In Figure 4, we illustrate the most popular categories in the Polyvore dataset. Each circle denotes a category, and each link denotes the matching relation between two categories (i.e., the two categories have appeared in the same outfit). The areas of circles and the widths of the links are proportional to the number of fashion items in the corresponding categories and the co-occurrence frequency between categories.

Similar to Figure 4, we construct a *Fashion Graph* $\mathcal{G} = (\mathcal{N}, \mathcal{E})$ according to the training dataset. Each node in the graph $n_i \in \mathcal{N}$ represents a category $c_i \in C$, so that $|\mathcal{N}| = |C|$. The edge represents interaction between nodes. If two categories have matching relation in the training dataset, there are two directed edges in reverse directions between the two corresponding nodes in *Fashion Graph*, since the interactions in two directions ought to different.

For example, one may select a pair of socks to match the shoes but less likely to select a pair of shoes to match socks particularly.

According to the training dataset, we calculate the weights of directed edges as follow,

$$w(n_i, n_j) = \frac{Count_{c_i,c_j}/Count_{c_j}}{\sum_k Count_{c_i,c_k}/Count_{c_k}}, \tag{1}$$

where $w(n_i, n_j)$ denotes the weight of edge from n_i to n_j, $Count_{c_i,c_j}$ is the co-occurrence frequency of category c_i and c_j, and $Count_{c_j}$ is the occurrence frequency of category c_j.

The constructed *Fashion Graph* has 120 nodes and 12500 directed and weighted edges. By putting each item into its corresponding node, an outfit can be represented as a subgraph of *Fashion Graph*. Then we use NGNN to infer the compatibility from the subgraph as described in the next section.

4.3 Node-wise Graph Neural Network

Our proposed method NGNN consists of three steps. The first step is to learn the initial node state. The second step is to model node interactions and update node state. The third step is to calculate the compatibility score with attention mechanism.

4.3.1 Learning Initial Node State. In NGNN, each node n_i is associated with a hidden state vector h_i, which will be updated dynamically. The input of NGNN is features (either visual or textual features) of items, which can be used to initialize the state of their corresponding nodes. For each item $v_i \in s$, we first map its feature f_i to a latent style space with the size of d. Considering the difference among the categories, we have a linear mapping matrix W_h^i for each category c_i. Thus, we can obtain the representation of item v_i in the latent space as follows,

$$r_i = W_h^i f_i. \tag{2}$$

We then use the representation to initialize the hidden state h_i^0 of its category corresponding node n_i as,

$$h_i^0 = tanh(r_i). \tag{3}$$

Thus, the size of node state is also d.

4.3.2 Modeling Node Interactions. Each time the nodes communicate (i.e., propagate their state information to others and receive others' information), which is called a propagation step, the state of nodes will be updated.

In the traditional GGNN, at propagation step t, the nodes will receive sum of neighbors' state as,

$$a_i^t = \sum_{n_j \to n_i \in \mathcal{E}} \mathbf{A}[n_j, n_i] W_p h_j^{t-1} + b_p, \tag{4}$$

where W_p and b_p are weights and biases of a shared linear transformation on all the edges. $\mathbf{A}$ is the adjacency matrix:

$$\mathbf{A}[n_i, n_j] = \begin{cases} w(n_i, n_j), \text{ if } n_i \to n_j \in \mathcal{E}, \\ 0, \text{ others }. \end{cases} \tag{5}$$

The traditional GGNN use the same W_p and b_p to model interactions between different nodes. However, it fails to model the complex and flexible interactions between them. Since the node interaction on each edge ought to be different, we aim to model edge-wise interaction. There is a straight-forward way to achieve edge-wise node interactions, that is to let each edge has its own transformation weight and bias W_p and b_p. However, it will cost a great parameter space with numerous edges in a graph and cannot be applied on large scale graphs.

To remedy the problem above, we have an output matrix W_{out}^i and an input matrix W_{in}^i for each node n_i in NGNN. The transformation function of edge $n_i \to n_j$ from node n_i to node n_j could be written as

$$W_p^{n_i \to n_j} = W_{out}^i W_{in}^j. \tag{6}$$

Thus, the Equation 4 could be rewritten as,

$$a_i^t = \sum_{n_j \to n_i \in \mathcal{E}} \mathbf{A}[n_j, n_i] W_{out}^j W_{in}^i h_j^{t-1} + b_p. \tag{7}$$

After receiving state information a_i^t, the state of node n_i will be updated as following,

$$z_i^t = \sigma(W_z a_i^t + U_z h_i^{t-1} + b_z), \tag{8}$$

$$r_i^t = \sigma(W_r a_i^t + U_r h_i^{t-1} + b_r), \tag{9}$$

$$\tilde{h}_i^t = tanh(W_h a_i^t + U_h(r_i^t \odot h_i^{t-1}) + b_h), \tag{10}$$

$$h_i^t = \tilde{h}_i^t \odot z_i^t + h_i^{t-1} \odot (1 - z_i^t), \tag{11}$$

where, $W_z, W_r, W_h, b_z, b_r, b_h$ are weights and biases of the updating function, which are similar to Gated Recurrent Unit (GRU) [18]. z_i^t and r_i^t are update gate vector and reset gate vector, respectively.

After T propagation steps, we can obtain the final state of nodes, which are also the final node representations. Then we can generate a graph-level output to serve as the compatibility score x_s of outfit s. We adopt the attention mechanism described in next section to compute the graph-level output.

4.3.3 Compatibility Calculating with Attention Mechanism. We contend two viewpoints on how fashion item influence the outfit compatibility here. The first viewpoint is that items have different influence on an outfit. For example, an improper top and an improper necklace have different influence to the outfit influence. The second is that the same item plays different roles in different outfits. For example, a coat maybe suitable for an outfit and promote the compatibility, while it will decrease the compatibility together with summer clothes. Thus, we aim to design an attention mechanism to model the influence of items on the outfit compatibility. Since a node receives state information from other nodes, their node representations are aware of the global information (i.e., other nodes' state). Similar with [18], we utilize self-attention [35, 37] to calculate the graph-level output and also the outfit compatibility score as following,

$$x_s = \sum_{i=1}^{|s|} \sigma(\theta(h_i^t)) \cdot \alpha(\delta(h_i^t)). \tag{12}$$

$\theta(\cdot)$ and $\delta(\cdot)$ are two perception networks to output a real value. $\theta(\cdot)$ is used to model the weights of items (i.e., importance of items' influence on the outfit compatibility), and $\delta(\cdot)$ is used to model the compatibility score of items (i.e., how the item goes with the other items in the outfit). $\alpha(\cdot)$ and $\sigma(\cdot)$ are leaky relu and sigmoid activate functions $\alpha(x) = max(0.01x, x), \sigma(x) = 1/(1 + e^{-x})$.

4.4 NGNN with Multi-modal Input

As described above, with the input of visual features or textual features of items, NGNN can be used to model the outfit compatibility from visual or textual modality. We here introduce how to jointly model the outfit compatibility from both visual and textual modality with NGNN.

We use two channels of NGNN, the input of a channel is visual features, and the input of another channel is textual features. Specifically, for each outfit s, we input the visual features and textual features to the two channels of NGNN respectively and obtain a visual compatibility score x_s^{vis} and a textual compatibility score x_s^{txt}. We calculate the final outfit compatibility score x_s as follow,

$$x_s = \beta x_s^{vis} + (1-\beta) x_s^{txt} \tag{13}$$

where β is a non-negative trade-off parameter.

As described in Section 4.3.1, for each item v_i, its visual feature f_i^{vis} and textual feature f_i^{txt} are mapped into a shared latent space respectively. We denote their representations in latent space as r_i^{vis} and r_i^{txt}. Considering the coherent relation between the visual and textual information of items, we use a regularization to ensure the consistency between the visual and textual feature of the same item in the shared latent space as follow,

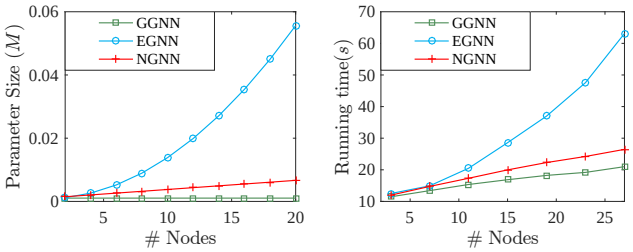
$$\mathcal{L}_{con} = \sum_{i=1}^{|s|} \left\| r_i^{vis} - r_i^{txt} \right\|^2 \tag{14}$$

4.5 Training Strategy

We denote outfits in the training dataset as positive outfits. For each outfit $s = \{v_1, v_2, ..., v_p, ...\} \in \mathcal{S}$, we randomly select an item v_p and replace it with a random item $v_q \in \mathcal{V}$ to form a negative outfit $s^- = \{v_1, v_2, ..., v_q, ...\}$. Thus, we can obtain a dataset $\mathcal{P}_{train}$ consisting of these pairs (s, s^-). Similar to Bayesian Personalized Ranking [28], we assume that the positive outfit has higher compatibility than the negative one. Therefore, we have the following objective function,

$$\mathcal{L}_{bpr} = \sum_{(s,s^-)\in\mathcal{P}_{train}} -\ln \sigma(x_s - x_{s^-}). \tag{15}$$

The objective function of NGNN is:



$$\mathcal{L}_1 = \mathcal{L}_{bpr} + \frac{\lambda}{2} \|\Theta\|^2, \tag{16}$$

where Θ refers to the set of parameters and λ is the hyper-parameter of L2 regularizer, which is designed to avoid overfitting.

When it comes to NGNN with multi-modal input, we have an additional loss function $\mathcal{L}_{con}$ as described in Section 4.4. Thus, we have the following objective function,

$$\mathcal{L}_2 = \mathcal{L}_{bpr} + \mathcal{L}_{con} + \frac{\lambda}{2} \|\Theta\|^2. \tag{17}$$

We only train NGNN on the subgraph of outfit each time. That is to say, only the nodes in the subgraph are trained and only their parameters are updated each time, which greatly reduces time complexity. When we have more data to train the model, we only need to update the parameters of concerned nodes without changing the parameters of edges or other nodes, which is effective in real applications.

(a) Parameter Size (b) Running Time

Figure 5: The parameter sizes and running time of GGNN, EGNN and NGNN on graphs with the number of nodes varying from 2 to 30. EGNN is a simple variant of GGNN, in which every edge has a different dtransformation matrix for propagating state information.

4.6 Model Analysis

In this section, we analyze the parameter space and time complexity of our proposed method NGNN.

4.6.1 Parameter Space. The parameter space of our proposed method consists of two parts: the parameters correlated to nodes and the perception networks in attention mechanism. For each node n_i, we have a linear mapping matrix W_h^i to map the input features into the latent space, an input matrix W_{in}^i and an output matrix W_{out}^i to propagate state information. Totally we have $3|\mathcal{N}|$ matrices, which are proportional to the number of nodes $|\mathcal{N}|$. In addition, we have two matrices of perception networks in the attention mechanism. Overall, we have $3|\mathcal{N}|$ matrices. Therefore, we say that the parameters of NGNN is node-wise.

4.6.2 Time Complexity. For each input outfit s, the time complexity of training process in NGNN consists of three parts. The first part is calculating the transformed state information nodes receive, which is $O(|s|)$. The second part is updating the state of the concerned nodes, which is also $O(|s|)$. The last part is updating the parameters of concerned nodes. Since the number of parameters correlated to the concerned nodes is $3|s|$ as described above, its complexity is also $O(|s|)$. According, the total complexity is $O(|s|)$.

We compare NGNN with GGNN [18] and Edge-wise GNN (EGNN). EGNN is a straight-forward way to achieve edge-wise interactions. In EGNN, each edge has an unique transformation matrix for propagating state information. We train the three models on a toy dataset consisting of outfits with the number of items varying from 2 to 30. In another word, the three models are trained on graphs with the number of nodes varying from 2 to 30. The parameter size and running time are shown in Figure 5. As can be seen, the parameter size and running time of EGNN increased quadratically while those of NGNN and GGNN increased linearly.

In summary, NGNN can better model edge-wise interactions and learn better node representations with appropriate parameter space and time complexity. When there are more training data, we can only update the parameters of concerned nodes offline and upload them online without changing the edges or other nodes, which is effective in real applications.

5 EXPERIMENTS

As the main contribution of this work is to model outfit compatibility, we aim to answer the following research questions via experiments.

- **RQ1** How does our proposed NGNN perform compared with other pair or sequence representation models?
- **RQ2** How do different components in NGNN effect the performance?
- **RQ3** How do different modalities influence the inference of compatibility?
- **RQ4** How do the hyper-parameters d and T effect the performance?

Next, we first describe the two tasks we conduct experiments on and the experimental settings. We then report the results by answering the above research questions in turn. Finally, we analyze the parameter space and time complexity of our proposed model.

5.1 Task Description

We conduct experiments on two tasks: fill-in-the-blank fashion recommendation and compatibility prediction on the polyvore dataset described in Section 3.1.

5.1.1 Fill-in-the-blank Fashion Recommendation. The task of fill-in-the-blank (FITB) in fashion recommendation is first introduced in [9]. In this task, Given a set of fashion items and a blank, we aim to find the most compatible item from the candidates set to fill in the blank as shown in Figure 6. This is a practical scenario in people's daily life. For example, a person wants to select clothes to match the pants, hat and shoes. Following [9], we create a fill-in-the-blank dataset based on the Polyvore test dataset. For each outfit in the test dataset, we randomly select an item from it and replace the item with a blank. By randomly select 3 negative items from $\mathcal{I}$ we can form a 4-length candidates set along with the positive one, assuming the negative items are less compatible than the positive one. In our work, we respectively put the four candidate items into the blank to form an outfit and calculate their compatibility scores with our model. The one which achieves the highest outfit compatibility score is chosen as the answer. The performance is evaluated by the accuracy of choosing the right answer from the four candidates (FITB accuracy), which is 25% by randomly selecting.

5.1.2 Compatibility Prediction. This task is to predict the compatibility score for any given outfit. To evaluate our model, we first construct a dataset $\mathcal{P}_{test}$ using the Polyvore test dataset. Specifically, for each positive outfit s in the Polyvore test dataset, we create a negative outfit s^- by randomly selecting $|s|$ items from $\mathcal{V}$. Thus, we can obtain a dataset $\mathcal{P}_{test}$ consisting of evaluation pairs (s, s^-). We then adopt the widely used metric AUC (Area Under the ROC curve) to evaluate the performance, which is defined as,

$$AUC = \frac{1}{|\mathcal{P}_{test}|} \sum_{(s,s^-)\in\mathcal{P}_{test}} \delta\left(x_s > x_{s^-}\right), \tag{18}$$

where $\delta(a)$ is an indicate function that returns one if the argument a is *true* and zero otherwise.

Table 1: The performance of models evaluated by Fill-in-the-blank accuracy and compatibility prediction AUC.

Method	Accuracy (FITB)	AUC (Compatibility)
Random	24.07%	0.5104
SiameseCNNs	48.09%	0.7087
LMT	50.91%	0.6782
Bi-LSTM	67.01%	0.8427
GGNN (visual)	72.78%	0.9516
GGNN (textual)	73.63%	0.9591
NGNN (visual)	77.01%	0.9600
NGNN (textual)	77.78%	0.9716
NGNN (multi-modal)	**78.13%**	**0.9722**

5.2 Experimental Settings

For optimization, we adopt the RMSProp optimizer. The optimal hyper-parameters (learning rate, batch size, trade-off parameter β, parameter for L2 regularization λ, hidden size d and the propagation steps T) are determined by the grid search strategy. We experimentally find that the model achieves optimal performance with the learning rate as 0.001, batch size as 16, β as 0.2, λ as 0.001, d as 12 and T as 3. We early stop the training process when the loss stabilizes, usually at 12 epoch. All the experiments were conducted over a sever equipped with 3 NVIDIA Titan X GPUs.

5.3 Model Comparison (RQ1)

To evaluate our proposed method, we compare it with the following state-of-the-art baselines. Note that SiameseCNNs and LMT focus on the compatibility between two items. In the task of outfit recommendation, we sum up the compatibility scores of all the pairs in the outfit as the score of the outfit.

Random: Randomly assign the compatibility scores of outfits.

SiameseCNNs: It's a pair-wise compatibility learning method [38], which minimizes the distance of image vectors between compatible items and maximums the distance between incompatible items. This method only focuses on the visual information.

LMT: Proposed by [23], it models compatibility between items in a style space via a single low-rank Mahalanobis embedding matrix. This method also focuses on visual modality.

Bi-LSTM: It's proposed by [9]. By viewing an outfit as a sequence, it uses the bidirectional LSTMs to predict the next item, taking multi-modal data as input, which can also predict the compatibility scores of outfits. This method focus on multi-modal information.

GGNN (visual / textual): We use GGNN to model the outfit compatibility with input of visual or textual features of items.

NGNN (visual / textual): We use our proposed NGNN to model the outfit compatibility with input of visual or textual features of items.

NGNN (multi-modal): We jointly models the outfit compatibility with NGNN from the visual and textual modalities.

We conduct comparison experiments on the tasks of fill-in-the-blank fashion recommendation and compatibility prediction. The results are shown in Table 1. Next we analyze the results of FITB accuracy and compatibility AUC respectively.

Figure 6: Comparison of our model and Bi-LSTM on several examples in fill-in-the-blank task. Green fonts represent the right chosen and red fonts represent wrong chosen.

Figure 7: Comparison of our model and Bi-LSTM on several example of task compatibility prediction. Green fonts represent the right evaluation and red fonts represent wrong.

5.3.1 FITB Accuracy. The comparison of FITB accuracy is shown in the middle column of Table 1. We can obtain the following observations from the table: (1) SiameseCNNs and LMT achieve worse performance compared with the other methods, which demonstrates that the pair representation ignores the integrity of outfit. (2) GGNN outperforms Bi-LSTM, suggesting that our proposed graph representation can better reflect the complex relations among items in an outfit than sequence representation. (3) NGNN achieves a better performance than GGNN, which proves that our proposed NGNN can better infer compatibility information from the graph by better modeling node interactions. (4) Using textual features achieves better performance than visual features for both GGNN and NGNN, which suggests that the textual features can better represent fashion items than visual features in that the titles accurately summarize the key features of items. (5) NGNN with Multi-modal input achieves best performance, proving that the visual and textual information are good supplements to each other. In addition, our proposed method can jointly model the outfit compatibility from multiple modalities. We randomly select several example outfits in the FITB dataset to test on our model and Bi-LSTM. The results are shown in Figure 6. From example 1, we can see that Bi-LSTM and our model can both correctly select the item of complementary category as the outfit lacks of a pair of shoes. In example 2, our model chooses the right item while Bi-LSTM choose the skirt wrongly, which conflicts with the pants. This may be because that the position of pants is far away from the blank so that it has little influence on it. In example 3, our model selects the most compatible bottom jeans with the whole set from the four bottoms while Bi-LSTM selects the white short skirt which may be most compatible with the white shirt, but not such compatible with the other items. The wrong chosen of Bi-LSTM may be because that the nearby white shirt has strong influence on the blank. From these example, we can draw a conclusion: the items have strong influence on nearby items in the sequence while have less influence on items faraway. This makes the sequence represented method relies on a proper sequence order. Compared with the sequence-represented model Bi-LSTM, our graph-represented model can better model the complex relations among items in an outfit.

5.3.2 Compatibility AUC. The performance comparison of models evaluated by compatibility AUC is shown in the third column of Table 1. Similar with the comparison of performance evaluated by FITB accuracy, NGNN achieves best performance, GGNN is second best, and then is the sequence represented method Bi-LSTM, the pair represented methods (SiameseCNNs, LMT) are worst. Using textual features can achieve better performance than visual features. NGNN with multi-modal data achieves the best performance. These observations support our analysis in Section 5.3.1. In addition, it can be seen that GGNN and NGNN all achieve great performance and the gap is small, which proves the superiority of graph representation on compatibility prediction. GGNN is already good enough for compatibility prediction.

