddings can improve relevance while its fast LSH approximation still preserves the most of its benefits.

ABSTRACT

The Knowledge graph (KG) uses the triples to describe the facts in the real world. It has been widely used in intelligent analysis and applications. However, possible noises and conflicts are inevitably introduced in the process of constructing. And the KG based tasks or applications assume that the knowledge in the KG is completely correct and inevitably bring about potential deviations. In this paper, we establish a knowledge graph triple trustworthiness measurement model that quantify their semantic correctness and the true degree of the facts expressed. The model is a crisscrossing neural network structure. It synthesizes the internal semantic information in the triples and the global inference information of the KG to achieve the trustworthiness measurement and fusion in the three levels of entity level, relationship level, and KG global level. We analyzed the validity of the model output confidence values, and conducted experiments in the real-world dataset FB15K (from Freebase) for the knowledge graph error detection task. The experimental results showed that compared with other models, our model achieved significant and consistent improvements.

1 INTRODUCTION

A knowledge graph (KG), aims to describe the various entities or concepts and their relationships existing in the objective world [43]. It usually stores knowledge in the form of triples (head entity, relationship, tail entity), which can be simplified to (h, r, t). It lays the foundation for the knowledge-based organization and intelligent application in the Internet age with its powerful semantic processing capabilities and open organization capabilities.

In recent years, an increasing number of researchers are committed to productively extracting information directly from unstructured web text, such as ORE [2, 9, 19], NELL [7], and to automatically constructing large-scale knowledge graphs, such as Freebase [3], DBpedia [1], and Wikidata[1]. However, some noises and errors are inevitably introduced in the process of automation. References [23] and [14] verify the existence and problems of errors in the KG. Existing knowledge-driven learning tasks or applications [11, 13, 22, 27], assume knowledge in the existing KG is completely correct and therefore bring about potential errors [28, 42].

For a piece of knowledge in a KG, especially from a professional field, it is difficult to clearly determine whether it is true when it is not tested in practice or is not strictly and mathematically proven. Therefore, we introduce the concept of KG triple trustworthiness, which indicates the degree of certainty that the knowledge expressed by the triple is true. It's value is set to be within the interval [0, 1]. The closer the value is to 0, the greater the probability that the triple is in error. Based on this, we can find possible errors in the existing KG and improve knowledge quality in the KG.

There are intricate relationships among the entities in the KG, the same relationship can occur between different entities, and multiple relationships can associate with the same entity at the same time. It is a challenge to study how to use appropriate methods to evaluate the trustworthiness for a knowledge triple. We propose a knowledge graph triple trustworthiness measurement model (KGTtm), which is a crisscrossed neural network-based structure. We measure the trustworthy probability from multiple levels, including the entity level (correlation strength between an entity pair), the relationship level (translation invariance of relation vectors), and the KG global level (inference proof of triple related reachable paths). Corresponding to different levels, we generate three essential questions and focus on solving them by designing three kinds of Estimators. Next, a comprehensive triple confidence value is output through a Fusioner.

The main contributions of this work include: (1) We propose a knowledge graph triple trustworthiness measurement method that makes comprehensive use of the triple semantic information and globally inferring information. We can achieve three levels of measurement and an integration of confidence value at the entity level, relationship level, and the knowledge graph global level. (2) We empirically verify the effectiveness of the triple trustworthiness on benchmark data created from a real-world, large-scale KG Freebase. Experimental results show that the error or noise instances are assigned low confidence values, meanwhile, high trustworthiness

for true triples. (3) The trustworthiness calculated by the KGTtm could be utilized in knowledge graph construction or improvement. We evaluate the model on the knowledge graph error detection task. Experimental results show that the KGTtm can effectively detect the error triples and achieve promising performances.

2 RELATED WORK

The concept of Trustworthiness has been applied to knowledge graph related tasks to some extent. Reference [42] proposed a triple confidence awareness knowledge representation learning framework, which improved the knowledge representation effect. There were three kinds of triple credibility calculation methods using the internal structure information of the KG. This method used only the information provided by the relationship, ignoring the related entities. The NELL [7] constantly iterated the extracting template and kept learning new knowledge. It used heuristics to assign confidence values to candidate relations and continuously updated the values through the process of learning. This method was relatively simple but lacked semantic considerations. Dong et al. [8] constructed a probabilistic knowledge base (Knowledge Vault), where the reliable probability of a triple was a fusion of some estimators. This method was tailored for their knowledge base construction and did not have good generalization capabilities. Li et al. [22] used the neural network method to embed the words in ConceptNet and provide confidence scores to unseen tuples to complete the knowledge base. This method considered only the triples themselves, ignoring the global information provided by the knowledge base. The above models used the trustworthiness to solve various specific tasks. It shows that the triple trustworthiness is important for applications and research. However, there is a lack of systematic research on the knowledge triple trustworthiness calculation method at present. Our work is devoted to this basic research and proposes a unified measurement model that could facilitate a variety of tasks.

In this work, we verify the effect of the triple trustworthiness on the knowledge graph error detection task. The Knowledge graph error detection task is dedicated to identifying whether a triple in the KG is in error. The error detection can actually be regarded as a special case of the trustworthiness measurement, which is divided into two kinds of Boolean value types: “true (trusted)" and “error (untrusted)". Traditional methods [7, 14, 16, 21] were still based on manual detection, and the cost was considerable. Recently, some people have begun to study automatic KG error detection methods [8, 23, 31, 35]. In particular, embedding-based methods [5, 22, 38] have gained a significant amount of attention. we can efficiently measure the semantic correlations of entities and relations in the vector space. Whether two entities have a potential relationship could be predicted by matrix-vector operations of their corresponding embeddings. They have good efficiency and prospect. Furthermore, the Knowledge representation learning (KRL) technology is used to project the entities and relations in the KG into a dense, real-valued and low-dimensional semantic embeddings. The main methods include TransE [5], TransH [41], TransR [25], TransD [18], PTransE [24], ComplEx [39] and others.

3 THE TRIPLE TRUSTWORTHINESS MEASUREMENT MODEL

The triple trustworthiness measurement (KGTtm) Model for knowledge graph is presented based on a crisscrossing neural network structure, as shown in figure 1. Longitudinally, it can be divided into two levels. The upper is a pool of multiple trustworthiness estimate cells (Estimator). The output of these Estimators forms the input of the lower-level fusion device (Fusioner). The Fusioner is a Multi-layer perceptron to generate the final trustworthiness value for each triple. Viewed laterally, for a given triplet (h, r, t), we consider the triple trustworthiness from three progressive levels and correspondingly answer three hierarchical questions. 1) Is there a possible relationship between entity pairs (h, t)? 2) Can a certain relationship r occur between entity pairs (h, t)? 3) From a global perspective, can other relevant triples in the KG infer that the triple is trustworthy? For answering these questions we designed three kinds of Estimators, as described below.

3.1 Is there a possible relationship between the entity pairs?

We use the association strength between a given entity pair (h, t) to measure the likelihood of an undetermined relationship occurring between the pair. If a pair of entities has heavily weak relevance, it seems to be hopeless that there is a relationship between the entity pairs. The trustworthiness of the triples formed by the entity pair will be greatly compromised. As shown in figure 2, there are dense edges (relationships) from node (entity) A to node E, that is, there is a high association strength about (A, E). We can easily guess that there is a relationship between entity pair (A, E). However, it is impossible to reach F from G following the directed edges. We can also guess that there is no a relationship between (G, F).

We propose an algorithm named **ResourceRank**, to characterize the association strength between an entity pair according to the idea of Resource allocation [24, 26, 42, 45]. The algorithm assumes that the association between entity pairs (h, t) will be stronger, and more resource is passed from the head h through all associated paths to the tail t in a graph. The amount of resource aggregated into t ingeniously indicates the association strength from h to t.

The ResourceRank algorithm mainly includes three steps: 1) Constructing a directed graph centered on the head entity h. 2) Iterating

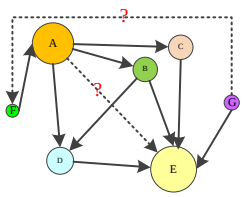

Figure 2: The graph of resource allocation in the ResourceRank algorithm.

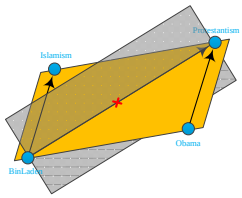

Figure 3: Effects display of the Translation based energy function.

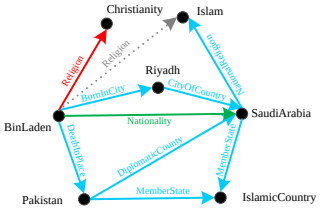

Figure 4: The inference instances for triple trustworthiness.

the flow of resources in the graph until it converges and calculates the resource retention value of the tail entity t. 3) Synthesizing other features and output the likelihood of $(h, ?, t)$.

Specific details are described below: Each entity is abstracted into a node. If there is a relationship from the entities e_1 to e_2, a directed edge will exist from node e_1 to e_2. Therefore, the KG can be mapped as a directed graph. This graph is weakly connected, but starting from h each node in the graph can be reached. In the initial state, the resource amount of h is 1, others is 0, and the sum of all nodes is always 1. If a node does not exist in the graph, then its resource is always 0. Moreover, there may be multiple relations between an entity pair (e_1, e_2) but only one directed edge from e_1 to e_2 in the graph. Depending on the number of these relations, each edge will have a different bandwidth. The larger the bandwidth is, the more resource flows through the edge.

The resource owned by node h will flow through all associated paths to each other nodes in the entire graph. We simulate the flow of resource flowing until distribution steady based on the PageRank [6, 33] algorithm. The value of the resource on the tail entity is $R(t \mid h)$, it is calculated as follows:

$$R(t \mid h) = (1-\theta) \sum_{e_i \in M_t} \frac{R(e_i \mid h) \cdot BW_{e_i t}}{OD(e_i)} + \frac{\theta}{N}. \tag{1}$$

Where, M_t is the set of all nodes that have outgoing links to the node t, $OD(e_i)$ is the out-degree of the node e_i and the $BW_{e_i t}$ is the bandwidth from the e_i to t. Thus, for each node e_i in M_t, the resource transferred from e_i to t should be $\frac{R(e_i|h) \cdot BW_{e_i t}}{OD(e_i)}$. Because the KG noises, the graph is imperfect. And there may be closed loops affecting the resources flowing. In order to improve the model fault-tolerance, we assume that the resource flow from each node may directly jump to a random node with the same probability θ. This part of resource that flows to t randomly is $\frac{1}{N}$, and N is the total number of nodes.

Different states of nodes in the graph reflect information of entity. Considering the following six characteristics: 1) $R(t \mid h)$; 2) In-degree of head node $ID(h)$; 3) Out-degree of head node $OD(h)$; 4) In-degree of tail node $ID(t)$; 5) Out-degree of tail node $OD(t)$; 6)The depth from head node to tail node Dep, we can construct a feature vector V. After being activating, the vector is transformed into a probability value as $RR(h, t)$, indicating the likelihood that there may be one or more relationships between the head entity h and the tail entity t. This transformation is:

$$\begin{cases} u = \alpha(W_1 V + b_1) \\ RR(h,t) = W_2 u + b_2 \end{cases} \tag{2}$$

Here, α is a nonlinear activation function, W_i and b_i are parameter matrices that can be trained during model training. The $RR(h, t)$ is within the range [0, 1]. The closer it is to 1, the more likely it is that there is a relationship between h and t, which answer the questions shown in the title in the entity layer.

3.2 Can the determined relationship r occur between the entity pair (h, t) ?

The above Estimator can only measure the likelihood that one undetermined relationship occurring between the entity pair, but not what kind of relationship. We next calculate the possibility of such a relation r occurring between the entity pair (h, t) by the **Translation-based energy function (TEF)** algorithm.

Inspired by the translation invariance phenomenon in the word embedding space [29, 30], the relationship in the KG is regarded as a certain translation between entities; that is, the relational vector $\mathbf{r}$ is as the translating operations between the head entity embedding $\mathbf{h}$ and the tail entity embedding $\mathbf{t}$ [5]. As illustrated in figure 3, in the vector space, the same relational vector can be mapped to the same plane and freely translated in the plane to remain unchanged. The triples (BinLaden, Religion, Islam) and (Obama, Religion, Protestantism) should be all correct. However, according to translational invariance of relation vectors, (BinLaden, Religion, Protestantism) must be wrong. Therefore, An trustworthy triple (h, r, t), should satisfy $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$. The energy function is defined as $E(h, r, t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|$. The higher the degree of fit between h, r, and t, the smaller the value of $E(h, r, t)$ will be. We believe that the smaller the $E(h, r, t)$ value is, the probability that the relationship r is established between the entity pair (h, t) will be greater, and the trustworthiness of (h, r, t) will be better, and vice versa.

The TEF algorithm operates as follows: Firstly, knowledge representation learning technology is used to implement a low-dimensional distributed representation for entities or relations, and we compute $E(h, r, t)$ for each triple. Then, a modified sigmoid function is used to convert $E(h, r, t)$ into the probability that the entity pair (h, t) constitutes the relationship r. The conversion formula is as follows:

$$P(E(h,r,t)) = \frac{1}{1 + e^{-\lambda(\delta_r - E(h,r,t))}} \tag{3}$$

Here, δ_r is a threshold related to the relationship r. When $E(h, r, t) = \delta_r$, the probability value P is 0.5. If $E(h, r, t) < \delta_r$, then $P > 0.5$. The λ is a hyperparameter used for smoothing and can be adjusted dynamically along with the model training. The $P(E(h, r, t))$ answers the second question in the relation layer.

3.3 Can the relevant triples in the KG infer that the triple is trustworthy?

Inspired by "social identity" theory [17, 40], we make an metaphor: regarding the KG as a social group, where each triple is an individual. The degree of acknowledgements from other individuals to the targeted individual (target triple) reflects whether the targeted individual can properly integrate into the society (i.e., the KG). We believe that only a true triple can achieve popular recognition. Vice versa, if a triple is well accepted, we tend to believe that it is trustworthiness. Therefore, the answer is yes to the question in the title. How to infer the credibility of the target triple by evaluating the acknowledgements of the relevant triples in the KG?

We design a **Reachable paths inference (RPI)** algorithm to meet it. There are many substantial multi-step paths from head entities to tail entities, which indicate the semantic relevance and the complex inference patterns among triples [34]. These reachable paths will be important evidences for judging the triple trustworthiness. For example, as shown in figure 4, there are multiple reachable paths between entity pairs "Bin Laden" and "Saudi Arabia". According to the path "Bin Laden $\overset{BornInCity}{\rightarrow}$ Riyadh $\overset{CityOfCountry}{\rightarrow}$ Saudi Arabia", we can firmly infer the fact triple (Bin Laden, Nationality, Saudi Arabia). In addition, we suppose there is a pseudo-triple (Bin Laden, Religion, Christianity) in the KG. The related paths will be very few and illogical, and we should doubt the credibility of this tuple. In contrast, we can find the correct triple (Bin Laden, Religion, Islam) because it gets good acknowledgements depending on multiple reachable paths. To exploit the reachable paths for inferring triple trustworthiness, we need to address two key challenges:

3.3.1 Reachable Paths Selection. In a large-scale KG, the number of reachable paths associated with a triple may be enormous. It is consuming to weigh all the paths. meanwhile, not all paths are meaningful and reliable. For example, the path "Bin Laden $\overset{DeathInPlace}{\rightarrow}$ Pakistan $\overset{DiplomaticCountry}{\rightarrow}$ Saudi Arabia" provided only scarce evidence to reason about the credibility of the triple (Bin Laden, Nationality, Saudi Arabia). Therefore, it is necessary to choose the most efficient reachable paths to use. Previous works believed that the paths that led to lots of possible tail entities were mostly unreliable for the entity pair. They proposed a path-constraint resource allocation algorithm to select relation paths [24, 42]. Such a method ignored the semantic information of the paths. However, we find that the reliability of the reachable path is actually a consideration of the semantic relevance of the path with the target triple. Therefore, we propose a **Semantic distance-based path selection** algorithm, which is described as Algorithm 1.

3.3.2 Reachable Paths Representation. After the paths are selected, it is necessary to map each path to a low-dimensional vector for subsequent calculations. The previous methods [24, 42] merely considered the relations in the paths. Here, we consider whole triple in the paths, including not only relations but also the head, tail entities, since the entities can also provide significant semantic information. The embeddings of the three elements of each triple are concatenated as a unit s. Therefore, a path is transformed into an ordered sequence $S = \{s_1, s_2, ..., s_n\}$. We use the recurrent neural networks (RNNs) [15], which are good at capturing temporal semantics of a sequence, to learn the semantic information contained in the path. The RNN layer encodes s_t by considering forward information from s_1 to s_t. We use the output vector $\mathbf{h_t}$ of the last time to represent the semantic information of each path. We stitch the output $\mathbf{h_t}$ of the $TopK$ paths together to form a vector. The vector is nonlinear transformed (using the method in eq(2).) into a recognition value as $RP((h, r, t))$, indicating the recognition degree that the relevant triples in the KG infer the target triple being credible.

Algorithm 1 Reachable Paths Selecting Algorithm

Require:
The knowledge graph (KG); A given target triple (h, r, t).
Ensure:
Multiple reachable paths most relevant to target triple.

1: Search the reachable paths from h to t in the KG and store in $P_{(h,r,t)} = \{p_1, ..., p_n\}$;
2: For each $p_i = \{(h, l_1, e_1), (e_1, l_2, e_2), ..., (e_{n-1}, l_n, t)\}$, calculate
1) the semantic distance between the r and all relations in p_i,
as, $SD(p_i(l), r) = \frac{1}{n} \sum_{l_j \in p_i(l)} \frac{r \cdot l_j}{\|r\| \|l_j\|}$;
2) the semantic distance between the t and all head entities in p_i, as, $SD(p_i(e), t) = \frac{1}{n} \sum_{e_j \in p_i(e)} \frac{t \cdot e_j}{\|t\| \|e_j\|}$;
3) the semantic distance between the h and all tail entities in p_i, as, $SD(p_i(e), h) = \frac{1}{n} \sum_{e_j \in p_i(e)} \frac{h \cdot e_j}{\|h\| \|e_j\|}$;
3: Calculate the average distance
$\bar{SD}(p_i) = \frac{1}{3}(SD(p_i(e), t) + SD(p_i(l), r) + SD(p_i(e), h))$;
4: Select first $TopK$ paths with the highest $\bar{SD}(p_i)$ scores.
5: Return $\{p_i \mid 1 \leqslant i \leqslant TopK, Sort(\bar{SD}(p_i), descend)\}$

3.4 Fusing the Estimators

We designed a Fusioner based on a multi-layer perceptron [12] to output the final triples trustworthiness values. A simple way to combine the above Estimators is to splice their outputs into a feature vector $f(s)$ for each triple $s = (h, r, t)$ and,

$$f(s) = \left[RR(h, t), p(E(s)), RP(s)\right] \tag{4}$$

The vector $f(s)$ will be inputted into the Fusioner and transformed passing multiple hidden layers. The output layer is a binary classifier by assigning a label of $y = 1$ to true tuples and a label of $y = 0$ to fake ones. A nonlinear activation function (logistic sigmoid) is used to calculate $p(y = 1|f(s))$ as,

$$\begin{cases} h_i = \sigma(W_{h_i} f(s) + b_{h_i}) \\ p(y = 1 \mid f(s)) = \varphi(W_o h + b_o) \end{cases} \tag{5}$$

Where h_i is the i_{th} hidden layer, W_{h_i} and b_{h_i} are the parameter matrices to be learned in the i_{th} hidden layer, and W_o and b_o are the parameter matrices of the output layer.

4 EXPERIMENTS

4.1 Experimental Settings

We focus on Freebase [4], which is one of the most popular real-world large-scale knowledge graphs, and we perform our experiments on the FB15K [5], which is a typical benchmark knowledge

graph extracted from Freebase. As for the FB15K, there are 1,345 relations and 14,951 entities and the corresponding 592,213 triples. We use all of the 592,213 triples to construct graphs which are described in Section 3.1. Each head entity is the core of a graph, so we can construct 14,951 graphs. These graphs are used for ResourceRank algorithm and Reachable paths inference algorithm.

There are no explicit labelled errors in the FB15K. Considering the experience that most errors in real-world KGs derive from the misunderstanding between similar entities, we use the methods described in [42] to generate fake triples as negative examples automatically where the picked entity should once appear at the same position. For example, (Newton, Nationality, American) is a potential negative example rather than the obvious irrational (Newton, Nationality, Google), given a true triple (Newton, Nationality, England), as England and American are more common as the tails of Nationality. We assure that the number of negative examples is equal to that of positive examples. In a random but quantitatively balanced manner, one of the three kinds of fake triples may be constructed for each true triple: one by replacing head entity, one by replacing relationship, and one by replacing tail entity. We assign a label of 1 to positive examples and 0 to negative examples. Therefore, we build a corpus for our experiments which contains double 592,213 triples. It is separated for training (double 483,142 triples), valid (double 50,000 triples), and testing (double 59,071 triples)

We implement the neural network using the Keras library[2][3]. The dimension of the entity and relation embeddings is 100. The batch size is fixed to 50. We use early stopping [10] based on the performance on the validation set. The number of RNN units is 100. Parameter optimization is performed with the Adam optimizer [20], and the initial learning rate is 0.001. In addition, to mitigate overfitting, we apply the dropout method [37] to regularize our model.

In addition, there are some adjustable parameters during the model training. θ is the probability that the resource flow from a node directly jumps to a random node. According to the value in the PageRank algorithm [6, 33], we set $\theta = 0.15$. We set $K = 4$ and $TopK = 3$. If the two parameters are set too large, the consumption of model training will be greatly increased. If they are set too small, the related algorithm will be affected. Thus this is the trade-off after repeated attempts. The relation-specific threshold δ_r can be searched via maximizing the classification accuracy on the validation triples, which belong to the relation r.

4.2 Interpreting the Validity of the Trustworthiness

To verify whether the triple trustworthiness outputs from KGTtm is valid, we do the following analysis on the test set.

We display the triple confidence values in a centralized coordinate system, as shown in figure 5(a). The left area shows the distribution of the values of the negative examples, while the right area shows that of the positive examples. It can be seen that the confidence values of the positive examples are mainly concentrated in the upper region (> 0.5)[4]. In contrast, the values of the negative examples are mainly concentrated in the lower region (< 0.5). It is consistent with the natural law of judging triple trustworthiness, proving that the triple confidence values output from our model are meaningful.

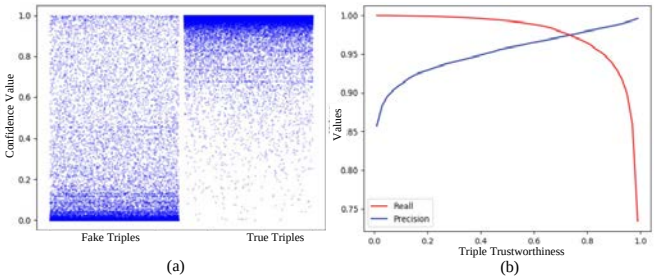

Figure 5: (a) The scatter plot of the triple confidence values distribution. (b) The various value cures of precision and recall with the triple confidence values.

In addition, by dynamically setting the threshold for the triple confidence values (only if the value of a triple is higher than the threshold can it be considered trustworthy.), we can measure the curves of the precision and recall of the output, as shown in figure 5(b). As the threshold increases, the precision continues to increase, and the recall continues to decrease. When the threshold is adjusted within the interval [0, 0.5], there is no obvious change in the recall, and it remains at a high level. However, if the threshold is adjusted within the interval [0.5, 1] , the recall tends to decline. In particular, the closer the threshold is to 1, the greater the decline rate will be. These show that the positive examples universally have higher confidence values (> 0.5). Moreover, the precision has remained at a relatively high level, even when the threshold is set to a small value, which indicates that our model can identify the negative instances well and assign them a small confidence value.

4.3 Comparing With Other Models on The Knowledge Graph Error Detection Task

The Knowledge graph error detection task is to detect possible errors in the KG according to their triple trustworthy scores. Exactly, it aims to predict whether a triple is correct or not, which could be viewed as a triple classification task [36].

We give several evaluation results. (1) The accuracy of classification. The decision strategy for classification is that if the confidence value of a testing triple (h, r, t) is below the threshold 0.5, it is predicted as negative, otherwise, it is positive. (2) The maximum F1-score when the given threshold is at [0, 1].

As shown in table 1, our model has better results in terms of accuracy and the F1-score than the other models. The Bilinear model [22] [32] [44] and Multi layer perceptron (MLP) model [8] [22] have been widely applied to the KG related tasks. They can calculate a score for the validity of triples through operations, such as tensor decomposition and nonlinear transformation. Here we convert the scores to the confidence values using the sigmoid function. Compared with the Bilinear and MLP models, our model shows improvements of more than 10% in the two evaluation indicators. We use the TEF algorithm (as illustrated in Section 3.2) to transform the output

[2]https://github.com/keras-team/keras
[3]The code can be obtained from https://github.com/TJUNLP/TTMF.
[4]The output-layer of our model is a binary classifier, and the confidence value of a triple is the probability that the triple is predicted as label=1, therefore we choose a threshold of 0.5.

Table 1: Evaluation results on the Knowledge graph error detection.

Models	MLP	Bilinear	TransE	TransH	TransD	TransR	PTransE	Ours_TransE	Ours_PTransE	Ours_TransH
Accuracy	0.833	0.861	0.868	0.912	0.913	0.902	0.941	0.977	0.978	**0.981**
F1-score	0.846	0.869	0.876	0.913	0.913	0.904	0.942	0.975	0.979	**0.982**

Table 2: Evaluation results of the three type noises.

Models	$(h, r, ?)$		$(h, ?, t)$		$(?, r, t)$	
	Recall	Quality	Recall	Quality	Recall	Quality
MLP	0.970	0.791	0.912	0.735	0.978	0.844
Bilinear	0.936	0.828	0.904	0.807	0.973	0.907
TransE	0.960	0.796	0.927	0.759	0.959	0.786
TransH	0.935	0.826	0.927	0.811	0.955	0.850

TransR	0.964	0.872	0.921	0.829	0.972	0.868
PTransE	0.944	0.841	0.973	0.888	0.957	0.863
Ours	**0.987**	**0.943**	**0.977**	**0.923**	**0.994**	**0.959**

Table 3: Evaluation results of each single estimator on the Knowledge graph error detection.

Models	TEF(TransE)	ResourceRank	RPI	KGTtm
Accuracy	0.868	0.811	0.881	0.977

of the embedding-based models of TransE, TransH, TransD, TransR, and PTransE into triple confidence values. These embedding-based models are better than the traditional method, but their results are affected by the quality of the embeddings. In comparison, our model does not rely on word embeddings. We introduce different embeddings into our model, as shown by Ours_TransE, Ours_TransH, and Ours_PTransE, which have very subtle effects. Since our model makes full use of the internal semantic information of the triple and the global inference information of the knowledge graph, it is more robust to achieve the three-level measure of trustworthiness.

4.4 Analyzing the ability of models to tackle the three type noises.

Three types of errors or noises are generated by replacing the head entity, tail entity, or relation in the triples. We measure the ability of the models to recall positive cases from candidate triples doped with a large number of noises.

We select only true triples (positive examples) in test set and divide them into three categories: all pairs of head and relation $(h, r, ?)$, all pairs of head and tail $(h, ?, t)$, and all pairs of tail and relation $(?, r, t)$. Then complement all empty positions with the objects in entity set or relationship set. In this way, for a certain pair of head and relation or a pair of tail and relation, 14,951 candidate triples can be constructed respectively. Similarly, for a pair of head and tail entities, 1,345 candidate triples can be generated. As for a complemented triple (h, r, t), we calculate its confidence value. When the value is higher than the threshold (> 0.5), we judge it to be correct. Two evaluation metrics are conducted as: (1) The recall of true triples in the test set (Recall). (2) The average trustworthiness values across each set of true triples (Quality) [22].

By analyzing the table 2, we find that our model achieves a higher recall on the three test sets compared to other models, it shows that our model can more accurately find the right from noisy triples. The average trustworthiness values of our model is higher than that of others, which show that our model can better identify the correct instances and with high confidence values. In addition, it can be found that the output of almost all models satisfies this phenomenon: The $(?, r, t)$ set achieves the best results, but the worst among the $(h, ?, t)$ set. It is difficult to judge the relation types of an entity pair, because there may be various relations between a certain entity pair, which increases the difficulty of model judgment.

4.5 Analyzing the Effects of Single Estimators

To measure the effect of single Estimators, we separate each Estimator as an independent model to calculate the confidence values for triples. The results in the knowledge graph error detection are shown in table 3. It can be found that the accuracy obtained by each model is above 0.8, which proves the effectiveness of each Estimator. Among them, the Reachable paths inference (RPI) based method achieves better results than the other two Estimators. After combining all the Estimators, the accuracy obtained by the global model (KGTtm) has been greatly improved, which shows that our model has good flexibility and scalability. It can well integrate multiple aspects of information to obtain a more reasonable trustworthiness.

It is worth emphasizing that our model is flexible and easy to extend. The newly added estimators can train their parameters together with the model frame. In addition, the confidence value generated by a single estimator can be extended to the feature vector $f(s)$ straightly.

5 CONCLUSION

In this paper, we establish a knowledge graph triple trustworthiness measurement model (KGTtm) to detect and eliminate errors in the KG. The KGTtm evaluates the trustworthiness of the triples from three perspectives and synthetically uses the triple semantic information and the global inference information of the knowledge graph. Experiments were conducted on the popular Freebase. The results confirmed the capabilities of our model. In the future, we will explore adding more estimators to the model to further improve the effectiveness of the trustworthiness. We will also try to apply the trustworthiness to more knowledge-based applications.

ABSTRACT

Residential buildings constitute roughly one-fourth of the total energy use across the globe. Numerous studies have shown that providing an *energy breakdown* increases residents' awareness of energy use and can help save up to 15% energy. A significant amount of prior work has looked into source-separation techniques collectively called non-intrusive load monitoring (NILM), and most prior NILM research has leveraged high-frequency household aggregate data for energy breakdown. However, in practice most smart meters only sample hourly or once every 15 minutes, and existing NILM techniques show poor performance at such a low sampling rate.

In this paper, we propose a TreeCNN model for energy breakdown on low frequency data. There are three key insights behind the design of our model: i) households consume energy with regular temporal patterns, which can be well captured by filters learned in CNNs; ii) tree structure isolates the pattern learning of each appliance that helps avoid magnitude variance problem, while preserves relationship among appliances; iii) tree structure enables the separation of known appliance from unknown ones, which de-noises the input time series for better appliance-level reconstruction. Our TreeCNN model outperformed seven existing baselines on a public benchmark dataset with lower estimation error and higher accuracy on detecting the active states of appliances.

1 INTRODUCTION

Residential buildings constitute roughly one-fourth of the total energy usage across the global [20]. Studies have shown that providing an energy breakdown can motivate behavioral changes, potentially reducing energy consumption by 15% [2].

Various energy breakdown approaches have been proposed since the pioneering work on non-intrusive load monitoring (NILM) [9]. NILM algorithms are designed for high-frequency data (sampling frequencies > 1/60 Hz), and do not apply when dealing with low sampling rates. However, high-frequency sensors are expensive; and smart meter specifications [21] across the world suggest that the largest proportion of smart meters sample at an hourly rate. This urges the need to develop algorithms suited for time series data with lower sampling rates. On the other end of the spectrum, there are approaches providing energy breakdown at a monthly level, e.g., using monthly bills as aggregate energy consumption [4, 6, 7]. The key idea is that common design patterns create a shared structure in residential buildings and give rise to a sparse set of features contributing to energy variations across homes. Matrix factorization [7] and kernel density estimation [6] techniques are introduced to exploit the sparsity structure. Nevertheless, such techniques cannot be directly applied to higher sampling rates, which rapidly increase the dimension of observations and model complexity.

Our extensive data analysis on a large public U.S. residential energy dataset suggests that sparsity and temporal regularity also exist in hourly appliance energy usage, such as the time of a day, day of a week. This motivates us to view such time series data as a high dimensional compound, rather than just a one-dimension sequence. For example, time of a day might differentiate the use pattern of microwaves from other appliances, while the day of a week might indicate usage pattern of dryers. Each of such temporal patterns creates a unique dimension to recognize a particular type of appliance's energy usage in the aggregate energy readings. But it is clearly impossible to manually exhaust such temporal patterns for each appliance beforehand. We appeal to a learning-based solution to automatically extract such patterns from data. We view each temporal pattern as a latent basis of the high dimensional compound, and assume each appliance can be uniquely characterized by a subset of them. The energy use of each appliance can be isolated

from the aggregate readings by applying its corresponding set of bases. For example, at mealtime, the observed energy consumption should more likely come from a microwave than a dryer.

In this paper, we perform household energy breakdown at an hourly rate. We extract the temporal bases and predict the appliance energy consumption from aggregate energy readings via a set of convolutional neural networks (CNN) [15], which are organized in a tree structure. Thus, we name the solution TreeCNN. At each node, a CNN model is placed to reconstruct appliance energy. The root node of the tree takes aggregate energy reading as input and reconstructs its designated appliance's reading as output. The residual, i.e., the difference between its input and output, is passed to the child node as its input. The reconstruction is thus performed by recursively traversing the tree. Such an iterative procedure isolates the appliance model learning in each step while preserving all appliances as a whole. Thus, each appliance's usage pattern is modeled with "refined" aggregate energy consumption to avoid the overshadow magnitude problem. Further, with such a tree structure, the unknown consumption can be modeled as a special appliance to further de-noise the aggregate readings. It is known that finding the optimal tree structure is NP-complete, and thus we introduce a greedy approach to find the tree structure.

We used the public Dataport [17] dataset for evaluation. We compared TreeCNN against nine state-of-the-art baselines and found TreeCNN provides the most promising performance. Our evaluation shows that the tree structure suggested by our greedy approach performs only 4% worse compared to the optimal order found via an exhaustive search.

2 RELATED WORK

The related work in energy breakdown can be broadly classified as: event-based and total-load based learning approaches.

Event-based methods [8] find step changes in the power signal and assign them to different appliances. Such methods are generally used when high sampling frequency is available, as the events cannot be recognized at low frequencies. Besides, they do not work well when appliances change states simultaneously, nor for appliances that have a highly variable power draw like electronics.

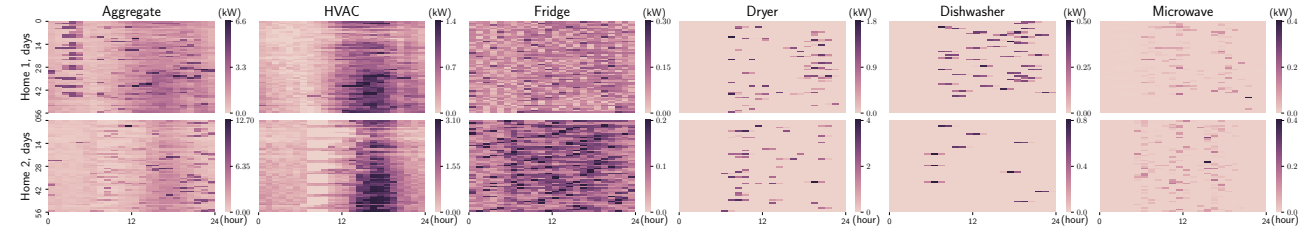
Total-load based methods model the aggregate consumption as a sum of constituent loads, while estimating these constituent loads at all sample points. Factorial Hidden Markov Model (FHMM) has been successfully applied to this problem [14], where each appliance is modelled as a Gaussian HMM. However, it only incorporates Markovian-type relationships in power draw and is not suited for capturing repeated patterns. There is a line of work for energy breakdown at a monthly level. The key insight of such approaches is that common design for buildings creates a sparse set of features contributing to energy variation across homes. Matrix factorization [7] and kernel density estimation [6] have been used to exploit such sparsity. But such solutions cannot be directly applied to higher sampling rate, as their model complexity increases exponentially with the sampling frequency. Sparse coding based approaches [13] have been proposed to address these techniques' limitations on hourly data. But all such solutions assume the aggregate equals to the sum of the appliances and thus suffer under practical settings.

Table 1: Energy statistics from Dataport dataset.

	HVAC	Fridge	Dryer	Dishwasher	Microwave
α(min)	5	5	5	5	2
δ_a	230	20	250	55	10
Active	73.9%	97.8%	4.9%	4.1%	11.3%
Max	5099.7	428.6	4364.1	1021.7	980.6
Mean	1162.7	88.6	1303.6	369.5	59.5
Std	800.2	40.2	756.2	206.5	53.1

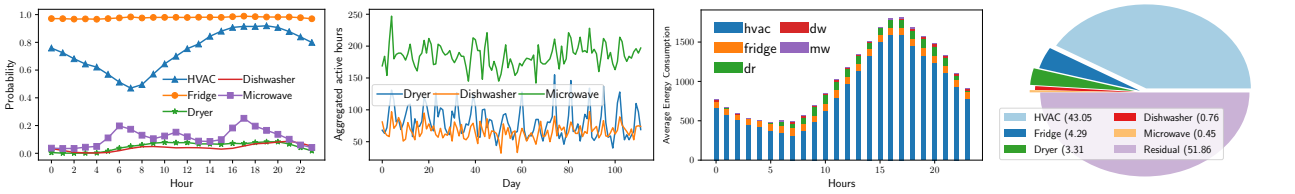
More recently, neural network based approaches for energy breakdown have been proposed: [11, 12] applied recurrent neural networks (RNN) to capture the time-series dependency of the energy signals sampled at a high frequency. However, a RNN model captures the one-dimension relationships in power draw, but is incompetent to capture other types of temporal dependencies. For example, in the hourly sampled data, appliances like microwave can be well recognized by the time-of-day pattern, while others like dryer is easier to be modelled by day-of-week pattern. Our solution considers time-series energy data as a high dimension compound of various temporal bases, and learns the bases from data to recognize different types of appliances from the aggregate readings.

3 DATA ANALYSIS OF APPLIANCE USAGE PATTERNS



The goal of this section is to explore the temporal patterns of energy consumption in residential buildings towards the development of our proposed energy breakdown method.

In this work, we use the public Dataport [17] dataset, which is the largest public residential home energy dataset. It contains power readings logged at minute intervals from hundreds of homes in the U.S.. We used 112 days worth data from 68 homes from mid-June on-wards for the year 2015, as this period has the least amount of data issues (missing or incorrectly collected data). We use the data of household total consumption and five major appliances: i) air conditioning system (HVAC); ii) fridge; iii) dryer; iv) dishwasher; v) microwave. These appliances contribute significantly to the total consumption. Besides, they also represent a diverse class of appliances: background (fridge) v.s. interactive (microwave), weather dependent (HVAC) v.s. time dependent (dryer, dishwasher).



Our focused appliances can generally be classified into two categories [3]: i) appliances that are constantly ON, such as fridge; and ii) ON/OFF appliances, such as washing machine. When dealing with low sampling rates, ON/OFF appliances introduce additional challenges - many of these appliances would only be used partially within an hour, which is the main reason that existing NILM algorithms fail at a low sampling rate. To understand the significance of this phenomenon in our dataset, we studied the shortest active time interval (α) of the 5 appliances (detailed results are in Table 1).

For hourly energy breakdown, the existence of short active intervals begs the question - how much energy should an appliance consume within an hour to be considered as "actively used". On consultation with domain experts, we set the active threshold δ_a for each appliance a as:

$$\delta_a = \frac{\alpha_a}{60} \times \frac{1}{H} \sum_{h}^{H} \max_{d,t} E_{h,a,d,t} \tag{1}$$

(a) Heatmap of aggregate and appliance-level energy consumptions from two randomly selected homes.

(b) Active probability. (c) Aggregated active hours. (d) Average consumption. (e) Consumption proportion.

Figure 1: Data analysis for residential home temporal energy consumption patterns.

where H represents the number of homes, $E_{h,d,a,t}$ is the energy consumed by appliance a on day d at hour t for home h, and α_a is the minimum active time for appliance a. As we know, for appliance occasionally used, it is easy to get good overall performance by giving all zero-predictions (e.g., microwave is OFF over 88% of time). However, such false negative prediction violates the original intention of energy breakdown, i.e., provide the opportunity of energy saving by informing users of how much energy each appliance consumes. With such an active threshold, we can recognize different states of appliances and evaluate a model's performance in two classes, i.e., error in ON/OFF states.

The basic statistics about this dataset with the active threshold are reported in Table 1. The constantly ON appliances, i.e., HVAC and fridge, are almost always on (active percentage: 73.9% and 97.8%); but their energy consumption patterns are different: fridge consumes roughly constant energy over time, while HVAC's consumption varies significantly (std = 800.2). For the ON/OFF appliances, such as dryer, it is seldom used, but once used, it consumes almost the highest energy. This macro-level analysis suggests the need of different temporal bases across appliances.

Previous works [4, 7] show that the energy consumption pattern is sparse owing to the common design of residential buildings. Our data analysis suggests that due to the temporal human behavior patterns, such sparsity also exists at an hourly and daily level. Figure 1a shows the aggregate and five appliances' energy consumption from two randomly sampled homes over 24 hours across 56 days. We can recognize strong patterns within a day across these 56 days: i) both homes tend to consume more energy by HVAC in the afternoon and less in the morning; ii) fridge constantly runs with regular working peaks; and iii) dishwasher and microwave are more likely to be used at the mealtime. Figure 1b, which presents the probability of appliances being in active state during 24 hours, further indicates the hourly patterns. Besides, Home 2 consumes less HVAC energy in the morning and this pattern only appears on the weekdays. Further, people tend to use dryer periodically across days. Figure 1c shows the aggregated active hours across homes in each day for the ON/OFF appliances. It shows that, for dryer, the total number of active hours has a peak every week while dishwasher and microwave are used on an everyday basis.

Besides, energy consumption is highly imbalanced among appliances. "Minor" appliances are often a problem for many existing NILM algorithms owing to their small magnitude of consumption. A detailed comparison is shown in Figure 1d. We can notice that throughout a day, most energy is consumed by HVAC. For those ON/OFF appliances, such as microwave and dryer, when both are on, the one with smaller energy consumption is overshadowed by the larger one, which makes it even harder to differentiate their uses, as "minor" appliances can be confused with "noise". It should be noted that despite low contribution, simply predicting zero use is misleading, and detecting the energy use of these appliances has been shown useful for applications such as elderly monitoring [1].

In addition to the known appliances, it is important to note that the aggregate consumption is often not equal to the sum of the considered individual appliances' consumption. For example, the aggregate consumption of Home 1 shows regular high consumption in the early morning, which is not observed in the known appliances. Such unknown consumption comes from various sources, such as the living room usage, or electric cars. Figure 1e shows the energy consumption proportion of different energy sources, where the unknown consumption can take up 51.86% total energy in a home, and the failure to model them leads an algorithm to classify them to known appliances. To improve the accuracy of energy breakdown, such unknown consumption has to be carefully handled.

4 METHODOLOGY

We study the problem of disaggregating the aggregate energy in a single home to its constituent appliances at hourly intervals. Based on previous discussions, the hourly sampled energy data has several important properties, i) the existence of sparsity and regularity in multiple temporal dimensions, ii) energy consumption magnitude varies significantly across appliances, and iii) the existence of unknown consumption sources. We will discuss our solutions to handle each of them in the following sections.

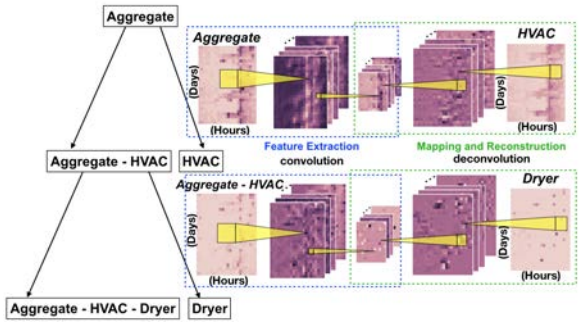


Figure 2: Our tree-structured iterative energy breakdown approach shown for two appliances (HVAC and Dryer).

4.1 TreeCNN Model

The key intuition of TreeCNN lies in two aspects: i) the distinct and multi-dimensional temporal patterns of appliance energy constitute the sparsity and regularity in appliance energy use; ii) the aggregate energy is a composition of various and complicated appliance energy, such that the decomposition should be performed in a joint and recursive manner to avoid the errors introduced by the magnitude problem and potential unknown consumption. We now discuss each component of our proposed TreeCNN model.

• **Convolutional Neural Network (CNN).** Our analysis results show that different appliances have distinct temporal patterns. But, simply modeling the hourly time-series data as a one-dimension sequence cannot fully describe appliances. For example, microwave is more frequently used during the meal time (a hourly pattern), while the dryer is easier to model across days for its periodical usage (a daily pattern). Thus, this time-series data should be viewed as a high dimensional compound of various temporal patterns.

Besides the patterns observed in the appliance usage data, there might also exist other higher order temporal patterns that cannot be simply exhausted manually. Thus, we turn to learning-based solutions to automatically extract the latent bases from data. Inspired by the successful applications of convolutional neural networks (CNN) in image analysis [15], we appeal to CNN models to extract energy usage basis. The key component of CNN model is the filters that capture the spatial features of an image. In an analogy, the hourly energy readings can also be viewed as a 2-D matrix (Figure 1a) and thus can be well described by the spatial filters learned from CNNs.

With CNN model, distinguishable filters can be learned for appliances with distinct temporal patterns. For example, filters learned on microwave may emphasize more on the hour dimension, filters for dryer will emphasize on the day dimension, and the filters for HVAC may be a compound of patterns on both dimensions. With such filters, the aggregate readings can be projected into its corresponding appliance usage. Figure 2 shows an example of a CNN model which learns the mapping from aggregate readings to HVAC consumption. In the convolution phase, CNN model takes the aggregate as input and tries to reduce it to a much denser representation. Due to the sparsity and granularity, the temporal patterns can be extracted and the input will be represented as a denser matrix with a lower dimensionality. In the deconvolution phase, the decoder performs the opposite operations that reverse the action of encoders.

• **Tree Structure.** The model complexity in energy breakdown increases exponentially with the number of sources constituting the aggregate. Further, the usage of some appliances can get overshadowed by others (Figure 1e) creating a "magnitude" problem.

Different from conventional techniques, which either estimate appliance usage independently, or disaggregate the energy altogether at once, we propose a tree-structured model to extract appliance patterns in a "stage-wise manner". With the tree structure, our approach performs an iterative energy breakdown: at each iteration, we subtract out a source from the aggregate and use it as input to recognize the designated appliance. Figure 2 depicts an example of our tree-structured model with HVAC and dryer. The root node takes the aggregate readings as input and reconstructs the HVAC consumption as its output. The difference between them will be passed to the child node as refined input for the next appliance, e.g., dryer in the figure. The magnitude problem is thus eased for the minor appliances, such as microwave, if we place them at the lower end of the tree. In contrast, if we jointly decompose the aggregate readings into appliances' readings, the minor appliances will be overshadowed by major appliances, and mostly given zero predictions, which defeats the original intention of energy breakdown.

In our TreeCNN model, we effectively simplify the energy breakdown iteratively. In each node, the CNN model performs an end-to-end learning for the target appliance, which isolates pattern learning across appliances to avoid the overshadow problem while preserving all appliances as a whole.

• **Modeling Unknown Consumption.** In addition to the magnitude problem caused by the various constitutes of aggregate, the unknown consumption also introduces errors in energy breakdown. From the previous analysis, the unknown energy consumption comes from various sources and therefore is hard to specify beforehand. To the best of our knowledge, no existing work models the unknown consumption. In our tree-structured model, the unknown consumption can be viewed as a special appliance which consists of multi-dimension temporal patterns. Modeling the unknown consumption makes it possible to remove such energy from the true aggregate consumption, which leads to a more accurate estimation of the observed appliances.

4.2 Tree Order

Given N appliances, we would have $N!$ possible tree structures. For a residential home at the U.S., one can usually expect 7-10 major appliances in monitoring. For any larger values of N, exhaustively finding the "optimal" tree order can be computationally expensive, where "optimality" is defined as per given energy breakdown metric M. Since the error of one decomposition will be propagated through the tree structure, the tree order is essential to our model.

We propose a greedy algorithm to find a suitable tree order to mitigate error and reduce the search space. The key operation is to estimate the overall performance with partial information via the inverse propensity weighting scheme [16, 22]. Assume we have N appliances and metric $M(E(a_i), \hat{E}(a_i))$ is used to compute the error for appliance a_i where $\hat{E}(a_i)$ and $E(a_i)$ denote the estimation and the ground-truth of appliance a_i. In the first iteration, we will create N candidate splits. Among these N models, we select k models with the smallest *estimated energy breakdown error* ($EEBE^{GR}$) on the validation set. Next, $(N-1)$ sub-trees are created for each selected

k parent tree. The selection repeats until we have constructed the whole tree. In particular, local metric $EEBE^{GR}$ is used to estimate the overall energy breakdown error, before the whole tree has been constructed. This metric calculates the ratio between a chosen metric for an appliance and the proportion of energy consumed by this appliance:

$$EEBE^{GR}(a_i) = \frac{M(E(a_i), \hat{E}(a_i))}{\frac{\sum_h \sum_d \sum_t E(h, a_i, d, t)}{\sum_h \sum_a \sum_d \sum_t E(h, a, d, t)}} \quad (2)$$

The rationale behind $EEBE^{GR}$ is that it assumes if an appliance has an error e and contributes x proportion to aggregate, then the aggregate would have an expected error of $\frac{e}{x}$ from this appliance. Thus, we can estimate the final error by estimating the prediction error of each appliance during the tree construction. In such way, we get the error of the entire tree before it is constructed, which makes the sequential decisions of tree order possible.

5 EMPIRICAL EVALUATION

In this section, we evaluate the our model on the hourly data collected from 68 homes over 112 days in the Dataport dataset.

5.1 Experimental settings

5.1.1 Baselines. We first describe the baselines

• **Mean Energy:** This baseline computes the predicted energy of an appliance as its mean energy in the training set.

• **Factorial Hidden Markov Model (FHMM):** FHMMs [14] model each appliance as a Gaussian hidden Markov model and couple the individual appliance HMM in a factorial structure.

• **Tensor Factorization:** Canonical polyadic decomposition [4] (CP) is used to factorize the energy tensor into latent matrices. They proposed a modified CP (MCP) to mitigate the scaling problem.

• **Sparse Coding:** Sparse coding [13] model approximates the bases and activations for each appliance with sparsity constraints. The authors also proposed a structured prediction based method called discriminative sparse coding (DSC).

• **Recurrent Neural Networks (RNN):** We performed the decomposition with individual RNN model and TreeRNN model, which captures the time-series dependency of the energy signals.

• **Convolutional Neural Networks (CNN):** We use individual CNNs and JointCNN. Individual CNNs estimates appliances' energy separately, and JointCNN estimates them all together at once.

5.1.2 Approach settings. Among all methods, we used 5-fold cross-validation in the experiments. The final 20% of the train set is set for validation purpose. For each algorithm, the optimal parameters are learned via grid search. The optimal parameters that give the best performance on the validation set are used for testing. For FHMM model, we vary the number of states per appliance from 2 to 5 [5, 23]. CP and MCP are optimized with Adagrad [4], and we vary the rank of latent factors from 1 to 12. For sparse coding models, we vary the rank of latent factors from 1 to 50.

We implemented all neural network models with PyTorch [19]. For RNN models, we have the following parameters: cell type: {GRU, LSTM, RNN}; number of hidden units: {20, 50}; number of layers: {1, 2, 3}; number of iterations: {1000, 2000, 3000}. For CNN models, complex network will easily cause overfitting due to the limited training data. Thus, we have the encoders consist of two convolutional layers and two deconvolutional layers with normalization [10] to accelerate the training process, and ReLU activation function to introduce non-linearity. We choose the learning rate from {0.01, 0.1, 1} and the number of iterations from {1000, 2000, 3000}. For tree-structured models, we perform both exhaustive and greedy search. We use top-k = 3 results at each stage of greedy search. We use the L1-loss as the objective function. For neural network based methods, we clamp the estimated consumption to a maximum of the observed aggregate energy. Our entire codebase, baselines, analysis and experiments can be found on Github [1].

5.1.3 Metric. Based on prior literature [4, 7], we evaluate the performance with mean absolute error (MAE). Denote the ground-truth and estimation for home h, appliance a, day d and hour t as $E(h, a, d, t)$ and $\hat{E}(h, a, d, t)$, for appliance a, MAE is computed as:

$$MAE(a) = \frac{\sum_h \sum_d \sum_t |E(h, a, d, t) - \hat{E}(h, a, d, t)|}{H \times D \times T} \quad (3)$$

where H, D, T indicate the number of homes and days, and hours in a day. We use the average MAE across appliances to measure the model accuracy. Lower mean MAE indicates better performance.

As shown before, in some ON/OFF appliances, the active time is generally low. The MAE alone cannot fully reflect the performance, as zero predictions can also give a good MAE. Thus, we separate MAE into two parts, corresponding to the active and inactive states based on the ground-truth (threshold is reported in Table 1).

5.2 Experiment Results

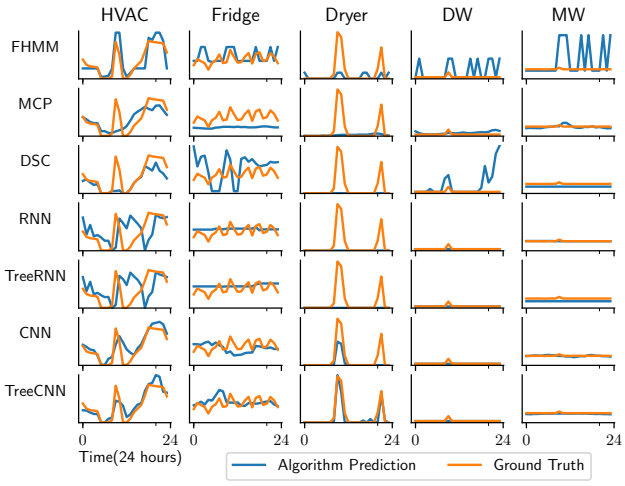

Figure 3: Comparison of baseline algorithms for a sample day. (DW: Dishwahser, MW: Microwave)

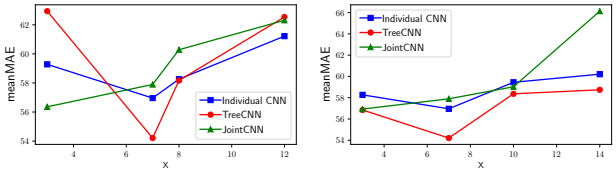

In the following sections, we first test the energy breakdown capabilities in an ideal case, where the aggregate energy equals the sum of selected appliances, and then perform the same experiments on the true aggregate dataset where the unknown consumption is included. Further, we compare the baselines and our TreeCNN model with and without modeling the unknown consumption to

Table 2: MAE on artificial aggregate and true aggregate dataset.

		FHMM	CP	MCP	SC	DSC	Mean	RNN	TreeRNN	CNN	JointCNN	TreeCNN
Artificial Aggregate	MAE	114.99	106.19	103.46	92.20	172.95	100.34	67.34	64.26	56.96	57.90	**51.64***
	MAE on Active	360.76	390.39	390.90	411.93	388.29	404.03	388.90	383.84	310.51	332.45	**261.30***
	MAE on Inactive	80.34	96.11	96.93	28.61	**15.03**	49.13	37.87	36.79	41.53	42.07	40.05
True Aggregate	MAE	134.99	123.90	125.30	245.70	218.43	126.86	97.8	94.52	89.15	91.35	**86.94***
	MAE on Active	400.76	414.01	412.33	515.54	521.35	421.50	43538	433.01	417.85	429.87	**391.50***
	MAE on Inactive	82.94	103.10	107.81	215.57	190.84	102.22	60.32	**54.85**	68.28	69.26	61.69

study the effectiveness of unknown consumption modeling. Last, we report the results of greedy algorithm on tree order estimation.

(a) Filter size: 7 × X **(b) Filter size: X × 7**

Figure 4: Effect of filter size tuning on CNN models.

5.2.1 Filter size in CNN models. In CNN-based models, filter size plays an important role in capturing the temporal patterns. We explored the effect of different filter sizes in the first layer of CNN models. From Figure 4, we can observe that the performance of CNN models is quite sensitive with the filter sizes. When the size equals to 7×7, most models achieve the best performance, as such filters can well capture the patterns across hours and days. With small sized filters, the model might miss some periodical patterns across multiple dimensions; and with large sized filters, it will fail to capture the local features and generate redundant information. In the following experiments, the filters of each layer are set to 7×7 and 2×2. And the decoder is a mirrored version of the encoders with two deconvolutional layers.

5.2.2 Ideal case. Like previous studies [13, 23], we simulate the ideal case by manually setting the artificial aggregate. Shown in Table 2, TreeCNN algorithm outperforms all the baselines (p-value is calculated between the predictions of TreeCNN and the second best model). Figure 3 shows the energy estimation from a set of baselines of a randomly chosen day of one randomly selected home.

FHMM assumes the appliances can be modeled with a Gaussian HMM using discrete states, which considers the transition and emission probabilities between states. But it is not well suited to sparsely used appliances. MCP and DSC algorithms are both of a similar vein focusing on learning various "basis" of energy consumption. Both algorithms performed reasonably well in general. However, they are not well-tuned for the instances when energy consumption patterns differ from the average patterns. And they are poor at capturing the active states of the ON/OFF appliances. From Table 2, we can observe that for MAE on Inactive, SC and DSC have better performance. This is because the design of their two-stage decomposition adds the equality constraint between the sum of appliances and aggregate readings. The mean baseline, though simple, performs reasonably well. However, it does so as it models the appliances to be mostly off and thus a low MAE for the inactive cases, but high MAE for the active cases.

Table 3: Effect of UC modelling. (UC: Unknown Consumption, DW: Dishwasher, MW: Microwave)

	HVAC	Fridge	Dryer	DW	MW	**Average**
TreeRNN w.o. UC	351.83	29.88	66.93	15.45	8.53	94.52
TreeRNN w. UC	337.69	30.02	67.16	15.43	8.43	91.75
TreeCNN w.o. UC	306.38	33.74	70.09	15.49	9.00	86.94
TreeCNN w. UC	296.11	33.34	69.01	15.45	8.83	**84.55**

Table 4: TreeCNN performance under different tree orders. (UC: Unknown Consumption, agg: aggregate)

	Worst	**Average**	**Greedy**	**Best**
Artificial agg	84.42	68.72	54.21	51.64
True agg w.o. UC	105.60	96.54	88.38	86.94
True agg w. UC	110.75	98.64	87.21	84.55

Compared with the non-neural network baselines, the MAE is largely reduced by RNN and CNN based models. Between the individual neural network models, CNN outperforms RNN. The main reason is with the learned filters, CNN can capture the multi-dimensional usage patterns, e.g., hourly pattern and daily pattern in our dataset, while RNN treats the energy readings as a one-dimension time-series ignoring the periodical patterns. For example, in Figure 3 with CNN models, the active states of the ON/OFF appliances, such as dryer, is well detected, while RNN gives zero predictions. From Table 2 and Figure 3, the performance of neural network models are both improved with the tree structure. Though JointCNN also encodes the relationship among appliances, direct decomposition could not overcome the magnitude problem, which generates significant larger error in MAE on Active as the "minor" appliances are easily overshadowed.

5.2.3 Real-world case. Now, we evaluate the models on the true aggregate dataset. From Table 2, we can see that with true aggregate, TreeCNN model still outperforms the other baselines. Comparing the results from these two settings, we can notice that all algorithms show poorer performance with true aggregate. As discussed before, this can be explained by the high amount and variety of unknown consumption. In our TreeCNN, the complex latent bases of unknown consumption can be captured via filters. Table 3 shows the improvement when we consider the unknown consumption in the model. Paired t-test shows almost all the estimations significantly improve except for the dryer. In this work, we only set one model for the unknown consumption, while it might come from a combination of various sources, which we defer to future work.

5.2.4 TreeCNN with greedy v/s exhaustive tree orders. Table 4 compares the mean MAE performance of TreeCNN model with the best

and worst tree orders found by exhaustive search and the order found with greedy search. We also report average MAE over all tree orders explored in the exhaustive search. It shows that our greedy algorithm performs substantially better than the average and is only about 4% worse than the best order found via exhaustive enumeration. The learned tree order also discloses interesting property of this problem: placing HVAC in the first few levels in the tree leads to poorer performance, as the HVAC energy is easily to be over-estimated to "eat" up the energy of other appliances.

6 CONCLUSIONS

In this paper, we presented a new approach for hourly energy breakdown. Our data analysis revealed that hourly energy data has notable high-dimensional sparsity and temporal regularity, which can be exploited for energy breakdown by learning their temporal bases. We introduced a tree-structured CNN model to estimate such temporal patterns and handle some of the shortcomings of existing methods. Empirical evaluation on a real-world household energy data set confirmed the effectiveness of our solution. With the vast amount of hourly smart meter data, we believe our approach has the scope to be scaled to millions of homes.

We would like to explore a few future extensions. First, TreeCNN currently treats the residual as one dummy appliance. However, residual could be a compound of various sources of energy consumption. We can introduce several residual models, or using prior models [18] to first extract latent appliances and generate a combined residual estimation. Second, our current approach does not fully incorporate the dependencies that might exist between different appliances (e.g., correlation between dryer and washing machine). We can incorporate such dependencies by creating additional links between different appliances, giving us a more general graph.

ABSTRACT

Sequence-to-Sequence (Seq2Seq) models have achieved encouraging performance on the dialogue response generation task. However, existing Seq2Seq-based response generation methods suffer from a *low-diversity problem*: they frequently generate generic responses, which make the conversation less interesting. In this paper, we address the low-diversity problem by investigating its connection with *model over-confidence* reflected in predicted distributions. Specifically, we first analyze the influence of the commonly used Cross-Entropy (CE) loss function, and find that the CE loss function prefers high-frequency tokens, which results in low-diversity responses. We then propose a Frequency-Aware Cross-Entropy (FACE) loss function that improves over the CE loss function by incorporating a weighting mechanism conditioned on token frequency. Extensive experiments on benchmark datasets show that the FACE loss function is able to substantially improve the diversity of existing state-of-the-art Seq2Seq response generation methods, in terms of both automatic and human evaluations.

1 INTRODUCTION

Recently, dialogue response generation has attracted a lot of attention due to its potential for applications, e.g., within intelligent customer service agents and personal assistants. Most state-of-the-art approaches to this task are based on *Sequence-to-Sequence* (Seq2Seq) frameworks [3, 11–13, 17, 19]. Current Seq2Seq frameworks suffer from a *low-diversity problem*. As a result, these approaches frequently generate generic responses such as "*I don't know*" or "*I'm sorry*" [3, 11, 12, 19].

To address the issue of low response diversity, previous studies have produced several hypotheses about the cause of the low-diversity problem with corresponding solutions. For example, Li et al. [3] argue that the usual max a posteriori (MAP) objective function might favor frequent responses. Instead, they propose to use a Maximum Mutual Information (MMI) objective function to encourage responses with higher mutual information regarding the user's utterance. The downside of this method is that it relies heavily on beam search and/or an inverse model that is trained by swapping inputs and outputs. Tao et al. [15] assume that the single attention layer commonly used in Seq2Seq models is only able to focus on a single semantic aspect of the input sequence, so they propose a Multi-Head Attention Mechanism (MHAM) to allow the decoder to generate more diverse responses. There are also studies that try to improve response diversity by introducing randomness [12, 19].

Recently, Jiang and de Rijke [1] have shown that there is a strong connection between the low-diversity problem and what they call *model over-confidence* following Pereyra et al. [10], the phenomenon that a model incorrectly assigns most probability to only a few tokens. However, the cause of this phenomenon remains unknown. In §2, we investigate and conclude that the model over-confidence problem is caused by an imbalanced training of tokens with variable frequencies, which favors frequent tokens and results in low-diversity. To correct for this, we propose a *Frequency-Aware Cross-Entropy* (FACE) loss function that improves the traditional *Cross-Entropy* (CE) loss function by taking token frequency into consideration. More specifically, we first analyze the influence of the commonly used CE loss function, and find that it prefers high-frequency tokens, which results in model over-confidence and low-diversity responses. Then we propose a FACE loss function that improves over the CE loss function by incorporating a weighting mechanism conditioned on token frequency.

The primary differences between FACE and previous studies in addressing the low-diversity problem are two-fold: (1) The diversity improvements brought by FACE do not rely on beam search or

Test rank	1 (72)	2 (7)	3 (5)	5 (3)	6 (3)	4 (2)
Training rank	1 (14)	7 (12)	3 (6)	6 (3)	8 (3)	4 (3)

randomness; and (2) FACE does not introduce new layers or hyper-parameters to Seq2Seq models.

We perform extensive experiments on two benchmark datasets, namely OpenSubtitles database (OSDb) and Twitter. Compared with deterministic Seq2Seq-based methods, like MMI [3] and MHAM [15], FACE achieves the highest diversity performance and it does so with minimum modifications to the original Seq2Seq model structure and existing hyper-parameters.[1]

The main contributions we make in this paper are:

- We examine the influence of token frequency on model over-confidence and response diversity.
- We propose a *Frequency-Aware Cross-Entropy* (FACE) loss function to balance the per-token loss, which alleviates model over-confidence and, hence, improves response diversity.
- We investigate two token frequency calculation methods and corresponding frequency-based weighting mechanisms for FACE.

2 LOW DIVERSITY, MODEL OVER-CONFIDENCE AND LOSS IMBALANCE

As illustrated by Jiang and de Rijke [1], model over-confidence [10] can cause Seq2Seq-based conversation models to have low response diversity. In this section, we show that model over-confidence and low-diversity are statistical and empirical symptoms of the same problem. Imbalanced training is the actual underlying reason.

Existing Seq2Seq-based conversation models tend to be over-confident during prediction and place most probability on only a few tokens. We define a *leading* token in a response to be a token that appears first. From Table 1, we can see that all of the most frequent leading tokens in model responses are actually very likely to appear first in training ground-truth responses, but the percentages of the top-ranked token "i" are much higher in the validation and test sets. This suggests that the model is over-fitting for frequent leading tokens. We also find that the frequency of some subsequent tokens (e.g., *'m* and *not*) is much higher in model responses than in the training ground truth, as illustrated in Table 2. This is also due to model over-fitting, since these tokens are *relatively* more frequent compared to other tokens. For example, given that the previous token is "i", the frequency of the following token "'m" is much higher than others in the training data.

To understand this phenomenon and introduce our solution, we first look into the commonly used *max a posteriori* (MAP) objective function of Seq2Seq models. Given a dataset of message-response pairs (X, Y), where $X = (x_1, x_2, \ldots, x_{|X|})$ and $Y = (y_1, y_2, \ldots, y_{|Y|})$ are the input and output sequences, respectively, the goal of Seq2Seq training is to maximize the conditional probability $P(Y|X)$. Since the decoder Recurrent Neural Network (RNN) can only give one output at each time step t, and to generate grammatical responses, we are actually maximizing token-wise probability at each time step during training:

$$\max P(Y|X) = \max \prod_{t=1}^{|Y|} P(y_t|y_{<t}, X), \tag{1}$$

where $y_{<t} = (y_1, y_2, \ldots, y_{t-1})$ are tokens generated in previous time steps. At test time, the response is generated with respect to:

$$\hat{Y} = \arg\max_Y P(Y|X). \tag{2}$$

In practice, we usually maximize the aforementioned conditional probability by minimizing the prediction loss at each step t, which is actually the Cross-Entropy (CE) loss:

$$\mathrm{CE}(y_t) = -\sum_{i=1}^{N} \delta_i(y_t) \log(P(c_i|y_{<t}, X)), \tag{3}$$

where $(c_1, c_2, \ldots, c_N)$ is the search space of y_t, $\delta_i(y_t) = 1$ if $y_t = c_i$ and 0 otherwise; $P(c_i|\cdot)$ is the predicted probability of candidate token c_i and is calculated using the softmax function:

$$P(c_i|y_{<t}, X) = \frac{\exp(f_\theta(h_{t-1}^{dec}, y_{t-1}, c_i, X))}{\sum_{j=1}^{N} \exp(f_\theta(h_{t-1}^{dec}, y_{t-1}, c_j, X))}, \tag{4}$$

where $f_\theta(\cdot)$ is a non-linear scoring function with parameters θ; $f_\theta(\cdot)$ takes the hidden state h_{t-1}^{dec}, last generation y_{t-1} and X as inputs, and calculates a score for each possible candidate c_i.

During training, the loss calculated using Eq. (3) is back-propagated through the whole network. The effect is that f_θ will assign higher scores for $c_i = y_t$ in the future, so that the loss in Eq. (3) will decrease, and meanwhile the predicted probability in Eq. (4) will increase. The ultimate effect is to maximize the probabilities of ground-truth outputs given input sequences, as illustrated in Eq. (1). The model is frequently penalized by a small number of frequent tokens, as a result of which the total loss (TL) for these tokens is higher than for less-frequent ones:

$$\mathrm{TL}(c_i) = \sum_{t=1}^{N_t} \mathrm{CE}(y_t = c_i), \tag{5}$$

where t denotes the time step, with maximum training steps N_t:

$$N_t = \sum_{i=1}^{N} \mathrm{freq}(c_i). \tag{6}$$

Here, $\mathrm{freq}(c_i)$ represents the frequency that c_i appears in the training ground truth. Assume that the expected value $\mathbb{E}[\mathrm{CE}(c_i)]$ is roughly the same for $c_i, \forall i \in \{1, 2, \ldots, N\}$, then tokens with a higher frequency will have a larger total loss during training. We refer to this phenomenon as *loss imbalance*.

Due to loss imbalance, a Seq2Seq model favors frequent tokens and thus is over-confident about them. This is especially true for the leading token as observed in Table 1, since the decoder language

model does not have a strong effect in the beginning of prediction. When a frequent token is selected as leading token, the search space for subsequent tokens is hugely restricted by the language model, and this will likely result in a frequent *generic* response.

3 FREQUENCY-AWARE CROSS-ENTROPY LOSS

Now that we have identified *loss imbalance* as a cause of low-diversity problems, we propose to balance the total loss for each token by applying a weight factor to TL:

$$\text{WTL}(c_i) = w_i \sum_{t=1}^{N_t} CE(y_t = c_i), \tag{7}$$

where w_i is the weight corresponding to c_i. By absorbing w_i into the CE loss function, we obtain the FACE loss function:

$$\text{FACE}(y_t) = -\sum_{i=1}^{N} w_i \delta_i(y_t) \log(P(c_i|y_{<t}, X)). \tag{8}$$

Our key solution to the low-diversity problem lies in the weight factors w_i. Based on the analysis in §2, one straightforward way to learning w_i is to take advantage of the token frequency $\text{freq}(c_i)$, so that frequent tokens will have lower weights. Below we propose two methods to estimate $\text{freq}(c_i)$: *ground-truth or GT frequency* and *output frequency*.

GT frequency: Token frequency in the ground-truth responses. As illustrated in Eq. (6), the number of training steps N_t equals the sum of frequencies of tokens in the training ground-truth responses, so it is intuitive to use these token frequencies to adjust the weight in Eq. (8). However, during training, the model is given data sequentially in random order. As a result, the real-time token frequency seen by the model is likely to differ from that of the entire training data. Our solution is to calculate the *batch* token frequency instead:

$$\text{freq}_b(c_i) = \text{freq}_{b-1}(c_i) + \text{freq}_o(c_i), \tag{9}$$

where b is the number of training batches seen so far and o represents the newly *observed* batch.

Output frequency: Token frequency in model responses. Alternatively, we can employ a train-and-refine strategy: the responses of a pre-trained Seq2Seq model can reflect which tokens the model is already overfitted for; by directly penalizing those tokens with a fine-tuning procedure, we can improve the response diversity without retraining it from scratch. The output frequency may have a more obvious effect on improving response diversity than the GT frequency, because diversity is directly exhibited by model outputs.

3.1 Weight calculation

Given the frequency of each token, we introduce the following two methods to calculate the weight factor.

3.1.1 Pre-weight. This method derives the weight factor w_i prior to seeing new training examples, i.e., *pre-weight function*:

$$w_i = a \times RF_i + 1. \tag{10}$$

Here we formulate it as a linear function of *relative frequency*: $RF_i = \text{freq}(c_i)/\sum_j \text{freq}(c_j)$, and $a = -1/\max RF_j, \forall j \in \{1, \ldots, N\}$, is the slope, and the bias is 1 so that w_i falls in $[0, 1]$. We then normalize $\{w_1, w_2, \ldots, w_N\}$ to have a mean of 1. The pre-weight function can make sure that tokens with a higher RF value will get lower weights. In other words, the influence of high frequency tokens will be penalized by using the pre-weight function.

3.1.2 Post-weight. This method tries to penalize the model's *conservativeness*: if the output token y_t has a higher frequency than the ground truth c_i, which indicates the model conservatively picked a "safe" token, then its loss will be scaled up by $w_i > 1$, otherwise $w_i = 1$ due to ReLU activations:

$$w_i = 1 + \frac{ReLU(\text{freq}(y_t) - \text{freq}(c_i))}{\sum_j^N \text{freq}(c_j)}. \tag{11}$$

Since we can only apply this weighting function after obtaining the model outputs, we refer to it as the *post-weight function*.

3.2 Empowered by confidence penalty

As illustrated in [1], *Confidence Penalty* (CP) methods can alleviate the low-diversity problem. In the experiments of this paper, we also test the performance of the CP function [1]:

$$\text{CP}(y_t) = \text{CE}(y_t) - \beta H(p(y_t|y_{<t}, X)), \tag{12}$$

where $p(y_t|y_{<t}, X)$ is the predicted distribution at t, and $H(\cdot)$ is its entropy. However, during experiments we found that the parameter β needs to be carefully chosen, otherwise the loss $\text{CP}(y_t)$ will be negative, which is counter-intuitive since losses should be greater than 0. Instead, we propose a *parameter-free* CP function:

$$\text{CP}_{free}(y_t) = \text{CE}(y_t) + \frac{1}{H(p(y_t|y_{<t}, X))}. \tag{13}$$

FACE and CP can be easily combined to further improve response diversity. A trivial combination is to replace the CE loss function with the FACE loss function in Eq. (12) and Eq. (13). We also propose a CP weighting function using the entropy in Eq. (13):

$$w = 1 + \frac{1}{H(p(y_t|y_{<t}, X))}, \tag{14}$$

where w (without subscript) is assumed to be independent of c_i, which is different from that in Eq. (10) and Eq. (11). By using w as the weight of FACE in Eq. (8), we can penalize the model confidence by adjusting the weight of FACE.

4 EXPERIMENTAL SETUP

To prove the effectiveness of our proposed methods, we design experiments to answer the following questions: (Q1) Which combination of our proposed frequency methods (GT frequency and output frequency) and weighting functions (pre- and post-weight) performs best? (Q2) Does FACE improve the diversity of Seq2Seq conversation models? (Q3) Does CP improve the diversity of Seq2Seq conversation models? (Q4) Does the combination of FACE and CP further improve performance? (Q5) Does FACE improve the response quality besides diversity?

4.1 Baselines and datasets

The first baseline is a vanilla Seq2Seq model with *general* attention [6] as implemented within the ParlAI platform [7]. We also choose the MMI models proposed in [3] and the MHAM models proposed in [15]. These models are all deterministic methods. In Table 3, we

[2]The MMI-bidi method needs a reverse model which is pre-trained using inverse training examples: (response, message).

Table 3: Components of different models.

Model	Greedy	BS	#Attn	Extras
Seq2Seq	Yes	No	1	No
MMI	No	Yes	1	Reverse[2]
MHAM	Yes	No	5	No
FACE	Yes	No	1	No
CP	Yes	No	1	No

list the main differences between our methods and the baselines in terms of greedy decoder, beam search (BS), number of attention layers (#Attn), and other mandatory components (Extras). To allow for a fair comparison, we implement all our methods and baselines using ParlAI. We choose two publicly available benchmark datasets: OSDb and Twitter, for evaluating the baselines and our proposed methods. We follow Li et al. [3], Tao et al. [15] to use short-history conversations; see below for details.