We randomly select several example outfits and show the compatibility scores predicted of Bi-LSTM and our model in Figure 7. In example 1, our model gives the outfit a high score correctly while Bi-LSTM gives it a relatively low score, which may be because that the sequence representation method fails to capture the high compatibility between the first top and the fifth handbag. While Bi-LSTM and our model both give the outfit a high score correctly

in example 2. In example 3, the fifth shorts conflict with the first skirts. Our model gives it a low score correctly while Bi-LSTM gives it a relatively high score, which may be because Bi-LSTM fails to capture the conflict of the two bottoms across a long distance. Examples 2 and 3 suggest that Bi-LSTM relies on a proper order of sequence, which is flexible and hard to learn. The influence between two items is inversely proportional to their distance in the sequence. Our model can better reflect the relation among items compared with Bi-LSTM. In example 4, our model gives it a low score to the positive outfit. A plausible explanation is that there is little matching of coat, sweater and shorts in training dataset.

Table 2: The performance of our proposed method with different components.

Method	FITB Accuracy	Compatibility AUC
NGNN(-W-A)	75.17%	0.9541
NGNN(-W)	75.71%	0.9559
NGNN(-A)	76.12%	0.9578
NGNN	**77.01%**	**0.9600**

5.4 Component Comparison (RQ2)

To investigate the effect of different components on the performance of our proposed method, we compare our method with different components.

NGNN (-W): NGNN without weighted adjacency matrix. Specifically, we use 0-1 adjacency matrix instead of the weighted one as described in Section 4.2.

NGNN (-A): NGNN without attention mechanism. We only use a perception network to model the compatibility scores of nodes and sum them up them.

NGNN (-W-A): NGNN with neither the attention mechanism nor weighted adjacency matrix.

The performances are shown in Table 2. If not specifically stated, we use visual features as input of NGNN. We observe that NGNN outperforms all the ablative methods, which proves the necessity of the two components in our model. NGNN (-W) achieves worse performance than NGNN, suggesting that the weighted adjacency matrix we calculated is a supplement to the information of graph. NGNN outperforms NGNN (-A), which confirms the necessity of our attention mechanism.

To intuitively illustrate how the attention mechanism works, we show the attention weights of several example outfits in Figure 8. The depths of color are proportional to the attention weight of items. The higher attention weight item has, the deeper the color of bar below it is, the stronger influence the item has to the outfit compatibility. As can be seen in example 1, the shirt, short skirt and necklace have distinct and compatible styles and they have strong influence to the outfit compatibility. The black bag and black shoes have little influence to outfit compatibility while they have ordinary styles. Similarly, the sweater, shoes and hat in example 2 are all of distinct rustic style and they have strong influence to the outfit compatibility. The jeans and shoes in example 3 can match well with most styles while they have little influence to the outfit compatibility. The white outwear and jeans which can match with many styles in example 4 also have little influence to outfit compatibility. From these examples, we can find that more distinct style items have, more influential they are to the outfit compatibility. On the contrary, more ordinary items are (i.e., can match with many styles), less influential they are. This is reasonable in common sense.

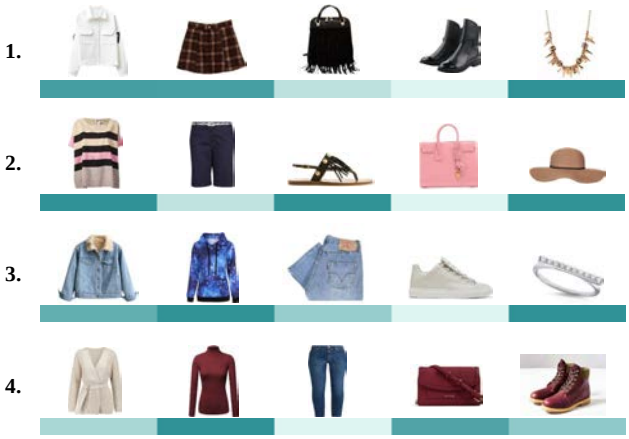


Figure 8: Illustration of attention mechanism. The depth of color are proportional to the attention weights of items.

5.5 Modality Comparison (RQ3)

To investigate the influence of different modalities on the performance, we compare the NGNNs (multi-modal) with different modality combinations. As described in Equation 13, β is the weight of visual compatibility score while that of textual compatibility score is $1-\beta$. Note that when $\beta = 0$ the model is actually NGNN (visual), when $\beta = 1$ it's NGNN (textual). In Figure 10, we show the performance of NGNN (multi-modal) with β varying from 0 to 1. It can be seen when $\beta = 0.2$, our model achieves the best performance, which suggests that the visual and textual information are good supplement to each other and both contribute s to the inference of compatibility. We can also see that using textual features can achieve better performance than visual features. A plausible explanation is that the textual information is more concise to capture the key features of items.

To intuitively see the difference of NGNN with visual, textual and multi-modal input, we show the comparison of them on several testing examples in Figure 9. In the example 1, Visual NGNN chose the false answer due to its similar color and material with the jacket, which the visual information can reflect. However the similarity between the textual information (titles) of the true answer and the dress, jacket directly reveals their high compatibility. In example 2, it's hard to choose the answer with textual input since the titles of the two answers are similar, while with visual input NGNN can distinct the high compatibility between the styles of the true answer and the outfit from visual information. In summary, the visual and textual information are great supplements to each other. By integrating them we can achieve better performance.

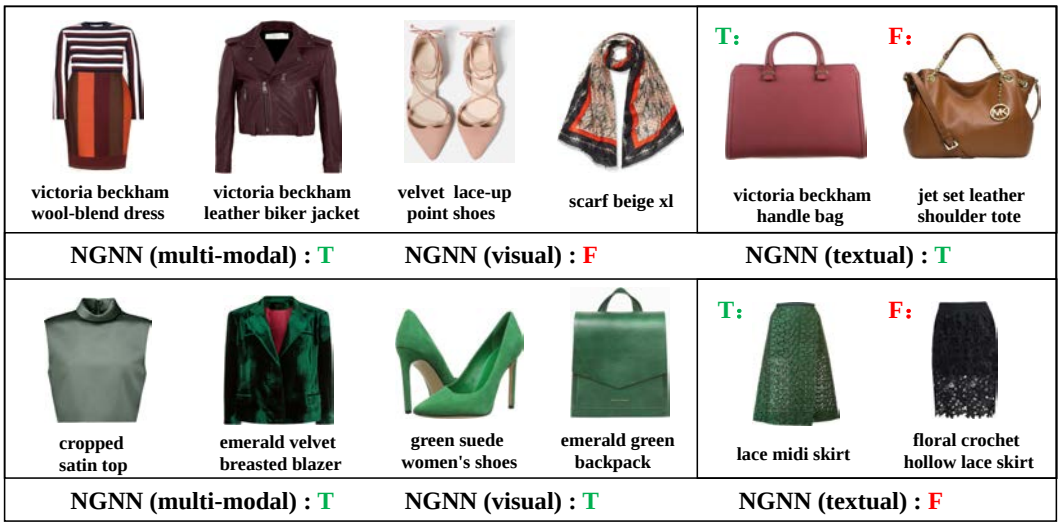

Figure 9: Comparison of NGNN(visual), NGNN(textual) and NGNN(multi-modal). For each outfit in the left, there is a true answer (T) and a false answer (F). Green fonts reprsent true chosen while red fonts represent false chosen.

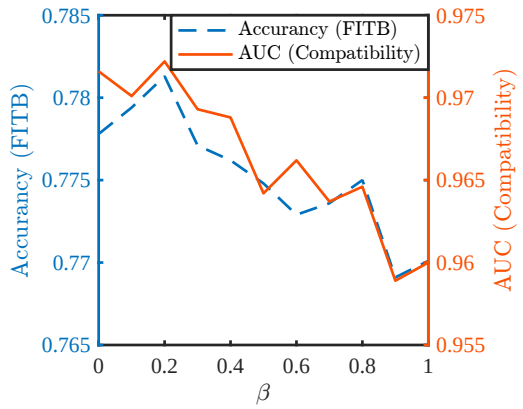

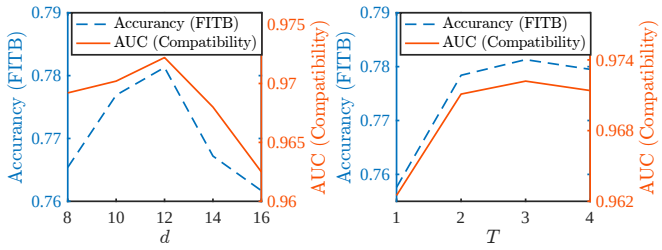

Figure 10: FITB accuracy and compatibility AUC of our model with different β.

(a) State dimensionality (b) Propagation times

Figure 11: AUC and FITB accuracy performance with different dimensionality d (left) and propagation times T (right).

5.6 Hyper-parameter Discussion (RQ4)

In this section, we examine how the dimensionality of hidden vectors d and the propagation time d affect the performance. Comparison experiments are conducted on NGNN (multi-modal). Figure 11 shows the performance of our model with varying d and d. From the figure in the left, we can observe that the FITB accuracy and compatibility AUC reach the highest point when d is around 12. When d is large than 12, the performance drops sharply. This indicates that there is no need to represent the node state with too much parameters. From the figure in the right, it can be seen that the performance saturates when T is 3 and the nodes in NGNN have interacted with others sufficiently, suggesting that it's important to model the multi-hop propagation so that the nodes are better aware of other nodes' information. Moreover, when T is high, the superfluous information propagation will confuse the nodes.

6 CONCLUSION

In this paper, we first propose to model the outfit compatibility by representing an outfit as a graph since the graph structure can better capture the complex relations among items in outfits. To infer the compatibility information from the graph, we further propose a novel model NGNN, which can better model flexible node interactions and learn better node representations. Our proposed method can model outfit compatibility not only from visual or textual modality respectively, but also from multiple modalities jointly. Experimental results on a real-world dataset (Polyvore dataset) prove the great superiority of our method over existing works. In the future, we aim to model personalized compatibility since people have different notions of fashion compatibility.

ABSTRACT

The proliferation of online communities has created exciting opportunities to study the mechanisms that explain group success. While a growing body of research investigates community success through a single measure — typically, the number of members — we argue that there are multiple ways of measuring success. Here, we present a systematic study to understand the relations between these success definitions and test how well they can be predicted based on community properties and behaviors from the earliest period of a community's lifetime. We identify four success measures that are desirable for most communities: (i) growth in the number of members; (ii) retention of members; (iii) long term survival of the community; and (iv) volume of activities within the community. Surprisingly, we find that our measures do not exhibit very high correlations, suggesting that they capture different types of success. Additionally, we find that different success measures are predicted by different attributes of online communities, suggesting that success can be achieved through different behaviors. Our work sheds light on the basic understanding on what success represents in online communities and what predicts it. Our results suggest that success is multi-faceted and cannot be measured nor predicted by a single measurement. This insight has practical implications for the creation of new online communities and the design of platforms that facilitate such communities.

1 INTRODUCTION

Understanding the complex ways in which communities are successful over time is essential for building and maintaining vibrant online communities [36, 39]. User-created online communities in social media platforms enable people with shared points of view and interest to connect with each other and are one of the main ways in which the Web has shaped how people interact and find each other. Although the low barrier for creating online communities has led to a large number of communities that are constantly involving and continually emerging, not all of them are successful. Fortunately, massive datasets from these online communities have allowed researchers to study the dynamics of the creation and lifecycles of online communities at a large scale [2, 8, 23, 34, 55, 59]. In particular, a problem of interest is to predict the eventual success of a new community from a set of community attributes that can be measured early in its lifetime. That is, *can we tell early on whether a community will be successful?*

An implicit yet important question is concerned with the definition of community success. In fact, most existing research takes a very narrow view of what defines success in online communities. Existing research has typically considered a single measure of community success and this measure is often determined by the number of users who eventually participate in the community [2, 8, 34, 55]. While this is a reasonable measure of success for many communities, it is not necessarily appropriate for all. Consider, for example, a community created with the goal of maintaining social relationships among the graduates from a small college on a given year. The members of such community would probably not define success by the size of their group, relative to other communities. A better measure of success in this case would be whether active members continue to stay active over time (i.e., retention). In contrast, a community created with the goal of raising awareness about an issue such as global warming would likely measure its success by how many people joined the cause.

We argue that, given the rich and complex nature of online communities, considering a single measure of success has limited our understanding on what makes communities successful. Our work aims to fill this gap by exploring a variety of success measures of newly created communities on Reddit. We consider four classes of success measures that should be generally desirable by most communities: (i) growth in the number of members; (ii) retention of members; (iii) long term survival of the community; and (iv) volume of activities within the community. We find that, while these measures are positively correlated, the correlations are not very

high, suggesting that each of the measures captures a fundamentally different aspect of a community's success. By focusing only on a community's growth in the number of members, we miss other dimensions that are also and sometimes even uniquely desirable.

Given the observed differences between our success measures, we then explore the features of newly created communities that are predictive of future success. Since we expect that different measures of success be predicted by different features, we consider a variety of features to capture different aspects of the community early in its lifetime. In our framework, we observe a community from the time of its creation until the time when it has attracted a fixed number of members. Then, using attributes of the community that can be measured up until that time, we predict the success of the community based on each of our success measures.

Specifically, we consider six different classes of features to predict success based on existing research and theory on online community success, group development, and organization theory: (i) the volume and speed of initial activities; (ii) the distribution of activities over users and time; (iii) the composition of its early members; (iv) linguistic style features of early content; (v) features of the communication network among early members; and (iv) the communities that early members belong to before they join the new community. We test the predictive performance of each class of features separately as well as all features combined. We find that no single class of features outperforms the combination of all regardless of the measure of success we use, suggesting that each class captures a meaningful dimension of the community's success. Furthermore, we find that the single most predictive class highly depends on the measure of success. For example, while linguistic style features are the best predictors of a community's survival, the distribution of activities over time best predicts retention.

While we find that different measures of success are predicted by different classes of features, we also identify community behaviors that predict success across different measures. A particularly robust example is the inequality in the distribution of posts and comments per user. We find that successful communities tend to distribute their activities in a highly skewed fashion, where a small number of users contribute a large fraction of the activity in the community. Our interpretation of this pattern is that for a community to be successful, it needs to have a small number of committed members that maintain the community active early in its lifetime until the community reaches a critical mass. These observations resonate with the importance of levels of activity and commitment of an online community's founders for its ultimate success [38].

Understanding and predicting the success of online communities early in their lifetime can provide hypotheses for experimental studies to identify causal relations and help community creators manage their communities in ways that are known to predict success. Our findings suggest that online communities can be successful in a variety of ways and are predicted by different early behaviors. Thus, depending on the goals of a community, its members should focus on different aspects of their behavior in order to maximize their chances of success. Our results can help us begin to understand success in online communities as a multi-faceted concept and identify the behaviors that drive each of its possible facets.

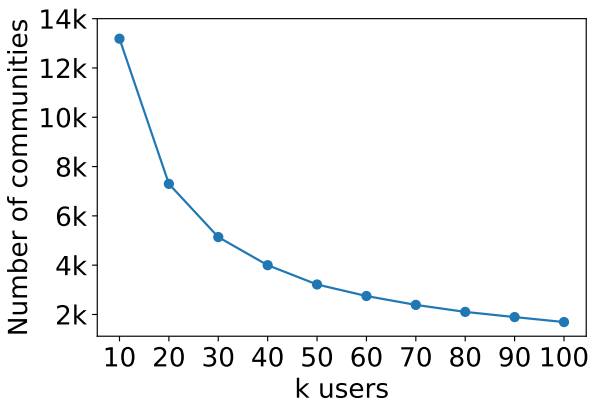

Figure 1: Number of communities that attract k users in at most 3 months, with k varying from 10 to 100.

2 REDDIT COMMUNITIES

We begin with a brief description of our testbed, Reddit. Reddit is a popular social news website and forum, which allows users to self-organize into user-created communities by areas of interest called subreddits. In Reddit, most communities are public and users can join as many public communities as they desire. Reddit also allows users to submit content, such as textual posts or URLs to other contexts, comment on posts, and upvote and downvote content. We consider a user a member of a community if they post or comment in that community.

We obtained all posts and comments from subreddits created in 2014 [4, 5]. Since our goal is to investigate the relationship between early community behavior and eventual success, we focus on communities that attracted at least k users within 3 months from the time when they were created so that we have sufficient data to measure the community's early behavior. We vary the value of k from 10 to 100 users. It follows that communities with less than 10 users within this time frame are not used in our analysis. Most subreddits exhibit very low activity after creation. Of all the communities created in 2014, only 5% attract 10 users within 3 months of their creation. Figure 1 shows the total number of communities created in 2014 that attracted k users in the first 3 months. As expected, the number of communities drops with k. However, even for relatively large values, such as $k = 100$, we will have more than 1,000 communities that pass the threshold.

3 CHARACTERIZING COMMUNITY SUCCESS

Although community success is an essential problem in understanding group dynamics [36, 39], success is an overloaded concept and has been defined in many different ways. For instance, a battery of studies have focused on growth [34, 55], which implies that communities that attract a lot of users are successful. These studies tend to focus on factors that attract new users such as social influence and tightly connect with research on diffusion [3, 8, 11, 48–50]. Another heavily studied metrics is retention, also known as churn prediction, which examines the likelihood that a user leaves the community after initial participation [18, 20, 33, 56]. A closely related metric to

retention is survival, which examines how long meaningful activity in a community is sustained [34, 59]. In practice, Web companies also use daily active users as a metric of success [37, 47].

An important open question is how these success metrics relate to each other and whether they capture the same underlying notion of "success", simply known as different names, or they capture inherently different types of success. In this section, we formally define multiple metrics of success and provide a large-scale characterization of these success metrics and their relations on Reddit communities. We believe that all these definitions can be appropriate yet *different* because success is not uni-dimensional and can differ due to the varying nature of communities. A successful online discussion group on political news likely present different desirable characteristics when compared to a group formed by editors of Wikipedia articles. For a political news group, an important goal is to sustain daily activity in order for the community to stay updated with daily news, while a group of Wikipedia editors may focus on producing high-quality articles, which requires retaining trained users for a long period of time rather than simply growing the number of users.

3.1 Defining Community Success

We consider four classes of success measures that should be generally desirable by most communities: (i) growth in the number of members; (ii) retention of members; (iii) long term survival of the community; and (iv) volume of activities within the community. In addition, submitting posts and commenting on posts or other comments are two different ways of engaging with a community and they may be valued differently across subreddits [1]. For example, KotakuInAction is dedicated to discussing controversy centered on issues of sexism and progressivism in video game culture and a single post can generate long discussions through thousands of comments. Other sudreddits are more focused on producing content through posts such as subreddits dedicated to breaking news. We thus further distinguish growth and activity in posts and comments.

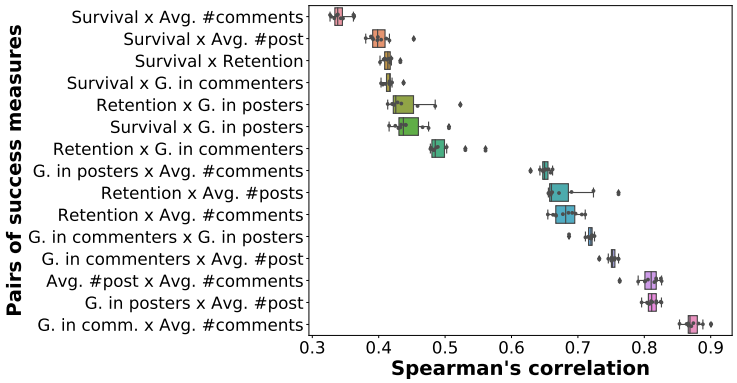
To define the success measures, we consider a fixed period after k users joined the new community and use month as the unit for measuring community characteristics. We define T_i^{posts} and T_i^{com} as the number of posts and comments in the community in month i, respectively. We let U_i^{all}, U_i^{posts}, U_i^{com} be all active users, users who posted, and users who commented in the community in month i, respectively. Finally, we let U^k be the initial k users who participated in the community and $U_{i\to i+1}$ be the subset of users that posted or commented in the community in month i and posted or commented again in the community in month $i+1$.