4.1.1 OSDb. The OSDb dataset [16] is an online-available corpus of movie subtitles.[3] Here, we use the 2011 version and set aside ~60M lines, which constitutes ~30M message-response pairs for training. Following Li et al. [3], we randomly select 2K pairs from the IMSDB dataset [18] for validation and test sets, respectively, and we filter out pairs whose responses or messages are shorter than 6 tokens.

4.1.2 Twitter. Twitter is a commonly used source of data in dialogue generation research. For ease of reproducibility of the results reported in this paper, we did not follow Li et al. [3], Sordoni et al. [13] who used ~130M context-message-response triples before preprocessing. Instead, we use the version released by [12] for training, which contains ~4M tweet IDs in total and can be scraped in 3 days.[4] After formatting the tweets as *context-message-response* triples, we have 904K training examples and we concatenate context-message as input. For the training, validation and test sets, we exclude all overlapping IDs. Then we restrict the sequence length in both validation and test sets to the range [6, 18], resulting in 18,162 validation and 1,897 test triples. Furthermore, since tuning the MMI models is quite time-consuming, we randomly select 2K triples from the validation set for hyper-parameter selection.

4.2 Evaluation

4.2.1 Automatic evaluation. Although reported not to correlate well with human judgments [5], we still report BLEU scores [8] for fair comparisons with baselines. To evaluate response diversity, we use the *d-1* and *d-2* metrics proposed in [3] that are calculated as the number of distinct uni- and bigrams, divided by the total number of tokens generated.

4.2.2 Human evaluation. Following Sordoni et al. [13], we recruit crowd-source workers to perform pairwise qualitative comparisons. Since the conversation history of the OSDb dataset is only a single turn, which is hard for human annotators to judge, we choose the Twitter dataset for human evaluation, which has two-turn histories. We randomly select 1K test examples from the Twitter test set, and paired model responses (*FACE* vs. *baseline*) are shown to 3 evaluators in random order. Evaluators are told to choose a better response in terms of *relevance*, *interestingness* and *grammar*. Ties are allowed. We then carry out Welch's t-test on the human preferences obtained in this manner.

[3] http://www.opensubtitles.org/

[4] On July 11 2018, when we finished scraping, only 2.6M IDs in total are still valid.

Table 4: Performance (%) on the OSDb dataset of different variants of FACE. Highest scores in bold face.

Model	d-1	d-2	BLEU
FACE-OPR	4.32	**20.47**	**8.03**
FACE-OPO	4.56	14.96	6.76
FACE-GPR	2.87	10.51	7.56
FACE-GPO	**5.03**	19.66	6.92

Table 5: Performance (%) on the Twitter dataset of different variants of FACE. Highest scores are in bold face.

Model	d-1	d-2	BLEU

FACE-OPO	5.73	17.95	**8.80**
FACE-GPR	4.13	15.03	7.99
FACE-GPO	5.69	17.78	8.72

4.3 Implementation details

For the OSDb and Twitter datasets, we keep the most frequent 25,000 tokens and replace other tokens with *_UNK_*. For the OSDb corpus, we use a 4-layer Long Short-Term Memory (LSTM) network for both encoder and decoder. The hidden size (HS) and word embedding size are set to 1,000. On the smaller Twitter corpus, we use a smaller network with a 2-layer LSTMs for encoder and decoder. The HS and word embedding sizes are set to 512 and 200, respectively. For both networks, we randomly initialize the model parameters from a uniform distribution $\mathcal{U}(-\sqrt{1/\text{HS}}, \sqrt{1/\text{HS}})$ and the word embeddings from a normal distribution $\mathcal{N}(0, 1)$. We also employ dropout [14] with drop ratio $p = 0.1$. We use Adam [2] as our optimization method. For the hyper-parameters of the Adam optimizer, we set the learning rate $\alpha = 0.001$, two momentum parameters $\beta 1 = 0.9$ and $\beta 2 = 0.999$, respectively, and $\epsilon = 10^{-8}$. We also clip gradients [9] to 5 during training to avoid gradient explosion. To speed up training and convergence, we use mini-batches of size 256. Since the model chosen with minimum training loss usually has very low diversity, we choose *d-1* as the early stopping criterion. A scheduler is used to reduce the learning rate by a factor of 0.5 when a *d-1* plateau is detected with $patience = 3$. β in Eq. (12) is set to 0.01.

5 RESULTS AND ANALYSES

5.1 FACE variants

To answer Q1, we first identify the best performing variant of FACE to be used in later experiments. In Tables 4 and 5, we list the scores for four variants of FACE, on the OSDb and Twitter datasets, respectively: Output token frequency & PRe-weight (*FACE-OPR*), Output token frequency & POst-weight (*FACE-OPO*), GT frequency & PRe-weight (*FACE-GPR*) and GT frequency & POst-weight (*FACE-GPO*).

Table 6: Results (%) on the OSDb dataset. Highest scores in each column are highlighted using bold face.

Model	d-1	d-2	BLEU
Seq2Seq	2.70	8.63	7.34
Seq2Seq-refine	3.61	14.16	7.61
MMI-antiLM	2.73	10.68	7.83
MMI-bidi	3.06	12.19	7.01
MHAM	3.03	9.47	7.13
CMHAM	4.10	12.92	6.88
FACE	4.32	**20.47**	**8.03**
CP	4.18	15.59	7.27
CP_{free}	**5.48**	18.59	7.08
FACE-CP	4.63	18.32	7.89
FACE-CP$_{free}$	4.69	18.67	6.98

Table 7: Results (%) on the Twitter dataset. Highest scores in each column are highlighted using bold face.

Model	d-1	d-2	BLEU
Seq2Seq	5.87	17.73	8.77
Seq2Seq-refine	5.69	17.54	8.82
MMI-antiLM	**6.23**	18.21	6.51
MMI-bidi	5.42	15.16	8.20
MHAM	5.52	17.04	**8.96**
CMHAM	4.99	14.91	8.71
FACE	**6.23**	**24.18**	8.33
CP	5.97	18.15	8.84
CP_{free}	6.00	18.67	8.82
FACE-CP	6.07	23.50	8.25
FACE-CP$_{free}$	5.89	17.81	8.85

On the OSDb dataset, we can see from Table 4 that *FACE-OPR* and *FACE-GPO* perform better than the other two in terms of diversity scores. Similar results are shown on the Twitter dataset in Table 5. By comparing the results in Table 4 and 5, we find that the performance of *FACE-OPR* is very stable. We therefore choose *FACE-OPR* as our primary model and refer to it as *FACE* in the following sections. In contrast, *FACE-GPR* performs worst on both datasets, which indicates that GT frequency does not work well with pre-weight. The BLEU scores in Table 4 and 5 show no obvious patterns.

It is worth noting that all variants reported in Table 4 and 5 are using the train-and-refine strategy: first training the Seq2Seq model with CE, then fine-tuning it with FACE. We also tried training from scratch using FACE. However, the performance did not show consistent improvements, which is probably because our *equal expected loss* assumption (under Eq. (6)) is violated in the early training stages.

Figure 1: Word cloud showing top-200 frequent tokens of model responses on the OSDb dataset. Left: the larger the font, the higher the frequency. Right: the larger the font, the higher the weight (pre-weight used). (Best viewed in color.)

5.2 Automatic evaluation

We turn to Q2, Q3, and Q4. The automatic evaluation results are shown in Tables 6 and 7. *Seq2Seq* is vanilla-Seq2Seq with *general* attention mechanism [6]. *Seq2Seq-refine* is a fine-tuned version of *Seq2Seq* with a smaller batch size of 30. *MMI-antiLM* adjusts the *Seq2Seq* prediction probability using the decoder language model, while *MMI-bidi* utilizes a reverse model. Both methods use beam size 200. *MHAM* projects encoder hidden-states to 5 different semantic spaces, and *CMHAM* forces those 5 spaces to be perpendicular to each other. All of our models are fine-tuned *Seq2Seq* models with a smaller batch size of 30. *FACE* is fine-tuned using the FACE function and output token frequency. *CP* and CP_{free} are fine-tuned using Eq. (12) and (13), respectively. *FACE-CP* is a linear combination of FACE and CP. *FACE-CP*$_{free}$ is the multiplicative combination of FACE and the CP weighting function in Eq. (14).

As shown in Table 6, all the methods proposed in this paper outperform the baselines in terms of diversity metrics on the OSDb dataset. *FACE* achieves the highest d-2 score (increase of 6.3%). *FACE-CP* and *FACE-CP*$_{free}$ achieve slightly higher d-1 and lower d-2 scores than *FACE*, which can be viewed as the trade-off between *FACE* and *CP*'s. Although the penalty strength β of *CP* is carefully selected, it is interesting to see that our hyper-parameter free method CP_{free} outperforms *CP* by a large margin and achieves the highest d-1 score (1.9% improvement), which demonstrates the effectiveness of Eq. (13). *FACE* performs best in terms of BLEU scores, which suggests that *FACE* can generate higher-quality responses.

Although the MMI-based and MHAM-based methods all exhibit various improvements over *Seq2Seq* in terms of d-1 and d-2 scores, they mostly perform worse than *Seq2Seq-refine*. This suggests that on the OSDb dataset, carefully designed MMI-based and MHAM-based methods are not able to outperform a fine-tuned *Seq2Seq* baseline.

Similar to Table 6, Table 7 shows that all our methods can increase the diversity of *Seq2Seq* on the Twitter dataset. *FACE* achieves the highest d-1 score (0.4% increase) together with *MMI-antiLM*, but the highest d-2 score of *FACE* (6.5% improvement) demonstrates that our method fares better.

In Table 7 however, *Seq2Seq-refine* decreases the diversity of *Seq2Seq*, indicating that fine-tuning does not help to address the low-diversity problem on the Twitter dataset. This is probably because

Table 8: Results of the pairwise human evaluation (%) on the Twitter dataset. "Win", "Lose" and "Gain" correspond to "FACE wins", "Baseline wins" and their difference (*Win* − *Lose*), respectively. Highest scores are highlighted in bold face, and *,**,*** symbols indicate significant improvements with *p-value* $< 0.05, < 0.01, < 0.005$, respectively.

Comparison	Win	Lose	Gain
FACE vs Seq2Seq	**38.61*****	21.54	17.07
FACE vs MMI-antiLM	**51.30*****	19.35	31.95
FACE vs MMI-bidi	**61.91*****	20.92	40.99
FACE vs MHAM	**50.93****	42.56	8.37
FACE vs CMHAM	**43.75***	38.85	4.90

the diversity of *Seq2Seq* is already relatively high on this dataset, and there is limited space for further improvements.

While *MMI-bidi* performs better than *MMI-antiLM* on the OSDb dataset, on the Twitter dataset, however, *MMI-bidi* performs much worse and degrades the diversity of the *Seq2Seq* model. The reason for this phenomenon is probably because of the reverse model of *MMI-bidi*: the input consisting of Twitter triples contains two turns from different speakers (*context-message*), thus given the *response* only, the prediction probability of *context-message* is very unreliable.

Although it achieves the highest BLEU score, *MHAM* slightly hurts diversity. Similarly, *CMHAM* degrades the diversity even more. Closer inspection reveals that most of the attention weights of both methods are on the first several tokens of the input sequence (i.e., *context*). It is unlikely to be able to properly learn the relation between *context-message* and *response* by only paying attention to the *context*.

To illustrate the effectiveness of the weighting function, we display the frequencies and the corresponding weights of some tokens in Figure 1. From this figure, we can see that the most frequent tokens have very small weights, and less frequent tokens receive larger weights. Please note that the tokens with the largest weights are in the scope of top-200 frequent tokens.

5.3 Human evaluation

We now turn to Q5. Human evaluation results are reported in Table 8. We can see that *FACE* is significantly better than all baselines. This means that by increasing response diversity, FACE can improve relevance and interestingness of responses, without sacrificing grammatical accuracy. Specifically, by penalizing frequent tokens, *FACE* gives more opportunities to less frequent tokens, so the interestingness is higher than *Seq2Seq*. While high-frequency tokens may be appropriate responses in more situations than low-frequency ones, it is for the same reason that higher frequency tokens convey less information, thus making the responses seem generic. Therefore, by encouraging low-frequency tokens, *FACE* has the potential to increase relevance of responses. By looking at the human evaluation scores in Table 8 together with the BLEU scores in Table 7, we can re-confirm that BLEU scores do not correlate well with human qualitative evaluation [5].

Since *FACE* learns a language model relying entirely on training data, the grammatical accuracy of *FACE* is as least as good as that of *Seq2Seq*. The examples in Table 9 show that *FACE* can actually

Table 9: Example responses from different models.

History	Responses
Context: i need 4 mo followers ..	***FACE***: no i do n't think so .. i 'm watching it now ..
Message: u ever watched criminal minds suspect behavior??	***Seq2Seq***: i do n't know what to say ..
Context: dont you dare steal my idea. i call shenanigans	***FACE***: well then you should have said it like that .
Message: Totally not stealing. Everyone collaborated on that idea.	***MMI-antiLM***: come on . come on go back to you*
Context: I never watched Spongebob's movie tho, was it good? You know Hey Arnold?	***FACE***: haha , i 'm watching it now , it 's so good : d
Message: yes it is good u should watch :D haha hey arnould with footballegg face :P	***MMI-bidi***: oh , that
Context: perhaps a recipe is in order? I have room in my fridge... ;)	***FACE***: sounds good ! i 'll be sure to check it out ! thanks for sharing the mocha cakes with the butter cakes ;)
Message: trying this one for 1st time LOL http://bit.ly/nrFMIU start from bottom recipe & work up	***MHAM***: i 'm sure you 'll find a recipe for me !
Context: Don't laugh at my picture! That's not nice.	***FACE***: i 'm not a fan of the picture but it 's not that bad , it 's just a pic of me saying " i 'm a girl " haha : -)
Message: i'm laughing because you actually posted the pic. I believed you:-) lol	***CMHAM***: i 'm not laughing at you .

generate more relevant and interesting responses. In contrast, although *MMI-antiLM* improves response diversity, it increases the risk of grammatical errors since it penalizes the language model. For example, the response of *MMI-antiLM* in the second example of Table 9 is ungrammatical and irrelevant to the conversation history. Similarly, *MMI-bidi* uses a reverse model to adjust the model outputs, in the hope that the responses can be more diverse and relevant. However, as explained earlier, the reverse model is highly unreliable, making many of the responses look weird, see, e.g., the third row of Table 9.

Although *MHAM* and *CMHAM* can improve response diversity to some extent, it is not guaranteed that the multiple attention heads are well distributed throughout the whole history. In fact, there are many cases where the attention weights are on the **Context** part of the history, making the responses irrelevant to the **Message**, such as the fourth and fifth examples in Table 9.

6 CONCLUSION

In this work, we have proposed a Frequency-Aware Cross-Entropy (FACE) function for tackling the low-diversity problem of Seq2Seq-based conversation models. Experiments on short-history conversation datasets demonstrate that the FACE loss function can effectively improve the diversity and quality of responses. FACE achieves the improvements with minimum modifications to the original Seq2Seq model, which makes it flexible to extend. We also propose a hyper-parameter free CP_{free}, which exhibits better performance than the original parameter-dependent CP.

A limitation of FACE is that the learning procedure is not as stable as CE, which increases the difficulty of training. In future work, we would like to investigate this phenomenon in depth. We also hope to test FACE in a long-history conversation setting by applying FACE to hierarchical Seq2Seq [11]. Besides, we also plan

to apply FACE to stochastic models [12, 19] and examine how FACE can be used in an adversarial dialogue generation setup [4].

ABSTRACT

Topic models have many important applications in fields such as Natural Language Processing. Topic embedding modelling aims at introducing word and topic embeddings into topic models to describe correlations between topics. Existing topic embedding methods use documents alone, which suffer from the topical fuzziness problem brought by the introduction of embeddings of semantic fuzzy words, e.g. polysemous words or some misleading academic terms. Links often exist between documents which form document networks. The use of links may alleviate this semantic fuzziness, but they are sparse and noisy which may meanwhile mislead topics. In this paper, we utilize community structure to solve these problems. It can not only alleviate the topical fuzziness of topic embeddings since communities are often believed to be topic related, but also can overcome the drawbacks brought by the sparsity and noise of networks (because community is a high-order network information). We give a new generative topic embedding model which incorporates documents (with topics) and network (with communities) together, and uses probability transition to describe the relationship between topics and communities to make it robust when topics and communities do not match. An efficient variational inference algorithm is then proposed to learn the model. We validate the superiority of our new approach on two tasks, document classifications and visualization of topic embeddings, respectively.

1 INTRODUCTION

Topic models, such as Latent Dirichlet Allocation (LDA) [3] and Probability Latent Semantic Analysis (PLSA) [11], have a variety of applications in areas such as Natural Language Processing (NLP). A limitation of traditional topic models is that, they have not considered the correlation between topics. Some studies have made effort to characterize topic correlations. For example, correlated topic models [1, 2, 5] replace Dirichlet distribution with logistic normal distribution, and topic embedding models [19] represent topics in a low-dimension embedding space.

Compared to correlated topic models, topic embedding modelling is a straightforward and efficient alternative with lower computational cost [9, 14]. In most topic embedding models, word embedding (instead of the traditional one-hot encoding for words) is applied, to describe the semantic correlations between words. Topic embedding is used by replacing the original word distribution of topics, to represent topics in a continuous low-dimensional space. A link function is then defined to connect word embeddings to topic embeddings to describe the relationship between words and

topics. The main merit of topic embedding models is their capacity for capturing words co-occurrence at different semantic levels to derive correlations between topics while they still have problems. On the one hand, there are often semantic fuzzy words in documents, which have ambiguous semantic meanings. E.g., the polysemous word 'apple' can mean a kind of fruit or a mobile phone brand, and the academic terms 'parallel' and 'efficient' belonging to high-performance computing area may be also included in a paper of artificial intelligence. The existence of these words affects the accurate semantic representation of word embeddings. On the other hand, word embeddings also influence topic representations since they are connected by link functions. Thus, the semantic fuzziness of word embeddings (brought by the existence of semantic fuzzy words) may also lead to the semantic fuzziness of topics in topic embedding models.

At the same time, links are ubiquitous among documents [27, 28]. E.g., papers are linked via citations in DBLP and webpages are connected via hyperlinks in Wikipedia. The linked documents can be represented as a document network. Different from documents themselves that capture objective semantics, network structure denoted by connections between documents often provides subjective semantics which may complement document contents. Then, a pair of linked documents should have similar topic distributions [13, 26]. By doing so, networks may be able to help mitigate the semantic fuzziness of topics. That is to improve topic embeddings and topic distributions of documents, which often suffer from the semantic fuzziness due to word embeddings of semantic fuzzy words. However, we also find that using links directly may not perform well on improving topics since this low-order network information is often sparse and noisy [16, 22, 24]. That is, some nearby documents may not be connected due to the sparsity of networks, and meanwhile, several uncorrelated documents may be connected due to noisy links. In special cases, this may even destroy the quality of topics.

Fortunately, community structure, as a type of high-order network information, may be suitable to solve this problem. A community in a document network consists of documents which are connected more tightly than those in different communities. Also, it is often believed that documents in the same community are often topic-related [10, 12, 30]. So, rather than using links directly, one may have a good reason to use communities, to make documents in a same community own similar topic distributions. By doing so, the problem brought by sparsity and noise of networks may be nicely alleviated.

To be specific, we present a generative topic embedding model, namely Community-Enhanced Topic Embedding (CeTe), which incorporates documents and network structure together. CeTe consists of two main components connected by a probability transition mechanism. The first is the document component which incorporates word embeddings into topic modelling to describe correlations between topics and capture the local word co-occurrence. The second is the network component in which communities are described based on stochastic blockmodels [17]. It plays the role of alleviating the problem of semantic fuzziness of topics with the help of topic-related network communities. We further use probability transition to describe the intrinsic relationship between topics and communities. In this way, the model will work robustly even when the topics (from documents) and communities (from networks) are not well matched. We finally give an efficient variational inference algorithm to learn the model.

The contributions of this paper are as follows:

- Topic embedding models suffer from the semantic fuzziness of topics brought by the semantic fuzziness of word embeddings caused by the existence of semantic fuzzy words. The low-order link information is not suitable to be used directly for this problem due to the sparsity and noise of networks. To the best of our knowledge, this is the first time high-order network information (i.e., communities that are topic related) is used to solve this problem.
- We give a novel generative topic embedding model by using documents with topics and network structure with communities together. Their relationship is further described by using probability transition to make this new model robust even when topics and communities do not match well. We derive an efficient variational inference algorithm to learn this model.
- The superior performance of CeTe is tested on two tasks, i.e. document classification by comparing with seven state-of-the-art methods and a topic visualization application.

2 THE MODEL

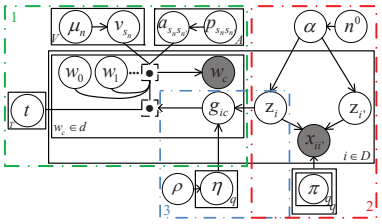

Figure 1: Graphical representation of CeTe. Part 1 in the green box (top left) denotes a document component describing topics. Part 2 in the red box (on the right) denotes a topological component describing network communities. Part 3 in the blue box (on the bottom) denotes the probabilistic transition mechanism connecting these two parts.

In this section, we give a formal description of the proposed model, i.e., Community Enhanced Topic Embedding (CeTe), with the purpose of improving document representation (topic distributions of documents) and topic embedding via introducing communities in networks. The graphical representation of this CeTe model is shown in Figure 1.

As shown in Figure 1, CeTe contains three components:

Document component with topics. This component depicts the generative process of each word given its topic and context words. In a set of documents $D = \{d_1, ..., d_N\}$ with K topics, each document d_i has L_i words, and the words in all documents form the vocabulary set $S = \{s_1, ..., s_W\}$. Each word w_{ij} in document d_i is assigned to a topic indexed by g_{ij}, where $\mathbf{G} = (g_{ij})_{N \times L_i}$ denotes the matrix of topics. Besides topics, the observed word is also affected by its context words. The context of a focus word w_c includes the c words before w_c in the document, denoted by $w_0 : w_{c-1}$. Both the topic and context words are represented in the

embedding vector form. That is, the embedding of word $w_{c'}$ and topic $g_{c'}$ are represented as $v_{c'}$ and $t_{g_{c'}}$, and we assume that their dimensions are the same. Then, matrices of all word embeddings and topic embeddings are $\mathbf{V} = (\mathbf{v}_{s_1},...,\mathbf{v}_{s_W})$ and $\mathbf{T} = (\mathbf{t}_1,...,\mathbf{t}_K)$. Thus the conditional distribution of a word given its context and topic can be factorized into two parts. The first is the distribution of this word and its context $P(w_c|w_0 : w_{c-1})$. It corresponds to the link function of a word embedding method such as PSDVec [20]. The distribution is:

$$P(w_c|w_0 : w_{c-1}) \approx P(w_c) \cdot exp\{\mathbf{v}_{w_c}^T \cdot \sum_{c'=0}^{c-1} \mathbf{v}_{w_{c'}} + \sum_{c'=0}^{c-1} a_{w_{c'}w_c}\}, \tag{1}$$

where $a_{w_{c'}w_c}$ is the bigram residual, which is non-linear and cannot be captured by $\mathbf{v}_{w_c}^T \mathbf{v}_{w_{c'}}$, and $P(w_c)$ is the probability of w_c appearing in the word corpus.

The second part is the distribution of the word and its topic. The topic can be also taken as a latent word, so that we can get the following distribution:

$$P(w_c|g_c) \approx P(w_c) \cdot exp\{\mathbf{v}_{w_c}^T \mathbf{t}_{g_c} + r_{g_c}\}, \tag{2}$$

where r_{g_c} is the logarithm of the normalized constant, which we call the topic residual. All topic residuals form a matrix $\mathbf{r}$=(r_1,...,r_K).

Since $\sum_{w_c \in S} P(w_c|k) = 1$ we can substitute it into Eq. (2) to approximate the r_k as:

$$r_k = -log\Big(\sum\nolimits_{s_j \in S} P(s_j) exp\{\mathbf{v}_{s_j}^T \mathbf{t}_k\}\Big). \tag{3}$$

Eq. (3) can be also represented in matrix form:

$$\mathbf{r} = -log\Big(\mathbf{u} exp\{\mathbf{V}^T \mathbf{T}\}\Big), \tag{4}$$

where $\mathbf{u}$ is the row vector of unigram probabilities.

Finally, according to Eqs. (1) and (2), we give the following link distribution for a document d_i:

$$\begin{aligned} &P(w_c|w_0 : w_{c-1}, g_c, d_i) \\ &\approx P(w_c) \cdot exp\{\mathbf{v}_{w_c}^T \cdot (\sum_{c'=0}^{c-1} \mathbf{v}_{w_{c'}} + \mathbf{t}_{g_c}) + \sum_{c'=0}^{c-1} a_{w_{c'}w_c} + r_{g_c}\}, \end{aligned} \tag{5}$$

where we simplify w_{ij} as w_c and $\mathbf{t}_{g_{ij}}$ as $\mathbf{t}_{g_c}$. Note that in order to avoid overfitting and alleviate the negative effect on topics, we constrain the magnitudes of all topic embeddings in a hyperball of radius λ.

Topological component with communities. This component describes the community structure that is often topic related to help model topics. Let a network have N documents which consist of Q communities. The adjacency matrix $\mathbf{X} = (x_{ii'})_{N \times N}$ is used to represent connections between documents. First, we generate $\boldsymbol{\alpha}$=(α_1,...,α_Q) by Dirichlet distribution, where α_q denotes the proportion of documents belonging to community q, and then get the following distribution:

$$P(\boldsymbol{\alpha}|\mathbf{n}^0) = [\Gamma(\sum\nolimits_{q=1}^{Q} n_q^0) / \prod\nolimits_{q=1}^{Q} \Gamma(n_q^0)] \prod\nolimits_{q=1}^{Q} \alpha^{n_q^0 - 1},$$

where $\mathbf{n}^0$=(n_1^0,...,n_Q^0) is the hyper-parameter and $\Gamma(\cdot)$ denotes the Gamma function.

Next, we use the Multinomial distribution to sample z_i in $\mathbf{Z} = (z_1, ..., z_N)$, where z_i is the community label of document d_i. Then, the distribution is defined as:

$$P(\mathbf{Z}|\boldsymbol{\alpha}) = \prod\nolimits_{i=1}^{N} P(z_i|\boldsymbol{\alpha}) = \prod\nolimits_{i=1}^{N} \alpha_{z_i}.$$

Finally, given the sampled community labels of documents d_i and d_j, i.e., z_i and $z_{i'}$, we sample $x_{ii'}$ from a Bernoulli distribution, defined as:

$$P(\mathbf{X}|\boldsymbol{\pi}, \mathbf{Z}) = \prod\nolimits_{i<i'} (deg_i deg_{i'} \pi_{z_i z_{i'}})^{x_{ii'}} (1 - deg_i deg_{i'} \pi_{z_i z_{i'}})^{1 - x_{ii'}}.$$

The distribution above is based on the degree-corrected stochastic block model [17]. Here, $\boldsymbol{\pi} = (\pi_{ql})_{Q \times Q}$ is the block matrix where π_{ql} denotes the connection probability between nodes from communities q and l, and deg_i is the degree of document d_i.

Probability transition connecting topics and communities. This component describes the transition process from communities to topics to make the model work even when communities and topics do not match well. First, the probability transition matrix $\mathbf{H} = (\eta_{qk})_{Q \times K}$ is generated by a Dirichlet distribution, where η_{qk} represents the probability that document d_i is in the k-th semantic topic given it belongs to the q-th community. This distribution is defined as:

$$P(\mathbf{H}|\boldsymbol{\rho}) = \prod\nolimits_{q=1}^{Q} [\Gamma(\sum\nolimits_{k=1}^{K} \rho_k) / \prod\nolimits_{k=1}^{K} \Gamma(\rho_k)] \prod\nolimits_{k=1}^{K} \eta_{ik}^{\rho_k - 1},$$

where $\boldsymbol{\rho}$ is the hyper-parameter.

Next, given the community label z_i of document d_i, we use a Multinomial distribution to sample g_{ij}, defined as:

$$P(\mathbf{G}|\mathbf{H}, \mathbf{Z}) = \prod\nolimits_{i=1}^{N} \prod\nolimits_{j=1}^{L_i} \eta_{z_i g_{ij}}.$$

After finishing the definition of these three components, a complete generative process of this model is shown in the following. Note that, word embedding $\mathbf{v}_{s_n}$ is drawn from a Gaussian distribution as well as bigram residuals $a_{s_n s_{n'}}$. But for clarity, here we only focus on modelling topic embeddings while ignoring the generative process of word embeddings.

1. Choose $\boldsymbol{\alpha} \sim Dir(\boldsymbol{n^0})$
2. For each community q: Choose $\boldsymbol{\eta_q} \sim Dir(\boldsymbol{\rho})$
3. For the k-th topic: Choose $\mathbf{t}_k \sim Unif(B_\lambda)$
4. For each document d_i:
   (a) Draw community assignment $z_i \sim Mult(\boldsymbol{\alpha})$
   (b) For each document $d_{i'}$ with $i' > i$:
   Draw link $x_{ii'} \sim Bernoulli(deg_i deg_{i'} \pi_{z_i z_{i'}})$
   (c) For the j-th word:
   (*i*) Draw topic assignment $g_{ij} \sim Mult(\boldsymbol{\eta}_{z_i})$
   (*ii*) Draw word w_{ij} from S according to $P(w_{ij}|w_{i,j-c}, w_{i,j-1}, g_{ij}, d_i)$

where Dir, $Unif$ and $Mult$ are the Dirichlet, Uniform and Multinomial distributions respectively.

Then, the complete data likelihood is:

$$\begin{aligned} &P(D, \mathbf{X}, \mathbf{A}, \mathbf{V}, \mathbf{T}, \mathbf{G}, \mathbf{Z}, \mathbf{H}, \boldsymbol{\alpha}|\boldsymbol{\pi}, \mathbf{n}^0, \boldsymbol{\rho}, \lambda, \boldsymbol{\mu}) \\ &= \prod_{n=1}^{W} P(\mathbf{v}_{s_n}; \mu_n) \prod_{n,n'=1}^{W,W} P\Big(a_{s_n s_{n'}}; f(p_{s_n s_{n'}})\Big) \prod_{k}^{K} Unif(B_\lambda) \\ &\cdot \prod_{i=1}^{N} \prod_{j=1}^{L_i} \Big(Mult(\boldsymbol{\eta}_{z_i}) \cdot P(d_i|\mathbf{V}, \mathbf{A}, \mathbf{T}, \mathbf{G})\Big) \prod_{i=1}^{N} Mult(z_i|\boldsymbol{\alpha}) \\ &\cdot \prod_{q=1}^{Q} Dir(\boldsymbol{\eta}_q|\boldsymbol{\rho}) \cdot Dir(\boldsymbol{\alpha}|\mathbf{n}^0) \prod_{i<i'} P(x_{ii'}|z_i, z_{i'}, deg_i deg_{i'} \pi_{z_i z_{i'}}). \end{aligned}$$

In the steps above, $P(\mathbf{v}_{s_n}; \mu_n)$ and $P(a_{s_n s_{n'}}; f(p_{s_n s_{n'}}))$ are both defined as Gaussian priors, and $P(d_i|\mathbf{V}, \mathbf{A}, \mathbf{T}, \mathbf{G})$ is a simple expression of $P(w_{ij}|w_{i,j-c}, w_{i,j-1}, g_{ij}, d_i)$.

3 MODEL OPTIMIZATION

In this section, we aim at learning the embeddings of words and topics $\{\mathbf{V}, \mathbf{T}\}$, model parameters $\{\mathbf{H}, \boldsymbol{\alpha}\}$, and latent variables $\{\mathbf{G}, \mathbf{Z}\}$. Due to the coupling between word-related variables $\{\mathbf{V}, \mathbf{A}\}$ and topic-related variables $\{\mathbf{T}, \mathbf{G}, \mathbf{Z}, \mathbf{H}\}$, their simultaneous optimization is too time consuming in general. So as was done by other topic embedding methods [19], we also use a word embedding method, i.e. PSDVec [20], to learn $\{\mathbf{V}, \mathbf{A}\}$ first, and then optimize $\{\mathbf{T}, \mathbf{G}, \mathbf{Z}, \mathbf{H}, \boldsymbol{\alpha}\}$ with the fixed $\{\mathbf{V}^*, \mathbf{A}^*\}$. But this is also a non-trivial task. For this optimization problem, we propose a variational expectation-maximization (EM) algorithm that includes variational inference and parameter maximization, respectively.

3.1 Variational Inference

In this step, we first fix $\mathbf{T}$ as the constant $\mathbf{T}^*$ and then maximize the posterior $P(\mathbf{G}, \mathbf{H}, \mathbf{Z}, \boldsymbol{\alpha}|D, \mathbf{X}, \boldsymbol{\pi}, \mathbf{T}^*, \mathbf{A}^*, \mathbf{V}^*)$ via variational inference. First, we define the following variational distributions:

$$q(\boldsymbol{\alpha}, \mathbf{H}, \mathbf{Z}, \mathbf{G}) = q(\boldsymbol{\alpha})q(\mathbf{H})q(\mathbf{Z})q(\mathbf{G}),$$

where the variables are mutually independent and their distributions are specified as follows:

$$q(\boldsymbol{\alpha}) = \prod_{q=1}^{Q} Dir(\alpha_q|n_q), \quad q(\mathbf{H}) = \prod_{q=1}^{Q}\prod_{k=1}^{K} Dir(\eta_{qk}|\gamma_{qk}),$$
$$q(\mathbf{Z}) = \prod_{i=1}^{N}\prod_{q=1}^{Q} Mult(z_{iq}|\tau_{iq}), \quad q(\mathbf{G}) = \prod_{i=1}^{N}\prod_{j=1}^{L_i} Mult(g_{ij}|\boldsymbol{\beta}_{ij}).$$

Variational inference here is to minimize the KL divergence between the true posterior distribution $P(\mathbf{G}, \mathbf{H}, \mathbf{Z}, \boldsymbol{\alpha}|D, \mathbf{X}, \boldsymbol{\pi}, \mathbf{T}^*, \mathbf{A}^*, \mathbf{V}^*)$ and $q(\boldsymbol{\alpha}, \mathbf{H}, \mathbf{Z}, \mathbf{G})$, so that the posterior of $\{\boldsymbol{\alpha}, \mathbf{G}, \mathbf{Z}, \mathbf{H}\}$ can be nicely approximated. This is equivalent to maximizing the evidence lower bound (ELBO) $L(q, \mathbf{T})$:

$$L(q, \mathbf{T}) \quad = E_q log\left(\frac{P(D, \mathbf{X}, \mathbf{A}, \mathbf{V}, \mathbf{G}, \mathbf{Z}, \mathbf{H}, \boldsymbol{\alpha}|\mathbf{T}, \boldsymbol{\pi}, \mathbf{n^0}, \boldsymbol{\rho}, \lambda, \boldsymbol{\mu})}{\mathrm{q}(\boldsymbol{\alpha}, \mathbf{H}, \mathbf{Z}, \mathbf{G})}\right).$$

Next, in order to maximize the ELBO $L(q, \mathbf{T})$, we calculate its partial derivative with respect to $n_q, \tau_{iq}, \gamma_{qk}$ and $\beta_{ij,k}$, respectively, and set these derivatives to 0. That is,

$$\nabla L(q, \mathbf{T}) = (\frac{\partial L}{\partial n}, \frac{\partial L}{\partial \tau}, \frac{\partial L}{\partial \gamma}, \frac{\partial L}{\partial \beta}) = 0.$$

After this inference, we can collect the optimal terms:

$$\mathrm{n}_q = n_q^0 + \sum_{i=1}^{N} \tau_{iq}, \tag{6}$$

$$\tau_{iq} \propto exp\Big\{\psi(n_q) - \psi(\sum_{q=1}^{Q} n_q) + \sum_{j=1}^{L_i}\sum_{k=1}^{K} \beta_{ij,k}\Big(\psi(\gamma_{qk}) - \psi(\sum_{k=1}^{K}\gamma_{qk})\Big) + \sum_{i'\neq i}^{N}\sum_{l=1}^{Q}\tau_{i'l}\Big(x_{ii'}log(deg_i deg_{i'}\pi_{ql}) + (1-x_{ii'})log(1-deg_i deg_{i'}\pi_{ql})\Big)\Big\}, \tag{7}$$

$$\beta_{ij,k} \propto exp\Big\{\sum_{q=1}^{Q}\tau_{iq}\Big(\psi(\gamma_{qk}) - \psi(\sum_{k=1}^{K}\gamma_{qk})\Big) + \mathbf{v}_{w_{ij}}^T\mathbf{t}_k + r_{ik}\Big\}, \tag{8}$$

$$\gamma_{qk} = \rho_k + \sum_{i=1}^{N}\sum_{j=1}^{L_i}\tau_{iq}\beta_{ij,k}, \tag{9}$$

where $\psi(\cdot)$ denotes the Digamma function.

3.2 Parameter Maximization

In this step, $\mathbf{n}, \boldsymbol{\tau}, \boldsymbol{\gamma}, \boldsymbol{\beta}$ are fixed, and our purpose is to optimize $\mathbf{T}$. First, we take the derivatives of $L(q, \mathbf{T})$ with respect to $\mathbf{T}$ as:

$$\frac{\partial L}{\partial \mathbf{T}} = \sum_{i=1}^{N}\sum_{j=1}^{L_i}(\mathbf{v}_{w_{ij}}\boldsymbol{\beta}_{ij}^T + \sum_{k=1}^{K}\beta_{ij,k}\frac{\partial r_k}{\partial \mathbf{T}}). \tag{10}$$

In the following, we set $\sum_{j=1}^{L_i}\beta_{ij,k} = \overline{m}_{ik}$, which is the sum of variational probabilities of every word in the document d_i being assigned into the k-th topic. Then we use the Gradient Descent method [19]. The k'-th column of the gradient matrix $\partial r_k/\partial \mathbf{T}$ is $\partial r_k/\partial \mathbf{t}_{k'}$. According to Eq. (3), when $k' = k$, we can derive the following equation:

$$\frac{\partial r_k}{\partial \mathbf{t}_k} = -exp\{r_k\}\cdot exp\{\mathbf{t}_k^T\mathbf{V}\}(\mathbf{u}\circ\mathbf{V}),$$

where $\mathbf{u}\circ\mathbf{V}$ denotes the element of each column of $\mathbf{V}$ multiplied by the corresponding element of $\mathbf{u}$. When $k' \neq k$, $\partial r_k/\partial \mathbf{t}_{k'} = \mathbf{0}$ can also be easily derived.

Based on the description above we have $\partial r_k/\partial \mathbf{T} = (\mathbf{0}, \ldots \partial r_k/\partial \mathbf{t}_k, \ldots, \mathbf{0})$. By substituting it into Eq. (10), we can obtain:

$$\frac{\partial L}{\partial \mathbf{T}} = \sum_{i=1}^{N}\Big(\sum_{j=1}^{L_i}\mathbf{v}_{w_{ij}}\boldsymbol{\beta}_{ij}^T + (\overline{m}_{i1}\frac{\partial r_1}{\partial \mathbf{t}_1}, \ldots, \overline{m}_{iK}\frac{\partial r_K}{\partial \mathbf{t}_K})\Big).$$

At this time, $\mathbf{T}$ can be optimized via a gradient descent process:

$$\mathbf{T}^m = \mathbf{T}^{m-1} + \Big(\sum_{i=1}^{N}\lambda(m, L_i)\Big)(\frac{\partial L}{\partial \mathbf{T}}), \tag{11}$$

where m is the ongoing iteration step during the update process, $\lambda(m, L_i) = \frac{L_0\lambda_0}{m\cdot\max\{L_i, L_0\}}$ is a function of the learning rate, λ_0 is the initial learning rate, L_i is the length of the i-th document, and L_0 is the threshold of document length. Besides, since the constraint $||\mathbf{t}_{ik}^{(m)}|| \leq \lambda$, we normalize it by $\lambda/||\mathbf{t}_k^{(m)}||$ when $||\mathbf{t}_k^{(m)}|| > \lambda$.

Also of note, after updating $\mathbf{T}_i$, we can further update the topic residuals $\mathbf{r}$ according to Eq. (4) to refine this process.

3.3 Algorithm and Complexity Analysis

The process of CeTe is shown in Algorithm 1, where we omit the word embedding process for clarity. In the step of variational inference, the time complexity for updating n_q, τ_{iq}, γ_{qk} and $\beta_{ij,k}$ is $O(N)$, $O(K + NQ)$, $O(N\bar{L})$ and $O(QK)$, respectively, where N,

K and Q are the number of documents, topics and communities respectively in the document network and $\bar{L}$ is the average number of words in all documents. Taking advantage of the sparsity of document networks, the above time complexities can be further reduced to $O(NQ)$, $O(K+NQ)$, $O(N\bar{L})$, $O(NQK+MQ^2)$, $O(QKN\bar{L})$ and $O(N\bar{L}QK^2)$, respectively, where M is the number of links in the network. In addition, the time complexity for the step of parameter maximization is $O(N(K+\bar{L}))$. Thus, the overall time complexity of this algorithm is $O(N\bar{L}QK^2+MQ^2)$, which is near linear on the scale of networks (N or M).

Algorithm 1 The Process of CeTe

Input: $\mathbf{X}$, D, Q, K, a threshold ε, $count_{max}$
Output: $\mathbf{T}, \mathbf{H}, \boldsymbol{\alpha}, \mathbf{G}, \mathbf{Z}$
1. Initialize $\boldsymbol{\pi}$, $\mathbf{T}$, $\mathbf{r}$ and variational parameters randomly
2. count=1
3. **repeat:**
   (a) Update $n_q, \tau_{iq}, \beta_{ij,k}, \gamma_{qk}$ via (6)-(9)
   (b) Update $\mathbf{T}$ via (11) and $\mathbf{r}$ via (4)
   (c) Calculate ELBO L^{count} and count=count+1
   Until $L^{count} - L^{count-1} < \varepsilon$ or $count > count_{max}$

4 EXPERIMENTS

We first introduce the experiment setup. We then use document classification, the gold method to validate topic embedding models, to evaluate the quality of document representations (the topic distribution of documents) derived by our new approach CeTe. Next, we demonstrate the visualization of topic embeddings to further validate its superiority. We finally use a case study to show why CeTe works.

4.1 Experiment Setup

4.1.1 Datasets. We conducted the experiments on three public datasets, including one DBLP dataset [25] and two hep-th datasets[1]. DBLP includes a collection of papers in computer field. In DBLP, the title and abstract are extracted as texts for each paper and the citation relationships are used to form links between papers. We extract its largest connected component as done by other related works [6, 17, 29]. The ground truth of the papers is fixed according to the CCF (China Computer Federation) classification. The hep-th includes a large corpus of physics-related papers. Its data processing method is similar to that used by DBLP, except that here we use Journals to form the ground truth. In addition, due to the high imbalance of document quantities in different categories for both DBLP and hep-th, we choose the five largest categories to form the DBLP dataset; and for hep-th, we use the four largest categories to form the first subdataset called large-hep, and the three smaller categories to form the other subdataset called small-hep. The datasets details are shown in Table 1.

4.1.2 Baselines. We test our approach against seven state-of-the-art methods, which can be divided into five categories. The first includes three topic models, i.e. Latent Dirichlet Allocation (LDA) [3], Laten Feature Topic Modelling (LFTM) [23] and GibbsLDA [7].

[1]https://www.cs.cornell.edu/projects/kddcup/datasets.html

Table 1: Datasets statistics.

Datasets	Documents	Edges	Words	Categories
DBLP	6,936	12,353	506,269	5
small-hep	397	812	18,718	3
large-hep	11,752	134,956	622,642	4

The second is a topic model that also incorporates network links, named Relational Topic Model (RTM) [4]. The third is a topic embedding method called TopicVec [19]. The fourth is a community detection method named Degree-Corrected Stochastic Block Model (DCSBM) [17], in which we use the community memberships of documents as their representations. The fifth is a document representation method called Doc2Vec [18].

4.1.3 Parameter Setting. As done by TopicVec [19], word embeddings are pre-trained by PSDVec [20] on the latest Wikipedia snapshot[2]. The dimensions of topic embeddings and word embeddings are both set to 500. For datasets DBLP, large-hep and small-hep, we set the number of topics to 500, 200 and 30, respectively. We set the hyper-parameters $n^0 = \rho = 1$ and $\lambda = 7$, which are similar with those used in baselines.

4.2 Test on Document Classification

On this test, according to [19], we first randomly select 80% of documents as the training set and 20% as the test set for each dataset. We then use ℓ-1 regularized SVM as classifier. We use the scikit-learn library[3] to train an ℓ-1 regularized linear SVM one-vs-all classifier for fairness. We adopt macro-averaged Precision, Recall and F1-Score as the evaluation indices. The document representations derived from each method compared are used as input instances to the classifier.

Based on the results shown in Table 2, our new approach CeTe performs the best on all datasets. Neither the topic models (LDA, GibbsLDA and LFTM) using documents alone, nor the community detection method (DCSBM) only using network topology performs well. While RTM (a topic model incorporating links) performs better in most cases, it is still not competitive with our approach CeTe. The reason should be that we introduce the words co-occurrence information at different levels and correlations between topics by using topic embedding to better model topic information. In addition, compared to the state-of-the-art topic embedding method TopicVec, our CeTe still has an obvious improvement. This should be because, by introducing the link information (especially the high-order community structure), the problem of semantic fuzziness of topics suffered by topic embedding methods has been alleviated by our approach. These all validate the effectiveness of this new approach.

4.3 Test by Visualization of Topic Embeddings

We illustrate the visualization of topic embeddings derived by our CeTe method to further validate its performance. The results on DBLP with 500 topics are shown in Figure 2. We find that some closely connected articles correspond to each topic. For example, in the upper-left set, the words 'wireless', 'communication', 'network' and 'sensor' are all related to a field of computer network.

[2]https://dumps.wikimedia.org/enwiki/
[3]http://scikit-learn.org/stable/modules/svm.html

Table 2: Performance of different methods on document classification. Bold indicates the best score.

	DBLP			small-hep			large-hep		
	Precison	Recall	F1-Score	Precison	Recall	F1-Score	Precison	Recall	F1-Score
LDA	0.700	0.457	0.404	0.287	0.287	0.281	0.414	0.411	0.401
GibbsLDA	0.786	0.722	0.715	0.399	0.400	0.396	0.346	0.405	0.346
Doc2Vec	0.523	0.496	0.448	0.454	0.438	0.431	0.385	0.394	0.350
LFTM	0.739	0.653	0.634	0.619	0.575	0.569	0.419	0.418	0.405
RTM	0.560	0.563	0.549	0.565	0.550	0.553	0.407	0.411	0.393
DCSBM	0.461	0.430	0.393	0.451	0.487	0.439	0.359	0.358	0.325
TopicVec	0.729	0.689	0.681	0.624	0.600	0.599	0.405	0.417	0.393
CeTe	**0.790**	**0.736**	**0.731**	**0.671**	**0.650**	**0.654**	**0.437**	**0.433**	**0.417**

It partly shows that the topic embeddings derived by our method have a high quality. We also noticed that, there is a word 'software' in the lower-middle set, which should originally belong to the 'software engineering' field, but actually belongs to the area of 'high-performance computing' here. That is, the keywords such as 'distributed', 'power' and 'energy' in this topic are all from 'high-performance computing', while there is another keyword 'software' which seems to be a mistake. But after a deep investigation we find that, the 'high-performance computing' topic also contains some papers using the idea of software engineering. At the same time, these papers are linked with other papers in 'high-performance computing' and are classified in the same community and thus corrected by our method. This just corresponds to the real situation where these papers (with semantic fuzzy words) belong to the field of 'high-performance computing'. This further validates that the problem of semantic fuzziness of topic embeddings brought by the existence of semantic fuzzy words has been addressed by using links with communities. This visualization can further help discover the meaningful semantic structures to understand topics in real applications.

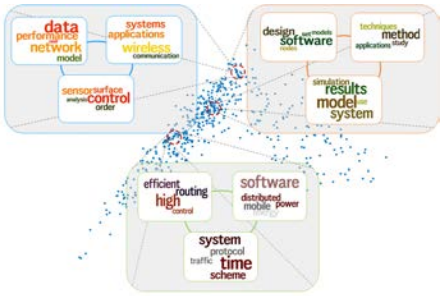

Figure 2: An example of visualizing the 500 topic embeddings derived by CeTe on the DBLP dataset. Each point in the cloud represents a latent topic. The distance between points indicates the correlation between topics, and smaller distance means stronger correlation. We mainly show three sets of points (topics) with small distance in the embedding space. Each topic is characterized by keywords according to the word distribution of this topic (by calculating the cosine similarity between topic embedding and word embeddings). The word sizes are proportional to the probability that this word belongs to the topic. Edges represent the strength of the correlations between topics.

4.4 A case study

Here is to illustrate how our new model CeTe alleviates the topical fuzziness problem of topic embedding methods by introducing the high-order community structure. We also test it on the DBLP dataset with three categories (i.e. theoretical computer science, high-performance computing and computer network), and compare it with TopicVec which is one of the state-of-the-art topic embedding models [19]. We randomly select 10% of the documents as test set, and use the topic distributions of documents derived from CeTe (and TopicVec) as document representations. There are 78 of 375 documents that are classified into wrong categories by TopicVec, while our method corrects about half of them. The results are shown in Figure 3. Due to space limit, we only discuss three of the papers in details since the rests are similar.

The first sample paper is 'Microcode compaction with timing constraints' which is clearly in the field of 'high-performance computing'. However, some words such as 'timing constraints', 'optimization' and 'heuristic' often appear in its maintext. The embedding of these fuzzy topical words is the reason why this paper is assigned to the 'theoretical computer science' category by TopicVec. However, this paper and other seven papers in 'high-performance computing' are divided into the same community by our CeTe, and thus have similar topic distributions. In other words, the topical fuzziness of this paper has been corrected.

The second is the paper 'MILP approach to pattern generation in logical analysis of data' which belongs to the 'theoretical computer science' category. But there are also some high-frequency fuzzy topical words such as 'linear', 'efficient', 'optimal' and 'hundreds of' in this paper which lead to that it is misplaced by TopicVec. However, through links, this paper and three other papers in 'theoretical computer science' are classified into the same community, and hence its topic is corrected again.

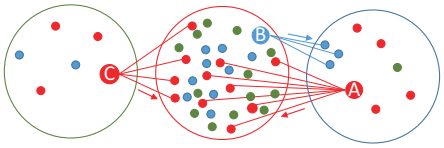

Figure 3: An example that uses network communities to correct inaccurate document representations suffered from the semantic fuzziness of topics. The blue, red and green circles are used to represent the three categories, i.e. theoretical computer science, high-performance computing and computer network, respectively. The blue (red or green) nodes denotes that it belongs to the blue (red or green) category. The nodes with connections in this figure denotes that they are divided into the same community by the topological component of our model. Here only some typical examples are shown in each category. Most of them are papers indeed influenced by semantic fuzziness of word embeddings, which are wrongly classified by TopicVec while corrected by our CeTe. Especially, the titles of papers A, B and C are 'Microcode compaction with timing constraints', 'MILP approach to pattern generation in logical analysis of data' and 'Fast Path-Based Neural Branch Prediction', respectively.

The third paper is 'Fast Path-Based Neural Branch Prediction' which belongs to 'high-performance computing'. But as shown in Figure 3, it is incorrectly assigned to 'computer network' by TopicVec. After a deeper investigation of its maintext, we found that

there are often some keywords such as 'latency', 'path', 'branch' and 'instructions' frequently appear in this paper which may mislead its topic distribution. But by utilizing links between papers, this paper and other three papers in 'high-performance computing' are assigned to the same community, which helps to correct its topic distributions by our CeTe.

To sum up, this case study further validates that, with the help of network community, the inaccurate topic distributions of documents brought by embedding semantic fuzzy words can be well alleviated by our CeTe approach.

5 CONCLUSION AND DISCUSSIONS

We proposed a novel generative topic embedding model CeTe using documents with topics and network structure with communities together, and developed an efficient variational expectation-maximization algorithm to learn the model. The new approach utilizes the high-order network information, i.e., community structure, to solve the problem of topical fuzziness suffered by topic embedding models which is from introducting the embeddings of semantic fuzzy words. The experiment results on two tasks (i.e. document classification and topic visualization) validate its superiority compared with the state-of-the-art methods.

There have been some topic embedding methods presented recently [14, 19, 21]. However, it is the first time, to the best of our knowledge, to use network topology, specifically the community structure, to improve their performance. In addition, there are also some topic models [4, 8, 15, 31] incorporating network information. However, they have essential differences. First, the introduction of links in topic models is to capture the additional correlations between documents, while our purpose is to use links to alleviate the topical fuzziness problem suffered by topic embedding methods (due to the introduction of word embeddings of the semantic fuzzy words). Second, rather than using the links directly, we use the high-order network information, i.e., community structure, to overcome the shortcomings brought by the noise and sparseness of networks. Third, we further use probability transition to describe the relationship between topics and communities, in order to make the method robust even when the topics and communities do not match very well.

ABSTRACT

We present the design and methodology for the large scale hybrid paper recommender system used by Microsoft Academic. The system provides recommendations for approximately 160 million English research papers and patents. Our approach handles incomplete citation information while also alleviating the cold-start problem that often affects other recommender systems. We use the Microsoft Academic Graph (MAG), titles, and available abstracts of research papers to build a recommendation list for all documents, thereby combining co-citation and content based approaches. Tuning system parameters also allows for blending and prioritization of each approach which, in turn, allows us to balance paper novelty versus authority in recommendation results. We evaluate the generated recommendations via a user study of 40 participants, with over 2400 recommendation pairs graded and discuss the quality of the results using P@10 and nDCG scores. We see that there is a strong correlation between participant scores and the similarity rankings produced by our system but that additional focus needs to be put towards improving recommender precision, particularly for content based recommendations. The results of the user survey and associated analysis scripts are made available via GitHub and the recommendations produced by our system are available as part of the MAG on Azure to facilitate further research and light up novel research paper recommendation applications.

1 INTRODUCTION AND RELATED WORK

Microsoft Academic[1] (MA) is a semantic search engine for academic entities [26]. The top level entities of the Microsoft Academic Graph (MAG) include papers and patents, fields of study, authors, affiliations (institutions and organizations), and venues (conferences and journals), as seen in Fig. 1. As of October, 2018, there are over 200 million total documents in the MA corpus, of which approximately 160 million are English papers or patents. These figures are growing rapidly [11].

The focus of this article is to present the recommender system and paper similarity computation platform for English research papers developed for the MAG. We henceforth define the term 'paper' to mean English papers and patents in the MAG, unless otherwise noted. Research paper recommendation is a relatively nascent field [3] in the broader recommender system domain but its value to the research community cannot be overstated.

The current approach to knowledge discovery is largely manual — either following the citation graph of known papers or through human curated approaches. Additionally, live feeds such as publisher RSS feeds or manually defined news triggers are used to gain exposure to new research content. This often leads to incomplete literature exploration, particularly by novice researchers since they are almost completely reliant on what they see online or their advisors and peer networks for finding new relevant papers. Following the citation network of known papers to discover content often leads to information overload, resulting in dead ends and hours of wasted effort. The current manual approaches are not scalable, with tens of thousands of papers being published everyday and the number of papers published globally increasing exponentially [11, 12]. To help alleviate this problem, a number of academic search engines have started adding recommender systems in recent years [1, 7, 18, 19, 28]. Still other research groups and independent companies are actively producing tools to assist with research paper recommendations for both knowledge discovery and citation assistance [2, 5, 13, 17]; both these use cases being more-or-less analogous.

Existing paper recommender systems suffer from a number of limitations. Besides Google Scholar, Microsoft Academic, Semantic Scholar, Web of Science, and a handful of other players, the vast majority of paper search engines are restricted to particular research domains such as the PubMed database for Medicine &

[1] https://preview.academic.microsoft.com

Figure 1: The Microsoft Academic Graph (MAG) website preview and statistics as of October, 2018.

Biology, and IEEE Xplore for Engineering disciplines. As such, it is impossible for recommender systems on these field-specific search sites to suggest cross-domain recommendations. Also, a number of proposed user recommender systems employ collaborative filtering for generating user recommendations [9]. These systems suffer from the well known cold-start problem[2]. There is little to no readily available data on metrics such as user attachment rates for research paper search and recommendation sites and so it becomes difficult to evaluate the efficacy of collaborative filtering techniques without a solid active user base. Moreover, with the introduction of privacy legislation such as the General Data Protection Regulation act (GDPR) in Europe, it is becoming increasing difficult and costly to rely on user data — which is why the Microsoft Academic website does not store personal browsing information — making collaborative filtering all the more difficult. Finally, besides Google Scholar, the self attested paper counts of other research paper databases are in the tens of millions while the estimated number of papers from our system (as well as Google Scholar estimates) put the total number of published papers easily in the hundreds of millions. Having a tenth of the available research corpus can heavily dilute recommendations, providing incomplete and unsatisfactory results. The MA paper recommender platform aims to alleviate some of the aforementioned shortcomings by,

(1) employing the entire MAG citation network and interdisciplinary corpus of over 200 million papers,
(2) using a combination of co-citation based and content embedding based approaches to maximize recommendation coverage over the entire corpus while circumventing the cold-start problem,
(3) and providing the computed paper recommendations to the broader research and engineering community so they can be analyzed and improved by other research groups.

We present two possible interaction modes with the MA paper recommender platform. The first mode is via the "Related Papers" section on the MA search engine paper details page. Users can browse the MA search site using the novel semantic interpretation engine powering the search experience to view their desired paper [26]. The paper details page, as seen in Fig.2, contains a tab for browsing related papers (with dynamic filters) that is populated using the techniques mentioned here. The second mode of interaction is via Microsoft Azure Data Lake (ADL) services. The entire MAG is published under the ODC-By open data license[3] and available for use via Microsoft Azure. Users can use scripting languages such as U-SQL and python not just to access the pre-computed paper recommendations available as part of the MAG but also to generate on-the-fly paper recommendations for arbitrary text input in a performant manner. The means by which this functionality is achieved is described in the following sections.

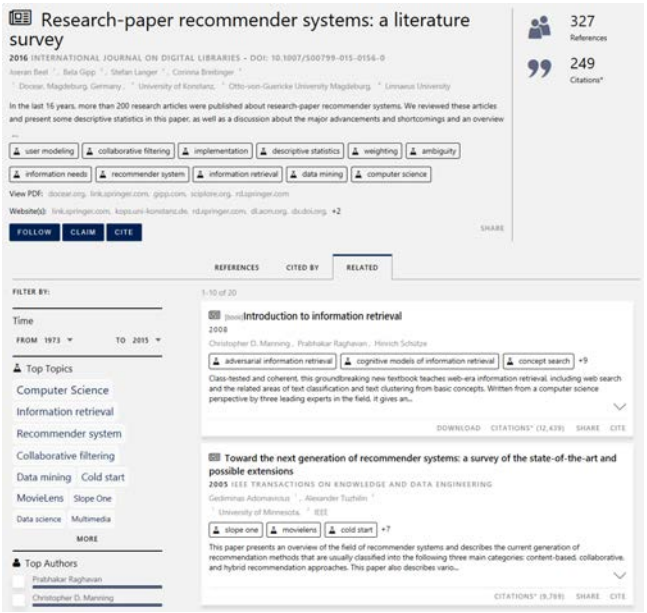

Figure 2: The "Related Papers" tab on Microsoft Academic website paper details page with additional filters visible on the left pane.

[2]Some collaborative filtering approaches assume paper authors will be system users and use citation information to indicate user intent. Even so, new authors/users still suffer from cold-start problem

[3]https://opendatacommons.org/licenses/by/1.0/

The complexity of developing a recommendation system for MA stems from the following feature requirements:

- **Coverage**: Maximize recommendation coverage over the MAG corpus.
- **Scalability**: Recommendation generation needs to be done with computation time and storage requirements in mind as the MAG ingests tens of thousands of new papers each week.
- **Freshness**: All new papers regularly ingested by the MA data pipeline must be assigned related papers and may themselves be presented as 'related' to papers already in the corpus.
- **User Satisfaction**: There needs to be a balance between authoritative recommendations versus novel recommendations so that newer papers are discoverable without compromising the quality of recommendations.

To tackle these requirements we have developed a hybrid recommender system that uses a tunable mapping function to combine both content-based (CB) and co-citation based (CcB) recommendations to produce a final static list of recommendations for every paper in the MAG. As described in [8], our approach employs a *weighted mixed* hybridization approach. Our content-based approach is similar to recent work done on content embedding based citation recommendation [5] but differs mainly in the fact that we employ clustering techniques for additional speedup. Using purely pairwise content embedding similarity for nearest neighbor search is not viable as this is an $O(n^2)$ problem over the entire paper corpus, which in our case would be over 2.56×10^{16} similarity computations.

2 RECOMMENDATION GENERATION

The process outlined in this section describes how the paper recommendations seen on the MA website, as well as those published in the MAG Azure database, are generated. More information on the MAG Azure database is available online[4] but the important thing to note is that our entire paper recommendation dataset is openly available as part of this database, if desired.

The recommender system uses a hybrid approach of CcB and CB recommendations. The CcB recommendations show a high positive correlation with user generated scores, as discussed in section 3, and so we consider them to be of high quality. But the CcB approach suffers from low coverage since paper citation information is often difficult to acquire. To combat this issue we also use content embedding similarity based recommendations. While CB recommendations can be computationally expensive, and of lower quality than CcB recommendations they have the major advantages of freshness and coverage. Only paper metadata including titles, keywords and available abstracts are needed to generate these recommendations. Since all papers in the MAG are required to have a title, we can generate content embeddings for all English documents in the corpus, just relying on the title if need be.

The resulting recommendation lists of both approaches are finally combined using a parameterized weighting function (see section 2.3) which allows us to directly compare each recommendation pair from either list and join both lists to get a final paper recommendation list for nearly every paper in the graph. These lists are dynamically updated as new information comes into the MAG, such as new papers, paper references or new paper metadata such as abstracts. The recommendation lists are thus kept fresh from week to week.

[4] https://docs.microsoft.com/en-us/academic-services/graph/

2.1 Co-citation Based Recommendations

Consider a corpus of papers $P = \{p_1, p_2, p_3 \dots p_n\}$. We use $c_{i,j} = 1$ to denote p_i is citing p_j, 0 otherwise. The co-citation count between p_i and p_j is defined as:

$$cc_{i,j} = \sum_{k=1}^{n} c_{i,k} c_{j,k} \tag{1}$$

When $c_{i,j} \geq 1$, we call that p_i is a co-citation of p_j and vice-versa. Notice, $cc_{i,j} = cc_{j,i}$. This method presumes that papers with higher co-citation counts are more related to each other. Alternatively if two papers are often cited together, they are more likely to be related. This approach of recommendation generation is not new, it was originally proposed in 1973 by Small et al. [27]. Since then others such as [14] have built upon the original approach by incorporating novel similarity measures. While we stay true to the original approach in this paper, we are investigating other co-citation and network based similarity measures as future work.

CcB similarity empirically resembles human behavior when it comes to searching for similar or relevant material. Having access to paper reference information is a requirement for generating CcB recommendations. This presents a challenge since reference lists are often incomplete or just unavailable for many papers, particularly for older papers that were published in print but not digitally. Moreover, CcB recommendations are biased towards older papers with more citations by their very nature. CcB recommendations prove ineffective for new papers that do not have any citations yet and therefore cannot have any co-citations. The MAG contains complete or partial reference information for 31.19% of papers, with each paper averaging approx. 20 references. As a result, only about 32.5% of papers have at least one co-citation. Nevertheless, CcB recommendations tend to be of high quality and therefore cannot be overlooked.

2.2 Content Based Recommendations

2.2.1 Generating paper embeddings. CB recommendations provide a few crucial benefits to overcome the information limitations from CcB recommendations as well as the privacy concerns, system complexity, and cold-start problem inherent in other user based recommender systems approaches such as collaborative filtering. CB recommendations only require metadata about a paper that is easy to find such as its title, keywords, and abstract. We use this textual data from the MAG to generate word embeddings using the well known *word2vec* library [22, 23]. These word embeddings are then combined to form paper embeddings which can then be directly compared using established similarity metrics like cosine similarity [21].

Each paper is vectorized into a paper embedding by first training word embeddings, $\boldsymbol{w}$, using the word2vec library. The parameters used in word2vec training are provided in Table. 1 The training data for word2vec are the titles, and abstracts of all English papers in the MA corpus. At the same time, we compute the term frequency

vectors for each paper (TF) as well as the inverse document frequency (IDF) for each term in the training set. A normalized linear combination of word vectors weighted by their respective TF-IDF values is used to generate a paper embedding, $\boldsymbol{D}$. Terms in titles and keywords are weighed twice as much terms in abstracts, as seen in Eqn. 2. This approach has been applied before for CB document embedding generation, as seen in [24], where the authors assigned a 3× weight to words in paper titles compared to words in the abstract. Finally, the document embedding is normalized, $\hat{\boldsymbol{D}} = \boldsymbol{D}/|\boldsymbol{D}|$. Since we use cosine similarity as a measure of document relevance [21] embedding normalization makes the similarity computation step more efficient since the norm of each paper embedding does not need to computed every time it is compared to other papers, just the value of the dot product between embeddings is sufficient.

$$\boldsymbol{D} = 2. \sum_{\substack{w \in title \\ w \in keywords}} TFIDF(w).\hat{\boldsymbol{w}} + \sum_{w \in abstract} TFIDF(w).\hat{\boldsymbol{w}} \tag{2}$$

2.2.2 Clustering paper embeddings. Our major contribution to the approach of CB recommendation is improving scalability using clustering for very large datasets. The idea to use spherical k-means clustering for clustering large text datasets is presented in [10]. The authors of [10] do a fantastic job of explaining the inherent properties of document clusters formed and make theoretical claims about concept decompositions generated using this approach. Besides the aforementioned benefits, our desire to use k-means clustering stems from the speedup it provides over traditional nearest neighbor search in the continuous paper embedding space. We utilize spherical k-means clustering [15] to drastically reduce the number of pairwise similarity computations between papers when generating recommendation lists. Using trained clusters drops the cost of paper recommendation generation from a $O(n^2)$ operation in the total number of papers to a $O(n * (|c| + \lambda_c))$ operation, where $|c|$ is the trained cluster count and λ_c is the average size of a single paper cluster. Other possible techniques commonly used in CB paper recommender system optimization, such as model classifiers [4], and trained neural networks [5] were investigated but ultimately rejected due to the their considerable memory and computation footprint compared to the simpler k-means clustering approach, particularly for the very large corpus size we are dealing with.

Cluster centroids are initialized with the help of the MAG topic stamping algorithm[25]. Papers in the MAG are stamped according to a learned topic hierarchy resulting in a directed acyclic graph of topics, such that every topic has at least one parent, with the root being the parent or ancestor of every single field of study. As of October, 2018 there are 229,370 topics in the MAG but when the centroids for clustering were originally generated — almost a year ago — there were about 80,000 topics. Of these, 23,533 were topics with no children in the hierarchy, making them the most focused or narrow topics with minimal overlap to other fields. The topic stamping algorithm also assigns a confidence value to the topics stamped for each paper. By using papers stamped with a high confidence leaf node topic we can guess an initial cluster count as well as generate initial centroids for these clusters. Therefore, our initial centroid count $k = 23,533$. Cluster centroids are initialized by taking at most 1000 random papers for each leaf node topic and averaging their respective paper embeddings together. Another initialization mechanism would be to take descriptive text (such as Wikipedia entries) for each leaf node topic and generate an embedding - in much the same way paper embeddings are generated using trained word embeddings - to act as an initial cluster centroid. The centroid initialization method choice is ultimately dependent on the perceived quality of the final clusters and we found that averaging paper embeddings for leaf node topics provided sufficient centroids for initializing clusters. The rest of the hyper parameters used for k-means clustering are provided in Table. 1.

k-means	init. clusters (k) 23,533	max iter. (n) 10	min error (δ) 10^{-3}
word2vec	method *skipgram*	emb. size 256	loss fn. *ns*
	window size 10	max iter. 10	min-count cutoff 10
	sample 10^{-5}	negative 10	

Table 1: Parameters used for spherical k-means clustering and word2vec training.

K-means clustering then progresses as usual until the clusters converge or we complete a certain number of training epochs. Cluster sizes range anywhere from 51 papers to just over 300,000 with 93% of all papers in the MAG belonging to clusters of size 35,000 or less. The distribution of cluster sizes is important since we do not want very large clusters to dominate computation time when generating CB recommendations. Remember that clustering reduces computation complexity of CB recommendation generation from $O(n^2)$ to $O(n * (|c| + \lambda_c))$ because each paper embedding now need only be compared to the embeddings of other papers in the same cluster. Here $|c| = k$ and λ_c is the average cluster size. For a single paper the complexity of recommendation generation is just the second term, i.e. $|c| + \lambda_{c_i}$ where c_i is the size of the cluster-i that the paper belongs to so if λ_{c_i} gets too large then it dominates the computation time. In our pipeline we found that the largest 100 clusters ranged in size from about 40,000 to 300,000 and took up more than 40% of the total computation time of the recommendation process. We therefore limit the cluster sizes that we generate recommendation for to 35,000. For now, papers belonging to clusters larger than this threshold (about 7% of all papers) only have CcB recommendation lists generated. In the future, we plan on investigating sub-clustering or hierarchical clustering techniques to break up the very large clusters so as to be able to generate CB recommendations for them as well.

2.3 Combined Recommendations

Finally, both CcB and CB candidate sets for a paper are combined to create a unified final set of recommendations for papers in the MAG. CcB candidate sets have co-citation counts associated with each paper-recommendation pair. These co-citation counts are mapped to a score between $(0, 1)$ to make it possible to directly compare them with the CB similarity metric. The mapping function used is

a modified logistic function as seen in Eq. 3.

$$\sigma\left(cc_{i,j}\right) = \frac{1}{1 + e^{\theta(\tau - cc_{i,j})}} \tag{3}$$

θ and τ are tunable parameters for controlling the slope and offset of the logistic sigmoid, respectively. Typically, these values can be estimated using the mean and variance of the domain distribution or input distribution to this function, under the assumption that the input distribution is Gaussian-like. While the distribution of co-occurrence counts tended to be more of a Poisson-like distribution with a long tail, the majority of co-occurrence counts (the mass of the distribution) was sufficiently Gaussian-like. We settled on values $\tau = 5$ and $\theta = 0.4$ based on the mean co-occurrence count of all papers and a factor of standard deviation, respectively. In general, changing the tunable parameters of Eq. 3 allows one to weigh CcB versus CB recommendations resulting in different final sets of recommendation lists that balance authoritative recommendations from CcB method with novel recommendations from the CB method. Once CcB and CB recommendation similarities are mapped to the same range $[0, 1]$ comparing them becomes trivial and generating a unified recommendation list involves ordering relevant papers from both lists just based on their similarity to the target paper.

3 USER STUDY

We evaluated the results of the recommender system via an online survey. The survey was set up as follows. On each page of the study, participants were presented with a pair of papers. The top paper was one that had been identified in the MAG as being authored (or co-authored) by the survey participant while the bottom paper was a recommendation generated using the hybrid recommender platform described in the previous section. Metadata for both papers as well as hyperlinks to the paper details page on the MA website were also presented to the participant on this page. The participant was then asked to judge — on a scale of 1 to 5, with 1 being *not relevant* to 5 being *very relevant* — whether they thought the bottom paper was relevant to the top paper (See Fig. 3). Participants could decide to skip a survey page if they were not comfortable providing a score and carry on with the remainder of the survey.

The dataset of paper/recommended-paper pairs to show for a particular participant were generated randomly selecting at most 5 of that participant's authored papers. This was done to ensure familiarity with the papers the participants were asked to grade, which we thought would make the survey less time consuming thereby resulting in a higher response rate. Note that while participants were guaranteed to be authors of the papers, they may not have been authors of the recommended papers. For each of a participant's 5 papers, we then generated at most 10 recommendations using the CcB approach, and 10 recommendations using the CB approach. Some newer papers may have had fewer than 10 co-citation recommendations. This resulted in each participant having to rate at most 100 recommendations. All participants were active computer science researchers and so the survey, as a whole, was heavily biased towards rating computer science papers. We wish to extend this survey to other domains as future work since the MAG contains papers and recommendations from tens of thousands of different research domains. For now, we limited our scope to computer science due to familiarity, the ease of participant access and confidence in participant expertise in this domain.

4 RESULTS AND DISCUSSION

The user survey was sent to all full-time researchers at Microsoft Research and a total of 40 users responded to the survey, resulting in 2409 scored recommendation pairs collected. Of these, 984 were CcB recommendations, 15 recommendation pairs that were both content and co-citation, and 1410 CB recommendation pairs. The raw result dataset is available on GitHub[5]. Since at most 10 recommendations were presented to a user using each of the two methods, we computed P@10 for CcB and CB recommendations as well as P@10 for combined recommendations.

Since we did not include any type of explicit score normalization for participants during the survey, Table 2 shows precision computed assuming, both a user score of at least 3 as a true positive result and another row assuming a score of at least 4 as a true positive result. Recall that users were asked to score recommended paper pairs on a scale of 1 being not relevant to 5 being most relevant. We also compute the normalized discounted cumulative gain (nDCG) for each of the three methods. Note that we use exponential gain, $(2^{score} - 1)/log_2(rank + 1)$ instead of linear gain when computing DCG.

	CcB	CB	Combined
P@10-3	0.315	0.226	0.533
P@10-4	0.271	0.145	0.41
nDCG	0.851	0.789	0.891

Table 2: Evaluation metrics for CcB, CB and combined recommender methods. P@10-N indicates that a user score at least N between $[1, 5]$ is considered a true positive.

We generated Fig. 4 to see how the similarities computed using the MA recommender system lined up with user scores from the study. Each bar in the figure is generated by first aggregating the similarity scores for all paper recommendation pairs that were given a particular score by users. The first column is all paper recommendation pairs given a score of 1 and so on. Each column is then divided into sections by binning the paper recommendation pairs according to the similarity computed using the combined recommender method, e.g. The orange section of the leftmost bar denotes all paper recommendation pairs with a similarity between $[0.6, 0.7)$ that were given a score of 1 by the user study participants. While the absolute values of the similarity is not very important, what is important to gather from this figure is that it shows a clear positive correlation between the similarity values computed by the hybrid recommender platform and user scores. This would seem to indicate that recommendation pairs with higher computed similarity are more likely to be relevant for users, which is the desired outcome for any recommender system. This fact is reinforced by the nDCG values of each of the recommender methods. A combined nDCG of 0.891 indicates a strong correlation between the system's computed rankings and those observed from the survey participants.

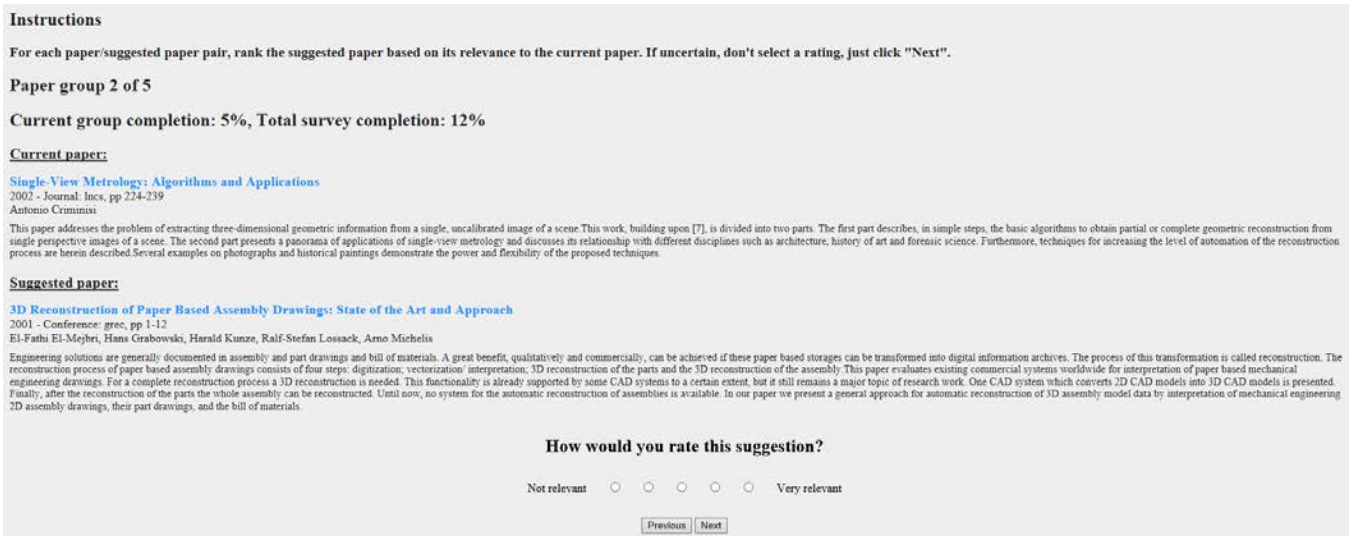

Figure 3: A screenshot of the online recommender system survey.