We then formalize our success measures in the following:

- **Growth** refers to the number of new users that joined the community in the one year window after the community reached k users. We consider two types of growth, growth in number of new users that commented (commenters) in the following year, $G^{\text{com}} = |\bigcup_{i=1}^{12} U_i^{\text{com}}|$, and growth in the number of users that posted in the following year, $G^{\text{posters}} = |\bigcup_{i=1}^{12} U_i^{\text{posts}}|$.
- **User retention** refers to the average monthly retention rate in the first year after reaching k, $R = \frac{1}{12}\sum_{i=1}^{12} \frac{|U_{i\to i+1}|}{|U_i^{all}|}$.
- **Long term survival of a community** is measured by computing the fraction of activity in the final part of our dataset for each community. That is, instead of looking at the following year, we investigate if the community "died", or stopped being active after two years. We measure the percentage of activities in the last 3 months of 24 months time window after the community size reaches k, $\frac{\sum_{i=22}^{24}(T_i^{\text{posts}}+T_i^{\text{com}})}{\sum_{i=1}^{24}(T_i^{\text{posts}}+T_i^{\text{com}})}$. Our intuition is that if the volume of activity during these final months is very small relative to the overall activity, then the community is not surviving in the long term.
- **Volume of activities** is divided in two types — the average number of posts in the first year after reaching k users, $\frac{1}{12}\sum_{i=1}^{12} T_i^{\text{posts}}$, and the average number of comments in the first year after reaching k users, $\frac{1}{12}\sum_{i=1}^{12} T_i^{\text{com}}$.

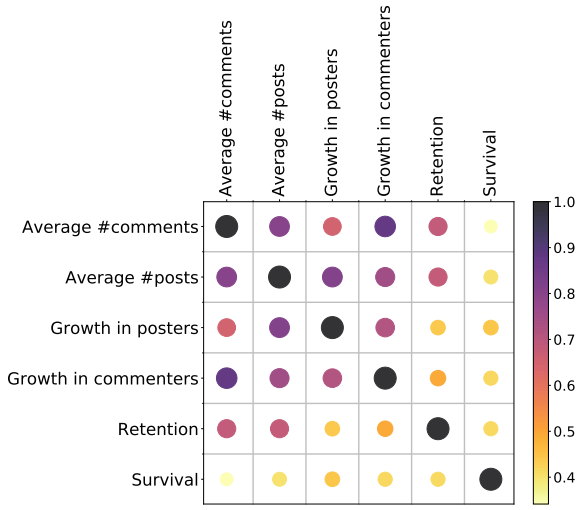
3.2 Correlation between Success Metrics

The premise for this paper is that online communities can be successful in different ways. Thus, our first task is to test this premise by exploring the relationship between the different success measures we identified. A high correlation between all of our success measures would indicate that, in reality, there is a single type of success that achieves all the desirable qualities we described.



We begin by computing all pairwise Spearman's correlations among the set of success measures,[2] which are shown in figure 2a in ascending order. Since we can compute the correlation between success measures for each value of k, the figure shows a box plot for each pair of success measures for the distribution across k. We observe that, while all pairs of success measures have a positive correlation, many pairs have a relatively small correlations — especially considering that all our success measures depend on users posting content on these communities.

We also present in Figure 2b a heatmap with the average Spearman's correlation between the success measures. We find that survival has among the lowest correlation when paired with another success measure — with all such pairs exhibiting a correlation of at most 0.5. This suggests that growth, retention, and high volume of activities do not necessarily imply survival. Similarly, retention exhibits correlations of less than 0.7 with other success measures, except for average #comments that presented a correlation of 0.75. Correlations are highest among measures of growth and volume of activity, which is not surprising considering that a community with many members will necessarily have a high number of posts and comments since membership is established by activity. The opposite does not necessarily hold. A community could have a small number of very active members.



These results suggest that indeed, there is significant diversity in the ways that communities achieve success. While some communities can grow and attract a large number of members, others can remain small but succeed by having a set of committed users who always return to the community or by exhibiting long term survival. They also suggest that measuring success with a single

[1] In fact, some prior studies only focus on posting behavior for this reason [55, 56].

[2] We obtain very similar results when we apply Kendall rank correlation [35].

(a) . Each box plot represents the distribution of average Spearman's correlation coefficient between two success measures (the number of samples in a box is 10, corresponding to $k = 10, 20, \ldots, 100$). Although all the pairwise correlations between success measures are positive, there is great variance with regard to how correlated they are, ranging from 0.34 (between survival and average #comments) to 0.86 (between growth in commenters and average #comments).

(b) Pairwise Spearman correlation between the success measures. Measures related to volume of activities and growth present highest correlations. While survival and retention present the lowest correlations.

Figure 2: Spearman's correlation between success measures. We chose Spearman's correlation because it is non-parametric, we also experimented with Kendall's Tau correlation and the results were similar.

metric can overlook important ways in which communities achieve success.

A case study between growth and retention (Figure 3). To further understand the differences between success measures, we show the scatter plot of user retention and growth in commenters for all communities that reach $k = 100$. In this scatter plot, successful communities can assume various combinations of values for both dimensions. Visually, the growth in commenters can take a wide range of values for communities with zero user retention. A closer examination of extreme points in this scatter plot reveals interesting examples. Consider the community */r/millionairemakers*. In this community, users organize themselves in a "lottery", where a user is randomly selected each month and everyone is encouraged to send this user $1. The winner typically receives between $1,000 and $5,000. This community exhibits a large number of commenters because users enter the lottery by leaving a comment. The low user retention might be explained by the fact that winning the lottery is highly unlikely, which may discourage users from participating multiple times. On the other hand, the community StoryBattles — a subreddit where users can post a picture and the rest of community is asked to write a story about it in the comment section, has very high retention but low growth in commenters. This behavior may be explained by the niche nature of the community, which targets at people interested in story writing. Most Reddit users are probably not interested in story writing, but those who are, return and contribute to this community repeatedly over time.

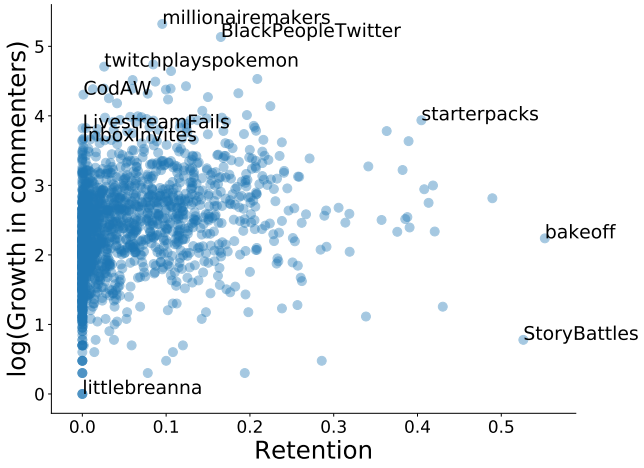


Figure 3: A case study to show the scatter plot between growth in commenters and retention for $k = 100$.

4 PREDICTIVE FEATURES OF SUCCESS

Given the relatively low correlation between success measures, it remains an open question what characteristics of communities predict future community success. Inspired by existing research and theory in online communities, group dynamics, and organization theory, we defined a set of features to be used later in our success prediction tasks (Section 5). We focus on features that generalize

across different types of communities. We divide these features into six categories which capture different dynamics of the communities. All of our predictive features are based on the actions taken by users between the time the community was created and the time its k^{th} user arrived.

Volume and speed of activities. The first set of features capture both the speed of and volume of activities early during the early stages of the formation of the community, which have been shown to predict future success [40]. It includes, the number of posters, the number of commenters, the date the community was created, the number of posts, the median number of replies received per posts, the median number of comments and posts per user, the number of days that the community took to attract k members. It also includes the speed at which comments and posts arrive — average number of days between posts and comments), which constitute strong baselines used in previous studies [10, 34].

Distribution of activities. Another important set of features we explore is related to how the content produced in the community is spread among users and over time (i.e. is a small number of users responsible for producing a large fraction of the activities in the community? Is the majority of the content concentrated in a certain point in time in a bursty fashion?). We capture this spread through the Gini coefficient [22], which is a measure of statistical dispersion commonly used to measure inequality. A Gini coefficient (Equation 1) of 0 indicates perfect equality where all members produced the same amount of content, while 1 indicates perfect inequality where a single individual generated all posts and comments. We compute the Gini coefficient of the number of posts and comments per users and the Gini coefficient of days between posts and comments. A high Gini coefficient in the number of posts or comments per user is indicative of a small number of community members who are committed to the community enough to produce a large fraction of its content. Such a small set of committed users could ensure the long term success of the community through committed leadership or suggest its demise due to the lack of participation by other community members.

$$Gini = \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} |x_i - x_j|}{2n \sum_{i=1}^{n} |x_i|} \tag{1}$$

User composition. The third set of features accounts for the users' activities *prior to joining the community*. It includes the median and standard deviation of users' score ($upvotes - downvotes$) received in posts and comments, the median and standard deviation of the number of users' prior activities and the median number of days users have been active on Reddit. Except for the number of days on the site, we limit this set of features to one month prior to joining the new community. We also measure the fraction of new users who do not have any previous community membership, which includes both new users on Reddit and Reddit users who did not post or comment in the one month before posting or commenting in the new community. As older, more experienced, and more successful users (with respect of upvotes and downvotes) tend to have more experience participating in communities, our hypothesis is that communities that attract more experienced users can benefit as those users were exposed to other communities norms, thus they might produce higher quality content and consequently help the community to achieve its goals. Previous studies have shown that the experience and expertise levels of founders is a good predictor of the success of online communities and offline firms [21, 38].

Linguistic style. The next set of features capture how the language in the content created in the communities can help understand the desirable characteristics of a community. Previous studies have revealed important stylistic changes in user-written language as users develop a sense of belonging to a community [13, 19, 31, 56] and how the sentiment present in the community's feedback affects the likelihood that users will remain engaged [16]. Language can also provide an important signal of users satisfaction, which is a key factor for successful communities, since satisfied users are more likely to contribute to the community and stay engaged [41]. First, we compute features that capture the length of the content created in the new community: median post, titles, and comments length and the size of the vocabulary used in the community, i.e. the number of unique words, after pre-processing the content produced by the first k users, divided by the number of posts and comments. Next, motivated by studies of socialization and engagement in online communities [19, 31, 43], we measure the distribution of categories from the psychological lexicon LIWC [1, 45] [3], which measures the various emotional, cognitive, and structural components present in text. Lastly, inspired by research on corporate success that has found that personality traits are predictive of employees engagement, which boosts the organizational productivity [32, 53, 60], we also include the Big Five personality traits [4]: Extraversion, Conscientiousness, Neuroticism, Agreeableness and Openness to Experience [28]. These five domains have been shown to be good at predicting behavioral patterns, such as well-being and mental health, job performance and marital relations [26]. We compute all measures separately for posts and comments.

Social networks. We also include in our analysis a set of features that represent the structure of communication and information exchange among the users in a community. We construct a communication network among early members and extract a variety of features that describe its structure. Network theory has received considerable attention when studying community success. We represent the social interaction among users as an undirected graph $G(V, E)$, where V is the set of vertices and E is the set of edges between a pair of vertices. Each vertex $v \in V$ represent a user in the community, and an undirected edge $e(i, j) \in E$ exists between user v_i and user v_j if user v_i has replied to user v_j or v_j has replied to v_i in a thread. Our choice for undirected edges is based on the assumption that when a post or a comment receives a reply, both users involved are exposed to each other's content. A user i must first make a post and a user j must read it in order to reply. Once j replies, we assume that i sees the reply. Thus, we consider that i and j interacted with each other.

We then compute the following network measures: transitivity, average clustering coefficient, density, fraction of users in the largest component and fraction singletons (i.e. fraction of isolated nodes in the graph) [6]. Density, fraction of users in the largest component, and fraction of singletons measure the extent to which the network is well-connected rather than fragmented into many

[3] http://www.liwc.net

[4] To compute the Big five personality traits we used the IBM Watson Personality Insights API (https://www.ibm.com/watson/services/personality-insights/).

disconnected pieces. In a fragmented network, users are not engaging with each other enough to form a large structural community, which could lead to polarization and structural holes [7]. Transitivity and average clustering coefficient measure the extent to which users have a tendency for sharing connections (or forming triangles). Social networks with high clustering are known to facilitate trust and social capital [14], which is important for community building. Several studies have investigated the relationship between network structure and how the groups change over time [2, 8, 30, 34, 46, 51, 55]. They show that social features are good predictors of communities desirable properties, with special attention given to groups' growth, often growth is treated as a process similar to the diffusion of innovations, where joining a new group is analogous to adopting an innovation.

Finally, we also measure the fraction of posts and comments that received at least one reply as it was shown that community feedback has a positive effect over users likelihood to return to the community [12, 16, 17].

Parents communities. The last set of features aims to reveal the emergence of communities through the relationship of the communities that early members were participating before joining the new community. Following Tan's work [55], we employ features derived from the genealogy graph of parents communities. In the genealogy graph, we consider an edge between two parent communities if they share at least two early members. Then we compute density, transitivity, and number of parents communities. We also include the maximum, minimum and standard deviation of the size of parent communities measured by the log of the number of members one month prior the creation of the new community). Additionally, we include the Gini coefficient of the number of users from the parent communities. Lastly we measure the median distance between the language model of the focal community and its parents communities (i.e., the median language distance (cross-entropy) between the new community and the parents communities). We consider large language distance as a sign of diversity as Uzzi et al. [57] has shown that atypical combination is related to scientific impact. Note that communities in Tan [55] are only based on posts, while we use both posts and comments.

5 PREDICTION RESULTS

We now test how well our features described in Section 4 predict the different measures of success described in Section 3.1.

5.1 Experimental Setup

The prediction for each success measure is framed as a binary task to predict whether that measure for a community will exceed the median value of that measure for all communities considered. This prediction setup naturally leads to a balanced classification task for all success measures. It also allows us to ask how the predictability of communities desirable properties varies over the range from small to large number of members.

We train separate logistic regression classifiers with *L2* regularization for each feature category as well as a single model with the combination of all features. For each classification task, we randomly split the data for training (80%) and testing (20%). The feature values are standardized to make regression coefficients comparable across features from different scales. Models are then evaluated using AUC; a random baseline achieves an AUC score of 0.5. We grid search the best regularization hyperparameter using 10-fold cross-validation on the training set. We do not report statistical significance for regression coefficients due to their opaque interpretation when using the biased estimates [27].

Models are trained on the Reddit communities that were created in 2014 and reached k users within three months, where the number of users is measured by the total number of unique users who posted or commented on the community. To capture differences in behavioral information at different stages of a community's early life, we vary k in 10-user increments from 10 to 100. Note that fewer communities reach 100 users than 10 users, so the total number of communities that we consider decreases with k (see Figure 1). We compute the median value of each success measure for each k separately to determine the label of each community (positive if its success measure exceeds the median).

5.2 Can Success Be Predicted?

Our experiments show that success can indeed be predicted: the best median AUC score for each task is at least 0.72 when predicting with the combination of all features. In the best case, the median AUC score is 0.84 when predicting users retention. The prediction performance results for each model are shown in Figure 4.

5.2.1 Community Growth. Although growth in posters and commenters are intuitively related, models varied surprisingly in their accuracy at predicting each version of growth. In particular, user features and parent communities perform substantially worse in predicting the eventual growth in users who post (Figure 4b) than growth in users who comment (Figure 4a). This may be related to the fact that the majority of early members based on our definition are commenters. For growth in commenters, the model trained on all available features have a median performance of 0.75, yet models trained on a single set of features perform substantially worse. Among the single-feature category, the distribution of activities is the strongest single set of features with a median model performance of 0.63. The performance gap between using all features and using distribution of activities is statistically significant ($p < 0.001$), suggesting no single model captures all the aspects involved in community growth in commenters. For growth in posters, volume and speed of activities is the strongest single feature set, which echoes previous results that predict growth only considering information about posts [10, 34, 55]. However, models in previous works excluded other community features, which when combined with volume and speed, substantially enhances our ability to predict both types of growth.

5.2.2 Users Retention. Results for the task of predicting retention are shown in Figure 4c. Our first observation is that this task appears to be easier to predict than future growth. Indeed, the set of all features combined presents the best performance with a median AUC of 0.84, which is larger than any other success measure. When looking for single set of features, there is a clear best model, with distribution of activities features performing stronger than the rest of the models, displaying an AUC of 0.82. The worst performing

model is the users features, which suggests that the users' background is not important for predicting if a user will become "loyal" to the community and return to it.

5.2.3 Survival. Survival is the most difficult type of success measure to predict from our features. The prediction results are shown in Figure 4d. In this task, our model with all features achieves an AUC of 0.72. The single best model is content features with an AUC of 0.67, followed by the users composition features with an AUC of 0.63. This observation further confirms the importance of the content generated in the community to keep users committed to the community. It also suggests that early members' previous experience and characteristics are important to community survival, which resonates with Kraut and Fiore [38] that found that founders social capital is a good predictor of online communities survival.

5.2.4 Activity level. Next, we evaluate the predictive power of our feature sets to predict the future activity level. The results for average #comments are shown in Figure 4e and results for average #posts are shown in Figure 4f. The results for the two tasks are similar, with the model with all features performing slightly better for average #comments. This can be explained by the performance of the social features model, which presented a better result (0.67 vs 0.58, $p < 0.001$) for the task of predicting average #comments. The model with all features outperformed the single features models for both tasks, but this difference was only statistically significant for the task of predicting average #comments (0.80 vs 0.76, $p < 0.001$.). The worst results for single features models were presented by the model with user features, which suggests that the users' history before joining a new community does not play an important role in the frequency of users to post/comment in the future.

5.3 How Early is Success Predictable?

Each of the box plots in Figure 4 contains the resulting AUC for each value of $k = 10, \ldots, 100$. One may expect the performance of the model to increase with k, as a higher k represents data from more users to predict the eventual success of the community. Surprisingly, most of the box plots display a small range of variation — indicating that the performance of the model is in fact not very sensitive to the number of early users we base our predictions on. In particular, the AUC for $k = 10$ is not very different from that of $k = 100$. Table 1 shows the standard deviation of the AUCs for all features combined when applied to all success measures. The small deviation values confirm our intuition that indeed the features are predictive since the community's infancy. This result is important for communities maintainers and moderators as they can diagnose their communities in their initial stage and identify "at risk" communities.

5.4 Which Features Predict Success?

In this subsection we examine the most predictive features of success when we combine all our features into a single model. Recall that we have a separate model for each value of k. For each k, we rank the features of the resulting model by the magnitude of its coefficient. We then use the mean reciprocal rank [15] of the features over the individual ranks for $k = 10, \ldots 100$ to generate a single ranking of the features. Figure 5 shows the top 10 features and their mean coefficients.

Success measure	Std. AUC
Growth in commenters	0.030
Growth in posters	0.020
Retention	0.006
Survival	0.022
Average #comments	0.023
Average #posts	0.024

Table 1: Standard deviation of results for the model with all features combined for all success measures.

The most important set of features is the distribution of activities. Its features appeared among the most predictive for all measures of success. It shows that except for average #posts, higher Gini coefficient of posts and comments per users is positively associated with all success measures, which means that if the initial activities in the community are concentrated in a small number of users, it increases the overall likelihood that the community will be successful. In early stages, when communities do not have many members or much content, they must rely on committed users that are more likely to engage and produce high-quality content.

We also find that the time the community takes to reach k users is predictive of all success measures, except growth in posters. However, the direction of the effect of this feature is not consistent across success measures. While a small number of days to reach k users (i.e. fast initial membership growth) increases the likelihood that a community will grow and survive, it decreases the ability of the communities to retain users. These findings resonate with research on the founding of organizations, which shows that fast initial growth predicts longer organization survival [38]. However, our results show that this long term survival can come at the cost of lower retention. Additionally, we note that average #posts and #comments are also affected differently by this feature. Though a small number of days to attract k new members predicts an increased average number of comments, but is related to an decreased future average #posts. Thus, it appears that communities that grow slowly in membership during early stages exhibit higher levels of interactions among users through comments at the cost of lower production of original content through posts.