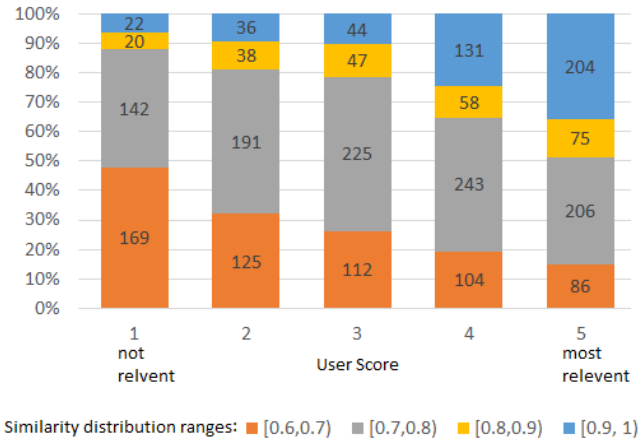

Figure 4: The distribution of similarity ranges over user responses ranging from 1 being *not relevant* to 5 being *most relevant.*

On the other hand, the observed precision values indicate that there is room for improving user satisfaction of the presented recommendations, particularly for the CB method. While we expected CcB recommendations to outperform CB results, having CB recommendations be half as precise as CcB recommendations would seem to indicate that additional effort needs to be spent in improving CB recommender quality.

5 CONCLUSION

A natural question to ask about this approach is why not use other vectorization techniques such as doc2vec[20], fasttext[6] or even incorporate deep learning language models such as ULMFit[16]? While we settled on word2vec for the current production system, we are constantly evaluating other techniques and have this task set aside as future work. A good experiment would be to generate a family of embeddings and analyze recommendation results, perhaps with the aid of a follow-up user study to understand the impact of different document vectorization techniques on the result recommendation set. Another avenue for further research lies in tuning the weights and hyper-parameters of the recommender, such as the θ and τ parameters in the co-citation mapping function (Eq. 3). We hypothesize that a reinforcement learning approach could be used to learn these parameters, given the user study as labeled ground-truth data for the training model.

In the broader scope of evaluating research paper recommender systems, there is a notable lack of literature that compares existing deployed technologies. Furthermore, there is a general lack of data on metrics such as user adoption and satisfaction, and no consensus on which approaches — like the content and co-citation hybrid presented in this paper, or collaborative filtering, and graph analysis to name a few others — prove the most promising in helping to tackle this problem. Part of the reason for this is that large knowledge graphs and associated recommender systems are often restricted behind paywalls, not open access or open source and hence difficult to analyze and compare. We hope to at least partly alleviate this problem by providing the entire MAG and precomputed paper recommendations under the open data license, ODC-By, so that other researchers may easily use our data and reproduce the results presented here as well as conduct their own research and analysis on our knowledge graph.

In conclusion, we presented a scalable hybrid paper recommender platform used by Microsoft Academic that used co-citation and content based recommendations in maximize coverage, scalability, freshness, and user satisfaction. We examined the quality of results produced by the system via a user study and showed a strong correlation between our system's computed similarities and user scores for pairs of paper recommendations. Finally, we made the results of our user study as well the actual recommendation lists used by MA available to researchers to analyze and help further research in research paper recommender systems.

Topic Structure-Aware Neural Language Model: Unified language model that maintains word and topic ordering by their embedded representations

Noriaki Kawamae
NTT COMWARE
Tokyo
kawamae@gmail.com

ABSTRACT

Our goal is to exploit a unified language model so as to explain the generative process of documents precisely in view of their semantic and topic structures. Because various methods model documents in disparate ways, we are motivated by the expectation that coordinating these methods will allow us to achieve this goal more efficiently than using them in isolation; we combine topic models, embedding models, and neural language models. As we focus on the fact that topic models can be shared among, and indeed complement embedding models and neural language models, we propose Word and topic 2 vec (Wat2vec), and Topic Structure-Aware Neural Language Model (TSANL). Wat2vec uses topics as global semantic information and local semantic information as embedding representations of topics and words, and embeds both words and topics in the same space. TSANL uses recurrent neural networks to capture long-range dependencies over topics and words. Since existing topic models demand time consuming learning and have poor scalability, both due to breaking the document's structure such as order of words and topics, TSANL maintains the orders of words and topics as phrases and segments, respectively. TSANL reduces the calculation cost and required memory by feeding topic recurrent neural networks, and topic specific word networks with these embedding representations. Experiments show that TSANL maintains both segments and topical phrases, and so enhances previous models.

1 INTRODUCTION

As many people are expressing their opinions on-line and their volume exceeds the analysis capabilities of any individual or group of individuals, Latent Dirichlet Allocation (LDA) [2] and related topic models have become popular tools for modeling documents. These models uncover the latent structure of a given document collection as topics, and so are enjoying commercial success. Each topic has own multinomial distribution over terms, and has statistical strength and structure that is shared among documents. While their topic representations offer some degree of human interpretability, they are strictly non-sequential models.

As phrases carry more meaning than the sum of the individual words and word meaning depends on context, phrases simplify the human interpretation of topics compared to unigrams. Although some models focus on the order of words [16], they assume that the assignment of a topic is independent from that of other topics. We ran LDA over 2022 ACM papers and show the transition probability between adjacent tokens in Figure 1. This figure shows that 1) these transitions probabilities are asymmetric, and 2) the transition probability to the same topic, p_{ii}, is higher than to other probabilities, $p_{ij}(j \neq i)$, and increases as the #topics increases (e.g. the average of p_{ii} with #topics=40, #topics=60, and #topics=80 is 0.51, 0.57, and 0.61, respectively). Here, we can say that topic appearance and order is affected by their continuity in each document and forms the syntactic structure seen.

Motivated by the above background, we propose both Word and Topic 2 Vec (Wat2Vec) and Topic Structure-Aware Neural Language Model (TSANL) to explain the generative process of documents as based both semantic information and syntactic structures. As we focus on the fact that topic models can be shared among, and indeed complement embedding models [1] and neural language models, we extend embedding models to Wat2vec, and propose TSANL as neural

Table 1: TSANL(+Wat2vec) inherits the interpretability of topic models, the semantic relationships of embedding models, and the prediction power of neural language models: The learning approaches u, and t, denote unified and two-step, respectively.

language model. Wat2vec uses topic models as global statistical information and local context information as embedding representations of topics and words. Unlike existing topic models, which break the document's structure such as the order of words and topics, TSANL uses these representations with LSTMs [8] to capture their long-range dependencies.

Through experiments, we confirm the key advantages of Wat2vec and TSANL as follows.

Theoretical contribution: Wat2vec embeds both words and topics in the same semantic space, and computes both the contextual word embeddings and topic embeddings for a word and topic given their context. As TSANL marries topic models with neural language models, it maintains the order of words and topics as phrases and segments, respectively.

Practical contribution: As learning phrases and segments is very time-consuming, we develop an efficient sampling technique. TSANL detects candidate phrases and assigns them to the same topic as a constraint in the inference stage.

2 PREVIOUS WORK

2.1 Topic models

To explore word co-occurrence patterns and their order, several topic models form N-grams via a predictive probability distribution for the next word conditioned on the previous words [11, 26, 31]. For example, Phrase Discovering LDA [16] segments a corpus into phrases of varying lengths and assigns topics. NTSeg [10] maintains the document's structure, such as paragraphs and sentences, by employing the notion of word-topics and segment-topics. NOC [12] reveals a tree of topics that captures the semantic relationship between topics from a given corpus as context, and enables each document to maintain its thematic coherence and form N-grams over context. As we are motivated by the observations that a sequence of topics exhibits their dependencies in the form of phrases, we extend these models to preserve the topic order in order to extract the syntactic structure.

2.2 Embedding models

Distributed representations with neural probabilistic language [1] have been proposed to represent words and documents as low-dimensional and dense real value vectors in single semantic spaces, and significant results in many tasks have been demonstrated [23]. Herbelot and Vecchi [7] explored word embeddings and their utility for modeling language semantics. Word2vec [21] is designed to capture a large number of syntactic and semantic word relationships by introducing the continuous Skip-gram model [19]; it achieves better NLP task performance by grouping similar words and gaining distributed representations of words.

Although the probability distributions gained from topic models describe the statistical relationships of word occurrences in the corpus rather than the best choice for feature representation [23], the combination of embedding models and topic models was proposed to represent words in one semantic space. Topical Word Embedding (TWE) [17] forms the topical word embedding by using pre-trained topic structures and concatenating the topical embedding with the word embedding. By integrating this local semantic information with neural language models, our approach captures the long-range dependencies at the embedding level and reduces the computation cost by decreasing the number of parameters.

2.3 Neural language models

While topic models reflect the co-occurrence relationships of words, they fail to sufficiently model the sequential dependency across sentences. Another approach to modeling the sequences of words and topics is employing RNN [20], such as Long Short Term Memory (LSTM) [8]. LSTMs require a large number of parameters, notwithstanding the simplicity of the underlying dynamics, rending the results uninterpretable [30], and models characterize the long range dependencies of a sequence. Topically Driven Neural Language Model (TDLM) [13] has two components, a language model and a topic model, which are jointly trained using neural networks. While Topic RNN [4] can be learned in an end-to-end fashion to directly capture long-range dependencies between words via latent topics, Latent LSTM Allocation (LLA) [30] models sequence of topics using LSTM and generate word similar to LDA. bridges the gap between RNN's and topic models, and model the dynamics of topic evolution. capture semantic meaning in an end-to-end fashion. Our approach uses topic models to learn topics, explore the embeddings of words and topics via learnt topics, and their embedding representation neural language models to maintain phrases, and segments.

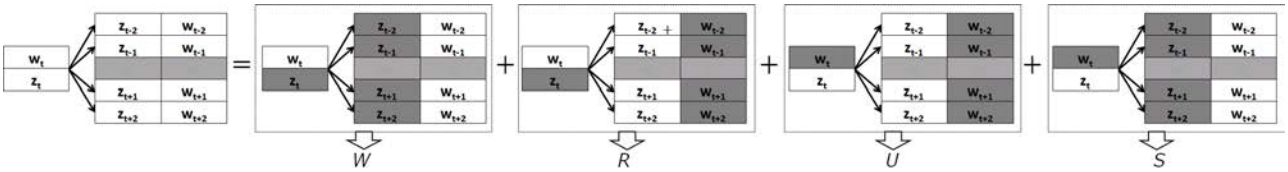

Figure 2: Learning architectures of Skip-gram of Wat2vec: In this figure, w_t is the t-th word token and z_t is the corresponding topic. Skip-gram predicts the surrounding words $(w_{t-2}, w_{t-1}, w_{t+1}w_{t+2})$ and topics $(z_{t-2}, z_{t-1}, z_{t+1}z_{t+2})$ from current word w_t and current topic z_t. We decompose this task into four tasks, where each word and topic predicts the surrounding words and topics individually. Then, Wat2vec learns embeddings using this framework individually with word-word co-occurrence matrix, W, word-topic co-occurrence matrix, R, topic-topic co-occurrence matrix, U, and topic-word co-occurrence matrix, S.

3 WORD AND TOPIC EMBEDDINGS

Inspired by TWE [17], our approach learns both topic and word embeddings to enhance the neural probabilistic language model. Our model receives embedding representations instead of words as input, as these representations learn the latent semantic for each word and so capture useful syntactic and semantic properties. Our proposal Wat2vec (embedding task, Word and Topic 2 vec) learns distributed word representations along with distributed topic representations. Like previous embedding models, Wat2vec requires Skip-gram [19], the state-of-the-art word embedding model, to gain continuous vector representations of words and topics from a given corpus. While Skip-Gram aims to predict context words given a target word in a sliding window, our model extends it to predict surrounding words $(w_{t-2}, w_{t-1}, w_{t+1}w_{t+2})$ and surrounding topics $(z_{t-2}, z_{t-1}, z_{t+1}z_{t+2})$ given current w_t and z_t. As TSNAL aims to predict context topics and words for a target topic and word in a sliding window, Wat2vec learns their embeddings symmetrically to exploit, in equal degree, their semantic and contextual information in the given corpus. That is, Wat2vec allows each word-topic pair w_t, and z_t to have own embedding parameters $\mathbf{a_t}$, and $\mathbf{c_t}$, and to share these parameters between the same words, and topics, respectively. As shown in Figure 2, the target word and its corresponding topic predict the identical surrounding words, and identical surrounding topics, individually.

As mentioned in Levy and Goldberg [14], the Skip-Gram framework with negative sampling (SGNS) is equivalent to implicitly factorizing a word-context matrix, the Pointwise Mutual Information (PMI) of the respective word and context pairs. After making the connection between Skip-Gram and PMI, Levy and Goldberg [14] show how to perform word embedding by spectral dimensionality reduction on the shifted positive PMI (SPPMI) matrix:

$$SPPMI(i,j) = max\{PMI(i,j) - logk, 0\}, \quad (1)$$

where k is a hyperparameter that controls the density of the SPPMI matrix. This matrix can be factorized by either using an eigenvalue method or solving the matrix factorization problem iteratively [29]. As SGNS does not require optimization procedure tuning and can capture the relationships between a word and its context within small sliding windows [19, 21], Wat2vec follows this approach, as do other models [15, 25]. Defining the word co-occurrence matrix, $\mathbf{W} \in \mathbb{V}^V (v = 1, ..., V)$ as the co-occurrence SPPMI matrix instead of the raw frequency matrix, yields word embedding matrix $\mathbf{A}$ and context word embedding matrix $\mathbf{B}$ by factorizing $\mathbf{W}$:

$$L_W = ||W - A^T B||_2^2 + \lambda_w(||A||_2^2 + ||B||_2^2), \quad A \ \ and \ \ B \geq 0, \quad (2)$$

where λ_w is the parameter that prevents overfitting.

Likewise, we construct the topic co-occurrence matrix, $\mathbf{U} \in \mathbb{O}^O (o = 1, ..., O)$ as the co-occurrence SPPMI matrix, and learn topic embedding matrix $\mathbf{C}$ and context topic embedding matrix $\mathbf{D}$ by factorizing matrix $\mathbf{U}$.

$$L_U = ||U - C^T D||_2^2 + \lambda_u(||C||_2^2 + ||D||_2^2), \quad C \ \ and \ \ D \geq 0, \quad (3)$$

where λ_u is the parameter that prevents overfitting.

Following the idea of SPPMI, Wat2vec exploits word and topic embeddings and the corresponding context topic and word, respectively, by factorizing matrix word-topic co-occurrence matrix, $\mathbf{R} \in \mathbb{V}^O$, and topic-word co-occurrence matrix, $\mathbf{S} \in \mathbb{O}^V$:

$$\begin{aligned} L_R &= ||R - A^T D||_2^2 + \lambda_r(||A||_2^2 + ||D||_2^2), \quad A \ \ and \ \ B \geq 0, \\ L_S &= ||S - C^T B||_2^2 + \lambda_s(||C||_2^2 + ||B||_2^2), \quad C \ \ and \ \ B \geq 0, \end{aligned} \quad (4)$$

where λ_r and λ_s are parameters that prevent overfitting.

Because word embedding matrix $\mathbf{A}$ appears in the factorization of both word-word co-occurrence matrix, $\mathbf{W}$, and word-topic co-occurrence matrix ,$\mathbf{R}$, and topic embedding matrix $\mathbf{C}$ appears in the factorization of both topic-topic co-occurrence matrix, $\mathbf{U}$, and topic-word co-occurrence matrix, $\mathbf{S}$, our approach exploits word and topic embeddings by factorizing matrix $\mathbf{W}$, $\mathbf{U}$, $\mathbf{R}$, and $\mathbf{S}$. The objective functions that combine these matrixes are written as::

$$\begin{aligned} L_{W,U,R,S} &= \omega_w(||W - A^T B||_2^2 + \lambda_w(||A||_2^2 + ||B||_2^2)) \\ &+ \omega_u(||U - C^T D||_2^2 + \lambda_u(||C||_2^2 + ||D||_2^2)) \\ &+ \omega_r(||R - A^T D||_2^2 + \lambda_r(||A||_2^2 + ||D||_2^2)) \\ &+ \omega_s(||S - C^T B||_2^2 + \lambda_s(||C||_2^2 + ||B||_2^2)) \end{aligned} \quad (5)$$

where ω_w, ω_u, ω_r, and ω_s are the parameters that control the weights of matrixes $\mathbf{W}$, $\mathbf{U}$, $\mathbf{R}$, and $\mathbf{S}$. This combination enables us to learn, in a balanced manner, the embeddings of words and topics that allow measurement of their similarities.

Following the Alternative Least Squares (ALS) matrix factorization method [9], we obtain the following closed form

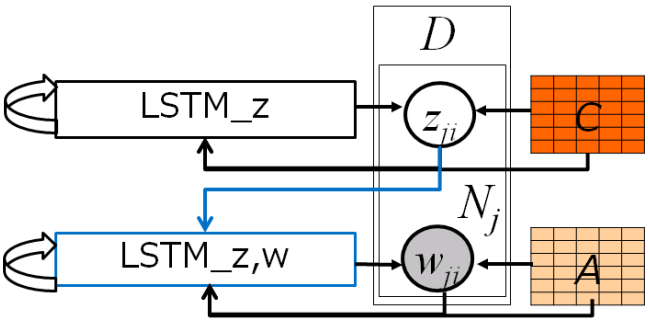

Figure 3: Architecture of TSANL: In this figure, TSANL is a neural language model. The i-th topic, z_{ji}, and word w_{ji} in the j-th document are fed to LSTMs together with their embeddings c_{ji} and a_{ji}, respectively

coordinate updates by iteratively setting the gradient to zero:

$$
\begin{aligned}
a_v &= (\omega_w \sum_{\dot{v}=1}^{V} b_{\dot{v}} b_{\dot{v}}^T + \omega_r \sum_{\dot{o}=1}^{O} d_{\dot{o}} d_{\dot{o}}^T + (\omega_w \lambda_w + \omega_r \lambda_r) I)^{-1} \\
&\times (\omega_w \sum_{\dot{v}=1}^{V} w_{v,\dot{v}} b_{\dot{v}} + \omega_r \sum_{\dot{o}=1}^{O} r_{v,\dot{o}} d_{\dot{o}}) \\
b_{\dot{v}} &= (\omega_w \sum_{v=1}^{V} a_v a_v^T + \omega_s \sum_{o=1}^{O} c_o c_o^T + (\omega_w \lambda_w + \omega_s \lambda_s) I)^{-1} \\
&\times (\omega_w \sum_{v=1}^{V} w_{v,\dot{v}} a_v + \omega_s \sum_{o=1}^{O} s_{o,\dot{v}} c_o) \\
c_o &= (\omega_u \sum_{\dot{o}=1}^{O} d_{\dot{o}} d_{\dot{o}}^T + \omega_s \sum_{\dot{v}=1}^{V} b_{\dot{v}} b_{\dot{v}}^T + (\omega_u \lambda_u + \omega_s \lambda_s) I)^{-1} \\
&\times (\omega_u \sum_{\dot{o}=1}^{O} u_{o,\dot{o}} d_{\dot{o}} + \omega_s \sum_{\dot{v}=1}^{V} s_{o,\dot{v}} b_{\dot{v}}) \\
d_{\dot{o}} &= (\omega_r \sum_{v=1}^{V} a_v a_v^T + \omega_u \sum_{o=1}^{O} c_o c_o^T + (\omega_u \lambda_u + \omega_r \lambda_r) I)^{-1} \\
&\times (\omega_u \sum_{o=1}^{O} u_{o,\dot{o}} c_o + \omega_r \sum_{v=1}^{V} r_{v,\dot{o}} a_v)
\end{aligned}
\tag{6}
$$

where $\mathbf{a_v}$, $\mathbf{b_{\dot{v}}}$, $\mathbf{c_o}$, and $\mathbf{d_{\dot{o}}}$ represent word embedding of the v-th word, context word embedding of the $\dot{v}$-th word, topic embedding of the o-th topic, and context topic embedding of the $\dot{o}$-th topic, respectively.

4 TOPIC STRUCTURE-AWARE NEURAL LANGUAGE MODEL

4.1 Motivation and Methodology

Here, we explain the motivation underlying Topic Structure-Aware Neural Language Model (TSANL); its concept is described using Figure 2. Because TSANL aims to explain the generative process of documents precisely in view of their global semantic and local semantic information and structures such as segments and phrases, it trains LSTMs by using embedding representations of topics and words. Like other topic models, TSANL represents each document as a mixture of underlying topics, $d_j = \{z_{j,1}, ..., z_{j,i}, ..., z_{j,N_j}\}$, and generates each word $w_{j,i}$ from one topic.

Unlike other topic models, TSANL preserves the sequence of ordered topics, instead of topic-collocations. As finding better ways to model long-range dependencies in language modeling is an open research issue [4], our model uses both global semantic and local semantic information to predict succeeding topics and words. That is, TSANL preserves the unit of topic as the document's structure, and segments a document into coherent topic sequences instead of topic-collocations. This allows TSANL, unlike other N-gram topic models [10, 11, 16, 27], to maintain correctly both an observed sequence of words and an observed sequence of topics. Since we assume that the sequence of topics conveys more meaning than the sum of the individual topics, TSANL forms these sequences, segments, by training LSTM, to directly predict the next topic conditioned on the sequence of topics, as does LLA [30]. LSTM keeps the internal state, and at each time step, takes an input and updates its state by applying the transition function consisting of the neural network of the previous time step's state and input. In order to incorporate the local context information, TSANL adds to LSTM the embedding of previous topic, $c_{j,i-1}$, instead of z_{ji}.

In forming a sequence of words over the same topic (phrases), TSANL trains LSTM to predict the embedding representation of the next word conditioned on the sequence of word embeddings on the same topic, unlike other neural language models, topicRNN [4], TDLM [13] and LLA, and to predict the next word that has the embedding representation vector closest to the embedding vector identified by LSTM.

4.2 Generative process

TSANL requires pre-trained topic models to gain embedding representations. With reference in the graphical model shown in Figure 2, we overview the procedure of TSANL as follows:
1. Initialize

- Initialize $LSTM_z$, and $LSTM_{z,w}$
- Initialize topic embedding representations, $\mathbf{C}$
- Initialize word embedding representations, $\mathbf{A}$

2. For each document d in Corpus D:

- For i-th token in j from 1 to N_j:
  - Get topic embedding representation, $a_{j,i}$ from the state of $LSTM_z$
  - Choose topic $z_{j,i}$ that has the topic embedding representation vector closest to the embedding vector, $c_{j,i}$, as found in the topic embedding look-up table, $\mathbf{C}$.
  - if $i \leq 1$ and $z_{j,i}! = z_{j,i-1}$, Chose $LSTM_{z,w}(c_{j,i})$
  - Get word embedding representation $a_{j,i}$ from the state of $LSTM_{z,w}(\mathbf{w})$, where $\mathbf{w}$ represents the sequence of preceding words over the same topic

Table 2: Basic statistics of the datasets in this paper

category		#documents (D)	#vocabulary (V)
20Newsgropus		11,296	10,785
Amazon	Movies and TV	20,197	45,155
	CDs and Vinyl	17,766	37,170

– Choose word $w_{j,i}$ that has the word embedding representation vector closest to embedding vector $a_{j,i}$, as found in the word embedding look-up table, $\mathbf{A}$.

In this process, topic and word embedding vectors are held in the lookup tables, $\mathbf{A} \in \mathbb{K}^{\mathbf{M}\times\mathbf{V}}$(word embedding vector), $\mathbf{C} \in \mathbb{K}^{\mathbf{M}\times\mathbf{K}}$(topic embedding vector), where M is the dimension of the vector, V is the size of vocabulary, and K is the number of topics.

4.3 Phrase detection

This task is optionally performed only once before the training step. Since conventional N-gram topic models obtain N-gram after inference terminates, they require both large memory and much time for their convergence, and yield low quality high-order $N(\geq 3)$-grams [5]. To conquer these problems, our approach mines candidates for these N-grams before the inference arep. By detecting candidates, Wat2vec restricts all constituent terms within each N-gram to those that share the same latent topic, and constructs a trie by inserting them. As this phase inherently makes N-grams of unlimited length, and to avoid phrase detection error, we use a trie [3] to highlight candidate phrases. A trie is an ordered tree structure that is used to store a dynamic set or associative array where the keys are usually strings, and all the descendants of a node have the common prefix of the string associated with that node. As this structure is composed of words instead of characters, we call this tree structure the candidate phrase trie.

4.4 Training

We outline here the execution of the whole learning process and inference step. As with language model learning, TSANL trains LSTMs to learn sequences of topics and words from a given corpus with the embeddings of observed words and topics learnt from this corpus. Each training pattern of these networks is comprised of N time steps in the embeddings of words, $(w_{t-N}...w_{t-1})$, and those of topics, $(z_{t-N}...z_{t-1})$, followed by one word, w_t, and topic, z_t, respectively. To create these sequences, we slide the window along the word and its topic assignment in the given corpus so that each word, and topic is learned from the preceding N words, and topics, respectively. That is, we train $LSTM_z$ to predict the embedding of topic, z_t, from the preceding N words' embedding representations, and $LSTM_{z,s}$ to predict the embedding of word, w_t, associated with topic z from the preceding N words' embedding representations over the same topic.

5 EXPERIMENTS

5.1 Datasets and Experiment design

We conducted evaluations using 20 Newsgroups data sets[1] and the Amazon review data sets[2], as they are well-known and publicly available [6, 17, 18, 28]. First, we selected two subsets from the Amazon review data sets, counted the number of reviews per product, and used the reviews of the top 137/115 products (object ID) in each subset, where each product had at least 100 reviews. Then, we removed the stop words and rare words (frequency lower than 5 in each collection) using NLTK[3], and converted all words to lowercase. Statistics about the data set are shown in Table 2.

To illustrate the utility of semantic relationships between words, we visualize the two-dimensional PCA projection of word embeddings, where we set the number of iterations to 5000. We calculated this projection from all words' embeddings, but show only the top 500 frequent words in Fig 4.

5.2 Document Classification

We evaluate embedding quality by using the quality of document classification results, a popular way of evaluating the effectiveness of a learned document representation yielded by a topic model [24, 25]. Generally speaking, more accurate topic modeling enables better document representation, resulting in improved document classification accuracy. As this experiment aims to evaluate the document-level representation, we use Doc2vec (PD-DBOW) as the document level representation benchmark, TWE(TWE-1) [4] with, GibbsLDA++[5] and CLM as the topic awareness embedding representation benchmark. Unless otherwise stated, documents are classified by Support Vector Machine (SVM) over each representation vector. As in [17], we represent the semantics of a document by aggregating over all topical word embeddings of each word in the document, i.e., $d = \sum_{w\in d} Pr(w|d)a_w$, where $Pr(w|d)$ can be weighted with TFIDF scores of the words in d. Since topic embeddings can be used as the semantic representation of a document by aggregating over all topic embeddings like word embeddings, i.e., $d = \sum_{w\in d} Pr(t|d)c_t$, where $Pr(t|d)$ can be weighted with TFIDF scores of the topics in d, we call these variations of TWE and Wat2vec as TWE(z) and Wat2vec(z), respectively.

Using their document-topic distribution or document embedding, each model was tasked with classifying 20Newsgroup documents, and Amazon reviews into 20 classes, where each corpus was randomly split into training and testing data sets at the ratio of 4:1. To compare the overall performance over all document classes or labels, we compared them using the macro-averaged precision, recall, and F1 coherence measure using gensim[6] over all models. The classifiers of TWE, CLM,

and Wat2vec were trained for each by applying the topic distribution of the training data set; the SVM classifier received the document embedding vectors as input.

Table 3 shows that our model yielded word representations effective for document classification; document-topic distributions yield better performance in this task than embedding models. While CLM and Wat2vec offer similar performance for word embeddings, Wat2vec(z) outperforms CLM for topic embeddings. This comparison demonstrates that the word embedding obtained from skip-grams with topics play an important role in allowing TSANL to learn LSTMs over topics.

6 DISCUSSION

The problem of employing deep learning for natural language processing is that it is difficult to attach a reasonable interpretation to each dimension of the generated distributions [1, 17, 22, 23]. Topic models and word embedding represent the global and local semantics, as topics encode word co-occurrence patterns in each document and the embedding representations elucidate context information. TSANL incorporates LSTM [8] as it supports both the sequential dependency of word and topic coherence.

7 CONCLUSION

This paper proposes Wat2vec as embedding models and TSANL as neural language models. As TSANL aims to capture long-range dependencies of topics and words, as segments and phrases, respectively, Wat2vec uses topics as global semantic information and local semantic information as embedding representations of topics and words, and embeds both words and topics in the same space. Experiments showed that Wat2vec learns these embedding representations for TSANL to maintain the ordering of both segments and topical phrases, and enhances previous models. Future work is to extend TSANL to deal with streaming data by developing an online algorithm.

ABSTRACT

As virtually all aspects of our lives are increasingly impacted by algorithmic decision making systems, it is incumbent upon us as a society to ensure such systems do not become instruments of unfair discrimination on the basis of gender, race, ethnicity, religion, etc. We consider the problem of determining whether the decisions made by such systems are discriminatory, through the lens of causal models. We introduce two definitions of group fairness grounded in causality: *fair on average causal effect* (FACE), and *fair on average causal effect on the treated* (FACT). We use the Rubin-Neyman *potential outcomes* framework for the analysis of cause-effect relationships to robustly estimate FACE and FACT. We demonstrate the effectiveness of our proposed approach on synthetic data. Our analyses of two real-world data sets, the Adult income data set from the UCI repository (with gender as the protected attribute), and the NYC Stop and Frisk data set (with race as the protected attribute), show that the evidence of discrimination obtained by FACE and FACT, or lack thereof, is often in agreement with the findings from other studies. We further show that FACT, being somewhat more nuanced compared to FACE, can yield findings of discrimination that differ from those obtained using FACE.

1 INTRODUCTION

With the growing adoption of algorithmic decision making systems, e.g., AI and machine learning systems, across many real-world decision making scenarios on the Web and elsewhere, there is a pressing need to make sure that such systems do not become vehicles of unfair discrimination, inequality, and social injustice [2, 3]. Of particular interest in this context is the task of detecting and preventing discrimination or unfair treatment of individuals or groups on the basis of gender, race, religion, etc. Such discrimination is traditionally addressed using one of two legal frameworks: *disparate treatment* (which aims to enforce procedural fairness, namely, the equality of treatment that prohibits the use of the protected attribute in the decision process); and *disparate impact* [3] (which aims to guarantee outcome fairness, namely, the equality of outcomes between protected groups relative to other groups). It is clear that enforcing procedural fairness within the disparate treatment framework does not guarantee non-discrimination within the disparate impact framework.

There is growing interest in algorithmic decision making systems that are demonstrably *fair* (see [4] for a review). Much of this literature relies on precise definitions that quantify fairness to avoid discrimination with respect to *protected* attributes, e.g., race, gender, on the basis of the legal notions of disparate treatment or disparate impact [3] (see [3, 4, 32, 40, 60] for reviews). Some examples include: fairness through unawareness [14], individual fairness [11], equalized odds [15, 54], calibration [8], demographic (or statistical) parity [6, 21–23], the 80% rule (disparate impact) [13, 55], representational fairness [33, 56], and fairness under composition [12].

Unfortunately, choosing the appropriate definition of fairness in a given context is extremely challenging due to a number of reasons. First, depending on the relationship between a protected attribute and data, enforcing certain definitions of fairness can actually increase discrimination [28]. Second, different definitions of fairness can be impossible to satisfy simultaneously [4, 8, 26]. Many of these difficulties can be attributed to the fact that fairness criteria are based *solely* on the joint probability distribution of the random variables of interest, namely, $\hat{Y}$ (predicted outcome), Y (actual outcome), $\tilde{X}$ (features), and A (sensitive attributes). [15] recently showed any such definition for fairness of a predictor that depends merely on the joint probability distribution is not necessarily capable of detecting discrimination. Hence, it is tempting to approach the problem of fairness through the lens of causality [1].

Answering questions of fairness through the lens of causality entails replacing the question "Is the decision discriminatory with respect to a protected attribute?" by: "Does the protected attribute have a causal effect on the decision?" A practical difficulty in using this approach is that, in general, establishing a causal relationship between a protected attribute and a decision requires the results of experimental manipulation of the protected attribute. Fortunately, however, existing frameworks for determining causal effects from observational data [20, 36] provide a rich set of theoretical results as well as practical tools for elucidating causal effects, and

specifically, answering questions about *counterfactuals* or *potential outcomes*, i.e., results of *hypothetical* experimental interventions from observational data, whenever it is possible to do so. Hence, there is a growing body of work (see [32] for a recent review) focused on explicitly causal (as opposed to purely joint distribution based or *observational*) definitions for fairness (e.g., [5, 7, 25, 28–30, 35, 50, 53, 57–59]). While some, e.g., [59], have focused on testing fairness (or conversely, determining whether there is discrimination), others, e.g., [25, 28] have sought to design machine learning algorithms that yield predictive models that are demonstrably fair. However, most of the existing work on defining fairness in causal terms has focused on variants of individual fairness. Against this background, we focus on robust methods for detecting and quantifying discrimination against protected groups, which is a necessary prerequisite for developing predictive models that are provably non-discriminatory.

Contributions. We reduce the problem of quantifying discrimination against protected groups to the well-studied problem of estimating the causal effect of some variable(s) on a target (outcome) variable. We introduce two explicitly causal definitions of fairness in a population, *fair on average causal effect* (FACE), and in a protected group, *fair on average causal effect on the treated* (FACT), both with respect to a protected attribute (e.g., gender, race). We use the Rubin-Neyman *potential outcomes* framework [20, 45, 49] for robust estimation of FACE and FACT. We demonstrate the effectiveness of the proposed approach in detecting and quantifying group fairness using synthetic data, as well as two real-world data sets: the Adult income data from the UCI repository [10] (with gender being the protected attribute), and the NYC Stop and Frisk data (with race being the protected attribute). We show that the evidence of discrimination, or lack thereof, obtained by FACE and FACT is often in agreement with other studies. We further show that FACT, being somewhat more nuanced compared to FACE, can yield findings of discrimination that differ from those obtained using FACE.

2 FAIRNESS: A CAUSAL PERSPECTIVE

Assume we have observational data on a population of individuals. Let $\tilde{X} \in \mathcal{X}$ be the vector of non-protected attributes, $A \in \mathcal{A} = \{a, a'\}$ be a binary protected attribute, and $Y \in \mathcal{Y}$ an outcome of interest. The question we want to answer is: Are individuals being discriminated against, on average, with respect to outcomes or decisions Y on the basis of a protected attribute A? From a causal perspective, such a question is *equivalent* to the following question: Does A have a causal effect on Y? In other words, how much would Y change, on average, were the value of A to change? Both Structural Causal Models [36] and the Rubin-Neyman Causal Model (RCM) [20] (also called the *potential outcomes* model) offer methods for estimating such causal effects from observational data.

We introduce two explicitly causal definitions for fairness "on average" in a population or a protected group (as opposed to causal definitions of individual fairness, e.g., counterfactual fairness [28]) with respect to a protected attribute (e.g., gender, race). Let $Y_i^{(a)}$ and $Y_i^{(a')}$ be the potential outcomes of a data point i had their value of A been a and a', respectively. Let $h : \mathcal{X} \times \mathcal{A} \to \mathcal{Y}$ be a decision function (or a predictive model trained using machine learning) that is used to support decision making. $\mathbb{E}[\cdot]$ is the expectation of a random variable. We define the following.

Definition 2.1. (FACE: Fair on Average Causal Effect). A decision function h is said to be fair, on average over all individuals in the population, with respect to A, if $\mathbb{E}[Y_i^{(a)} - Y_i^{(a')}] = 0$.

Definition 2.2. (FACT: Fair on Average Causal Effect on the Treated). A decision function h is said to be fair with respect to A, on average over individuals with the same value of A, if $\mathbb{E}[Y_i^{(a)} - Y_i^{(a')} \mid A_i = a] = 0$.

Example. Imagine we are given the hiring data of a company containing demographic information about applicants, as well as A = {male, female} as their gender, and Y = {hired, rejected} as whether they were hired by the company. Our task is to determine whether the company's hiring decisions are fair on average with respect to gender. FACE contrasts the expected outcomes (i.e., hiring) between men vs. women with the expectation taken over the entire population. FACT contrasts the expected outcomes observed for a specific protected group (e.g., women) and the hypothetical (counterfactually inferred) outcomes for the group had they not been members of the protected group (with the expectation taken only over the members of the protected group), e.g., hiring outcomes for women contrasted with outcomes for the same individuals had their gender been different with all other attributes remaining unchanged. Obviously, such counterfactual outcomes cannot be obtained from observational data[1] and ought to be estimated.

3 ESTIMATING FACE AND FACT

We use tools offered by the potential outcomes framework [20] to estimate FACE and FACT. These tools rely on the following key assumptions: i) *Consistency* which requires that for a data point i, the potential outcome of i under any level of treatment a, i.e., Y_i^a, equals the *actual* outcome observed for that data point, Y_i^{obs}, had they been exposed to treatment a. Formally, under consistency, $Y_i^{obs} = a\, Y_i^{(a)} + a'\, Y_i^{(a')}$ would hold for all i. This assumption, used in existing literature [7, 34, 35, 38], is a rather natural one to make in our setting. ii) *Positivity* which asserts that the probability $Pr(A = a \mid X = x) > 0$ for all values of A. In our setting, this means each value of the protected attribute has a non-zero probability. iii) *Stable Unit Treatment Value Assumption (SUTVA)* [47] which consists of two sub-assumptions: 1) Absence of *interference* between individuals [9], which means that an individual's potential outcome is unaffected by the treatment assigned to any other individual. While this assumption is plausible in our setting, it may be violated in some settings, in which case, such violations should be accounted for [16]. 2) Presence of only one form of treatment (and control). For example, if a treatment involves administering a drug, then all individuals who take the drug, take it in the same form (e.g., injection). This assumption is trivially satisfied in our setting because treatment is simulated by the protected attribute. iv) *Unconfoundedness of the treatment mechanism* which implies that given a set of observables, the potential outcomes of each individual are jointly independent of the corresponding treatment [46]. Unconfoundedness cannot be verified or contradicted entirely on the

[1] This is called the Fundamental Problem of Causal Inference (FPCI) from observational data [18].

basis of observational data. However, sensitivity analysis [31, 42] can be a useful tool for analyzing the estimated causal effects under violations of the unconfoundedness assumption. Strong ignorability refers to the combination of unconfoundedness and positivity [43]. Strong ignorability is a sufficient condition for the causal effect to be identifiable [16] and is equivalent to the *back-door criterion* [37], which is required for identifiability of the causal effects in Pearl's model of causality [37]. In our work, as in the case of existing work on causal definitions of fairness [35], we assume strong ignorability.

3.1 Estimating and Interpreting FACE

We use Inverse Probability Weighting (IPW), also known as Inverse Probability of Treatment Weighting (IPTW) in Marginal Structural Models (MSM) [39] to estimate FACE. Specifically, for each individual i, we calculate a *stabilized weight*: $sw_i = \frac{Pr(A_i=a)}{Pr(A_i=a \mid \tilde{X}_i=\tilde{x}_i)}$ (call it the weight model). We obtained stabilized weights using the R package *ipw* (version 1.0-11) [52]. Assigning such a weight to every data point, we generate a "pseudo-population" in which there are sw_i copies of each data point i. Subsequently, the associative parameter β in the weighted regression (call it the outcome model) of the (continuous) outcome Y on the protected attribute A: $\mathbb{E}[Y^{(A)}] = \delta + \beta A + \tilde{\theta}^\top \tilde{X}$, would be the causal effect of A on Y. For a binary output Y, we use the weighted logistic regression model: $\text{logit}\,(\mathbb{E}[Y^{(A)}]) = \delta + \beta A + \tilde{\theta}^\top \tilde{X}$. In the absence of unmeasured confounders, if *either* the weight model *or* the outcome model are correctly specified, then $\hat{\beta}$ is an unbiased estimator of the average causal effect [39]. For example, suppose Y is salary and A is gender. At the chosen level of statistical significance α, $\hat{\beta} = 0$ implies that salary is fair with respect to gender on average over the entire population of individuals; $\hat{\beta} \neq 0$ implies that, on average, women's salary differs from that of men by a factor of $\hat{\beta}$ (across the entire population). For a continuous outcome Y, $\hat{\beta}$ is simply the average causal effect of A on Y. For a binary outcome Y, $\hat{\beta}$ corresponds to the causal odds ratio of salary for women versus men.

3.2 Estimating and Interpreting FACT

We use *matching* to estimate FACT. Consider the example of salary discrimination based on gender. For a woman, we can never observe what the salary would have been, *had she been a man* (i.e., her counterfactual salary). Hence, we estimate the counterfactual salary as follows [20]: 1) Using a suitable matching technique (see Section Matching Methods), we match the woman i, to a man j who is closest to i with respect to a distance measure $d(i, j)$. 2) The matching process is repeated as needed until matches are of acceptable quality (see Section Quality of Matches). 3) After matching, we use the salary of the matched man j (i.e., Y_j), as the counterfactual salary of the woman i.

Matching Methods. The results of matching depend on the choice of distance measure $d(\cdot, \cdot)$ as well as the matching process. Several matching methods exist (see [51] for a survey). In what follows, for simplicity and brevity, we refer to individuals with protected attribute set to $A = a$ as the *treated* individuals and those with the protected attribute set to $A = a'$ as the *controlled* individuals. We used the matching methods implemented within the R package *MatchIt* (version 3.0.2) [17] with all parameters set to their default values unless otherwise noted: (i) Exact Matching (EM); (ii) Nearest Neighbor Matching (NNM) with propensity score [43]. Following [48], we estimated the propensity scores using the logit link and transformed them to the linear scale. Then, we ran NNM with replacement, based on the linear propensity scores, and discarded the data points (both from treated and controlled) that fall outside the support of the distance measure; (iii) Nearest Neighbor Matching with a Propensity Caliper (NNMPC). NNMPC includes only matches within a certain number of standard deviations of the distance measure and discards the rest. In NNMPC, we use the same procedure as in NNM, augmented with a caliper = 0.25 [44], resulting in the matches outside 0.25 times the standard deviation of the (transformed) linear propensity score, being discarded; (iv) Mahalanobis Metric Matching within the Propensity Caliper [48] (MMMPC). MMMPC determines for each data point, a "donor pool" of available matches within the propensity caliper. Mahalanobis metric matching is then performed among the data points chosen in the previous step mimicking blocking in randomized experiments [48]. We ran MMMPC with caliper, replacement, and discarding strategy as described above in NNM; and (v) Full Matching (FM) [41]. We used the same distance measure and discarding strategy as described above in NNM.

Quality of Matches. To ensure accurate estimation of FACT, it is crucial to measure the "goodness-of-match." If the data points are well matched, then one can proceed to estimate FACT. Common diagnostics for examining the quality of match include both numerical and graphical criteria. Among the numerical criteria, following [48], we compare the standardized difference in the means of the treated and the controlled data points in terms of the distance measure. We denote the absolute value of this difference in means on the original, and matched data, by $\overline{D}_{a,a'}$, and $\overline{D}^m_{a,a'}$, respectively. For the match to be of good quality, $\overline{D}^m_{a,a'}$ has to be close to 0. Among the graphical criteria, we use quantile-quantile (QQ), and jitter plots recommended by [17, 51].[2]

Outcome Analysis After Matching. With good quality matched pairs identified, we can proceed to conduct outcome analysis for FACT estimation. Matching methods often assign appropriate weights to the matched data points to balance the treated and controlled data distributions. After obtaining the weights via matching, we run the following weighted regression models: $\mathbb{E}[Y^{(A)}] = \delta + \gamma A + \tilde{\theta}^\top \tilde{X}$, for continuous, and $\text{logit}\,(\mathbb{E}[Y^{(A)}]) = \delta + \gamma A + \tilde{\theta}^\top \tilde{X}$, for binary outcomes, both *on the matched data set*, to estimate FACT. The estimated coefficient for A in the equations above, i.e., $\hat{\gamma}$, estimates FACT. The resulting estimate is "doubly robust" in that if *either* the matching model, *or* the outcome model, are correctly specified, $\hat{\gamma}$ would be statistically consistent [17].

Interpreting $\hat{\gamma}$ as a Measure of FACT. Suppose Y is salary and A is gender. At the chosen level of statistical significance α, $\hat{\gamma} = 0$ implies that there is no significant difference in expected salary for women compared to what their salary would have been had

[2] We avoid the commonly used hypothesis tests for *assessing feature balance* in diagnosing the quality of matches because such tests have been shown to be misleading in general [19].

they been men (with all non-protected attributes $\tilde{X}$ remaining unchanged, a condition that is approximated by counterfactual inference using matching), thus implying no gender-based discrimination in salary for women; $\hat{\gamma} \neq 0$ implies that, on average, women's salary is statistically significantly different from what it would have been, had they been men, thus implying gender-based discrimination in salary. For a continuous outcome Y, e.g., the salary in US dollars, if statistically significant, $\hat{\gamma} \neq 0$ means that on average, *considering men and women that are matched based on their feature vector* $\tilde{X}$, the difference between women's salary and that of men is $\hat{\gamma}$. For a binary outcome, e.g., salaries binarized with an arbitrary threshold τ, $\hat{\gamma}$ is the causal odds ratio of women's salary compared to that of men, for those women and men who are similar.

Impact of Unmeasured Confounders on $\hat{\gamma}$. What if the strong ignorability assumption (i.e., no hidden confounders) is violated? In the absence of unmeasured confounding, matching estimators are unbiased if the matching model is specified correctly, i.e., if balance is achieved over the *observed attributes*. However, it is conceivable that the results of matching could change in the presence of *unobserved confounders* (i.e., hidden bias). We perform sensitivity analysis [31, 42] to investigate the degree to which the unmeasured confounders impact $\hat{\gamma}$. Let Γ be the odds ratio of matched (using any matching method) data points i and j receiving a treatment. Sensitivity analysis proceeds by first assuming $\Gamma = 1$ (i.e., no hidden bias). Then, it increases Γ (e.g., $1, \ldots, 5$), thus mimicking the presence of hidden bias, and examines the resulting changes to statistical significance of $\hat{\gamma}$. The Γ at which the significance of the upper bound for the p-value would change (e.g., from < 0.05 to > 0.05) is the point at which $\hat{\gamma}$ is no longer robust to hidden bias. We ran sensitivity analysis using the R package *rbounds* (version 2.1) [24].

4 EXPERIMENTS AND RESULTS

We tested our approach on a synthetic data set (where the discrimination based on a protected attribute can be varied in a controlled fashion), and two real-world data sets that have been previously used in studies of fairness. In each case, we designated a protected attribute and estimated FACE and FACT as measures of discrimination based on that attribute. We run all of our statistical significance tests with $\alpha = 0.05$. We proceed to describe the data sets, experiments, as well as our FACE and FACT analyses in detail.

4.1 Data sets

Synthetic data set. We generated 1000 data points, each with a feature vector $\tilde{X} = (X_1, \ldots, X_5)$, a protected attribute $A \in \{0, 1\}$, and an outcome variable Y according to the following: $X_1, \ldots, X_5 \overset{iid}{\sim} \mathcal{N}(0, 1)$; $A \mid X \sim \text{Bernoulli}\left(\text{logit}^{-1}(\sum_{i=1}^{5} X_i)\right)$; $Y \mid X, A = \sum_{i=1}^{5} X_i W_i$, where $\tilde{W} = (W_1, \ldots, W_5)$ is a weight vector (fixed for all data points) with each element drawn randomly in [0,1]. The resulting generative model ensures there are no hidden confounders and there is no discrimination, as measured by FACE and FACT, with respect to the outcome variable Y on the basis of the protected attribute A.

The Adult data set. The Adult income data set [27][3], contains information about individuals as well as their salaries. The data set includes 48842 individuals each with 14 attributes, 6 continuous and 8 categorical, including demographic and work-related information such as age, gender, hours of work per week, etc. We examined whether there is gender-based discrimination in salaries by designating *gender* as the sensitive attribute. We encoded categorical variables using one-hot-encoding and removed data records with missing values, yielding a data set with 46033 individuals and 45 features (excluding gender, the protected attribute). We designated the outcome Y to be a binary variable denoting whether the person's annual salary is $> \$50K$ (Y=1), or $\leq \$50K$ (Y= 0).

The NYC Stop and Frisk (NYCSF) data set. We retrieved the publicly available stop, search, and frisk data from The New York Police Department (NYPD)[4] website which serves demographic and other information about drivers stopped by the NYC police force. Our question is whether the arrests made after stops have been discriminatory with respect to race. Following [28], we restricted our experiment to the year 2014 yielding a total of 45787 records. We selected the subset of records corresponding to only Black-Hispanic and White men. We designated *race* as the protected attribute with $A = 1$ denoting Black-Hispanic and $A = 0$ denoting White. We dropped the data records with missing values and encoded categorical variables with one-hot-encoding. The resulting data consist of 7593 records each with 73 features (excluding race, the sensitive attribute). The outcome Y denotes whether an arrest was made ($Y = 1$), or not ($Y = 0$).

4.2 FACE Check: Fairness Analysis Using FACE

We report our analysis of fairness using FACE, for the synthetic, Adult, and NYCSF data sets. The estimated FACE ($\hat{\beta}$) are shown in Table 1. In all cases, the null hypothesis is $H_0 : \beta = 0$. In the case of synthetic data, we find insufficient evidence to reject H_0, suggesting the outcome is fair with respect to the protected attribute (an expected conclusion given the design of the generative model in Section 4.1, which ensures that the outcome is fair with respect to the protected attribute). In the case of Adult data, we reject H_0 and find that $\hat{\beta}$, the average causal effect of gender on salaries, is -1.069. This means that on average, over the entire population, the odds of women having a salary $> \$50K$ a year is $\exp(-1.069) \approx 0.34$ times that of men, suggesting gender-based discrimination against women as measured by FACE. This finding is in agreement with the conclusions reported in [30, 35]. In the case of NYCSF data, we reject H_0 and find that $\hat{\beta}$ is 0.273 which means that on average, the odds of Black-Hispanics being arrested after a stop by the police, is $\exp(0.273) \approx 1.31$ times that of Whites, suggesting possible racial bias against non-Whites.

4.3 FACT Check: Fairness Analysis Using FACT

We report our analysis of fairness using FACT, for the synthetic, Adult, and NYCSF data sets.

Matching Quality Analyses. Because the quality of matched pairs used to estimate FACT impacts the conclusions that can be

[3] https://archive.ics.uci.edu/ml/datasets/adult
[4] https://www1.nyc.gov/site/nypd/stats/reports-analysis/stopfrisk.page

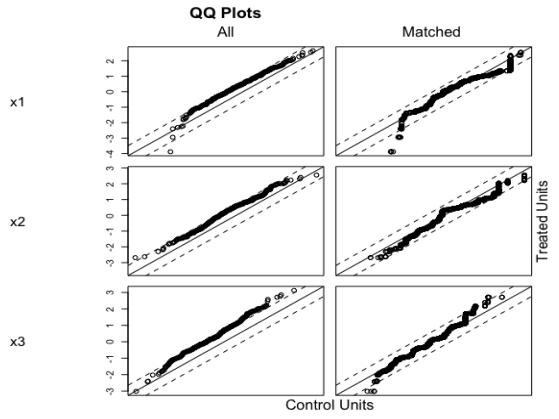
Table 1: Estimates of FACE ($\hat{\beta}$) obtained on the synthetic, Adult, and NYCSF data sets.

Data set	$\hat{\beta}$	Standard Error	P-value
Synthetic	-1.130×10^{-16}	6.991×10^{-17}	**0.106**
Adult	**−1.069**	3.614×10^{-1}	0.003
NYCSF	**0.273**	1.259×10^{-1}	0.030

drawn using it, we compare the FACT estimates obtained using several widely-used matching methods described in Section 3.2. We present some analyses to verify that the generated matches are of sufficiently high quality for estimating FACT.

We observe that before matching, $\overline{D}_{a,a'}$ is 1.6400, 3.3508, and 1.1616, on the synthetic, Adult, and NYCSF data sets, respectively. The matching methods dramatically reduced $\overline{D}_{a,a'}$ on all of the data sets (see Table 2). Overall, NNM and FM achieved the lowest $\overline{D}^m_{a,a'}$ as compared to other matching methods on all data sets. The greater the number of pairs that are matched, the harder it is to achieve balance, and the trade-off between the two can be application dependent. We observed that considering the trade-off between the number of matches and $\overline{D}^m_{a,a'}$, FM yields higher quality matches on all data sets as compared to other methods.

The QQ plots are generated for each feature in each data set. In Figure 1 we show the QQ plots before and after FM for the first three features of the synthetic data set. The features lie far away from the 45 degree line before FM. After FM, the features are much better aligned to the diagonal line showing a more desirable feature balance. We also show the jitter plots of FM on all data sets in Figure 2. It is clear that the distribution of propensity scores of the treated and controlled data points are very similar to each other after matching. Having verified that the results of matching are of adequate quality, we proceed to use them for estimating FACT.



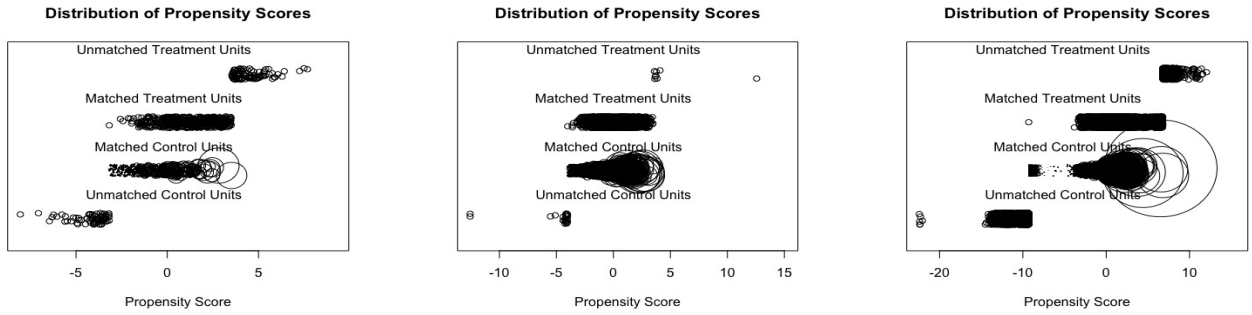


Figure 1: QQ plots of the first three features from the synthetic data set before (left) and after (right) FM.

FACT Estimates. The results of FACT analyses on the synthetic, Adult, and NYCSF data sets are summarized in Table 2 (Note that EM did not yield any matches and hence is omitted from Table 2). In all cases, the null hypothesis is $H_0 : \gamma = 0$. In the case of synthetic data, FACT analyses show that for NNM and MMMPC, there is not enough evidence to reject H_0. The p-values in the case of NNMPC and FM are < 0.05, but the magnitude of the estimated $\hat{\gamma}$ is close to zero. We conclude that the synthetic data set is fair on average with respect to FACT. On the Adult data, we can reject H_0, suggesting that salaries of women are significantly lower than those of men who match them on the non-protected attributes. For example, using FM, we find that $\hat{\gamma} = -0.573$, thus the odds of women earning $> \$50K$ a year, is $\exp(-0.573) \approx 0.56$ times that of men. We conclude that in the Adult data, there is evidence of gender-based discrimination in salary, on average, against women. On the NYCSF data, interestingly, FACT analyses show that H_0 cannot be rejected, suggesting a lack of evidence for racial bias, on average, in arrests after stops (when Black-Hispanics are compared with Whites who match them on non-protected attributes). This conclusion contradicts the finding of racial bias based on counterfactual fairness analysis (Supplementary Material S6 in [28]) which suggests discrimination against *individuals*, as well as FACE analysis (see Section 4.2). We conjecture that the apparent discrepancy can be explained by noting that (i) fairness (or discrimination) on average does not necessarily imply individual-level fairness (or individual-level discrimination), and (ii) FACT compares the observed outcomes of members of a protected group with the hypothetical (counterfactual) outcomes they would have experienced had they not been members of the protected group (with all non-protected attributes remaining unchanged), whereas FACE compares such counterfactual outcomes on the entire population.

Impact of Unmeasured Confounders. We ran sensitivity analysis of our estimates of FACT for $\Gamma = 1, \ldots, 10$ (where larger values of Γ correspond to greater bias introduced by hidden confounders) on the Adult and NYCSF data sets. We find that all of our estimates obtained with various matching methods are quite robust to hidden confounder bias. Specifically, on the Adult data set, for all matching methods except FM, the estimates are robust to such bias, and for FM, they are robust up to $\Gamma = 4.5$, which corresponds to a fairly large amount of bias. On the NYCSF data set, estimates obtained via NNM and MMMPC are robust to hidden confounder bias, and NNMPC and FM are robust up to Γ equals 8.5, and 3, respectively. These results mean that our FACT estimates (and hence our findings of discrimination on the basis of protected attributes, or lack thereof) are fairly robust to hidden confounder bias.

5 SUMMARY AND DISCUSSION

We have approached the problem of detecting whether a group of individuals that share a sensitive attribute, e.g., race, gender, have been subjected to discrimination in an algorithmic decision-making system, through the lens of causality. We have introduced two explicitly causal definitions of group fairness: *fair on average causal effect* (FACE), and *fair on average causal effect on the treated* (FACT). We have shown how to robustly estimate FACE and FACT, and use the resulting estimates to detect and quantify discrimination based on specific attributes (e.g., gender, race). The results of our experiments on synthetic data show that our proposed methods are effective at detecting and quantifying group fairness. Our analyses of the Adult data set for evidence of gender-based discrimination

(a) Synthetic data set. **(b) NYCSF data set.** **(c) Adult data set.**

Figure 2: Jitter plots of distribution of the propensity scores on the linear logit scale after FM on the synthetic (left), NYCSF (middle), and Adult (right) data sets. Each circle represents a data point. Area of the circle is proportional to the weight given to the data point. Female, Black-Hispanic = treated, and male, White = controlled.

Table 2: Estimates of FACT ($\hat{\gamma}$) obtained via various matching methods on the synthetic, NYCSF, and Adult data sets.

Synthetic data set						
Matching Method	# of Treated Matches	# of Control Matches	$\overline{D}^m_{a,a'}$	$\hat{\gamma}$	Standard Error	P-value
NNM	454	155	0.0032	-6.972×10^{-17}	4.947×10^{-17}	0.159
NNMPC	454	168	0.0234	-9.196×10^{-17}	3.020×10^{-17}	0.002
MMMPC	454	174	0.0308	7.424×10^{-18}	3.192×10^{-17}	0.816
FM	454	386	0.0031	-8.263×10^{-17}	3.702×10^{-17}	0.026
Adult data set						
Matching Method	# of Treated Matches	# of Control Matches	$\overline{D}^m_{a,a'}$	$\hat{\gamma}$	Standard Error	P-value

in salary, and of the NYCSF data set for evidence of racial bias in arrests after traffic stops, yield evidence of discrimination, or lack thereof, that is often in agreement with other studies.[5] We show on the real-world data that our estimates of FACE and FACT are robust to unmeasured confounding. Our results further show on the real-world data that FACE and FACT based findings do not always agree. Our FACT analyses also demonstrate that group-fairness (or discrimination) does not necessarily imply individual-level fairness (or individual-level discrimination).

Some directions for further research include: relaxing the assumption that the data are independent and identically distributed (i.i.d.) in settings where individuals are related to each other through family ties or other relationships; examining the relationships between different causal notions of fairness; and designing automated decision support systems that are demonstrably non-discriminatory with respect to given outcome(s) and protected attribute(s).

[5] The regression and matching-based methods we employed to estimate FACE and FACT adjust for covariates that might be potential confounders of the protected attribute, which although necessary in general, may be unnecessary in the case of gender and race, because they are unlikely to be caused by any other covariate. Consequently, the reported estimates of FACE and FACT are likely to represent *direct* causal effects as opposed to *total* causal effects.

ABSTRACT

In recent times, fake news and misinformation have had a disruptive and adverse impact on our lives. Given the prominence of microblogging networks as a source of news for most individuals, fake news now spreads at a faster pace and has a more profound impact than ever before. This makes detection of fake news an extremely important challenge. Fake news articles, just like genuine news articles, leverage multimedia content to manipulate user opinions but spread misinformation. A shortcoming of the current approaches for the detection of fake news is their inability to learn a shared representation of multimodal (textual + visual) information. We propose an end-to-end network, Multimodal Variational Autoencoder (MVAE), which uses a bimodal variational autoencoder coupled with a binary classifier for the task of fake news detection. The model consists of three main components, an encoder, a decoder and a fake news detector module. The variational autoencoder is capable of learning probabilistic latent variable models by optimizing a bound on the marginal likelihood of the observed data. The fake news detector then utilizes the multimodal representations obtained from the bimodal variational autoencoder to classify posts as fake or not. We conduct extensive experiments on two standard fake news datasets collected from popular microblogging websites: Weibo and Twitter. The experimental results show that across the two datasets, on average our model outperforms state-of-the-art methods by margins as large as ~6% in accuracy and ~5% in F_1 scores.

CCS CONCEPTS

1 INTRODUCTION

The change to neoteric methods of news consumption in recent times has brought the issue of fake news and misinformation to the forefront of discussion. As thousands of new news articles proliferate social media networks every day, with each having neither a credibility nor a validation check, an ecosystem fuelled by misinformation (the inadvertent sharing of false information) and disinformation (the deliberate creation and sharing of information known to be false) has been established. Social media networks have enabled news articles to evolve from traditional text-only news to news with images and videos which can provide a better storytelling experience and has the ability to engage more readers. Recent fake news articles leverage this very change to visual context aided news. Fake news articles can now contain misrepresented, irrelevant and forged images to mislead readers. Peer-to-peer networks (primarily social media networks) allow fake news (propaganda) to be targeted at users who are more likely to accept and share a particular message. Fake news has been in the limelight in recent years for having an extensive negative effect on public events. A major turning point of realization was the 2016 U.S. presidential elections. It was believed that within the final three months leading up to the election, fake news favoring either of the two nominees was accepted and shared by more than 37 million times on Facebook [1]. This makes the task of detecting fake news a crucial one.

Figure 1 shows three examples of fake news from the Twitter dataset. Each tweet has certain textual content and an image associated with it. For the tweet on the left, both the image and text indicate that it is probably a fake news. In the tweet on the right, the image does not add substantial information but the text indicates that it may be a fake news. In the tweet in the middle, it is difficult to reach a conclusion from the text, but the morphed image suggests that it is possibly a fake news. This example reflects the hypothesis

Text: **Elephant carved out of solid rock. Magnificent!**

Text: **New species of fish found in Arkansas.**

Text: **Woman, 36, gives birth to 14 children from 14 different fathers**

Figure 1: Fake News examples from the Twitter dataset

that pairs of visual and textual information can give better insights into fake news detection.

On a conceptual level, the task of detecting fake news has undergone a variety of labels from misinformation to rumor. The target of our study is detection of news content that is fabricated and can be verified to be false. Rumor and fake news detection techniques range from traditional learning methods to deep learning models. Initial approaches [4] tried to detect fake news using only linguistic features extracted from the text content of news stories. Ma et al. [14] explored the possibility of representing tweets with deep neural networks by capturing temporal-linguistic features followed by Chen et al. [5] who built upon this by introducing attention mechanism into the RNNs.

Recent works [26] in the field of deep learning to detect fake news have shown performance improvements over traditional methods due to their enhanced ability to extract relevant features. Jin et al. [9] combine visual, textual and social context features, using an attention mechanism to make predictions about fake news. Wang et al. [26] use an additional event discriminator to learn common features shared among all the events with the goal of doing away with non-transferable event-specific features, and claim that they can handle novel and newly emerged events better. A shortcoming of the existing models is that they do not have any explicit objective function to discover *correlations across the modalities*.

Our work, inspired by the idea of autoencoders tries to learn shared representations in a multimodal setting. Kingma et al. [12] proposed that latent variable models act as a powerful approach to generatively model complicated distributions and brought forth the ideas of Variational Autoencoder (VAE). VAEs can learn probabilistic latent variable models by optimizing a bound on the marginal likelihood of the observed data. Overcoming the limitations of the current models, we propose a multimodal variational autoencoder capable of learning shared (visual + textual) representations, trained to discover correlations across modalities in tweets. The VAE is then coupled with a classifier to detect fake news.

To summarize, the contributions of our work are as follows:

- We propose a novel approach for classifying social media posts using only the content of the post, i.e., the text and the attached image.
- The proposed MVAE model uses a Multimodal Variational Autoencoder trained jointly with a Fake News Detector to detect if a post is fake or not.
- We extensively evaluate the performance of our model on two real-world datasets. The results reveal that our proposed model learns better multimodal features and outperforms the state-of-the-art multimodal fake news detection models.
- We show that our proposed model is able to discover correlations across the modalities and thus come up with better multimodal shared representations.

The rest of this paper is organized as follows: In Section 2, we discuss previous work on fake news detection and basics of autoencoders. In Section 3, we present our proposed model and its different components. In Section 4, we describe the datasets, baselines and provide the implementation details of our proposed model. Results and analysis are shown in Section 5, and we conclude with a brief summary in Section 6.

2 RELATED WORK

The task of fake news detection is similar to various other interesting challenges ranging from spam detection [29] to rumor detection [24] to satire detection [20]. As every individual may have their very own intuitive definition of such related ideas, each paper embraces its own definition. Following the previous work [21, 22], we specify that the target of our study is detecting news content that is fabricated and can be verified as false.

A few early studies tried to detect fake news based on linguistic features extracted from the text of news stories. Castillo et al. [4] employ a set of linguistic features such as special characters, sentiment positive/negative words, emojis, etc. to detect fake news. Popat et al. [19] use stance and language stylistic features like assertive verbs, discourse markers, etc. to assess the credibility of a claim. Context-free grammar rules were used to identify deception in Feng et al. [6]. Ma et al. [14] were the first to explore the possibility of representing tweets with deep neural networks by capturing temporal-linguistic features. Chen et al. [5] incorporated attention mechanism into recurrent neural networks (RNNs) to pool out distinct temporal-linguistic features with a particular focus.

The social connection established as a result of the interaction between users and tweets give birth to rich social context for posts. Wu et al. [28] infer embeddings of social media user profiles and leverage an LSTM network over propagation pathways to classify fake news. Liu et al. [13] model the propagation path of a news story as a multivariate time series and detect fake news through propagation path classification with a combination of RNNs and CNNs. Ma et al. [15] learn representations of a tweet using recursive neural models based on tree-structured neural networks. Jin et al. [8] used hand-crafted social context features such as the number of followers, retweets, etc. Most social context features are unstructured and usually involve an intensive amount of manual labour to collect. Also, they cannot provide sufficient information for newly emerged events.

Recent studies have shown that visual features (images) play a very important role in detecting fake news [27]. However, verifying the credibility of multimedia content on social media has received less amount of scrutiny. Extraction of basic features of attached images has been explored in [18]. However, these features are still hand-crafted and can hardly represent complex distributions of image content.

Deep neural networks have yielded immense success in learning image and textual representations. They have been successfully applied to various tasks including image captioning [10, 25], visual

question answering [2], and fake news detection [8, 26]. Jin et al. [8] proposed a model which extracts the visual, textual and social context features, and fuses them by attention mechanism. Wang et al. [26] learn event-invariant features using an adversarial network along with a multimodal feature extractor. However, both these models do not have any explicit objective to discover *correlations across the modalities*.

To overcome the limitations of the existing multimodal fake news detectors, we propose a multimodal variational autoencoder (MVAE) that learns a shared representation of both the modalities, text as well as image. The multimodal variational autoencoder is trained to reconstruct both the modalities from the learned shared representation and thus discovers *correlations across modalities*. We jointly train the multimodal variational autoencoder along with a classifier to detect fake news. Also, we use less information than our baselines to detect fake news i.e. we don't use any social or event related information.

3 THE PROPOSED MVAE MODEL

3.1 MVAE Overview

We propose a novel deep multimodal variational autoencoder (MVAE) to address the problem of fake news detection. The basic idea behind MVAE is to learn a unified representation of both the modalities of a tweet's content. The overall architecture of the proposed MVAE is illustrated in Figure 2. It has three main components:

- Encoder: It encodes the information from text and image into a latent vector.
- Decoder: It reconstructs back the original image and text from the latent vector.
- Fake News Detector: It uses the learned shared representation (latent vector) to predict if a news is fake or not.

3.2 Encoder

The inputs to the encoder are the text of the post as well as the image attached to it, and it outputs a shared representation of the features learnt from both the modalities. The encoder can be broken down into two sub-components: textual encoder and visual encoder.

3.2.1 Textual Encoder. The input to the textual encoder is the sequential list of words in the posts, $T = [T_1\ T_2\ \dots\ T_n]$, where n is the number of words in the text. Each word $T_i \in T$ in the text is represented as a word embedding vector. The embedding vector for each word is obtained with a deep network which is pre-trained on the given dataset in an unsupervised way.

To extract features from textual content, we use recurrent neural networks (RNNs) with Long-Short Term Memory (LSTM) cells. RNNs are a class of artificial neural networks which utilize sequential information and maintain history through their intermediate layers. A vanilla RNN has an internal state whose output at every time-step can be expressed in terms of the previous time step. However, it has been seen that vanilla RNNs suffer from a problem of vanishing and exploding gradients [7, 17]. This leads to the model learning inefficient dependencies between words that are a few steps apart. To overcome this problem, LSTM extends the basic RNN by storing information over long time periods by their use of memory units and efficient gating mechanisms.

Let $[h_1\ h_2\ \dots\ h_n]$ represent states of the LSTM and its state updates satisfy the following equations:

$$\left[f_t,\ i_t,\ o_t\right] = \sigma\left(Wh_{t-1} + Ux_t + b\right) \tag{1}$$

$$c_t = f_t \circ c_{t-1} + i_t \circ \tanh\left(Wh_{t-1} + Ux_t + b\right) \tag{2}$$

$$h_t = o_t \circ \tanh\left(c_t\right) \tag{3}$$

where, σ is the logistic sigmoid function, f_t, i_t, o_t represent the forget, input and output gates respectively , x_t denotes the input, h_t represents the hidden state at time t. The forget, input and output gates control the flow of information throughout the sequence. W, U are matrices which represent the weights and b are the biases associated with the connections.

We employ stacked bi-directional LSTM units to extract textual features. The final hidden state of LSTM is obtained by concatenating the forward and backward states. Finally, we pass the LSTM output through a fully connected layer (enc text fc) to get the textual features.

$$R_T = \phi\left(W_{tf}R_{lstm}\right) \tag{4}$$

where, R_{lstm} is the output of the LSTM, W_{tf} is the weight matrix of the fully connected layer and ϕ is the activation function used.

3.2.2 Visual Encoder. The input to the visual encoder is the image attached with the post, V. As seen in various visual understanding problems, image descriptors trained using convolutional neural networks (CNNs) over large amounts of data have proven to be very effective. The implicit learning of spatial layout and object semantics in the later layers of the network has contributed to the success of these features.

We employ the pre-trained network of VGG-19 architecture [23] trained over the ImageNet database and use the output of the fully-connected layer (FC7). During the joint training process, we freeze the parameters of the VGG network to avoid parameter explosion. Finally, we pass the VGG output through multiple fully connected layers (enc vis fc*) to get the same sized representation of the image as that of text.

$$R_V = \phi\left(W_{vf}R_{vgg}\right) \tag{5}$$

where, R_{vgg} is the feature representation obtained from the VGG-19, W_{vf} is the weight matrix of the fully connected layer and ϕ is the activation function used.

The textual feature representation R_T and the visual feature representation R_V are then concatenated and passed through a fully connected layer to form the shared representation. We then obtain two vectors μ and σ from the shared representation. They can be treated as the mean and variance respectively of the distribution of the shared representation. Furthermore, a random variable ϵ is sampled from a previous distribution (e.g., Gaussian distribution). The final reparameterized multimodal representation denoted by R_m can be calculated as follows:

$$R_m = \mu + \sigma \circ \epsilon \tag{6}$$

We denote the encoder as $G_{enc}(M,\ \theta_{enc})$, where θ_{enc} denotes all the parameters to be learned in encoder, and M represents the set of multimedia posts. Hence, the output of the encoder for a multimedia post, m, is the multimodal representation:

$$R_m = G_{enc}\left(m,\ \theta_{enc}\right) \tag{7}$$

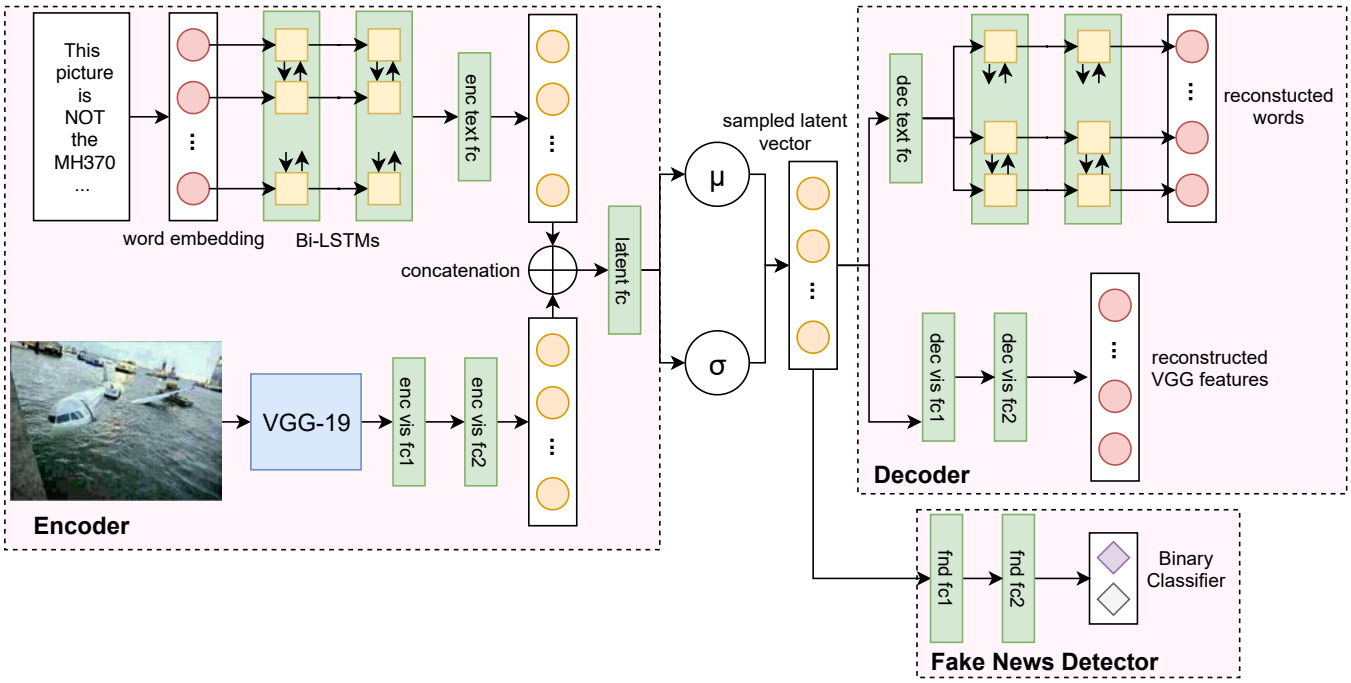

Figure 2: Network architecture of the proposed Multimodal Variational Autoencoder (MVAE). It has three components: Encoder, Decoder and Fake News Detector.