Regarding social features, increased average clustering and fraction of users in the largest connected component are negatively associated with growth, while transitivity is positively associated with user retention, which is in accordance with previous results in groups growth [2, 30, 34], where users in very clustered groups tend to persist in the community. However, this property also decreases overall growth and the likelihood to survive longer. In addition, when members are too tightly connected to the largest component, as they are in groups with high transitivity, groups might become too closed, restricting the possibility of gaining new information and attracting new members [34]. Lastly, increased density predicts increased level of activities, which suggests that social interaction predicts future activity level.

In term of linguistic features, we note an interesting negative association between the use of first-person plural pronouns "*we*" and a community's long term survival and growth. This finding

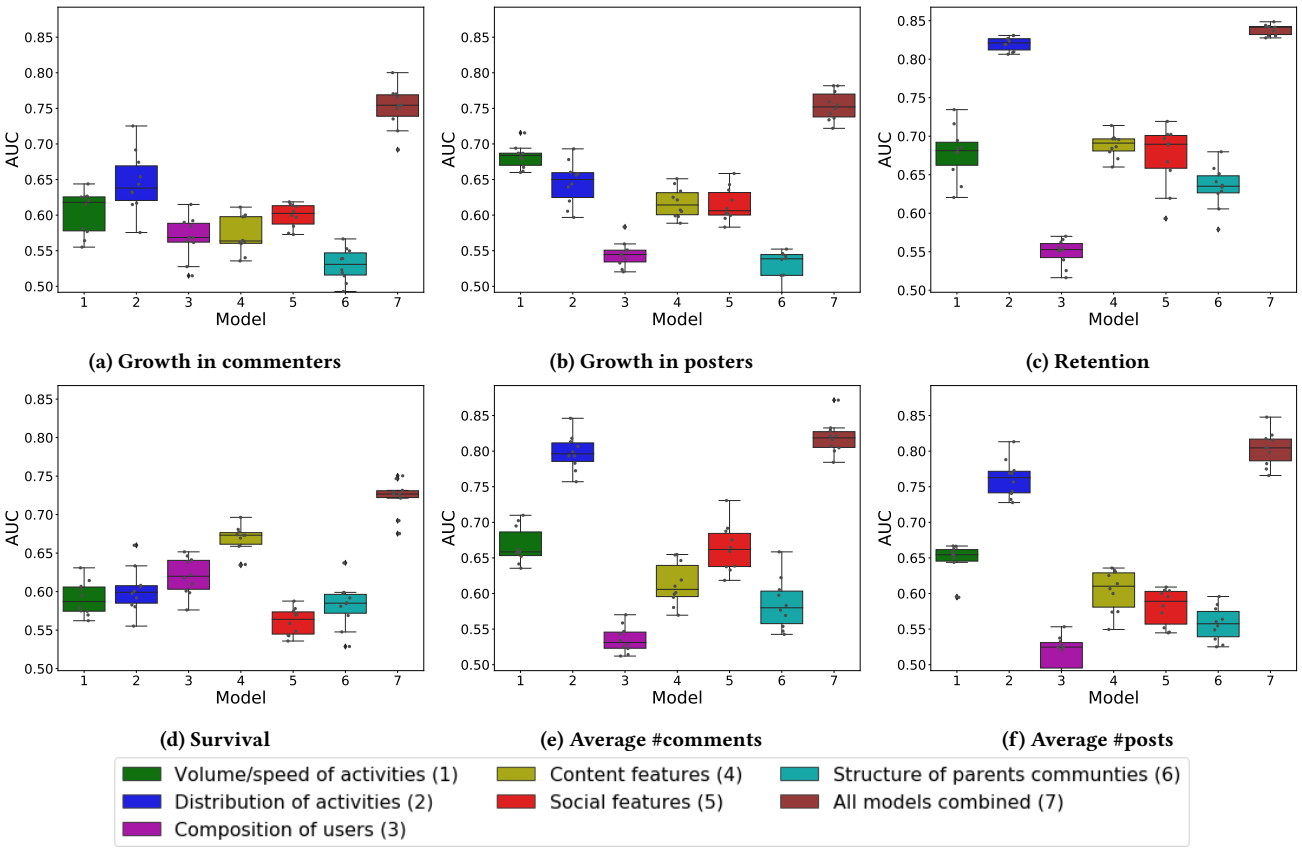

Figure 4: Results for the predictive tasks of success measures. Box plots graphically depict the results for k varying from 10 to 100 users. They show that our features sets are predictive of communities' success measures, the model of all features combined presents at least 0.72 AUC for all task.

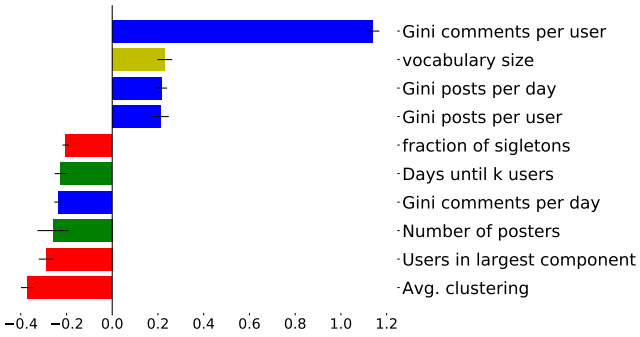
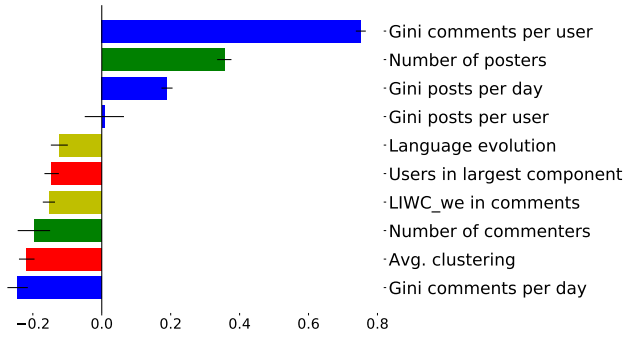
indicates that users in large communities that survive longer are less likely to assume a collective identity, which echoes Palla et al. [44] that suggests a connection between fluid dynamics in membership and a group's long-term survival. In contrast, findings from sociolinguistics show that loyal members (in terms of user preference and commitment) of communities presented a higher use of first-person plural pronouns "*we*" and language that signals collective identity [13, 31, 52]. The diverging effect of "*we*" confirms the low correlation between retention and survival, and further demonstrates the multi-faceted nature of success.

6 DISCUSSIONS



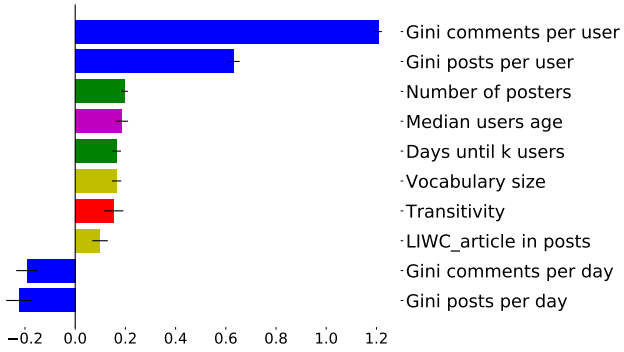
6.1 Limitations

Not controlling for effect of a community's topic. It is possible that communities related to certain topics have different likelihoods to be successful. Although we do not control for the topic of the communities or how its chosen topic fits within the larger ecosystem, we aim to identify a set of features that generalize across topics and types of communities such that our recommendations are general enough and can be applied to any type of new community.

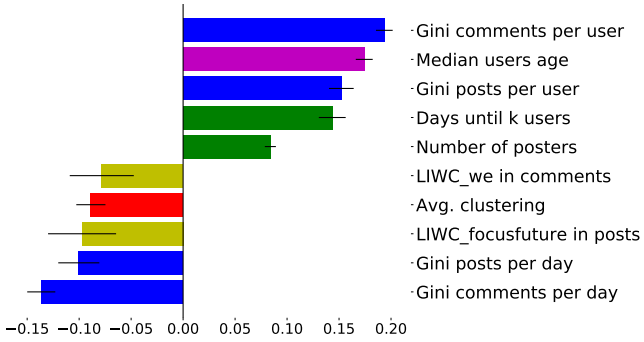


Experiments focus on subreddits created in 2014. Our entire study is based on 2014 Reddit data, which is late (8 years) into the Reddit ecosystem, when many communities have already been established. While analyzing success of communities in the earlier stage of Reddit could reveal interesting patterns, the analysis would be more challenging as Reddit was changing its platform and evolving rapidly during its early years. Additionally, the large number of potential missing (i.e. deleted users) data from Reddit's earliest years may also introduce biases to the analysis [25]. However, a replication of our analysis using a much larger time period or studying Reddit alternatives during their formative growth periods [42] could determine if the predictors of success change over time.

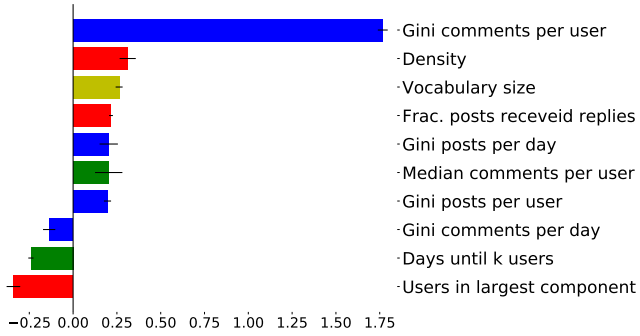
Causality. In our models, we have interpretable features, but we do not have a causal model to suggest that the presence of a feature *causes* the community to succeed. Applying experimental or other causal inference techniques such as propensity score matching would be a possible line of future research to establish a causal link between community behaviors and success.



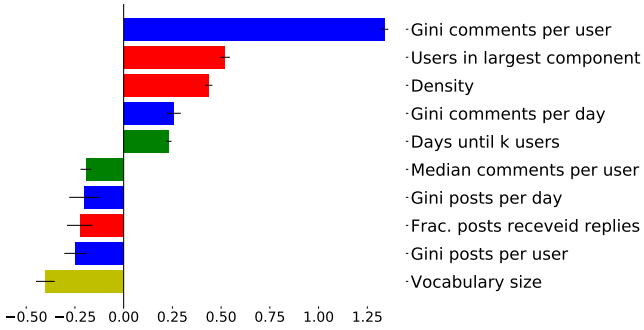
Our analysis only uses posts and comments. There are other aspects of Reddit communities that may be informative such as stated community norms, moderator behaviors such as banning users or removing posts. However, currently this type of data is



(a) Top 10 features for growth in commenters.



(b) Top 10 features for growth in posters.



(c) Top 10 features for users retention.

(d) Top features for community survival.

(e) Top 10 features for average #comments.

(f) Top 10 features for average #posts.

Figure 5: Top 10 most predictive features for the model with all features combined

either not available or it's difficult to obtain a historical version, which makes their use impractical in our analysis [9].

6.2 Design implications

New online communities are formed every day. Given that very early behaviors of such communities is strongly predictive of multiple types of success, we discuss design implications for new community organizers to increase their likelihood of success. We reiterate the important caveat that our study is purely observational and does not establish causal relations between behaviors and success.

High Gini in posts and comments per user always predict success, regardless of success measure, which results from having a few users that perform most of the activities. This result suggests that having a small group of highly committed groups of participants early on is key to future success. Community organizers need not necessarily worry when not all participants engage frequently, but need to ensure that a sufficient number of members engage at producing content in order to establish a critical mass, which is responsible for helping the community to become self-sustaining and create further growth [29, 48].

Taking longer to attract k members is negatively associated to growth in commenters, survival and average #comments, but predicts retention and average #posts. We interpret these results as reflecting two kinds of community goals. For those communities

that want to attract many users, stay active longer and have its activities primarily concentrated on discussions, attracting users quickly is important. However, for retaining those users, what matters is getting the right type of users who are likely to remain active, which may take longer initially.

Transitivity—which is highly correlated to average clustering—is predictive of retention, suggesting that having a close-knit set of participants who bond well with each other is important for retention but not growth, which is consistent with existing literature on community growth [2, 30, 34]. Combined with our result for timing, we posit these results may point to the importance of a sense of belonging and identity within a community; users who join a rapidly growing community (low time-to-k) may find themselves lost in the mix and slow to accumulate social capital. It also suggests the importance of strong relationships, which take more time to build and are the combination of frequent engagement, deep interaction, and time spent together in the communities.

The distribution of arrival rates for comments and posts (measured through the Gini coefficient of gaps) point to two diverging recommendations. Bursty commenting followed by long droughts (high Gini in comment gaps) is negatively associated to all measures of success, except average #posts. Uniform arrival rates for comments leads to more success — though as the first recommendation suggests, these comments need not come from a large group of contributors. Here, we posit that because comments are a form of interaction and accumulation of social capital, regular arrival rates encourages users to come back frequently and follow up on existing discussions. This also might be explained by the *anticipation and uncertainty of reward mechanism* present in social media, where constant arrival of new content stimulates the production of the hormone Dopamine, a chemical produced in various parts of the brain and controls moods, motivation and sense of reward, which is linked to users' increased presence and activity in social media [54]. This result suggests that new community organizers should encourage new comments on regular intervals to promote opportunities for others to become involved in the discussion.

7 RELATED WORK

A large body of literature investigates how community-level characteristics influence the success of online communities. Here we discuss how the literature defines success and how the early users affect the likelihood of communities becoming successful.

Success as the number of members. The majority of works on community success adopt a very narrow view of how success manifest in communities. Most existing work tries to predict the volume of popularity of communities, such as the growth in the number of members the community. Often, the growth in membership is treated as process similar to the diffusion of innovations, where joining a new group is analogous to adopting an innovation [2, 8, 30, 34, 55]. Two works present a broader view of success, Kairam *et. al.* investigate how communities social networks predict growth and community survival, their definition of survival is based on the time the community stops to grow rather than stop to produce content, while Ellis et. al. [24] estimate the health of a community by measuring the retention rate of participants and the period of time the group stays active.

On the importance of early members. Another important line of work focuses on predicting the success of communities is the characteristics of its early members. Inspired by research on offline organizations that demonstrated the importance of the early members for organization success [21], they investigate whether user characteristics and behavior early in a community's history predict community success [55, 58, 59]. Early members are responsible for creating the initial content and norms of the community, acting as recruiters of new members. For example, Kraut and Fiore [39] found that human and social capital, such as users' age and experience with other communities' early decisions are predictive of success. Their findings suggest that the resources early members bring to the group are important, but they can also be detrimental if the group depends on them too much.

Our work contributes to prior research in two major aspects. First, we shed light over the idea that success is a complex concept and can be described in multiple dimensions that depend on the goal of a community. We thus investigate success across four desirable properties. Second, we present a set of features that represent the communities' behaviors and can generalize across the different types of communities. Finally, we show that success can be predicted and reveal which features are the most important for each success definition.

8 CONCLUSIONS

New groups are created frequently in online platforms. What does it take for a new group to succeed and how do we measure success? We answer these questions using a large-scale study on tens of thousands of groups on Reddit. Our work offers two main contributions. First, we quantify success using four measures and show, surprisingly, that success according to one measures is not necessary met with success with the other three. Instead, while the measures are positively correlated, groups succeed in their own way, in part due to the diversity of *why* a group forms. A small community may thrive through consistent posting, while never growing large, whereas another group may expand to a massive number of users, with only a few core people participating. Second, we show that the future success of a group can be predicted along each of the four measures. Drawing upon prior work and theories of group organization, we quantify six different group behaviors to test their predictiveness of success. Our results show that no single behavior drives a group to be successful in each dimension. For example, while retention and growth are well-predicted by the inequality of creating content, group longevity is best predicted by the linguistic style of the content. Further, predictive accuracy is enhanced when combining all behaviors, suggesting that each behavior plays a role in the eventual success (or failure) of a community.

Together, our results point to the complex roles groups serve online: each group is created with a different purpose and the success of that group is dependent in part on cultivating the types of behaviors needed. Our results also provide practical advice for individuals wanting to start their own new community online.

ABSTRACT

Network Embedding is the task of learning continuous node representations for networks, which has been shown effective in a variety of tasks such as link prediction and node classification. Most of existing works aim to preserve different network structures and properties in low-dimensional embedding vectors, while neglecting the existence of noisy information in many real-world networks and the overfitting issue in the embedding learning process. Most recently, generative adversarial networks (GANs) based regularization methods are exploited to regularize embedding learning process, which can encourage a global smoothness of embedding vectors. These methods have very complicated architecture and suffer from the well-recognized non-convergence problem of GANs. In this paper, we aim to introduce a more succinct and effective local regularization method, namely adversarial training, to network embedding so as to achieve model robustness and better generalization performance. Firstly, the adversarial training method is applied by defining adversarial perturbations in the embedding space with an adaptive L_2 norm constraint that depends on the connectivity pattern of node pairs. Though effective as a regularizer, it suffers from the interpretability issue which may hinder its application in certain real-world scenarios. To improve this strategy, we further propose an interpretable adversarial training method by enforcing the reconstruction of the adversarial examples in the discrete graph domain. These two regularization methods can be applied to many existing embedding models, and we take DeepWalk as the base model for illustration in the paper. Empirical evaluations in both link prediction and node classification demonstrate the effectiveness of the proposed methods.

1 INTRODUCTION

Network embedding strategies, as an effective way for extracting features from graph structured data automatically, have gained increasing attention in both academia and industry in recent years. The learned node representations from embedding methods can be utilized to facilitate a wide range of downstream learning tasks, including some traditional network analysis tasks such as link prediction and node classification, and many important applications in industry such as product recommendation in e-commerce website and advertisement distribution in social networks. Therefore, under such great application interest, substantial efforts have been devoted to designing effective and scalable network embedding models.

Most of the existing works focus on preserving network structures and properties in low-dimensional embedding vectors [4, 35, 37]. Firstly, DeepWalk [35] defines random walk based neighborhood for capturing node dependencies, and node2vec [13] extends it with more flexibility in balancing local and global structural properties. LINE [35] preserves both first-order and second-order proximities through considering existing connection information. Further, GraRep [4] manages to learn different high-order proximities based on different k-step transition probability matrix. Aside from the above mentioned structure-preserving methods, several research works investigate the learning of property-aware network embeddings. For example, network transitivity, as the driving force of link formation, is considered in [26], and node popularity, as another important factor affecting link generation, is incorporated into RaRE [14] to learn social-rank aware and proximity-preserving embedding vectors. However, the existence of nosiy information in real-world networks and the overfitting issue in the embedding learning process are neglected in most of these methods, which leaves the necessity and potential improvement space for further exploration.

Most recently, adversarial learning regularization method is exploited for improving model robustness and generalization performance in network embedding [8, 41]. ANE [8] is the first try in this direction, which imposes a prior distribution on embedding vectors through adversarial learning. Then, the adversarially regularized autoencoder is adopted in NetRA [41] to overcome the mode-collapse problem in ANE method. These two methods both encourage the global smoothness of the embedding distribution based on generative adversarial networks (GANs) [11]. Thus, they have very complicated frameworks and suffer from the well-recognized hard training problems of GANs [3, 29].

In this paper, we aim to leverage the adversarial training (AdvT) method [12, 34] for network embedding to achieve model robustness and better generalization ability. AdvT is a local smoothness regularization method with more succinct architecture. Specifically, it forces the learned classifier to be robust to adversarial examples generated from clean ones with small crafted perturbation [34]. Such designed noise with respect to each input example is dynamically obtained through finding the direction to maximize model loss based on current model parameters, and can be approximately computed with fast gradient method [12]. It has been demonstrated to be extremely useful for some classification problems [12, 23].

However, how to adapt AdvT for graph representation learning remains an open problem. It is not clear how to generate adversarial examples in the discrete graph domain since the original method is designed for continuous inputs. In this paper, we propose an adversarial training DeepWalk model, which defines the adversarial examples in the embedding space instead of the original discrete relations and obtains adversarial perturbation with fast gradient method. We also leverage the dependencies among nodes based on connectivity patterns in the graph to design perturbations with different L_2 norm constraints, which enables more reasonable adversarial regularization. The training process can be formulated as a two-player game, where the adversarial perturbations are generated to maximize the model loss while the embedding vectors are optimized against such designed noises with stochastic gradient descent method. Although effective as a regularization technique, directly generating adversarial perturbation in embedding space with fast gradient method suffers from interpretability issue, which may restrict its application areas. Further, we manage to restore the interpretability of adversarial examples by constraining the perturbation directions to embedding vectors of other nodes, such that the adversarial examples can be considered as the substitution of nodes in the original discrete graph domain.