3.3 Decoder

The architecture of the decoder is similar to that of the encoder but inverted. The goal of the decoder is to reconstruct data from the sampled multimodal representation. Just like the encoder, it can be broken down into two sub-components: textual decoder and visual decoder.

3.3.1 Textual Decoder. The textual decoder takes as input the multimodal representation and reconstructs the words in the text. The multimodal representation is passed through a fully connected layer (dec text fc) to create inputs for the bi-directional LSTM. Then, we have similar stacked bi-directional LSTM units as used in the textual encoder sub-network. Finally, we pass the LSTM outputs through a time distributed fully connected layer with softmax activation to get the probability of each word in that time step.

3.3.2 Visual Decoder. The goal of the visual decoder is to reconstruct the VGG-19 features from the multimodal representation. The visual decoder sub-network is just the reverse of the visual encoder's corresponding sub-network. The multimodal representation is passed through multiple fully connected layers (dec vis fc*) to reconstruct the VGG-19 features.

We denote the decoder as $G_{dec}(R_m,\ \theta_{dec})$, where θ_{dec} denotes all the parameters in the decoder. Hence, the output of the decoder for a multimedia post, m, is a matrix of probability of every word for each position in the text, $\hat{t}_m$, and the reconstructed VGG-19 features of the image, $\hat{r}_{vgg_m}$.

$$\left(\hat{t}_m, \hat{r}_{vgg_m}\right) = G_{dec}\left(R_m,\ \theta_{dec}\right) \tag{8}$$

VAE models are trained by optimizing the sum of the reconstruction loss and the KL divergence loss. Therefore, we employ categorical cross-entropy loss for reconstruction of text and mean squared error for reconstruction of image features. The KL divergence between two probability distributions simply measures how much they diverge from each other. Minimizing the KL divergence here means optimizing the probability distribution parameters (μ and σ) to closely resemble that of the target distribution (Normal distribution). These can be calculated as follows:

$$\mathcal{L}_{rec_{vgg}} = \mathbb{E}_{m\sim M}\Big[\frac{1}{n_v}\sum_{i=1}^{n_v}\left(\hat{r}_{vgg_m}^{(i)} - r_{vgg_m}^{(i)}\right)^2\Big] \tag{9}$$

$$\mathcal{L}_{rec_t} = -\mathbb{E}_{m\sim M}\Big[\sum_{i=1}^{n_t}\sum_{c=1}^{C}\mathbf{1}_{c=t_m^{(i)}}\log\hat{t}_m^{(i)}\Big] \tag{10}$$

$$\mathcal{L}_{kl} = \frac{1}{2}\sum_{i=1}^{n_m}\left(\mu_i^2 + \sigma_i^2 - \log(\sigma_i) - 1\right) \tag{11}$$

where, M is the set of multimedia posts, n_v is the dimensionality of VGG-19 features, n_t is the number of words in text, n_m is the dimensionality of multimodal features, and C is the vocabulary size. We minimize the VAE loss by seeking optimal parameters $\hat{\theta}_{enc}$ and $\hat{\theta}_{dec}$ and this can be represented as follows.

$$\left(\theta_{enc}^*, \theta_{dec}^*\right) = \underset{\theta_{enc},\theta_{dec}}{\operatorname{argmin}}\left(\mathcal{L}_{rec_{vgg}} + \mathcal{L}_{rec_t} + \mathcal{L}_{kl}\right) \tag{12}$$

3.4 Fake News Detector

Fake News Detector takes multimodal representation as input and aims to classify the post as fake or not. It consists of multiple fully connected layers with corresponding activation functions. We

denote the fake news detector as $G_{fnd}(R_m,\ \theta_{fnd})$, where θ_{fnd} denotes all the parameters in the fake news detector. The output of the fake news detector for a multimedia post, m, is the probability of this post being a fake news.

$$\hat{y}_m = G_{fnd}\left(R_m,\ \theta_{fnd}\right) \tag{13}$$

We can view the value of $\hat{y}_m$ as a label 1 meaning the multimedia post m is fake, and 0 otherwise. In order to constrain the values between 0 and 1, we use the sigmoid logistic function. Hence, to calculate the classification loss, we employ cross-entropy as follows.

$$\mathcal{L}_{fnd}\left(\theta_{enc}, \theta_{fnd}\right) = -\mathbb{E}_{(m,y)\sim(M,Y)}\Big[y \log\left(\hat{y}_m\right) + \left(1-y\right)\log(1-\hat{y}_m)\Big] \tag{14}$$

where, M represents the set of multimedia posts and Y represents the set of ground truth labels. We minimize the classification loss by seeking the optimal parameters $\hat{\theta}_{fnd}$ and $\hat{\theta}_{enc}$, and this can be represented as follows.

$$\left(\theta^*_{enc}, \theta^*_{fnd}\right) = \underset{\theta_{enc}, \theta_{fnd}}{\operatorname{argmin}}\ \mathcal{L}_{fnd} \tag{15}$$

3.5 Putting it all together

The complete architecture of the proposed MVAE model is shown in Figure 2. The output of the encoder is fed to the decoder as well as the fake news detector. The decoder aims to reconstruct the data, while the fake news detector aims to classify the post as fake news or not. We jointly train the VAE and the fake news detector. Hence, the final loss can be written as follows.

$$\mathcal{L}_{final}\left(\theta_{enc}, \theta_{dec}, \theta_{fnd}\right) = \lambda_v \mathcal{L}_{rec_{vgg}} + \lambda_t \mathcal{L}_{rec_t} + \lambda_k \mathcal{L}_{kl} + \lambda_f \mathcal{L}_{fnd} \tag{16}$$

where, λs can be used to balance the individual terms of the loss function. In this paper, we simply set all the λs as 1. The optimal parameters can then be calculated by minimizing the final loss as follows.

$$\left(\theta^*_{enc}, \theta^*_{dec}, \theta^*_{fnd}\right) = \underset{\theta_{enc}, \theta_{dec}, \theta_{fnd}}{\operatorname{argmin}}\ \mathcal{L}_{final}\left(\theta_{enc}, \theta_{dec}, \theta_{fnd}\right) \tag{17}$$

4 EXPERIMENTS

In this section, we first describe the two social media datasets used in the experiments. We then discuss in brief the state-of-the-art fake news detection approaches along with some state-of-the-art language-vision models.

4.1 Datasets

Given the sparse availability of structured multimedia data, we make use of two standard datasets to evaluate our architecture for fake news detection. The two datasets consist of real social media information collected from Twitter and Weibo. To the best of our knowledge, these are the only available datasets that have paired image and textual information.

4.1.1 Twitter Dataset. As part of MediaEval [3], the Twitter dataset was released for Verifying Multimedia Use task. The task was aimed at detecting fake multimedia content on social media. The dataset consists of tweets (short messages posted on Twitter) and each tweet has textual content, image/video and social context information associated with it. The dataset has around 17000 unique tweets spanning over different events. The dataset is split into two parts: the development set (9000 fake news tweets, 6000 real news tweets) and the test set (2000 tweets). They are split in such a manner that the tweets have no overlapping events. Given our focus on the image and textual information, we filter out all tweets which have videos attached to them in the set. We use the development set for training and the test set for testing to keep the same data split scheme as the benchmark.

Table 1: Performance of MVAE vs other methods on two different datasets

Dataset	Method	Accuracy	Fake News			Real News		
			Precision	Recall	F_1	Precision	Recall	F_1
Twitter	Textual	0.526	0.586	0.553	0.569	0.469	0.526	0.496
	Visual	0.596	0.695	0.518	0.593	0.524	0.7	0.599
	VQA	0.631	0.765	0.509	0.611	0.55	0.794	0.65
	Neural Talk	0.610	0.728	0.504	0.595	0.534	0.752	0.625
	att-RNN	0.664	0.749	0.615	0.676	0.589	0.728	0.651
	EANN	0.648	**0.810**	0.498	0.617	0.584	0.759	0.660
	MVAE	**0.745**	0.801	**0.719**	**0.758**	**0.689**	**0.777**	**0.730**
Weibo	Textual	0.643	0.662	0.578	0.617	0.609	0.685	0.647
	Visual	0.608	0.610	0.605	0.607	0.607	0.611	0.609
	VQA	0.736	0.797	0.634	0.706	0.695	0.838	0.760
	Neural Talk	0.726	0.794	0.713	0.692	0.684	0.840	0.754
	att-RNN	0.772	0.854	0.656	0.742	0.72	**0.889**	0.795
	EANN	0.782	0.827	0.697	0.756	0.752	0.863	0.804
	MVAE	**0.824**	**0.854**	**0.769**	**0.809**	**0.802**	0.875	**0.837**

4.1.2 Weibo Dataset. The Weibo dataset, used in [8] for the task of fake news detection consists of data collected from Xinhua News Agency, an authoritative news source of China and Weibo, a Chinese microblogging website. The fake news collected from Weibo is obtained over a span of time ranging from May 2012 to January 2016 and is verified by Weibo's official rumour debunking system. The system encourages common users to report suspicious tweets on Weibo which are then examined by a committee of reputable users that classify the suspicious tweet as false or real. In accordance with previous work [14, 27], this system also acts as the authoritative source for collecting rumour news. The non-rumour tweets are tweets verified by the Xinhua News Agency. Preprocessing of the dataset is done using a method similar to that of [8]. Preliminary steps involve removal of duplicate images (using locality sensitive hashing) and low-quality images to ensure homogeneity across the dataset. The dataset is then split into training and testing sets with an approximate tweet ratio of 4:1 as in Jin et al. [8].

4.2 Experimental Settings

For word embeddings, we employ the distributed Word2Vec representation for words [16]. For the Twitter dataset, we have posts which are not in English, so we translated them into English to keep the data coherent. We follow standard text pre-processing for the Twitter dataset. For the Weibo dataset, text is in Chinese. Chinese text is written without spaces between words. We use the Stanford Word Segmenter for Chinese text tokenization into words.

We pre-train the Word2Vec model on the training dataset in an unsupervised fashion, with dimension size of 32.

For visual features, we use the output of the second to the last layer of a 19-layer VGGNet pre-trained on ImageNet set [23]. The dimensions of features obtained from VGG-19 is 4096. We do not fine tune the weights of the VGG, i.e., the weights of the VGG network are frozen.

The textual encoder consists of LSTMs with dimension size of hidden layers as 32. The fully connected layer used in the textual encoder is of size 32. The visual encoder consists of two fully connected layers of size 1024 and 32. The decoder consists of layers with the same dimensions as that of the encoder. The fake news detector has two fully connected layers of size 64 and 32.

We use a batch size of 128 instances in the training of the whole network. The model is trained for 300 epochs with a learning rate of 10^{-5} with an early stopping to report the results. We use the hyperbolic tangent function as the non-linear activation function. To prevent overfitting, we use L2-regularizer on the weights of our model. We experimented with a weight penalty of [0, 0.05, 0.1, 0.3, 0.5] and set it to 0.05 for the encoder and the decoder, and 0.3 for the fake news detector. To seek optimal parameters for our model, we use Adam [11] as the optimizer. We make the code publicly available[1].

4.3 Baselines

To validate the performance of the proposed multimodal variational autoencoder, we compare it with two categories of baseline models: single modality models and multimodal models.

4.3.1 Single Modality Models. MVAE leverages information from both visual and textual data to identify potentially fake news. As against such multimodal approaches, we also experimented with two unimodal models as described below.

- **Textual**: This model uses only textual information present in posts to classify them as fake or not. Each word is represented as a 32-dimensional vector. The word-embeddings are trained on the text content of the posts. Individual posts are then fed into a Bi-LSTM to extract textual features F_T. F_T is then fed into a 32-dimensional fully connected layer with a softmax function coupled with the Bi-LSTM that is responsible for making final predictions.
- **Visual**: The visual model uses only images from posts to classify them as fake or not. Images are fed into a pre-trained VGG-19 network with a fully-connected layer to extract visual features F_V. Similar to the textual model, the visual features F_V are then fed into a 32-dimensional fully connected layer for making the prediction.

4.3.2 Multimodal Models. Multimodal approaches utilize information from multiple modalities for the task of fake news classification.

- **VQA** [2]: Visual Question Answering aims to answer questions about given images. We adapted the Visual QA model which was originally designed for a multi-class classification task to our binary classification task. This is done by replacing the final multi-class layer with a binary-class layer. We use a one-layer LSTM with number of hidden units set to 32.
- **Neural Talk** [25]: The work of Vinyals et al. [25] in the domain of image captioning, proposes generation of natural language sentences describing an image using a deep recurrent framework. Following a structure similar to theirs, we obtain latent representations by averaging the output of the RNN at each time step as the joint representation of the image and text in tweets. These representations are then fed into a fully connected layer followed by an entropy loss layer to make predictions.
- **att-RNN** [8]: att-RNN uses attention mechanisms to combine textual, visual and social context features. In this end-to-end network, image features are incorporated into the joint representation of text and social context, obtained using an LSTM network. The neural attention from the outputs of the LSTM is an integral part for fusing the visual features. For a fair comparison, in our experiments, we remove the part dealing with social context information.
- **EANN** [26]: The Event Adversarial Neural Network (EANN) consists of three main components: the multimodal feature extractor, the fake news detector and the event discriminator. The multimodal feature extractor extracts textual and visual features from posts. It works with the fake news detector to learn the discriminative representation for detection of fake news. The event discriminator is responsible for removing any event-specific features. It is also possible to detect fake news using only two components, the multimodal feature extractor and the fake news detector. Hence, for a fair comparison, in our experiments, we work with a variant of EANN which does not include the event discriminator.

Note that fair comparisons with methods proposed in [13, 15] are not possible since they use addition information like tweet propagation data. Also, these methods are not developed for multimodal datasets. We report the accuracy, recall, precision, and F_1 scores of all the baselines along with our proposed model in Table 1.

5 RESULTS AND ANALYSIS

Table 1 shows the results of the baselines as well as our proposed method on both the datasets. We report the accuracy of our fake news detector as well as the precision, recall and F_1 score of our method for both fake news and real news. We can clearly see that our proposed method performs much better than the baselines.

On the Twitter dataset, among the single modality models, the visual model performs better than the textual model. This can be attributed to the fact that image features learnt with the help of VGG-19 have more shareable patterns to classify news as compared to textual features. Although visual features perform better than textual features, single modality models perform worse than the multimodal models.

Among multimodal models, att-RNN beats EANN which tells us that the attention mechanism can help in improving the performance of the model by considering the parts of the image which are related to the text. Our proposed model MVAE outperforms the baseline models by a huge margin and increases the accuracy from 66.4% to 74.5% and increases the F_1 scores from 66% to 73%.

On the Weibo dataset, we see similar trends in the results. The textual model beats the visual model in single modality models.

[1] https://github.com/dhruvkhattar/MVAE

Among multimodal methods, EANN and att-RNN which were proposed for this task perform better than Neural Talk and VQA. MVAE outperforms all the baselines and boosts the performance from 78.2% to 82.4% in terms of accuracy and shows an increase of ∼5% in F_1 scores, compared to the previous best baseline. This validates the effectiveness of our proposed method MVAE in detecting fake news on social media.

6 CONCLUSIONS

In this work, we explored the task of multimodal fake news detection. Overcoming the limitations of the current models, we tackle the challenge of learning correlations between modalities in tweets and to do so, propose a multimodal variational autoencoder that learns shared (visual + textual) representations to aid fake news detection. Our model consists of three main components, an encoder, a decoder and a fake news detector. Our proposed model, MVAE is trained by jointly learning the encoder, decoder and the fake news detector. The performance of our proposed architecture is evaluated on two real-world datasets. The MVAE model outperforms the current state-of-the-art architectures. In the future, we plan to extend MVAE using tweet propagation data and user characteristics.

ABSTRACT

To improve mobile application (App for short) user experience, it is very important to inform the users about the apps' privacy risk levels. To address the challenge of incorporating the heterogeneous feature indicators (such as app permissions, user review, developers' description and ads library) into the risk ranking model, we formalize the app risk ranking problem as an exclusive sparse coding optimization problem by taking advantage of features from different modalities via the maximization of the feature consistency and enhancement of feature diversity. We propose an efficient iterative re-weighted method to solve the resultant optimization problem, the convergence of which can be rigorously proved. The extensive experiments demonstrate the consistent performance improvement using the real-world mobile application datasets (totally 13786 apps, 37966 descriptions, 10557681 user reviews and 200 ad libraries).

1 INTRODUCTION

Improving user experience is an important task to increase app user engagement and monetize mobile apps. Risk management and assessment has been proposed to improving the user experiences from analysis and diagnosis of potential hazards and risk factors that may cause harm to the mobile app users, such as release of location, user preference, contact and even other personal bio-metric information. A privacy risk score quantifies the risk levels of mobile apps, which allows the users to better perceive the risk levels, which has been shown to have a "significant positive effects" [11] to improving user experience.

Figure 1: Mobile app risk ranking using heterogeneous privacy risk indicators, including user review, description, permission and ads. The demonstrated four apps, i.e., `Yahoo finance`, `Tango message`, `Angry bird`, and `Fruit Ninja` are categorized as `none`, `low`, `medium` and `high`, respectively.

To efficiently and effectively perceive the risk of apps is a challenging task, which generally requires the deep understanding of mobile app framework, and expert knowledge of app permission and advertisement libraries. Therefore, machine learning technique is naturally applied to learn the risk scores of apps. Given the heterogeneous risk features indicating different attributions of risks, how to combine them to give a comprehensive assessment by leveraging feature correlations, consistency and diversity, is under-explored but highly desirable. Unfortunately, recent works, including permission usage pattern mining [9] [7], app permission prediction from meta-data [28] [19], malicious app detection [15] [39], API link analysis [24], mobile app recommendation [44] [21], deep model compression on mobile device [20] [18], however, do not essentially solve this problem. To bridge this gap, in this paper, we propose a novel approach to rank app risks using heterogeneous features from multiple sources in a unified optimization framework, which considers both intra-view and inter-view feature information while encouraging their competitions. With our method, one can easily understand which feature play more important role for risk ranking and therefore the result is *interpretable* for illustrating the underlying reasons. Further, once the model is well-trained using the labeled app corpus, the model can be easily deployed and served to automatically label the new apps in the market with high accuracy. To summarize, the key contributions are listed as follows.

• To the best of our knowledge, this paper is the first work that explores heterogeneous privacy indicators for app risk ranking, which, we believe, is very important for improving user experience on mobile platforms.

• We formalize the risk ranking problem as a multi-view feature learning problem via exclusive sparse coding strategy, which can

Table 1: Mobile app risk category

Category	Examples
High	Drag Racing, Fruit Ninja, $\cdots$
Medium	Angry bird, $\cdots$
Low	Temple Run 2, Tango message, $\cdots$
Few/None	Wechat, Yahoo Finance, Instagram, $\cdots$

Table 2: Notations used in the paper

notation	description
$\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n]$	$\mathbf{x}_i^v \in \Re^{p_v}$, v-th view of feature
$\mathbf{Y} = [\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_n]$	$y_i \in \Re^K$, risk category for app i
w_k^v	the weight for category k with the v-th view indicator

automatically select the most discriminant features by enforcing both inter-view and intra-view feature competitions.

• We derive a *novel* iteratively re-weighted algorithm to tackle the resultant optimization problem, which can actually handle *any* feature group structures, regardless of coherent or exclusive group feature patterns.

• We crawled real-world datasets (totally 13, 786 apps, 37, 966 descriptions, 10, 557, 681 user reviews and 200 ads libraries), and used them to comprehensively evaluate the effectiveness of our approach. Our method not only consistently outperforms the baseline methods, but also offers valuable insights to understand the risk features attributed to different sources.

Notations Let n be the number of data points, p_v be the dimension for data from view v, k be the number of class in dataset, V be the number of total views. For any vector $\mathbf{x} \in \Re^p$, ℓ_q norm of $\mathbf{w}$ is $\|\mathbf{w}\|_q = (\sum_{i=1}^p \|w_i^q\|)^{\frac{1}{q}}$ for $\forall q \in (0, 2)$.

2 PROBLEM STATEMENT

More formally, assume we have n mobile apps, each mobile app is abstracted as a data point $\mathbf{x}_i$ denoting the privacy indicators extracted from the app. In the paper next, we denote the features extracted from v–th privacy indicator ($1 \le v \le V$) as the v-th view feature. In mobile app context, let $\mathbf{x}_i^v \in \Re^{p_v}$ be v-th view feature (*i.e.*, features extracted from permission, user review, description, ads library, *etc*) of a mobile app i. Consider all the mobile apps, $\mathbf{X}^v = [\mathbf{x}_1^v, \mathbf{x}_2^v, \cdots, \mathbf{x}_n^v]$, where each data column vector is $\mathbf{x}_i^v \in \Re^{p_v \times 1}$. The simple concatenation of all views of apps gives:

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}^1 \\ \mathbf{X}^2 \\ \vdots \\ \mathbf{X}^V \end{bmatrix} = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n], \quad \mathbf{x}_i = \begin{pmatrix} \mathbf{x}_i^1 \\ \mathbf{x}_i^2 \\ \vdots \\ \mathbf{x}_i^V \end{pmatrix}.$$

with dimension $p = \sum_v p_v$.

Given the task of risk ranking for mobile apps, the risk of mobile app is categorized into four classes[1]:

`High > Medium > Low > None`,

where the risk levels rank from high to none.

Then each mobile is assigned to a single category. For example, *Yahoo Finance* belongs to *none* risk category. Table 1 gives examples of risk levels for different mobile apps. More formally, let $\mathbf{y}_i$ be risk class label for each $\mathbf{x}_i$ then $\mathbf{y}_i \in \Re^K$ where K is number of categories (K=4 in our case). Written in a matrix format, $\mathbf{Y} = [\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_n]$, where $\mathbf{Y} \in \Re^{K \times n}$. The goal of multi-view feature learning task is to learn the projection matrix $\mathbf{W} \in \Re^{p \times K}$ such that the risk levels can be projected into features from different sources, i.e.,

$$\mathbf{W} = [\mathbf{w}_1 \cdots \mathbf{w}_K], \quad \mathbf{w}_k = [\mathbf{w}_k^1, \mathbf{w}_k^2, \cdots, \mathbf{w}_k^V]^T, \tag{1}$$

where $\mathbf{w}_k^v$ has the same size as data $\mathbf{x}_i^v$ from view v. Table 2 summarizes the notations used throughout the paper.

Table 3: Privacy risk issues

Privacy risk issue	Behavior Descriptions
Spamming	Advertisement in notification bar, ads via email, ads via SMS, Pop-up ads, Fishing, *etc*
Financial	Paid for In-App-Purchase (IAP), but do not get the item, free to premium, *etc*
Over-claimed Permission	Request too much permissions than users' expectations
Data leakage	Access privacy data without user acknowledgement, *e.g.*, user account, contact, location, *etc*

An illustration In the proposed risk ranking framework, after learning the projection $\mathbf{W}$, we can automatically label the risk category for the new apps following the same feature extraction strategy. For each app, the extracted features $\mathbf{x}_i^v$ are from four perspectives including: (i) permission features with one-hot coding denoting the critical resources (e.g., location, contact) that an app allows to access, (ii) developer description features via tf-idf representation reflecting the developers' awareness [30], (iii) user review features using annotated semantics that provide valuable feedback of users by considering users' expectations (shown in Table 3), (iv) advertisement library features via one-hot coding relating to monetizing purpose [8] with users' personal data.

3 HETEROGENEOUS RISK LEARNING

In this section, we propose a new method for risk ranking using the heterogeneous features. The key idea of our approach to leverage the rich information from different views of features that indicate different aspects of risk of apps while considering both inter-view feature competitions and intra-view feature correlations, which is guided by the following key observations.

(i) For each app risk level, the discriminant features for decision could be different. For example, the dominant features that are used to determine *high* and *none* categories might be "location" and "game", respectively.

(ii) Given the app risk level, some views of features are more important than other views. The competition among the features from different view exists, *i.e.*, *not* all features from each view are needed for risk ranking. For example, in terms of category *low* and *medium*, *advertisement* features are generally more important than other features because mobile apps usually access or even send out users' data stealthily whereas "*permission*" features may be more important for differentiating *high* from *medium* category.

(iii) For the features from the same view, there exist feature correlations and redundancies. From information gain perspective, *less is more*. Thus Feature selection is necessary to select the discriminant features in each view, so as to achieve the minimum

[1]This category is based on expert suggestions from Android developers. `privacygrade: https://www.hcii.cmu.edu/research/privacygrade` from CMU adopts the same category.

redundancy while maintaining maximum relevance at intra-view level.

Based on the above observations, in order to find the projection matrix $\mathbf{W} \in \Re^{p\times K}$ that can map the input features into the risk category, we propose to solve the following objective function:

$$\min_{\mathbf{W}} f(\mathbf{W};\mathbf{X},\mathbf{Y}) + \alpha\|\mathbf{W}\|_{\mathrm{G}} + \beta\|\mathbf{W}\|_{EG} \tag{2}$$

where $f(\mathbf{W};\mathbf{X},\mathbf{Y})$ is a loss function given multi-view data matrix $\mathbf{X} \in \Re^{p\times n}$ and class labels $\mathbf{Y} \in \Re^{K\times n}$, which is used to minimize the distance between the observations and prediction. Any loss function can be applied here, e.g., cross-entropy loss, logistic loss, hinge loss, etc. For example, with cross-entropy loss, the objective function is:

$$f(\mathbf{W};\mathbf{X},\mathbf{Y}) = \sum_{ik} -Y_{ik} log\widehat{Y_{ik}}, \tag{3}$$

$$\widehat{Y_{ik}} = \frac{1}{1+\exp^{-\mathbf{w}_k^T\phi(\mathbf{x}_i,\theta)}}, \tag{4}$$

where $\phi(\mathbf{x}_i,\theta)$ represents features after projection, either can be in the original feature space, i.e.,

$$\phi(\mathbf{x}_i,\theta) = \mathbf{x}_i, \tag{5}$$

or in projected space after multiple layer non-linear projection:

$$\phi(\mathbf{x}_i,[\theta,\varphi]) = \varphi_L\Big(\theta_L^t[...[\varphi_1(\theta_1^t\mathbf{x}_i)]]\Big), \tag{6}$$

where L is the number of layers, θ_ℓ, φ_ℓ is the feature projection and activation function (such as ReLu, tanh function) for layer ℓ.

The regularization terms are used to incorporate both *local intra-view* via $\|\mathbf{W}\|_{EG}$ and *global inter-view* information via $\|\mathbf{W}\|_{\mathrm{G}}$ given the projection $\mathbf{W} = [\mathbf{w}_1\mathbf{w}_2\cdots\mathbf{w}_K]$, i.e.,

$$\|\mathbf{W}\|_{\mathrm{G}} = \sum_{k=1}^{K}\sum_{v=1}^{V}\|\mathbf{w}_k^v\|_2, \quad \|\mathbf{W}\|_{EG} = \sum_{k=1}^{K}\sum_{v=1}^{V}\|\mathbf{w}_k^v\|_1^2. \tag{7}$$

Essentially, we explore both *local intra-view* and *global inter-view* features for multi-view feature selection purpose.

Mathematical Explanation In optimization of $\mathbf{W}$, we optimize each $\mathbf{w}_k(1 \le k \le K)$ separately, because it is corresponding to the feature coefficient computed from class k, independent of $\mathbf{w}_\ell$ from class ℓ, $\forall k \ne \ell$. This indicates that the selected features are unique to each category (as evident in observation i).

(i) $\|\mathbf{W}\|_{\mathrm{G}}$ is used to enforce feature competitions at inter-view level. As a result, features from several views are selected. This term has the same structure as that of group lasso [41] or $\ell_{2,1}$ norm [22] but is applied for multi-view setting. The "group" concept is naturally extended for each view, instead of traditional feature selection ([1, 26]) (as evident in observation ii).

(ii) $\|\mathbf{W}\|_{EG}$ is used to enforce feature competitions at *intra-view* level, because generally features from the same views, could be highly correlated. Thus, as evident in observation (iii), we let features in the same view compete for survival, *i.e.*, only a few number of features in each view could survive. This is achieved by by applying LASSO exclusively on features in each view.

4 OPTIMIZATION ALGORITHM

Fortunately, all terms of Eq.(2) are convex functions, and thus we can obtain a global optimal solution. It is generally felt that joint $\ell_{2,1}$ and $\ell_{1,2}$ terms are much more difficult to solve than the lasso term via shrinkage thresholding. Existing algorithm can formulate them as a quadratic programming problem [27], which can be solved by interior point method or active set method. However, the computational cost is expensive, which limits its use in practice. Recently, a primal-dual algorithm [38] is proposed to solve the similar problem, which casts the non-smooth problem into a min-max problem. However, the algorithm is a gradient descent type method and converges slowly. Moreover, the algorithm is designed for multi-task learning problem, and cannot be applied directly for both group and exclusive lasso problem.

4.1 Proximal Gradient Optimization

Proximal gradient method (a.k.a FISTA method) [25] is widely used to solve $\min_{\mathbf{W}} f(\mathbf{W}) + \Omega(\mathbf{W})$ problem. Here we adopt this method to solve Eq.(2). The key idea of proximal gradient method is to optimize $\mathbf{W}^t$ at each iteration t, *i.e.,*

$$\begin{aligned}\mathbf{W}^{t+1} &= \arg\min_{\mathbf{U}} \quad f(\mathbf{W}^t) + \nabla f(\mathbf{W}^t)^T(\mathbf{U}-\mathbf{W}^t) \\ &\qquad +\frac{L}{2}\|\mathbf{U}-\mathbf{W}^t\|_F^2 + \Omega(\mathbf{U}) \\ &= \arg\min_{\mathbf{U}} \quad \frac{1}{2}\|\mathbf{U}-\mathbf{A}\|_F^2 + \frac{1}{L}\Omega(\mathbf{U}),\end{aligned} \tag{8}$$

where $\mathbf{A} = \mathbf{W}^t - \frac{1}{L}\nabla f(\mathbf{W}^t)$, and L is a parameter chosen at each iteration using certain searching strategy, $\Omega(\mathbf{U})$ is the regularization term and $\Omega(\mathbf{U}) = \alpha\|\mathbf{U}\|_{\mathrm{G}} + \beta\|\mathbf{U}\|_{EG}$. Thus the problem is transformed to the minimization problem of Eq.(8).

Their major computation efforts in each iteration is to compute the gradient of $\nabla f(\mathbf{W}^t)$ depending on $f(\mathbf{W}^t)$. For example, for least square loss, it can be computed within $O(pnK)$. For logistic type loss $g(\mathbf{W})$,

$$g(\mathbf{W})' = g(\mathbf{W})(1-g(\mathbf{W})). \tag{9}$$

With appropriate choose of step size L, the proximal gradient method will achieve ϵ-optimal solution in $O(\frac{1}{\sqrt{\epsilon}})$ iterations. Then the key step is to solve the associated proximal operator:

$$\min_{\mathbf{U}} \quad \frac{1}{2}\|\mathbf{U}-\mathbf{A}\|_F^2 + \frac{1}{L}\Omega(\mathbf{U}). \tag{10}$$

4.2 Iteratively re-weighted method

We present an iteratively re-weighted algorithm to solve Eq.(10). Let $\mathbf{u}_k$ be k-th column of $\mathbf{U}$, the same for $\mathbf{a}_k$. Notice that

$$\begin{aligned}&\frac{1}{2}\|\mathbf{U}-\mathbf{A}\|_F^2 + \frac{1}{L}\Omega(\mathbf{U}) \\ &= \sum_k\Big[\frac{1}{2}\|\mathbf{u}_k-\mathbf{a}_k\|_2^2 + \sum_{v=1}^{V}(\alpha'\|\mathbf{u}_k^v\|_2 + \beta'\|\mathbf{u}_k^v\|_1^2)\Big],\end{aligned} \tag{11}$$

where $\alpha' = \frac{\alpha}{L}, \beta' = \frac{\beta}{L}$. Then we only need to minimize $J_1(\mathbf{u})$ w.r.t to $\mathbf{u} \in \Re^{p\times 1}$, *i.e.,*

$$J_1(\mathbf{u}) = \frac{1}{2}\|\mathbf{u}-\mathbf{a}\|^2 + \sum_{v=1}^{V}(\alpha'\|\mathbf{u}^v\|_2 + \beta'\|\mathbf{u}^v\|_1^2). \tag{12}$$

To the best of our knowledge, this is the *first* work which can tackle both $\ell_{2,1}$ and $\ell_{1,2}$ terms simultaneously. The idea is to find an auxiliary function for Eq.(12) which can be easily solved. Then the updating rules for $\mathbf{u}$ is derived. Finally, we prove the solution is

exactly the optimal solution we are seeking for the original problem. Since Eq.(12) is convex, the optimal solution is exact the global optimal solution. The algorithm is named as *iteratively reweighted method*, because it updates $\mathbf{u}$ iteratively, until the algorithm converges. Moreover, our algorithm can be easily extended to handle arbitrary feature structures, such as linear structure [40], tree structure [23], graph structure [16], forest structure [6], etc

4.2.1 Algorithm. Instead of directly optimizing Eq.(12), we propose to optimize the following objective (the reasons will be seen immediately below), i.e.,

$$J_2(\mathbf{u}) = \frac{1}{2}||\mathbf{u}-\mathbf{a}||^2 + \frac{1}{2}\alpha'\mathbf{u}^T\mathbf{E}\mathbf{u} + \frac{1}{2}\beta'\mathbf{u}^T\mathbf{F}\mathbf{u}, \tag{13}$$

where $\mathbf{E}, \mathbf{F} \in \Re^{p\times p}$ are both diagonal matrices, and given by

$$\mathbf{E}_{ii} = \frac{1}{\sqrt{\sum_{j\in v(i)}\mathbf{u}_j^2}}, \quad \mathbf{F}_{ii} = \frac{2\sum_{j\in v(i)}|\mathbf{u}_j|}{|\mathbf{u}_i|}, \tag{14}$$

where $v(i)$ denotes the view where feature i belongs to. Note the computation of $\mathbf{E}, \mathbf{F}$ depends on $\mathbf{u}$, thus minimization of $\mathbf{u}$ depends on both $\mathbf{E}, \mathbf{F}$ respectively. In the following, we propose an iteratively re-weighted algorithm to find out the optimal global solution for $\mathbf{u}$, where in each iteration, $\mathbf{u}$ is updated using current $\mathbf{E}, \mathbf{F}$, and $\mathbf{E}, \mathbf{F}$ are updated using current $\mathbf{u}$. This process is iterated until the algorithm converges. Taking the derivative of Eq.(13) w.r.t $\mathbf{u}$ and set it to zero. We have

$$\frac{\partial J_2}{\partial \mathbf{u}} = \mathbf{u} - \mathbf{a} + \alpha'\mathbf{E}\mathbf{u} + \beta'\mathbf{F}\mathbf{u} = 0. \tag{15}$$

Thus we obtain the optimal solution for Eq.(13) is given by,

$$\mathbf{u} = (\mathbf{I} + \alpha'\mathbf{E} + \beta'\mathbf{F})^{-1}\mathbf{a}. \tag{16}$$

Note $\mathbf{E}, \mathbf{F}$ are all diagonal matrix, and thus the $(\mathbf{I} + \alpha'\mathbf{E} + \beta'\mathbf{F})^{-1}$ can be efficiently computed, where $\mathbf{I} \in \Re^{p\times p}$ is identity matrix. Let $\mathbf{e} \in \Re^p, \mathbf{f} \in \Re^p, e_i = E_{ii}, f_i = F_{ii}, \mathbf{Q} = (\mathbf{I} + \beta_1\mathbf{E} + \beta_2\mathbf{F})^{-1}$, then $\mathbf{Q}$ is a diagonal matrix and given by,

$$\mathbf{u} = \mathbf{Q}\mathbf{a}, \quad \mathbf{Q}_{ii} = \frac{1}{1 + \alpha' e_i + \beta' f_i}. \tag{17}$$

Using the updating rule of Eq.(17), we can obtain the global optimal solution for Eq.(12). To summarize, Algorithm 1 gives the whole updating process of each individual variable $\mathbf{u}$, $\mathbf{E}$, $\mathbf{F}$.

Algorithm 1 Iterative reweighted algorithm to solve Eq.(12)

Input: $\mathbf{a}$, α', β'
Output: $\mathbf{u}$
Procedure:
1: $t = 0$.
2: **while** Not converge **do**
3: Update $\mathbf{u}^t$ using Eq.(17).
4: Update $e_i^t = \frac{1}{\sqrt{\sum_{j\in v(i)}\mathbf{u}_j^2}}, f_i^t = \frac{2\sum_{j\in v(i)}|\mathbf{u}_j|}{|\mathbf{u}_i|}$ of Eq.(14)
5: $t = t + 1$.
6: **end while**

Time complexity analysis In practice, we find the above algorithm converges very fast. Typically, it converges to global optimal solution within 10-20 iterations (to precision 1e-6). Moreover, the running time of our algorithm is also very fast, because both $\mathbf{E}$ and $\mathbf{F}$ are diagonal matrices. In each iteration, we need to update $\mathbf{u}, \mathbf{e}, \mathbf{f}$ iteratively, which takes time cost $O(p), O(pV), O(pV)$, respectively, where V is the number of view. Thus the total time cost of each iteration is $O(pV)$, which is linear w.r.t the number of features and the number of groups. The convergence analysis is left in Appendix.

Table 4: Descriptions of several mobile datasets crawled in `Google play` at different periods, including user reviews and textual info. The ads and permission are encoded with one-hot coding.

Dataset	#app	#comment	# textual info
D1	6,234	5,028,359	18,157
D2	6,940	4,958,209	16,357
D3	612	571,113	3,452

5 RELATED WORKS

Structure sparsity (e.g.,LASSO [32], group LASSO [41], [37]) has been widely applied for feature learning, which can be extended for processing multi-view feature learning problem. Co-training [2] is widely applied to train two or more separate classifiers by exploring multi-view features. Multiple kernel learning [12] via a combination on the kernel-based method, multi-view deep ranking [4], joint subspace learning by learning a latent view shared by multi-view features [31], multi-Layer multi-View classification for Alzheimer's disease [42], deep heterogeneous feature learning for face recognition [3], multi-view correlated feature learning by uncovering shared component [35] [17], *etc* are also proposed for handling different multi-view learning problems. More detailed survey of multi-view learning can be found in [43], [34]. None of the above works, however, tackles the problem of heterogeneous data ranking problem in the context of app risk ranking. Moreover, most of the above works focus on image data and structured data. Due to the difference between image data and text data (and other unstructured data) investigated in this work, we offer a novel approach for capturing feature correlations and competitions across different views for both text and unstructured data.

6 EXPERIMENT RESULTS

Dataset Collection & Preparation We collected our dataset from *Google Play*. On *Google Play*, user reviews about Apps that he/she used are publicly available. Once we obtain the Google ID of a user, we can locate all Apps the user has reviewed. Therefore, we obtain a list of Google user IDs and write a crawler to retrieve all rated Apps of these users. We collect three datasets at different period in 2017. The first dataset (D1) is collected from Google Play at March which contains 6,234 apps. The second dataset (D2) contains 6,940 apps at July and the third dataset (D3) is collected from top 1000 most popularly apps (by removing the overlaps with D1 and D2). There are no overlaps for the above datasets, and the apps are from a wide range of functionalities, including `game, news, music, social, movies/TV, travel, life`, *etc.* The details are summarized in Table 4.

Multi-view feature pool F For each retrieved App, we crawled its reviews, developer descriptions and apk file as in [33]. Therefore, we have V=4 types of privacy indicators: including permission, user-review, descriptions and advertisement. For each mobile app,

the permission feature is encoded using one-hot encoding as 235-dimensional binary vector[2]. We adopt the annotation tool [5] developed to automatic label the user review at app-level with 11 privacy binary labels. The description texts are properly preprocessed and the *tf-idf* feature for each term w in App i's description is computed as $log(TF_w^i + 1)log(\frac{\#App}{DF_w+1})$, where TF_w^i is the term frequency of w for App i's description and DF_w is the number of Apps that have w in their descriptions. Regarding the advertisement feature, we use the method proposed in [13] as a guideline to implement our own analysis tool to extract the ads libraries and then generate the features using one-hot encoding. We carefully generate these features in experiments, and we believe feature construction and feature engineering are important parts in building the model. That is also the reason why we generate the heterogeneous features for app risk categorization.

For the ground-truth of risk category results, we use majority voting[3] based on three experts: (1) two android experts from the major Android phone company; (2) CMU `privacygrad`[4]. If all three reach an agreement, then the label is consistent. If two of them have the same decision, we use the agreement as the final label. If three of them are different, we use the *median* value of their votes as the labeling result.

6.1 Experimental setting

After generating the heterogeneous features, we learn the projection $\mathbf{W}$ in our model. Parameters of α, β are searched in the range of $(10^{-5}, 10^{-4}, \cdots, 10^4, 10^5)$. We feed the learned $\mathbf{W}$ for classification purpose. We compare our method against the following methods:

• Feature sets from each individual view: ads, user-review, description and permission. We view the result from each single-view as a baseline method.

• A simple concatenation of all features (shown as *CF*) and then feed all the features into logistic regression classifier. Notice that these heterogeneous features have different scales and dimensions, and therefore some feature may dominate the classification process while others are diluted.

• Features learned from only group lasso method (shown as *Group*) (i.e., $\beta = 0$ in Eq.(2) using standard logistic loss, where features in each view are put in the same group, without any distinction.

• Feature learning from standard structural sparsity with logistic loss functio using ℓ_{21}-based feature selection [1].

• Feature learning from standard LASSO (shown as *LASSO*) with logistic loss.

• Mixture of Hierarchical Naive Bayes model[5] [29] with all features feeding into the model, which automatically correlates the risk ranking with the features in a generative way.

• Gradient boost decision tree (GBDT) [10] with an ensemble of a series of decision trees using all the heterogeneous features for categorization purpose. The tree number is set 30–50, number of leaf node=30, learning rate=0.8 and sampling rate=0.8.

• Multi-view unified subspace learning (MVLR) [36] jointly conducts multi-view representation learning and subspace learning.

• Multiview Canonical Correlation Analysis (MCCA) [14] aims to find the common representation that maximizes class separation while minimizing the noises.

• Feature correlation learning (FCL) [35] learns the individual information in each view and captures feature correlations among multiple views after learning the shared component.

[2]Android system has 235 permissions

[3]We are not saying our decision is perfect, but at least is a good solution to eliminate the bias based on the expert voting.

[4]`https://www.hcii.cmu.edu/research/privacygrade`

[5]However, Peng et al [29] only applied this model to distinguish benign apps from malicious apps only using `permission` features.

Table 7: Comparisons of our method against other methods in terms of classification performance (mean ± standard deviation) on D3 dataset.

Method	dataset:D3
Ads library (only)	60.08 ± 2.31
Permission (only)	75.72 ± 1.75
User comments (only)	74.91 ± 0.81
Description (only)	51.13 ± 0.35
Feature concatenation	70.43 ± 1.50
Group [41]	79.23 ± 0.47
LASSO [32]	78.41 ± 1.56
$\ell_{2,1}$ [1]	79.98 ± 0.32
HMNB [29]	76.74 ± 0.83
GBDT [10]	78.08 ± 1.55
MVLR [36]	75.47 ± 0.32
MCCA [14]	77.98 ± 0.10
FCL [35]	79.05 ± 0.27
GElvL (logistic+our method)	82.32 ± 1.29
GElvNL (MLP+our method)	**82.96 ± 2.44**

• Our method with two versions: (i) GElvL:using logistic loss in Eq.(2); (ii) gElvNL: we use multi-layer perception (MLP) with 3-layers and ReLu activation function in Eq.(2).

6.2 Risk ranking result comparisons

On each dataset, we do five-fold cross validation, i.e., randomly select 80% apps as the labeled apps, and use the rest ones for testing the performance of different algorithms. The above process is repeated for 5 times before reporting the average performances. We use the measurement *accuracy* to evaluate the performance of risk ranking. The performance using 5-fold cross validation are shown in Tables. 5, 6 and 7.

We make several important observations from experiment results. **(i)** Proposed exclusive feature learning method consistently performs better than the other baselines by exploiting the feature correlations while promoting feature diversity. **(ii)** Compared to the performance from the best single-view features, exclusive feature fusion provides better results. **(iii)** For each single-view feature set, their performances vary differently. **(iv)** The performance uplift over group lasso is 4%− 5% on average. **(v)** Our method outperforms the HMNB because simple concatenation will treat features of different views equally, and therefore the learned parameters are biased due to the misalignment among different feature space. GBDT is popularly used for web ranking, however, its performance degrades when it is applied for the classification instead of a typical point-ranking task in the context of mobile apps. **(vi)** Subspace and feature correlation learning generally performs well on image datasets while our method excels on text and unstructured features for mobile apps. **(vii)** Our method gives slightly better performance when applying MLP to embed features in non-linear space, compared to logistic loss.

Discussions on feature types (i) On all datasets, permission indicator contributes the most for ranking the risks of mobile apps, which explains why researches [11] use the permission as the only risk ranking indicator. However, permission indicator is not the only contributor for risk ranking. If multi-modal features are used, the performance is improved. This suggests the necessity of using multi-modal features. **(ii)** Besides permission indicator, the user review contributes the second most for the risk ranking. From users' perspective, the user reviews reveal how the users feel about the app based on their personal experiences. Users' expectation plays a big role in on how much the users can tolerate the apps' behavior, and understand the apps' security risks. **(iii)** Ads-library is also an important indicator to infer the security risks of mobile apps, since the ads libraries communicate with the ads network to get and show ads, based on the app context and users' personal information such as location, context, etc. We believe the ads library will bring serious privacy risk for a mobile app. **(iv)** It is generally felt that developers' description may be more helpful to infer the risks of mobile apps. Our results, however, indicate that description is not as important as we think for evaluating the risks of different mobile apps. This is due to the fact that most of the descriptions are related to the functionality and quality of the app, while only few descriptions mention security/privacy concerns.

Case study. For a game app named `Cut the Rope FULL FREE` [6], it falls into `high` risk category because it loads many ads libraries such as `facebook`, `admob`, `flurry`, *etc*; it requires location, account and other sensitive resources; and users also complain about the ads and finance issues.

7 CONCLUSION

This paper presents a novel approach to learn app risk from heterogeneous features. We address the automatic feature learning problem from features generated from different views, where $\ell_{2,1}$-norm is enforced to select features at inter-view level, and exclusive $\ell_{1,2}$ is enforced to select features at intra-view level. We propose an effective iterative re-weighted algorithm to solve the problem, whose convergence is rigorously proved. We apply the method to solve the mobile app risk ranking problem, and extensive experiments on mobile app risk categorization tasks demonstrate the good performance of our method.

8 APPENDIX: ALGORITHM ANALYSIS

Theorem 8.1. *Under the updating rule of Eq.(16),* $J_1(\mathbf{u}^{t+1}) - J_1(\mathbf{u}^t) \leq 0$.

To prove Theorem 1, we need two lemmas.

Lemma 8.2. *Under the updating rule of Eq.(16),* $J_2(\mathbf{u}^{t+1}) < J_2(\mathbf{u}^t)$.

Lemma 8.3. *Under the updating rule of Eq.(16),*

$$\Big(J_1(\mathbf{u}^{t+1}) - J_1(\mathbf{u}^t)\Big) \leq \Big(J_2(\mathbf{u}^{t+1}) - J_2(\mathbf{u}^t)\Big). \tag{18}$$

ABSTRACT

Knowledge graphs such as DBPedia and Freebase contain sparse linkage connectivity, which poses severe challenge to link prediction between entities. In addressing this sparsity problem, our studies indicate that one needs to leverage model with low complexity to avoid overfitting the weak structural information in the graphs, requiring the simple models which can efficiently encode the entities and their description information and then effectively decode their relationships. In this paper, we present a simple and efficient model that can attain these two goals. Specifically, we use a bag-of-words model, where relevant words are aggregated using average pooling or a basic Graph Convolutional Network to encode entities into distributed embeddings. A factorization machine is then used to score the relationships between those embeddings to generate linkage predictions. Empirical studies on two real datasets confirms the efficiency of our proposed model and shows superior predictive performance over state-of-the-art approaches.

1 INTRODUCTION

Knowledge Bases (KBs) such as DBPedia [8], Yago [18] and Freebase [1] contain precious large collaborative intelligence, on which many state-of-the-art NLP applications heavily rely, including question -answering [5], entity disambiguation [3], and information retrieval [4], amongst many others [7, 22, 23]. Knowledge within such graphs is typically represented as a triple (h, r, t), which indicates that there is a relation r from head entity h to tail entity t.

Unfortunately, the complexity of the real-world makes these knowledge graphs far from complete. In particular, the structural information provided in the existing knowledge triples is typically very sparse, which poses a severe challenge for link prediction in such graphs. For example, in the DBPedia knowledge graph, there are 99.41% entities (42966066 of entities in total) with at most 43 relations. Similarly, the Yago graph contains 95.17% of entities(38734252 of entities in total) but with at most 39 linkages [25]. To cope with such data scarcity, it is desirable to exploit additional information contained in the text descriptions of the entities and relations. To date, the distributed representations of the entities and relations are primarily constructed via encoding their corresponding text information. However, since an entity is only observed to participate in very few relations, and in more extreme cases, to participate in no relations at all (which gives rise to the OOKB, namely "out-of-knowledge-base" link prediction problem), each training example (an entity-relation-entity triple) only contains very weak supervisory signal to train the text encoder. Furthermore, this problem can be aggravated when the number of entities and the vocabulary size of the text are large, which is the case for current popular knowledge graphs. In such a scenario, one is naturally motivated to use a simple text encoder as possible so as to maintain a low model complexity and avoid over-fitting resulting from data sparsity.

In this paper, instead of promoting the use of sophisticated text encoders such as convolutional neural networks (CNNs), we advocate the philosophy of returning to the more basic bag-of-words models. Specifically, we propose a neural bag-of-word (NBOW) modelling framework, which contains three simple modules: selecting keywords to form bags of words, encoding entities from the bags of words, and computing the score of a triple using a factorization machine. To this end, we present two concrete examples in this framework, in which the entity encoding is carried out by simply averaging the word vectors in its bag of words or further modelled using a graph convolutional network (GCN) respectively. Our experimental results on two datasets, both old and new, demonstrate that a bag-of-words model is more effective than a CNN method in terms of entity encoding for link prediction in sparse knowledge graphs. In particular, we empirically show that, such simple models outperform significantly more sophisticated models, including the current art method ConMask in link prediction over sparse knowledge bases, for out-of-knowledge-base (or "open-world") link prediction. Our simple models have established new state-of-the-art results for the two benchmark datasets.

The rest of this paper is organized as follows: In Section 2, we present prior works on link prediction in knowledge base completion. In Section 3, we describe our model for entity encoding and relation scoring for knowledge base instances. In Section 4, we perform an experimental comparison of current methods against our model. We perform these experiments on the datasets DBPedia50K[17] and FB15K-237* which we generate from FB15K-237. We show that our method for link prediction is scalable and outperforms 'state-of-the-art' method, ConMask [17] in link prediction performance for the open-world assumption. We give concluding remarks in Section 5.

2 RELATED WORKS

Knowledge Base Completion (KBC) is one of the most important tasks in NLP. Many efforts have been invested in the link prediction task of KBC. For a typical link prediction model, we have an encoder and a decoder. An encoder learns feature representations of entities or relations and the decoder exploits these representations to predict the truth value of a given triple.

One of the first works of KBC falls under translation-based models [2, 9, 20]. These models generally adopt the same principle, $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$, if the triple (h, r, t) is indeed a fact. More specifically, TransE [2] assumes a score funtion

$$f_r(h, t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_2^2 \tag{1}$$

which captures one-one relations, while other expressive translation-based models [9, 20] are capable of capturing other relations such as one-many, many-one and many-many by introducing a relationship-dependent parameter for the translation of head and tail entities.

Aside translational models, we have models such as ANALOGY [10] and its sub-models HolE [11], ComplexE [19], DistMult [24] addressing the problem of link prediction. ANALOGY addresses the problem by imposing analogical properties for the multi-relational encoding of entities and relations. ANALOGY decodes by using a relation-specific normal matrix W_r as a composition operator on the head and tail entity embeddings. The goal of ANALOGY is to receive a high score for a factual triple (h, r, t), where the score is formulated as

$$f_r(h, t) = \mathbf{h}^T W_r \mathbf{t} \tag{2}$$

ProjE[16] views the link prediction task as a ranking problem. ProjE is a neural model with a combination layer and a projection layer. Given a tail entity, the combination layer combines the tail entity embedding with a relation embedding. The resulting embedding vector is projected to all candidate head entities to compute a score for the head entity. The goal is to ensure that, top-ranked entities are the correct entities in the relation. The score for a candidate head h given a tail entity t and relation r is formulated as

$$f_h(t, r) = g(\mathbf{h} f(\mathbf{t} \oplus \mathbf{r}) + b_p) \tag{3}$$

where f and g are activation functions and $\oplus$ is a learnable combination operator.

Despite the promising successes in link prediction, the above model architectures restrict representation learning on the KB's structure. This constrains learning for only entities and relations in the KB. It also makes it non-trivial to leverage information captured in descriptions of entities which are usually accompanied with entities. Some recent works have addressed these issues and have achieved a boost in link prediction performance [17, 21].

DKRL [21] takes into account the textual information accompanied with entities. DKRL proposed a continuous bag-of-words model (CBOW) and a convolutional neural network (CNN) to build representations for word-based entity descriptions. Representations for RDF triples are learned from the structure of the KB. With the representations for both RDF triples and entity descriptions, they employ a translation-based model for decoding in the link prediction problem. ConMask [17] on the other hand uses a relationship-content mask, semantic averaging and a CNN to learn relationship-dependent embeddings for word-based entities. ConMask outperforms DKRL in link prediction at the expense of a high order of magnitude in parameters. In both models, they employ a CNN to assist in extracting representations for word-based entities. However, we show that a simpler framework, specifically, a neural bag-of-words model can be used to learn representations for word-based entities more efficiently.

In the present work, we develop a neural bag-of-words model, a simple model for link prediction in knowledge bases. We model the entity encoding for link prediction by constructing a bipartite graph of word-entity connectives, where entities are represented by their names or part of its descriptions (see Figure 1). Motivated by some recent works [15, 26] which employs a GCN to deal with highly multi-relational data such as knowledge graphs, we develop the encoder that operates directly on the bipartite graph and further employ a factorization machine for the link prediction task.

3 NEURAL BAG-OF-WORDS MODEL

3.1 Problem Definition

A Knowledge Base is a graph $\mathcal{G} = \{E, R, T\}$, where E is a set of entities-nodes, R is a set of relations-edges and T is a set of factual triples. $T = \{(h, r, t), h, t \in E, r \in R\}$. An entity of a triple may have a relevant textual description. We call this a snippet. We respectively denote h_s, t_s as the snippets of h, t. We denote (h', r, t') as a negative triple, i.e. a triple which does not exist in a knowledge base.

Similarly, snippets of entities of a negative triple is also denoted as h'_s and t'_s.

Our NBOW approach aims to find missing factual triples

$$T' = \{(h, r, t) | (h, r, t) \notin T, h, t \in E', r \in R\},$$

where E' is a set of entities such that $E \subset E'$. That is, OOKB entities belong to the set $E' \backslash E$.

For the link prediction task, the NBOW method consists of two steps: 1) encoding an entity's name, along with its snippet, and 2) predicting the possible linkage between encoded entities. We will discuss the two steps in the next two sections.

3.2 Entity Encoding

The entity encoding process aims to first extract keywords from an entity's name or description, resulting in a bag of words for each entity. The information in the bag of words is aggregated to form the distributed representation for the entity's name or its snippet. The aggregation can be efficiently achieved by either simply averaging the word vectors in its bag or leveraging a graph convolutional network to better capture the structural information of the words in the bag.

3.2.1 Content Extraction. We first extract relevant words from the entity's description. To this end, we use TF-IDF to highlight the important words (keywords) in the entity's description. Other works, such as ConMask [17] use a relation-dependent mask to extract relevant text given a relation. Unlike their model, the extracted content using TF-IDF can simultaneously involve several relations. We address this challenge by using a relation-attentive factorization model (we will discuss this in Section 3.3.1).

After having all distinct words from entity names and their snippets, we then construct a word embedding matrix $V \in \mathbb{R}^{l^w \times d^w}$ where l^w is the size of the vocabulary and d^w is the word embedding dimension. For a given triple (h, r, t), we build entity name representations $\mathbf{h}$ and $\mathbf{t}$ for both h and t. Each draws values from $\mathbb{R}^{d^w}$. We do this by aggregating the information in the bag for the entity, either by simply averaging the embeddings in the bag or leveraging a graph convolutional network to better infuse the knowledge in the bag. Similarly, we build entity snippet representations $\mathbf{h_s}$ and $\mathbf{t_s}$ for both h_s and t_s.

3.2.2 Aggregate Bag-of-Words with Average Pooling. The aggregation process (ψ) is defined as a function $\psi : S \to \mathbb{R}^{d^w}$, mapping a set of vectors drawn from $\mathbb{R}^{d^w}$ to the vector space $\mathbb{R}^{d^w}$. For n vectors, S can be represented as the set $S = \{v_1, v_2, \ldots, v_n\}$. The encoder $\psi(S)$ can take the following forms:

$$\psi(S) = \sum_{i=1} v_i \quad \text{(sum pool)} \tag{4}$$

$$\psi(S) = \frac{1}{n} \sum_{i=1} v_i \quad \text{(average pool)} \tag{5}$$

$$\psi(S) = \max(S) \quad \text{(max pool)} \tag{6}$$

where the function $\max(\cdot)$ is an elementwise max function [6]. In this paper, the average pool function is chosen due to its superior performance.

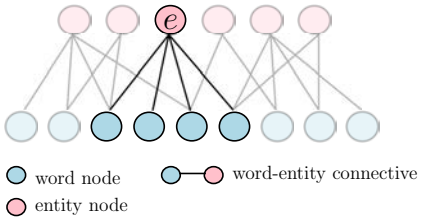

Figure 1: A bipartite graph induced from the KB. A word node is given by its word embeddings. An entity node is a word-based entity given by a feature vector resulting from the aggregation of word embeddings of its neighbors. An entity is connected to a word if that entity contains that word. As an example, the highlighted neighbors of entity e is aggregated using a continuous-bag-of-words encoder to form a feature representation for e.

3.2.3 Aggregating Bag-of-Words with GCN. Although one can leverage the simple average pool for aggregating information out of the bag-of-words model, other simple strategies can be used to further improve the information aggregation. To this end, we devise a basic graph convolutional network (GCN) model for this purpose.

We make use of word-based entities to induce two bipartite graphs $\mathcal{G}'_1$ and $\mathcal{G}'_2$ from $\mathcal{G}$ (see Figure 1). $\mathcal{G}'_1$ is a bipartite graph decomposed into word nodes and nodes for entity names, given by real-valued vectors. Similarly, $\mathcal{G}'_2$ is also decomposed into word nodes and nodes for relevant entity descriptions, given by real-valued vectors. Due to the similarity of the structure of $\mathcal{G}'_1$ and $\mathcal{G}'_2$, we denote either one of the bipartite graphs as $\mathcal{G}'_e$. Nodes are connected in $\mathcal{G}'_e$ if they share common words. Here and throughout the present work, we represent a word-based entity (entity name or entity snippet) as the italic word *entity* for simplicity and clarity.

The input to the GCN model is the bipartite graph $\mathcal{G}'_e$, where word nodes are initialized with pretrained word embeddings and *entity* nodes are initialized by the aggregation of the feature vectors of its neighbors. The GCN model proposed here makes efficient use of edges of subgraphs of $\mathcal{G}'_e$ to propagate and share information between nodes. More precisely, edges in $\mathcal{G}'_e$ serves as a transmission medium which has the sole purpose of propagating information to and from word nodes to *entity* nodes for the update of their embeddings. The GCN model is equipped with a CBOW encoder which extract *entity* embeddings for *entity* nodes by aggregating the word embeddings of its neighbors. The neighborhood of any node in $\mathcal{G}'_e$ is a bipartite subgraph which can be interpreted as an information propagation neural network. These subgraphs share parameters defining how information is transformed and propagated within the graph. The GCN encoder model learns convolution operators on these subgraphs for the transformation of information and the propagation across their edges to update embeddings of nodes.

When the GCN model operates on $\mathcal{G}'_e$, taking into account only the first-order neighborhood of nodes (word, *entity*), we learn parameters for a single update of the node embeddings. At each convolutional layer, convolution operations are imposed on the graph to update word nodes and *entity* nodes. To learn more informative representations, we successively apply convolutions on $\mathcal{G}'_e$

across the k-th order neighborhood. The GCN model architecture is illustrated in Fig. 2.

A single update for a word node takes the following form:

$$h_w^{k+1} = \phi\left(\sum_{j \in \mathcal{N}_w} \frac{1}{c_w} w_j^k h_j^k,\ w_w^k h_w^k\right) \tag{7}$$

Similarly, an update for an *entity* node takes the following form:

$$h_e^{k+1} = \phi\left(\sum_{j \in \mathcal{N}_e} \frac{1}{c_e} w_j^k h_j^k,\ w_e^k \psi(\mathcal{N}_e)\right) \tag{8}$$

where $(\cdot, \cdot)$ is an element-wise product, $h_e^k, h_w^k \in \mathbb{R}^{d^w}$ are the hidden state representation of *entity* e and word w respectively for the k-th convolutional layer of the neural network. $\mathcal{N}_w, \mathcal{N}_e$ correspond to the neighborhood of word w and *entity* e respectively. $\frac{1}{c_e}, \frac{1}{c_w}$ are normalization constants, where $c_e = |\mathcal{N}_e|$ and $c_w = |\mathcal{N}_w|$. $\psi(\cdot)$ is the bag-of-words model which we discussed in the previous section. $\phi(\cdot)$ is a non-linear activation function. For our model, we choose tanh function as the activation function $\phi(\cdot)$. w_j^k is a trainable parameter on layer k for the node j.

In short, for a given triple (h, r, t) with corresponding entity snippets h_s and t_s, the GCN model outputs real-valued representations $\mathbf{h}, \mathbf{t}, \mathbf{h_s}$ and $\mathbf{t_s}$.

3.3 Relation Scoring

To score the linkage predictions, we leverage a simple factorization machine which aggregates scores for different pairs of representations of a given triple. Traditional methods for interaction pair selection, specifically, [2, 20] measure scores of a candidate triple (h, r, t) by calculating the distance between the embedding $\mathbf{h}+\mathbf{r}$ and $\mathbf{t}$. Other expressive relation-dependent operators have successfully measured the score on candidate triples [11, 19].

The main assumption in these methods is that, there is a relation specific interaction which captures the relation r between h and t of any given triple. However, the presence of additional features h_s and t_s, the relevant descriptions of h and t offers new opportunities. ConMask incorporates some of these ideas by fusing different pair of variables in their model and achieve state-of-the-art results. In our approach, we postulate that, the pairs $h{-}r, t{-}r, h{-}t, h{-}t_s, h_s{-}t_s$ and $h_s - t$ captures informative interactions which can improve the link prediction task.

3.3.1 Relation-Attentive FM. We present a relation-attentive factorization model, a decoder which measure scores for different pair of representations. The decoder is likened to a factorization machine [13, 14] which highlights strong relationships between a pair of variables using a relation interaction parameter.

To capture interactions of pairs, we recall a training instance as a triple $(h, r, t) \in T$ with additional features h_s and t_s denoting snippets of the head entity h and tail entity t. Let $\mathcal{X}$ denote a training instance consisting of the set of variables $\{h, r, t, h_s, t_s\}$. We model the link prediction problem by measuring the overall scores of $h - r$ interactions, $t - r$ interactions, $h - t$ interactions, $h - t_s$ interactions, $h_s - t_s$ interactions and $h_s - t$ interactions for a training instance. Here, we extract *entity* embeddings from the encoder and initialize the relation r with a random vector. We define an interaction set I consisting of the 6 pair of interaction variables. For a given unordered pair $\{e_1, e_2\} \in I$, where $e_1, e_2 \in \mathcal{X}$, we formulate a relation interaction parameter γ(different from the embedding of relation r) which focuses on relation-specific parts of the interacting pair to compute a response. We define a score for the interaction of a pair as

$$g_\gamma(e_1, e_2) = \langle \mathbf{e_1} \odot \mathbf{e_2}, \gamma \rangle \tag{9}$$

The score assigns a scalar value to show the strength of interaction of a pair. This architecture enables the attention on latent information of a pair of variables which is closely related to the relation itself. This process is similar to that of ConMask, where a relationship-dependent content mask highlights relevant text at an early stage. We aggregate scores across all pairs in I. The total score for a training instance takes the form

$$f(\mathcal{X}) = \sum_{\{i,j\} \in I} g_\gamma(i, j) \tag{10}$$

The goal is to learn the relation interaction parameter γ such that, the model score high values for factual triples and low values for negative triples. See figure 3 for an illustration of this model.

3.3.2 Optimization Objective. For the model to distinguish factual triples from negative triples, we evaluate the model by generating a set of negative triples for each factual triple and add to the training set T. The optimization function we wish to minimize is

$$\mathcal{L} = -\sum_{\mathcal{X}, y} y \log \sigma(f(\mathcal{X})) - (1 - y) \log(1 - \sigma(f(\mathcal{X})) \tag{11}$$

where $\sigma(\cdot)$ is a softmax activation function, y is a binary value set to +1 if we have a factual training instance and 0 if we have a negative training instance.

4 EXPERIMENTS

In this section, we evaluate our NBOW model. The two versions of our model are denoted as AFM, where entity embeddings are extracted by aggregating relevant word embeddings using a CBOW encoder, and GCN+AFM, where the aggregated word embeddings are further enhanced using a GCN. In both models, we employ a factorization machine for the link prediction task in the open-world assumption. We propose both models to observe the boost in performance when we employ a GCN to model the noisy dependency of the entity embeddings. We compare our simple methods to the current state-of-the-art strategy ConMask and two more competitive baselines. In our evaluation, we report measures for Filter Mean Rank (FMR), Filtered Hit@10 (FHIT), Filtered Mean Reciprocal Rank (FMRR).

4.1 Datasets

We perform experiments on an extracted DBPedia dump; DBPedia50K introduced in [17]. DBPedia50K originally contains 32K entities. There are 28K redundant entities, thus, these entities have no factual triples in the dataset. Hence, they do not influence results for any model but just lead to a statistic for the number of entities as shown in Table 1. DBPedia50K is very different from some standard dataset like FB15K and FB15K-237. DBPedia50K has a sparse KB structure and a dense GCN graph structure. But FB15K and FB15K-237 have a dense KB structure and sparse GCN graph structure. To validate the efficiency of our model on the open-world

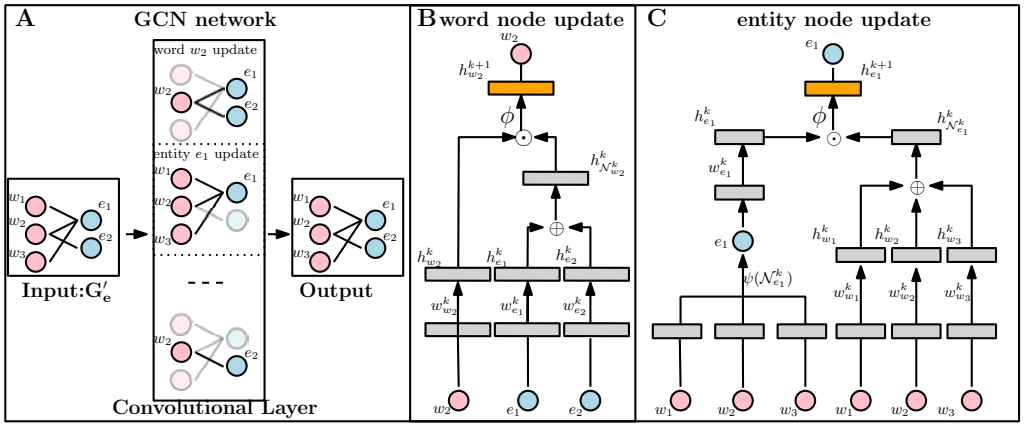

Figure 2: (A) Overview of a single layer GCN model architecture with first-order filters for word-based entity encoding. (B) Shown is a first-order filter imposed on the neighborhood of the word node (pink) to transform and propagate information from *entity* nodes (blue) to learn a representation for the word node. (C) Similar to that of B for information transformation, shown here is the propagation of information from the neighborhood of *entity* node to update its representation. Before update, a CBOW encoder ϕ aggregates the neighbors of the *entity* node resulting to an initial *entity* representation for the learning process. $\oplus$ is a vector summation operator and $\odot$ is an element-wise operator (B and C is based on the example given in A and follows Eq. 7 and 8 respectively)

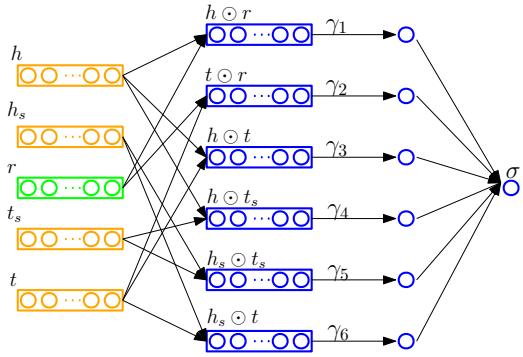

Figure 3: Relation-attention FM architecture

assumption for link prediction, we introduce a new dataset based on FB15K-237. We refer to this new dataset as FB15K-237*. FB15K however has many reciprocal triples so we don't generate an open world version of it.

FB15K-237* is generated by randomly selecting 10% of entities in the KB. These selected entities are classified as open-entities. Triples in the KB which contain these open-entities are held out for test and validation. All other triples are used for training. We define the validation set on 10% of the held out triples, the remaining 90% is used for the test set. The statistics of all datasets are shown in Table 1.

4.2 Parameter Settings

For a comparable study, we use similar parameters used in ConMask. We set the word embedding size $k = 200$ and draw embeddings from 200-dimensional trained GloVe vectors which have been made publicly available [12]. Maximum length for entity name $k_n = 32$, maximum length for entity snippet $k_c = 128$. Given a training instance $\mathcal{X} = \{h, t, h_s, t_s, r\}$, the encoder extracts *entity* embeddings for h, t, h_s, t_s and initializes a random vector for r. The relation-attentive model learns interactions from 6 unordered 2-tuples in the set $\{\{h, r\}, \{t, r\}, \{h, t\}, \{h, t_s\}, \{h_s, t_s\}, \{h_s, t\}\}$. During training, our neural network is composed of 1 convolutional layer as seen in (A) of Fig. 2. The batch size we use is $k_b = 200$ and we choose Adam as our optimizer with learning rate $lr = 0.01$. For a factual triple, we have 10 negative triples constructed by randomly corrupting either the head or tail entity. We train our model for 200 epochs.

4.3 Open-World Link Prediction

We follow evaluation protocols used in ConMask [17] for a comparable analysis. For the open-world link prediction task, we aim to predict missing entities h or t for a given factual triple (h, r, t). Given a partial triple $(?, r, t)$ or $(h, r, ?)$, this task requires that we rank a set of candidate entities for the position of missing entity. We refer to this missing entity as the target entity e. At the testing phase, for each partial test triple $(?, r, t)$ or $(h, r, ?)$, we apply a filtering method to rank specific entities. The filter skips all target entity candidates which have never been connected to the relation r in the training set. As noted by [17], it avoids the ranking of relation instances which might be nonsensical. For every target entity selected, we compute a similarity score according to our proposed score function f on the training instance $\mathcal{X}$ for the candidate triple (e, r, t) or (h, r, e). We use these scores to rank entities e in descending order and measure the performance of the model with the following evaluation metrics: (1) the average rank of correct entities (denoted as Filtered Mean Rank), (2) the proportion of correct entities in the top 10 of all entities (denoted as Filtered Hits@10), and (3) a filtered mean reciprocal rank. Note that, an effective model scores a *low* filtered mean rank (FMR), a *high* filtered mean reciprocal rank (FMRR) with a *high* Flitered Hits@10 (FHIT).

Table 1: Dataset Statistics: #Closed Ent. is the number of entities in the KB, #Open Ent. is the number of OOKB entities & #Words is the number of words we learn embeddings for the word-based entity embedding extraction task

We evaluate AFM and GCN+AFM on the link prediction task in open-world KBC for the datasets summarized in table 1. We report results for models AFM, GCN+AFM, ConMask and other baseline methods implemented in the works of [17]. [17] re-implemented the method for DKRL [21] to handle the OOKB link prediction task. The overall performance of the models on DBPedia50K and FB15K-237* are shown in Table 2. The best performance are bold-faced.

As we can observe, AFM generally achieves better performance than the baseline methods on both datasets. More importantly, it shows evidence of superior performance to the state-of-the-art method ConMask in both DBPedia50K and FB15K-237*. To compare the detail performance metrics, we observe that AFM managed to outperform ConMask entirely on DBPedia50K, showing a significant boost for FMR, FHIT and FMRR in both head and tail target entity prediction. On the FB15K-237* dataset, the results are competitive for both ConMask and AFM. Here, we observe that AFM impressively outperforms ConMask when predicting head target entities. On the other hand, for the tail target entity prediction, AFM has a slight degradation in performance (lower by 0.01) in terms of FHIT, a higher FMR (higher by 5), and equal FMRR when comparing to ConMask. Promisingly, when we augment AFM with the GCN, namely the GCN+AFM model, it would be reasonable to expect a boost in predictive performance since we expect the GCN to enhance the entity embeddings. We clearly observe that this is the case, GCN+AFM outperforms all baselines including ConMask in every metric on the two datasets.

4.3.1 Scalability. In our efficiency analysis, we calculate the computational time for training an epoch (measured in seconds) on the DBPedia50K dataset. All training is done on a GeForce Titan Xp system with 2×12GB memory. We compare training times of our models and that of ConMask in particular. This result is significant because knowledge bases are known to be usually large in size and will therefore have a large number of training instances. For example, DBPedia500K [17] has 3, 102, 677 training instances. With this large number of instances, state-of-the-art models like ConMask with complex architectures requiring the tuning of hundreds of hyperparameters will take a longer time to train in 1 epoch. Models for KBC tasks must therefore be as simple as possible but efficient to learn large KBs. From the analysis, we observed that ConMask used 80*s* to complete an epoch training on DBPedia50K, while GCN+AFM required only 50*s* and AFM executed much faster as expected. Our proposed methods reduces about 40% of execution time when compared to that of ConMask. These results suggests that our simple methods have better scalability to large knowledge graphs. The results also informs us that our model makes better use of its parameters, and benefits from simplicity and efficiency compared to ConMask which has a significant model complexity.

5 CONCLUSION

In this study, we advocate the philosophy of exploiting simple models for link prediction in large knowledge graphs due to their sparse linkage connectivity between entities. We propose a simple neural bag-of-words model for link prediction in large knowledge graphs, named GCN+AFM, which accounts for both entity representation and link prediction. Specifically, our proposed model utilizes TF-IDF and average pooling and then enhances entity representations via a GCN. Experimental results show that the two versions of our model, namely AFM and GCN+AFM, achieve superior performance and reduce an order of magnitude in the number of parameters needed and about 40% execution time when compared to the current art model. We also demonstrate that the simple version of our proposed model, named AFM, achieves better performance to state-of-the-art methods. These facts make our proposed strategy suitable for learning from large real-world knowledge graphs with sparse entity connectivity.

ABSTRACT

Ranking, used extensively online and as a critical tool for decision making across many domains, may embed unfair bias. Tools to measure and correct for discriminatory bias are required to ensure that ranking models do not perpetuate unfair practices. Recently, a number of error-based criteria have been proposed to assess fairness with regard to the treatment of protected groups (as determined by sensitive data attributes, e.g., race, gender, or age). However this has largely been limited to classification tasks, and error metrics used in these approaches are not applicable for ranking. Therefore, in this work we propose to broaden the scope of fairness assessment to include error-based fairness criteria for rankings. Our approach supports three criteria: *Rank Equality, Rank Calibration*, and *Rank Parity*, which cover a broad spectrum of fairness considerations from proportional group representation to error rate similarity. The underlying error metrics are formulated to be rank-appropriate, using pairwise discordance to measure prediction error in a model-agnostic fashion. Based on this foundation, we then design a fair auditing mechanism which captures group treatment throughout the entire ranking, generating in-depth yet nuanced diagnostics. We demonstrate the efficacy of our error metrics using real-world scenarios, exposing trade-offs among fairness criteria and providing guidance in the selection of fair-ranking algorithms.

1 INTRODUCTION

As sophisticated machine learning increasingly impacts our lives on and offline, there is growing concern that discriminatory practices will be baked into automated decision models [3]. The potential for harm is vast, highlighting the need for open and transparent procedures to audit and correct for unfair bias. To address this, recent work on algorithmic fairness assesses the treatment of protected groups by examining the errors made by automated decision making procedures. The main focus of this prior research has been on classification tasks, where predictive models determine a binary outcome [7, 8, 15, 17, 23, 27, 31]. In our work, we broaden the scope of error-based fairness assessment to include rankings.

Motivation. Evaluating ranked data is the de facto process used today for decision making, in particular to make sense of the vast amount of information available online. Rankings simplify the information, helping us to make sense of options and limiting the scope of choices to consider. We rely on ranking models for everyday tasks such as purchasing products to pivotal life decisions such as applying to colleges or jobs. Companies rely on rankings to organize information, whether evaluating candidates to hire [1], or evaluating potential customers using credit scoring [20].

However, rankings can have major pitfalls. Large socio-economic datasets cannot easily be distilled into simple rankings without exploiting patterns that exist in the data, including subtle encodings of historical inequalities. This may lead to unfair decisions, in particular for regulated domains such as employment, education, and lending [3]. For instance, Amazon recently revealed a failed attempt to design a hiring algorithm to screen candidates which they found inadvertently encoded a gender bias against women [10]. Use of such a tool risks automating illegal discrimination. Yet, the development of ranking algorithms for hiring is widespread [1], while no systematic approaches to audit these methods are available to date. Or, consider college rankings published online and used by students and faculty. Highly ranked colleges often have poor outcomes for low-income students, such as lower graduation rates or excessive debt after graduation [29]. The rankings could be considered unfair for only providing utility to high-income students. Left unchecked, such harm compounds through the creation of negative feedback loops. Colleges consistently given a low rank will attract less talent, decreasing their potential to improve [16, 26]. These institutions are entrenched in the position determined by the ranking model - often proprietary and not disclosed.

State-of-the-Art in Fair Ranking. To avoid these kinds of unfair and potentially illegal discriminatory practices, mechanisms to audit ranking models that drive our decision making are essential. Initial methods for measuring unfairness in rankings have recently been put forth [5, 28, 30, 32]. However, they target only a single type of fairness criterion, namely, *statistical parity*. This criterion requires that members of different groups have the same proportional representation among desirable outcomes, i.e., in a top position in the ranking. In our hiring example, such a criterion would dictate that the top candidates in the ranking have a similar proportion of men and women as in the entire applicant pool.

However, this particular criterion may not be appropriate for all applications. Alternatively, a rich variety of fairness criteria available in the literature for classification are *error-based*, meaning

they require that the predictive model make the same "mistakes" about each group. In our college example, such a criterion might dictate that colleges not be erroneously ranked lower than their counterparts solely due to supporting low income students. We postulate that there is value in considering error-based fairness criteria for rankings, which to date have not yet been applied.

Challenges. For classification, *error-based* definitions of unfairness are measured by within-class error rates, such as True Positive Rate, True Negative Rate or probability of assignment to positive class, for members of different groups [17, 23]. However these metrics require binary class labels, and cannot be applied to rankings learned from training data with non-binary labels. Measuring error made by a ranking model therefore requires metrics appropriate to the task. Ranking models optimize for different types of often application-specific error. For instance, in their fair ranking method, Singh and Joachims [28] define criteria specific to online search, balancing the item exposure in a ranked list of search results with considerations such as document relevance and click-through rate. This narrow definition cannot be directly applied for other ranking applications such as our college ranking example. Instead, a general approach to fair error-based ranking is preferable.

Further, notions of fairness for classification depend on a *preferred outcome* determined by membership in the positive class. Recent methods define an analogous notion based on the prefix of the ranking. While this approach appears to naturally capture the preferred rank outcome, focusing only on the top items in a ranking has severe shortcomings. For many applications, accuracy throughout the entire ranking matters. If the rank position determines funding, bottom-ranked institutions could lose resources and be forced to close. If rankings are used to determine peer groups for tournament-style competitions, inaccuracies low in the ranking would result in mismatched opponents. *In short, accuracy is important at all positions of the ranking.*

Proposed Approach. In this work, we design the first comprehensive auditing methodology for error-based fairness assessment of rankings. In particular, we design analogues for the three core types of fairness criteria in the literature on fair classification [7, 8, 13, 15, 17, 23, 27, 31]. Our proposed criteria, *Rank Equality*, *Rank Calibration*, and *Rank Parity*, together give a comprehensive nuanced assessment of group unfairness in rankings. Our analysis rests on the development of appropriate error metrics for fair ranking. For this, pair inversions, as in foundational rank evaluation techniques [22], are leveraged as basic building block for measuring rank errors. This proposed fairness assessment is model-agnostic and applicable for a wide range of ranking applications.

Further, we propose an auditing mechanism to apply our proposed criteria to measure fairness throughout an entire ranking instead of only in the top results. Our approach, called FARE (for Fair Auditing based on Rank Error), uses a sliding window technique to measure ranges of ranking error and generates error sequences which capture each group's treatment throughout the entire ranking. Custom FARE diagnostics provide a nuanced summary of results, while remaining interpretable to stakeholders who rely on rankings for decision making.

We evaluate our fairness metrics in a comprehensive experimental analysis. Using our FARE framework, we evaluate rankings created using state-of-the-art fair ranking methods [32] on real-world datasets [2, 19]. Our analysis identifies strengths and weaknesses of these existing techniques with regard to fairness. We demonstrate how our analysis guides the choice of appropriate fair ranking correction method to apply.

Key contributions of our work include:

(1) We define a new set of fairness criteria customized for rankings: *Rank Equality, Rank Calibration, and Rank Parity* based on novel rank-specific error metrics. These criteria are model-agnostic and applicable for many ranking applications, capturing key notions of fairness previously applied only for classification.
(2) We present FARE, the first comprehensive framework to audit ranking models using error-based fairness criteria. FARE offers a suite of fairness diagnostics for ease of interpretation.
(3) We demonstrate the application of our FARE framework to assess the capability of state-of-art rank correction methods to achieve fairness, and illustrate the power of FARE's diverse criteria to account for unfair bias in rankings across domains.

2 RELATED WORK

Measuring Fairness in Classification. No single rule has been shown to definitively determine the fairness of an algorithm. The majority of criteria for evaluating fairness focus on the treatment of *groups* determined by some protected data attribute. *Error-based group fairness criterion* [7, 17, 23, 27] are concerned with whether the predictions of a classifier are fair with respect to the group membership of items in the training dataset. To verify this, fairness assessment checks whether groups are treated 'similarly,' meaning error rates for each group are within some threshold. It has been observed that all criteria cannot necessarily be satisfied at the same time [7, 23]. Therefore the appropriate choice of fairness metric is context-dependent. Group fairness criteria can be categorized as:

- **Equalized Odds**, coined by Hardt et al. [17], seeks to ensure that the probability of an object being assigned a particular label by the classifier is independent of its group membership, conditional on the true class label [7, 17, 23]. To verify this, Equalized Odds stipulates that the *false positive and true positive error rates* must be similar across all groups.
- **Calibration**, a group-wise measure of fairness for probabilistic classifiers, requires that the calibration error for each group is similar [7, 23, 27]. Calibration error indicates the difference between the true likelihood of membership in the positive class and the probability given by the classifier. For example, if there are 100 objects assigned a 90% chance of being in the positive class by the classifier, approximately 90 of these objects should actually be positive.
- **Statistical Parity** requires proportional representation of each group [8, 15, 31]. This is similar in spirit to the 80% rule for evaluating disparate impact in judicial rulings [15] and affirmative action quotas employed by many institutions. Typically the desired outcome is that some minimal proportion of minority group members are predicted as positive.

Measuring Fairness in Rankings. Recent work has begun to address group fairness concerns in rankings [5, 28, 30, 32]. Most works [5, 30, 32] focus on enforcing only *Statistical Parity* criterion, and detect unfairness only in the top-k prefix of a ranking. Criteria

based on prediction error have not yet been applied for fair ranking to our best knowledge.

Yang and Stoyanovich [30] measure fairness according to a discounted cumulative scoring metric that evaluates the proportional representation of groups. In [5] fairness is defined according to a threshold on the maximum proportion of the majority group allowed in the prefix. Zehlike et al. [32] extend these statistical parity approaches, designing a greedy algorithm to ensure the ranking meets the criterion while optimizing for utility. Singh and Joachims target fair ranking in information retrieval specifically [28]. Metrics favoring accuracy at the top of the ranking are well-suited here since, out of possibly thousands of documents returned for a query, only a few top results are likely to be clicked. While they broaden their fairness definitions beyond statistical parity, metrics proposed in [28] are application-specific, defining fairness in terms of item exposure to users, clickthrough rates, and document relevance.

3 FAIR RANKING PROBLEM FORMULATION

Ranking can have different meanings in different contexts, and ranking models can be trained over various types of ground truth information. Rank predictions can be learned from training data with binary labels (e.g., in bipartite ranking [9]) or discrete labels with ordered classes (i.e., ordinal regression [18] with labels such as "best", "neutral", "worst"). Traditional regression ranks according to continuous scoring functions. Learning-to-rank approaches also include pairwise and listwise models [25].

Therefore, to be widely applicable, we target general rankings with a model-agnostic approach. We assume only that an ordering is imposed over a set of objects X according to some function which assigns each $x_i \in X$ a position relative to all others. Following previous work on error-based criteria for fair classification [7, 8, 13, 15, 17, 23, 27, 31], we formulate the task of auditing the fairness of a ranking as a supervised learning problem in that the true ranking over X is known. [1] Unique to the context of fairness analysis, objects have an associated *protected attribute*, such as gender, age, or race, which partitions the objects into a set of two or more disjoint *groups* $A = \{A_1, \ldots, A_m \mid \cup_{i=1}^{m} A_i = X, A_i \cap A_j = \emptyset, \forall i \neq j\}$. We consider only a single protected attribute, leaving intersectional fairness considerations with multiple protected attributes to future work.

Let $\rho = [x_1 \succ x_2 \succ \ldots \succ x_n]$ be the true ranking over all objects $x_i \in X$, where $\succ$ is an ordering relation on X such that $x_i \succ x_j$ implies that x_i appears at a more preferred position in the ranking than x_j. The number of items in the set is denoted by $|X| = n$. The position of a single object x_i in the true ranking is denoted $\rho(x_i)$. Our task is to evaluate a learned ranking $\hat{\rho}$ according to a given *Fairness Criterion* which relies on a group error function L.

Definition 1. *Given a group error metric $L_{A_i}(\rho, \hat{\rho})$, a* ***Fairness Criterion*** *(FC) is an evaluation rule which designates a ranking $\hat{\rho}$ as fair in relation to a true ranking ρ if:*

$$L_{A_i}(\rho, \hat{\rho}) \cong L_{A_j}(\rho, \hat{\rho}) \;,\; \forall A_i, A_j \in A,\; i \neq j$$

Fairness is evaluated by checking whether the error for each group is similar, or within some threshold, indicated by the symbol $\cong$. The larger the difference in the errors for each group, the more unfair the ranking is considered to be. Our assessment therefore hinges on the choice of a rank-appropriate group error function L.

[1] While a "truly fair" ground truth ranking may not be available, this assumption allows us to distinguish whether a proposed ranking is more or less fair than an alternative.

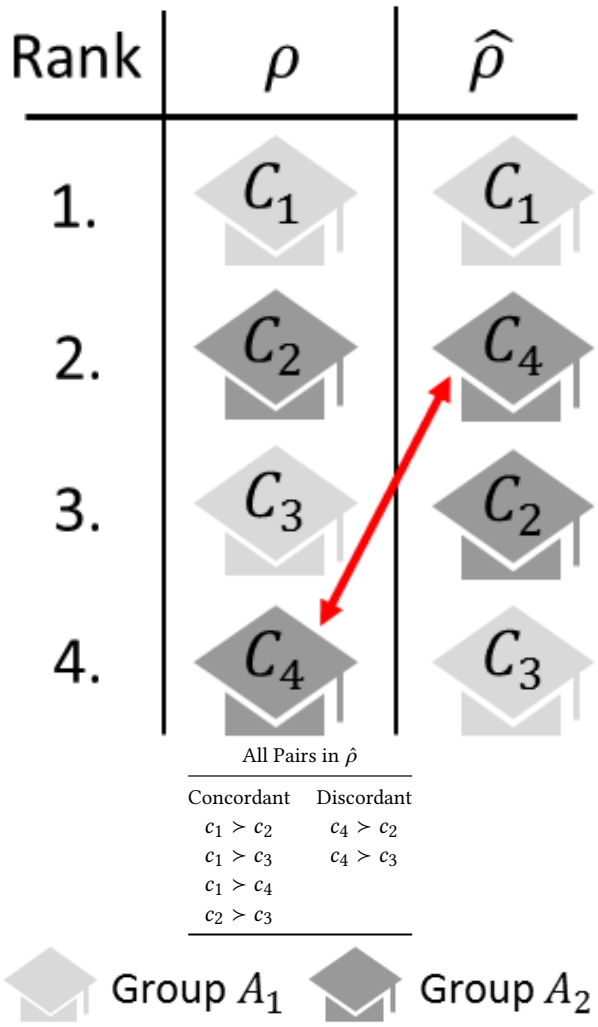

Figure 1: On the left is a true ranking of colleges ρ and predicted ranking $\hat{\rho}$ over two groups of colleges. The resulting discordant and concordant pairs are shown on the right.

4 PROPOSED ERROR METRICS FOR RANK FC

4.1 Pairwise Comparison of Group Errors

To design a general approach for evaluating group error in rankings, we consider foundational approaches [11]. One classic method is to sum the absolute difference in rank position between the true and predicted rankings for each object in the dataset (i.e., to use the Spearman footrule distance). Another popular methodology uses the pairwise error, or Kendall Tau distance [22], by counting the number of inverted pairs of objects in the predicted ranking compared to the true ranking. These two classic approaches to measuring rank similarity have been shown to be *equivalent*, meaning

the Kendall Tau is always within a constant factor of the Spearman footrule distance [12, 24]. Given this insight, the two metrics have been used interchangeably for tasks such as rank aggregation [14, 24]. For fairness assessment, the same reasoning applies in that either rank error metric could be applied. However, since we are concerned with the comparative ranking outcomes for different groups, the pairwise approach provides a natural formulation.

Given the position in the true ranking of a pair of objects where $\rho(x_i) \succ \rho(x_j)$, they are said to be discordant if $\hat{\rho}(x_i) \prec \hat{\rho}(x_j)$. Figure 1 shows the sets of concordant and discordant pairs resulting from an error between two rankings of colleges. We observe that a ranking containing objects from two different groups, A_i and A_j, can be divided into three subsets of pairs: those containing only objects from group A_i, those containing only objects from A_j, and the set of "mixed" pairs containing one object from each group. The total number of unordered pairs in a ranking over X is $\phi(X) = |X|(|X|-1)/2$. The cardinality of the set of mixed pairs is $\phi(X) - \phi(A_i) - \phi(A_j)$. We denote the number of discordant pairs in a set X as $\phi^D(X)$ and concordant pairs as $\phi^C(X)$. The number of mixed pairs favoring objects from one group A_i over another group A_j is denoted by $\phi_{i>j}(X)$. For instance, the cardinality of the set of discordant pairs favoring A_i over A_j is indicated as $\phi^D_{i>j}(X)$.

For simplicity, we henceforth consider two groups. However, rank error based on discordant pairs can easily be extended to multiple groups. For instance, to compute the number of discordant pairs favoring group A_1 given m groups, we compute $\sum_{i=2}^{m} \phi^D_{1>i}(X)$.

4.2 Proposed Rank Equality Criterion

The Equalized Odds criterion for classification measures fairness in terms of the rate at which groups are falsely assigned to the preferred or non-preferred classes. When evaluating a ranking, there are no binary assignments by which to gauge preference. However, *position* in a ranking does indicate a preferred or undesirable outcome - the top of the ranking being analogous to the positive class. When an object is overestimated by the model it is incorrectly assigned a more preferred position than in the true ranking. This is similar in effect to a false positive error made by a classifier. Accordingly, underestimating the position of an object in the ranking incorrectly penalizes it, as in a false negative. Following this principle, we compute the Rank Equality error for group A_i in terms of the number of discordant pairs which favor A_i over items from another group A_j. This proposed metric (Definition 2) captures the number of times that an object from group A_i is incorrectly *overestimated* compared to objects in A_j. The error is then normalized by the total number of mixed pairs ensuring that the error falls in a range of $[0, 1]$. Normalization creates an interpretable measure of preference and accounts for any imbalance in the size of the groups. To apply the Rank Equality FC, we simply compare the *Req* error for each group.

Definition 2. ***Rank Equality Error***

$$Req_{A_i}(\rho, \hat{\rho}) = \frac{\phi^D_{i>j}(X)}{\phi(X) - \phi(A_i) - \phi(A_j)}$$

where $\phi^D_{i>j}(X)$ denotes the number of discordant pairs which favor the target group A_i over A_j, $i \neq j$.

Rank Equality dictates that no group should be unfairly privileged or penalized compared to another group. As an example, consider the rankings shown in Figure 1. To compute the Rank Equality error for group A_2, we count the number of discordant pairs where an item from A_2 is favored over an item from A_1. Four pairs contain an object from each group: $(c_1, c_2), (c_1, c_4), (c_2, c_3), (c_3, c_4)$. One of these pairs (c_3, c_4) is discordant, since $\hat{\rho}(c_4) \succ \hat{\rho}(c_3)$ and $\rho(c_3) \succ \rho(c_4)$, and favors A_2. Thus $Req_{A_2}(\rho, \hat{\rho}) = \frac{1}{4}$.

4.3 Proposed Rank Calibration Criterion

Calibration is used to evaluate probabilistic classifiers in terms of the confidence of the model, using the mean squared error between predicted likelihood of assignment in the positive class and an estimated "true" probability [4]. Applied as an FC, this criterion checks how well the classifier predicts objects in each group. To evaluate the calibration of a ranking $\hat{\rho}$ for a group A_i, we propose to measure error in predicted rank position by counting the number of discordant pairs which contain at least one member of A_i, as given in Definition 3. This captures the overall error made for items in the group. The value is normalized by the total number of pairs containing objects from A_i. For example, the pairs containing objects from group A_2 in Figure 1 are $(c_1, c_2), (c_1, c_4), (c_2, c_3), (c_2, c_4), (c_3, c_4)$. Pairs (c_2, c_4) and (c_3, c_4) are both discordant, therefore following Definition 3, the rank calibration error is $Rcal_{A_2}(\rho, \hat{\rho}) = \frac{2}{5}$.

Definition 3. ***Rank Calibration Error***

$$Rcal\ _{A_i}(\rho, \hat{\rho}) = \frac{\phi^D_i(X)}{\phi(X) - \phi(A_j)}$$

Where $\phi^D_i(X)$ denotes the number of discordant pairs containing at least one object from the target group A_i.

4.4 Proposed Rank Parity Criterion

Finally, we also apply pair inversion to design a statistical parity metric like those explored in previous work on fair ranking [5, 30, 32]. Here, the goal is to ensure fair representation of members of each group among objects given a favorable rank position. We propose to capture this idea by counting the pairs in which one group is favored over the other in the learned ranking, regardless of their positions in the true ranking. We again normalize by the total number of mixed pairs in the learned ranking.

Definition 4. ***Rank Parity Error***

$$Rpar_{A_i}(\rho, \hat{\rho}) = \frac{\phi_{i>j}(X)}{\phi(X) - \phi(A_i) - \phi(A_j)}$$

Where $\phi_{i>j}(X)$ is the number of pairs of objects which favor a member of group A_i over a member of A_j, $i \neq j$.

In Figure 1, two pairs in $\hat{\rho}$ favor group A_2 over group A_1: (c_2, c_3) and (c_4, c_3). Therefore, $Rpar_{A_2}(\rho, \hat{\rho}) = \frac{2}{4}$. This matches our intuition of parity, since the groups are still somewhat evenly distributed through the ranking $\hat{\rho}$ in spite of the incorrect placement of c_4.

4.5 Discussion: Ranking Criteria and Their Interrelationships

We now analyze our metrics to understand their interrelationships and scope of applicability. Given a ranking $\hat{\rho}$ over g groups, there

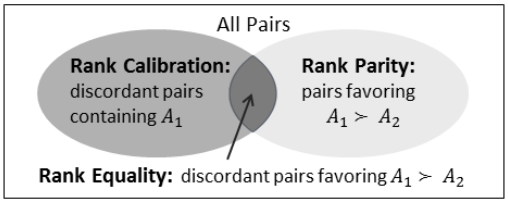

Figure 2: Relationship between the types of pairs used to compute the error for group A_1 (corresponding to Table 1).

are g^2 ways of choosing two objects from the ranking, allowing for group repetition. These pairs may be either *concordant* or *discordant*, resulting in $2g^2$ types of pairs. Table 1 shows the categories of pairs that can be formed for $g = 2$ groups. The colors in the table correspond to the colors in the Venn diagram in Figure 2, illustrating the relationship between the types of pairs used to compute errors for a single group, A_1.

Since our fairness analysis is concerned with the relative error made for each group, within-group concordant pairs are not considered when computing error metrics. All other types of pairs are included in the definition of at least one error metric. Discordant mixed pairs are used to compute all three error metrics. These pairs of objects intuitively capture the *major disparity between groups*: cases where one group is erroneously favored over the other. We define this as Rank Equality. Rank Calibration instead measures the *total error* for each group. This metric counts all pairs containing objects from a single group, capturing within-group as well as across-group errors. Finally, Rank Parity considers the *total advantage* of one group over the other.

FC are compatible in extreme cases. In a perfect prediction there is no error between $\hat{\rho}$ and ρ. In this case $Req = Rcal = 0$ for all groups, since no pairs are discordant. The corresponding FC deem $\hat{\rho}$ fair since the group errors are identical. The *Rpar* error in this case will simply measure the relative advantage of each group in the true ranking. It may be considered fair or unfair depending on the distribution of the objects in each group. Since this is independent of the other metrics, it is therefore possible for a perfect prediction to satisfy all three criteria. In the worst case, $\hat{\rho}$ ranks the objects in the reverse order from ρ. In this case $Rcal = 1$ since all pairs are discordant. Each group is predicted with the same amount of error, therefore by the Rank Calibration FC, $\hat{\rho}$ is considered fair. In this case no pairs are concordant, therefore $Req = Rpar$. Whether the ranking is considered fair according to the corresponding FC again depends on the distribution of groups throughout the ranking.

5 FAIR AUDITING BASED ON RANK ERROR

The FARE Methodology. We next design a non-parametric approach to assess rankings using our proposed error metrics. We want to understand the entire ranking of items from the preferred positions at top of the ranking to the lowest ranked objects. Aggregating the entire treatment of each group using a single fairness score provides only a coarse assessment. Therefore our FARE methodology (for Fair Auditing based on Rank Error) generates *sequences of within-range errors* for each group. The differences in these sequences tell a richer story than would a single value for each group, revealing disparity throughout the entire ranking.

Table 1: Categorization of pairs in $\hat{\rho}$ over two groups A_1, A_2.

Discordant	Concordant
$A_1 \succ {A_1}^D$	$A_1 \succ {A_1}^C$
$A_2 \succ {A_2}^D$	$A_2 \succ {A_2}^C$
$A_1 \succ {A_2}^D$	$A_1 \succ {A_2}^C$
$A_2 \succ {A_1}^D$	$A_2 \succ {A_1}^C$

To start, FARE sorts the data according to the predicted ordering $\hat{\rho}$ and bins it into k subsets $\langle B_1, B_2, \ldots B_k \rangle$. Error metrics are then applied to the objects in each bin. In the case of two groups A_1 and A_2 we evaluate errors $l_{1i} = L_{A_1}(\beta_i, \hat{\beta}_i)$ and $l_{2i} = L_{A_2}(\beta_i, \hat{\beta}_i)$ for the data in each bin B_i. This produces two error sequences: $S_1 = \langle l_{11}, l_{12}, \ldots l_{1k} \rangle$ and $S_2 = \langle l_{21}, l_{22}, \ldots l_{2k} \rangle$. An equi-width binning strategy compares the top-k ranked items across both groups in the first bin, the next k in the next bin, and so on. An equi-depth strategy is also possible, where each bin measures how well the ranking predicts $\frac{|A_i|}{k}\%$ of items from each group.

If the number of bins k is so large that there are only a few objects in each, then the sequence of error measurements may exhibit a high degree of variance. This could exaggerate differences between groups in the case where one is a minority. On the other hand, if bins contain many objects, the result is a rather coarse estimate. To capture the error at a sufficient number of positions throughout the ranking while achieving a reasonable bin size, we adopt a *sliding window approach*. This introduces a smoothing transformation over the data to account for high variance across bins. Each consecutive bin of size w overlaps the previous, offset by a fixed step size $s < w$. The first bin B_1 contains objects $\{x_1, x_2, .., x_w\}$, ordered according to their predicted positions $\hat{\rho}(x_i)$, the second bin $B_2 = \{x_{s+1}, x_{s+2}, \ldots x_{s+w}\}$, and so on. Each error sequence S_i contains $\lfloor \frac{|A_i|}{s} \rfloor$ bins.

Diagnostics for Analyzing Fairness. The next step in the auditing procedure is to compare the error sequences S_1 and S_2 produced by our FARE framework to see if they are similar, and therefore meet the fairness criterion, or if they differ in ways which indicate an unfair ranking. To facilitate this, FARE offers *audit plots*. Similar to reliability diagrams for assessing the calibration of classifiers [4], these visual depictions reveal differences in the shapes, patterns and values of the error sequences. Since our proposed error metrics are normalized, the y-axis on each plot has a fixed range of $[0, 1]$, providing an easily interpretable snapshot view of the error sequences generated during the audit process.

Audit plots are augmented by compact statistics, or *fairness scores*, indicating whether the ranking model satisfies the FC. Conceptually, any diagnostic metrics comparing the sequences can be plugged into the framework. We employ a distance diagnostic $dist(S_1, S_2) = \frac{1}{k} \sum_{i=1}^{k} |l_{1i} - l_{2i}|$ to summarize the similarity of the error sequences as a single value. These scores can be thresholded to flag unfair cases where the average magnitude of error for one group is much larger than the other or to apply strict FC cutoffs.

Complexity. A simple pair counting algorithm can be used to compute each of our proposed error metrics in $O(nlog(n))$ time

using an adaptation of the mergesort algorithm. Performing an audit using the FARE methodology can therefore also be done in logarithmic time, requiring $O(n/s(wlog(w))$ time for step size s and window size w to compute the error sequences for each group. In cases where performance is an issue, we can improve the pair counting procedure to run in $O(n\sqrt{log(n)})$ time [6].

6 EXPERIMENTAL EVALUATION: AUDITING RANK CORRECTION METHODS

We demonstrate the power of our proposed error metrics using FARE to audit post-processing techniques from the literature designed to correct existing rankings. Two state-of-the-art fair ranking methods which enforce statistical parity notions of fairness are compared. Using the FARE methodology, we reveal the resulting tradeoffs between this criterion and the prediction error introduced. We evaluate these fair ranking algorithms using FARE audit plots (Figure 3) and FARE distance diagnostics (Table 2).

State-of-Art Fair Correction Methods. We reproduce a subset of experiments presented by Zehlike et al. [32] using implementation and data made available by the authors."FA*IR" rankings are generated using a greedy algorithm proposed in [32] to create a fair top-k prefix ranking. The rankings target a user-specified minimum proportion of the minority group, subject to a statistical significance test. The proportion is indicated in the method name, e.g., FA*IR2 for 20%. Here we use the same proportions as the authors, chosen to be close to the actual group ratio over the entire dataset.

The "Feldman" method [15] is proposed as pre-processing step for fair classification in which data are ranked. In this method the utility scores for objects in the minority group are adjusted to match the distribution of the majority. We compare these rankings against a baseline of the true ranking with no correction.

Datasets. We evaluate the rank correction methods using two datasets. The Statlog German Credit Dataset [19] provides a "ground truth" ranking of people according to their credit-worthiness for our experiments. Three "fair" rankings are then created using *age* < 25, *age* < 35 and *gender* = female as protected group attributes. Prefix rankings with $k = 100$ are generated. Audit parameters for this dataset are $w = 30, s = 10$. The COMPAS recidivism dataset published by ProPublica in their investigation of racial bias in the criminal justice system is also utilized [2]. This dataset is ranked according to COMPAS scores indicating the likelihood of re-offending for the "true" ranking with $k = 1000$. "Fair" rankings are generated according to groups *race* = African American and *gender* = male. Audit parameters are $w = 100, s = 10$.

Metrics. We produce audit plots using our proposed metrics *Req*, *Rcal* and *Rpar*, and summarize the results using FARE distance diagnostics. In their experiments, Zehlike et al. [32] use a number of metrics to gauge the tradeoff between parity and prediction accuracy. We include two metrics for comparison: *NDCG*: normalized discounted cumulative gain [21] (commonly used in search), and *rank drop*: the maximum number of positions lost by an object.

Discussion. Table 2 summarizes the FARE diagnostics for our experiments. The rankings deemed most fair in this audit are highlighted in bold. Asterisks mark the conclusions which align with the analysis in [32]. For three out of five rankings FA*IR clearly outperforms Feldman, satisfying multiple fairness concerns.

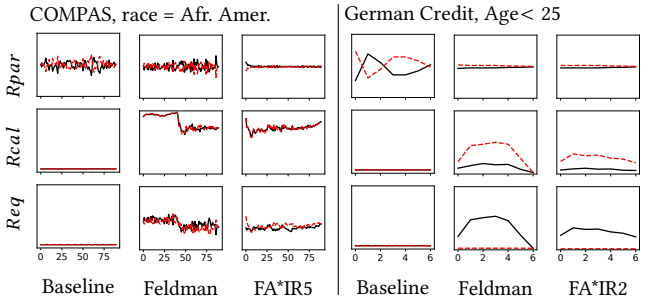

Figure 3: Audit plots for rank correction methods illustrate how errors (plotted on the y-axis and normalized between 0 and 1), manifest throughout the ranking. The x-axis represents the sliding window moving from highly ranked items on the left to the lowest on the right. Errors for group A_1 are shown as a solid black line, group A_2 as dashed red line.

The impact of both the FA*IR and Feldman rank correction techniques on statistical parity concerns is apparent, as measured by our Rank Parity FC. For instance, for the German Credit dataset using *age* < 25, *Rpar* distance is 0.25 in the baseline "true" ranking. Both methods are able to reduce this to 0.03. The degree to which error is introduced as a result of the correction algorithm is reflected in the *Req* and *Rpar* scores. By comparison, the NDCG metric is not sensitive to the rank correction methods, and therefore not expressive enough to capture unfairness. The rank drop values tend to align with the FARE diagnostics. However, this value is not very interpretable. We cannot observe which group had the farthest drop, or whether the position of many items dropped.

For such nuanced analysis we turn to our FARE audit plots, shown in Figure 3. For the German Credit dataset, we can visually discern that both FA*IR and Feldman systematically introduce *Req* and *Rcal* errors that indicate an unfair disparity in the treatment of the groups throughout the ranking. For the COMPAS dataset, we observe similar patterns and magnitude of error throughout the rankings for both groups. In this case, the correction methods are introducing error in a fair manner. Feldman shows a drop midway through the *Rcal* sequence while the FA*IR error appears more consistent. FARE compliments the use of these ranking methods by providing this in-depth view of the treatment of each group.

In the interest of reproducibility, all code, data, and a full analysis including additional diagnostics and datasets is available online:

7 CONCLUSION

In this work we present the first methodology for auditing rankings using group error metrics which capture popular notions of fairness. Our proposed fairness criteria together with our FARE auditing method comprise a powerful diagnostic tool for nuanced analysis of the treatment of groups being ranked. FARE can be applied in a general and model-agnostic fashion, for many applications where rankings are used to simplify complex socio-economic datasets, providing a crucial service of debunking unfair rankings.

Table 2: Fairness evaluation for rank correction methods. FARE distance diagnostics are shown in the center, and compared to standard error metrics.

			FARE				
Dataset	**Group**	**Method**	*Rpar*	*Rcal*	*Req*	**NDCG**	**Drop**
German Credit k=100	age< 25	Baseline	0.25	0.00	0.00	1.00	0
		Feldman	**0.03**	0.23	0.33	1.00	8

ABSTRACT

Citizen engagement and technology usage are two emerging trends driven by smart city initiatives. Typically, citizens report issues, such as broken roads, garbage dumps, *etc.* through web portals and mobile apps, in order for the government authorities to take appropriate actions. Several mediums – text, image, audio, video – are used to report these issues. Through a user study with 13 citizens and 3 authorities, we found that image is the most preferred medium to report civic issues. However, analyzing civic issue related images is challenging for the authorities as it requires manual effort. In this work, given an image, we propose to generate a *Civic Issue Graph* consisting of a set of objects and the semantic relations between them, which are representative of the underlying civic issue. We also release two multi-modal (text and images) datasets, that can help in further analysis of civic issues from images. We present an approach for adversarial adaptation of existing scene graph models that enables the use of scene graphs for new applications in the absence of any labelled training data. We conduct several experiments to analyze the efficacy of our approach, and using human evaluation, we establish the appropriateness of our model at representing different civic issues.

1 INTRODUCTION

In recent years, there has been a significant increase in smart city initiatives [8, 26, 27]. As a result, government authorities are emphasizing the use of technology and increased citizen participation for better maintenance of urban areas. Various web platforms – SeeClickFix [23], FixMyStreet [1], ichangemycity [13] – have been introduced across the world, which enable the citizens to report civic issues such as poor road condition, garbage dumps, *etc.*, and track the status of their complaints. This has resulted in exponential increase in the number of civic issues being reported [2]. Even social media sites (Twitter, Facebook) have been increasingly utilized to report civic issues. These issues are reported online through various mediums – textual descriptions, images, videos, or a combination of them. Previous work [9] highlights the importance of different mediums in citizen participation. Yet, no prior work has tried to understand the role of these mediums in reporting of civic issues.

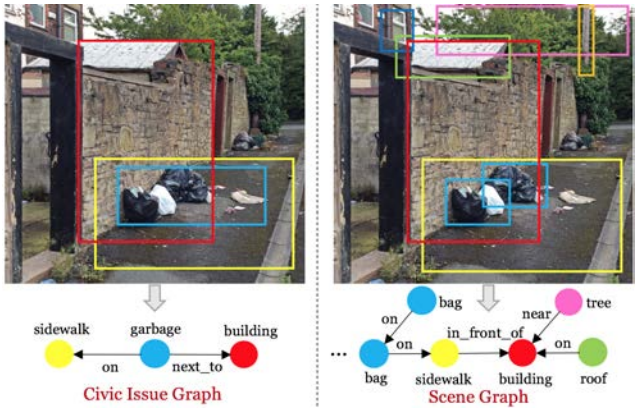

Figure 1: Comparison between Civic Issue Graph and Scene Graph for a given image. The scene graph provides a complete representation of all objects and relationships in the image, while the Civic Issue Graph only consists of those objects and relations which are representative of the civic issue.

In this work, we first identify the most preferred medium for reporting civic issues, by conducting a user study with 13 citizens and 3 government authorities. Using the 84 civic issues reported by the citizens using our mobile app, and follow-up semi-structured interviews, we found that images are the most usable medium for the citizens. In contrast, authorities found text as the most preferred medium, as images are hard to analyze at scale.

To fill this gap, several works have proposed methods to automatically identify a specific category of civic issues from images, such as garbage dumps [24] and road damage [20]. However, their methods are limited to the specific categories that they address.

Furthermore, existing holistic approaches of analyzing civic issues are limited to text [4]. To this end, we propose an approach to understand various civic issues from input images, independent of the type of issue being reported.

In the field of image understanding, scene graphs [14], are used to get a complete representation of all objects in an image along with the relations between them. However, to understand a civic issue, only certain crucial objects and the relations between them need to be detected, which are representative of the civic issue in the image. Inspired from the task of scene graph generation, we propose to generate *Civic Issue Graphs* that provide complete representations of civic issues in images.

Figure 1 shows a comparison between the two representations. In contrast to the scene graph, the Civic Issue Graph only consists of objects conveying a civic issue, their bounding boxes, and the relation between these objects. We present a formal definition of this representation in Section 5.

Training a scene graph model requires a large amount of data consisting of images with grounded annotations (objects and relations in the images). Due to the lack of sufficient annotated images of civic issues, we use an existing scene graph model in a cross-domain setting, with partially annotated and unpaired data. We utilize a dataset extracted by collating and processing images from civic issue complaint forums, for training our model, and make this dataset publicly available. We present a novel adversarial approach that uses an existing scene graph model for a new task in the absence of any labelled training data. We conduct various experiments to establish the efficacy of our approach using metrics derived from standard scene graph evaluation metrics. Finally, through human evaluation, we demonstrate that civic issues from images can be appropriately represented using our Civic Issue Graph.

To summarize, the major contributions of this paper are: (i) understanding the usability of different mediums for reporting civic issues, (ii) introducing an unsupervised mechanism using adversarial adaptation of existing scene graph models to a new domain, (iii) experimental evaluation indicating significant performance gains for identification of civic issues from user uploaded images, and (iv) releasing two multi-modal (text and image) datasets with information on civic issues, to encourage future work in this domain.

2 RELATED WORK

Civic Issue Detection and Analysis. Social media provides a convenient interface that allows citizens to report civic issues [3, 15]. Several works try to analyze online platforms to automatically mine issues related to civic amenities [22, 25], but the analysis is limited to textual descriptions. Specific to images, [20] and [24] use object detection and image segmentation techniques to identify road damage and garbage dumps respectively, from input images. However, their methods are also limited to the specific category of civic issues that they address. One of the more recent works, 'Citicafe' [4] employs machine learning techniques to understand and analyze different types of civic issue from the user input. However, they do not provide a method for understanding images reporting civic issues, as we do in this paper.

Scene-Graph Generation. Several works [16, 33] propose methods for generating scene graphs from images to represent all objects in an image and the relationships between them. Zellers et al. [33] present the state-of-the-art for generating scene graphs by establishing that several structural patterns exist in scene-graphs (which they call motifs) and showing how object labels are highly predictive of relation labels by analyzing the Visual Genome dataset [17]. However, their approach requires a large set of images for training with grounded annotations for objects and relations. Some works [19, 34] utilize zero shot learning for generating a scene-graph. However, their results show that the learning is restricted to the task of detecting new predicates which were not seen during the training phase. Our approach can be used to generalize existing scene graph models to predict new relations belonging to a different domain, which are absent from the training data.

Domain Adaptation. Domain adaptation is a long studied problem, where approaches range from fine-tuning networks with target data [28] to adversarial domain adaptation methods [31]. Adversarial methods [10, 29, 31] employ a domain classifier to learn mappings from the source domain to target domain, and these mappings are used to generalize the model to the target domain. These methods have shown promising results for image understanding tasks such as captioning [5] and object detection [7]. In this work, we propose to use Adversarial Discriminative Domain Adaptation (ADDA) [31] for adapting scene graph models to our new task.

3 USER STUDY

We conducted a user study to understand the preference of different mediums – text, audio, image and video – to report civic issues, both from citizens and authorities perspective. For this, we developed a custom Android app, with the landing page having four buttons, each corresponding to the four mediums. To report an issue, any of the medium(s) could be used any number of times, *e.g.,* a report can comprise of 1 video, few lines of text, and 2 images.

13 participants (9 male, 4 female, age=28.5±6.1 years) reported civic issues over a period of 7-10 days. All the participants were recruited using word-of-mouth and snowball sampling. All of them were experienced smartphone users, using it for the past 6.2±2.2 years, and well educated (highest education: 1 high school, 3 Bachelors, 6 Masters, 4 PhDs). However, only two of them have previously reported civic issues on online web portals. At the end of the study, a 30-mins semi-structured interview was conducted, to delve deeper into the reasons for (not) using specific medium(s).

Furthermore, we interacted with 3 government authorities (3 male, age = 35-45 years) for 30-mins each, to understand their perspective on the medium of the received complaints. All interviews were audio-recorded, and later transcribed for analysis.

Results: Overall, 84 (6±3.7) civic issues were reported by the 13 participants, mainly in the category of garbage (11/13 participants), potholes (9), blocked sidewalk (6), traffic (5), illegal car parking (3), and stray dogs (3). 81 of these issues consisted of image, text, or their combination, while only 2 had audio and 1 had video. Hence, we only focus on image and text as preferred mediums.

A majority of the participants (10/13) found images the best for reporting civic issues, followed by text (2/13) and video (1/13). Images were preferred primarily as it is quick and easy to click an image, and they convey a lot of information: "*An image is worth 1000 words.*"-P_4, "*its super quick to take pics... even when I pause at a traffic signal, I can take a pic*"-P_{10}. Participants also felt that images are best for conveying the severity of an issue. Interestingly, participants thought that images can "*act as a proof of the problem... images don't lie*"-P_6. Participants felt that people might '*bluff*'/'*exaggerate*' when reporting issues using text. However, participants complained that images can not be used to capture the temporal variations of civic problem, *e.g.*, "*images can't say tell you for how long the garbage has been lying there*"-P_2. For reporting the temporal variations, participants favored text. But participants also found that texting requires more time and effort, compared to clicking images.

When participants were asked to choose the best combination of mediums for reporting civic issues, majority of them (9/14) chose image with text. The combination allows them the freedom to show severity and truthfulness of the issue using image(s), along with adding other details in text.

Following this, we interviewed 3 government authorities, and found about the process of human annotators analyzing the received images to generate captions describing the issue. These captions are then passed on to the relevant authority in writing or via phone calls to take appropriate actions. Also the authorities confirm that a majority of the received complaints comprise of images. However, these images never reach them due to lack adequate technological infrastructure. This confirms that image is the most preferred medium for users, but authorities rely only on textual complaints. To bridge this gap, in this work, we generate text-based descriptions of images that are used for reporting civic issues.

4 DATASET

An extensive dataset of images with annotations for a wide variety of civic issues is currently unavailable. To this end, we mined 485,927 complaints (with 131,020 images) from two civic issue reporting forums – FixMyStreet [1] and ichangemycity [13]. We use them to generate two datasets.

Dataset-1 consists of human-annotated images with the bounding boxes and object labels for 4 object categories – *garbage, manhole, pothole, water logging*. Some of these object categories are not present in any publicly available image datasets. We utilize the annotations from two existing datasets for garbage [24] and potholes [20], and add new images representative of the new object categories along with their annotations, to build Dataset-1, with a total of 1505 images and 2302 bounding boxes.

Dataset-2 consists of examples of Civic Issue Graphs, represented through triples of the form $[object1, predicate, object2]$, specifying the relationship ($predicate$) between a pair of objects ($object1$ and $object2$). We use natural language processing techniques [21, 30] to extract these triples from complaint descriptions. We manually define a set of 19 target object categories which are relevant to the civic domain and map the objects from these triples to our set of target objects based on semantic similarity [12]. We retain only those triples where the predicate defines positional relations (manually determined) and for which both objects are matched with a similarity value greater than 0.4. This dataset consists of 44,353 Civic Issue Graphs, where 8204 are paired with images. There are total 5799 unique relations with 19 object classes and 183 predicate classes. These datasets can be found here[1].

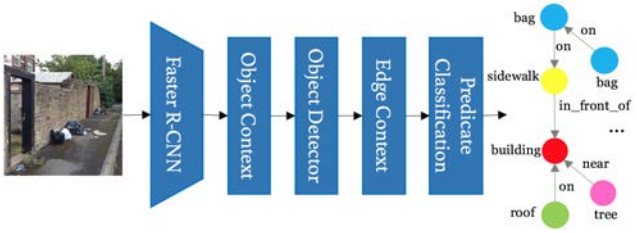

Figure 2: An overview of the MotifNet model

5 CIVIC ISSUE GRAPH GENERATION

We now present our approach for understanding civic issues from input images. We first present the formal definition of Civic Issue Graphs, followed by our detailed approach, consisting of scene graph generation and adversarial domain adaptation.

Formal Definition: A scene graph is a structured representation of objects and the relationships present between them in an image. It consists of triples or relations (used inter-changeably) of the form $[object1, predicate, object2]$ where $predicate$ defines the relationship between the two objects and both $object1$ and $object2$ are grounded to their respective bounding box representations in the image. While a scene graph provides a complete representation of the contents of the scene in an image, our proposed Civic Issue Graph (CG) only consists of objects conveying a civic issue, their bounding boxes, and the predicate between these objects. We use the following notations to define a CG:

- $B = \{b_1, \ldots, b_n\}$: Set of bounding boxes $b_i \in \mathbb{R}^4$;
- $O^1 = \{o_1^1, \ldots, o_n^1\}$: Set of objects essential for defining a civic issue, *e.g.*, '*pothole*', '*garbage*', *etc.*
- $O^2 = \{o_1^2, \ldots, o_n^2\}$: Set of objects that define the context of objects in O^1, *e.g.*, '*street*', '*building*', *etc.*
- $O = O^1 \cup O^2$: Set of all objects that assign a class label $o_i \in O$ to each b_i
- $P = \{p_1, \ldots, p_n\}$: Set of predicates defining geometric or position-based relationships between $o_i^1 \in O^1$ and $o_i^2 \in O^2$, *e.g.*, '*above*', '*next_to*', '*in*', *etc.*
- $R_{CG} = \{r_1, \ldots, r_n\}$: Set of CG relations with nodes $(b_i, o_i^1) \in B \times O^1$, $(b_j, o_j^2) \in B \times O^2$, and predicate label $p_{i \to j} \in P$, *e.g.*, $[garbage, on, street]$, where *'garbage'* $\in O^1$, *'street'* $\in O^2$, and *'on'* $\in P$

5.1 Scene Graph Generation

The MotifNet model, proposed by Zellers et al. [33], is the current state-of-the-art for generating scene graphs and we utilize this model for demonstrating our approach. However, the approach is generic and can be applied to other models with similar architecture.

[1] https://github.com/Sshanu/civic_issue_dataset

MotifNet Model: Fig 2 presents a high-level overview of the MotifNet model. The model consists of an *Object Detector* that provides object labels and their bounding regions in the input image. Following this, the *Object Context* module uses bidirectional LSTMs to generate contextualized representation for each object, and this representation is used by the *Object Decoder* to predict the final object labels. The *Edge Context* module then generates the contextualized representation for each object pair using additional bidirectional LSTMs. Finally, *Predicate Classification* contains a softmax layer to identify the predicate label, using the object-pair representation as input. The reader may refer to the extended version of this work [18] or the original MotifNet paper [33] for a detailed explanation about the individual modules and their mathematical formulations.

5.2 Adversarial Domain Adaptation

Domain adaptation involves using an existing model trained on 'source' domain where labelled data is available, and generalizing it to a 'target' domain, where labelled data is not available. Domain adaptation has been helpful for tasks such as image captioning [6] that require a large corpora of images and their labels, as getting this data for each and every domain is unfeasible. More recently, adversarial methods for domain adaptation [31] have also been proposed, where the training procedure is similar to the training of Generative Adversarial Networks (GANs) [11]. We present an adversarial training approach for a scene graph model, which, to the best of our knowledge, has not been explored before. Domain adaptation for scene graphs is challenging due to the large domain shift in the images as well as the feature space of relations. For instance, the Visual Genome dataset (VG) [17] used for training scene graph models, consists of a mix of indoor and outdoor scenes with more object instances, whereas our dataset of civic issues consists of specific outdoor scenes depicting a civic issue. Moreover, some of the relations observed in the civic issue domain are not even present in the visual genome dataset (e.g., $[garbage, on, street]$). In the following subsections, we provide more details about our cross-domain setting followed by our approach for adversarial domain adaptation.

5.2.1 Cross-Domain Setting. Scene graph models trained on a particular dataset can detect only those relations that are already *seen* by the model, or in other words, present in the training dataset. For our task of generating *CG*, the model needs to detect R_{CG}, *i.e.*, the set of relations contained in *CG*. Note that the set of relations in R_{CG} can be further divided into R_s and R_n, where R_s is the set of relations previously *seen* by the model, *e.g.*: $[tree, over, fence]$ and R_n is the set of relations previously *unseen* by the model *e.g.*: $[garbage, on, street]$. In the absence of any labelled data for R_n, we want to generalize the model trained on R_s, to adapt to R_n as well.

5.2.2 Adversarial Approach. Adversarial approach for domain adaptation consists of two models – a pre-trained generator model and a discriminator model. In our setting, we use the MotifNet model pre-trained on VG dataset as the generator and propose a discriminator model that can distinguish between R_s and R_n. During pre-training, the MotifNet model learns a representation for the object pairs which is used to predict the final set of relations (R_s). Without adversarial training, the model has not learned the representation for any *unseen* pair of objects from the civic domain and will not be able to predict such relations (R_n). Therefore, during adversarial training, the objective of the MotifNet model is to learn a mapping of target object pairs (*unseen*) to the feature space of the source object pairs (*seen*). This objective is supported via the discriminator, which is a binary classifier between the source and target domains. The MotifNet model can be said to have learned a uniform representation of object pairs corresponding to R_s and R_n, if the classifier trained using this representation can no longer distinguish between R_s and R_n. Therefore, we introduce two constrained objectives which seek to – i) find the best discriminator model that can accurately classify R_s and R_n, and ii) "maximally confuse" the discriminator model by learning new mapping for R_n. Once the source and target feature spaces are regularized, the predicate classifier trained on the *seen* object pairs can be directly applied to *unseen* object pairs, thereby eliminating the need for labelled training data.

Fig 3 summarizes our adversarial training procedure. We first pre-train the MotifNet model on the VG dataset using cross-entropy loss and then update it using adversarial training. During adversarial training, the parameters for the MotifNet model and the discriminator are optimised according to a constrained adversarial objective. To optimize the discriminator model, we use the standard classification loss (L_d). In order to optimize the MotifNet model, we use the standard loss function (L_a) with inverted labels (seen $\rightarrow$ unseen, unseen $\rightarrow$ seen) thereby satisfying the adversarial objective. This entire training process is similar to the setting of GANs. We iteratively update the MotifNet model and the Discriminator with a ratio of N_m:N_d with $N_m < N_d$, *i.e.*, the Discriminator is updated more often than the MotifNet model. We now provide a mathematical formulation of our training approach.

Discriminator We define the Discriminator as a binary classifier with *seen* and *unseen* as the two set of classes. For each object pair (o_i, o_j), the Discriminator is provided with two inputs: 1) $\mathbf{g}_{i,j}$: final representation of the object pair generated by the model and 2) $(\mathbf{W}_h \mathbf{d}_i) \circ (\mathbf{W}_t \mathbf{d}_j)$: contextualized representation of the object pair without the visual features. We further experimented with different inputs to the discriminator (details provided in the extended version of this work [18]). The Discriminator consists of 2 fully connected layers, followed by a softmax layer to generate probability $C_d(l|o_i, o_j)$, where $l \in \{seen, unseen\}$. The mathematical formulation of the discriminator for a given object pair (o_i, o_j) is:

$$\mathbf{F}_{i,j} = \mathbf{Dis}([\mathbf{g_{i,j}}; (\mathbf{W_h d_i}) \circ (\mathbf{W_t d_j})]) \tag{1}$$

$$\mathbf{C}_d = softmax(\mathbf{W}_d \mathbf{F}_{i,j} + \mathbf{b}_d) \tag{2}$$

Training Discriminator Let OP_{cv} be the set of all object pairs identified by the model for an image, I_{CV} belonging to the civic domain.

$$OP_{cv} = MotifNet(\mathbf{I_{cv}})$$

The goal of the Discriminator is formulated as a supervised classification training objective:

$$\mathcal{L}_d(\theta_d) = -\sum_{OP_{cv},\ n=1}^{N} \log \mathbf{C}_d(l^n|y^n) \tag{3}$$

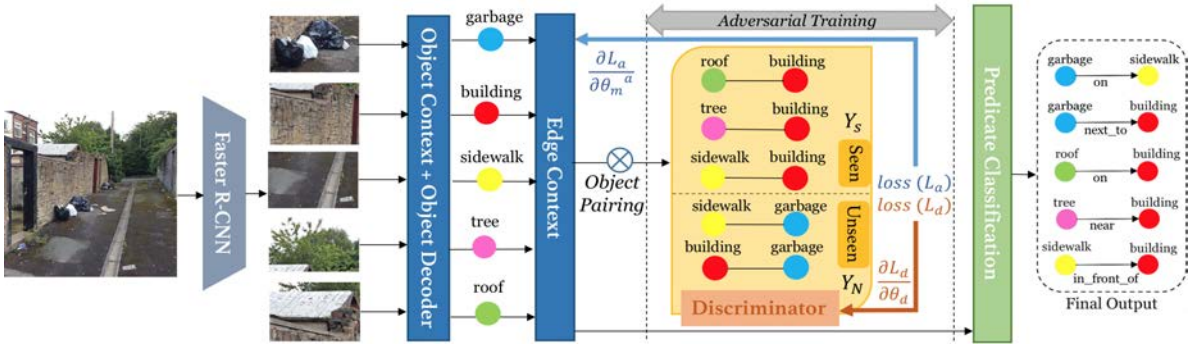

Figure 3: An illustration of our model: Faster R-CNN provides the object labels and their bounding regions. Object context generates a contextualized representation for each object. Edge context generates a contextualized representation for each edge using the representation of the object pairs. During *adversarial training*, information regarding the edge context is passed on to the Discriminator, which learns to distinguish between the *seen* and *unseen* object pairs. The training objective of the Discriminator results in gradients flowing into the Discriminator as well as the edge context layer. The loss for the model decreases as the model learns to fool the Discriminator by adapting a uniform representation for *seen* and *unseen* classes.

$$l^n = \begin{cases} 1(seen) & \text{if } y^n \in Y_s \\ 0(unseen) & \text{if } y^n \in Y_n, \end{cases}$$

where $y^n = (o_i, o_j)^n$, and Y_n and Y_s are the set of object pairs corresponding to R_n and R_s, respectively. θ_d denotes the parameters of the Discriminator to be learned. We minimize $\mathcal{L}_d$ while training the discriminator.

Training Model In accordance with the inverted label loss described above, the training objective of the model is as follows:

$$\mathcal{L}_a(\theta_m^a) = -\sum_{OP_{cv},\, n=1}^{N} \log \mathrm{C}_d(l^n|y^n) \quad \forall y^n \in Y_n$$

Here $\theta_m^a : \{\mathbf{W}_h, \mathbf{W}_t\}$ denotes the parameters of the model that are updated during adversarial training. We minimize $\mathcal{L}_a$ while updating the model.

6 EXPERIMENTS AND EVALUATION

The simplest approach to identify the civic issue from an image is to classify the image into predefined categories. To this end, we trained a classifier using a set of 10 most frequent categories as defined on FixMyStreet forum. On the test dataset, while the accuracies for the three most accurate classes were 86.5%, 83.6% and 75.2%, 4 out of 10 classes had their accuracy less than 17%. Such large variation in accuracies for different classes indicates that classifying images into pre-defined categories is not sufficient. For more details of the classifier, please refer to the extended version of this work [18]. We now provide the implementation details of our model.

6.1 Implementation Details

Discriminator used in adversarial training consists of 3 fully connected layers: two layers with 4096 hidden units followed by the final softmax output. Each hidden layer is followed by a batch normalization, leakyReLU activation function with negative slope of 0.2 and apply a dropout in the training phase with keeping probability of 0.5. Both discriminator and model are trained using ADAM optimizer with a learning rate of 1.2 x 10^{-2} and 1.2 x 10^{-3}, respectively. The value of N_d is set to 150 steps, while N_m is set to 50 steps, with the model and the discriminator being trained iteratively for 12 epochs. For complete implementation details regarding the pre-training of the scene graph model and the Faster R-CNN training, please refer to the extended version of this work [18].

6.2 Evaluation Metrics

Previous work [32] defines three modes for analyzing a scene graph model: 1) Predicate Classification (PredCls) which measures the model's performance for detecting the predicate, given a set of object pairs, in isolation from other factors, 2) Scene Graph Classification (SGCls), which measures the model's performance for predicting the right object labels and predicates, given a set of localized objects, and 3) Scene Graph Generation (SGGen), which requires the model to simultaneously detect the set of objects and predict the right predicate for each object pair. For our approach of generating *CG* using existing scene graph models, it is appropriate to report: (i) the performance of the existing model when generalized to this new domain, and (ii) the accuracy of the output *CG* for representing the civic issue in the image. Deriving from the existing set of tasks, we define a new set of tasks which can help in evaluating our model along these dimensions:

- **OPCls**: the task is to predict the set of object pairs which are indicative of the civic issue present in the image.
- **CGCls**: the task is to predict the set of relations which can represent the civic issue present in the image.
- **CGGen**: the task is to simultaneously detect the region in the image and predict the relations indicative of the civic issue.

For task **OPCls**, we report the experimental results, and use human evaluation for the task **CGCls** and **CGGen**. In accordance with previous work, for **OPCls**, we report results for the image-wise recall metrics (R@k). Since our task is to predict object pairs which are found in civic domains, we report results for *R*@1, *R*@5, *R*@10 & *R*@20 metrics. For **CGCls** and **CGGen**, we report the results using both Precision and Recall metrics ($k : \{1, 3, 5\}$)

Figure 4: Qualitative examples presenting the Civic Issue Graphs generated by our model. We show the top 3 relations and highlight the ones that are representative of the civic issue along with their bounding regions

6.3 Experimental Results

6.3.1 Removing Object Decoder. The MotifNet model after adversarial training performed poorly when tested on the images from civic domain ($R@10 = 10.5$). We found that the object decoder is not able to predict the correct object labels when the input image contains new objects from the civic domain, as the model has not been trained on these labels. On removing the decoder during test time (denoted as $MotifNet_{Adv}$ in the table), the performance improves significantly ($R@10 = 76.0$, Table 1). Adapting the decoder to a new domain requires ground-truth data in terms of the sequence of objects and the labels, which may not be possible for the civic domain. Therefore, we decided to pre-train the MotifNet model without the decoder (denoted by $MotifNet^{wd}$) and directly use the object labels predicted by the Faster R-CNN. On updating the new model using adversarial training (denoted by $MotifNet^{wd}_{Adv}$), the performance improved significantly, particularly for $R@1$ and $R@5$. Table 1 shows the comparison between the different settings with $MotifNet^{wd}_{Adv}$ performing significantly better than all other models, for all the metrics.

6.3.2 Adversarial Training vs Fine-tuning. The results so far show that using adversarial training can significantly improve the performance of the model. As an alternative approach, we also try to adapt the pre-trained model to our new domain by fine-tuning the predicate classification in the model. Mathematically, we aim to increase the value of $\mathbf{P}(p_{i\to j}|B, O))$, where $(o_i, p_{i\to j}, o_j)$ correspond to R_{CG}. The training objective for this phase is defined as:

$$\mathcal{L}_f(\theta^f_m) = -\sum_{OP_{cv},\ n=1}^{N} l \log \mathbf{P}(p^n_{i\to j}|B^n, O^n) \tag{4}$$

$$l = \begin{cases} 1 & \text{if } p^n_{i\to j} \in R_{CG} \\ 0 & \text{otherwise,} \end{cases}$$

where $\theta^f_m : \{\mathbf{W}_r, \mathbf{w}_{o_i,o_j}\}$, *i.e.*, the weights and bias of the predicate classifier of the model. We minimize L_f while fine-tuning the model which is trained for 6 epochs. Table 1 shows that fine-tuning a pre-trained MotifNet model ($MotifNet^{wd}_{fine}$) brings slight improvement in the performance when compared to the original model ($MotifNet$). However, the model with adversarial training ($MotifNet^{wd}_{Adv}$) performs significantly better than the fine-tuned model ($MotifNet^{wd}_{fine}$). Fine-tuning the model will only improve the detection of relations which are already *seen* by the model, while adversarial training will generalize the performance across both *seen* and *unseen* classes. Further fine-tuning the adversarially updated MotifNet ($MotifNet^{wd}_{Adv+fine}$) model brings no improvement in the performance.

Model Settings	R@1	R@5	R@10	R@20
MotifNet	35.6	64.9	75.4	79.7
$\text{MotifNet}_{\text{Adv}}$	37.7	65.7	76.0	79.8
$\text{MotifNet}^{\text{WD}}$	37.7	63.0	73.3	78.9
$\text{MotifNet}^{\text{WD}}_{\text{Adv}}$	**43.3**	**67.7**	**76.3**	**80.2**
$\text{MotifNet}^{\text{WD}}_{\text{FINE}}$	38.9	63.6	73.8	79.2
$\text{MotifNet}^{\text{WD}}_{\text{Adv+FINE}}$	43.1	67.7	76.3	80.2

Table 1: Recall for different settings; *Adv*: Adversarial Training; *fine*: fine-tuning; *wd*: *without decoder* setting

6.4 Human Evaluation

To establish the efficacy of our model at appropriately representing civic issues from images, we recruited Amazon Mechanical Turk workers. We randomly sampled 300 images from the test set; each image was evaluated by 3 workers. In accordance with our definition of *CG*, we retained only the top 5 relations from the output relations for which $o_i \in O_1$ and $o_j \in O_2$, where (o_i, o_j) denotes the unordered pair of objects in a relation.

The evaluation was carried out for the tasks **CGCLS** and **CGGEN** in two phases. For **CGCLS**, workers were shown an image along with 5 relations and were asked to select 0 or more relations that appropriately represented the civic issue(s) in that image. An option was also given to specify any additional relations separately. For **CGGEN**, we retrieved the relations which were marked as relevant for a given image. For each such relation, workers were shown the bounding regions for the objects present in the relation, and asked to evaluate the coverage of these bounding regions, on a scale of 0-10. We report two metrics – Precision and Recall, for both the tasks and consider only the majority voted relations with a minimum average rating of 5 for the bounding regions. Table 2 shows the performance of our model. The results show that 83.3% of the times, the relation representing a civic issue is present in the top 3 relations of our *CG*, and 53.0% of the times, the top relation itself represents a civic issue in the image. The accuracy on the **CGGEN** task further indicates that our model is capable of generating accurate groundings for the objects representing the civic issue.

7 CONCLUSION

We introduce a novel unsupervised mechanism of adapting existing scene graph models via adversarial training and present an application of our approach for generating Civic Issue Graph. Our approach can be utilized in existing platforms, which allow users to report civic issues using images. Once the user uploads an image,

	CGCLS			CGGEN		
	@1	@3	@5	@1	@3	@5
Precision	53.0	31.9	24.7	50.9	30.3	24.1
Recall	53.0	84.0	99.0	50.9	83.3	99.0

Table 2: Precision and Recall values for the tasks CGCLS and CGGEN based on human evaluation

our model can automatically generate text-based relations (*e.g.,* garbage-on-street, garbage-next to-building) depicting the civic issue in the input image. These text-based relational descriptions can be shared with the authorities, which can be utilized for large scale analysis, thereby automating the process and removing any dependency on the actual image uploaded by the user. Furthermore, if needed, natural language descriptions can be generated from these relations using a template-based approach. Our experimental analysis helps provide a framework for adapting scene graph models to other settings as well. We also release two multi-modal (text and images) datasets with information of civic issues, to encourage future work in this domain.

ABSTRACT

The Bitcoin payment system involves two agent types: Users that transact with the currency and pay fees and miners in charge of authorizing transactions and securing the system in return for these fees. Two of Bitcoin's challenges are (i) securing sufficient miner revenues as block rewards decrease, and (ii) alleviating the throughput limitation due to a small maximal block size cap. These issues are strongly related as increasing the maximal block size may decrease revenue due to Bitcoin's pay-your-bid approach. To decouple them, we analyze the "monopolistic auction" [8], showing: (i) its revenue does not decrease as the maximal block size increases, (ii) it is resilient to an untrusted auctioneer (the miner), and (iii) simplicity for transaction issuers (bidders), as the average gain from strategic bid shading (relative to bidding one's true maximal willingness to pay) diminishes as the number of bids increases.

1 INTRODUCTION

Bitcoin's security relies on its ability to attract honest miners and to incentivize them to invest large amounts of computational power [13]. This is done by rewarding miners for the creation of new blocks. The payment comprises a block reward that is a fixed amount per block, and a fee that each transaction pays for its inclusion in the block. Since the block reward is cut in half approximately every 4 years, transaction fees gradually become the miners' main incentive to participate. The decision on which transactions to include in the block is made using a "pay-your-bid" auction: each transaction submits its fee for its inclusion in the block. A miner, in turn, includes the highest bidding transactions that fit in the block. In this auction, larger block sizes imply smaller transaction fees, since all transactions will aim to pay the lowest possible fee for its inclusion in the block. The Bitcoin block size therefore significantly influences miners' revenue. Indeed, one of the main arguments against a block-size increase in Bitcoin has been that it may cause transaction fees to drop significantly. Thus, two of the Bitcoin system's main problems, i.e., obtaining sufficient revenue for the miners as the block reward gradually decreases and the throughput limitation as a result of the maximal block size, are in fact strongly related. This connection, however, is a major obstacle to their resolution. Our motivation in this paper is to decouple the issues of revenue and maximal block size (which should be determined according to other technical considerations, like block propagation times) and to provide scalability from the economic perspective of the fee market.

While most of auction theory assumes a trusted auctioneer that honestly follows the protocol, a miner (the auctioneer of the block) cannot be trusted. If adding fake bids can increase profit, a miner can add transactions by moving funds from one of its accounts to another. Similarly, a miner can ignore bids. An untrusted auctioneer can manipulate a 2^{nd} price auction, for example, by adding a fake bid that is very close to the highest bid. Bidders will realize that and shade down their bids. Though cryptography can, in general, help resolve some of these issues, as far as the authors are aware, cryptographic techniques are not applicable to Bitcoin: they assume a trusted setup, that the auctioneer is known in advance, or multiple communication rounds between all parties as in secure multi-party computation [1, 4, 12, 14].

We analyze here a potential solution to these issues, the *monopolistic auction* [8].[1] We observe that in the Bitcoin setting, the monopolistic auction is immune to untrusted auctioneers, on the one hand, and it decouples the revenue issue from the maximal block size issue, on the other. In this auction, given bids $b_1, ..., b_n$, the miner chooses which transactions to include in the block. All chosen transactions pay the same fee – the lowest bid in the block (as must be verified by the protocol). The maximal revenue resulting from this method cannot be increased by adding fake bids or by ignoring true bids. Other manipulations like side payments between miners and users are also not beneficial. In fact, we are not aware of any beneficial miner manipulation that can be exploited in the frame of this auction. Additionally and in contrast to a pay-your-bid auction, increasing the maximal block size does not decrease the revenue of the monopolistic auction. Choosing a threshold price is conceptually similar to dynamically choosing the block size – the miner chooses the size of the block it creates as a function of the

[1] Termed the "optimal single price omniscient auction" in [8], this auction was suggested as a benchmark, and as far as we know, its game-theoretic properties have not been analyzed in the Bitcoin context.

bids received. In some bid instances, blocks will be small, while in others they will be large.

In a pay-your-bid auction, a user must strategically determine the lowest bid it can submit such that it will be included in the block ("bid shading"). Indeed, Bitcoin wallets use various fee estimation techniques. It is not clear how to do this optimally, and in any case, it requires some non-trivial computational effort (data gathering, statistical analysis, etc). Bid shading can also help in worst-case instances of the monopolistic auction, and as a result, [8] do not analyze its strategic properties but suggest it only as a benchmark for other truthful auctions they define. These other truthful auctions from [8] are less applicable vis-a-vis our needs (see Section 5). Although the approach is not truthful, in the monopolistic auction, a user, rather than paying her bid, pays some threshold value (a function of all bids) which w.h.p is only remotely related to one's bid. The main technical novelty of this paper is to show that the expected gain from optimal bid shading relative to truthfully bidding the maximal willingness to pay decreases to zero as the number of bids grows. On average, all users will benefit very little, if at all, from bid shading in the monopolistic auction. Since a near optimal strategy is to bid the maximal willingness to pay, bidding in the monopolistic auction is simpler. Section 2 defines the formal framework used and proves this statement, and Section 4 verifies it via simulations using synthetic and actual Bitcoin bid distributions. The greater simplicity of the monopolistic auction is another of its advantages over the pay-your-bid auction.

This analyzes a single block creation. "Patient users", who willing to wait for future blocks, might lower their bids if they anticipate less competition in the future. Two important issues that remain to be investigated in future research are (1) how patient users shade down their bids and (2) how non-myopic bidders who create persistent transactions affect the bid distribution. Note that these issues affect the revenue not only of the monopolistic auction, but also of the pay-your-bid auction. We do not know, however, which of the two auctions is more strongly affected. Our analytical results suggest that the monopolistic auction collects at least as much revenue from impatient users as Bitcoin's current mechanism.

Related Work. There are relatively few works devoted to analyses of the Bitcoin fee market and fewer still that suggest modifications to the basic mechanism. [10] provided an early analysis of the economics of Bitcoin mining, including a game theoretic analysis of the incentives to mine on the longest chain. [2] considered the incentives of miners to distribute transactions to each other and designed ways to share the fees in exchange for distribution. [6] explored the security of Bitcoin and the incentive to mine blocks properly when block rewards diminish and fees dominate the revenue of miners. They showed that variance in fees may undermine the security of the protocol and subject it to different forms of deviations and attacks. [5] explored related bribery attacks on the protocol that are paid for through promises of higher rewards for attackers that construct blocks off the longest chain. [15] considered the removal of the block limit altogether, arguing that delays in large block propagation times, which, in turn, imply a higher likelihood that the block is abandoned (often referred to as an orphaned block), will cause miners to restrict their own block sizes. The paper analyzed the resultant fee market that emerges. [9] modeled the transaction fee market and assumed that users benefit less if their transactions are delayed. They showed that such delays together with the congestion that may naturally occur in blocks due to queuing effects can lead to non-zero bids for transacting users even if blocks are not completely full. As far as we are aware, no previous work has explored a different mechanism for the fee market in crypto-currencies.

After the preprint version of this manuscript was published, Andrew Chi-Chih Yao [17] further analyzed the monopolistic price as a fee mechanism for Bitcoin, in the process resolving our main conjecture, Conjecture 2.6 – see the discussion there.

Basu, Easley, O'Hara and Sirer [3] used a modified monopolistic price auction to determine inclusion in the block. They penalize miners if the blocks are not full, and additionally, they average the reward from blocks between different miners. Their goal is to maximize social welfare rather than the miners' revenue. The main analytical difference between their work and ours is that theirs is based mostly on simulations while ours is proved for the most part formally. In terms of abstract conclusions, our results agree with theirs: they also establish that the incentive of miners and users to manipulate diminishes as n grows.

A full version with greater detail and the full proofs is in Ref. [11].

2 THE MONOPOLISTIC AUCTION

There are n transactions, each of which has a privately known maximal willingness to pay v_i for its inclusion in the block, e.g., an alternative transaction cost via a bank, credit card, etc. Transactions submit bids, and based on these, the miner decides which transactions to include in the block. The bid vector is sorted so that $\boldsymbol{b} = (b_1, \ldots, b_n)$ satisfies $b_1 \geq \ldots \geq b_n$. Let $k^*(\boldsymbol{b})$ be the index k that maximizes $k \cdot b_k$. In case of ties, k^* is chosen to be the maximal such index. Define:

$$R(\boldsymbol{b}) = k^*(\boldsymbol{b}) \cdot b_{k^*(\boldsymbol{b})} \ , \ p^M(\boldsymbol{b}) = b_{k^*(\boldsymbol{b})}, \tag{1}$$

where $R(\boldsymbol{b})$ is termed the "monopolistic revenue" and $p^M(\boldsymbol{b})$ is termed the monopolistic price. In the monopolistic auction, the miner includes in the block the $k^*(\boldsymbol{b})$ transactions who submitted the highest bids and charges a payment of $p^M(\boldsymbol{b}) = b_{k^*(\boldsymbol{b})}$ from each of these transactions. The miner's revenue from this block is therefore $R(\boldsymbol{b})$.

An untrusted auctioneer that can add fake bids does not have any incentive to do so in this auction. Specifically, the Bitcoin protocol can verify that all transactions in the same block pay the same price. However, it cannot prevent miners from adding fake bids by exploiting transactions that move funds between two accounts of the same miner. These fake bids can affect the payments of the "real" bids and increase the revenue of the auctioneer, as is the case in a second-price auction. In the monopolistic auction,in contrast, the addition of fake bids cannot increase the revenue: given any vector of real bids $\boldsymbol{b}$, since all transactions in the block pay the same price, the maximal revenue is $R(\boldsymbol{b})$ if the miner does not create another block in the near future. However, a bidder might benefit from submitting $b_i < v_i$, as demonstrated by the following examples:

Example 2.1. Suppose n bidders that have the same maximum fee $v_i = 1$. If all bids are $b_i = v_i$, then $R(\boldsymbol{b}) = n, k^*(\boldsymbol{b}) = n$, and

$p^M(\boldsymbol{b}) = 1$, i.e., all bids get accepted to the block and they all pay 1. A strategic bidder, say 1, can reduce her payment by reducing her bid to $b_1 = \frac{n-1}{n}$. With this bid, the monopolistic price decreases to $\frac{n-1}{n}$: if all bids of value 1 are accepted, the revenue is $n-1$, and if all bids of value at least $b_1 = \frac{n-1}{n}$ are accepted, the revenue is still $n-1$.

The gain from bid shading in this example vanishes as the number of users (and the block size) increases. In other cases, gains do not vanish even when the number of bidders grows:

Example 2.2. $v_1 = \ldots = v_{\frac{n}{2}+1} = 2, v_{\frac{n}{2}+2} = \ldots = v_n = 1$. Bidder 1 can reduce her price by bidding $\frac{n-1}{n}$ instead of 2.

However, if the values for example 2.2 are taken from realistic distributions, then the probability that it will be realized will usually be very small.

Therefore, rather than allege that there are no profitable deviations from truth-telling, we will only claim that the expected gain from any non-truthful bid diminishes as n grows. For example, if the distribution of values has a finite support, bidding the next lower value in the support *weakly dominates* truth-telling. Though more pronounced bid shading may be beneficial, it will not be a dominant strategy. We will show, however, that the expected gain from such a deviation or from any other deviation becomes extremely small as n grows. Therefore, we believe that it makes sense to conclude that only small deviations will likely happen.

Example 2.3. Consider the simplest equal-revenue distribution F with a finite support: $\Pr[v = 1] = 0.5, \Pr[v = 2] = 0.5$. For simplicity, assume that bidders can only submit bids of 1 or 2. Every bidder with $v = 2$ has a dominant strategy to bid 1, since she derives 0 utility when the monopoly price is set to be 2, and by bidding 1 she increases the chance that the monopoly price will be 1. The probability that a bidder with $v = 2$ can improve the outcome (i.e., change the empirical monopoly price from 2 to 1) by bidding b=1 in a 2n bidder auction is $\frac{\binom{2n}{n+1}}{2^{2n}} = \Theta\left(\frac{1}{\sqrt{n}}\right)$.

We validate this intuition more generally via both theoretical and empirical analyses. First we define some terms. Fix a user i and a vector of bids $\boldsymbol{b}_{-i} \equiv (b_1, \ldots, b_{i-1}, b_{i+1}, \ldots, b_n)$ of the other users.

$$p^S(\boldsymbol{b}_{-i}) \equiv \min\{b_i \in \mathbb{R} \mid p^M(b_i, \boldsymbol{b}_{-i}) \leq b_i\}.$$

In words, $p^S(\boldsymbol{b}_{-i})$ is the lowest possible bid for i to be included in the block. Figure 1 gives an example. This definition does not capture a case where a bidder can provide false-name bids (i.e., can split her transaction into several transactions), which is discussed in Section 3.