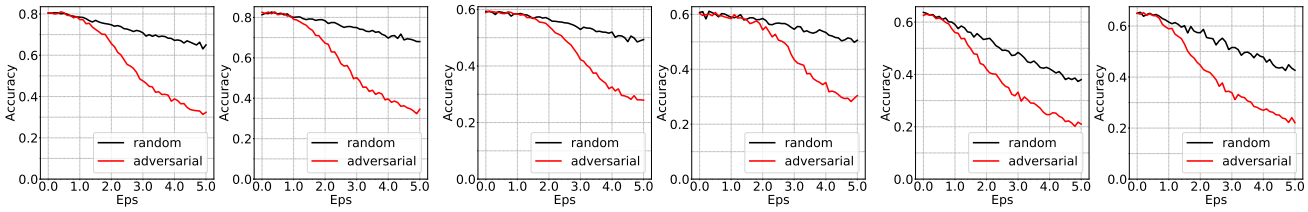
Empirical evaluations show the effectiveness of both adversarial and interpretable adversarial training regularization methods by building network embedding method upon DeepWalk. It is worth mentioning that the proposed regularization methods, as a principle, can also be applied to other embedding models with embedding vectors as model parameters such as node2vec and LINE. The main contributions of this paper can be summarized as follows:

- We introduce a novel, succinct and effective regularization technique, namely adversarial training method, for network embedding models which can improve both model robustness and generalization ability.
- We leverage the dependencies among node pairs based on network topology to design perturbations with different L_2 norm constraints for different positive target-context pairs, which enables more flexible and effective adversarial training regularization.
- We also equip the adversarial training method with interpretability for discrete graph data by restricting the perturbation directions to embedding vectors of other nodes, while maintaining its usefulness in link prediction and only slightly sacrificing its regularization ability in node classification.
- We conduct extensive experiments to evaluate the effectiveness of the proposed methods.

2 BACKGROUND

2.1 Framework of Network Embedding

The purpose of network embedding is to transform discrete network structure information into compact embedding vectors, which can be further used to facilitate downstream learning tasks, such as node classification and link prediction. The research problem can be formally formulated as follows: Given a weighted (unweighted) directed (undirected) graph $G(V, E, A)$ ($N = |V|$), with $V = \{v_i\}_{i=1}^{N}$ as the node set, $E = \{e_{ij}\}_{i,j=1}^{N}$ as the edge set, and A as the weighted adjacency matrix with A_{ij} quantifying the strength of the relationship between node v_i and v_j, network embedding is aimed at learning a mapping function $f : V \mapsto U$, where $U \in R^{N \times d}$ ($d \ll N$) is the embedding matrix with the ith row $\boldsymbol{u}_i{}^T$ as the embedding vector of node v_i. Note that for many network embedding models, a context embedding matrix U' will also be learned. For these methods, embedding matrix U is also called target embedding matrix.



The learning framework of many famous network embedding methods, such as DeepWalk [27], LINE [35] and node2vec [13], can be summarized into two phases: a sampling phase that determines node pairs with strong relationships, and an optimization phase that tries to preserve pairwise relationships in the embedding vectors through the negative sampling approach [22]. In particular, in the first phase, these three methods capture structural information by defining different neighborhood structures, such as random walk explored neighborhood in [13, 27], first-order and second-order proximities in [35]. We denote the generalized neighbors (not restricted to directly connected nodes) of node v_i as $\mathcal{N}(v_i)$, i.e., nodes in this set are closely related with v_i and should be close with v_i in the embedding space. The loss function of this framework can be abstracted as follows:

$$\begin{aligned}\mathcal{L}(G|\Theta) = -\sum_{v_i \in V}\sum_{v_j \in \mathcal{N}(v_i)} \{\log \sigma(s(v_i, v_j|\Theta)) \\ + \sum_{k=1}^{K} \mathbb{E}_{v_k \sim P_k(v)}[\log \sigma(-s(v_i, v_k|\Theta))]\},\end{aligned} \tag{1}$$

where Θ represents model parameters such as target and context embedding matrices, $s(v_i, v_j|\Theta)$ represents the similarity score of node v_i and v_j based on model parameters Θ, and $\sigma(\cdot)$ is the sigmoid function. $P_k(v)$ denotes the distribution for sampling negative nodes, and a simple variant of unigram distribution is usually utilized, i.e., $P_k(v) \propto d_v^{3/4}$, where d_v is the out-degree of node v. Eq. (1) is actually a cross entropy loss with closely related node pair (v_i, v_j) as positive samples and (v_i, v_k) as negative samples, and thus network embedding can be considered as a classification problem.

2.2 Adversarial Training

Adversarial training [12, 34] is a newly proposed effective regularization method for classifiers which can not only improve the robustness of the model against adversarial attacks, but also achieve better generalization performance on learning tasks. It augments the original clean data with the dynamically generated adversarial examples, and then trains the model with the newly mixed examples. Denote the input as $\boldsymbol{x}$ and model parameters as $\boldsymbol{\theta}$. The loss on adversarial examples can be considered as a regularization term in

(a) Cora, training ratio=50%, 80%. (b) Citeseer, training ratio=50%, 80%. (c) Wiki, training ratio=50%, 80%.

Figure 1: Impact of applying adversarial and random perturbations to the embedding vectors learned by DeepWalk on Cora, Citeseer and Wiki on multi-class classification with training ratio as 50% and 80%. Note that "random" represents random perturbations (noises generated from a normal distribution), while "adversarial" represents adversarial perturbations.

the trained classifier $p(y|\cdot)$, which is as follows:

$$-\log p(y|\boldsymbol{x}+\boldsymbol{n}_{adv};\boldsymbol{\theta}), \tag{2}$$

$$where\ \boldsymbol{n}_{adv} = \underset{\boldsymbol{n},\ \|\boldsymbol{n}\|\leq\epsilon}{\arg\min} \log p(y|\boldsymbol{x}+\boldsymbol{n};\hat{\boldsymbol{\theta}}), \tag{3}$$

where $\boldsymbol{n}$ is the perturbation on the input, ϵ represents the norm constraint of $\boldsymbol{n}$, and $\hat{\boldsymbol{\theta}}$ are current model parameters but fixed as constants. We employ L_2 norm in this paper, while L_1 norm has also been used in the literature [12]. Eq. (2) means that the model should be robust on the adversarial perturbed examples. Before each batch training, the adversarial noise $\boldsymbol{n}$ with respect to the input $\boldsymbol{x}$ is firstly generated by solving optimization problem (3) to make it resistant to current model. Since it is difficult to calculate Eq.(3) exactly in general, fast gradient descent method [12] is widely used to obtain the adversarial noise approximately by linearizing $\log p(y|\boldsymbol{x};\boldsymbol{\theta})$ around $\boldsymbol{x}$. Specifically, the adversarial perturbation with L_2 norm constraint can be obtained as follows:

$$\boldsymbol{n}_{adv} = -\epsilon \cdot \frac{\boldsymbol{g}}{\|\boldsymbol{g}\|_2}\ where\ \boldsymbol{g} = \nabla_{\boldsymbol{x}} \log p(y|\boldsymbol{x};\hat{\boldsymbol{\theta}}). \tag{4}$$

It can be easily calculated with backpropagation method.

2.3 Motivation

To improve the generalization ability of network embedding models, two ways have been used: firstly, some denoising autoencoder based methods [5, 8] improve model robustness by adding random perturbation to input data or hidden layers of deep models; secondly, some existing methods [8, 41] regularize embedding vectors from a global perspective through GAN-based method, i.e., encouraging the global smoothness of the distribution of embeddings. In this paper, we aim to introduce a novel, more succinct and effective regularization method for network embedding models, i.e., adversarial training (AdvT) [12]. AdvT generates crafted adversarial perturbations to model inputs and encourages local smoothness for improving model robustness and generalization performance, which can be expected to be more effective than the random perturbation methods [5] and global regularization methods [8, 41]. In the following, we would like to compare the impact of adversarial and random perturbation on embedding vectors to better motivate this new regularization method.

However, it is not clear how to integrate adversarial training into existing network embedding methods. Graph data is discrete, and the continuous adversarial noise can not be directly imposed on the discrete connected information. To bypass this difficulty, we seek to define the adversarial perturbation on embedding vectors instead of the discrete graph domain as inspired by [23]. We define the adversarial perturbation on node embeddings as follows:

$$\boldsymbol{n}_{adv} = \underset{\boldsymbol{n},\ \|\boldsymbol{n}\|\leq\epsilon}{\arg\max}\ \mathcal{L}(G|\hat{\Theta}+\boldsymbol{n}), \tag{5}$$

which can be further approximated with fast gradient method as presented in Eq. (4).

Take DeepWalk [27] with negative sampling loss as an illustrative example. We explore the effect of adversarial perturbations on embedding vectors by adding them to the learned embedding vectors from DeepWalk, and then perform multi-class classification with the perturbed embeddings on several datasets. Besides, we choose random perturbations as the compared baseline, i.e., noises generated from a normal distribution. Figure 1 displays node classification results with varying L_2 norm constraints on the perturbations. We can find that embedding vectors are much more vulnerable to adversarial perturbations than random ones. For example, when ε is set to 2.0, the performance of node classification with training ratio as 80% on Cora drops 3.35% under random perturbation, while that decreases 16.25% under adversarial perturbation which is around 4 times more serious. If the embedding vectors can be trained to be more robust on adversarial noises, we can expect more significant improvements in generalization performance.

3 PROPOSED METHODS

In this section, we first describe the adapted adversarial training method for network embedding models, and present the algorithm based on DeepWalk. Then, we will tackle its interpretability issue by designing a new adversarial perturbation generation method.

3.1 Adversarial Training DeepWalk

Figure 2 shows the framework of DeepWalk with adversarial training regularization. It consists of two phases: a sampling phase that determines node pairs with strong relationships, and an optimization phase that tries to preserve pairwise relationships in the embedding vectors based on negative sampling approach. Note that in this paper we take DeepWalk as the illustrative example, and the proposed framework can be applied to the network embedding methods, such as LINE and node2vec, with the main difference in the sampling phase only.

In the first phase, DeepWalk transforms the network into node sequences by truncated random walk. For each node $v_i \in V$, η

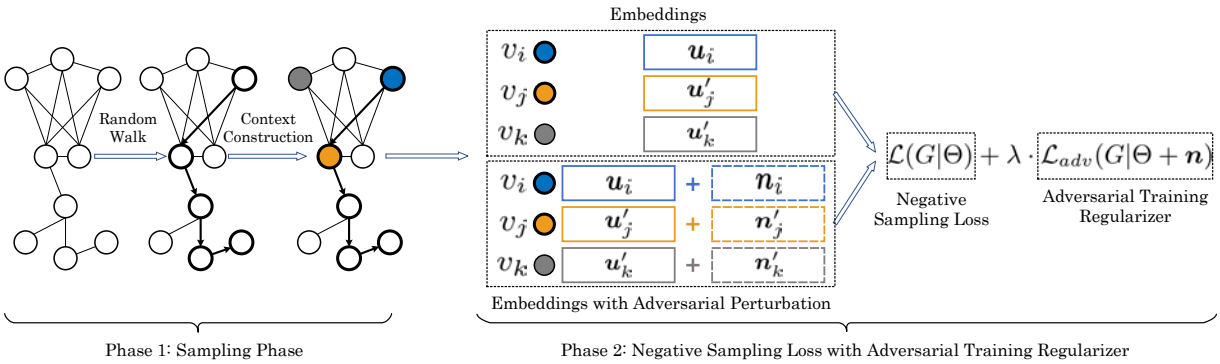


Figure 2: DeepWalk with Adversarial Training Regularization

sequences each with l nodes will be randomly sampled based on network structure with v_i as the starting point. In every walking step, the next node v_j will be sampled from the neighbors of current node v_k with the probability proportional to the edge strength A_{kj} between v_k and v_j. In practice, the alias table method [19] is usually leveraged for node sampling given the weight distribution of neighbors of current node, which only takes $O(1)$ time in a single sampling step. Then in the context construction process, closely related node pairs will be determined based on the sampled node sequences. Denote a node sequence as S with the ith node as s_i. The positive target-context pairs from S is defined as $\mathcal{P} = \{(s_i, s_j) : |i-j| \leq c\}$, where c represents the window size. With the constructed node pairs, the negative sampling loss will be optimized, which is defined as follows:

$$\begin{aligned}\mathcal{L}(G|\Theta) = -\sum_{v_i \in V}\sum_{v_j \in N(v_i)} \{\log \sigma(\boldsymbol{u'}_j^T \cdot \boldsymbol{u}_i) \\ + \sum_{k=1}^{K} \mathbb{E}_{v_k \sim P_k(v)}[\log \sigma(-\boldsymbol{u'}_k^T \cdot \boldsymbol{u}_i)]\},\end{aligned} \tag{6}$$

where (v_i, v_j) is from the constructed positive target-context pairs, and $\boldsymbol{u}_i$ and $\boldsymbol{u'}_j$ are the target embedding of node v_i and context embedding of node v_j respectively.

For the adversarial version of DeepWalk, an adversarial training regularization term is added to the original loss to help learn robust node representations against adversarial perturbations. The regularization term shares the same set of model parameters with the original model, but with the perturbed target and context embeddings as input. Existing methods consider the input examples independently, and impose the unique L_2 norm constraint on all adversarial perturbations [12, 23]. For graph structured data, entities often correlate with each other in a very complicated way, so it is inappropriate to treat all positive target-context relations equally without discrimination. Adversarial regularization helps alleviate overfitting issue, but it may also bring in some noises that can hinder the preservation of structural proximities, i.e., adding noises to those inherently closely-related node pairs will prevent them from having similar embeddings. Thus, we take advantages of the dependencies among nodes to assign different L_2 norm constraints to different positive target-context relations adaptively. Specifically, the more closely two nodes are connected, the smaller the constraint should be. The intuition is that less noises should be added to those node pairs which are inherently strongly-connected in the original network, thus they can be pushed closer in the embedding space with high flexibility, while for those weakly-connected pairs larger constraint can help alleviate the overfitting issue.

We obtain the similarity score of two nodes through computing the shifted positive pointwise mutual information matrix [18]:

$$M_{ij} = \max\{\log(\frac{\hat{M}_{ij}}{\sum_k \hat{M}_{kj}}) - \log(\beta), 0\}, \tag{7}$$

where $\hat{M} = \hat{A} + \hat{A}^2 + \cdots + \hat{A}^t$ captures different high-order proximities, $\hat{A}$ is the 1-step probability transition matrix obtained from A after the row-wise normalization, and β is a shift factor. We set t to 4 and β to $\frac{1}{N}$ in the experiments. Then, the adaptive scale factor for the L_2 norm constraint of the target-context pair v_i and v_j is calculated as below:

$$\Phi_{ij} = 1 - M_{ij} / \max\{M\}, \tag{8}$$

where $\max\{M\}$ represents the maximum entry of matrix M. Since $M_{ij} > 0$ $(\forall i, j)$, $\Phi_{ij} \in [0, 1]$. For those strongly-connected target-context pairs, the adaptive scale factor can help scale down the L_2 norm constraint of the adversarial perturbation, and thus alleviate the negative effect from the noises.

Then, the adversarial training regularizer with scale factor for L_2 norm constraint is defined as follows:

$$\begin{aligned}&\mathcal{L}_{adv}(G|\Theta + \boldsymbol{n}_{adv}) \\ &= -\sum_{v_i \in V}\sum_{v_j \in N(v_i)} \{\log \sigma((\boldsymbol{u'}_j + \Phi_{ij} \cdot (\boldsymbol{n'}_j)_{adv})^T \cdot (\boldsymbol{u}_i + \Phi_{ij} \cdot (\boldsymbol{n}_i)_{adv})) \\ &\quad + \sum_{k=1}^{K} \mathbb{E}_{v_k \sim P_k(v)}[\log \sigma(-(\boldsymbol{u'}_k + (\boldsymbol{n'}_k)_{adv})^T \cdot (\boldsymbol{u}_i + (\boldsymbol{n}_i)_{adv}))]\},\end{aligned} \tag{9}$$

where $(\boldsymbol{n}_i)_{adv}$ and $(\boldsymbol{n'}_j)_{adv}$ represent the original adversarial perturbation for target embedding of node v_i and context embedding of node v_j respectively.

Finally, one key problem is how to compute the adversarial perturbation for the given embedding vector of a node v. Here, we follow the famous adversarial training method directly [12, 34], and generate the perturbation noises to maximize model loss under current model parameters. The adversarial perturbation for node v is defined as follows:

$$\boldsymbol{n}_{adv} = \underset{\boldsymbol{n},\, \|\boldsymbol{n}\| \leq \epsilon}{\arg\max}\, \mathcal{L}(G|\hat{\Theta} + \boldsymbol{n}). \tag{10}$$

Algorithm 1: The adversarial training DeepWalk

Input : graph $G(V, E, A)$, window size c, embedding size d, walks per node η, negative size K, walk length l, adversarial noise level ϵ, adversarial regularization strength λ, batch size b

Output : Embedding matrix U

1 Initialize target and context embeddings with DeepWalk;
2 **while** *not converge* **do**
3 Generate a set of positive target-context pairs $\mathcal{P}$ with random walk based method;
4 **repeat**
5 Sample a batch $\mathcal{B}$ of target-context pairs from $\mathcal{P}$;
6 // Generate adversarial perturbations
7 $\boldsymbol{n}_{adv} = \epsilon \frac{\boldsymbol{g}}{\|\boldsymbol{g}\|_2}$ where $\boldsymbol{g} = \nabla_{\boldsymbol{u}} \mathcal{L}(G|\hat{\Theta})$ for each node v in the batch;
8 // Optimize model parameters
9 Update target and context embeddings by applying gradient descent technique to Eq. (12) ;
10 **until** $[|\mathcal{P}|/b]_+$ *times*;
11 **end**

It can be further approximated with fast gradient method as follows:

$$\boldsymbol{n}_{adv} = \epsilon \frac{\boldsymbol{g}}{\|\boldsymbol{g}\|_2} \ where \ \boldsymbol{g} = \nabla_{\boldsymbol{u}} \mathcal{L}(G|\hat{\Theta}). \tag{11}$$

Therefore, the overall loss for the proposed adversarial training DeepWalk is defined as follows:

$$\mathcal{L}(G|\Theta) + \lambda \cdot \mathcal{L}_{adv}(G|\Theta + \boldsymbol{n}_{adv}), \tag{12}$$

where λ is a hyperparameter to control the importance of the regularization term.

In this paper, we utilize DeepWalk with negative sampling loss as the base model for building the adversarial version of network embedding methods. Since the original implementation is based on the well encapsulated library, which lacks flexibility for further adaption, we re-implement the model with tensorflow [1] and utilize a slightly different training strategy. Specifically, in each training epoch, we independently construct positive target-context pairs with random walk based method, and then optimize model parameters with mini-batch stochastic gradient descent technique. Algorithm 1 summarizes the training procedure for the adversarial training DeepWalk. The model parameters are firstly initialized by training DeepWalk with the method introduced above. For each batch training, adversarial perturbations are generated with fast gradient method for each node in the batch as presented in Line 7. Then, the target and context embeddings will be updated by optimizing the negative sampling loss with adversarial training regularization as shown in Line 9. Asynchronous version of stochastic gradient descent [25] can be utilized to accelerate the training as DeepWalk. Note that we ignore the derivative of $\boldsymbol{n}_{adv}$ with respect to model parameters. The adversarial perturbations can be computed with simple back-propagation method, which enjoys low computational cost. Thus, the adversarial training DeepWalk is scalable as the base model.