Figure 2 presents the strategic prices in an example with $n = 256$ users. In this example, p^S is monotonically decreasing among winning bidders (higher winning bids imply lower strategic prices) but not among all bidders. This property is formally proved in the full version [11]. Additionally, here and in most other simulations, almost all winning bids have the same strategic price, the exception being the very few lowest winning bids (i.e., those with prices slightly higher than the monopolistic price). The strategic price of these bids is higher, i.e., they gain less from being strategic.

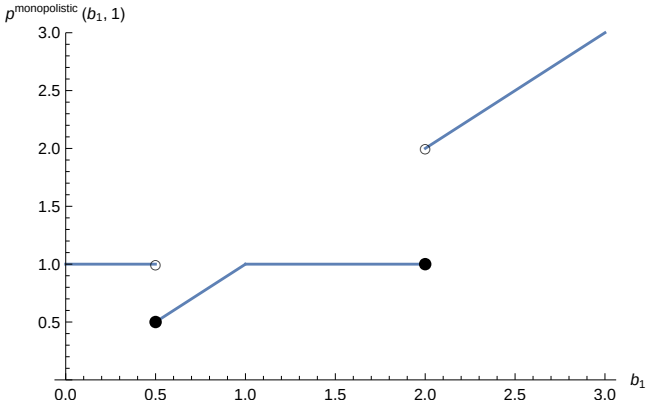

Figure 1: The function $p^M(b_1, 1)$ as a function of b_1, demonstrating that p^M is neither monotone nor continuous. As can be seen, the strategic price of the first bidder is 0.5.

While $p^S(\boldsymbol{b}_{-i})$ is the minimal price that bidder i must pay to be included in the block, she will pay $p^M(v_i, \boldsymbol{b}_{-i})$ if she bids her true maximal willingness to pay. This possible gain from bid shading is captured by the notion of the "discount ratio":

$$\delta_i(v_i, \boldsymbol{b}_{-i}) = \begin{cases} 1 - \frac{p^S(\boldsymbol{b}_{-i})}{p^M(v_i, \boldsymbol{b}_{-i})} & \text{if } v_i \geq p^S(\boldsymbol{b}_{-i}) \\ 0 & \text{otherwise.} \end{cases}$$

Clearly, $0 \leq \delta_i(v_i, \boldsymbol{b}_{-i}) \leq 1$. If $v_i < p^S(\boldsymbol{b}_{-i})$, every bid of at most v_i loses. Hence, the gain from bid shading is 0. If $v_i \geq p^S(\boldsymbol{b}_{-i})$, bidder i can win and pay $p^S(\boldsymbol{b}_{-i})$. With an honest bid, she will pay $p^M(v_i, \boldsymbol{b}_{-i})$. She can thus save a percentage of $1 - \frac{p^S(\boldsymbol{b}_{-i})}{p^M(v_i, \boldsymbol{b}_{-i})}$ from her price by strategic bid shading.

As we showed above that the discount factor can be large in the worst case, we therefore conduct an average-case analysis. Assume that all true values are drawn i.i.d. from some distribution F on $\mathbb{R}_{>0}$. The average discount ratio is then $\Delta_n^{average} = \mathbb{E}_{(v_1,\ldots,v_n)\sim F}[\delta_1(v_1, \boldsymbol{v}_{-1})]$ (the choice of bidder 1 is arbitrary since all are symmetric a-priori).

We also consider two stronger notions. In the first, for each realization $v_1, \ldots, v_n$, we consider the maximal discount ratio among all bidders:

$$\delta_{max}(\boldsymbol{v}) = \max_i \delta_i(v_i, \boldsymbol{v}_{-i}) \ , \ \Delta_n^{max} = \mathbb{E}_{(v_1,\ldots,v_n)\sim F}[\delta_{max}(\boldsymbol{v})]$$

Clearly, for all n, $\Delta_n^{max} \geq \Delta_n^{average}$ since for every $\boldsymbol{v}$ and every i, $\delta_{max}(\boldsymbol{v}) \geq \delta_i(v_i, \boldsymbol{v}_{-i})$.

Theorem 2.4. *For any distribution F with a finite support size,* $\lim_{n\to\infty} \Delta_n^{max} = 0$.

Section 2.1 proves this theorem.

In the second extension, defined only for distributions with a finite bounded support, we fix player 1 and assume that she deterministically has a value that maximizes her discount ratio (the worst possible value for her, from our perspective) while all other values are probabilistic. This depicts a situation commonly assumed in game theory wherein a user knows her own value and (only) the

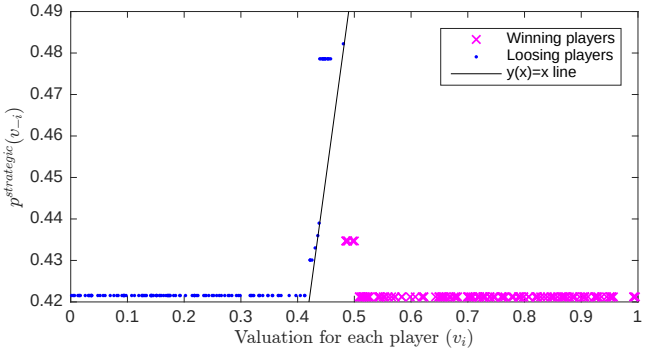

Figure 2: An example with $n = 256$ bids sampled i.i.d. from the uniform distribution on $[0, 1]$. For each user, the x-axis shows her values and the y-axis shows her strategic price. Winning bids, which are marked with 'x', must be at least as high as their respective strategic price, i.e., to the right of the black line.

distribution of the other values.

$$\delta_n^{GT}(\boldsymbol{b}_{-1}) = \max_{v_1 \in \text{Support}(F)} \delta_1(v_1, \boldsymbol{b}_{-1})$$

$$\Delta_n^{GT} = \mathbb{E}_{(v_2,\ldots,v_n)\sim F}[\delta_n^{GT}(\boldsymbol{v}_{-1})]$$

Theorem 2.5. *For any distribution F with a finite support size, $\lim_{n\to\infty} \Delta_n^{GT} = 0$.*

The proof of this theorem is very similar to that of Theorem 2.4.

Our empirical analysis focuses on Δ_n^{max}, since it is well-defined even for distributions with unbounded support.

While $\lim_{n\to\infty} |\Delta_n^{GT} - \Delta_n^{max}| = 0$, the relation between Δ_n^{GT} and Δ_n^{max} depends on the distribution, i.e., one term is not always larger than the other – see the full version for concrete examples. The e-print version contained the following conjectures:

Conjecture 2.6 (Nearly Bayesian-Nash Incentive-Compatibility).

1. *For any distribution F, $\lim_{n\to\infty} \Delta_n^{average} = 0$. In particular, $\Delta_n^{average} = O\left(\frac{1}{\sqrt{n}}\right)$, where the constant in the $O(\cdot)$ notation may depend on F.*
2. *If F has a bounded support (still possibly with an infinite cardinality) $\lim_{n\to\infty} \Delta_n^{\max} = 0$. In particular, $\Delta_n^{\max} = O\left(\frac{1}{\sqrt{n}}\right)$. The same holds for Δ_n^{GT}.*
3. *There exists a distribution F with unbounded support such that $\lim_{n\to\infty} \Delta_n^{\max} > 0$. The same holds for Δ_n^{GT}.*

The $O\left(\frac{1}{\sqrt{n}}\right)$ in the above conjecture can be achieved by Example 2.3.

Recently, Andrew Chi-Chih Yao resolved many issues that were left open in this work. Indeed, "The main purpose [of Yao's paper] is to settle the Nearly IC Conjecture for the monopolistic price in the positive" [17]. Specifically, the first sentences in items 1 and 2 were proved, and a slightly weaker claim was shown than the "in particular" claims in these items. This was proved also when accounting for multiple strategic bids – see Section 3. Item 3 was proved for the inverse distribution (see Eq. (3)), which was our primary candidate for this conjecture based on numerical data – see Section 4.

2.1 Proof of Theorem 2.4

Given $\boldsymbol{v}$, define: $i^* = \text{argmax}_{i=1,\ldots,n} v_i$, $k^* = k^*(\boldsymbol{v}_{-i^*})$, $p^H = p^M(\boldsymbol{v})$, and $p^S = p^S(\boldsymbol{v}_{-i^*})$.

Lemma 2.7. *For any F with finite support size, there exists a constant $c > 0$ (which may depend on F but not on n) s.t. $\lim_{n\to\infty} \Pr[k^* < c \cdot n] = 0$.*

Proof. Let $v_{max} = \max \text{Support}(F)$, k_{max} be the number of bidders in $\boldsymbol{v}$ who bid v_{max}, and $p_{max} = \Pr_{v_i\sim F}[v_i = v_{max}]$. By linearity of expectation, $\mathbb{E}[k_{max}] = p_{max} \cdot n$. A Chernoff bound implies that $\lim_{n\to\infty} \Pr\left(k_{max} < \frac{9np_{max}}{10}\right) = 0$. Bidders who bid v_{max} win; therefore, $k^* + 1 \geq k_{max}$. Thus, $\lim_{n\to\infty} \Pr\left(k^* + 1 < \frac{9np_{max}}{10}\right) = 0$. Choosing $c = \frac{8p_{max}}{10}$ completes the proof of the lemma. □

The following three claims are proved in the full version [11]:

Claim 1. $\forall \boldsymbol{v}, i,\ p^M(p^S(\boldsymbol{v}_{-i}), \boldsymbol{v}_{-i}) = p^S(\boldsymbol{v}_{-i})$.

Claim 2. $\forall \boldsymbol{v}, i, j$: *$v_i \geq v_j$ implies $\delta_i(v_i, \boldsymbol{v}_{-i}) \geq \delta_j(v_j, \boldsymbol{v}_{-j})$.*

Claim 3. *Let y be the smallest element in the support of F that is at least p^S. Then, $y = p^H$ implies $p^S \geq \frac{k^*}{k^*+1} \cdot p^H$.*

With these claims, we prove a second lemma:

Lemma 2.8. $\lim_{n\to\infty} \Pr(p^S < \frac{k^*}{k^*+1} p^H) = 0$.

Proof. Define A as the event where $p^S < \frac{k^*}{k^*+1} p^H$. The proof defines an event B s.t. (i) $\lim_{n\to\infty} \Pr(B) = 0$, and (ii) $A \subseteq B$. This implies $\lim_{n\to\infty} \Pr(A) = 0$ as claimed.

To define event B, fix any arbitrary two $x, y \in \text{Support}(F)$ such that $x > y$. Define $\text{num}(\boldsymbol{v}, z) \equiv |\{v_i | v_i \geq z\}|$. Define the random variables $n_z = \text{num}(\boldsymbol{v}, z)$ for any real number z, $h(x) = n_x \cdot x$, and $g(x) = (n_x - 1) \cdot x$. We first aim to bound the probability that $h(x) > h(y) \geq g(x)$. This is the same as the probability that $n_x > \frac{y}{x} n_y \geq n_x - 1$, which is true only if $n_x = \lfloor \frac{y}{x} n_y + 1 \rfloor$. The triple $(n_x, n_y - n_x, n - n_y)$ is a trinomial distribution with probabilities $p_1 = \Pr_{v_i\sim F}(v_i \geq x), p_2 = \Pr_{v_i\sim F}(x > v_i \geq y), p_3 = \Pr_{v_i\sim F}(v_i < y)$ (p_i depends on F but not on n). By simple analysis of the trinomial distribution, we show in the full version that

$$\lim_{n\to\infty} \Pr(h(x) > h(y) \geq g(x)) = 0. \tag{2}$$

Let B be the event in which $\exists x, y \in \text{Support}(F)$ s.t. $x > y$ and $h(x) > h(y) \geq g(x)$. Since the support is of finite size, there is a fixed number of such pairs $x > y \in \text{Support}(F)$. By Eq. (2) and the union bound, we conclude that $\lim_{n\to\infty} \Pr(B) = 0$. We show that $A \subseteq B$, i.e., $p^S < \frac{k^*}{k^*+1} p^H$ implies $\exists x > y \in \text{Support}(F)$ s.t. $h(x) > h(y) \geq g(x)$. Let $x = p^H$ and let y be the smallest element in the support of F, which is at least p^S. By Claim 3, the event $p^S < \frac{k^*}{k^*+1} p^H$ implies $x > y$. Since $p^M(v_{i^*}, \boldsymbol{v}_{-i^*}) = x$, it follows that $h(x) = n_x \cdot x > n_y \cdot y = h(y)$. Furthermore,

$$h(y) \geq h(p^S) = n_{p^S} \cdot p^S = \text{num}(\boldsymbol{v}, p^S) \cdot p^S = \text{num}((p^S, \boldsymbol{v}_{-i^*}), p^S) \cdot p^S$$
$$\geq \text{num}((p^S, \boldsymbol{v}_{-i^*}), x) \cdot x = (n_x - 1) \cdot x = g(x)$$

where the first step follows since $n_y = n_{p^S}$ and $p^S \le y$, the fourth step follows since $v_{i^*} \ge x > y \ge p^S$, the fifth step follows from Claim 1 that shows that $p^M(p^S, \boldsymbol{v}_{-i^*}) = p^S$, and the sixth step follows since $v_{i^*} \ge x > y \ge p^S$. □

Let the "bad" event E_1 be the case where $k^* < c \cdot n$ (c is taken from Lemma 2.7) and the "bad" event E_2 be the case where $p^S < \frac{k^*}{k^*+1} p^H$. By Claim 2, $\delta_{max}(\boldsymbol{v}) = \delta_{i^*}(\boldsymbol{v})$. Therefore, $\Delta_n^{max} = \mathbb{E}_{\boldsymbol{v}}[\delta_{i^*}(\boldsymbol{v})]$. If E_2 does not hold, then $p^S \ge \frac{k^*}{k^*+1} p^H$, and therefore, $\delta_{i^*}(\boldsymbol{v}) \le \frac{1}{k^*+1}$. To conclude:

$$\begin{aligned}
\lim_{n\to\infty} \Delta_n^{max} &= \lim_{n\to\infty} \Big[\Pr[E_1 \cup E_2]\, \mathbb{E}_v[\delta_{i^*}(v_{i^*}, v_{-i^*}) | E_1 \cup E_2] \\
&\quad + \Pr[E_1^c \cap E_2^c]\, \mathbb{E}_v \left[\delta_{i^*}(v_{i^*}, v_{-1}) | E_1^c \cap E_2^c \right] \Big] \\
&\le \lim_{n\to\infty} \left[\Pr[E_1] + \Pr[E_2] + \Pr[E_1^c \cap E_2^c] \cdot \mathbb{E}_v[\frac{1}{k^*+1} | E_1^c \cap E_2^c] \right] \\
&\le \lim_{n\to\infty} \left[\Pr[E_1] + \Pr[E_2] + \Pr[E_1^c \cap E_2^c] \cdot \frac{1}{c \cdot n} \right] \\
&\le \lim_{n\to\infty} \left[\Pr[E_1] + \Pr[E_2] + \frac{1}{c \cdot n} \right] = 0,
\end{aligned}$$

implying Theorem 2.4.

3 MULTIPLE STRATEGIC BIDS

In some cases, it is beneficial to split one's bid into separate transactions with several separate bids. In fact, such a strategy sometimes enables a losing transaction to be included in the block:

Example 3.1. Let $\boldsymbol{v} = (5, 2, 1, 1)$. With bids $\boldsymbol{b} = \boldsymbol{v}$, the monopolistic price is 5 and the second bidder loses. However, if she submits two separate bids of 1 each, the monopolistic price will be 1 and all bids will be included.

Our empirical evaluation below accounts for such situations, showing that the benefit from using multiple bids also goes to zero as n increases. In all the distributions we examined, except the discrete distribution, we *never* encountered a case in which the strategic player has an advantage placing multiple bids. Even in the discrete case, the effect of such multiple bids was negligible. See the full version for more detail.

4 EMPIRICAL EVALUATION

We provide empirical evidence to support the above conjectures and to supply greater detail on the rate at which the discount ratio converges to zero. We use both synthetic data as well as transaction data taken from the Bitcoin blockchain. The synthetic data are generated using four distributions:

(1) A uniform discrete distribution over the integers $1, \ldots, 100$. This distribution has a finite support size and therefore satisfies the requirements of Theorem 2.4.
(2) The uniform distribution over $[0, 1]$. Notice that here the support size is infinite.
(3) The half normal distribution. Here, the probability for maximum fee x decreases exponentially with x, hence, even though arbitrarily high transaction fees will be seen, they are highly unlikely.

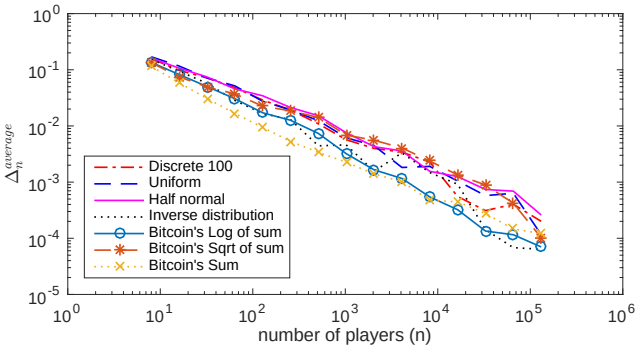

Figure 3: The average discount ratio of a player from selfish bidding as a function of the number of players that participate.

(4) The inverse distribution

$$F(x) = 1 - \frac{1}{x}, \quad x \in [1, \infty). \tag{3}$$

Here, the probability for a maximum fee x decreases polynomially with x.

The uniform distribution has no tail, the half normal distribution has a light tail (it decreases exponentially fast), and the inverse distribution has a heavy tail.

Bitcoin blockchain data was collected from 1000 consecutive blocks, which constitute roughly one week of activity ending on October 28th, 2016. The data obviously do not contain the maximum willingness to pay, since this is not how Bitcoin operates. The simulations estimate the maximum willingness to pay, v, as a function $v = v(x)$ of the transaction size x (x is the sum of all outputs of the Bitcoin transaction). We use three alternative functions: $v(x) = \log x, v(x) = \sqrt{x}, v(x) = x$. Note that multiplying all bids by a scalar does not change the discount ratio, which is the case when, e.g., the maximum willingness to pay is some percentage of $v(x)$.

We empirically evaluated $\Delta_n^{average}$ and Δ_n^{max} as a function of the number of bids, n. For each $n \in \{2^3, 2^4, \ldots, 2^{17}\}$, we conducted 100 simulation runs. Each run samples n bids and calculates the n empirical discount ratios. $\Delta_n^{average}$ is the average of the n individual discount ratios and Δ_n^{max} is the maximum over the n individual discount ratios. Each point in the graph is the average of 100 runs.

Figure 3 shows that $\Delta_n^{average}$ behaves almost identically for all tested distributions. In particular, as stated in the first part of Conjecture 2.6, $\Delta_n^{average}$ decreases linearly with the number of bids n and for all distributions, even those with an infinite and unbounded support size.

Figure 4 shows that Δ_n^{max} behaves differently for some of the tested distributions. For the uniform distribution, Δ_n^{max} decreases linearly with the number of bids, supporting the second part of Conjecture 2.6. The half normal distribution behaves similarly (even though it is not bounded). For the inverse distribution, Δ_n^{max} does not seem to decrease with the number of users, and we believe that this is in fact an example that supports the third part of Conjecture 2.6. The three Bitcoin distributions behave as follows: the log of the sum decreases the fastest, the square root of the sum decreases

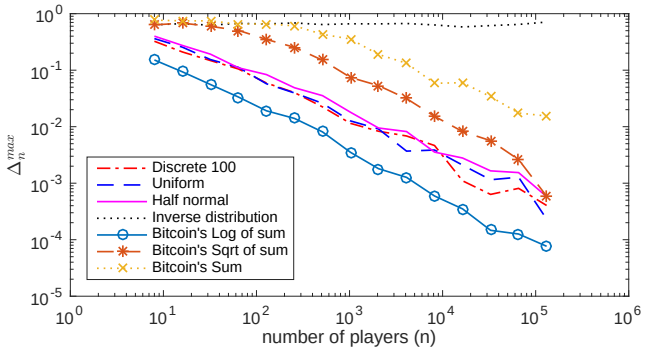

Figure 4: The maximal discount ratio of a player from selfish bidding as a function of the number of players.

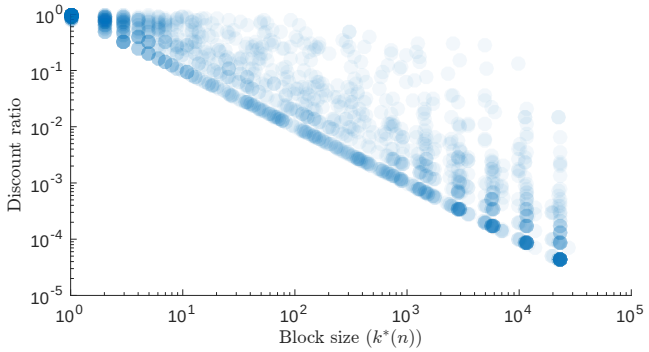

Figure 5: A scatter plot of all simulation points for the Bitcoin distribution with $v(x) = \log x$.

more slowly, and the sum decreases the slowest. For example, for $n = 2048$ (roughly the current Bitcoin block-size), Δ_n^{max} is about 0.2%, 5%, and 19% for the three distributions, respectively. When $n = 2^{17} \approx 130,000$, Δ_n^{max} is about 0.0007%, 0.05%, and 1%.

These findings show that there is a qualitative difference between $\Delta_n^{average}$ and Δ_n^{max}, mainly for the inverse distribution and for the Bitcoin distribution with $v(x) = x$. In these distributions, although the average transaction will benefit very little from bid shading, some transactions can nonetheless obtain significant benefit. This outcome can, in principle, result from two different reasons. The first is that $\Delta_n^{average}$ also accounts for the losing bidders, whose discount ratio is zero. The second is that Δ_n^{max} only accounts for the single winning bidder with the maximal discount ratio. However, typical bidder behavior (as demonstrated in Figure 2) shows that almost all winning bids have the lowest strategic price and, therefore, the highest discount ratio. Thus, the explanation for the difference between the two discount ratios seems to be the first.

Figure 5 shows all simulation points for the Bitcoin log of of sum distribubtion. The x-axis is the resulting *block size* of the simulation run (in the previous figures it was n) and the y-axis is the maximal discount ratio of the simulation run. Three main conclusions can be drawn from Figure 5. First, block sizes (number of winners) range from 1 to about 25,000 when $v(x) = \log x$ (recall that the total number of bids ranges from 2^3 to 2^{17}).[2] Second, this range in block sizes is the main reason why Δ_n^{max} is smaller in the Bitcoin log of the distribution of sums, as larger block sizes imply smaller discount factors. Third, the distribution of the simulation points, which include outliers, is not normal. We do not have an explanation for this finding. The last two remarks apply to all tested distributions.

5 SUMMARY AND CONCLUDING REMARKS

The simple pay-your-bid fee mechanism used in Bitcoin has several disadvantages: (i) A fixed (hard-coded) maximal block size implies non-optimal revenue extraction when the pre-fixed block-size is too small or too large for the current bid instance, (ii) Bitcoin wallets must invest computational effort in bid shading, and (iii) deciding on the maximal block size involves economic rather than purely technological considerations (e.g., block propagation time [7, 16]). For single block creation, the proposed monopolistic auction effectively solves all these issues while maintaining miner non-manipulability.

The monopolistic auction is ϵ-truthful (ϵ goes to zero as the number of bidders grows). Alternatively, we can take a truthful auction where a bidder cannot influence its winning price, e.g., the RSOP auction is truthful and its revenue $RSOP(\boldsymbol{v})$ satisfies $\lim_{n\to\infty} \max_{\boldsymbol{v}} \frac{R(\boldsymbol{v})}{RSOP(\boldsymbol{v})} = 1$ [8]. The full version describes an implementation in Bitcoin (e.g., the required randomness needs to be verified by other miners) and discusses major drawbacks of it. In light of these shortcomings, we believe that the monopolistic auction is better suited to implement improvements in Bitcoin's fee market.

Future Work. One important issue we did not cover is that of the temporal implications of patient users who are willing to wait for transactions to be included in future blocks, as in the current analysis we only address impatient users. The monopolistic auction can also be explored further via a careful equilibrium analysis. The astute reader may notice that the current model allows for an equilibrium in which all bidders bid 0, an unrealistic setting since in practice there exists a maximum limit on the block size, and not all transactions can be included in the block. We believe that in such a setting, no other meaningful equilibria exist other than truthfulness, which is an ϵ-BNE. To reach a definitive conclusion, however, a careful analysis is required.

6 ACKNOWLEDGMENTS

We thank Alaa Mozalbat, who designed and implemented the simulation code, and Reshef Meir for valuable discussions. R.L. was partly supported by a Marie-Curie fellowship "Advance-AGT", by an ARCHES award from the MINERVA foundation, and by the ISF-NSFC joint research program (grant No. 2560/17). O.S. was supported by ERC Grant 280157, by the Israel Science Foundation (grant 682/18), and by the Cyber Security Research Center at Ben-Gurion University. A.Z. was supported by the Israel Science Foundation (grant 616/13) and by a grant from the HUJI Cyber Security Research Center in conjunction with the Israel National Cyber Bureau (grant 039-9230).

[2]The throughput when $v(x) = \log x$ will therefore be about $0.1n$ (n is the number of all transactions). For $v(x) = x$, block sizes range from 1 to about 1,500, implying a throughput of about $0.01n$.

ABSTRACT

There is a growing concern about the extent to which algorithmic personalization limits people's exposure to diverse viewpoints, thereby creating "filter bubbles" or "echo chambers." Prior research on web search personalization has mainly reported location-based personalization of search results. In this paper, we investigate whether web search results are personalized based on a user's browsing history, which can be inferred by search engines via third-party tracking. Specifically, we develop a "sock puppet" auditing system in which a pair of fresh browser profiles, first, visits web pages that reflect divergent political discourses and, second, executes identical politically oriented Google News searches. Comparing the search results returned by Google News for distinctly trained browser profiles, we observe statistically significant personalization that tends to reinforce the presumed partisanship.

1 INTRODUCTION

When a person looks up information on a search engine, the search does not occur in a vacuum. Before any particular search is made, the person has already lived an active digital life—reading news stories, liking pages on online social media, and posting comments on blogs—activities that are tracked across the Web to train personalization algorithms. In the current divisive political climate [9], people might be more likely to access content online that conforms to their political ideologies, but little is known about whether accessing certain political content impacts personalization of other elements of a person's online life. In this paper, we ask: *If a person's digital life demonstrates a political bias, does that person receive personalized search results and do those search results reflect that person's bias?*

Researchers have long been concerned about the effect of selective exposure—seeking information that reinforces preexisting beliefs while avoiding other information—on democratic societies [38, 43]. Through selective exposure, people with biases seek out content that conforms with their preexisting beliefs. For example, selective exposure to conservative news is associated with support for strict immigration policies [44], and people who score high on a scale of modern racism are more likely to view non-traditional Internet sources as credible sources of news [26]. Researchers have recently started to question whether algorithms create distinct personalized experiences for users, leading to so-called "filter bubbles" or "echo chambers" [7, 19, 31]. Algorithms reflect the societies in which they are produced, so it is unsurprising that they are encoded with biases [13]. For example, personalization algorithms have been found to discriminate against women [11] and people of color [29].

While selective exposure requires deliberate acts of media choice, algorithmic personalization interprets past behavior as precedent for future preference. In other words, algorithmic personalization can intensify selective exposure beyond a person's choice, resulting in a vicious cycle that can contribute to an increasingly polarized society. According to Pew Research, Americans are more ideologically polarized now than at any point in the last two decades [9]. This increase in polarization coincides with the rise of search engines and social media sites as primary sources of information. Thus, it is important to study the role of personalization algorithms employed by search engines in reinforcing pre-existing biases.

Prior research has reported significant personalization in online advertising based on a user's browsing history. Personalization in online advertising [8, 11, 37, 41] is not surprising because behavioral targeting is its key design feature. To target ads, advertisers employ sophisticated online tracking techniques for profiling users' browsing habits across the Web [12]. Naturally, we would expect search engines to leverage browsing history information obtained by online tracking for search personalization as well. However, prior studies [16, 20, 42] have reported significant search personalization mainly based on location, not browsing history.

In this paper, we set out to study search personalization in Google News using a "sock puppet" auditing system [36] in which we use automated programs to impersonate users with different political ideologies. While controlling for other factors, we train a pair of fresh browser profiles by visiting websites that reflect pro-immigration and anti-immigration stances. We show that Google can infer browsing histories of our trained profiles through its pervasive online tracking network and can leverage it to personalize search results based on recent changes in its privacy policy [2, 6]. We then execute search queries on Google News related to a variety of political topics. We analyze the search results to quantify the magnitude and direction of personalization. While personalization varies depending on the search term, overall we are able to conclude that profiles trained by browsing websites reflecting distinct political positions indeed receive significant personalization that tends to reinforce the presumed partisanship.

We highlight the key contributions of our work as follows.

• **Methodology:** We expand on previous work (e.g., [15, 16]) by refining the sock puppet methodology for auditing algorithmic personalization. Our sock puppet system is designed to reflect the behavior of Twitter accounts with opposing political views. Specifically, we train browser profiles by visiting URLs extracted from the timelines of these Twitter accounts. We then search Google News simultaneously from the trained browser profiles using different search terms related to popular political issues such as immigration and foreign policy.

• **Findings:** Our comparative analysis of the search results returned by Google News provides evidence of personalization based on browsing history. Specifically, while personalization varies across different search terms, we note that the search terms receiving most personalization tend to get personalized results that reinforce the presumed partisanship. We believe that our findings are different from those reported in prior work on personalization in part because of our refined sock puppet system design.

Our work presents empirical evidence of political personalization on Google News based on browsing history. The results not only set the baseline for search personalization based on political biases in browsing history, but also contribute to the broader understanding of selective exposure and algorithmic personalization.

2 SOCK PUPPET AUDITING SYSTEM

The overarching goal of our study is to examine the extent to which a user's web browsing history affects algorithmic personalization in web search. We seek to understand both whether algorithmic personalization exists and whether it reinforces or dampens the preferences displayed in web browsing history. To this end, we design and implement a sock puppet auditing system to train fresh browser profiles by visiting hyperlinks that embody distinct political discourses and then compare Google News search results for identical politically oriented search terms. Figure 1 depicts the four main components of our system that are discussed below.

2.1 Identifying Partisan Hyperlinks

We aim to evaluate Google News personalization based on browsing histories that reflect different stances on the topic of immigration. We focus on immigration because it was a key campaign issue in the recent 2016 U.S. presidential election [5, 23]. Our goal was to find a list of websites that reflect pro- and anti-immigration stances in the context of U.S. politics. To this end, we rely on two popular Twitter accounts that reflect both discourse communities. Discourse communities are groups of people that come together, whether physically or virtually, for the purpose of building community through shared goals and forms of speech [39]. For the anti-immigration stance, we use @wginfonetorg, which belongs to a popular anti-immigrant website whitegenocide.info that is dedicated to "fighting the crime of white genocide." For the pro-immigration stance, we use @DefineAmerican, which belongs to a popular pro-immigrant website defineamerican.com that is dedicated to "shift the conversation about immigrants, identity, and citizenship in a changing America." Both of these Twitter accounts are very active and fairly popular. As listed in Table 1, @wginfonetorg has posted more than 63K tweets and has 9.4K followers while @DefineAmerican has posted more than 17K tweets and has 30.3K followers. Because both accounts frequently share content from other websites that support their respective views on immigration, we collected the hyperlinks posted on the timelines of these Twitter accounts over the duration of two weeks in March 2017. We treat these two sets of hyperlinks as representations of pro- and anti-immigration discourses.

Screen Name	Number of Favorites	Number of Followers	Number of Followings	Number of Tweets	Account Creation
@DefineAmerican	10,043	30,253	1,776	17,350	May 2011
@wginfonetorg	1,253	9,424	223	63,916	April 2014

Table 1: Statistics of pro-immigration and anti-immigration Twitter accounts.

2.2 Training Browser Profiles

Using the two sets of hyperlinks collected from pro- and anti-immigration Twitter accounts, we now train fresh browser profiles. Specifically, to train the pro-immigration browser profile, we install a fresh copy of Firefox web browser and open hyperlinks from the timeline of the pro-immigration Twitter account. Similarly, to train the anti-immigration browser profile, we install a fresh copy of Firefox web browser and open hyperlinks from the timeline of the anti-immigration Twitter account. We take several steps to imitate a real user during browser profile training. First, we limit the number of hyperlinks that we use for training per day to 50. To this end, we randomly sample a subset of 50 hyperlinks from the hyperlinks posted on the timelines of both Twitter accounts. Second, we add a random delay averaged at five minutes between opening consecutive hyperlinks during training. Finally, we conduct the training between 9 am and 11 pm local time to reflect diurnal user activity.

It is noteworthy that we do not create or log-in to a Firefox account during training because it can save bookmarks, passwords, browsing history, and cookie information. We also do not create or log-in to a Google account that may be used by Google to link our account information with browsing history. Therefore, the only way for Google to know about our browsing history during training would be via third-party tracking using its own advertising/analytics network (e.g., DoubleClick and Google Analytics) via cookies or browser fingerprinting [12, 24]. As discussed in related work, prior research has reported on the extensive third-party tracking capabilities of Google.

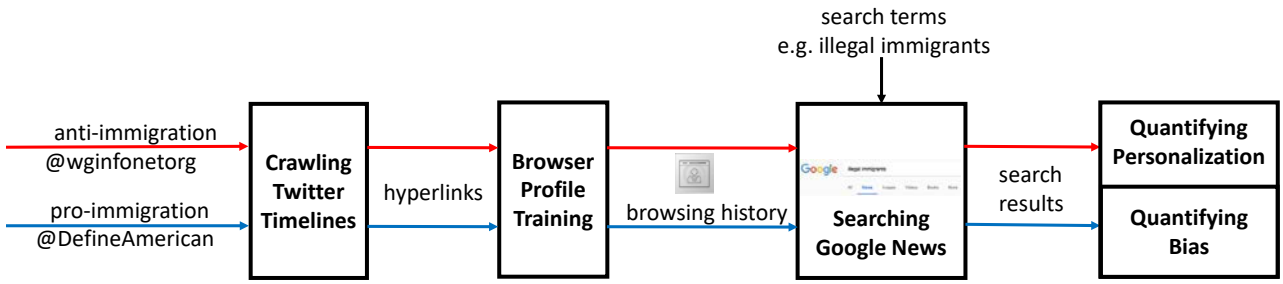

Figure 1: Our sock puppet auditing system to measure political personalization of Google News search.

Our analysis of the set of hyperlinks used for training browser profiles shows that pro-immigration training hyperlinks belong to more mainstream news outlets such as Washington Post while anti-immigration training hyperlinks belong to more alternative news sites such as Breitbart and user-generated content sites such as YouTube and WordPress. We find that several Google owned domains are top third-parties on these training hyperlinks. For example, doubleclick.net is the top third-party tracker on both anti- and pro-immigration training hyperlink sets. Thus, we conclude that Google is able to learn the browsing histories of our trained pro- and anti-immigration browser profiles and *can* later use it for personalization of search results.

2.3 Searching Google News

After training fresh browser profiles using hyperlinks crawled from pro- and anti-immigration Twitter accounts, we are set to conduct Google News searches. We are interested in testing if web browsing histories that reflect these divergent discourses would result in search personalization along politically partisan lines.[1] In other words, we want to test whether a user who consistently consumes anti-immigration content would receive more or less Republican-leaning news stories in the search results. We execute searches from three sets of browser profiles: (1) pro-immigration, (2) anti-immigration, and (3) control. The control browser profile, which is not trained (i.e., by visiting hyperlinks), provides us a "neutral" perspective to judge whether personalization occurs for pro- and/or anti-immigration profiles. We execute Google News searches using different search terms about a wide variety of political topics. We decide to search for news related to the top-10 most discussed policy issues on Twitter [23] during the 2016 U.S. presidential election campaign. We use five different search terms for each of these policy issues: Immigration, Foreign Policy, Healthcare, Economy, Abortion, Gay Rights, Gun Control, Climate Change, Education, and Veterans. For each search term, we repeat the search process every day over the duration of one week.

To ensure that the search results returned by Google are not impacted by anything other than the browsing histories, our search process is designed as follows. First, we use Selenium WebDriver [1] to automatically conduct searches using the Google News web interface instead of Google's search API. We configure Google News to return up to 100 search results. Second, we use a wait period of 11 minutes between consecutive searches to eliminate any carry-over effect [16]. Third, we conduct searches from pro-immigration, anti-immigration, and control browser profiles in a synchronized fashion to eliminate any temporal effects. Fourth, each browser profile conducts search queries on a separate Amazon EC2 cloud instance to avoid any interdependencies between different profiles.[2] Fifth, we use a static DNS entry for Google News to ensure that our search queries are routed to the same datacenter. Finally, to eliminate potential noise in search results due to A/B testing [30], we train four separate profiles for pro-immigration, anti-immigration, and control browser profiles. In the absence of A/B testing, we would expect the same search results for these four profiles. When there is A/B testing, we can mitigate its effect by eliminating search result differences. To this end, we compute the pairwise intersection of search results among the four profiles. We then use search results from a randomly selected profile from the pair with the maximum intersection.

2.4 Quantifying Search Personalization

We use trained browser profiles for both pro- and anti-immigration stances as well as a control browser profile to execute Google News searches. We can quantify personalization by comparing the presence and ranking of search results across different browser profiles. First, we quantify personalization simply in terms of the differences in search results. Let P and A respectively denote the lists of search results for the pro- and anti-immigration browser profiles. Let C denote the list of search results for the control browser profile. We can measure the differences in search results by comparing P, A, and C in a pairwise manner. To this end, let $P - A$ represent the set of unique search results for the pro-immigration profile that do not appear for the anti-immigration profile. Let $P - C$ and $A - C$ respectively represent the set of unique search results for the pro-immigration and anti-immigration profiles with respect to the control. We use $|P - A|$, $|P - C|$, and $|A - C|$ to quantify the differences in search results in the range of [0%,100%], where 0% indicates no personalized search results and 100% indicates all 100 search results are personalized. Note that since we get 100 search results for each search term, we have $|P| = |A| = 100$. In this case,

[1]Note that the extreme anti-immigration position of those concerned about white genocide are not wholly aligned with the Republican Party's nor are the political views of our pro-immigration profile identical to the Democratic Party platform.

[2]Note that while each Amazon cloud instance has a different IP address, they all belong to the same /24 IP prefix range geolocated in Oregon. Therefore, we do not expect any IP geolocation based search personalization as has been reported in prior work [16, 20].

the difference in search results is symmetric in terms of quantities (i.e. $|P - A| = |A - P|$) although it may be not be symmetric as the set (i.e. $P - A \neq A - P$). Second, we quantify personalization while taking into account the ranking of search results across different browser profiles. To this end, we measure edit distance among P, A, and C in a pairwise manner. Specifically, we compute the Damerau-Levenshtein distance [10] which represents the number of deletions, insertions, or substitutions needed to make a pair of lists identical. If two lists are identical, the edit distance is 0. The greater the edit distance, the more different the lists are in terms of their membership and ordering. Note that both the difference and edit distance are calculated based on search results as URLs and we do not consider title or text of these URLs.

In addition to quantifying personalization, we also analyze whether personalized search results reflect political bias. To assess political bias, we prefer automatic methods over manual coding because the latter are expensive and time consuming. Thus, we first try to use methods in prior literature [21, 22] that can automatically measure political bias of URLs by analyzing their sharing patterns on Twitter. Since these methods require a large number of tweets containing the news URLs, we cannot use them because very few of the personalized search results (URLs) are frequently tweeted. Therefore, we use mediabiasfactcheck.com which provides the political bias of 1,540 media sources (identified as domains) on a 5-point scale: left, left-center, center, right-center, and right [4]. For further quantification, we convert this 5-point scale to specific scores as: left = -100, left-center = -50, center = 0, right-center = 50, and right = 100. Note that mediabiasfactcheck.com provides the political bias for domains (e.g., nytimes.com) not URLs. Since we cannot automatically measure the political bias of personalized news URLs, we estimate their political bias using their domain's political bias from mediabiasfactcheck.com.

3 EVALUATION

Table 2 reports the personalization results quantified as pairwise difference and edit distance across pro-immigration (P), anti-immigration (A), and control (C) profiles.

In terms of difference, although it varies across different search terms, the average difference between pro-immigration and anti-immigration ($P - A$) is 3.2%, between pro-immigration and control ($P - C$) is 3.9%, and between anti-immigration and control ($A - C$) is 3.8%. Using the standard t-test, we are able to conclude that these average differences are significantly different from zero at 0.0001 significance level. The average edit distance between pro-immigration and anti-immigration is 8.4, between pro-immigration and control is 10.3, and between anti-immigration and control is 10.3. Using the standard t-test, we are again able to conclude that these edit distances are significantly different from zero at 0.0001 significance level. The edit distance values are higher than the difference because edit distance not only considers the difference in two lists of search results but also the changes in relative rankings of search results. Since difference and edit distance show the same trend in personalization across different search terms, we focus on the difference metric for discussion in the rest of this section.

To analyze personalization across different search terms, we sort search terms in Table 2 in descending order of $P - A$ values for each policy category. Note that the noise in search results due to A/B testing among four identical browser profiles for both pro- and anti-immigration is 0.5% on average. Thus, we focus our attention on search terms for which $P - A$ average difference exceeds 5% because it is at least an order of magnitude more than the average noise. A total of nine search terms meet this criterion: (1) comprehensive immigration reform, (2) uninsured Americans, (3) medicare for all, (4) national debt, (5) flat tax, (6) pro-life, (7) Paris climate agreement, (8) carbon footprint, and (9) support our veterans.

The comparison of pro-immigration versus anti-immigration and control profiles for these search terms reveals interesting insights.

Policies	Search Terms	Difference (%)			Edit Distance		
		$P-A$	$P-C$	$A-C$	$E(P,A)$	$E(P,C)$	$E(A,C)$

Table 2: Personalization (quantified using difference and edit distance) for 50 search terms. Note that $E(P,A)$, $E(P,C)$, and $E(A,C)$ are pairwise edit distance among pro-immigration, anti-immigration, and control profiles.

Top-k Search Results	Difference (%)			k-Edit Distance		
	$P-A$	$P-C$	$A-C$	$E(P,A)$	$E(P,C)$	$E(A,C)$
k = 10	2.3	2.4	2.7	5.7	5.7	6.7
k = 20	2.2	2.4	2.5	6.4	6.3	7.4
k = 30	2.4	2.5	2.7	6.6	7.3	8.0
k = 40	2.6	2.9	3.0	7.1	8.3	8.7
k = 50	2.7	3.2	3.1	7.5	8.9	9.1
k = 60	3.0	3.4	3.3	7.9	9.4	9.5
k = 70	3.2	3.7	3.6	8.3	9.9	9.9
k = 80	3.2	3.8	3.7	8.5	10.1	10.2
k = 90	3.3	3.8	3.7	8.6	10.2	10.2
k = 100	3.2	3.9	3.8	8.4	10.3	10.3

Table 3: Average personalization for all 50 search terms according to top-k (k∈{10,20,...,100}) ranked search results. We normalize edit distance (as k-edit distance) to make a fair comparison across different k values.

First, we observe that five of them (comprehensive immigration reform, uninsured Americans, national debt, Paris climate agreement, and support our veterans) also have high $P-C$ and $A-C$ differences. For example, national debt search term has 12.0% $P-A$ difference, 16.5% $P-C$ difference, and 12.2% $A-C$ difference. This shows that both pro- and anti-immigration profiles receive personalized search results that are different from each other as well as different from the control. Second, we observe that three of them (flat tax, medicare for all, and carbon footprint) have high $P-C$ difference but low $A-C$ difference. For example, flat tax search term has 6.7% $P-A$ difference, 6.2% $P-C$ difference, and 1.0% $A-C$ difference. This shows that the pro-immigration profile receives personalized search results that are different from both the control and anti-immigration profile. Third, we observe that only one of them (pro-life) has a high $A-C$ difference but low $P-C$ difference. Specifically, pro-life search term has 5.7% $P-A$ difference, 2.3% $P-C$ difference, and 4.0% $A-C$ difference. This shows that the anti-immigration profile receives personalized search results that are different from both the control and pro-immigration profile.

Note that there are search terms for which $P-A$ difference is not high (e.g., < 1.5%), but it does not necessarily mean that there is no personalization because their differences to control (both $P-C$ and $A-C$) may be high. This is because both pro- and anti-immigration profiles receive similar personalized search results with respect to the control so they are not much different from each other. For example, Benghazi search term has only 1.3% $P-A$ difference, but 5.7% $P-C$ difference and 6.0% $A-C$ difference.

Next, we study the rank of personalized search results to gauge whether they disproportionately appear at the top or bottom of the list of results. Table 3 reports the average personalization for all search terms based on the top-k (k∈{10,20,...,100}) search results. We note that average $P-A$ difference started at 2.3% for k=10, slightly increases for increasingly k values, and reaches 3.2% for k=100. We observe a similar trend for $P-C$ and $A-C$ differences as well as in terms of edit distance. Note that we normalize edit distance as k-edit distance (edit distance/k) for a fair comparison across different k values. Overall, while personalization slightly increases at bottom ranks, we conclude that personalization remains substantial for top ranked search results. Since personalization (in terms of both difference and edit distance) for several search terms exceeds the average by multiple factors, we gather that there exists significant personalization even in top-10 search results.

Search Terms	Political Bias		
	$B(P)$	$B(A)$	$B(P)-B(A)$
Carbon footprint	-30.0	10.0	-40.0
Comprehensive immigration reform	-35.3	-3.1	-32.2
Paris climate agreement	-23.3	-5.9	-17.4
Pro-life	36.1	52.8	-16.7
Support our veterans	14.3	25.0	-10.7
Uninsured Americans	-18.8	-10.9	-7.9
Flat tax	-4.5	-13.3	8.8
Medicare for all	-27.8	-37.0	9.2
National debt	11.5	-6.5	18.0
Average	-8.6	1.3	-9.9

Table 4: Political bias for nine top-personalized search terms. Note that $B(P)$, $B(A)$, and $B(P)-B(A)$ respectively are political bias of personalized search results for the pro-immigration and anti-immigration profiles, and the difference between their political bias. Table is sorted in ascending order of $B(P)-B(A)$ values. A negative $B(P)-B(A)$ value indicates the pro-immigration profile received more Democratic-leaning personalized search results, while a positive $B(P)-B(A)$ value indicates the pro-immigration profile received more Republican-leaning personalized search results.

We further analyze political bias of the personalized search results for the nine most personalized search terms in Table 2. Using mediabiasfactcheck.com, we are able to estimate the political bias of 373 news stories out of 792 (47%) personalized results for these nine most personalized search terms. Table 4 reports the average political bias of personalized search results for the pro- and anti-immigration profiles, and the difference between their political bias averages. The average political bias of pro-immigration profile is -8.6 which is Democratic-leaning and that of anti-immigration profile is 1.3 which is Republican-leaning (negative values represent Democratic-leaning and positive values represent Republican-leaning). In other words, the pro-immigration profile receives more Democratic-leaning personalized search results than that of the anti-immigration profile. We use the Kolmogorov-Smirnov test [25] to compare the political bias distributions of personalized search results for pro- and anti-immigration profiles. We are able to reject the null hypothesis that both distributions are the same at the 0.05 significance level. Thus, we conclude that the search terms receiving most personalization tend to get personalized results that reinforce the presumed partisanship. Note that political bias of personalized search results varies across different search terms. Personalization reinforces the presumed partisanship for six out of nine (carbon footprint, comprehensive immigration reform, Paris climate agreement, pro-life, support our veterans, and uninsured Americans) search terms that received most personalization. For the remaining search terms, it counters the presumed partisanship.

4 RELATED WORK

The most ubiquitous application of personalization is in online behavioral advertising, which targets users with personalized ads based on their browsing history. Several studies have reported personalization in online advertising [8, 11, 14, 41]. Researchers have also investigated personalization in terms of price steering and price discrimination on ecommerce sites [17, 27, 28, 40].

A long line of research has looked at web search personalization. Hannak et al. [16] examined several features such as browser user-agent, user's ethnicity, browsing history, and search query that Google can use to personalize search results. However, they only found significant personalization based on Google account login status and IP geolocation. In a follow-up [18], the author extended this study to Bing and DuckDuckGo. They found that, on average, 15.8% search results on Bing are different due to personalization based on the same features as on Google. They found no significant personalization on DuckDuckGo.

To further examine the role of location in triggering personalization, Xing et al. [42] used a browser extension called Bobble and reconfirmed that a user's location (inferred by geolocating IP addresses) is the most dominant trigger factor for personalization. Furthermore, Kliman-Silver et al. [20] examined the relationship between distance and location-based personalization, and the impact of location-based personalization on different types of queries. They found that the differences between search results grow as the physical distance between locations of the users increases.

Puschmann [32, 33] analyzed crowdsourced Google search results from approximately 4,000 users for 16 terms related to German political parties and candidates [3]. He found that search results are personalized primarily based on location, language, and time. He concluded that a small fraction of personalized search results, which could not be explained based on the aforementioned factors, may be trigged by latent (or non-observable) factors such as browsing history and Google account information that they did not collect from users.

Robertson et al. [35] audited personalization on Google Search by asking crowd workers to install a browser extension which collected Google search results for a variety of political search queries in standard and incognito modes. They found significant personalization based on Google account login status, self-reported usage of Google/Alphabet services such as YouTube, and self-reported rating of Trump but not self-reported political party affiliation. In a follow-up [34], the authors reported that personalized search results have minimal differences in terms of political bias.

While there is evidence of personalization in ads and ecommerce sites based on browsing history [8, 41], prior research has found Google search personalization primarily due to geolocation and account login status. In contrast to prior work, we believe that our sock puppet auditing system can help reveal the impact of browsing histories, which are explicitly designed to reflect different political ideologies, on search personalization.

5 DISCUSSION AND CONCLUSION

Overall, we observe significant personalization based solely on browsing history. The personalized results tend to reinforce the presumed partisanship of browser profiles that are trained by visiting web pages reflecting divergent political discourses. Our findings provide further empirical evidence for the underlying causes of filter bubbles or echo chambers. The explanation of why we found evidence of significant web search personalization while past work did not could be due to the following.

First, our research is different from prior work in terms of the methodology in training browser profiles. While previous work [15, 16] trained browser profiles to reflect different demographics, we trained browser profiles to reflect different political stances. Specifically, both Hannak et al. [16] and Haim et al. [15] trained browser profiles to represent different demographic groups such as gender, age, income, lifestyle, and ethnicity. In contrast, we trained browser profiles to explicitly reflect opposing views on the topic of immigration rather than different demographics. Specifically, we trained browser profiles using news stories posted by Twitter accounts who clearly demonstrated distinct political stances on the topic of immigration.

The second reason could be the difference in search terms that were used to test personalization. Prior literature reported that different search terms can trigger different magnitudes of personalization [16, 21]. Unlike previous work [15, 16, 35] which used search terms covering a variety of topics popular at the time, we used search terms related to the training topic of immigration. Specifically, Haim et al. [15] used general search terms such as "Germany". Hannak et. al. [16] used general search terms about topics such as news sources and literature. Robertson et al. [35] used general political search terms such as "US President." In contrast, after training browser profiles reflecting opposing views on the topic of immigration, we used immigration-related search terms such as "comprehensive immigration reform" and "illegal immigrants". We also used search terms about other relevant political topics [23] such as foreign policy.

Last but not least, the changing nature of Google's personalization algorithm could be another reason. Google is known to continuously tinker personalization algorithms as well as update their data sources over time. For example, Google changed its privacy policy in 2012 [2] and more recently in 2016 [6] allowing them to combine user data collected across all of its services (e.g., Search, Gmail, Google Analytics, DoubleClick) for targeted advertising and content personalization. Thus, Google can now more effectively personalize search results based on a user's browsing history inferred from its third-party analytics and tracking network. Since personalization algorithms are continuously being tweaked, we plan to longitudinally study personalization for different search terms over an extended period of time as part of our future work.

Prior work using controlled experiments as well as surveys of real users [15, 16, 32–35] has not found evidence of significant web search personalization based on browsing history. While simulating behaviors of real users completely will always be impossible, controlled experiments such as our sock puppet auditing system enable us to isolate the effect of different types of browsing history on search personalization. Thus, in this paper, we studied search personalization on Google News in a controlled setting by using browser profiles that were specifically trained to reflect strongly divergent opinions on the topic of immigration. Using this strategy, we find evidence of significant search personalization on Google News. This finding creates an opportunity to conduct further research on other factors that can trigger search personalization.

ABSTRACT

Modeling user behaviors as sequences provides critical advantages in predicting future user actions, such as predicting the next product to purchase or the next song to listen to, for personalized search and recommendation. Recently, recurrent neural networks (RNNs) have been adopted to leverage their power in modeling sequences. However, most of the previous RNN-based work suffers from the complex dependency problem, which may lose the integrity of highly correlated behaviors and may introduce noises derived from unrelated behaviors. In this paper, we propose to integrate a novel **Ti**me **S**lice **S**elf-**A**ttention (TiSSA) mechanism into RNNs for better modeling sequential user behaviors, which utilizes the time-interval-based gated recurrent units to exploit the temporal dimension when encoding user actions, and has a specially designed time slice hierarchical self-attention function to characterize both local and global dependency of user actions, while the final context-aware user representations can be used for downstream applications. We have performed experiments on a huge dataset collected from one of the largest e-commerce platforms in the world. Experimental results show that the proposed TiSSA achieves significant improvement over the state-of-the-art. TiSSA is also adopted in this large e-commerce platform, and the results of online A/B test further indicate its practical value.

1 INTRODUCTION

Due to the increasing abundance of information on the Web, helping users filter information according to their current intents/preferences is more and more required, which emphasizes the importance of personalized search and recommendation. Analogous to the assumption in natural language processing (NLP) that the topic of an article can be represented by the sequential words or sentences of the article [22], user's current intents/preferences can be captured by his/her sequential behaviors over the timeline. To model sequential user behaviors for downstream applications, recurrent neural network (RNN) has been considered [14, 26, 29], due to its remarkable performance on many sequential learning problems. For example, [26] endowed both users and movies with a long- and short-term memory (LSTM) to predict user's future behavioral trajectories. Despite a certain success of above RNN-based methods, modeling sequential user behaviors remains a challenging problem.

One issue is that long-term dependencies are still very hard to preserve while maintaining middle- and short-term user behaviors. Recent work has indicated that attention mechanism can help to achieve state-of-the-art performance on a large number of NLP and computer vision (CV) tasks, such as neural machine translation [1] and image captioning [13]. Attention mechanism introduced into deep networks provides the functionality to focus on portions of input data or features to fulfill the given task, which might bring benefits for the problem of complex dependencies within user historical behaviors.

However, previous work along this line for modeling sequential user behaviors has some limitations [16, 19, 28, 31]. Both of [16, 19] only considered the primary attention mechanisms, which need to be better designed. Furthermore, they employ the bi-directional RNN structure, which is quite complicated and makes it challenging to be parallelized in the real world. [28, 31] abandoned RNN structures and proposed the self-attention architecture instead for different type sequential user behaviors. Nevertheless, the sequence structure information is incomplete or even lost in the RNN-free framework, whereas RNN's autoregressive modeling can, in theory, capture potentially infinitely long-term sequence with a small number of parameters [3].

Another critical issue is that most of the previous work projects each user action into an individual embedding vector. However, user sequential behaviors are usually not consistent with action time and intents, which is hard to be distinguished and encoded [32]. Consequently, the single user action embedding is not always robust. In recent work, [20] demonstrated that taking session-level representations could have very different expressive power. Nevertheless, it is not still reasonable to divide sequential user behaviors according to fix-length time window or online session of users. Furthermore, the relationships among sessions are not considered in previous session-based related work [8, 9].

These two issues need to be optimized in advanced approaches and systems. In this paper, we propose a time slice self-attention approach and corresponding ranking system, called TiSSA, for modeling sequential user behaviors, which we currently use for the personalized recommendation. We first project user sequential behaviors into session-level representations by our proposed time-interval-based gated recurrent unit (GRU). Then we split these session-level representations into slices according to the multi-scale time window. The intra-slice self-attention is performed on each slice independently, to capture the local dependency within each slice. We further perform inter-slice self-attention for outputs of each slice to exploit the global dependency. Finally, a feature fusion gate combines the outputs of intra- and inter-slice self-attention to generate context-aware representations for the user. We perform vanilla attention between these context-aware representations and the ranking item vectors, whose outputs are fed into a ranking neural network for making recommendations. The effectiveness of our adapted approach and ranking system is evaluated in our offline and online experiments on Tmall[1].

2 BACKGROUND AND RELATED WORK

2.1 Gated Recurrent Units

A gated recurrent unit (GRU) was proposed by [5] to overcome drawbacks of normal RNNs, i.e., vanishing and exploding gradients. Specifically, the activation h_t of the GRU at time t is a linear interpolation between the previous activation h_{t-1} and the candidate activation $\tilde{h}_t$:

$$h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t \tag{1}$$

where $\odot$ is an element-wise multiplication, and an update gate z_t decides how much the unit updates its activation. The update gate is computed by

$$z_t = \sigma(W_z^{(1)} x_t + W_z^{(2)} h_{t-1}) \tag{2}$$

where x_t is input at time t, and σ is sigmoid function. The candidate activation $\tilde{h}_t$ is computed by

$$\tilde{h}_t = tanh(W_h^{(1)} x_t + W_h^{(2)} (r_t \odot h_{t-1})) \tag{3}$$

where r_t is a reset gate and computed by

$$r_t = \sigma(W_r^{(1)} x_t + W_r^{(2)} h_{t-1}) \tag{4}$$

In Eq. 2 - Eq. 4, weight parameters W_z^*, W_h^* and W_r^* connect different inputs and gates.

2.2 Attention Mechanism

Vanilla attention is introduced by [1] firstly in the encoder-decoder framework, to provide more accurate alignment for each position in the machine translation task. In particular, given token embeddings of a source sequence $\mathbf{x} = \{x_1, x_2, ..., x_n\} \in \mathcal{R}^{d \times n}$ and the vector of a query $q \in \mathcal{R}^d$, where d is the feature size of x_i and q, attention computes the alignment score between x_i and q by a function $f(x_i, q) \in \mathcal{R}$. A softmax function then transforms the scores $\{f(x_i, q)\}$ to a probability distribution $p(a|\mathbf{x}, q)$ by normalizing over all the n tokens of $\mathbf{x}$. Here a is an indicator of which token in $\mathbf{x}$ is important to q on specific task. Then the attention-based pooling can be formularized as $C = \sum_{i=1}^{n} p(a = i|\mathbf{x}, q) x_i \in \mathcal{R}^d$. In reality, additive attention is usually used, whose $f(x_i, q)$ is formulated as

$$f(x_i, q) = w^T \sigma(W^{(1)} x_i + W^{(2)} q) \tag{5}$$

where w is a weight vector to project additive function $\sigma(W^{(1)} x_i + W^{(2)} q)$ to a scalar.

Self-attentions are also studied in different mechanisms [25], which are very expressive and flexible for capturing inner-relations of the data at the encoder side. "Token2entirety" self-attention [12, 15] is one of widely used self-attention mechanism, which explores the importance between token x_i and the entire sequence $\mathbf{x}$, and compresses the sequence $\mathbf{x}$ into a vector. It removes q from Eq. 5 and adds bias term, i.e.,

$$f(x_i) = w^T \sigma(W^{(1)} x_i + b^{(1)}) + b^{(2)} \tag{6}$$

Recently, [23] further demonstrated the advantage of mask-style "token2token" self-attention mechanism, which explores the dependency between token x_i and token x_j from the same sequence $\mathbf{x}$, and generates context-aware coding for each element. At the same time, lots of work have shown that linear projections over multi-subspaces could improve the performance in various tasks [25, 31].

Another work related to our paper is hierarchical attention mechanism, which is also demonstrated as a practical design in CV/NLP tasks [17, 24, 27]. It is also a valid design for our problem, as it addresses the local and global dependency issue, which profoundly influences the accuracy of user intention summarization.

3 TWO PROPOSED IMPROVEMENTS

We propose two significant improvements to GRU structure and basic attention mechanism in this paper.

3.1 Time-GRU

Since GRU is originally designed for NLP tasks, there is no consideration of time intervals within inputs, which are very important for modeling sequential user behaviors. Furthermore, as discussed in Section 1, we argue that taking session-level inputs could have very different expressive power comparing to inputs of individual user behaviors (c.f. Section 5.4 for an in-depth analysis). Because that user behavior sessions are changing along time with the property of overlapping [7], the natural idea is to divide and embed user behaviors into sessions over behavior time smoothly. Inspired by some previous work with multi-timescale designs [18], we propose a time-interval-based GRU, called Time-GRU, to model user session-level representations. Specifically, we rewrite reset gate as a time-dependent format:

$$r_t = \sigma(W_r^{(1)} x_t + W_r^{(2)} h_{t-1} + W_r^{(3)} \triangle t_t + b_r) \tag{7}$$

Similarly, we have time-dependent update gate:

$$z_t = \sigma(W_z^{(1)} x_t + W_z^{(2)} h_{t-1} + W_z^{(3)} \triangle t_t + b_z) \tag{8}$$

In Eq. 7 and Eq. 8, $\triangle t_t \in \mathcal{R}$ is the time interval between adjacent actions, and b_* are bias terms. Our motivation is to utilize time interval information as a filter. In this way, the final activation h_t

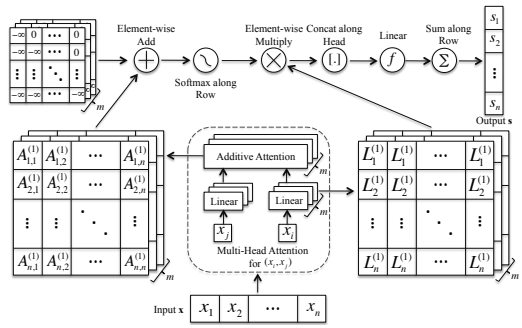

Figure 1: The proposed directional multi-head attention mechanism. Here, we use $A_{i,j}^{(k)}$ and $L_i^{(k)}$ to denote $head_{i,j}^{(k)} \in \mathcal{R}$ and $(x_i W_{ck}) \in \mathcal{R}^{d_c}$ in Eq. (9), respectively, where $k \in m$.

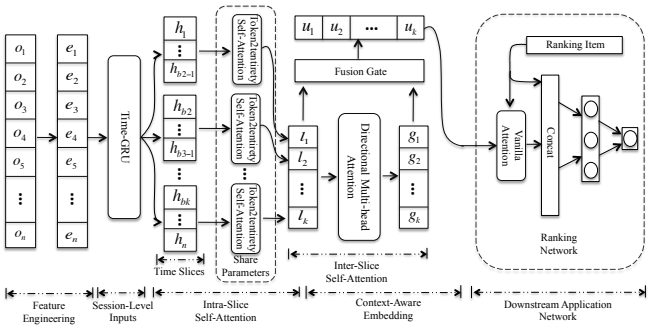

Figure 2: The proposed Time Slice Self-Attention approach and ranking system.

captures the session-level information by time t over changing time smoothly.

3.2 Directional Multi-Head Attention

Inspired by previous work [23, 31], we propose a new token2token self-attention mechanism to introduce the advantage of linear projections over multi-subspaces, which relates elements at directional positions from a single sequence by computing the multi-head attention [25] between each pair of tokens and generates context-aware coding for each $x_i \in \mathbf{x}$. In particular, as illustrated in Fig. 1, multi-head attention between each $x_i \in \mathbf{x}$ and $x_j \in \mathbf{x}$ is firstly computed. We linearly project x_i and x_j, which are both d-dimensional vectors, m times with different, learned linear projections to d_c and d_q dimensions, respectively. Then attention heads are computed. Specifically, for the k-th head of x_i and x_j, we have

$$head_{i,j}^{k} = w^T \sigma(W^{(1)}(x_i W_{ck}) + W^{(2)}(x_j W_{qk})) \tag{9}$$

where the projections are parameter matrices $W_{ck} \in \mathcal{R}^{d \times d_c}$, $W_{qk} \in \mathcal{R}^{d \times d_q}$, and $head_{i,j}^{k} \in \mathcal{R}, k \in m$. In practice, we set $d_c = d_q = d/m$. All attention heads are organized as a matrix $Rel \in \mathcal{R}^{n \times n \times m}$, whose each element is an attention scalar. Linear projections of x_i are organized as another matrix $Pro \in \mathcal{R}^{n \times n \times m}$, whose each row has the same element $(x_i W_{ck}) \in \mathcal{R}^{d_c}$.

In order to preserve temporality information in sequence, a directional mask matrix M with the same dimension with Rel is proposed,

$$M_{ij}^{k} = \begin{cases} 0, & i < j \\ -\infty, & otherwise \end{cases} \tag{10}$$

Given M and Rel, we perform an element-wise add operation, and follow a softmax normalization, each element of whose results is the attention weight for corresponding element in Pro. After weighting Pro with element-wise multiplication, matrix Pro is concatenated along attention heads as a new matrix with $n \times n$ dimensions, whose each element is a $(m \times d_c)$-dimentional vector and then projected to d-dimentional vector with a sharing learnable linear function. Finally, the projected matrix is summed along matrix row to generate token2token self-attention for all elements from $\mathbf{x}$, which is $\mathbf{s} = \{s_1, s_2, ...s_n\} \in \mathcal{R}^{d \times n}$ with the same dimensions with $\mathbf{x}$.

4 TIME SLICE SELF-ATTENTION APPROACH AND RANKING SYSTEM

A user can be represented as all his/her sequential behaviors $u = \{(o_i, t_i) | i = 1, 2, 3, ..., n\}$, where (o_i, t_i) indicates the interaction between user u and object o_i at timestamp t_i. For recommendation task, the objective of modeling sequential user behaviors is to predict the conditional probability of user's next action $p(o|u)$ for a certain given user u.

In the following of this section, we introduce our proposed time slice self-attention approach (TiSSA) and ranking system in detail, and the overall system is illustrated in Fig. 2. We divide the framework into several parts for a better description.

Feature Engineering. In our work, we take the user behavior object with deep and wide features as inputs, which is illustrated in Fig. 3. Each object o is represented by a multi-hot vector $o = \{v_1, v_2, ..., v_F\}$, where v_i indicates i-th one-hot feature such as ID-features and discretized statistical features. Following multi-hot vector inputs, behavior embedding layer transforms the multi-hot vector of o_i into a low-dimensional dense vector $e_i \in \mathcal{R}^{d_e}$ by linear mapping each feature of o_i, e.g., item id, to a dense vector and concatenating them. Note that, we enable embedding sharing when objects have features in common, e.g, item id and shop id, referring to the same entities. Then we have the behavior embedding vector for acted object o_i,

$$e_i = [W_{emb}^{(1)} v_1, W_{emb}^{(2)} v_2, ..., W_{emb}^{(F)} v_F] \tag{11}$$

where $[.]$ denotes concatenating operation and $W_{emb}^{(i)}$ is learnable embedding function parameters for i-th feature.

Session-Level Inputs. As discussed in Section 1 and 2, we prefer to employ session-level representations as inputs for better capacity. In particular, we put behavior embedding vectors $e \in \mathcal{R}^{d_e \times n}$ into our proposed Time-GRU sequentially, whose hidden states $\mathbf{h} \in \mathcal{R}^{d_h \times n}$ represent the session-level inputs. In Time-GRU, sessions of user behaviors are distinguished by time intervals smoothly.

Hierarchical Self-Attention. Since much previous work indicates that time information has substantial power in modeling user intents, we further divide session-level inputs $\mathbf{h}$ into k multi-scale time slices, which is proved as a simple yet efficient method (c.f. Section 5.4). Different user behavior platforms have different granularities of time slicing, which are hyper-parameters. After that,

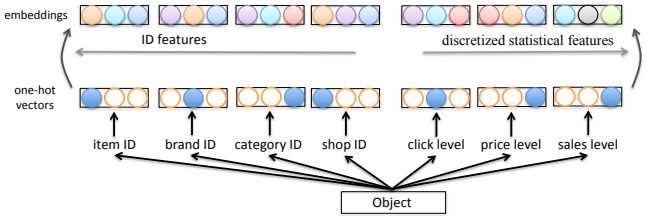

Figure 3: Feature engineering, which integrates both ID-features and statistical features.

we perform intra-slice and inter-slice self-attention hierarchically for modeling sequence dependencies at different levels.

Intra-Slice Self-Attention. We have two considerations for this level of self-attention. One is to project variable-length behaviors in different time slices into a fix-length encoding vector (zero-vector for empty time slice). The other is to capture the local dependency within a time slice. In particular, we employ token2entirety self-attention (c.f. Section 2.2) for this purpose, where shares all parameters in Eq. 6. Finally, local-context representations $\mathbf{l} = \{l_1, l_2, ..., l_k\} \in \mathcal{R}^{d_l \times k}$ at intra-slice level are generated by intra-slice self-attention, where k is the amount of time slices.

Inter-Slice Self-Attention. Another important challenging for modeling sequential user behaviors is to exploit the long-range global dependency among time slices. We perform our proposed directional multi-head self-attention (c.f. Section 3.2) after the intra-slice self-attention mechanism, which can not only capture dependencies but also preserve temporal orders. The outputs of inter-slice self-attention operation have the same dimension with inputs $\mathbf{l}$, which are denoted as $\mathbf{g} = \{g_1, g_2, ..., g_k\} \in \mathcal{R}^{d_g \times k}$.

Feature Fusion. The final context-aware representations $\mathbf{u} \in \mathcal{R}^{d_u \times k}$, where $d_u = d_g = d_l$, for each time slice is obtained by combining local and global context representations with a fusion gate. Motivated by the update processing of GRU, we design feature fusion gate as follows,

$$F = \sigma(W_F^{(1)}\mathbf{g} + W_F^{(2)}\mathbf{l} + b_F) \tag{12}$$

$$\mathbf{u} = F \odot \mathbf{l} + (1 - F) \odot \mathbf{g} \tag{13}$$

where W_F^* and b_F are learnable parameters.

Downstream Application Network. With generated context-aware representations, we can ensemble various kinds of neural networks according to downstream task requirement. In this paper, we focus on evaluating predictions of interactions within the user and items, and we set the downstream application network to be a point-wise ranking network. For each candidate item, its embedding vector q is calculated by the same embedding layer in our framework, and vanilla attention between $\mathbf{u}$ and q is performed to produce the attention pooling vector for the given user. After a concatenating operation and two fully connected layers, we have final sigmoid cross entropy loss function:

$$-\sum_{u,q} y_q \ log\, \sigma(f(u,q)) + (1 - y_q) \ log\, (1 - \sigma(f(u,q))) \tag{14}$$

where $y_q \in \{0, 1\}$ is the ground truth that indicates the user interacts the candidate item or not, and f is the downstream application network.

It is notable that feature engineering strategy can apply to many machine learning models where the designed features and ID-features exist. Time slice self-attention approach can be generalized to handle tasks involving sequential data with time intervals. The final context-aware representations can be further utilized by various downstream applications such as the clustering task.

5 EXPERIMENT

5.1 Offline Dataset

This huge dataset is real data and collected from Tmall, which describe the entire page viewed items and user feedbacks. Each instance contains user historical sequential clicked items with timestamps and the observed items currently. All items contain item id, category id, shop id, brand id and pre-designed discretized statistical features, including price level, sales level and click level. In our task, the target is to predict whether the user would have click/purchase behavior for each item in currently viewed items. 15 days user click-through behaviors are sampled for training, and we evaluate the data of the next day. Related statistics are shown in Table. 1.

5.2 Compared Approaches

We compared our proposed TiSSA approach and ranking system against several baselines from different aspects.

libFM. The task in this paper can also employ traditional recommendation methods that capture the content and collaborative information. In our work, we use the popular libFM model [21] as a representative of these methods.

Wide and Deep network (WD) [4]. This method only employs the wide and deep features of current items to construct deep neural network without consideration of sequential information.

Time-GRU. The method in [30] is employed, whose LSTM structure are replaced as our proposed Time-GRU in this paper because of the adoption of Time-GRU in our framework.

Time-GRU + Attention. A vanilla attention is added on top of Time-GRU method.

EDRec [16]. EDRec employs a bi-directional RNNs as an encoder for modeling user sequential behaviors and a traditional vanilla-attention-based RNN as a decoder to predict the user's next action.

ATRank[2] [31] and **SHAN** [28]. Two very recent state-of-the-art work on modeling user behaviors, which only utilize fully connected layer with specially designed attention mechanism. Both of them employ the same downstream application network and loss function with TiSSA.

Variant TiSSA. To justify each component in our proposed TiSSA approach, we separate out each component in TiSSA systematically, including TiSSA without RNNs (TiSSA w/o RNNs), TiSSA without Time Slices (TiSSA w/o TiS), TiSSA without Inter-Slice Self-Attention (TiSSA w/o Inter-SSA), TiSSA without multi-head attention (TiSSA w/o Multi-head) and TiSSA with Fix-Scale Time Slices (TiSSA w. Fix-TiS).

5.3 Implementations and Metrics

Our method and all compared approaches use common raw features as inputs, whose hyper-parameters are tuned on the validation

[2]https://github.com/jinze1994/ATRank

Table 1: Statistics of offline dataset. PV denotes page view. Avg. Len. and Med. Len. indicate average and median length of user historical sequential behaviors, respectively.

Data	Users	Items	Categories	Shops	Brand	PV	Avg. Len.	Med. Len.
Amount	62.6 M	27.5 M	10.6 K	0.18 M	0.16 M	1.2 B	85.8	46

set using random search [2]. All approaches are implemented on the TensorFlow machine learning system, utilizing 100 parameter servers and 2000 workers, each of which runs with 15 CPU cores.

For libFM, we extract tuples $\langle user_id, item_id, label \rangle$, where the label is 1 if the user has an action on the item and 0 otherwise. Then the multi-hot vectors of ID-features and discretized statistical features are concatenated to be $\mathbf{x}$ and the label is $\mathbf{y}$ in libFM. For other methods based on neural network, we have following settings.

Feature Engineering. All methods based on neural network employ the same feature embedding network (c.f. Section 4). All embeddings are randomly initialized with mean value 0.0 and standard deviation 1.0. We set the embedded dimension size of item IDs and category IDs, shop IDs, brand IDs as 64, 32, 32, 32, respectively. All discretized statistical features are embedded into 16 dimensions, which include click level, price level and sales level. All of these embedding dimensions result from tuning on the validation set.

Network Shape. All hidden states sizes in the RNNs structure are set to be 64. For variant TiSSA except for TiSSA w. Fix-TiS, we set time slices as $[0, 1)$, $[1, 2)$, $[2, 4)$, ..., $[2^7, +\infty)$ (#hour) based on the prior knowledge of the property of time decay, and set the amount of attention heads of inter-slice self-attention as 8 according to [25]. Time slices of TiSSA w. Fix-TiS are $[0, 2)$, $[2, 4)$, $[4, 6)$, ..., $[14, +\infty)$ (#day) for comparison. Sizes of remaining fully connected layers of all approaches are set to be 128, which also results from tuning on the validation set.

Batch Size. The batch size of all methods is set to be 512. All the batches in the data set are trained for two epochs.

Optimizer. We use AdaGrad [6] as the optimizer for all approaches. The initial learning rate is 0.01 for variant TiSSA, and 0.1 for rest approaches. The l_2-loss weight of regularization is set to 10^{-6} for RNN-based methods, and 5×10^{-5} for rest methods.

Note that, items embedding can be pre-computed and stored, and each hidden state of GRU only depends on the last one. In the inference procedure of real-world applications, TiSSA can save historical hidden states and employ parallel computing processes similar to RNN-free models, e.g., ATRank, after computing one GRU cell. Specifically, in our practical online large e-commerce platform, for one user and a batch of 3K items, TiSSA runs less than 50ms to give ranking results.

To measure the performance of each model, we follow the practice in [31]. Specifically, Area Under ROC Curve (AUC) is employed. The larger the value of AUC, the better the performance is.

5.4 Experimental Results on Offline Dataset

Firstly, we report the overall performance. Table. 2 shows the AUC results for measuring the performance of different methods. According to overall AUC results, we can observe that TiSSA achieves significant improvement than all other methods, which demonstrates the rationality of our motivations and the effectiveness of TiSSA approach on modeling sequential user behaviors, on the macro level. Next, we make some comparisons and summarize our findings as follows.

Table 2: Comparison results on offline dataset. Overall AUC denotes AUC for the entire dataset, while Long-Term AUC indicates AUC for users with more than 150 historical behaviors and 3 active days. Bold typeset indicates the best performance. The improvements from baselines to TiSSA is statistically significant according to two-tailed t-test ($p < 0.05$).

Method	Overall AUC	Long-Term AUC
libFM	0.696	0.695
WD	0.697	0.697
Time-GRU	0.702	0.698
Time-GRU + Attention	0.709	0.714
EDRec	0.709	0.711
ATRank	0.724	0.721
SHAN	0.714	0.711
TiSSA w/o RNNs	0.732	0.726
TiSSA w/o TiS	0.729	0.733
TiSSA w/o Inter-SSA	0.735	0.732
TiSSA w/o Multi-head	0.740	0.739
TiSSA w. Fix-TiS	0.737	0.738
TiSSA	**0.742**	**0.744**

Baselines libFM and WD captures content and collaborative filtering features at the same time but fails to capture the sequential information of user behaviors, while other methods capture all these information. This fact explains why libFM and WD perform worse than other models.

Due to the limitation of Time-GRU in modeling complex dependency, Time-GRU performs worse than Time-GRU + Attention and TiSSA, which reveals the benefits of attention mechanism. TiSSA w/o RNNs exhibits the improvement of overall AUC by a remarkable margin comparing to ATRank and SHAN. This result owes to the advantage that our proposed time slices hierarchical self-attention mechanism cannot only capture local dependency but the long-range global dependency of user historical behaviors efficiently. TiSSA, ATRank and SHAN outperform EDRec by a significant improvement indicate that special designed attention-mechanism brings much more benefits.

Comparing TiSSA to TiSSA w/o RNNs, TiSSA achieves improvements as much as 1.4% for AUC. As the only difference between

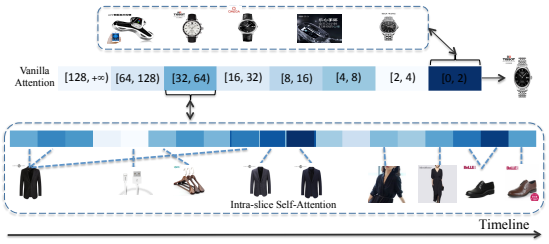

Figure 4: (Best view in color). Case study of making prediction on whether the user interacts with next item according to historical sequential behaviors. Deeper color in the heat map indicates higher attention weight.

them is whether taking session-level representations as inputs, this result validates the motivation of adoption of Time-GRU for transforming individual behaviors into session-level representations. In the comparison results of TiSSA w/o TiS, TiSSA w/o Inter-SSA and TiSSA, we demonstrate the effectiveness of the hierarchical self-attention designs. AUC declines when we remove multi-head attention in inter-slice attention mechanism. One explanation is that multi-head attention captures the relationship of inter-slice more detailed by projecting source token into multiple subspaces. Moreover, the result of TiSSA w. Fix-TiS is worse than TiSSA, which is consistent with previous studies on user behaviors on e-commerce websites [10], e.g., the property of time decay.

For the in-depth analysis of the problem of long- and short-term dependencies, we also report long-term AUC results in Table. 2, which relies heavily on the modeling of long- and short-term dependencies. The results show that TiSSA achieves the best performance against all other methods. We also observe that performances of methods without RNNs or attention mechanism drop a lot compared with overall AUC, which is reasonable for the advantage of RNNs + Attention framework at modeling long-term sequential data. Long-term AUC of TiSSA w/o Inter-SSA also drops due to the capacity of Inter-SSA for capturing long-range global dependency.

Table. 3 shows average attention scores for different time slices over all offline Dataset, which decrease with time generally except middle slices, e.g., [8, 16). It is because of the properties of user behaviors on e-commerce websites, such as time decay and cross-time dependency. Then we present a real case in Fig. 4. The middle heat map is attention scores for different time slices with target item (a mechanical watch), which is easy to understand the reason that [0, 2) slice has the highest attention score (the top line of Fig. 4). It is interesting to find that [32, 64) slice has the second high attention score. With in-depth analysis, we can find that the user has lots of interactions with formal wear at [32, 64) slice (the bottom line of Fig. 4), which is highly related to the target item and captured by our context-aware representations produced by TiSSA. Intra-slice self-attentions of [32, 64) slice are also shown in Fig. 4.

5.5 Online A/B Test on Tmall

Online test with real-world e-commerce users is carried out to study the effectiveness of our proposed method. In particular, we integrate TiSSA into the search engine of Tmall. A standard A/B test is conducted online [11]. Users of Tmall are randomly divided into multiple buckets, and we randomly select two buckets for experiments. For users in A bucket, we use the existing highly optimized ranking solution of Tmall search engine, which ensembles results from many powerful models. For users in B bucket, we further integrate the results produced by TiSSA. Specifically, for a given user, his/her context-aware representations are produced by TiSSA in real time according to collected sequential behaviors. All recall items of the search engine are preformed downstream application network in this paper and produced an interacting probability to attend existing online item ranking strategy, i.e., LTR. The test was performed within 12 days, and comparative results are given in Table. 4. It can be observed that our proposed TiSSA achieves 1.56% and 2.09% relative improvement for uCTR and uCVR than the baseline, respectively. We perform the statistical test and the resulting p-values for uCTR and uCVR are 9.1×10^{-12} and 0.0414, respectively, both less than 0.05. Thus, we think the improvement is significant. Such improvements are significant for Tmall search engine systems and have significant business value. Furthermore, the key metric to optimize in Tmall, i.e. GMV (Gross Merchandise Volume), has an improvement of 3.66%. Considering the traffic of Tmall, it would result in a significant boost in revenue. TiSSA has been adopted into the search engine of Tmall.

6 CONCLUSION

In this paper, we propose a time slice hierarchical self-attention approach to generate user context-aware representations for modeling sequential user behaviors called TiSSA, which captures both local and long-range global dependency of user actions. We also propose a Time-GRU structure to produce session-level inputs for better robustness and a directional multi-head attention. The empirical evaluations on a huge dataset collected from the real world for prediction of user interaction task show that our proposed approach can be the new state-of-the-art solution for related tasks. The ablation analyses on the separate parts of our TiSSA demonstrate the importance of each proposed component in our model. Results of online A/B test on Tmall search engine further demonstrate its practical value.

ABSTRACT

Music listening is a commonplace activity that has transformed as users engage with online streaming platforms. When presented with anytime, anywhere access to a vast catalog of music, users face challenges in searching for what they want to hear. We propose that users who engage in domain-specific search (e.g., music search) have different information-seeking needs than in general search. Using a mixed-method approach that combines a large-scale user survey with behavior data analyses, we describe the construct of search mindset on a leading online streaming music platform and then investigate two types of search mindsets: focused, where a user is looking for one thing in particular, and non-focused, where a user is open to different results. Our results reveal that searches in the music domain are more likely to be focused than non-focused. In addition, users' behavior (e.g., clicks, streams, querying, etc.) on a music search system is influenced by their search mindset. Finally, we propose design implications for music search systems to best support their users.

CCS CONCEPTS

• **Information systems → Users and interactive retrieval**.

1 INTRODUCTION

Music listening has long been recognized as an important part of everyday life. As proposed by Merriam in 1964, *"... There is probably no other human cultural activity which is so all-pervasive and which reaches into, shapes and often controls so much of human behavior"*[32]. Over the past few decades, there has been a shift in how people access and consume music. Advances in technologies have enabled listeners to move from physical storage devices (e.g., cassettes or CDs) to digital storage through computers or mobile devices. Currently, supported by online music streaming services and platforms (e.g., Apple, Spotify), music consumption is even more pervasive than ever before – people can access millions of songs almost anywhere at anytime through a variety of modalities[39].

However, the ability to access vast amounts of music can contribute to information overload for users. While an abundance of content is available for consumption, only a small amount is actually relevant to users and their desired listening goals. Although music streaming platforms provide strategies to guide and recommend users to discover relevant music through personalization[12, 31], search remains an important way for users to find music.

Prior research in general web search categorized search activities into two broad categories: lookup and exploratory[30]. Lookup searches have well-defined information needs in the searcher's mind, whereas exploratory searches usually involve an open-ended, persistent and multi-faceted information seeking problem[48]. In addition, researchers have observed that lookup searches can be different than exploratory searches in terms of users' search activities, behaviors and strategies[1]. Because the user's information needs and goals can differ on whether or not that search is exploratory, search systems that fulfill lookup searches well may not perform as well when users want to engage in exploratory search[48].

However, we have little knowledge on whether this holds true for searches within the music domain since information needs for music listeners are specific and can be different than general web searchers. The most common reason of seeking music was to "listen for entertainment[25]". In addition, people who consume music are driven by their emotional, social, and cognitive needs[16], which suggests that user goals in music search may be driven by broader needs than those described by [6] and [40]. In a recent qualitative study of music search on an online music streaming platform, researchers identified the existence of distinct music search **mindsets** – focused, open and exploratory[17]. Results suggested that

users searching with a focused mindset had a particular item in mind. In an open mindset, users had a seed of an idea in mind while searching. The exploratory mindset described users who employed search to learn more deeply about music.

In this mixed-method study, our goal is to characterize and distinguish between focused mindsets and non-focused mindsets to validate the findings from prior qualitative research[11] and identify associated behavior patterns at a large scale. We choose to collapse mindsets into two categories as users could distinguish actions and behaviors for focused mindset searches clearly [11]. First, we design a pop-up survey to collect users' mindset in real-time when they approach a music search. To further observe how mindset influences search behavior, we analyzed the surveyed users' behavior as they continued to use the platform. Specifically, our study answers the following three research questions:

RQ1: How does music search mindset vary among users?
RQ2: How does users' search behavior differ between mindsets?
RQ3: Can we infer users' mindset based on their behavioral signals when they interact with the music streaming platform?

Our research extends the previous literature in the general search domain and provides a novel contribution by studying the music search mindset. We found that music search mindset can depend on users' music preference and influence user behavior and activities in variety of ways. These behavioral signals can then be used to infer the search mindset. Altogether, our study provides insights for music as well as other content discovery and consumption services to best support their users when they approach a search.

2 RELATED WORK

Categorization of general search activities. Research in general web search have put considerable effort into understanding and characterizing the needs and goals of users. Search activity has been categorized as navigational (e.g., finding the URL of a desired web page) , informational (e.g., learning something from a web search) and transactional (e.g., performing a desired activity) [6, 40]. Beyond user goals, search behavior is influenced by factors such as the perceived task complexity and knowledge of the user[2, 27–29]. Liu et al.[29] found that web search behaviors, such as task completion time, number of different search engines used, and queries issued are all affected by the complexity and the preciseness of the search goal. Aula et al.[2] found that when tasks become more difficult, users issued numerous search queries, viewed many results, and spent more time on search result pages. Because these goals are meant to characterize general web search, they are broader in nature and describe user motivations that may not be consistent with how music listeners approach search.

Examples of domain-specific search. Music search is a type of a domain-specific search where user goals and needs may differ from general web search. Bainbridge et al. [3] found that users express their music needs in variety ways, ranging from bibliographic queries, genre and lyrics. Laplante and Downie [24] distinguish between hedonic and utilitarian outcomes in music information seeking. For utilitarian outcomes, users are looking for something to listen to or hoping to gain information about music.

Another example of domain-specific search is product search. Although product search has similar search categories as web search (browsing vs. directed search)[41], the shoppers' decision-making process is different[26]. Recent studies focus on using behavioral data to improve the search experience to better align with shoppers' needs. Wu et al.[49] used implicit feedback to identify two stages of searching: comparing search result pages and deciding to purchase on description pages. Researchers from Pinterest have revealed that goal specificity (e.g., visiting a web site for a specific goal) and temporal range (e.g., when the user envisions the goal will be achieved) influence user intent[10]. Su et al. [47] determined three types of product search intents in a commercial product search engine that also range in specificity and focus.

Prior work in describing information needs in product search suggests that there is a value in differentiating between general web search and more targeted domain-specific search, such as music. In this paper, we describe the particular information seeking behavior of music listeners when they either have something specific they want to consume, or they are more open to suggestion.

The role of music in society. Scholars from various disciplines have long studied the origin and purposes of music and why people listen to music. In general, scholars agree on the fundamental function that music provides for humans – to produce pleasure[46] and pass the time[18]. One line of research focuses on the broad impact of music on culture and society, referring music as a medium with multiple social and cultural benefits[4, 18, 32, 33, 36]. Other studies focus on the ways in which people use music in their everyday lives [43–45].

User characteristics influencing music consumption. Research has suggested that the behavior of people interacting with music can be shaped by listener's individual differences such as age[9, 34], gender[5, 9, 23, 34], culture [37], personality traits[8, 9, 13], and musical preferences [15, 42–44]. Studies also demonstrate that music listening is context-dependent and influenced by the situations (e.g., where and when). Researchers have observed that music listening predominantly occurs at home, while driving, or while using public transport [14, 22, 35]. Krause et al. [22] found that the intensity of the consequences of music listening varies across listening locations. The time of day or the day of the week when music listening occurs is also important – music is more likely to help people concentrate during the workday (8:00 a.m. – 4:59 p.m.) than during the evening (5:00 – 11:00 p.m.)[35, 38].

In sum, as music serves different functions for society and individuals, our study intends to extend prior work on general web search to examine search in the music domain.

3 RESEARCH PLATFORM

We conduct our study on Spotify, a widely used music streaming platform available on mobile devices. Search is a prominent feature on this platform and it requires users to type into a search bar located at the top of the screen. Currently, the feature relies on an instant search system, which updates the search engine results page (SERP) with each keystroke. The SERP itself features a single top result displayed prominently at the top. For some artist or genre searches, the SERP features a carousel of relevant playlists that users can scroll through horizontally underneath the top result. Other relevant results follow, clustered according to entity type in the following order: songs, artists, podcasts, albums, playlists, podcast

Table 1: Feature definitions

User features		
Demographics	Gender/Age	User's self report gender (female or male) and age
Engagement	Account age	The total days as a user of the platform
	Days active	The total days active
Music Preference	Music discovery rate	The percentage of novel tracks listened to by the user in the past month.
Session features		
Session context	Time of the day	Day parts include: early morning, morning, noon, afternoon, evening, night
	Weekend	Weekdays or weekends (Saturday and Sunday)
Session length	Session duration	Time duration from start until the end of the focal session (in seconds)
Session switching activities	Number of switching activities	Number of times the user switches between behavior types (e.g., keystrokes, clicks, streams, etc.)
Activity features		
Query	Query edit distance	Max edit distance [20] of the queries issued in the focal session.
	Final query length	Number of characters of the final query issued in the focal user session.
	Query keystroke shape	Query shapes (D, B, L, and Γ patterns) [7] for all search queries issued in the focal user session.
Searching	Search duration	Time spent engaging in search activity (in seconds)
	Number of searches	Number of searches conducted within the focal session
	Number of addition/deletion	Number of characters typed/deleted
Clicking and Streaming	Time to first click	Time (in seconds) spent from the start of the session to the first click
	Rank of the first/last click	Rank position of the first/last click
	Entity type of the first/last click	Entity type: playlist, track, album, artist, and others
	Music stream	Whether the current user session includes a music stream longer than 30 seconds

episodes, and user profiles. In addition, users are able to click on a context menu for each song result, where they can take actions such as saving the song, adding to playlist, sharing, or viewing the album/artist.

4 SURVEY DESIGN AND DATA COLLECTION

4.1 Survey Design and Usability Test

Our survey design is guided by usability tests. We ran the tests with 10 users (4 internal employees and 6 external participants) to ensure that we understood a) whether our survey was able to capture respondents' mindset with fidelity; b) how respondents would interpret and answer the questions; c) how the survey triggering process could possibly impact users' subsequent experience. To qualify for the usability study, participants needed to be Android mobile phone users and had to have searched on Spotify at least 3 times in the week before our study. Participants ranged in age from 21 to 39, and included six females and four males. External participants in the usability study received a $50 gift card.

We conducted face-to-face, 30 minute usability tests combined with semi-structured interviews with each of the participants. The entire study included three phases: warm-up, search tasks, and post-interview. We began the study with a warm-up phase by discussing participants' music taste and habits in general and then narrowed the conversation to focus on search in the platform. In the search tasks phase, participants were asked to recall their most recent searches under three different scenarios: a general search (any recent search), a non-focused mindset search (open-ended music needs), and a focused mindset search (specific music needs). For each scenario, we asked participants to provide details and walk us through their search process using an Android mobile phone that we provided. The survey was triggered when participants navigated to the search page. During each task, we observed participants' reaction and recorded their responses. We followed up by asking the questions "What do the survey question/response options mean to you?" and "How did you decide your answer?' After completing the tests, we concluded the study with a brief interview to understand the participants' overall experience with the survey and the triggering process. We wanted to ensure that surveying the user's mindset was reasonable, and the process was not overly disruptive nor changed user's subsequent experience.

We designed the survey to have only one multiple-choice question because we wanted to minimize the interruption of the pop-up survey and allow users to continue their desired behavior as quickly as possible. The survey question and the response options intended to capture the current mindset of users while searching. We tested different versions of the survey question and response options, and we updated the design based on the results of the usability test.

After several rounds of feedback, the final survey design included the question: "Do you know what exactly you want to find?" Response options included *"Yes. I am looking for one thing"* to capture the users' **focused** mindset, and *"No. I am open to suggestions"* to capture the users' **non-focused** mindset. Users could also opt-out from the survey at anytime by clicking the "DISMISS" button. Based on our usability tests, this version best captured the users' search mindset. For this final version, study participants reported that the survey question and selections are "clear and answerable." In addition, they reported that the final version would not change their subsequent experiences in using the platform. In terms of the triggering process, users reported that the "it would be annoying if this happens on my phone every time...one time would be OK though." We therefore decided that the survey would only be triggered once in a user's lifetime on the platform.

We sent out the surveys in three waves to 50,000 Android users in the United States during the month of July 2018. To qualify for the survey, users had to have searched at least 3 times on Spotify in the week before we sent out the survey. We chose this cutoff to make sure that users had encountered the search feature prior to receiving the survey. To minimize the coverage bias, we used random sampling and controlled for the product type – free users and subscription users were equally likely to receive the survey.

4.2 Survey Responses and Observational Data

User Session. The second component of our methodology captured users' behavioral data when they interact with the search platform. As users interact with the search platform, the system records a constant stream of search event logs. User sessions are then segmented: each user session begins with a keystroke where the user types something in the search bar, and it ends if the user is idle for more than 10 minutes[19]. We summarize each user session using three general sets of features to describe: the users who conduct a search, the search session and its context, and the user activities in the session. Informed by the prior research in Section 2, we construct the three categories of features for each user session: user features, session features and activity features (see Table 1).

Survey Responses and User Sessions. The survey remained live for two weeks for data collection during the month of July 2018. In the end, 16% of the surveyed users triggered the survey, and 27% of them responded the survey. In total, 2,234 users responded to the survey and generated 27,504 user sessions within the two weeks.

To understand how the users' behavior is associated with different search mindsets, we focus on the search activities in the *first user session* immediately following the survey response time. As some users responded to the survey without searching for anything within 10 minutes, we excluded those user responses. In total, we had 1,779 survey responses that we were able to associate with a user session. We refer this set of session data for 1,779 unique users as the *labeled dataset*. The median time interval from the survey response time to the start of the first search activity is 3.6 seconds. We refer to the rest of 25,725 user sessions without a mindset label as the *unlabeled dataset*. User search sessions have a median time duration of 23.7 seconds and the median number of searches is two.

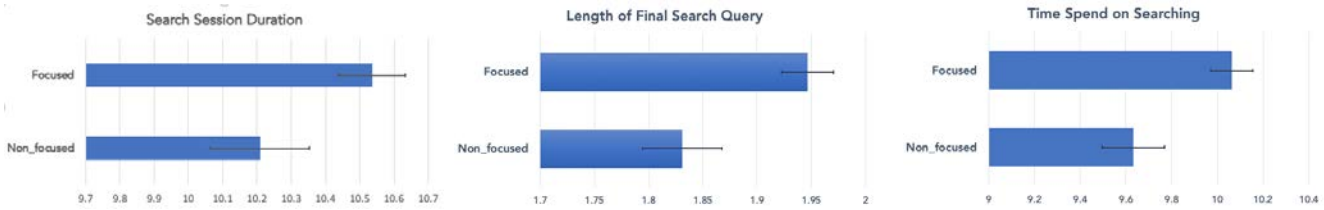
5 ANALYSES AND RESULTS

In this section, we address our three research questions. We used the *labeled dataset* to discover the patterns associated with the different music search mindsets and then utilized the *unlabeled dataset* to validate those patterns at scale. To answer RQ3, we built a supervised machine learning model based on the features in Section 4.2.

RQ1: Music searches are more likely to be focused, and the search mindsets depend on user's personal music preference.

From the survey responses, we observed that music search mindsets vary across users. Our data indicated that users are more likely to have a focused mindset when they approach a search: 65% of the survey responses indicated focused searches. In addition, we performed a regression analysis to assess the main effects of the user features described in Table 1 to their search mindsets. The regression analysis was conducted with each user session as the unit of analysis with the search mindset as a binary dependent variable and user features as independent variables. Overall, there is a significant effect of user's *Music Discovery Rate* (Wald χ^2=4.039, df=1. Sig.<.05). Users who discovered more novel music tracks within the past month are associated with an increased likelihood (β = 0.635) to search with a non-focused mindset. We found no significant effects of user gender, account age, and days active on the search mindset.

RQ2: Users' searching, clicking and streaming behavior differ between focused vs. non-focused mindsets.



Sessions. Our second analysis focused on assessing each mindset's relationship to the search session features in terms of the session context, the duration and the number of switching activities. We conducted a regression analysis with the search mindset as a binary dependent variable and session features as independent variables. The analysis was conducted with each user session as the unit of analysis nested within the user gender, to account for the non-independence of sessions among users with the same gender. We include other user features (i.e. user age, account age, active, discovery rate) in the model as control variables. The results demonstrate a significant association between the session duration and mindset (Wald χ^2=4.049, df=1. Sig.<.05): search sessions with the focused mindset tend to last longer (β = 0.037) than the search sessions with the non-focused mindset (Figure 1a). There exists no significant effects of the search context on the mindsets: user search mindset does not vary by time of day or day of week.

Activities. To evaluate if user activities differ between search mindsets, we conducted three regression analyses to assess the relationships between search mindset and queries, search behavior, and clicking and streaming activities. These analyses were conducted separately to avoid the effect of multicollinearity. All the regression analyses modeled search mindset as a binary dependent variable, and each analysis included the query features, searching features, and clicking/streaming features separately as independent variables. The analyses have each user session as the unit of analysis nested within the user gender and session context, to account for the non-independence of sessions among users with the same gender and searching at the same time. We included other user and session features as control variables.

Query: We found that there are significant associations between search mindset and querying behavior. Features including query length (Wald χ^2=3.885, df=1. Sig.<.05) and keystroke patterns (Wald χ^2= 4.850, df=3. Sig.<.05) have significant effects. Specifically, users search with focused mindset tend to issue longer queries using more characters (β = 0.151) than the queries issued by non-focused mindset search (Figure 1b). In addition, users searching with focused mindset are less likely to issue D-shape[7] queries (β = -0.132) compared to non-focused mindset.

Searching: Users' search activities in terms of the search duration (Wald χ^2= 9.507, df=1. Sig.<.01) and the total number of characters the user typed (Wald χ^2= 6.888, df=1. Sig.<.01) significantly differ between search mindsets. Specifically, users who search with a focused mindset tend to spend a longer time while searching (β = 0.171) and have more total number of characters added (β = 0.148) than those users with a non-focused mindset. Figure 1c illustrates the estimated mean of time spent for search under each mindset.

Clicking: Users' clicking behaviors, such as time to the first click (Wald χ^2= 4.677, df=1. Sig.<.05), rank of the first click (Wald χ^2= 11.842, df=1. Sig.<.001), entity type of the first click (Wald χ^2= 15.211, df=4. Sig.<.01) and last click (Wald χ^2= 16.649, df=4. Sig.<.001), differ significantly between search mindsets. Users searching with a focused mindset tend to spend more time before their first click (β = 0.023). The first clicked entity by users with a focused mindset tend to have larger rank positions (β = .141), which suggest that they tend to scroll down and click on a lower ranked entity. In

(a) Mean of session duration (in seconds) for focused searches vs. non-focused searches

(b) Mean of final search query length issued by focused vs. non-focused searches

(c) Mean of time (in seconds) spent on search for focused vs. non-focused searches

Figure 1: RQ2: Users' behavior differs between mindsets

terms of their clicked entity type, we observed that the non-focused mindset searchers are more likely to click on a playlist compared with other types of entities such as tracks, albums, or artists. A playlist can be generated by editors based on certain topics or popularity, by algorithms based on the personalized recommendation, or even by other users. Therefore, it may contain a more diverse set of musics favored by the users who search with a non-focused mindset.

Streaming: We found that focused mindset search sessions are less likely to involve a music streaming (Wald χ^2= 3.165, df=1. Sig.=.075, β = -0.045) directly after a search, but they are more likely to have clicks on the Context Menu button (Wald χ^2= 3.223, df=1. Sig.=.073, β = 0.093) – this button is one step before users saving search results to their personal music repository. However, the two observations are marginally significant with small effect sizes.

Unsupervised clustering validates the patterns at scale. So far, we have identified a set of behavior patterns using the labeled dataset. Next, we validate the patterns at scale based on the clustering analysis of the larger unlabeled dataset and interpreting each cluster. We ran K-means clustering, and used the "elbow test" to set the optimized number of clusters (k)[21].

We report the results of our clustering analysis in Figure 2. Figure 2 is a column-standardized heatmap of the cluster centers for six groups with respect to the features. We found that the clusters reflect the behavior patterns described in Section 5, which correspond to focused and non-focused search sessions. Specifically, the user sessions from cluster 6 have a longer search duration and time to first click. Users from this cluster had more keystrokes, issued long queries, scrolled down and clicked on the lower-ranked entities. They used the context-menu button frequently, but engaged less with music streaming and playlist clicks. We interpret this cluster as the "**focused mindset**." In contrast, the user sessions from cluster 5 had shorter search duration and time to first click. Users from these search sessions used fewer keystrokes and issued short queries, but they clicked on playlists more frequently. This cluster includes user sessions whose behavior patterns correspond closely to the patterns identified for the **non-focused mindset**.

Interestingly, the clustering results suggest that the search mindset may be related to user goals, which is consistent with the findings from the prior work about user goals[17]. User sessions from clusters 2 and 4 spent more time searching, querying and music

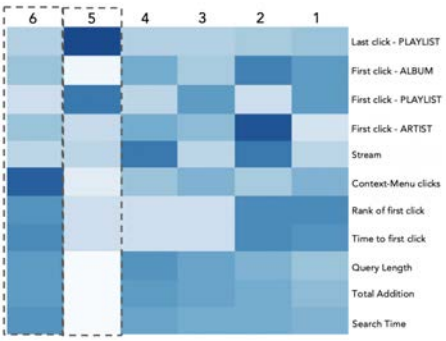


Figure 2: Clustering heatmap: 5 & 6 represent the non-focused and focused mindset session cluster respectively

streaming, suggesting that user goals in these clusters may be listening. However, these two clusters presented behaviors (e.g. time to first click, rank of clicked entities, clicked entity type) associated with different mindsets. User sessions from cluster 2 demonstrate the behavior patterns corresponding to a focused mindset – users engaged a longer time before the first click, clicked on lower ranked entities, and clicked on artists and albums frequently, whereas user sessions from cluster 4 follow the behavior patterns that we observed for the non-focused mindset.

RQ3: Search mindset can be inferred from lower-level user behavioral signals.

So far, we have described how music search mindset is associated with different behavior patterns. However, is it possible to use these behavioral signals to infer users' search mindset? Such information would be useful in adjusting the user interface and search results to better serve users based on their needs. In this section, we answer our third research question by building predictive models.

We utilized the features proposed in Section 4.2 and consider the following two prediction tasks: 1) how is the prediction power improved by adding behavior features chronologically throughout the session, and 2) after we have observed all the features within a session, can we predict whether the search mindset was focused or non-focused? As different features can be observed in chronological order during the user session, these two tasks can not only indicate how well we can infer the search mindset, but can also suggest how quickly we can infer search mindset. For example, user features and session context features are available before the start of a user

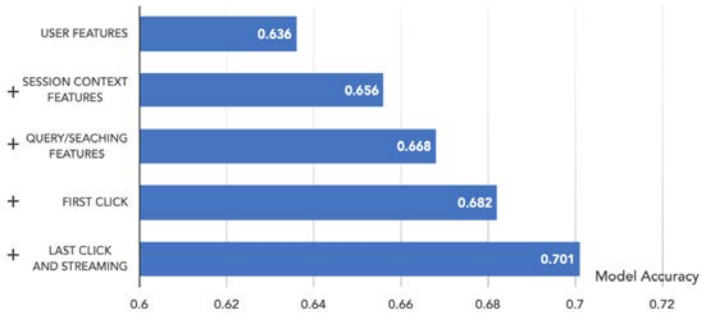

Figure 3: Model performance improved by adding features

session, but we can only obtain the clicking and streaming features at the end of the user session.

We implemented several supervised machine learning models to predict the search mindset for a user session using the labeled dataset as ground truth. As the dataset is unbalanced with majority user sessions having a focused mindset, a random guess would achieve classification accuracy of a 65% in predicting focused mindset. We trained our model by adding class weights to consider for the unbalanced data. We used logistic regression as a baseline model, and three separate models using bagging, boosting and random forest ensemble methods on a decision tree classifier to improve the model performance. We split the dataset to have 70% training data and 30% test data. We conducted a three-fold cross validation on the training data to find the optimized parameters for the model and applied the trained model into the test dataset. We report our model performance using accuracy, precision, recall, and F1 score.

Overall, our results demonstrate the potential to infer music search mindset based on our proposed user session features. Figure 3 demonstrates the improvement of the model predictive power by adding features based on the approximate chronological order that they can be observed throughout the user session. By including all the features, the model is able to predict the focused mindset with an accuracy rate of 70.1% (F1 = 0.806, Recall = 0.917, Precision = 0.718), a significant improvement of accuracy rate from both the random condition and the baseline model.But, when we only include the user and session context features in the model, the predictive power is quite low (65.6%) and the user's music discovery rate is still the most individually predictive feature. This result also indicates that it can be very challenging to predict search mindset at the session start. But the model's predictive power improves by including more user activities. Specifically, by adding features from search and query activities that occur in the early stage of a user session, the model performance improves to 66.8% accuracy. Eventually, by adding features extracted from users' clicking and streaming activities that occur in the late stage of a user session, the model performance achieves its best performance.

6 DISCUSSION AND CONCLUSION

Our results demonstrate that users' behaviors differ between search mindsets during search sessions. Specifically, users expend more effort while conducting **focused mindset** searches: they issue longer search queries, spend a longer time searching and a longer time to first click. In addition, they scroll further down the search result list and click on lower-ranked entities. They tend not to listen and stream these search results directly after the search, but are more willing to add the search results into their saved music library immediately after the search. Users searching with a **non-focused mindset** tend to put in less effort but rely more on the system for good search results and suggestions. For these users, their queries are shorter; they spend less time on searching and before their first click; but they are more willing to click on the very first entity the system returned, and those clicked entities are more likely to be a playlist. Finally, based on supervised machine learning techniques, we used these discovered behavioral patterns to recover a user's music search mindset in a user session.

These insights provide opportunities for content discovery and consumption services broadly (e.g., YouTube or Netflix) to develop strategies to better serve their users when they approach a search. Although it may be very challenging to infer search mindset at the very beginning of the search session, users' past music or content discovery preferences can provide a baseline estimation of what the search mindset for the current session is likely to be. As users' activities and behavior signals increase chronologically, the search system and interface can be adjusted at real-time to accommodate for the specific needs of distinct user mindsets. For focused mindset searches, the system should provide support that reduces users' searching and querying efforts, such as query auto-completion tools. To address non-focused mindset searches, the system can offer additional content recommendations, as these users rely more on the system for search results and music suggestions. For example, music streaming services can prioritize showing the playlists for non-focused mindset searches while showing the specific and targeted content (e.g., music track or album) for focused mindset searches.

Several limitations exist in the current study. First, the survey triggered only once per user's lifetime, so our labeled dataset includes only one session per user. As users' previous search sessions can also impact their current search session, we can potentially include that information when inferring searching mindset. Second, mindset may change over time. We partially mitigate this issue: we survey user mindset immediately before the beginning of the session and consider only the first user session, which tends to be relatively short with a median time duration of 23.7 seconds. Future studies can investigate whether and how the user's search mindset would change over time. Third, while we sought to present a broad overview of search behaviors and activities associated with two types of mindsets, our results from the clustering analysis suggest that user goals in searching music can also play a role. Future work can more deeply investigate the role of user goals as they differ across types of mindsets. Finally, as our data consists of Android users on one specific music streaming platform within one country over two weeks, future work can reproduce the current study by collecting more data with from a broader set of users across different content streaming systems for a longer time period to validate generalizability across platforms.

ABSTRACT

Search engine users always endeavor to formulate proper search queries during online search. To help users accurately express their information need during search, search engines are equipped with query suggestions to refine users' follow-up search queries. The success of a query suggestion system counts on whether we can understand and model user search intent accurately. In this work, we propose Click Feedback-Aware Network (*CFAN*) to provide feedback-aware query suggestions. In addition to modeling sequential search queries issued by a user, *CFAN* also considers user clicks on previous suggested queries as the user feedback. These clicked suggestions, together with the issued search query sequence, jointly capture the underlying search intent of users. In addition, we explicitly focus on improving the robustness of the query suggestion system through adversarial training. Adversarial examples are introduced into the training of the query suggestion system, which not only improves the robustness of system to nuisance perturbations, but also enhances the generalization performance for original training data. Extensive experiments are conducted on a recent real search engine log. The experimental results demonstrate that the proposed method, *CFAN*, outperforms competitive baseline methods across various situations on the task of query suggestion.

1 INTRODUCTION

The effectiveness of keyword-based search engines depends largely on the ability of a user to formulate expressive search queries. Expressive search queries clearly and unambiguously describe users' search intents and bring users directly to the desired information. In practice, translating human thoughts into concise sets of keywords to form queries is never straightforward [2]. This is particularly true for search engine users, who are mostly untrained casual users. In many cases, casual users have very limited background knowledge about the information they are searching for. To assist users in formulating queries, modern search engines are equipped with query suggestions [5, 16, 17, 20]. Given a user query, a query suggestion system deduces the search intent of the user by recommending a set of queries that are more expressive than the original user input. Our goal is to investigate the key concerns of existing query suggestion systems and to propose a novel approach to improve the suggestion performance.

Web search queries are usually very short, typically with only one or two keywords each [13, 24]. Short queries lead to the ambiguity issue. The ambiguity weakens the expressiveness of queries because the search engine may not understand the users' hidden search intents. This results in poor rankings of retrieval results and jeopardizes user experiences consequently.

A successful query suggestion system depends on understanding and modeling user search intents accurately. The user search intents lie in interactions, i.e., searches and clicks, between users and search engines. These interactions are generally partitioned into groups to form search sessions based on the time when they happened. Each search session is driven by consecutive related search queries and clicks of search engine users. In a search session, a user refines his/her original query and submits a sequence of follow-up queries to pinpoint his/her information need. Between two issued queries, the user may also click suggested queries to explore. The issued queries, together with the clicks, jointly allow us to accurately understand users' hidden search intents and come up with appropriate queries as suggestions. Unfortunately, most existing works merely consider clicked suggestions as feedback when modeling user search intents.

To conduct feedback-aware query suggestions, we mine search logs. A search log contains historical records, each of which registers the details of a web search conducted by a user. Table 1 shows some sample records extracted from the search log of a real search engine. Each record includes a query string, an anonymous user ID by whom the query was formulated, query submission time, the

Table 1: Sample search log records

UserID	Query String	Time	Clicked Suggestion	Suggested Queries
A	apple	2018-07-01 09:10:01	apple stock	apple store, **apple stock**, apple.com, apple iphone xs max
				apple id, itunes, icloud, google maps
A	apple price	2018-07-01 09:11:03	apple price per share	apple price targets, iphone apple price, **apple price per share**, apple
				apple fruit price, apple stock price, does apple price match, apple price today
B	disney	2018-07-03 12:12:02	disney cartoons	walt disney world, disney world tickets, disney world, disney experience
				disney orlando, **disney cartoons**, disney store, disney junior
B	disney shows	2018-07-03 12:22:20	disney channel cartoons	disney shows list, disney xd shows, disney tv shows, popular disney shows
				disney channel cartoons, list of disney tv series, 2018 disney channel shows

query suggestion subsequently clicked by the user (if done), and the suggested queries shown on the search page with the clicked ones highlighted in bold. The sample records show two search sessions. In the first session, user A first submitted query "apple" to the search engine, and then clicked the second query suggestion "apple stock" in the suggestion list. After that, the user issued the second query "apple price", and clicked the suggestion "apple price per share". The second search session involved a different user, B. S/he started searching with the query "disney", and then clicked "disney cartoons" in the suggestion list. He/she continued the search with the query "disney shows" and clicked "disney channel cartoons" subsequently. From the first search session, we can see that the clicked suggestion "apple stock", as feedback of the user, compensates for the ambiguity of the second issued query "apple price". It provides us with extra information to infer the underlying search intent of the user, which is to know the stock price of Apple instead of the price of Apple electronic products, such Apple iPhone. The clicked suggestion "disney cartoons" in the second search session also implicitly indicates that the user was interested in disney cartoons shows when the user search for "disney shows". These observations motivate us to include user feedback when modeling the search intents of search engine users.

Various research works have been carried out to tackle the task of query suggestion. Among them, neural network based models have made impressive progress over the past few years [7, 20, 25]. Deep neural network models mimic the learning process of human brains. Training these neural network models generally requires a large amount of training data to achieve excellent performance. However, for search related tasks, search queries involved are very sparse, and generally follow a long-tail distribution. Thus, those tail queries, with low probabilities in the data distribution, lack abundant training supports. In addition, the suggested queries are highly relevant to each other in most cases because they are all related to the search query in semantics. Distinguishing suggestions to be clicked from the ones that won't be clicked and ranking them take extreme efforts. Therefore, there tends to be a great performance gap between training and test. The trained model can be very sensitive to unseen perturbed queries. This is because queries are very short and a subtle perturbation on a query can lead to different or even the opposite search intent. In general, human perception and cognition are robust to a vast range of nuisance perturbations. However, neural networks are currently far from achieving the same level of tolerance of such perturbations [21]. This motivates us to investigate the robustness property of modern query suggestion systems and propose an appropriate method to achieve high tolerance.

Before we proceed to describe the details of the proposed approach, we enumerate the key properties that a good query suggestion system should observe:

- **[Context-Awareness]** The recommender should be aware of the sequential search queries issued by the user. These sequential queries implicitly inform the search intent of the user.
- **[Feedback-Awareness]** The recommender should also be aware of user clicks. User clicks, as an additional information source, can potentially reduce query ambiguities and allow us to understand user search intent comprehensively and more accurately.
- **[Robustness]** The recommender should increase the generalization of the original training data and improve the resistance to nuisance perturbations to the extent as extreme as possible. This reduces the performance gap between training and test, and provides favorable rankings of suggestions robustly.

2 RELATED WORK

Deep neural networks have been applied to many prediction and recommendation tasks successfully [11, 26, 27]. It also demonstrated excellent performances in query suggestion tasks [7, 15, 20, 25]. HRED [20], as the first study, employs a hierarchical encoder-decoder model to achieve context-aware query suggestion. [7] introduces the copy mechanism in addition to employing the encoder-decoder framework to generate suggested queries. [25] employs a feedback memory network to model titles of user clicked URLs. Reformulation inference network (RIN), proposed in [15], explicitly incorporates query reformulations during training.

Our work differs from the above neural network based works in that previously user clicked suggestions are explicitly incorporated as feedback. In addition, adversarial examples [6, 8] are dynamically constructed during the training of *CFAN*, which not only significantly improve the robustness of the model but also dramatically enhance the generic ranking performance.

3 PROBLEM STATEMENT

In this section, we formally define the objective of this paper. A search sequence S, represented as a sequence of search queries $<Q_1^S, Q_2^S, ..., Q_{M_1}^S>$, is submitted successively by a single user within a time interval. Each query in the search query is associated with corresponding click-through information (if happens), which is a set of clicked suggestions for that query. A clicked suggestion sequence C, $<Q_1^C, Q_2^C, ..., Q_{M_2}^C>$, is formed by ordering the clicked suggestions increasingly by the time the clicks happens. The goal of

this paper is: Given a set of candidate queries $\boldsymbol{Q}_{\text{can}}$, we would like to generate a ranking of candidates, with each candidate $Q_{\text{can}} \in \boldsymbol{Q}_{\text{can}}$, so that the ones to be clicked rank as high as possible.

4 METHODOLOGY

In this section, we discuss how to make query suggestions based on the search and click interactions between users and search engines. To achieve effective and efficient query suggestions, we decompose the task into two components. First, based on the search query, we generate a set of relevant queries as suggestion candidates. These suggestion candidates are informative to cover different interpretations and aspects of the search query. Second, we rank the suggestion candidates based user's entire search query sequence and clicked feedback. Only the top ones are selected and shown to the user as query suggestions.

4.1 Candidate Generation

Given a search query Q, the candidate generation component is responsible for constructing an informative set of expressive queries $\boldsymbol{Q}_{\text{can}}$ as suggestion candidates. An expressive suggestion candidate clearly and unambiguously describes the search intent of the user. An informative set of suggestion candidates are queries, that are diversified to cover different interpretations and aspects of the search query.

To generate such diversified informative and expressive suggestion candidates, multiple sources can be incorporated, such as search sessions and contextual information in search logs, related keywords from trending news, etc. In this work, we incorporate two sources based on the search log. The first source generates suggestion candidates based on query dependencies in search sessions. Given a search query, the follow-up search queries in the same search session tend to be more expressive and informative. Therefore they are adopted as suggestion candidates. Another source for candidate generation is based on prefix matching between the search query and historical search queries in the search log.

After generating suggestion candidates, the candidates are further ranked based on a combination of statistical features, i.e., the total number of submissions within last week, last month, and last year. Only top suggestion candidates are kept for further ranking in the candidate ranking component (see Section 4.2), while others are filtered out. The purpose of filtering out these less frequent suggestion candidates is to not only generate popular and fresh candidates, but also guarantee that recommendation services respond in real time. In a nutshell, given an input query Q, the candidate generation component returns a set of relevant queries as suggestion candidates.

4.2 Candidate Ranking

In this section, we discuss how we rank the suggestion candidates by mining the historical interactions between users and search engines. To better explain the ranking process, we first discuss the construction of training instances. Then, we go into details on how to utilize these instances to train *CFAN*.

Training instances are constructed from the historical search logs. Each instance contains a sequence of user issued queries S, a sequence of user clicked queries C, and a candidate suggested query Q_{can}. Two types of instances are constructed, i.e., positive instances and negative instances, denoted as Ins^+ and Ins^-, respectively. A positive instance is constructed if S and C jointly lead to the click of Q subsequently, while a negative instance is constructed if a query $\tilde{Q}$ is not clicked after S and C. In particular, to generate strong negative instances, only query $\tilde{Q}$, shown together with Q after searching the last query in S, is considered as a candidate query in the construction of negative instances. Positive instances Ins^+ and negative instances Ins^- jointly define the overall matching and ranking performance among a search query sequence S, a clicked suggestion sequence C, and a set of suggestion candidates $\boldsymbol{Q}_{\text{can}}$. We further define such a set of Ins^+ and Ins^- as a training view, denoted as V.

The clicks in the constructed training views allow us to tap into the wisdom of the crowds and provide a more favorable ranking of suggestions when running into the same or similar search and click scenarios. Given such scenarios, we expect the previously clicked suggestions rank ahead of those unclicked ones. To achieve this goal, Equation 1 shows the ranking loss function in *CFAN* over one training view V.

$$\text{Loss}_{\text{ranking}}(\Theta) = -\log\left(1 + \frac{\sum\limits_{\mathbf{ins}^+ \in V} g_\Theta(\mathbf{ins}^+)}{\sum\limits_{\mathbf{ins}^+ \in V} g_\Theta(\mathbf{ins}^+) + \sum\limits_{\mathbf{ins}^- \in V} g_\Theta(\mathbf{ins}^-)}\right), \tag{1}$$

where Θ is a set of parameters defining the ranking model, and $g_\Theta(\mathbf{ins})$ is a scoring function, which gives the ranking score of an instance. We use $\mathbf{ins}/\mathbf{ins}^+/\mathbf{ins}^-$ to represent the embedding of a general/positive/negative instance, respectively. By minimizing Equation 1 over all training views, $g_\Theta(\mathbf{ins}^+)$ is trained to have a high ranking score for clicked suggestions, while for unclicked suggestions, $g_\Theta(\mathbf{ins}^-)$ is trained to have a low score.

4.2.1 Search Intent Encoder. As we mentioned in the introduction, a user's search queries and clicked queries jointly help pinpoint his/her information need. A good search intent encoder is expected to incorporate both of them when modeling search intents. Note that both user search queries and clicked queries are inherently a sequence of queries; therefore, we first discuss how to model a single query through a query encoder. Then, we move on to the discussion of sequential query modeling through a query sequence encoder.

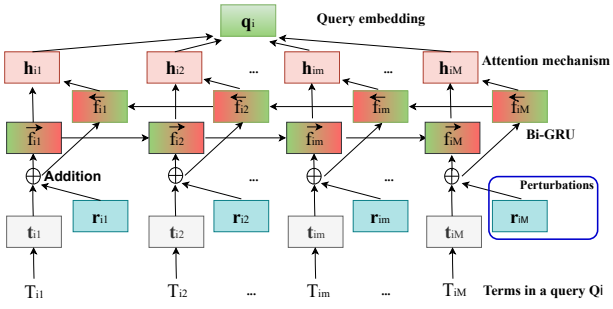

Figure 1: Query encoder with perturbed embeddings.

[Query Encoder.] Generally, queries contain different numbers of terms. In addition, different terms in a query contribute unequally

to the meaning of the query. For example, to search for the height of Barack Obama, users may formulate queries such as "how tall is Barack Obama", "height of Barack Obama", or even "Obama height". These three queries contain five, four, and two terms, respectively. Consider term importance in the first query, "tall", "Barack", and "Obama", these three terms, contribute more to understand the search intent of the query than the other terms, i.e., "how" and "is", which are generally less informative. In this work, we apply bidirectional GRU [18] and attention mechanism [22] to derive embeddings for a query Q.

Figure 1 shows the architecture of the query encoder. Given a query Q_i, composed of a sequence of terms $<T_{i1}, ..., T_{im}, ..., T_{iM}>$, where M is the number of terms in Q_i, we first embed each term T_{im} to an vector $\boldsymbol{t}_{im}$ through an embedding matrix as shown in Equation 2. To train robust models, adversarial examples are introduced by adding perturbed embeddings $\boldsymbol{r}$ into $\boldsymbol{t}$ (See more details in Section 4.2.3). We then use a bidirectional GRU to get the query embedding by summarizing information from both directions for terms in a query. The bidirectional GRU contains a forward GRU $\overrightarrow{f}$ which reads query Q_i from T_{i1} to T_{iM} and a backward GRU $\overleftarrow{f}$ which reads from T_{iM} to T_{i1}:

$$\boldsymbol{t}_{im} = Emb_t(T_{im}), m \in [1, M]. \tag{2}$$

$$\overrightarrow{\boldsymbol{f}}_{im} = \overrightarrow{GRU}(\boldsymbol{t}_{im}), m \in [1, M]. \tag{3}$$

$$\overleftarrow{\boldsymbol{f}}_{im} = \overleftarrow{GRU}(\boldsymbol{t}_{im}), m \in [M, 1]. \tag{4}$$

We obtain a representation $\boldsymbol{h}_{im}$ for each term T_{im} in query Q_i by concatenating the forward hidden state $\overrightarrow{\boldsymbol{h}}_{im}$ and backward hidden state $\overleftarrow{\boldsymbol{h}}_{im}$, i.e., $\boldsymbol{h}_{im} = [\overrightarrow{\boldsymbol{h}}_{im}; \overleftarrow{\boldsymbol{h}}_{im}]$, which summarizes the information of the whole query but centered around term T_{im}.

Since not all terms in a query contribute equally to the search intent embedded in the search query, attention mechanism is applied to extract such informative contributing terms and aggregate the embeddings of these terms to construct a query vector.

$$u_{im} = tanh(\boldsymbol{W}_w \boldsymbol{h}_{im} + b_w). \tag{5}$$

$$\alpha_{im} = \frac{\exp(u_{im}^T u_w)}{\sum_m \exp(u_{im}^T u_w)}. \tag{6}$$

$$\boldsymbol{q}_i = \sum_m \alpha_{im} \boldsymbol{h}_{im}. \tag{7}$$

Equations 5, 6, and 7 show the attention process on the query term level. The term embedding $\boldsymbol{h}_{im}$ is first fed into a one-layer MLP to get u_{im}. Then, u_{im} is further used to derive the normalized importance weight α_{im} through a softmax function. Finally, the query vector $\boldsymbol{q}_i$ is computed as a weighted sum of the term embeddings based on the weights.

[Query Sequence Encoder.] A query sequence is composed of a sequence of queries $<Q1, ...,Q_i, ..., Q_N>$, where N is the number of queries in the sequence. Both user search queries and clicked queries are essentially query sequences. Given a query sequence $<Q1, ...,Q_i, ..., Q_N>$, the query sequence encoder is expected to encode the hidden search intent in it. Similar to the structure of query encoder, the query sequence encoder contains a bidirectional GRU layer and an attention layer. The differences are two-fold. First, the query sequence encoder takes query embeddings as inputs. Second, there are no perturbations in query sequence encoder. Formally, a bidirectional GRU is first applied to encode the query sequence:

$$\overrightarrow{\boldsymbol{f}}_i = \overrightarrow{GRU}(\boldsymbol{q}_i), i \in [1, N], \tag{8}$$

$$\overrightarrow{\boldsymbol{f}}_i = \overleftarrow{GRU}(\boldsymbol{q}_i), i \in [N, 1], \tag{9}$$

The representation of a query Q_i in the sequence is constructed by concatenating $\overrightarrow{\boldsymbol{f}}_i$ and $\overrightarrow{\boldsymbol{f}}_i$, i.e., $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i]$. $\boldsymbol{h}_i$ summarizes the neighbor queries around query Q_i but still focus on the meaning of query Q_i.

To reward queries that pinpoint the search intent of the user, query level attention mechanism is applied.

$$u_i = tanh(\boldsymbol{W}_s \boldsymbol{h}_i + b_s). \tag{10}$$

$$\alpha_i = \frac{\exp(u_i^T u_s)}{\sum_i \exp(u_i^T u_s)}. \tag{11}$$

$$\boldsymbol{s} = \sum_i \alpha_i \boldsymbol{h}_i. \tag{12}$$

Equations 10, 11, and 12 summarizes the attention process on query level. Finally, $\boldsymbol{s}$ gives the query sequence embedding that captures the search intent embedded in sequential queries $<Q1, ...,Q_i, ..., Q_N>$. In a nutshell, given a query sequence, we first use query encoder to derive the embedding for each query in the sequence. Then, we use query sequence encoder to further construct the embedding of the query sequence.

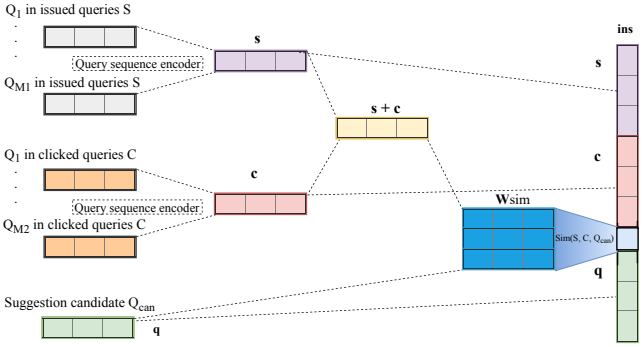

Figure 2: Training instance construction based on search sequence S, clicked sequence C, and suggestion candidate Q_{can}.

Given a training instance Ins, which is composed of a search query sequence S, a clicked query sequence C, and a suggestion candidate Q_{can}, we use the same query sequence encoder to derive the embeddings for S and C, denoted as $\boldsymbol{s}$ and $\boldsymbol{c}$, respectively, and we use a query encoder to encode the candidate Q_{can}, with its embedding denoted as $\boldsymbol{q}$. We use the concatenation of $\boldsymbol{s}$, $\boldsymbol{c}$, and $\boldsymbol{q}$, i.e., $[\boldsymbol{s}; \boldsymbol{c}; \boldsymbol{q}]$ to get the embedding **ins** to represent the instance Ins. Figure 2 summarizes the process.

4.2.2 Matching query sequences and suggestion query. Given a sequence of issued queries S, a sequence of clicked queries C, and a suggestion candidate Q_{can}, we aim to explicitly derive the matching among S, C, and Q_{can}. We follow approaches [3] and [19]. We define the matching score among $\boldsymbol{s}$, $\boldsymbol{c}$, and $\boldsymbol{q}$ as follows:

$$\text{Sim}(S, C, Q_{\text{can}}) = (\boldsymbol{s} + \boldsymbol{c})^T \boldsymbol{W}_{\text{sim}} \boldsymbol{q}, \tag{13}$$

where $\boldsymbol{W}_{\text{sim}} \in \mathbb{R}^{|\boldsymbol{s}|\times|\boldsymbol{q}|}$ is a similarity matrix. In this module, $\boldsymbol{s}+\boldsymbol{c}$ explicitly combines the search intent embedded in search queries S and clicked suggestions C. We seek a transformation of the candidate query Q_{can} that is the closest to $\boldsymbol{s}+\boldsymbol{c}$. The similarity matrix $\boldsymbol{W}_{\text{sim}}$ is a parameter of the network and is optimized during training. $\text{Sim}(S, C, Q_{\text{can}})$ is then explicitly appended to **ins** as a feature.

4.2.3 Learning and Optimization. When learning *CFAN* without adversarial examples, *CFAN* is optimized by learning only the ranker, formulated as finding a set of parameters Θ, that minimize an empirical ranking loss as shown in Equation 1 for a given set of training views. In adversarial training, we construct adversarial perturbations on training instances in order to cause a misbehavior of *CFAN* on a training view V. The misbehavior refers to the event that *CFAN* ranks unclicked suggestions ahead of clicked suggestions. To construct such adversarial perturbations, we introduce a binary classifier, which learns the labels of training instances in V. For each instance, the loss function $\text{Loss}_{\text{cls}}(\Theta)$ of the classifier focuses on reducing the binary cross-entropy [10] between the predicted probabilistic score $\hat{y}^{\Theta}_{\textbf{ins}}$ and the gold standard $y_{\textbf{ins}}$ as follows:

$$\text{Loss}_{\text{cls}}(\Theta) = -[y_{\textbf{ins}} \log(\hat{y}^{\Theta}_{\textbf{ins}}) + (1 - y_{\textbf{ins}}) \log(1 - \hat{y}^{\Theta}_{\textbf{ins}})], \quad (14)$$

where $\hat{y}^{\Theta}_{\textbf{ins}} = g_{\Theta}(\textbf{ins})$.

To increase the classification difficulty, we aim to identify a bounded perturbation $\boldsymbol{r}_{\text{adv}}$ for each **ins** such that the classification loss on $\textbf{ins} + \boldsymbol{r}_{\text{adv}}$ is as large as possible. The adversarial loss of the classifier becomes:

$$\text{Loss}_{\text{cls adv}}(\Theta) = -[y_{\textbf{ins}} \log(\hat{y}^{\Theta}_{\textbf{ins}+\boldsymbol{r}_{\text{adv}}}) + (1-y_{\textbf{ins}}) \log(1-\hat{y}^{\Theta}_{\textbf{ins}+\boldsymbol{r}_{\text{adv}}})], \quad (15)$$

where

$$\boldsymbol{r}_{\text{adv}} = \arg \min_{\boldsymbol{r}, ||\boldsymbol{r}|| \le \epsilon} [y_{\textbf{ins}} \log(\hat{y}^{\hat{\Theta}}_{\textbf{ins}+\boldsymbol{r}}) + (1 - y_{\textbf{ins}}) \log(1 - \hat{y}^{\hat{\Theta}}_{\textbf{ins}+\boldsymbol{r}})]. \quad (16)$$

$\hat{\Theta}$ is the set of current parameters defining the classifier, $\boldsymbol{r}$ is a perturbation on the input **ins**, $\hat{y}^{\hat{\Theta}}_{\textbf{ins}+\boldsymbol{r}}$ gives the predicted score of the perturbed instance based on the current set of parameters, and ϵ is a parameter to bound the perturbations.

Calculating the exact value of $\boldsymbol{r}_{\textbf{adv}}$ is not feasible, because exact minimization of Equation 16 with respect to $\boldsymbol{r}$ is intractable. To derive dynamic perturbations efficiently, we apply fast gradient sign method [8] to approximate the perturbation $\boldsymbol{r}_{\textbf{adv}}$. We linearize the cost function 16 around the current value of $\hat{\Theta}$, and obtain an optimal max-norm constrained perturbation of

$$\boldsymbol{r}_{\textbf{adv}} = -\epsilon \boldsymbol{l} / ||\boldsymbol{l}||_2, \quad (17)$$

where

$$\boldsymbol{l} = \nabla_{\textbf{ins}} \text{Loss}_{\text{cls}}(\hat{\Theta}). \quad (18)$$

Based on Equations 17 and 18, the perturbation for each instance can be calculated efficiently via back-propagation. Adversarial instances can be constructed by adding the derived perturbations $\boldsymbol{r}_{\text{adv}}$ to the corresponding instance embeddings **ins**.

To train a robust suggestion system with good ranking performance, the objective of *CFAN* combines the loss functions of both adversarial classification and ranking as follows:

$$\text{loss}(\Theta) = \sum_{\text{ins} \in V} \text{loss}_{\text{cls adv}}(\Theta) + \text{loss}_{\text{ranking}}(\Theta). \quad (19)$$

The classification component and the ranking component share the same set of parameters. The classification component dynamically generates adversarial instances, while the ranking component generates favorable rankings of query suggestions, pushing clicked suggestions to top positions and pulling unclicked suggestions to bottom positions in ranking lists.

5 EXPERIMENTS

In this section, we conduct extensive experiments and in-depth analysis to verify the performance of *CFAN* for query suggestions.

5.1 Datasets and Experimental Settings

Table 2: The statistics of queries with different context lengths in the training and test datasets.

Dataset	Context Length		
	Short (1 query)	Medium (2-3 queries)	Long (4+ queries)
Training	284,273	105,647	103,944
Test	31,577	11,998	11,566

Dataset. We use a search log collected from one of the largest search engines in the world. We pre-processed the data by eliminating non-alphanumeric characters, spelling error correction, and lower-casing. Then we segmented the search log into sessions, using a standard segmentation heuristic, i.e., intervals of at least 30 minutes idle time denotes a session boundary [12]. To partition search sessions into training and test sets, the first 90% data are utilized for training while the remaining sessions are the test data. Among the training data, 10% of sessions are randomly sampled as the validation set for parameter tuning. Finally, there are 3,684,008 training queries within 493,864 sessions and 406,063 test queries within 55,141 sessions. Furthermore, to evaluate the performance using different context lengths, the test set is partitioned into three subsets, including *Short Context* (1 query), *Medium Context* (2 to 3 queries), and *Long Context* (4 or more queries). Here the context length refers to the number of search queries in a search session. Table 2 shows the statistics of queries with different context lengths in the training and test datasets.

5.2 Evaluation Metrics

We employ Mean Reciprocal Rank (MRR) score [23] as the evaluation metric. Given a search query Q, let $Y(Q)$ be a ranked list of recommended queries determined by a suggestion method. We use $\text{rank}_1(Y(Q))$ to denote the rank of the first clicked query in $Y(Q)$. Formally,

$$\text{MRR} = \frac{1}{\text{rank}_1(Y(Q))}. \quad (20)$$

Essentially, the MRR score summarizes the ranks of the first clicked queries in the recommendation list $Y(Q)$ - A larger score indicates that the first clicked queries are ranked higher in the list.

5.3 Baselines Methods

In our evaluations, we evaluate the MRR performance of *CFAN* against the following state-of-the-art methods.

Table 3: The MRR performance of different methods in the test sets with different context lengths for the task of query suggestion.

Dataset	QVMM [9]	FBS [28]	RC [14]	MPS [7, 20]	Hybrid [1]	HRED [20]	RIN [15]	CFAN
Overall Context	0.441	0.458	0.466	0.478	0.473	0.556	0.573	**0.650**
Short Context (1 query)	0.446	0.473	0.460	0.476	0.473	0.548	0.563	**0.639**
Medium Context (2 to 3 queries)	0.430	0.438	0.477	0.483	0.473	0.564	0.591	**0.661**
Long Context (4 and more queries)	0.431	0.440	0.469	0.474	0.475	0.574	0.593	**0.682**

- **[Query-based Variable Markov Model (QVMM)]** [9] makes query suggestions by learning the probability of query transitions over search sessions with the variable memory Markov model.
- **[Feature Based Suggestion (FBS)]** [28] counts on statistical features to make suggestions. Suggestion candidates are generated based on 1) term matching between search queries and candidates and 2) query co-occurrences in search sessions. Query suggestions are made by ranking candidates based on a combination of statistical features.
- **[Reformulation-based Completion (RC)]** [14] is a non-deep learning based method exploiting query suggestions. 43 reformulation based features are proposed to capture user reformulation behaviors over search sessions with LambdaMART [4].
- **[Most Popular Suggestion (MPS)]** [7, 20] is a maximum likelihood method, which relies on "wisdom of the crowd". It ranks queries by the co-occurrence to the last query in the search sequence.
- **[Hybrid Suggestion (Hybrid)]** [1] considers both the context information and the popularity by ranking candidate queries based on a linear combination between the popularity and the similarity to recent search queries.
- **[Hierarchical Recurrent Encoder-Decoder (HRED)]** [20] is a deep learning based query suggestion method. HRED constructs a hierarchical encoder-decoder structure to model the sequential and hierarchical dependencies across terms and queries to make query suggestions.
- **[Reformulation inference network (RIN)]** [15] is the most state-of-the-art query suggestion method. Query reformulations between consecutive queries in search sessions are explicitly modeled in RIN to make suggestions.

5.4 Experimental Results

Table 3 shows the MRR performance of different methods over various context lengths. QVMM, a variable-memory Markov model, achieves the worst MRR performance among all the query suggestion methods. QVMM counts on query dependencies in search sessions to make query suggestions. The sparsity of search sessions leads to the poor ranking performance of QVMM. Feature based method (FBS) first selects candidate queries based on prefix matching and query dependencies. Then, candidate queries are ranked based on statistical popularity features. Compared with QVMM, FBS improves the overall MRR from 0.441 to 0.458. The reformulation-based completion method (RC) outperforms both QVMM and FBS. Its overall MRR score reaches 0.466. RC relies on generalized query dependency rules to make query suggestions. The improvements against QVMM and FBS demonstrate that generalized reformulation rules are more informative and powerful than simple query dependencies in search sessions. The popularity-based baseline method (MPS) slightly outperforms RC. The overall MRR score further increases from 0.466 to 0.478. It indicates that the query popularity plays an important role in driving users to click the suggestions. This is mainly because when query suggestions are highly related to the search query, users tend to click those popular and trending ones as follow-up search queries to explore. The hybrid suggestion method (Hybrid) performs slightly worse than MPS. The overall MRR score decreases from 0.478 to 0.473. This can be explained by the fact that the term-level similarities between suggestion candidates and search queries in Hybrid are not capable of capturing the their relationship in semantic, and thus fail to rank suggestion candidates properly when most suggestion candidates are similar to search queries in term levels.

Neural network based methods HRED, RIN, and *CFAN* outperform non-deep learning based methods by a large margin in general. HRED achieves MRR scores of 0.556, 0.548, 0.564, and 0.574 on overall, short, medium, and long contexts, respectively. RIN achieves MRR score of 0.573 on average. Among all the methods, *CFAN* achieves the best MRR performance. The MRR scores reach 0.650, 0.639, 0.661, and 0.682 on overall, short, medium, and long search contexts, respectively. In particular, *CFAN* achieves excellent ranking performance when the context information is rich. Rich context contains more user search queries and click feedback, which help deduce the query ambiguity and thus contribute to the ranking performance.

6 CONCLUSION AND FUTURE WORK

In this paper we investigated the problem of feedback-aware query suggestion. A novel neural network based method, *CFAN*, is proposed, which models both user search sequence and click sequence.In addition, to improve the robustness of the query suggestion system, adversarial examples are constructed via a classifier. *CFAN* is optimized by training the adversarial classifier and a ranker simultaneously. Extensive experiments demonstrate that our proposed model significantly outperforms the baseline methods for the task of query suggestion. The improvements are consistent across different datasets of various context lengths.

ABSTRACT

We propose a novel training scheme for fast matching models in Search Ads, motivated by practical challenges. The first challenge stems from the pursuit of high throughput, which prohibits the deployment of inseparable architectures, and hence greatly limits its model accuracy. The second problem arises from the heavy dependency on human provided labels, which are expensive and time-consuming to collect, yet how to leverage unlabeled search log data is rarely studied. The proposed training framework targets on mitigating both issues, by treating the stronger but undeployable models as annotators, and learning a deployable model from both human provided relevance labels and weakly annotated search log data. Specifically, we first construct multiple auxiliary tasks from the enumerated relevance labels, and train the annotators by jointly learning from those related tasks. The annotation models are then used to assign scores to both labeled and unlabeled training samples. The deployable model is firstly learnt on the scored unlabeled data, and then fine-tuned on scored labeled data, by leveraging both labels and scores via minimizing the proposed label-aware weighted loss. According to our experiments, compared with the baseline that directly learns from relevance labels, training by the proposed framework outperforms it by a large margin, and improves data efficiency substantially by dispensing with 80% labeled samples. The proposed framework allows us to improve the fast matching model by learning from stronger annotators while keeping its architecture unchanged. Meanwhile, it offers a principled manner to leverage search log data in the training phase, which could effectively alleviate our dependency on human provided labels.

1 INTRODUCTION

The recent decade has witnessed a booming of sponsored search due to the outburst of search demands, which raises severe challenges to the design of practical search algorithms. As a starting step of typical sponsored search systems, the fast matching model discussed here is designed to recall from the entire ad corpus a list of candidates best matching a given query. All the subsequent processing steps will be applied on the selected list only. The extremely intensive user requests of Search Ads system poses stringent online latency requirement on the fast matching model. To some extent, its accuracy and latency forms the upper bound of the overall performance. To improve the fast matching model, we need either to leverage more powerful model architectures, or more effective training strategies. However, both directions turn out to be difficult, and will suffer from restrictions from both system and data.

The first restriction relates to model architecture. Commercial search engines need to handle extremely intensive user requests by searching from a daunting ad corpus, and their pursuit of high throughput prohibits the deployment of inseparable model architectures, especially those involving heavy online computations. For this reason, relevance model is usually implemented as Siamese networks such as CDSSM [25], which transforms the input query and ad individually to representing vectors residing in a common inner-product space, without knowledge of each other. Such an architecture allows us to reduce online computations following a space-for-time strategy, by hosting online a dictionary of precomputed ad vectors. When a query is issued, the model simply retrieves relevant ad vectors by matching it from the dictionary, and the matching could be effectively done by resorting to approximate nearest neighbor search algorithms such as NGS [28]. However, due to the deferment of interactions between queries and ads, Siamese

networks often suffer from losing details important to the matching task in the forward pass [11], which greatly limits matching performance. Note that better accuracy could also be achieved using more complex model architectures, especially those involving interactions between query and ad such as Deep Crossing, or model ensembles involving crossing features. However, such models are mostly inseparable, hence could not be deployed in the same way as Siamese networks.

The second restriction comes from the training data. Relevance model is typically trained on human provided labels, which is expensive and time-consuming to collect. In contrast to this, the search log contains tremendous amount of data, but relevance labels are unavailable. An alternative solution is to employ user clicks as a surrogate of relevance labels, by taking clicked <*query*, *ad*> pair as positive, and synthesizing negative pairs by fixing a query while randomly sampling ads from the same training batch. This strategy oversimplifies the learning task by transforming matching to a classification problem [29], and introduces ambiguities from three aspects. First of all, the arbitrariness and subjectivity of user behavior leads to a misalignment between user clicks and true relevance labels, polluting the training set with false positives. Secondly, data synthesizing may introduce false negatives, and most of the synthetic negative pairs share no common terms in queries and ads. Learning on such data may mislead the model to consider common terms as critical evidences of relevance, whereas lexically similar query and ad may have totally different intents, such as *iphone* and *iphone cover*. Last but not least, human labels typically have enumerated values to distinguish relevance with finer granularity, which are difficult to approximate by binary-valued clicks.

This paper targets on mitigating both the aforementioned issues. For this purpose, we employ powerful but undeployable models to assign weak annotations or scores to unlabeled data, and improve the deployable model by learning from both the weak annotations and true human labels. A schematic illustration of the proposed framework is plotted in Figure 1, which consists of four major steps. Specifically, we first construct auxiliary tasks using enumerated relevance labels, and train annotators by jointly learning multiple tasks, following the idea of Multi-task Learning (MTL). The learnt annotators are then used to assign scores to both unlabeled and labeled samples. Based on this, a deployable model is trained firstly on the scored unlabeled data, and then fine-tuned on scored labeled data. A label-aware weighted loss function is proposed in the last step to leverage both labels and scores.

The advantages of the proposed framework are twofold. At the foremost, it offers us great flexibility in the architecture design of fast matching model, since we can improve it by learning from stronger annotators, while keeping the model to be deployed as efficient as possible. Because the annotation model runs offline only, it is allowed to explore complicated model architectures involving heavy computations, and is able to leverage either policy-driven rules or features that might be too heavy to access for online processing. Secondly, this framework provides a principled way to leverage unlabeled data for learning fast matching models, which dispenses entirely with user clicks to avoid data pollution.

According to our experiments, compared with training directly on relevance labels, the proposed framework is able to improve *ROC AUC* by 4.5% and *PR AUC* by 3.2%, demonstrating the effectiveness of improving relevance model by leveraging unlabeled data and stronger annotators. In addition, with only 20% labeled samples, we are able to achieve performance comparable to the baseline trained on the entire labeled set, which effectively alleviates our dependency on human provided labels.

Our main contributions are summarized as follows.

- we propose a novel training framework for the learning of fast matching models in search ads, which is able to leverage more powerful but undeployable models as weak annotators, and learn a simple and deployable model from both the weak annotations and the true human labels. The weak annotators are trained following MTL scheme to fully leverage the fine-grained relevance labels, and a label-aware weighted loss is proposed to softly combine the weak annotations and human provided labels.
- we evaluate the proposed training framework on large datasets, where both *PR AUC* and *ROC AUC* are significantly improved, demonstrating its effectiveness. Our experiments also shows that training by the proposed framework could greatly reduce our dependency on human labels.

2 RELATED WORK

The proposed framework is mainly fueled by the recent progress in web search and model compression.

Existing methods on semantically matching queries and documents could be roughly grouped into two categories, namely traditional approaches and deep learning based models. Representative methods falling into the former category include LSA [5], pLSA [10], topic models such as LDA [3], Bi-Lingual Topic Models [7], etc. Methods belonging to the latter category are designed to extract semantic information via deep learning architectures, including auto-encoders [20], Siamese networks [6, 11, 12, 22, 24–26], interaction-based networks [11, 15, 27, 30, 31], and lexical and semantic matching networks [8, 17], etc. Readers may refer to [16] for a tutorial on this topic. The framework proposed in this paper adopts CDSSM [25] and Deep Crossing [23] as key building blocks. However, instead of improving its architecture, we alternatively attempt to improve its training scheme in this paper.

The proposed framework also draws inspirations from the teacher-student scheme in model compression. As an initial attempt, the authors of [4] train a smaller model using synthetic data labeled by a teacher model. In [1], the authors propose to train the student model by mimicking the logit values of the teacher model, instead of directly learning the softmax outputs. This is extended later in [19], by incorporating intermediate hidden layer outputs as target values as well. Hinton et al. [9] propose to adjust the temperature variable in the softmax function. Recently the authors of [21] introduce a noise-based regularizer while training student models. In this paper, the teacher-student framework is adapted in several aspects to improve relevance algorithms in sponsored search.

While writing this paper, we also notice a recent work in [29], which extends the teacher-student scheme to the learning of retrieval-based chatbots, where a sequence-to-sequence model is employed as a weak annotator, and the student model is trained by learning from both the weak signals and the unlabeled data. Both [29] and

our proposed framework are motivated by the success of teacher-student scheme, but we adapt it in different directions to align with our respective task.

3 PROPOSED FRAMEWORK

3.1 Overview

3.1.1 Sponsored Search. Below we list some useful terminologies, and we refer readers to [23] for more details.

Impression is an instance of an ad displayed to a user. *Click* indicates whether an impression is clicked by a user. *Click-Through Rate* or *CTR* is the ratio of the total number of clicks to total number of impressions. *Query* is a text string issued by a user in a search engine. *Keyword* is a text string concerning a certain product, specified by an advertiser. *Landing Page* or *LP* refers to the web page a user reaches after clicking the corresponding ad of a product. A brief description of the product is usually displayed as the title of the *LP*, called *LP* title. *Ad Copy* or *AC* refers to the content seen by a user before clicking, which typically includes ad title, description, displayed URL, landing page link, etc. *Listing* contains the bided keywords associated with Ad Copy, bid, etc. *Relevance labels* are a set of predefined judgements used to characterize the relevance of query and ad listing. We have two label sets, namely *AC* labels that measure the relevance between query and Ad Copy contents, and *LP* labels that measure relevance between query and landing page contents. Throughout this paper, our label set is {0, 1, 2, 3, 4} for *AC* labels, and {0, 1, 2, 3, 4, 5} for *LP* labels, with higher labels indicating better relevance.

Our system is akin to the one described in [14], which consists of several steps including *selection*, *relevance filtration*, *CTR prediction*, *ranking* and *allocation*.

3.1.2 Proposed Framework. Figure 1 sketches the main idea of the proposed framework, which contains four major steps. The first step trains annotation models on human labeled data, by jointly learning multiple related tasks. The second step scores both the labeled and unlabeled data using this annotation model. In the following step, a deployable model is trained on the scored unlabeled data. Finally, the deployable model is fine-tuned on both the labels and scores of the labeled data, by minimizing the label-aware weighted loss. All steps involve purely offline computations; only the final simple model will be deployed online. We instantiate our deployable model as CDSSM [24], and implement two annotation models, i.e. Deep Crossing (abbreviated as DC) in [23] and a decision tree ensemble model (abbreviated as DT) in [14].

3.2 Annotation Model Training via MTL

Two annotation models are considered in this paper, i.e. Deep Crossing and decision tree ensemble. Figure 2 shows the structure of Deep Crossing, which contains an input layer, an embedding layer, multiple residual layers, and a scoring layer. Deep Crossing introduces feature interactions immediately after embedding layers, hence is inseparable. Our decision tree ensemble model follows the one described in [14], which takes as input a set of features, some of which are difficult to access in the recall phase. Therefore, both annotation models could not be deployed as fast matching models directly. Annotation models are trained on labeled data, where each sample is a triple of query, ad listing and human judged relevance label chosen from a predefined label set, see Section 3.1.

We construct several auxiliary classification tasks by partitioning the label sets with different pivots, as shown in Table 1, where four auxiliary tasks are constructed for *LP* labels, and three for *AC* labels, along with the main task. The final loss is calculated as a weighted sum of the individual loss for each task, with the main task weighted as 0.5 while all the auxiliary tasks evenly weighted. The final score is computed analogously.

Table 1: Constructing auxiliary tasks.