3.2 Interpretable Adversarial Training DeepWalk

Adversarial examples refer to examples that are generated by adding viciously designed perturbations with norm constraint to the clean input, which can significantly increase model loss and probably induce prediction error [34]. Take an example from [12] for illustration, a "panda" image with imperceptibly small adversarial perturbation is assigned to be "gibbon" by the well-trained classification model with high confidence, while the original image can be correctly classified. Such adversarial examples can be well interpreted since the perturbations are imposed on the input space. For the adversarial training DeepWalk, adversarial perturbations are added to node embeddings instead of the discrete nodes and connected relations, and thus can not be easily reconstructed in the discrete graph domain. Though effective as a regularizer for improving model generalization performance, it suffers from lack of interpretability, which may create a barrier for its adoption in some real-world applications.

In this section, we propose an interpretable adversarial DeepWalk model by restoring the interpretability of adversarial perturbations. Instead of pursuing the worst perturbation direction only, we restrict the direction of perturbations toward a subset of nodes in the graph in the embedding space, such as the neighbors of the considered node. In this way, the adversarial perturbations in the node embedding space might be interpreted as the substitution of nodes in the original input space, i.e., the discrete target-context relations. However, there might be a certain level of sacrifice on the regularization performance because of the restriction on perturbation directions.

The *direction vector* from node v_t to v_k in the embedding space is defined as follows:

$$\boldsymbol{v}_k^{(t)} = \frac{\tilde{\boldsymbol{v}}_k^{(t)}}{\|\tilde{\boldsymbol{v}}_k^{(t)}\|_2}, \ where \ \tilde{\boldsymbol{v}}_k^{(t)} = \boldsymbol{u}_k - \boldsymbol{u}_t. \tag{13}$$

Denote $V^{(t)} \subseteq V$ ($|V^{(t)}| = T$, $|V^{(t)}| \ll |V|$) as a set of nodes for generating adversarial perturbation for node v_t. We define $V^{(t)}$ as the top T nearest neighbors of node v_t in the embedding space based on current model parameters. To improve model efficiency, we can also obtain $V^{(t)}$ based on the pretrained model parameters, and fix it for all training epochs. We use the latter strategy for experiments in this paper. Denote $\boldsymbol{w}^{(t)} \in \mathcal{R}^T$ as the weight vector for node v_t with $w_k^{(t)}$ representing the weight associated with direction vector $\boldsymbol{v}_k^{(t)}$, where v_k is the kth node in $V^{(t)}$. The interpretable perturbation for v_t is defined as the weighted sum of the direction vectors starting from v_t and ending with nodes in $V^{(t)}$:

$$\boldsymbol{n}(\boldsymbol{w}^{(t)}) = \sum_{k=1}^{T} w_k^{(t)} \boldsymbol{v}_k^{(t)}, \ v_k \in V^{(t)}, \ \forall k = 1, \cdots, T. \tag{14}$$

The adversarial perturbation is obtained by finding the weights that can maximize the model loss:

$$\boldsymbol{w}_{iAdv}^{(t)} = \underset{\boldsymbol{w}^{(t)}, \|\boldsymbol{w}^{(t)}\| \leq \epsilon}{\arg\max} \mathcal{L}_{iAdv}(G|\Theta + \boldsymbol{n}(\boldsymbol{w}^{(t)})), \tag{15}$$

where $\mathcal{L}_{iAdv}$ is obtained by replacing $\boldsymbol{n}_{adv}$ in Eq. (9) with $\boldsymbol{n}(\boldsymbol{w}^{(t)})$. In consideration of model efficiency, the above regularization term is approximated with first-order Taylor series for easy computation as

Table 1: Statistics of benchmark datasets

Name	Cora	Citeseer	Wiki	CA-GrQc	CA-HepTh
$\|V\|$	2,708	3,264	2,363	5,242	9,877
$\|E\|$	5,278	4,551	11,596	14,484	25,973
Avg. degree	1.95	1.39	4.91	2.76	2.63
#Labels	7	6	17	-	-

in [12]. Thus, the weights for constructing interpretable adversarial perturbation for node v_t can be computed as follows:

$$\boldsymbol{w}_{iAdv}^{(t)} = \epsilon \frac{\boldsymbol{g}}{\|\boldsymbol{g}\|_2} \; where \; \boldsymbol{g} = \nabla_{\boldsymbol{w}^{(t)}} \mathcal{L}_{iAdv}(G|\Theta + \boldsymbol{n}(\boldsymbol{w}^{(t)})). \quad (16)$$

Substituting $\boldsymbol{w}_{iAdv}^{(t)}$ into Eq. (14), we can get the adversarial perturbations $\boldsymbol{n}(\boldsymbol{w}_{iAdv}^{(t)})$. Further, by replacing $\boldsymbol{n}_{adv}$ with $\boldsymbol{n}(\boldsymbol{w}_{iAdv}^{(t)})$ in Eq. (9), we can have the interpretable adversarial training regularizer for DeepWalk. The algorithm for interpretable adversarial training DeepWalk is different from Algorithm 1 in the way of generating adversarial perturbations, and thus we do not present it in this paper due to space limitation. Since $|V^{(t)}| \ll |V|$, the computation of adversarial perturbation for one node takes constant time. Therefore, the time complexity of this model is also linear to the number of nodes in the graph as DeepWalk.

4 EXPERIMENTS

In this section, we empirically evaluate the proposed methods through performing link prediction and node classification on several benchmark datasets.

4.1 Experiment Setup

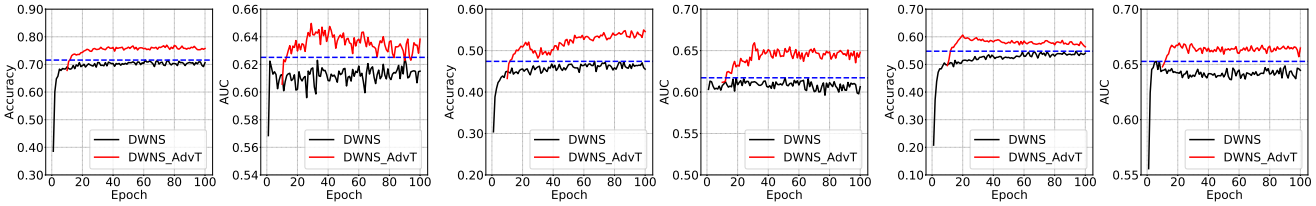
4.1.1 Datasets. We conduct experiments on several benchmark datasets from various real-world applications. Table 1 shows some statistics of them. Note that we do some preprocessing on the original datasets by deleting self-loops and nodes with zero degree. Some descriptions of these datasets are summarized as follows:

- **Cora, Citeseer** [21]: Paper citation networks. Cora consists of 2708 papers with 7 categories, and Citeseer consists 3264 papers including 6 categories.
- **Wiki** [31]: Wiki is a network with nodes as web pages and edges as the hyperlinks between web pages.
- **CA-GrQc, CA-HepTh** [17]: Author collaboration networks. They describe scientific collaborations between authors with papers submitted to General Relativity and Quantum Cosmology category, and High Energy Physics, respectively.

4.1.2 Baseline Models. The descriptions of the baseline models are as follows:

- **Graph Factorization (GF)** [2]: GF directly factorizes the adjacency matrix with stochastic gradient descent technique to obtain the embeddings, which enables it scale to large networks.
- **DeepWalk** [27]: DeepWalk regards node sequence obtained from truncated random walk as word sequence, and then uses skip-gram model to learn node representations. We directly use the publicly available source code with hierarchical softmax approximation for experiments.
- **LINE** [35]: LINE preserves network structural proximities through modeling node co-occurrence probability and node conditional probability, and leverages the negative sampling approach to alleviate the expensive computation.
- **node2vec** [13]: node2vec differs from DeepWalk by proposing more flexible method for sampling node sequences to strike a balance between local and global structural properties.
- **GraRep** [4]: GraRep applies SVD technique to different k-step probability transition matrix to learn node embeddings, and finally obtains global representations through concatenating all k-step representations.
- **AIDW** [8]: AIDW is an inductive version of DeepWalk with GAN-based regularization method. A prior distribution is imposed on node representations through adversarial learning to achieve a global smoothness in the distribution.

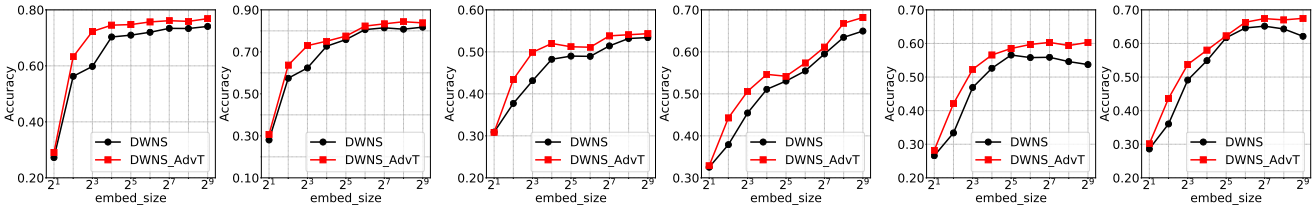
Our implemented version of DeepWalk is based on negative sampling approach, thus we denote it as Dwns to avoid confusion. We also include a baseline, namely Dwns_rand, with noises from a normal distribution as perturbations in the regularization term. Following existing work [30], we denote the adversarial training DeepWalk as Dwns_AdvT, and the interpretable adversarial training DeepWalk as Dwns_iAdvT in the rest of the paper.



4.1.3 Parameter Settings. For Dwns and its variants including Dwns_rand, Dwns_AdvT and Dwns_iAdvT, the walk length, walks per node, window size, negative size, regularization strength, batch size and learning rate are set to 40, 1, 5, 5, 1, 1024 and 0.001, respectively. The adversarial noise level ϵ has different settings in Dwns_AdvT and Dwns_iAdvT, while Dwns_rand follows the settings of Dwns_AdvT. For Dwns_AdvT, ϵ is set to different value for different datasets. Specifically, ϵ is set to 0.9 for Cora, 1.1 for Citeseer in both link prediction and node classification, and 0.6 and 0.5 for Wiki in node classification and link prediction respectively, while it is set to 0.5 for all other datasets in these two learning tasks. For Dwns_iAdvT, ϵ is set to 5 for all datasets in both node classification and link prediction tasks, and the size of the nearest neighbor set T is set to 5. Besides, the dimension of embedding vectors are set to 128 for all methods.

4.2 Impact of Adversarial Training Regularization

In this section, we conduct link prediction and multi-class classification on adversarial training DeepWalk, i.e., Dwns_AdvT, to study the impact of adversarial training regularization on network representation learning from two aspects: model performance on different training epochs and model performance under different model size.



Node classification is conducted with support vector classifier in Liblinear package[1] [10] in default settings with the learned embedding vectors as node features. In link prediction, network embedding is first performed on a sub-network, which contains 80% of edges in the original network, to learn node representations. Note that the degree of each node is ensured to be greater than or equal to 1 during subsampling process to avoid meaningless embedding vectors. We use AUC score as the performance measure, and treat

Figure 4: Performance comparison between DWNS and DWNS_AdvT on multi-class classification with training ratio as 10% (left) and 50% (right) respectively under varying embedding size.

link prediction as a classification problem. Specifically, a L_2-SVM classifier is trained with edge feature inputs obtained from the Hadamard product of embedding vectors of two endpoints as many other works [13, 40], positive training samples as the observed 80% edges, and the same number of negative training samples randomly sampled from the network, i.e., node pairs without direct edge connection. The testing set consists of the hidden 20% edges and two times of randomly sampled negative edges. All experimental results are obtained by making an average of 10 different runs.

4.2.1 Training Process. We train DWNS model for 100 epochs, and evaluate the generalization performance of the learned embedding vectors in each epoch with node classification and link prediction on Cora, Citeseer and Wiki. We also conduct similar experiments on DWNS_AdvT for 90 epochs with the model parameters initialized from those of DWNS after $10th$ training epochs. Figures 3 shows the experimental results.

In general, adversarial training regularization can bring a significant improvement in generalization ability to DWNS through the observation of training curves in both node classification and link prediction. Specifically, after 10 training epochs, the evaluation performance has little improvements for all datasets in two learning tasks with further training for DWNS, while adversarial training regularization leads to an obvious performance increase. In Figure 3, the blue line is drew by setting its vertical coordinates as the maximum value of the metrics of DWNS in the corresponding experiments. We can find that the training curve of DWNS_AdvT is continuously above the blue line in different training epochs. Particularly, there is an impressive 7.2% and 9.2% relative performance improvement in link prediction for Cora and Citeseer respectively. We notice that the performance of DWNS_AdvT drops slightly after about 40 training epochs for Cora in link prediction, and about 20 training epochs for Wiki in node classification. The reason might be that some networks are more vulnerable to overfitting, and deeper understanding of this phenomenon needs further exploration.

4.2.2 Performance vs. Embedding Size. We explore the effect of adversarial regularization under different model size with multi-class classification. Figure 4 demonstrates the classification results on Cora, Citeseer and Wiki with training ratio as 10% and 50%. In general, adversarial training regularization is essential for improving model generalization ability. Across all tested embedding size, our proposed adversarial training DEEPWALK can consistently outperform the base model. For two models, when varying embedding size from 2 to 512, the classification accuracy firstly increases in a relatively fast speed, then grows slowly, and finally becomes stable or even drops slightly. The reason is that model generalization ability is improved with the increase of model capacity firstly until some threshold, since more network structural information can be captured with larger model capacity. However, when the model capacity becomes too large, it can easily result in overfitting, and thus cause performance degradation. We notice that the performance improvement of DWNS_AdvT over DWNS is quite small when the embedding size is 2. It is probably because model capacity is the main reason limiting model performance and model robustness is not a serious issue when embedding size is too small.

4.3 Link Prediction

Link prediction is essential for many applications such as extracting missing information and identifying spurious interaction [20]. In this section, we conduct link prediction on five real-world networks,

and compare our proposed methods with the state-of-the-art methods. The experimental settings have been illustrated in Section 4.2. Table 2 summarizes the experimental results.

It can be easily observed that both our proposed methods, including Dwns_AdvT and Dwns_iAdvT, performs better than Dwns in all five datasets, which demonstrates that two types of adversarial regularization methods can help improve model generalization ability. Specifically, there is a 4.62% performance improvement for Dwns_AdvT over Dwns on average across all datasets, and that for Dwns_iAdvT is 4.60%, which are very impressive.

We noticed that AIDW has a poor performance in link prediction. The reasons can be two-folds: firstly, AIDW encourages the smoothness of embedding distribution from a global perspective by imposing a prior distribution on them, which can result in over-regularization and thus cause performance degradation; secondly, AIDW suffers from mode-collapse problem because of its generative adversarial network component, which can also result in model corruption. Besides, Dwns_rand has similar performance with Dwns, which means that the regularization term with random perturbation contributes little to model generalization ability. By comparison, our proposed novel adversarial training regularization method is more stable and effective.

It can be observed that the performance of Dwns_AdvT and Dwns_iAdvT are comparable. Either Dwns_AdvT or Dwns_iAdvT achieves the best results across the five datasets, which shows the remarkable usefulness of the proposed regularization methods. For Cora and CA-GrQc, Dwns_iAdvT has better performance, although we restrict the perturbation directions toward the nearest neighbors of the considered node. It suggests that such restriction of perturbation directions might provide useful information for representation learning.

4.4 Node Classification

Node classification can be conducted to dig out missing information in a network. In this section, we conduct multi-class classification on three benchmark datasets, including Cora, Citeseer and Wiki, with the training ratio ranging from 1% to 90%. Tables 3, 4 and 5 summarize the experimental results.

Firstly, Dwns_rand and Dwns have similar performance in all three datasets. For example, the average improvement of Dwns_rand over Dwns is 0.16% across all training ratios in Wiki, which can be negligible. It validates that random perturbation for the regularization term contributes little to the model generalization performance again. It is understandable, since the expected dot product between any reference vector and the random perturbation from a zero mean gaussian distribution is zero, and thus the regularization term will barely affect the embedding learning.

Secondly, Dwns_AdvT and Dwns_iAdvT consistently outperform Dwns across all different training ratios in the three datasets, with the only exception of Dwns_iAdvT in Citeseer when the training ratio is 3%. Specifically, Dwns_AdvT achieves 5.06%, 6.45% and 5.21% performance gain over Dwns on average across all training ratios in Cora, Citeseer and Wiki respectively, while the improvement over Dwns for Dwns_iAdvT are 2.35%, 4.50% and 2.62% respectively. It validates that adversarial perturbation can provide useful direction for generating adversarial examples, and thus brings significant improvements to model generalization ability after the adversarial training process. For Dwns_iAdvT, it brings less performance gain compared with Dwns_AdvT, which might because the restriction on perturbation direction limit its regularization ability for classification tasks. In this case, there is a tradeoff between interpretability and regularization effect.

Thirdly, AIDW achieves better results than DeepWalk, LINE and GraRep, which shows that global regularization on embedding vectors through adversarial learning can help improve model generalization performance. Our proposed methods, especially Dwns_AdvT, demonstrate superiority over all the state-of-the-art baselines, including AIDW and node2vec, based on experimental results comparison. We can summarize that the adversarial training regularization method has advantages over the GAN-based global regularization methods in three aspects, including more succinct architecture, better computational efficiency and more effective performance contribution.

4.5 Parameter Sensitivity

We conduct parameter sensitivity analysis with link prediction and multi-class classification on Cora, Citeseer and Wiki in this section. Here we only present the results for Dwns_AdvT due to space limitation. Adversarial training regularization method is very succinct. Dwns_AdvT only has two more hyperparameters compared with Dwns, which are noise level ϵ and adversarial regularization strength λ. Note that when studying one hyper-parameter, we follow default settings for other hyper-parameters. The experimental settings of link prediction and node classification have been explained in Section 4.2.

Fig. 5(a) presents the experimental results when varying ϵ from 0.1 to 5.0. For both learning tasks, we can find that the performance in these three datasets first improves with the increase of ϵ, and then drops dramatically after ϵ passing some threshold. It suggests that appropriate setting of ϵ improves the model robustness and generalization ability, while adversarial perturbation with too large norm constraint can destroy the learning process of embedding vectors. Besides, it can be easily noticed that the best settings of ϵ are different for different datasets in general. Specifically, Citeseer has the best results in both link prediction and node classification when $\epsilon = 1.1$, Cora achieves the best results when $\epsilon = 0.9$, while the best setting of ϵ for Wiki is around 0.5. Based on the experimental results on these three datasets only, it seems that the denser the network is, the smaller the best noise level parameter ϵ should be.

We conduct link prediction and node classification on three datasets with the adversarial regularization strength λ from the set $\{0.001, 0.01, 0.1, 1, 10, 100, 1000\}$. Fig. 5(b) displays the experimental results. For node classification, the best result is obtained when λ is set to around 1, larger values can result in performance degradation. For example, the classification accuracy on Wiki drops dramatically when λ reaches 10, and larger setting produces worse results. For link prediction, the performance is quite consistent among the three datasets. Specifically, when λ increases from 0.001 to 10, the AUC score shows apparent increase for all datasets, and then tends to saturate or decrease slightly. Empirically, 1 is an appropriate value for the adversarial regularization strength λ.

5 RELATED WORK

Network Embedding. Some early methods, such as IsoMap [36] and LLE [28], assume the existence of a manifold structure on input vectors to compute low-dimensional embeddings, but suffer from the expensive computation and their inability in capturing highly non-linear structural information of networks. More recently, some negative sampling approach based models have been proposed, including DeepWalk [27], LINE [35] and node2vec [13], which enjoys two attractive strengths: firstly, they can effectively capture high-order proximities of networks; secondly, they can scale to the widely existed large networks. DeepWalk obtains node sequences with truncated random walk, and learns node embeddings with Skip-gram model [22] by regarding node sequences as sentences. node2vec differs from DeepWalk by proposing more flexible random walk method for sampling node sequences. LINE defines

(a) Noise level ϵ.

(b) Adversarial regularization strength λ.

Figure 5: Impact of hyperparameters on node classification (left, training ratio 50%) and link prediction (right).

first-order and second-order proximities in network, and resorts to negative sampling for capturing them.