Label Set	Task	Negative Labels
AC	main task	{0}
LP		{0}
AC	aux. task 1	{0, 1}
	aux. task 2	{0, 1, 2}
	aux. task 3	{0, 1, 2, 3}
LP	aux. task 1	{0, 1}
	aux. task 2	{0, 1, 2}
	aux. task 3	{0, 1, 2, 3}
	aux. task 4	{0, 1, 2, 3, 4}

3.3 CDSSM Training using Scores

The architecture of CDSSM is shown in Figure 3, which contains an input layer, a word hashing layer to transform each word into a count vector of letter-tri-grams, a convolutional layer to extract sliding window based contextual features around each word, a max-pooling layer to summarize most salient contextual features, followed by a semantic layer and the final cosine scoring layer.

The scores from the annotation models could be leveraged either in a hard manner by thresholding them to binary values, or in a soft way by maintaining their original values. In addition, the reliability of the scores also needs investigation. For this purpose, we define the targets and weights of the unlabeled samples as functions of annotation model scores:

$$y_i = f(s_i), \tag{1}$$

$$\omega_i = g(s_i), \tag{2}$$

where y_i, ω_i and s_i are the target, weight, and annotation model score for the ith sample in the unlabeled dataset, respectively, while $f(\cdot)$ and $g(\cdot)$ are mapping functions from scores to targets and weights. When multiple annotation models are available, s_i is calculated as their arithmetic mean. Following this definition, we define several mapping functions as below:

$$f_1(s_i) = \begin{cases} 1, & 0.5 \le s_i < 1; \\ 0, & 0 < s_i < 0.5; \end{cases} \tag{3}$$

$$f_2(s_i) = s_i, \tag{4}$$

$$g_1(s_i) = \begin{cases} 0, & t_1 < s_i < t_2; \\ 1, & \text{o.w.} \end{cases} \tag{5}$$

$$g_2(s_i) = \left|2s_i - 1\right|^p, \tag{6}$$

$$g_3(s_i) = 1. \tag{7}$$

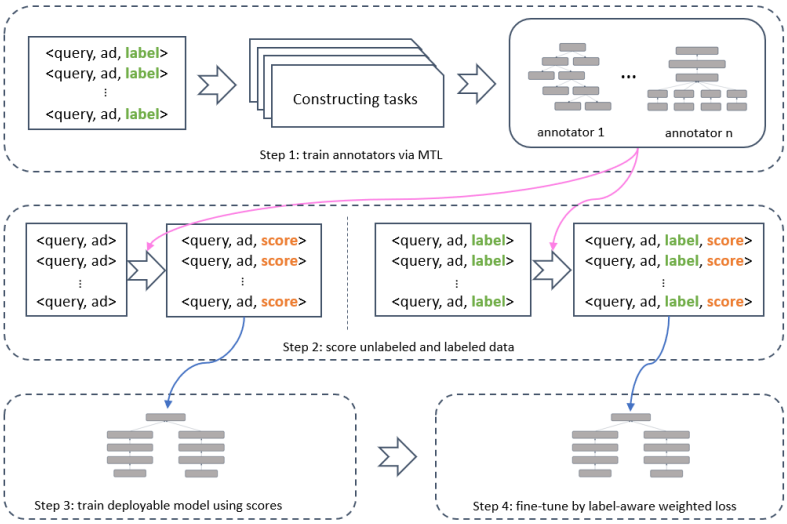

Figure 1: Illustration of the proposed framework, which includes four steps. The first step constructs multiple related tasks, and trains annotation models using labeled data, via MTL. The second step scores both the labeled and unlabeled data using the annotators. A deployable model is trained on the scored unlabeled data in the third step. In the last step, the deployable model is fine-tuned by minimizing the label-aware weighted loss. All steps involve offline computations only.

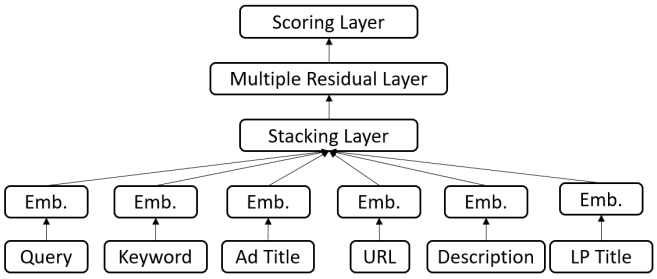

Figure 2: Architecture of Deep Crossing, which is inseparable and cannot be deployed as a fast matching model.

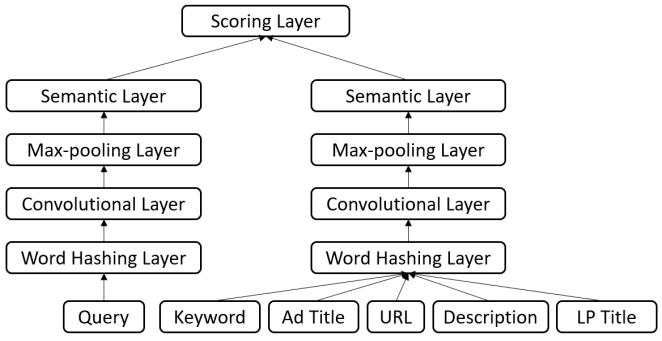

Figure 3: Architecture of CDSSM, which is separable and takes identical inputs with Deep Crossing.

Equation (3) defines a hard target mapping, and Equation (4) defines a soft one. Equation (5) to Equation (7) define three weight mappings. In implementation, Equation (3) is trained by minimizing cross-entropy loss, while Equation (4) by weighted mean square error (MSE) loss. Specifically, denoting the predicted score from CDSSM as $\hat{y}_i$ for the ith sample, we define its sample loss as below:

$$\ell_i = \omega_i \cdot (y_i - \hat{y}_i)^2. \tag{8}$$

3.4 Fine-tuning by Label-aware Weighted Loss

To balance human judged relevance labels and annotation model scores, we propose the label-aware weights, as illustrated in Figure 4. Denote the binary relevance labels as $\tilde{y}_i$ for sample i, where the binary labels are defined according to the main task in Table 1. As shown in the left of Figure 4, $\tilde{y}_i = 1$ indicates that sample i has positive relevance labels, making it more acceptable when the predicted score $\hat{y}_i$ is greater than the target value y_i obtained from annotation models, and less acceptable when $\hat{y}_i < y_i$. To reflect such differences, we define a weight $\tilde{\omega}_i$ for sample i, with $\tilde{\omega}_i < 1$ for acceptable loss and $\tilde{\omega}_i = 1$ otherwise. The right part of Figure 4 shows the opposite case, where $\tilde{y}_i = 0$ makes $\hat{y}_i > y_i$ less acceptable.

To facilitate the formulation of label-aware weights, we first define a sign function as shown below:

$$\delta_\theta(x) = \begin{cases} \theta, & \text{if } x \le 0; \\ 1, & \text{if } x > 0, \end{cases} \tag{9}$$

where $0 \le \theta \le 1$ is a hyper-parameter indicating the discount of punishment imposed on acceptable loss. Based on the sign function in Equation (9), our label-aware weighted loss could be defined as

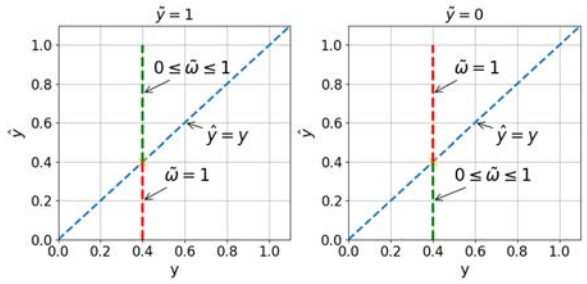

Figure 4: Illustration of the label-aware weights, where $\tilde{y}$ is the binary label, y is the target from annotation model scores, and $\hat{y}$ is the prediction of CDSSM. When $\tilde{y}_i = 1$ (left), $\hat{y}_i > y_i$ appears more acceptable than $\hat{y}_i < y_i$, and hence is assigned a smaller weight, as highlighted by green. The right part shows $\tilde{y}_i = 0$, where $\hat{y}_i < y_i$ is given a smaller weight.

Table 2: Statistics of datasets.

	Unlabeled	Clicked	Labeled	
			positive	negative
train	159,352 K	168,671 K	5,115 K	9,752 K
test	–	–	132 K	120 K

follows:

$$\begin{aligned}\tilde{\ell}_i &= \delta_\theta(y_i - \hat{y}_i)^{\tilde{y}_i} \cdot \left(\theta + 1 - \delta_\theta(y_i - \hat{y}_i)\right)^{(1-\tilde{y}_i)} \cdot \\ &\quad (y_i - \hat{y}_i)^2 \\ &\triangleq \tilde{\omega}_i \cdot (y_i - \hat{y}_i)^2, \end{aligned} \tag{10}$$

where label-aware weight $\tilde{\omega}_i$ is a function of y_i, $\tilde{y}_i$ and $\hat{y}_i$.

4 EXPERIMENTS

4.1 Experimental Setup

4.1.1 Datasets. Validating the proposed framework needs three datasets: a labeled one with human judged relevance labels (referred to as labeled), an unlabeled one with both clicked and unclicked samples (referred to as unlabeled), and an unlabeled one with only clicked samples (referred to as clicked). The unlabeled and clicked datasets are sampled from the search log of a commercial search engine. A subset with comparable size to the test set is randomly sampled from the training labeled set for validation. Statistics of the three datasets are shown in Table 2.

4.1.2 Implementation. We implement Deep Crossing following the description of [23], with several modifications including adding Batch Normalization [13] and soft-aligning query and ad using the neural attention similar to [2, 18], by concatenating ad inputs into a single string. We use identical CDSSM architecture in the last two steps in Figure 1. we conduct evaluations using *ROC AUC* and *PR AUC* as measurements, which represent the area under the Receiver Operating Characteristic curve and the Precision-Recall curve, respectively.

Table 3: Comparison of performance.

Annotator	CDSSM	*ROC AUC*	*PR AUC*
–	CDSSM-click	0.7185	0.7890
	CDSSM-labeled	0.8131	0.8711
DC	–	0.8425	0.8946
DT		0.8448	0.8940
DC + DT		0.8578	0.9034
DC	CDSSM	0.7937	0.8625
DT		0.7936	0.8604
DC + DT		0.8155	0.8753
DC	CDSSM-ft	0.8394	0.8939
DT		0.8442	0.8941
DC + DT		**0.8497**	**0.8990**

4.2 Performance

Table 3 summarizes our main results, where DC and DT represent Deep Crossing and decision tree ensemble, respectively, and DC + DT represents their combination. CDSSM-ft refers to fine-tuning using labeled data after training CDSSM on scored, unlabeled samples. As mentioned in Section 1, training by clicked data means taking clicked <*query*, *ad*> pair as positive, and randomly synthetic query and listing pairs as negative.

The first row in Table 3 presents the results of our click and labeled baseline, obtained by training CDSSM purely on user clicks and relevance labels. The next row gives results of our annotation models, where DC and DT achieves comparable performance. Their combination brings further improvements. Training by the proposed framework with DC as annotation model outperforms the click baseline by 9.8% for *ROC AUC*, and 9.32% by *PR AUC*. Very close result is observed for DT. Learning by the proposed framework achieves comparable performance to the labeled baseline when combining DT and DC. Finally, when further fine-tuned on labeled data, the *ROC AUC* using annotation model DC and DT outperforms the labeled baseline by 2.6% and 3.82% respectively. Combining DC and DT as annotation model outperforms the labeled baseline by a large margin of 4.5% for *ROC AUC*, and 3.2% for *PR AUC*. This demonstrates evidently the effectiveness of the proposed framework.

4.3 Annotation Models and Mapping Functions

Several configurations of annotation models and mapping functions are compared, with results summarized in Table 4. Specifically, the annotation model is implemented as several variants of Deep Crossing, including the original version, Deep Crossing with Batch Normalization (BN), Deep Crossing with BN and Attention (abbreviated as A), Deep Crossing with BN and MTL, and Deep Crossing with BN, attention and MTL. For each annotation model, three mapping functions are implemented, and *AUC* before and after fine-tuning are reported, with $\theta = 1$.

As shown in Table 4, the performance of CDSSM are highly correlated with that of annotation models. In addition, Table 4 also demonstrates that training annotation models by jointly learning multiple tasks could bring about considerable gains in both annotation models and CDSSM, despite its simplicity. Table 4 also reveals

Table 4: Influence of annotation models and mapping functions.

Annotator	*AUC*-annotator		*AUC*-CDSSM						
			before/after	f_1 g_1		f_1 g_2		f_2 g_3	
	ROC	*PR*	fine-tune	*ROC*	*PR*	*ROC*	*PR*	*ROC*	*PR*

			after	0.8254	0.8838	0.8268	0.8848	0.8330	0.8887
DC-BN-MTL	0.8391	0.8932	before	0.7823	0.8565	0.7847	0.8578	0.7890	0.8605
			after	0.8277	0.8857	0.8296	0.8868	0.8343	0.8896
DC-BN-A-MTL	0.8425	0.8946	before	0.7761	0.8527	0.7851	0.8571	0.7937	0.8625
			after	0.8281	0.8863	0.8309	0.8887	0.8372	0.8922

Table 5: Comparison of different fine-tuning methods.

		ROC AUC	*PR AUC*
baseline	hard	0.8271	0.8833
	soft	0.8372	0.8922
θ	0.0	0.8390	0.8935
	0.2	0.8391	0.8935
	0.5	**0.8394**	0.8939
	0.8	0.8378	0.8926

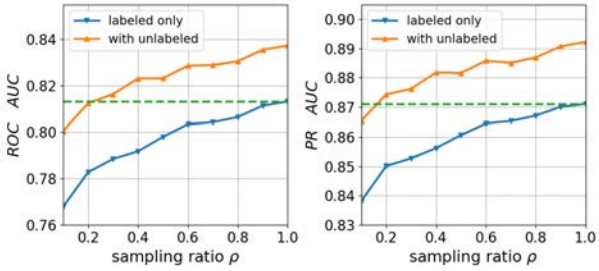

Figure 5: Performance of sampling labeled data by different ratios. Blue curves represent training on the sampled data, yellow curves represent training by the proposed method.

the importance of mapping functions, where the third configuration outperforms others in most cases, across different annotation models. This may due to the reason similar to prior analysis in [9], that the soft targets could offer more information than hard targets.

4.4 Label-aware Weights

To show the influence of label-aware weights, we conduct experiments on DC-BN-A-MTL by setting θ to be {0, 0.2, 0.5, 0.8, 1.0}, with results summarized in Table 5, where the hard baseline refers to directly learning binary label $\tilde{y}$, and the soft baseline refers to learning target y.

According to Table 5, fine-tuning by the hard baseline yields suboptimal performance, which coincides with prior analysis in [9]. In addition, the best *AUC* is achieved at $\theta = 0.5$, which equivalents to setting the weights for unacceptable loss twice as much as that of the acceptable ones. Compared with the case $\theta = 0.5$, both $\theta = 0$ and $\theta = 1$ give inferior performance. More specifically, $\theta = 1$ exhibits a larger gap with $\theta = 0.5$, due to its inability to leverage human provided labels. In contrast, $\theta = 0$ simply spares all acceptable loss, and hence has limited influence on the overall performance.

4.5 Improve Data Efficiency

This section investigates the potential of complementing labeled data using unlabeled samples. To figure out this, we randomly sample 9 subsets from the labeled data using a sampling ratio ρ ranging from 0.1 to 0.9, and repeat the steps in Figure 1 using the sampled labeled data only. The results are shown in Figure 5, where the blue curves show the *AUC* obtained by training CDSSM directly on the sampled labeled data, while the yellow curves denote performance achieved by following the proposed framework.

According to Figure 5, all *AUC* curves grow monotonically as ρ gets larger, but both *ROC AUC* and *PR AUC* grows slower and slower, indicating decreasing data efficiency. The green dashed lines in Figure 5 highlight the upper bound of the blue curves, which is easily exceeded when training using the proposed framework: the same *AUC* is achieved by the orange curve with only 20% labeled data. This validates that training by the proposed framework could greatly improve data efficiency. With 80% knowledge could be obtained from unlabeled data, our dependency on the expensive human labels could be greatly reduced.

5 CONCLUSIONS

This paper proposes a novel framework for learning the relevance model in sponsored search, allowing us to learn a simple model from stronger but undeployable annotators, and offers a principled way to leverage unlabeled data by completely dispenses clicks. Our main experimental results include 1) training by the proposed framework could substantially improve the performance of relevance models, and 2) the proposed framework is able to significantly increase data efficiency, so that training by 20% labeled data could achieve comparable results with the baseline trained by all labeled samples.

ABSTRACT

Under a newly introduced setting of multistream classification, two data streams are involved, which are referred to as source and target streams. The source stream continuously generates data instances from a certain domain with labels, while the target stream does the same task without labels from another domain. Existing approaches assume that domains for both data streams are identical, which is not quite true in real world scenario, since data streams from different sources may contain distinct features. Furthermore, obtaining labels for every instance in a data stream is often expensive and time-consuming. Therefore, it has become an important topic to explore whether labeled instances from other related streams can be helpful to predict those unlabeled instances in a given stream. Note that domains of source and target streams may have distinct features spaces and data distributions. Our objective is to predict class labels of data instances in the target stream by using the classifiers trained by the source stream.

We propose a framework of multistream classification by using projected data from a common latent feature space, which is embedded from both source and target domains. This framework is also crucial for enterprise system defenders to detect cross-platform attacks, such as Advanced Persistent Threats (APTs). Empirical evaluation and analysis on both real-world and synthetic datasets are performed to validate the effectiveness of our proposed algorithm, comparing to state-of-the-art techniques. Experimental results show that our approach significantly outperforms other existing approaches.

1 INTRODUCTION

Data streams are crucial in the modern connected Internet world, and they have attracted the attention of researchers worldwide. Given important applications of data streams–such as IoT, social networks, and surveillance–mining them properly is becoming a more and more important topic to explore. However, data stream mining is also a challenging task due to its distinctive nature, e.g., theoretically infinite in length, heterogeneous domains, and lack of label for emerging data [12, 14]. These unique properties are discussed seperately in the following context.

Regarding *data stream mining*, concept drift had been a challenge problem due to its theoretical infinite length. Detecting it in multivariate data streams concentrates on tracking any changes in the posterior class distribution, $P(y|x)$. Instead of tracking changes in $P(y|x)$ directly, the approaches proposed in [13] adopt the principle [11] to detect this change indirectly by tracking drift in the error rate of the underlying classifier. However, tracking drift in the error rate requires true labels of test data instances, which are scarce in practice. Recent studies focus on confidence [8] to detect changes in distribution between two different time windows or always buffering the most recent concept [19]. Apart from working on a single stream, these methods explicitly detect change points.

For *domain adaptaion*, the problem setting described in this paper is motivated by a Multistream Classification framework [8]. One of fundamental assumptions in data mining, known as the "stationary distribution assumption", is that both the training and test data are generated from the same domain and thus represent the same data distribution [25]. Therefore, common techniques normally cannot be directly deployed when training and test data are from different domains. The differences between domains can be normally considered as two aspects: 1. distinct number of features; 2. distinct feature distributions. Several approaches have been proposed to learn a

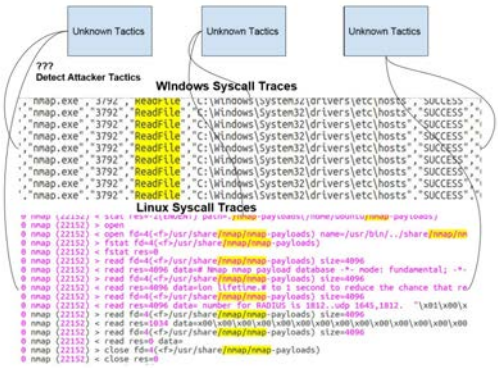

Figure 1: Sample Trace File showing syscall traces for an attacker scanning session with nmap network scanning tool

common feature representation for domain adaptation [2, 20, 23, 26]. The state-of-the-art methods, including deep learning, mostly address domain adaptation problems for stationary data except [26]. Thus, fitting domain adaptation frameworks to online data streams is yet to explore.

The multistream setting is very common in *cyber security area*. For example, organizations deploy threat monitoring tools that collect network system call events as data streams. Linking low-level traces to attacker tactics and intent is challenging. In Figure 1, a snapshot of a trace file is shown as scanning session of an attacker using the nmap tool to scan a victim's network. Also, data streams obtained from Linux machines cannot be used to predict attack events on a host with a Windows operating system. This is due to the difference in the way events are recorded on both systems (features may vary from Linux to Windows or vice versa). Machine learning algorithms have been deployed to learn attackers' behavioral patterns either using host-based [1, 6, 7, 24] or network-based [3, 10, 16, 17] techniques.

To sum up, the problem that we are trying to solve involves two data streams with heterogeneous feature spaces, and this is the aspect which no researchers have been working on in the past.

This paper proposes a framework, called MultiStream Domain Adaptation (MSDA), to handle the issues described above. The main idea is to find a common feature space for two distinct data streams. By applying the proposed projection algorithm, we try to find a latent feature space that the distributions in original and latent feature space are similar. Meanwhile, the structure of data should be preserved, which means distinct classes are still far apart, and the decision boundaries for different categories should still be preserved. Thus the core problem here is to find a feature space that maximize the similarity between original and projected latent feature space. Main contributions of this paper are as follows:

(1) An embedding-based domain adaptation method is introduced in multistream setting, to address the challenges of adapting source and target domains in a non-stationary environment.
(2) A concept drift detection method is deployed under the new multistream setting with domain adaptation. Under this setting, true labels in the target stream is not required, while only true labels in the source stream is used.

Table 1: Notations

Symbol	Meaning
D_s	Domain of source stream
D_t	Domain of target stream
S	Source stream data
T	Target stream data
X_s, X_t	Feature space of source stream with dimension m and that of target stream with dimension n
Y_s, Y_t	Label space of source and target stream
x_s, x_t	Data instance of source and target stream
y_s, y_t	True and predicted label of a data instance in source stream
W_s, W_t	Projection function to the source and target space
L_s, L_t	Projected data from source and target domain to latent space
P_s, P_t	Probability distribution function of source and target data
N_m	Size of sliding window

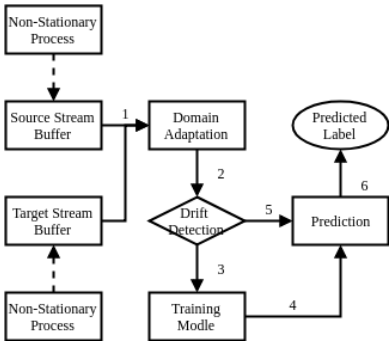

Figure 2: Multistream Classification with Domain Adaptation

(3) Our approach is empirically evaluated over several benchmark datasets, including security and non-security datasets. The results are compared with state-of-the-art methods. The performance of our proposed method is significantly better than the other three methods.

2 PROBLEM FORMULATION

2.1 Notations and Problem Statement

In Table 1, frequently used symbols in this paper are listed. There are two continuous stream of data instances generated from source domain D_s and target domain D_t. A data instance is denoted as (x, y), where x is a vector (m-dimensional in source stream and n-dimensional in target stream), and y is the corresponding class label. In the source stream, both x_s and y_s are available, while in the target domain only x_t is available. Therefore, a multistream classification with domain adaptation problem can be described as follows:

Suppose X_s is a set of m-dimensional vectors and Y_s is the corresponding labels in a source stream from a certain domain D_s, whereas X_t is a set of n-dimensional vectors in target stream from another domain D_t. In our problem setting, $m \neq n$. The objective is to construct a classifier M that predicts class labels of $x_t \in X_t$ using X_s, and Y_s.

18:    ŷ_t ← getPrediction(M, L_t)
```

2.2 Challenges

In the problem setting of multistream classification with domain adaptation, there are two major challenges at the same time. The first challenge is the adaptation of both source and target domain, and it can be represented as $D_s \neq D_t$. Two streams may have different number of instances. However, without loss of generality, buffers (windows) from these streams representing contiguous data points will have the same number of instances N_m. Furthermore, each data point in source stream may have a different number of features compared to those in the target stream. Therefore, source data cannot be directly used as training data to learn the target task, and discovering a latent feature space with k dimensions is the key to handling the feature heterogeneity issue. The second challenge is the asynchronous concept drift in both source and target streams. This phenomenon means that the data pattern evolves, or more formally, the conditional probability distribution changes over time in both streams. Here, the problem can be described as $P_s^t(y \mid \mathbf{x}) \neq P_t^t(y \mid \mathbf{x})$ at time t. Furthermore, we assume that source and target data streams have asynchronous concept drifts, which means that the drifts in both streams occur independently.

3 PROPOSED APPROACH

In this paper, we propose a Multistream Domain Adaptation (MSDA) framework to address the major issues in our problem setting. To achieve this goal, we establish a framework with the following modules:

(1) A domain adaptation module that helps find an optimized latent subspace for both source and target streams.
(2) A concept drift detection module that detects concept drift in both source and target streams.

Applying these two modules together, once a concept drift is detected, we use data instances from both streams in the most recent window to update the feature mapping, so that the domain adaptation problem can be addressed. The diagram of this algorithm can be found in Figure 1.

First, a domain adaptation module is triggered to learn projection functions for both source and target data instances. Newly arriving instances are transformed to latent feature representation accordingly (line 8-11). Second, the change point detection module detects if there is a significant change in either source or target streams within the sliding windows Third, once a change point is detected, new classifiers are trained based on these two buffers from B_s and B_t (step 3 & line 12-16). Finally, the newly updated classifiers are used to predict the labels of adapted data instances from target stream T (step 4-6 & line 17-18). Details of our proposed method is as follows.

3.1 Initialization and Domain Adaptation

In our proposed framework, instances from source and target streams are stored in B_s and B_t respectively. Recalling our problem setting, data in B_s have true labels, while data in B_t come without true labels. The domain adaptation method is indeed a optimization problem solved by feature embedding [23]. Also, for computational purposes, we design our approach in a way that buffer size in both source and target streams are the same, which means the numbers of data instances in processing window for source and target streams are identical. Thus, given a certain time t, data that we have are: source stream window matrix $B_s \in \mathbb{R}^{N_m \times m}$; source stream window labels vector $Y_s \in \mathbb{R}^{N_m \times 1}$, and target stream window matrix $B_t \in \mathbb{R}^{N_m \times n}$. In this case, the best projection strategy of L_s and L_t in the latent feature space would be the minimization of following objective function:

$$O = \min_{L_s, L_t} \ell(B_s, L_s) + \ell(B_t, L_t) + \beta \mathbf{D}(L_s, L_t) \tag{1}$$

where $\ell(\cdot, \cdot)$ is a distance function that evaluates the differences between the original data and projected data. $\mathbf{D}(\cdot, \cdot)$ is the co-regularizer that promotes the similarities between the two projected domains (L_s and L_t). β is a parameter that determines how desirable the two projected data are similar. The first two terms are expected to preserve the structure of the original data as much as possible. Therefore, we define the loss function $\ell(\cdot, \cdot)$ as the Frobenius norm, which can also be expressed as a matrix trace norm $\ell(B_s, L_s)$ equals $\|B_s - L_s W_s\|_F^2$, and $\ell(B_t, L_t)$ equals $\|B_t - L_t W_t\|_F^2$.

Furthermore, we define $\mathbf{D}(Ls, L_t)$ as follows:

$$\mathbf{D}(L_s, L_t) = \frac{1}{2}\ell(B_s, L_t) + \frac{1}{2}\ell(B_t, L_s) \tag{2}$$

which is the mean value of cross-similarity between the original data and projected data. Finally, the parameter β controls the trade-off of importance of semantic similarity co-regularization by minimizing the differences between $\mathbf{D}(L_s, L_t)$.

Combining Equation 1 and 2 together, we obtain the overall optimization objective function as follows:

$$\begin{aligned} O = &\|B_s - L_s W_s\|_F^2 + \|B_t - L_t W_t\|_F^2 \\ &+ \frac{1}{2}\beta \|B_s - L_t W_s\|_F^2 + \frac{1}{2}\beta \|B_t - L_s W_t\|_F^2 \end{aligned} \tag{3}$$

Notice here the projection itself will perform rotation and scaling on the target matrix to minimize the difference. Since L_s and L_t are

Algorithm 2 ChangeDetection: Change Detection

Require: Source instances $B_s = \{B_s\}^{i=1}$, target instances $B_t = \{B_t\}^{j=1}$, new instance x, initial mean discrepancy $Disc$, the change parameter τ.

Ensure: $True$ if drift is detected, else $False$.

1: /* Instance is from source stream */
2: **if** $x \in S$ **then**
3: $B_s^{(i)}, L_s^{(i)} \leftarrow B_s^{(i+1)}, L_s^{(i+1)}, i = 1, ..., N_m$.
4: $B_s^{(N_m+1)}, L_s^{(N_m+1)} \leftarrow x, xW_s^+$.
5: $\mu_S = \frac{1}{N_m} \sum_{i=1}^{N_m} L_s^{(i)} W_s^+$.
6: Go to line 11.
7: /* Instance is from target stream */
8: $B_t^{(N_m+1)}, L_t^{(N_m+1)} \leftarrow x, xW_t^+$.
9: $B_t^{(j)}, L_t^{(j)} \leftarrow B_t^{(j+1)}, L_t^{(j+1)}, j = 1, ..., N_m$.
10: $\mu_T = \frac{1}{N_m} \sum_{j=1}^{N_m} L_t^{(j)} W_t^{-1}$.
11: /* Calculate the mean discrepancy $Disc_t$ at time t: */ $Disc_t = \|\mu_s^t - \mu_t^t\|^2$.
12: $s = ln \frac{Disc_t}{Disc_0}$.
13: **Return** $s > -ln(\tau)$.

orthogonal matrices, $B_s^\top B_s = I$. Also, we are applying the cyclic permutation property of trace. Thus, Equation 3 can be expanded by the representation of trace.

After the steps described above, the optimal projection for both source and target stream to the latent feature space would be formed accordingly.

3.2 Classification Module

We start to train a classifier with a small set of data instances from both S and T, which are referred to as the initialization data. The new data representation is obtained by using initialization data from B_s and B_t as follows:

$$\begin{cases} L_s^{(i)} = B_s^{(i)} W_s^+ & B_s^{(i)} \in B_s \\ L_t^{(j)} = B_t^{(j)} W_t^+ & B_t^{(j)} \in B_t \end{cases} \tag{4}$$

where W_s^+ and W_t^+ are the Moore-Penrose inverse of the matrix W_s and W_t respectively, which can be represented as $(W_s^\top W_s)^{-1} W_s^\top$ and $(W_t^\top W_t)^{-1} W_t^\top$.

As new instances arrive in S or T, the classifier is updated if there is a drift to ensure that it represents the current concepts. A new classification model is trained using data in B_s and B_t at that time. Concept drift detection and the updating method used by MSDA will be discussed in the next subsection. MSDA predicts the class label of an incoming target instance from the target stream after projecting the instance into the new data format.

3.3 Change Detection Module (CDM)

Previous work [8] of multistream classification uses prediction confidence to detect changes in distribution between two different time windows. Due to possible asynchronous concept drifts between source and target streams, an ensemble of classifiers is maintained and updated if a concept drift is detected in either of these streams of data. Therefore, complex ensemble algorithms may lead to very slow execution.

Table 2: Datasets

Data type	Datasets	# features	# instances
APT detection	Win	28	10587
	Linux	105	10801
Dark web	BlackHat	38	32414
	Nulled	38	9930
	Darkode	67	100,000
	Hack	67	100,000
Digits	USPS	256	10,000
	MNIST	780	60,000
Amazon review	Video	100	5,000
	DVD	200	30,000
	Music	300	30,000
Synthetic data	Syn01	100	10,000
	Syn02	200	20,000

We adopt the Maximum Mean Discrepancy (MMD) as the distance measure to compare different distributions. The distance between two distributions can be computed between the sample means of the two domains in the k-dimensional embeddings:

$$Disc(L_s, L_t) = \left\| \frac{1}{N_m} \sum_{i=1}^{N_m} L_s^{(i)} W_s^+ - \frac{1}{N_m} \sum_{j=1}^{N_m} L_t^{(j)} W_t^+ \right\|^2 \tag{5}$$

where L_s, L_t are the set of projected data points in the source and target windows.

The difference between the distributions is determined by the log ration between MMD. Therefore, a concept drift point is detected if it is more than a user-defined threshold τ, as follows. And details regarding online updating algorithm for change point detection can be found in Algorithm 2.

$$S = \log \frac{Disc_t(L_s^t, L_t^t)}{Disc_0(L_s^0, L_t^0)} > \tau \tag{6}$$

3.4 Complexity Analysis

In our proposed approach, an update model is trained from source to target stream anytime when a concept drift point is detected. Hence, the time complexity of classification module is significant in determining the overall model complexity. Within the classification model, the training process, which is the updating model determines the complexity of whole algorithm.

MSDA has three modules, Domain Adaptation (DA) module, Change Point Detection (CDM) module, and classification module. The DA module learns projection matrix W_s W_t respectively, and from the instances stored in the source and target sliding window. Since it is a sequence of matrix transformation, the processing time is $O(kN_m)$. The time complexity of CDM module is $O(N_m^2)$. The time complexity of classification depends on the learning algorithm used as the base model. Therefore, MSDA has total time complexity of $O(kN_m + N_m^2)$.

4 EXPERIMENT

4.1 Baseline Methods

To evaluate the effectiveness of our proposed our method MSDA, we compare it with several state-of-the-art domain adaptation or online learning frameworks. Also, we applied two different variations of our method, which are MSDA-SVM and MSDA-LR. These

Table 3: Comparison of performance (Error %)

	Video → DVD	35.88 ± 0.88	40.28 ± 0.52	40.09 ± 0.61	**32.35 ± 0.49**	33.84 ± 0.65
Synthetic data	Syn01 → Syn02	37.53 ± 1.37	41.83 ± 0.83	42.12 ± 1.06	**33.50 ± 0.97**	35.47 ± 0.92

two methods are different in a way that classifiers applied are SVM and Logistic Regression. The following paragraphs describe details of baseline methods.

OTL [26]. Online Transfer Learning (OTL) uses a co-regularized method to project target domain data into the source domain. This method is applied in a supervised manner, which means that data in source domain are offline, while data in target domain are online. Furthermore, there is a strong assumption that features in source stream are a subset of those in target stream.

HeMap [23]. Heterogeneous Mapping (HeMap) projects data in two domains with correspondence onto a common latent space. This method is designed as a batch training, which means both source and target data are offline. Also, this method requires class labels in the target dataset. We adapt HeMap into our problem by applying sliding windows. Meanwhile, two classifiers, SVM and LR, are also applied in this method as variations, which are referred as HeMap-S and HeMap-L respectively.

4.2 Datasets

As shown in Table 2, we use both synthetic and real-world datasets to evaluate our methods [4]. Specifically, we incorperate security related datasets as well as non security related datasets here to validate our proposed framework.

Win and **Linux** This dataset consists of system-call events traces from windows host machine and linux host machines. We generated various attack instances which consist of attacks e.g. malicious exfiltration of data, password theft and scanning the system and services on a victim's network with nmap. For benign instances, we generated data which include web browsing activities and remote login using ssh. We collected the system call traces using sysdig trace tool for linux and procmon tool for windows. In total, we collected 10,587 and 10,801 trace instances. With Ngram, we extract features from contiguous sequences of system calls. Our goal is to classify whether a trace in the target stream is an attack.

BlackHat, Nulled, Darkode and **Hack** [21] are datasets extracted from dark web forums where illegal items are listed and sold . Note that all forums here are English forums. Our goal is to extract words that are products on the dark web forums. To satisfy the multistream setting with different domains, for BlackHat and Nulled, we extract the features using Penn Part of Speech Tags [22]. While, for Darkode and Hack datasets, features are extracted following the Stanford pos- tagger system [9]. Since forum posts are posted within a long time period, these streams satisfies the concept drift assumption.

USPS [15] and **MNIST** [18] contain gray-scale images of handwritten digits collected from different sources. In order to satisfy the concept drift assumption in this paper, we shift the concept of positive and negative classes in the middle of datasets. That is, in the first half of both USPS and MNIST, labels 0-4 represent "-" and labels 5-9 represent "+", while in the second half class labels 3-7 mean "+" and the rest class labels mean "-". Therefore, the concept drift assumption of data stream is satisfied in this setting.

Music, **DVD**, and **Video** [5] are text datasets generated by Amazon reviews based on product categories. We process these datasets in the same way as described in [5]. Since data in this stream covers more than one year, we assume that there are concept drift along the change of time by nature in these data streams.

Syn01, **Syn02** [4] are synthetic datasets that are generated by MOA framework. These datasets are generated in a way that the number of features in Syn01 is 100 while that in Syn02 is 200, so that our domain adaptation assumption can be satisfied. Meanwhile, we artificially add abrupt concept drift at the half position in these data streams.

4.3 Experiment Setup

Our MSDA approach involves multiple parameters. We use $N_m = 400$ as our default setting in the experiment. Meanwhile, $\beta = 1$, $k = 4$, and $\tau = 0.1$ are selected to conduct our initial experiment here. The sensitivity of parameters will be discussed later in this section.

4.4 Result Analysis

Figure 3 shows the distribution of features in the latent space. For a single window ($N_m = 400$), we plot the transformed source and target window together in one figure. Also, t-SNE is applied here to reduce the feature space to 2D. From this figure, we can see that binary classes from both source and target stream are well separated in two part of the latent space. This good separation makes it possible to find a hyper-plane in the space between two classes, which gives us confident and evidence to apply classifiers in this feature space.

Table 3 shows the average prediction error on the target stream T: $\frac{A_{wrong}}{m}$, where A_{wrong} is the total number of instances identified incorrectly, and m is the number of instances in the target stream. For security related datasets, for instance, the APT attack detection datasets, our method has 21.33% error rate, which outperforms all other benchmark algorithms. It has a better performance as the projected latent feature space. Also, our proposed framework has the best performance on identifying items on dark web forum datasets. Regarding non security datasets, we can tell that MSDA-S outperforms competing methods on almost every datasets. Also,

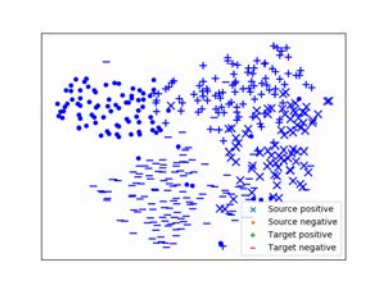

Figure 3: Latent Feature Embedding USPS→MNIST

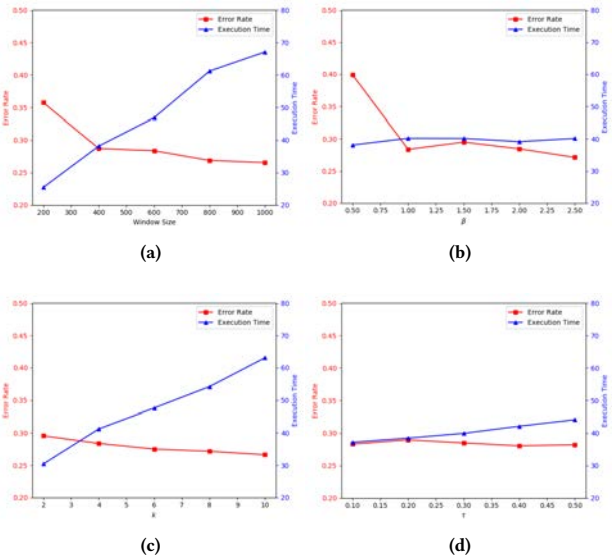

Figure 4: Sensitivity Analysis on USPS→MNIST

due to the fact that digits datasets are indeed very similar (all handwriting digits), which means that the source and target domain are pretty similar in this case, our algorithm shows best performance not only comparing to other benchmark methods, but also among all non security datastes. Furthermore, we can observe that our method works better when adapting from small feature space to larger feature space.

For example, the error rate of OTL, HeMap-S and MSDA-S on USPS → MNIST are 32.31%, 38.19% and 28.72% respectively. We can see that our proposed method has better performance by a significant margin compared to baseline methods. The reason is that for OTL, the algorithm has a strong assumption that features in the source data are a subset of those in the target stream, which is not quite the case here. Not all features in Video would exist in the DVD dataset in our settings. When it comes to HeMap, it also has its own shortcomings. HeMap is an offline method, which makes it not able to adapt the concept drift assumption in our problem. In this dataset specifically, the concept in the second half of data shifts from the first half of data (described in datasets section). Since we applied periodic updates every 4000 instances for the HeMap method, there is a delay on updating the model comparing our proposed MSDA-S approach.

In synthetic datasets, we observe similar phenomenon. Since the MOA framework can help generate concept drifts in the data stream, the two variations of HeMap don't perform well on this dataset. On the other hand, OTL seems to track the concept drift along the stream, however, since the dataset doesn't quite satisfy its assumption, the overall performance of MSDA-S beats other benchmarks by a significant margin.

4.5 Sensitivity Analysis

The results of our proposed method are further analyzed by tuning defined parameters N_m, β, k, and τ. All experiments are conducted on USPS → MNIST dataset. In this section, we vary N_m by setting it to {200, 400, 600, 800, 1000}, β to {0.5, 1, 1.5, 2, 2.5}, k to {2, 4, 6, 8, 10}, and τ to {0.1, 0.2, 0.3, 0.4, 0.5} respectively.

First, we can see in Figure 4 that the average error decreases along with window size increases, while the execution time increases with increasing window size. This is close to our expectation, as we state that the execution time of MSDA depends on N_m. Based on this observation, we should choose a medium value so that both error rate and execution time could be balanced.

Second, β determines the similarities between projected domains from both source and target stream. From Figure 4, we can tell that the error rate decreases significantly when β increases from 0.5 to 1. If $\beta > 1$, the decreasing trend of error rate is becoming not significant. Also, we can see from the figure that the execution time regarding different β remains similar in the experiment. Thus, we choose $\beta = 1$ as our recommended parameter here.

Third, parameter k determines how large the feature space is to apply our classifiers. From Figure 4, we can see that the performance of the model has improved marginally while the execution time increases dramatically as k increases. Thus, we need to choose as small k as possible, meanwhile we need to make sure that performance doesn't degrade. Thus, we choose $k = 4$ for our approach.

At last, we can see that for τ, which controls the threshold for concept drift detection. In this case, the performance of model doesn't quite change when τ varies. Therefore, based on performance of execution time, we need to choose a smaller τ. Hence, we select $\tau = 0.1$ in our model.

In all, sensitivity experiments indicate that MSDA is sensitive to N_m and k, while not quite sensitive to β and τ.

5 CONCLUSIONS

In this paper, a multistream classification framework that incorporates domain adaptation techniques is proposed. Two major challenges, namely heterogeneous domain and concept drift, are addressed simultaneously in two data streams. Our solution involves an embedding-based mapping approach to find a common latent space for both source and target streams, and an online update mechanism using MMD for concept drift correction. Additionally, the prediction model is updated if a concept drift is detected. Extensive experiments with both real-world and synthetic data show that our approach has significantly better performance in terms of error rate on various datasets, compared to existing state-of-the-art solutions.

ABSTRACT

Predicting pregnancy has been a fundamental problem in women's health for more than 50 years. Previous datasets have been collected via carefully curated medical studies, but the recent growth of women's health tracking mobile apps offers potential for reaching a much broader population. However, the feasibility of predicting pregnancy from mobile health tracking data is unclear. Here we develop four models – a logistic regression model, and 3 LSTM models – to predict a woman's probability of becoming pregnant using data from a women's health tracking app, Clue by BioWink GmbH. Evaluating our models on a dataset of 79 million logs from 65,276 women with ground truth pregnancy test data, we show that our predicted pregnancy probabilities meaningfully stratify women: women in the top 10% of predicted probabilities have a 89% chance of becoming pregnant over 6 menstrual cycles, as compared to a 27% chance for women in the bottom 10%. We develop a technique for extracting *interpretable* time trends from our deep learning models, and show these trends are consistent with previous fertility research. Our findings illustrate the potential that women's health tracking data offers for predicting pregnancy on a broader population; we conclude by discussing the steps needed to fulfill this potential.

1 INTRODUCTION

Predicting pregnancy is a fundamental problem in women's health [11, 13, 27, 41]. Modeling the probability of pregnancy, and identifying behaviors which affect it, allows for more efficient family planning. Identifying people with a very low chance of becoming pregnant is important for targeting and treating infertility, which can be a devastating experience [18]. Because of the importance of predicting and facilitating pregnancy, the fertility services market is predicted to grow to $21 billion by 2020 [38].

Attempts to predict pregnancy go back decades, often using Bayesian methods [11, 13, 27, 41] to capture the complex dynamics which govern fertility. Many factors influence fertility, including age [12] and medical conditions [24, 30]. Fertility fluctuates over the course of the menstrual cycle (which averages 28-29 days in length, although this varies across women [8]), peaking during the "fertile window", around 14 days before the end of the cycle. For women with a regular cycle of 28-29 days, the fertile window occurs approximately midway through the cycle [3, 50]. Because the timing of the fertile window varies, and intercourse during the fertile window is much more likely to result in pregnancy, fertility prediction methods often focus on detecting and predicting the fertile window, using ovulation tests and measurements of cervical mucus and basal body temperature [5, 16].

Previous studies of fertility have relied on carefully curated data from medical studies [3, 11, 13, 27, 39–41, 43]: for example, participants are generally asked to regularly monitor critical features like basal body temperature and menstrual cycle starts and to take pregnancy tests after each menstrual cycle. Many people are unwilling or unable to engage in such careful monitoring, limiting the applicability of these methods to the general population.

In the last few years, the growing use of health tracking mobile apps offers a new potential data source for predicting pregnancy in broader populations. Health tracking apps have been recognized as delivering a "data bounty" [19] for healthcare [32, 49]. Within women's health specifically, health tracking apps are used by millions of women worldwide [7, 15, 37], and have already been used to study sexually transmitted infections [2], menstrual cycle fluctuations [35, 47], and menstrual cycle lengths [21]. These apps allow

users to create profiles which include age and birth control information and keep daily logs of symptoms relevant to pregnancy, including basal body temperature, period starts, and ovulation tests. Crucially, they also allow women to log positive and negative pregnancy tests, providing a ground truth source of pregnancy data. Pregnancy data collected by women's health mobile apps differs from that collected in medical studies in three ways:

(1) **Larger datasets.** The dataset we consider in this paper contains tens of millions of observations from tens of thousands of women, orders of magnitude more than previous datasets [14]. Complex models developed for these smaller datasets, which often rely on computationally intensive techniques like MCMC sampling, will not scale to datasets from mobile health tracking apps, necessitating new methods.
(2) **Broader populations.** While previous fertility studies have predominantly focused on filtered, mostly healthy or proven fertile populations that volunteer for research within a single country, health tracking apps can be used by anyone with a smartphone, and are used by women all over the world.
(3) **Missing data.** Critical features like basal body temperature (BBT) and pregnancy tests are less reliably recorded in mobile health tracking datasets than in medical studies, making missing data a pressing concern.

Mobile tracking datasets thus present new challenges but also new opportunities for predicting pregnancy in a much broader population. To this end, a number of companies have announced initiatives to predict pregnancy or fertility using mobile tracking data [1, 28, 33, 42]. To date, however, it is unclear whether their fertility prediction algorithms are reliable, because they are proprietary (so they cannot be compared to or independently assessed) and their efficacy has been disputed [26, 31, 46].

This work. Here we present what is to our knowledge the first study of pregnancy prediction using fully described methods applied to large-scale women's health tracking app data. Using a dataset from a women's health tracking app which includes ground truth data on pregnancy tests, we develop and assess four pregnancy prediction models — an interpretable logistic regression model, and three LSTM models — which integrate traditional fertility modeling methods and modern time series prediction methods. We first show that our models meaningfully stratify women by their probability of becoming pregnant: women in the top 10% of predicted probabilities have a 89% chance of becoming pregnant over 6 menstrual cycles, while women in the bottom 10% have only a 27% chance. We further provide an intuitive technique for extracting *interpretable* time trends from our LSTM models, overcoming a common failing of deep learning models, and show that these time trends are consistent with previous fertility research. Finally, we discuss the steps that should be taken to maximize the efficacy of pregnancy prediction from women's health tracking data.

2 PROBLEM SETUP

Our task is predicting, on the basis of the health tracking data a woman logs during a single menstrual cycle, whether she will log a positive pregnancy test at the end of that cycle. We first describe our dataset and then describe our task in more detail.

2.1 Dataset

We use data from the Clue women's health tracking app [17]. The app has been rated the most accurate menstrual cycle tracking app by gynecologists [29] and previously used in studies which show that it reliably replicates known women's health findings [2, 21, 35]. All data is de-identified and analysis was determined to be exempt from review by the Stanford Institutional Review Board.

Features. Our dataset consists of two types of features:

- **User features.** Users can record age and birth control method (e.g., "None", "Condoms", "IUD", or various types of birth control pill). We encode age using a two-element vector: a binary element which indicates whether age data is missing, and a continuous element which is the value of age if it is present, and 0 otherwise. We encode birth control using a vector with indicator variables for each type of birth control; the vector is all zeros if birth control data is missing.
- **Daily feature logs.** Each row in this dataset consists of one log of one feature for one user on one date. Users can log 110 *binary* features, including positive/negative pregnancy tests (which we use to define ground truth, and do not include in the inputs to our model), period bleeding, mood and behavior features (eg, happy mood or exercise:running), and taking daily birth control. Users can also log 3 *continuous* features: basal body temperature (BBT), resting heart rate, and body weight. We list all daily features in Table 1.

Data filtering. To ensure that users are regularly using the app, we filter for users who enter at least 300 daily feature logs. We apply basic quality control filters to the three continuous features to remove unreliable values (for example, BBT $> 110^{\circ}F$). To minimize the chance that users are already pregnant, we filter out all cycles after a user has logged a positive pregnancy test.

Defining menstrual cycle starts. Because fertility fluctuates over the course of the menstrual cycle, defining menstrual cycle starts – when the period begins – is necessary to predict pregnancy. We define a *cycle start* as a start of bleeding after the user has not recorded any bleeding for at least 7 days. So, for example, if the user records bleeding on May 1, 2, and 29, the cycle starts would be May 1 and May 29. A user's *cycle day* is the number of days since their most recent cycle start, with 0 denoting the day of cycle start.

Encoding continuous features. We encode continuous features (eg, weight) using a two-element vector: a binary element which indicates whether data is present or missing, and a continuous element which is the value for the feature if present, and 0 otherwise. For each cycle and each user, we subtract off the mean for each continuous feature (since the *change* in features like BBT is most indicative of cycle phase and therefore fertility [6]). We include each user's average value of the three continuous features as a user-specific feature.

2.2 Prediction task

Our task is predicting from the first 24 days of a user's cycle whether she will become pregnant in that cycle. We choose the 24-day interval because most women are very unlikely to become pregnant past this interval [50]. Our prediction task is binary, and each example

Table 1: All daily features which appear in our data. Each feature has both a category and a type. Features are binary except for those in the "continuous" category. While pregnancy tests are included in the binary features, we do not use them as predictive features. HBC=hormonal birth control; TNP=type not provided.

Category	Type
Ailment	Allergy, Cold/Flu Ailment, Fever, Injury
Appointment	Date, Doctor, Ob Gyn, Vacation
Collection Method	Menstrual Cup, Pad, Panty Liner, Tampon
Continuous	BBT, Resting Heart Rate, Weight
Craving	Carbs, Chocolate, Salty, Sweet
Digestion	Bloated, Gassy, Great Digestion, Nauseated
Emotion	Happy, PMS, Sad, Sensitive
Energy	Energized, Exhausted, High Energy, Low Energy
Exercise	Biking, Running, Swimming, Yoga
Fluid	Atypical, Creamy, Egg White, Sticky
Hair	Bad, Dry, Good, Oily
Injection HBC	Administered, Type Not Provided
IUD	Inserted, Removed, Thread Checked, TNP
Medication	Antibiotic, Antihistamine, Cold/Flu Medication, Pain
Mental	Calm, Distracted, Focused, Stressed
Motivation	Motivated, Productive, Unmotivated, Unproductive
Pain	Cramps, Headache, Ovulation Pain, Tender Breasts
Party	Big Night Party, Cigarettes, Drinks Party, Hangover
Patch HBC	Removed, Removed Late, Replaced, Replaced Late, TNP
Period	Heavy, Light, Medium, Spotting
Pill HBC	Double, Late, Missed, Taken, TNP
Poop	Constipated, Diarrhea, Great, Normal
Ring HBC	Removed, Removed Late, Replaced, Replaced Late, TNP
Sex	High Sex Drive, Protected, Unprotected, Withdrawal
Skin	Acne, Dry, Good, Oily
Sleep	0-3 Hrs, 3-6 Hrs, 6-9 Hrs, 9 Hrs, TNP
Social	Conflict, Sociable, Supportive, Withdrawn
Test	Ovulation Neg, Ovulation Pos, Pregnancy Neg, Pregnancy Pos

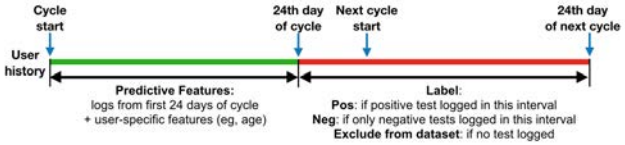

Figure 1: Prediction task. The model makes predictions using logs from the first 24 days of a cycle (green interval), and the cycle is labeled using pregnancy tests taken after day 24 of the cycle and before day 24 of the next cycle (red interval). The vast majority of pregnancy tests in our dataset are taken near when the user's cycle is supposed to start, consistent with proper use of pregnancy tests, so any positive pregnancy tests likely result from activity during the green interval, which will be included in the feature vector.

is one cycle for one woman. We define positive examples as cycles in which the woman logs a positive pregnancy test after day 24 of the cycle and before day 24 of the next cycle (Figure 1); we define negative examples as cycles with a negative pregnancy test and no positive pregnancy test. Thus, our dataset consists only of cycles followed by positive or negative pregnancy tests[1]. Importantly, predicting whether a test will be positive or negative is a difficult and useful prediction task, because it occurs in settings where the woman herself is sufficiently uncertain about whether she is pregnant that she believes taking a test is worthwhile. Our dataset consists of 16,580 positive cycles, 88,685 negative cycles, 65,276 women, and 79,423,281 symptom logs. The proportion of cycles which are positive in our dataset (16%) is consistent with previous work [10]. We use data from 90% of users for training/validation and report results on a test set of the remaining 10% of users. We train on a dataset balanced for positive and negative examples by downsampling each training batch (a standard technique for training on unbalanced data [23]). Following standard practice, we report all results on the unbalanced test dataset.

3 PREVIOUS WORK

Our predictive models rely on ideas both from the fertility modeling literature and from the deep learning time series prediction literature. We now summarize work in both areas.

[1]We define positive and negative examples in this way to mitigate missing data concerns. The alternative (i.e. assuming that any cycle without a positive pregnancy test is a negative example) is problematic for two reasons. First, some users may not bother to log positive tests, so the negative label is a false negative. Second, some users may not bother to log birth control, concealing the fact that they have very little chance of getting pregnant—consistent with this, we find that the fraction of positive examples using this method, even for users who log no birth control, is far lower than the previous literature would imply.

3.1 Fertility modeling

We briefly summarize three main approaches in the extensive fertility modeling literature; [14] provides a lengthier review.

(1) **Time-to-pregnancy (TTP) models** [20, 36, 44, 48] assume each individual menstrual cycle results in pregnancy with some probability μ which can vary across couples and over time. These models are useful for capturing the high level covariates which influence μ (eg, age) but they do not capture detailed daily dynamics within a single cycle (eg, sex during the fertile window is more likely to result in pregnancy). Therefore, they are less useful for modeling the health-tracking datasets we consider, whose strength is their detailed daily information.

(2) **Barrett-Marshall and Schwartz (BMS) models** [3, 11, 13, 39, 43, 45] allow for more detailed modeling of daily activity within each cycle. They assume each act of sex contributes independently to the probability a cycle results in pregnancy. The probability that someone becomes pregnant in a cycle is thus

$$1 - \prod_d (1 - f_d)^{S_d},$$

where d is the cycle day, f_d is the probability of getting pregnant by having sex only on day d, and S_d is a binary variable indicating whether sex occurred on day d. The term inside the product is the probability that day d does *not* result in pregnancy; it is 1 if S_d is 0, indicating that no sex occurred, and $1 - f_d$ if S_d is 1. Schwartz [43] extends this model by assuming that the overall probability of pregnancy also depends on a couple-specific parameter which captures, for example, the fact that some couples are infertile irrespective of sexual activity patterns. However, this additional parameter creates model identifiability problems.

(3) **Extended Time-to-Pregnancy (ETTP) models** [9, 40] provide an approximation to the BMS model by assuming that only sex on the most fertile day contributes to the probability of pregnancy, and sex on other days has no effect. As this model is only a pragmatic approximation to the true generative process, we instead develop a computationally efficient implementation of the BMS model.

All three of the above models were developed for datasets orders of magnitude smaller than the one we consider. Consequently, they perform parameter inference by estimating the posterior distribution, often using computationally intensive techniques like MCMC, and will not scale to our dataset. Therefore, in this work, we extend the BMS model using a scalable deep-learning-based model. Our extension scales to health-tracking datasets because it relies on more efficient backpropagation-based optimization.

3.2 Deep learning for time series prediction

Long Short Term Memory (LSTM) neural networks [22] have been successfully used to model medical time series data [4, 25, 34]. They maintain a hidden state at each timestep which can be used for prediction, and are a natural choice for prediction on time series with discrete timesteps (in our case, days of the menstrual cycle). Because they rely on more scalable backpropagation methods, they also scale to large health-tracking datasets.

4 MODELS

We develop four models. We select model hyperparameters – learning rate, hidden size, number of layers, batch size, dropout rate, and regularization strength – using grid search. Our models are publicly available at https://github.com/AndyYSWoo/pregnancy-prediction.

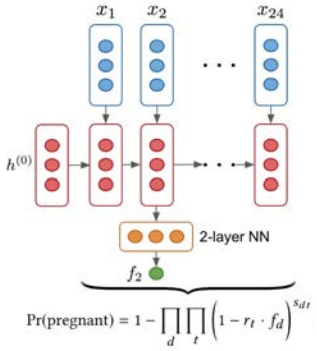

Figure 2: LSTM + BMS fertility model: we feed the daily features x (blue) into an LSTM model to obtain the hidden state h (red). f_d is then a function of the hidden state h parameterized by a neural network. The probability of becoming pregnant in a cycle is the function shown at bottom.

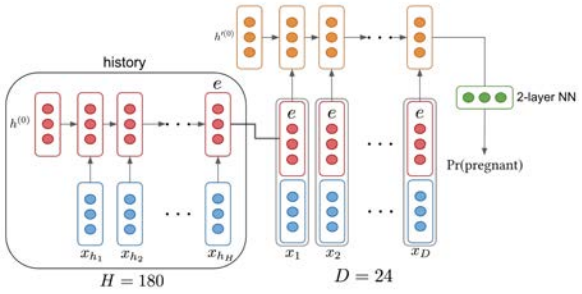

Figure 3: LSTM + user embedding: we use the history features, x_h, in the previous $H = 180$ days for the user and feed them into the "user history LSTM" (shown at left). The final hidden state becomes the user embedding vector e, which is then concatenated with the daily features from the current cycle and fed into the pregnancy prediction LSTM (right).

(1) **Logistic regression**. As an interpretable baseline, we use logistic regression with coefficients for each feature and each cycle day (for example, having unprotected sex on cycle day 14), and coefficients for each user-specific feature. Our feature vector for each example consists of 2,771 features.

(2) **LSTM**. We use an LSTM network with 24 timesteps (one for each cycle day). For each time-step, we feed as input the observed features for that cycle day (binary features plus continuous features, encoded as described in Section 2.1)

along with the cycle averages for continuous features. The final hidden state of the LSTM is concatenated with the user-specific features and fed into a fully connected layer to produce the prediction.

(3) **LSTM + BMS fertility model**. We develop an LSTM-based extension of the BMS model. As described in Section 3.1, the BMS model assumes each act of sex contributes independently to the probability a cycle results in pregnancy. Thus, we model a user's probability of becoming pregnant in a cycle as

$$\Pr(\text{pregnant}) = 1 - \prod_d \prod_t \left(1 - r_t \cdot f_d\right)^{s_{dt}}$$

where d is cycle day, t the type of sex (protected, unprotected, withdrawal, or none[2]), s_{dt} indicates if sex of type t was logged on day d, $f_d \in (0, 1)$ is the contribution of sex on cycle day d towards pregnancy, and $r_t \in (0, 1)$ is a learned parameter capturing the risk of a kind of sex (eg, $r_{\text{unprotected}} > r_{\text{protected}}$). The term inside the product is the probability that an act of sex of type t on cycle day d does *not* result in pregnancy. We model f_d as a function of the daily features x_d using an LSTM, as illustrated in Figure 2.

(4) **LSTM + user embeddings**. Using only the user's current cycle does not account for their full history: eg, a user who has frequently logged unprotected sex for a long time but has not yet become pregnant may be less fertile. To incorporate information prior to the current cycle, we use a "user history LSTM" to encode the 180 days of user history prior to the user's current cycle, then use this LSTM's final state as a user embedding vector which we concatenate onto the other features and feed into a second LSTM as before. We jointly train both LSTMs. Figure 3 illustrates the model architecture.

5 RESULTS

5.1 Predictive performance

Metrics. We evaluate model performance using AUC. Importantly, becoming pregnant is inherently a somewhat random process: it is impossible to *guarantee* a woman will become pregnant in a particular cycle. Consequently, achieving a very high AUC on our task is unlikely to be feasible, and we would not expect AUC to be very high. Nonetheless, we report AUC because it is a standard metric. As a second metric, we compare the probability p_{preg} that a user will log a positive pregnancy test after a cycle for the users in the top 10% of predicted pregnancy probabilities and users in the bottom 10% of predicted probabilities. (Note that p_{preg} is the true, not the predicted, probability of a positive pregnancy test.) However, the goal of fertility counseling is not to guarantee a woman will get pregnant in a particular cycle, but rather that over some reasonable time period (eg, 6 cycles) she has a good chance of becoming pregnant if she continues her current pattern of behavior. Thus, we also compute the 6-cycle probability of becoming pregnant, assuming that each cycle contributes independently to the probability of pregnancy and that woman continues her current pattern of behavior. For example, if a woman's single-cycle p_{preg} is 0.2, her six-cycle p_{preg} is $1 - (1 - 0.2)^6$.

Results. The LSTM with user embeddings has the highest AUC (0.67) (Table 2). This model is able to meaningfully stratify users by their probability of getting pregnant: for example, the top 10% of users have an 89% chance of pregnancy over 6 cycles, whereas the bottom 10% have only a 27% chance. While the other three models have somewhat lower AUCs, all four models usefully stratify users by pregnancy probability. The BMS model slightly worsens LSTM performance, possibly because of the more restrictive assumptions of its probability model – that is, that the overall probability of not getting pregnant in a cycle is the product of the probabilities of not getting pregnant on each cycle day. This demonstrates that traditional fertility models may not yield optimal predictive performance on mobile health datasets.

5.2 Interpretability

We next assess whether our models learn *interpretable* time trends which are consistent with prior fertility research. Because sexual activity is the feature most fundamentally associated with pregnancy, we examine time trends for the three types of sex logged in Clue data: unprotected, protected, and withdrawal sex.

Interpreting the logistic regression model. Extracting time trends from the logistic regression model is straightforward, because the model is specifically developed to be interpretable. To understand how a feature contributes to the probability of pregnancy, we simply plot the coefficients for logging the feature on each day (Figure 4, left). The daily feature which is most strongly associated with positive pregnancy tests (averaging weights across all cycle days) is unprotected sex; the feature which is most strongly associated with negative pregnancy tests is protected sex.

Interpreting the LSTM models. Interpreting deep learning models is much less straightforward, since they are high-dimensional and nonlinear and their coefficients do not have clear meanings. We use the following technique to quantify how logging binary feature b on day d influences the model's inferred probability of pregnancy:

(1) For each example in our test set, we set binary feature b to 1 on day d, and compute the modeled probability of pregnancy for the example, $\Pr(\text{preg}|x_{bd} = 1)$.
(2) For each example in our test set, we set binary feature b to 0 on day d, and compute the modeled probability of pregnancy for the example, $\Pr(\text{preg}|x_{bd} = 0)$.
(3) We compute $\Pr(\text{preg}|x_{bd} = 1) - \Pr(\text{preg}|x_{bd} = 0)$, averaging across examples. This corresponds to the average difference in modeled probabilities when the user does and does not log feature b on day d.

Figure 4 (right) shows results for the LSTM model with the best predictive performance (LSTM + user embeddings); results for the other two LSTM models are qualitatively similar. Like the logistic regression model, the LSTM model learns that unprotected sex (blue) is more positively associated with positive tests than protected sex (green) or withdrawal sex (orange). Unprotected sex during the middle of the cycle shows the strongest positive association.

[2]We allow the model to learn a non-zero probability of getting pregnant even if no sex is logged to account for missing data, where users neglect to log sex but still get pregnant; this significantly improves the BMS model's predictive accuracy.

Table 2: Predictive performance of all models. The third column provides the probability a pregnancy test is positive for users in the top 10% vs bottom 10% of pregnancy risk; the fourth column provides the probability over six cycles.

Model	AUC	Single cycle p_{preg}	Six cycle p_{preg}
Logistic regression	0.63	28% vs 5%	86% vs 26%
LSTM	0.65	30% vs 4%	88% vs 23%
LSTM + BMS	0.64	29% vs 4%	87% vs 22%
LSTM + user embeddings	0.67	30% vs 5%	89% vs 27%

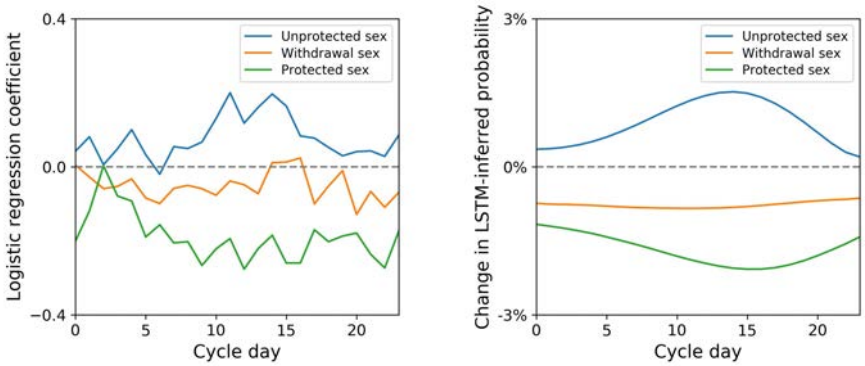

Figure 4: Model-learned time trends are interpretable for both the simple logistic regression model (left plot) and the best-performing LSTM + user embedding model (right plot). The horizontal axis is the cycle day. The vertical axis in the left plot is the logistic regression weight for logging a feature on that cycle day. The vertical axis in the right plot is how much logging a feature on a cycle day affects the LSTM-inferred probability of pregnancy. In both plots, positive y-values indicate associations with positive pregnancy tests, and negative y-values indicate associations with negative pregnancy tests. Both models learn that protected sex (green line) is negatively associated with pregnancy, while unprotected sex (blue line) is positively associated, particularly during the fertile window, and withdrawal sex (orange line) is intermediate.

Consistency with prior research. These modeled time trends are consistent with previous fertility research, which finds that unprotected sex during the "fertile window" [50] is most likely to result in pregnancy. The modeled increase in pregnancy probability due to unprotected sex on a single day is fairly small (<2% for the LSTM model); a plausible explanation for this is that many users are taking birth control. The negative weights for protected and withdrawal sex are of interest because they indicate that the associations learned by the model do not necessarily have causal interpretations. Obviously, having protected sex never reduces the chance of pregnancy in a *causal* sense; rather, it indicates that the woman is trying to avoid becoming pregnant. Overall, this analysis demonstrates that we can extract interpretable, biologically plausible time trends for sexual activity, the feature most fundamentally associated with pregnancy, for both the simple logistic regression model and the predictively superior LSTM models.

6 DISCUSSION

We develop four models for pregnancy prediction, combining ideas from both classical fertility modeling and modern deep learning techniques, and assess them using women's health tracking mobile data. We show we can stratify women by their probability of becoming pregnant and learn interpretable time trends consistent with prior fertility research. We develop a simple, intuitive technique to extract time trends from our LSTM models which is more broadly applicable to other time series datasets.

Based on our study, we recommend two steps to enable women's health tracking apps to reach their full potential for pregnancy prediction. First, companies should fully describe the algorithms used for pregnancy prediction; this will facilitate constructive criticism and increase confidence in the algorithms. Second, incentivize users to provide more complete data. In the Clue dataset, most users do not log pregnancy tests or predictively useful features like BBT; encouraging users to provide this data will improve predictions.

These two improvements can facilitate prediction tasks which build on the one described here. For example, early identification of people who are very unlikely to become pregnant can allow faster referrals to infertility treatment. Modeling the behaviors which *causally* contribute to pregnancy can be used to recommend behavior: for example, having sex during a person-specific fertile window. Progress on these prediction tasks will improve well-being for the millions of people pursuing pregnancy.

ABSTRACT

In traditional machine learning, classifiers training is typically undertaken in the setting of single-task learning, so the trained classifier can discriminate between different classes. However, this must be based on the assumption that different classes are mutually exclusive. In real applications, the above assumption does not always hold. For example, the same book may belong to multiple subjects. From this point of view, researchers were motivated to formulate multi-label learning problems. In this context, each instance can be assigned multiple labels but the classifiers training is still typically undertaken in the setting of single-task learning. When probabilistic approaches are adopted for classifiers training, multi-task learning can be enabled through transformation of a multi-labelled data set into several binary data sets. The above data transformation could usually result in the class imbalance issue. Without the above data transformation, multi-labelling of data results in an exponential increase of the number of classes, leading to fewer instances for each class and a higher difficulty for identifying each class. In addition, multi-labelling of data is very time consuming and expensive in some application areas, such as hate speech detection. In this paper, we introduce a novel formulation of the hate speech type identification problem in the setting of multi-task learning through our proposed fuzzy ensemble approach. In this setting, single-labelled data can be used for semi-supervised multi-label learning and two new metrics (detection rate and irrelevance rate) are thus proposed to measure more effectively the performance for this kind of learning tasks. We report an experimental study on identification of four types of hate speech, namely: religion, race, disability and sexual orientation. The experimental results show that our proposed fuzzy ensemble approach outperforms other popular probabilistic approaches, with an overall detection rate of 0.93.

1 INTRODUCTION

Traditional supervised learning typically involves training of a classifier on a single-labelled data set, i.e. each instance is assigned one label only. In this context, each label is treated as a single class and different classes are assumed to be mutually exclusive. However, this assumption does not always hold in real world applications. For example, images can be labelled to show different concepts, different people and different objects. Also, a movie can be included in multiple categories. Therefore, researchers have been motivated to transform the problem to multi-label classification (learning).

In the context of multi-label learning, each instance can be assigned more than one label. Each distinct set of labels *LS* assigned to one or more instances can be generally treated as a single class C_k, such that the training of a classifier can still be undertaken through discriminating one class from the other classes. This strategy is referred to as 'Label Power-set' [1] in the setting of single-task learning, which aims to allow a traditional learning approach to be used for training a single classifier on multi-labelled data [22] as a single task. On the other hand, a multi-labelled data set D can also be transformed into n binary data sets $D_1, D_2, ..., D_n$ (each one D_k per label l_k), such that a traditional learning approach can be used to train a binary classifier h_k on each data set D_k for identifying the corresponding label l_k. This strategy is referred to as 'Binary Relevance' [39] in the setting of multi-task learning and the training of the binary classifiers is treated as multiple tasks [22]. A more detailed review of multi-label learning can be found in [32, 39].

In general, different labels can have specific relationships such as mutual independence and positive correlation (co-occurrence) , if the labels are not mutually exclusive. In this context, if the labels assigned to each instance are mostly independent of each other, the above Label Power-set strategy for handling multi-labelled data could result in an exponential increase of the number of classes and a reduced number of instances for each class [23, 32]. In this case, the complexity of the learning task is much increased leading to a higher risk of overfitting [30]. Also, if the labels assigned to each instance have some positive correlations, the above Binary Relevance strategy through data transformation would not only result in the class imbalance issue but also fail to identify potential correlations between labels [22, 30]. In addition, data labelling is very time consuming and expensive in some application areas such as hate speech detection [2], which indicates a higher degree of infeasibility of multi-labelling of data in these areas.

In order to overcome the above limitations, in this paper, we propose a three-level framework for hate speech detection, which involves identification of the presence or absence of hate speech in level 1, identification of the types of hate speech in level 2 and identification of topics and contexts of hate speech in level 3. However, we focus on level 2, since different types of hate speech could have some intersectionality [9] increasing the complexity of this problem and an appropriate formulation of this problem is needed to achieve effective identification. In particular, we propose a fuzzy ensemble approach for hate speech type identification in the setting of multi-task learning. In this setting, we show how single-labelled data can be used to enable semi-supervised multi-label learning through a new problem formulation and two new metrics are also defined for effective evaluation of the performance for this kind of learning tasks. An experimental study is reported to show that the proposed fuzzy approach is more suitable and effective for this kind of learning tasks, comparing with the popular approaches.

The rest of this paper is organized as follows: Section 2 provides an overview of cyberhate research. In Section 3, we introduce the proposed three-level framework in general and focus on illustration and justification of the proposed fuzzy approach for semi-supervised multi-label learning. In Section 4, we provide the general description of the data used for this experimental study and show the results for evaluation of the proposed approach in comparison with the state of the art ones. In Section 5, the contributions of this paper are summarized and further directions are suggested towards further advances.

2 RELATED WORK

Since the spread of online hate speech could lead to disruptive anti-social outcomes, cyberhate has thus been considered as a legal issue in many countries [5]. In particular, many European countries have already initiated legal actions to prevent online hate speech to be posted [6]. However, it has been complicated to take such actions since the World Wide Web is naturally borderless [25]. Also, due to different laws from different countries, it has become more difficult to prosecute the senders of online hate speech and this even results in the lack of power for removing any hateful contents posted from a location outside their territory [5]. Outside of legal procedures, social network providers, such as Facebook and Twitter, have also been responsible to take any necessary steps towards restricting online hate speech significantly [4]. This has motivated researchers to develop automatic tools for hate speech detection, such that the post of hateful contents can be effectively prevented [2]. In particular, machine learning has become a very popular tool for automatic detection of hate speech [8, 35, 40].

In the context of machine learning based cyberhate detection, some traditional learning algorithms, such as Support Vector Machines (SVM) [9], Naive Bayes (NB) [15, 29], Logistic Regression (LR) [33, 35] and Random Forests (RF) [8], have also been used in the previous studies. A pragmatic approach was proposed in [34] for detecting hateful and offensive expressions, based on unigrams and automatically collected patterns for training classifiers by using SVM, DT and RF. Also, some other state-of-the-art methods of feature extraction, such as N-grams (NG) [14] and Typed Dependencies (TD) [8, 9] and Text Embedding [26], have been used to capture hateful characteristics. In general, text embedding shows its advantages (in terms of reduction of the dimensionality and the sparsity) and better performance than the other methods, while the three learning algorithms SVM, NB and DT generally show their better suitability for training classifiers.

In recent years, deep learning methods have also been used for both feature extraction and training of classifiers. In particular, Gamback and Sikdar have recently used Convolutional Neural Networks (CNN) in [12] for classifying hate speech using different types of features and they showed that the use of embedding features extracted through word2vec led to the best performance on a data set that involves multiple classes [33]. In [3], multiple deep neural network (DNN) architectures, such as CNN and Long Short Term Memory (LSTM) Networks, were compared using the same data set. The DNN architectures were adopted to learn semantic word embeddings as features for training classifiers. The experimental results reported in [3] show that the use of embedding features led to better classification performance than the use of features extracted through BOW or NG. In terms of training classifiers on the above embedding features, the results show that GBT outperformed DNNs and traditional learning methods (SVM and LR).