Further, some works [4, 26, 39] tried to preserve various network structural properties in embedding vectors based on matrix factorization technique. GraRep [4] can preserve different k-step proximities between nodes independently, HOPE [26] aims to capture asymmetric transitivity property in node embeddings, while N-NMF [39] learns community structure preserving embedding vectors by building upon the modularity based community detection model [24]. Meanwhile, deep learning embedding models [5, 32, 33, 37] have also been proposed to capture highly nonlinear structure. DNGR [5] takes advantages of deep denoising autoencoder for learning compact node embeddings, which can also improve model robustness. SDNE [37] modifies the framework of stacked autoencoder to learn both first-order and second-order proximities simultaneously. DNE-SBP [33] utilizes a semi-supervised SAE to preserve the structural balance property of the signed networks. Both GraphGAN [38] and A-RNE [9] leverage generative adversarial networks to facilitate network embedding, with the former unifies the generative models and discriminative models of network embedding to boost the performance while the latter focuses on sampling high-quality negative nodes to achieve better similariy ranking among node pairs.

However, the above mentioned models mainly focus on learning different network structures and properties, while neglecting the existence of noisy information in real-world networks and the overfitting issue in embedding learning process. Most recently, some methods, including ANE [8] and NetRA [41], try to regularize the embedding learning process for improving model robustness and generalization ability based on generative adversarial networks (GANs). They have very complicated frameworks and suffer from the well-recognized hard training problems of GANs. Furthermore, these two methods both encourage the global smoothness of the embedding distribution, while in this paper we utilize a more succinct and effective local regularization method.

Adversarial Machine Learning. It was found that several machine learning models, including both deep neural network and shallow classifiers such as logistic regression, are vulnerable to examples with imperceptibly small designed perturbations, called adversarial examples [12, 34]. This phenomenon was firstly observed in areas like computer vision with continuous input vectors. To improve model robustness and generalization ability, adversarial training method [12] is shown to be effective. It generates adversarial perturbations for original clean input with the aim of maximizing current model loss, and further approximates the difficult optimization objective with first-order Taylor Series. Such method has also been applied to text classification problem in [23, 30] by defining the perturbation on continuous word embeddings, and recommendation in [15] by generating adversarial perturbations on model parameters. However, to the best of our knowledge, there is no practice of adversarial training regularization for graph representation learning.

For graph structured data, they are fundamentally different from images because of their discrete and indifferentiable characteristics. Some existing works [6, 7, 42] aimed to explore how to generate the adversarial examples in the discrete, binary graph domain, and whether similar vulnerability exists in graph analysis applications. In [7], adversarial attacks are generated by modifying combinatorial structure of graph with a reinforcement learning based method, which is shown to be effective in Graph Neural Network models. Both [42] and [6] designed attack methods to Graph Convolutional Network [16]. Particularly, NETTACK [42] focuses on attributed graph classification problem and FGA [6] tackles network representation learning. However, all of them studied adversarial attack methods without providing any defense algorithms for improving the robustness of existing methods against these attacks. Differently, in this paper, we aim to propose adversarial regularization method for network embedding algorithms to improve both model robustness and generalization ability.

6 CONCLUSION

In this paper, we proposed two adversarial training regularization methods for network embedding models to improve the robustness and generalization ability. Specifically, the first method is adapted from the classic adversarial training method by defining the perturbation in the embedding space with adaptive L_2 norm constraint. Though it is effective as a regularizer, the lack of interpretability may hinder its adoption in some real-world applications. To tackle this problem, we further proposed an interpretable adversarial training method by restricting the perturbation directions to embedding vectors of other nodes, such that the crafted adversarial examples can be reconstructed in the discrete graph domain. Both methods can be applied to the existing embedding models with node embeddings as model parameters, and DeepWalk is used as the base model in the paper for illustration. Extensive experiments prove the effectiveness of the proposed adversarial regularization methods for improving model robustness and generalization ability. Future works would include applying adversarial training method to the parameterized network embedding methods such as deep learning embedding models.

ABSTRACT

Finding diagrams that contain a specific part or a similar part is important in many engineering tasks. In this search task, the query part is expected to match only a small region in a complex image. This paper investigates several local matching networks that explicitly model local region-to-region similarities. Deep convolutional neural networks extract local features and model local matching patterns. Spatial convolution is employed to cross-match local regions at different scale levels, addressing cases where the target part appears at a different scale, position, and/or angle. A gating network automatically learns region importance, removing noise from sparse areas and visual metadata in engineering diagrams.

Experimental results show that local matching approaches are more effective for engineering diagram search than global matching approaches. Suppressing unimportant regions via the gating network enhances accuracy. Matching across different scales via spatial convolution substantially improves robustness to scale and rotation changes. A pipelined architecture efficiently searches a large collection of diagrams by using a simple local matching network to identify a small set of candidate images and a more sophisticated network with convolutional cross-scale matching to re-rank candidates.

1 INTRODUCTION

In large engineering organizations that manufacture complex products, many engineers at different locations may collaborate to design a product. Searching a corpus of engineering diagrams for similar parts helps staff estimate production costs for new parts based on the costs of similar existing parts; and reduce production costs by using existing parts or replacing several slightly different parts with a new, more widely applicable part.

Engineering diagrams use line drawings and metadata such as part reference numbers to represent the elements of a part or an assembly of parts. Often they are created by computer-aided design (CAD) systems. However, the detailed descriptions stored in CAD systems are unwieldy, often unnecessary, and sometimes too sensitive to be shared widely within an organization. Thus, engineering diagrams – *images* – are the main method of describing parts and assemblies for many tasks. Finding engineering diagrams that contain a specific part or assembly is a type of *image retrieval*.

Image retrieval is a long-studied research area. Most prior research focuses on pictures, and specifically how to represent pictures so that similar pictures are easy to recognize. The recent advances achieved by convolutional neural networks (CNN) create opportunities for generating competitive image representations. Several works investigate taking the output of the network, or aggregating intermediate convolution features, to create an image feature vector that can be used for retrieval via k-nearest neighbour search [1, 2, 7, 11, 25]. Most existing CNN-based image search approaches use a single representation of the entire image; we call this a *global* representation. Global representations have many advantages: they are fast, suppress or generalize unnecessary detail, and describe the main elements of an image. However, they also lose detail, which can be a problem for engineering diagram search.

Engineering diagram search has specific characteristics. Often, the query diagram is expected to match only a small region of an engineering diagram, for example, to find every diagram that uses a specific part. Thus, it is a more *local* matching problem. Engineering diagrams differ from most pictures. Typical engineering diagrams are gray-scale line drawings that have little texture. They have a visual syntax and contain visual metadata elements, for example, locator elements that place the diagram within a larger context; callouts that provide other perspectives; bubbles that provide additional detail; and lines that illustrate relationships among selected parts. It is an open question whether existing image retrieval algorithms based on global, general visual features are effective for engineering diagram search. This paper investigates several global and local approaches for engineering diagram search.

One of our new approaches is an unsupervised ranker called **DI**agram **S**earc**H** with Local Histogram Pooling Matching Network (DISH-HP). DISH-HP models the relevance of a diagram to a query based on the similarity of local regions, using histogram pooling to combine evidence [8]. It first extracts local convolution features from the middle layers of a pretrained network, such as VGG-16

[26]. Each local feature represents a small region in the original diagram. DISH-HP calculates the similarity scores between every pair of query and document regions. It then groups the region pairs into bins according to their similarity scores. Two diagrams are considered similar if many of the region pairs fall into the high similarity bins. The histogram-based method is efficient so that DISH-HP can scan over all diagrams in a collection to find the most similar candidates.

The second of our new approaches is called Diagram Search with Local Convolutional Matching Network (DISH-Conv). It was inspired by Conv-KNRM, a state-of-the-art neural text ranking model, that uses convolutional neural networks to match text n-grams [3]. The new DISH-Conv model employs spatial convolutional neural networks to build feature vectors for larger regions from small regions, generating multi-scale region representations. A cross-scale matching layer calculates the similarity between regions of different scales, enabling a smaller region in the query to match to a larger region in the candidate diagram. A *gating* network is proposed that automatically detects unimportant regions of a diagram, reducing noisy signals from low-density regions and visual metadata such as callouts. DISH-Conv can be trained end-to-end with relevance signals, so that the convolution, matching, and gating are optimized towards the specific dataset and task.

DISH-HP and DISH-Conv can be used in a pipelined re-ranking architecture. DISH-HP is the first stage that quickly ranks images. The top N candidates are passed to DISH-Conv to refine the ranking. N is limited to a few hundred or a few thousand, so that the second stage is able to use a more accurate ranking model that would be too computationally expensive for the first stage brute-force search.

Evaluation was done on a new diagram search dataset developed by crawling furniture assembly manuals from the Ikea™ website. Queries were generated automatically by extracting query-like regions from diagrams and transforming them in various ways, for example, by changing position, scale, and/or rotation. Experiments on large-scale auto-generated relevance labels show that DISH-HP is more accurate than several unsupervised rankers that use global image representations. Using DISH-Conv to re-rank DISH-HP results improves accuracy substantially. Larger improvements over baseline models are shown on more difficult queries that have rotation and scale changes. Evaluation with a small set of manual relevance assessments further confirms these results. Analysis reveals that the advantage of DISH-Conv is a combination of its abilities to transform rotation changes through the convolutions, match at multiple scale level through the cross-matching layer, and suppress unimportant regions through the gating network.

The rest of this paper is organized as follows. Sections 2 gives a brief overview of related work. Section 3 and 4 introduce the proposed models DISH-HP and DISH-Conv. Section 5 discusses the Ikea diagram search dataset and our experimental methodology. Section 6 reports and discusses experimental results. Section 7 summarizes and concludes the paper.

2 RELATED WORK

Image Search. Until recently, the vast majority of image search approaches were variants of the bag-of-words model [24] based on hand-crafted features, typically SIFT [13]. In the recent decade, out-of-the-box features from pre-trained Convolutional Neural Networks (CNNs) were shown to give state-of-the-art results in many computer vision tasks, including image search. The early CNN-based image retrieval work [2, 7] takes the activation of fully connected layers as *global* descriptors. Later works shift the focus to convolution layers because lower layers preserve more detailed visual information and are more suitable for the search task. The convolution features are extracted from sliding windows at different image regions, hence are usually considered as *local* features. Most prior work used max/sum pooling over the convolution features to produce the single image representation Babenko and Lempitsky [1], Jimenez et al. [11], Kalantidis et al. [12], Tolias et al. [25]. Although local convolution features are used, they are pooled into a single representation, hence the image matching is still performed *globally*. It may raise problems for diagram search where tasks include matching *part* of one diagram to *part* of another diagram.

Patch-based approaches aim to represent a image with multiple image patches to address the problem when the item of interest has appeared on a different scale at an arbitrary position in the relevant image [7, 21]. Patch-based methods are computationally expensive because each individual patch is resized to the same size as the original image and fed forward into a deep convolutional neural network to extract features.

Most CNN-based image retrieval work focused on real-world photographs [1, 2, 11, 25]. They were tested against benchmark datasets consisting of landmark photographs, such as the Oxford Buildings dataset [18], the Paris Dataset [19], and the INRIA Holidays dataset [10]. The effectiveness of CNN based features on engineering diagrams remains to be explored,

Engineering Diagram Search. A lot of work on image-based engineering diagram search were developed before the bag-of-word model [24] was widely applied in image search. These systems often take several steps to first identify lines and shapes and then to calculate similarities between two diagrams. Task specific features and matching criterias were designed, leading to complex systems and extensive feature engineering [6, 15, 20]. A more recent work by Eitz et al. [5] published in 2011 demonstrates the effectiveness of bag-of-words models with SIFT-style features on line-drawings and sketch-based image retrieval. To the best of our knowledge, little exploration has been made on using deep convolution networks for engineering diagram search.

Neural Ranking Models for Text Search. Large progress has been made recently on using deep neural networks for text search. Recent neural ranking models can be categorized as *representation-based* and *interaction-based* [8]. Representation-based models use global representations of the query and document and match in the representation space [9, 22]. They are similar to most image search approaches based on global image representations. Interaction-based models use local interactions between the query and document words and neural networks that learn matching patterns [3, 8, 27]. The DRMM model [8] uses histogram pooling to summarize word-word interactions. It builds a word-word similarity matrix from word embeddings, groups the word-word soft matches into a histogram based on the similarity score, and learns to combine the bins. It allows the model to take into consideration both strong word matches and weaker word matches. The paper also proposed two methods to suppress unimportant query words; one method is

based on term frequency signals and the other is based on the word embedding. The K-NRM model [27] integrates DRMM with the ability to learn customized embeddings. It uses kernel-pooling, an approximation of the histogram with RBF kernels. Kernel-pooling shares the advantage of histogram pooling while also being differentiable so that word embeddings can be learned end-to-end and align with the search task. The Conv-KNRM model [3] extends K-NRM by using convolutional neural networks to build n-gram representations. It uses different sizes of convolutions to build unigram, bigram and trigram embeddings from word embeddings. A *cross-matching* layer compares across n-grams of various lengths in the unified embedding space. It allows the query bi-gram "deep learning" to be matched to the document tri-gram "convolutional neural network". The n-gram matching signals improve ranking accuracy over the unigram models.

3 DISH-HP: LOCAL HISTOGRAM POOLING MATCHING NETWORK

Interaction-based text retrieval models, which match a query to localized regions of a document, are more accurate than representation-based models because i) text queries are not expected to match all, or even most, of a text document, ii) local interactions provide multiple and detailed match signals, and iii) irrelevant regions have no effect. Interaction-based models could be beneficial to diagram search by modeling the interactions of a local region from the query diagram and a local region from the document diagram.

The section describes a diagram search model based on *Local Histogram Pooling Matching Network* (**DISH-HP**). DISH-HP is inspired by the histogram pooling technique proposed by Guo et al. [8]. It models the relevance between two diagrams based on how similar their local regions are.

The input to DISH-HP is a list of local convolution feature vectors extracted from the query diagram Q and the document diagram D. In our experiments, features are extracted from the last convolution layer of the VGG-16 network [26]. This layer divides the image into $R = W \times H = 14 \times 14 = 196$ grids, each corresponding to a 16 pixel $\times$ 16 pixel rectangular region in the diagram. For each of the R regions, a $d = 512$ dimension feature vector is generated. Hence, Q and D are represented by matrices of size $[R, d] = [196, 512]$.

Given the feature matrices of Q and D, DISH-HP collects the similarity scores between every pair of query region and document region. It then groups the region pairs into bins based on the similarity scores and builds a histogram. The histogram is pooled to produce a relevance score, where two diagrams are considered similar if many of the region pairs fall into the high similarity bins. More specifically, DISH-HP builds a similarity matrix M of size $[R, R]$ where the cell $M_{i,j}$ is the cosine similarity between the i-th query feature and the j-th document feature. A histogram is built for each row of the similarity matrix by assigning the similarity values into 10 bins: $B_1 = [0.8, 1]$, $B_2 = [0.6, 0.8)$, ..., $B_{10} = [-1, -0.8)]$. DISH-HP then counts the points in each bin. The counts indicate how many document regions are very similar to the query region (e.g., bin $[0.8, 1]$), how many are somewhat similar (e.g., bin $[0.6, 0.8)$), and how many are dissimilar. The number of points in the first K high-similarity bins $\{B_1, ..., B_K\}$ are taken as the score for the document diagram to match the i-th query region:

$$s(Q_i, D) = \sum_{j=1...K} |B_j|. \quad (1)$$

The final relevance score is the log-sum of counts from every query region:

$$s(Q, D) = \sum_{i=1...R} \log s(Q_i, D). \quad (2)$$

Log-sum squashes very high values into smaller values. It helps to avoid the matching being dominated by a few query regions that are repeatedly matched in the document diagram.

One issue with the above method is that the relevance score is often overwhelmed by noisy match signals from low-density regions. Engineering diagrams are often very sparse; blank or near-blank regions will dominate the high-similarity bins. To address this issue, features from low-density regions are filtered out before computing the similarity matrix. A feature vector is removed if its L2-norm is smaller than a threshold T, with the assumption that lower L2-norm indicates lower density of that region. The L2-norm threshold T is a hyper-parameter to be tuned.

In summary, DISH-HP explicitly models the similarity between local regions from the query and the document. DISH-HP is expected to retrieve more-relevant documents than global matching methods because the local, region-level matching provides more evidence than matching at the global image level. In terms of efficiency, DISH-HP is slightly slower than global methods. DISH-HP needs to compute R^2 cosine similarity values for a document with R local regions; global methods only need to compute a single global cosine similarity. The bottleneck for both global and local method lies in extraction features from the query using a deep convolutions neural network.

4 DISH-CONV: LOCAL CONVOLUTIONAL MATCHING NETWORK

DISH-HP is designed to be simple and efficient in order to be used for initial ranking. However, the simple architecture has several drawbacks that may limit its search effectiveness. First, DISH-HP uses several heuristics, such as which bins are used and how low-density areas are detected. These heuristics may not be optimal. More importantly, the local features are only for a fixed size of image regions (e.g. 16 pixel $\times$ 16 pixel), while in many cases the same part may be drawn at different scales in different diagrams.

This section proposes DISH-Conv, a supervised neural diagram search model based on *Local Convolutional Matching Network* (**DISH-Conv**). The drawbacks of DISH-HP are addressed by using machine-learned weights to replace heuristics and using better network architectures to generate richer features.

DISH-Conv is inspired by Conv-KNRM, a state-of-the-art neural ranking model proposed by Dai et al. [3]. It adapts the use of convolutions and cross-matching from text search to diagram search. The architecture of DISH-Conv is shown in Figure 1. Given local convolution features from a query and a document diagram, it builds multi-scale region representations through spatial convolutions, mutes unimportant region features through a gating network,

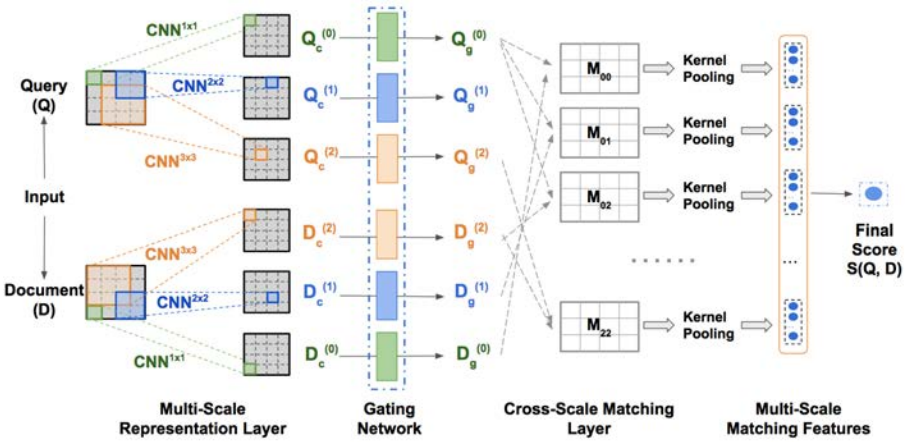

Figure 1: The DISH-Conv architecture. Query and document diagrams are input. The multi-scale representation layer uses spatial convolutions of different kernel sizes to generate features at multiple scales. The gating network computes the importance of each feature, and suppresses features from unimportant areas. The cross-scale matching layer compares the similarity between query regions and document diagram regions of different sizes, and forms the similarity matrices for different scales. The kernel pooling aggregates the similarity matrices into cross-scale matching features. A *learning-to-rank* layer combines all features and generate a final score.

and generates cross-scale local match signals through the cross-matching layer. It then ranks diagrams with the cross-scale match signals using kernel-pooling and learning-to-rank.

4.1 Generating Multi-Scale Representations

DISH-Conv starts with the same process as DISH-HP. Local feature vectors are extracted from the query diagram Q and the document diagram D. The feature vectors are organized in a 3D array of size $[H, W, d]$: $H \times W$ local regions each with a d dimension feature vector.

Intuitively, features extracted from regions of different sizes could improve the robustness on diagrams of different scales. Following this intuition, DISH-Conv uses 2D spatial convolutions to generate features for larger regions. A 2×2 kernel builds representations from 4 adjacent regions, generating a new feature vector whose receptive fields is 4 times larger than the original feature vector. Similar, 3×3 kernels generate representations for even larger regions. We also employ a 1×1 convolution. It has the same receptive fields as the input features, but can transform the features to better fit the ranking task.

The convolutions form a pyramid of region representations at multiple scale levels. In addition to scale, the convolution can also learn other types of transformation. It is able to model rotation because rotation changes are essentially a linear transformation of the pixel coordinates. It can also learn transformation in texture and structure, optimizing the input features toward the specific task and dataset.

4.2 Gating Network

During the development of DISH-HP, we identified that the model should ignore unimportant regions of a diagram. DISH-HP employed a heuristic that compares the L2-norm of local feature vectors to a fixed threshold. However, it is not guaranteed that the features of

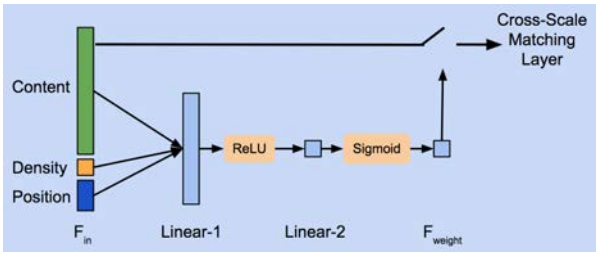

Figure 2: The gating network architecture.

blank areas are always close to zero; and, some high-density areas are also unimportant, for example, callouts and bubbles.

A gating network was developed to automatically learn the importance of local features and to down-weight unimportant features during the matching process (Figure 2). The gating network predicts the importance of a region based on three types of signals: content, position, and density. The content is represented by the region emebedding from the multi-scale representation layer (C features, C is the number of convolution channels). The position features are the coordinates of the center of the perceptive field (2 features). The density feature is the L2-norm as used in DISH-HP (1 feature). These signals are concatenated, generating a $C + 3$ dimension input vector F_{in}, and passed through a 2-layer Perceptron [16]:

$$\vec{h} = ReLU(W_1 \vec{F}_{in} + B_1) \tag{3}$$

$$F_{weight} = \sigma(W_2 \vec{h} + B_2), \tag{4}$$

where W_1, B_1, W_2, and B_2 are the trainable parameters of the Perceptron. σ is the Sigmoid function that converts the free-range network output into the range of $[0, 1]$. The output, $F_{weight} \in [0, 1]$, is multiplied to the original feature vector. F_{weight} close to 1 means that the local feature vector is important and is allowed to pass

through the gate; F_{weight} close to 0 means that the feature vector is unimportant and its effect on the ranker should be muted.

The gating network is trained jointly with the other parts of DISH-Conv, so that it automatically learns to recognize regions that are important for the search task. The importance of a local feature vector is based on not only the density, but more importantly, its content. It allows dense but meaningless regions, such as bubbles, to be detected.

4.3 Ranking with Cross-Scale Match Signals

The multi-scale local region representations, with unimportant regions suppressed by the gating network, are sent to the next cross-scale matching layer. This layer calculates the similarity between each pair of query-document regions. The regions can be taken from different scales. For example, a 16×16 pixel area in the query diagram is compared to 16×16, 32×32, and 48×48 areas in the candidate diagrams (from 1×1, 2×2, and 3×3 convolution). In total, the match is performed at 9 different scales.

For each of the 9 scale combination, the match signals are aggregated through *kernel-pooling* [27]. Kernel-pooling is a soft version of the histogram pooling used in DISH-HP that approximates the histogram function with RBF kernels. It makes the histogram pooling differentiable so that gradients can be back-propagated to the previous convolution layer. The resulting kernel features are similar to the histogram features in DISH-HP. The kernel features from all 9 scale combinations are then combined by a learning-to-rank layer to generate the final score. The learning-to-rank layer assigns different importance to local match signals with different strength (e.g. 'strongly similar', 'weakly similar', 'dissimilar') and at different scales (e.g. 'small query region to small document region' or 'large query region to medium document region'). The output is the predicted relevance score between the query and the document $s(Q, D)$.

DISH-Conv is trained to minimize a standard pairwise loss function:

$$L(Q, P, N) = max(0, \alpha - s(Q, P) + s(Q, N)). \quad (5)$$

The loss function keeps relevant diagrams P closer than any negative diagrams N for each query Q, with a margin α. A query's relevant documents are taken as positive examples. Negative examples are sampled uniformly from the dataset.

4.4 Summary

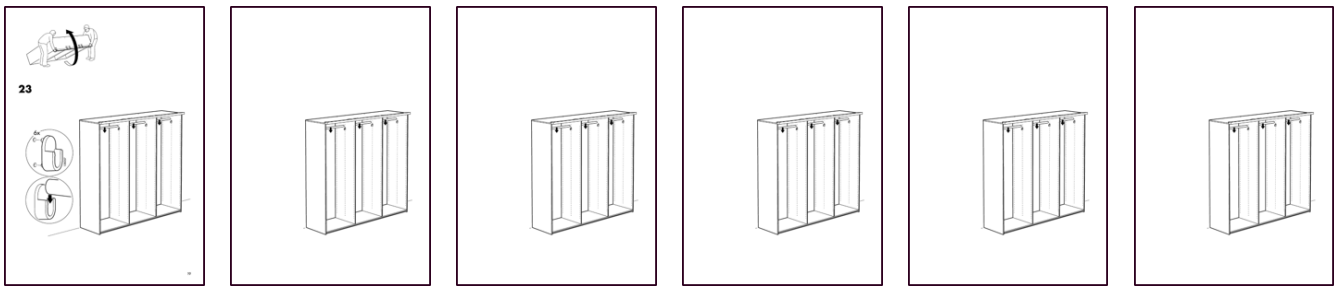
DISH-Conv is motivated by the interaction-based neural ranking models designed originally to model word-word interaction in text search [3, 8, 27]. DISH-Conv treats local regions as words and models region-region interactions between two diagrams. Its architecture was inspired by the convolution and cross-matching technique proposed by Dai et al. [3]. However, our intuition of using the convolutions and cross-matching is very different from Dai et al. [3]. Our focus is on *scales* and *rotations* while the goal of the original work was to match phrases. We employ spatial convolutions to learn scale-invariant and rotation-invariant transformations, and use cross-matching to generate match signals across multiple scales. A novel gating network is proposed to learn local region importance from position, density, and more importantly, content. Collectively, these elements address several issues identified in DISH-HP, and should enable DISH-Conv to produce more accurate rankings.

5 EXPERIMENTAL METHODOLOGY

This section introduces a new dataset used for experimental evaluation, and the baseline algorithms that were used for comparison.

5.1 Datasets

Although our work is motivated by common tasks in large engineering organizations, there are no standard datasets to use for evaluation because engineering diagrams tend to be proprietary data. A new dataset based on Ikea™ furniture assembly manuals was developed to support experimental evaluation. Although we are unable to redistribute the dataset, others can create a substantially similar dataset based on the descriptions below and additional information posted on our website[1].



Images: We downloaded product assembly manuals from Ikea™ [2]. Each manual was split into page images. Images that were entirely blank, primarily text, or duplicates of other images were discarded. The result was a corpus of 13,464 furniture assembly diagrams (the Ikea dataset). Each diagram was a black-and-white pdf document. Resolutions of the diagrams vary, with most diagrams around 1000*600 or 600*1000. See Figure 3(a) for an example.

Queries and Relevance Assessments: An automated query generator was developed to create a large set of queries. It tries to locate parts in a diagram that would make reasonable queries. It first selects the zone with relatively high black pixel density as an initial query region, and then gradually expands it by merging the current region with adjacent zones. This process is repeated until the black pixel density of the query region is lower than a threshold. Next, the query region is validated to make sure that it is not too small, too large, entirely black or filled with text. Finally, a query is defined by inserting the validated region into a white background, keeping the image size and the position of the region exactly the same as the original query.

In typical use, queries would not have the same position, scale, and rotation as a region of a relevant diagram. The initial set of queries is named *psr* queries, with lower case letters indicating that the position (p), scale (s), and rotation (r) of the query image are unchanged. Four additional sets of queries were generated to have specific characteristics and increasing difficulty for use in diagnosing weaknesses in retrieval algorithms. The names of these query sets use capitalized letters to mark relative changes. *Psr* queries change the position of the query image, but keep scale and rotation invariant. *pSr* queries change the scale of the query image within the range $[0.5, 2]$. *psR* queries change the rotation 0 to 360 degrees. *PSR* queries change position, scale, and rotation simultaneously. Figures 3b-3f show examples of all five types of queries.

When generating queries, a position, scale, or rotation change is generated randomly within an appropriate range. The transformed query is required to fit entirely within the image boundary so that it does not lose information during the transformation. For position and scale changes, simple rules ensure that the transformed query

[1] A URL will be provided in the camera-ready copy.
[2] https://www.ikea.com/ms/en_US/customer_service/assembly_instructions.html

(a) A relevant document. (b) Query with no change (psr). (c) Query with changed position (Psr). (d) Query with changed scale (pSr). (e) Query with changed rotation (psR). (f) Query with changed position, scale, and rotation (PSR).

Figure 3: Five types of automatically-generated queries for the Ikea dataset.

Table 1: The Ikea Dataset Characteristics

	Description	Number
Corpus	Diagrams from Ikea manuals	13,464
psr	No change	3,649
Psr	Random position change	3,649
pSr	Random scale change (0.5 to 2)	3,649
psR	Random rotation change (0 to 360)	2,988
PSR	Position, scale, & rotation change	3,005

lies within the image boundary. For rotation changes, it is more complex to predict the part boundaries. Therefore, if the rotated query was not entirely within the image boundaries, the change was discarded, and a new random rotation angle generated. If the rotation change failed five times, the image was discarded from the set of queries. Thus, the *psr*, *Psr*, and *pSr* query sets all have the same number of queries (3,649), but the *psR* and *PSR* query sets are somewhat smaller (about 3,000). Table 1 shows the characteristics of the Ikea collection and queries.

Metrics: In the automated query generation process, the source diagram is treated as the query's (only) relevant document. A good retrieval system should rank that document highly. Mean Reciprocal Rank (MRR) is a common metric when there is one relevant document. We also want to know the number of queries for which the relevant document appears at rank 1 and in the top 10 results, thus we also use Recall at cutoff at 1 and 10 (R@1 and R@10). A small set of *manual* labeled queries with multiple relevant documents were studied at Section 6.5.

5.2 Proposed Models and Baselines

Proposed models include two local matching networks, DISH-HP and DISH-Conv. DISH-HP is the unsupervised ranking algorithm proposed in Section 3. DISH-Conv is the supervised local convolutional matching network proposed in Section 4. The proposed models are compared to several baselines, including a bag-of-words image retrieval model based on SIFT features, a neural image retrieval model based on CNN features, and an encoder-decoder network designed specifically for line drawings.

LIRE [14] is an open source image retrieval system based on Lucene. It uses bag-of-words image retrieval models with SIFT features. The indexing and retrieval are unsupervised. We used the open source software [3] to index the images in our corpus and perform the retrieval.

FG-SBIR [17] is a neural retrieval system designed for sketches and line drawings. It is based on an encoder-decoder architecture. The encoder is based on the VGG-16 network [23]; the decoder consists of a chain of upsampling blocks to reconstruct the sketch image from the VGG-16encoder's fully connected layer, helping the encoder to learn a richer representation. The output from the encoder is taken as the image descriptor and used for retrieval. We used the open source implementation [4]. FG-SBIR is a *global* matching approach as the entire image is encoded into a single embedding; local region features are not preserved.

CAM [11] is a state-of-the-art instance retrieval approach based on deep convolutional neural networks. It uses CNN features extracted from an off-the-shelf VGG convolution network trained on ImageNet [4]. For each pre-defined class in ImageNet, CAM generate a class-focused image vector by weighted-summing the CNN features based on their activation to this class. The vectors from all classes are then normalized, whitened, and sum-pooled into a single image vector. Image retrieval is based on the Euclidean distance between the final image vectors. We took the pre-trained CAM model released by the authors [5]. We did not re-train CAM on the Ikea dataset due to lack of class labels. CAM is also a *global* matching approach as local region features are not preserved

The above three baselines used off-the-shelf software. We do not have control over how they process data and extract features. To gain better understanding of the proposed models, we created a set of DISH variants as additional controlled baselines. They differ from DISH-HP and DISH-Conv only in the architectures of the matching networks. The implementation framework, data processing, and feature extraction are controlled to be exactly the same.

DISH-SPoC and DISH-MPoC are two global variants of DISH-HP. They were created to test the effectiveness of local matching against global matching. DISH-SPoC is based on the SPoC descriptor proposed by Babenko and Lempitsky [1], but uses the DISH framework. It takes the same CNN features as DISH-HP, and applies the same filtering on white areas. The filtered CNN features are then aggregated through sum-pooling to generate a single, global image feature vector. The similarity between the query and a document

[3] http://www.lire-project.net/
[4] https://github.com/zoeyangdw/FG-SBIR
[5] https://github.com/imatge-upc/retrieval-2017-cam

diagram is calculated from the cosine similarity between the corresponding vectors. DISH-MPoC is a similar method that replaces the sum-pooling with max-pooling. DISH-SPoC and DISH-MPoC are unsupervised methods.

DISH-Conv-N is DISH-Conv without the spatial convolution; the letter N stands for 'No convolution'. In DISH-Conv-N, the input local CNN features are directly used to calculate region similarities. The model lacks the multi-scale region representation and cross-scale matching in DISH-Conv. DISH-Conv-N can also be viewed as a supervised version of DISH-HP with the hard histogram replaced by soft RBF kernels. DISH-Conv-N is a supervised model.

DISH-Conv-S is a simplified version of DISH-Conv that replaces the spatial convolution with spatial pooling when generating multi-scale region representations. The spatial pooling takes the average of features from smaller regions to generate features for larger regions. Pooling does not have additional parameters, so this model is faster and easier to tune compared to DISH-Conv. DISH-Conv-S separates the effects of convolution from the effects of aggregating small regions into larger regions. It is also a supervised model

Initial Ranking and Re-ranking: We employed a two-stage search pipeline. In the first stage, an initial ranker takes the query and compares it against all diagrams in the corpus, and returns a list of similar diagrams as candidates. In the second stage, a different ranker re-ranks the top 2,000 candidates. DISH-HP, DISH-SPoC and DISH-MPoC are simple models designed for efficient ranking; they were tested on the initial ranking task. DISH-Conv, DISH-Conv-N, and DISH-Conv-S were designed to improve DISH-HP with more complex models; they were tested on the re-ranking task. LIRE, FG-SBIR, and CAM were tested in both stages, providing baselines for both tasks.

5.3 Model Configuration and Implementation

Feature extraction: Off-the-shelf baselines (LIRE, FG-SBIR, and CAM) used their own implementations for feature extraction. All DISH models took the features from an off-the-shelf VGG-16 network trained on ImageNet[6]. Following prior research [21], we extracted features from the last convolution layer. This layer divides the image into $R = W \times H = 14 \times 14 = 196$ grids, each corresponding to a 16 pixel $\times$ 16 pixel rectangular region in the diagram. For each of the 196 regions, a $d = 512$ dimension feature vector is generated. We did not fine-tune the VGG-16 network on engineering diagrams, as the focus of this work is on *matching* local features.

Model Training: Supervised models (DISH-Conv, DISH-Conv-N, and DISH-Conv-S) were trained and tested via 5 fold cross-validation. For each query we sample 10 negative examples. We used the Adam optimizer with batch size 16, learning rate 0.001, and a learning rate decay of 0.5 when validation loss does not decrease. The training stops after 30 epochs or when learning rate drops below $3.12e-5$. The models were implemented in PyTorch.

Hyper Parameters: For DISH-HP, the top $K = 2$ bins were used and low-density area filter threshold T was set as 30. The parameters were chosen through a simple parameter sweep. The kernel pooling layers in DISH-Conv, DISH-Conv-N, and DISH-Conv-S all followed the configurations suggested by prior research [27] and used 11 kernels. The first kernel is the exact match kernel where $\mu = 1, \sigma = 10^{-3}$, or bin $[1, 1]$. The other 10 kernels equally split the cosine range $[-1, 1]$: the μ of bin centers were: $\mu_1 = 0.9, \mu_2 = 0.7, ..., \mu_{10} = -0.9$. The σ of the soft match bins were set to be 0.1. The multi-scale presentation layer in DISH-Conv uses three types of spatial convolutions with different kernel sizes ($1 \times 1, 2 \times 2, 3 \times 3$), 128 output channels, and a stride of 1.

6 EXPERIMENTAL RESULTS

Two experiments on the Ikea dataset tested the accuracy of the different methods of retrieving diagrams in ranking and re-ranking configurations on large-scale auto-generated relevance labels. Two analyses investigate the behavior and effectiveness of the convolutions and the gating network. An evaluation on a small set of manually-judged queries were conducted to confirm the results from experiments with auto-generated relevance labels.

6.1 Initial Ranking Performance of DISH-HP

DISH-HP is simple, fast, and does not require training. It was tested on the first stage ranking task where the query is compared to all diagrams in the collection. As shown in Table 2, DISH-HP outperforms all other methods by large margins.

Baselines. Among the baselines, only LIRE uses SIFT features; the rest use deep CNN features. LIRE is the least accurate, demonstrating the effectiveness of deep CNN features on engineering diagrams (Table 2). FG-SBIR, which is designed for sketches and line drawings, has higher precision (MRR and Recall@1), but CAM retrieves more relevant diagrams (Recall@10). These results indicate that CNN feature extractors learned from photographs can also extract useful patterns from engineering diagrams.

DISH-SPoC and DISH-MPoC outperforms FB-SBIR and CAM. These four methods are all global matching methods based on CNN features. The main differences of DISH-SPoC and DISH-MPoC with FG-SBIR and CAM are i) they have low-density region filtering, and ii) they use simple sum/max to aggregate local CNN features while FG-SBIR and CAM learn feature aggregation from a dataset. Low-density region filtering is important because these regions bring in noisy signals. The simple pooling functions are task-neutral, while FG-SBIR and CAM are tuned for their training datasets. DISH-MPoC is the strongest baseline.

Local vs. Global. DISH-HP outperforms all other methods by large margins. Like DISH-MPoC, DISH-HP uses deep CNN features and filters blank regions. However, DISH-HP is a local matching method that leverages local region matching evidence. In global methods such as DISH-MPoC, matching is at the entire image level; no local, regional similarity signals are used. They squeeze the image into a 512 dimensional vector. The vector is effective at capturing high-level visual features, such as the shape of a part. However, it loses information at lower granularity levels. As a result, irrelevant diagrams are retrieved, for example, a wheel is retrieved for a round washer because they have similar shapes. Global match methods also missed documents that are partially matched to the query because the other parts in the diagram make the feature vector less similar to the query's feature vector. On the other hand, DISH-HP leverages local similarity signals that tell if the sub-parts between two diagrams are similar. It helps to filter out irrelevant documents and to retrieve partially matched documents.

Table 2: Ranking accuracy on several types of queries. The query is compared to all document diagrams in the Ikea datset.

Method	Invariant (psr)			Position (Psr)			Scale (pSr)			Rotation (psR)			ALL (PSR)		
	MRR	R@1	@10	MRR	R@1	R@10	MRR	R@1	R@10	MRR	R@1	R@10	MRR	R@1	R@10

DISH-Conv-S	**0.94**	**89%**	**99%**	**0.90**	**84%**	**98%**	0.74	65%	86%	0.22	17%	31%	0.10	6%	16%
DISH-Conv	0.91	87%	97%	0.82	74%	94%	**0.78**	**70%**	**90%**	**0.38**	**28%**	**57%**	**0.17**	**10%**	**30%**

Sensitivity to position, scale and rotation changes. DISH-HP is robust to position changes. It had almost the same performance on the position changed queries (Psr) compared to the invariant queries (psr), whereas DISH-MPoC suffered a significant drop when the query is shifted. DISH-HP was relatively sensitive to scale changes: the Recall@10 decreased from 84% to 70% when the query scale was changed (pSr). Rotation changes were more difficult: the Recall@10 was only 21% on rotation changed queries (psR). Queries that simultaneously changed position, scale and rotation (PSR) were the most difficult.

In summary, the experimental results on the baselines show the effectiveness of deep CNN features on engineering diagrams compared to hand-crafted SIFT features. A comparison between models learned on ImageNet and models learned on line drawings indicate that off-the-shelf CNN feature extractors can achieve good Recall, although tuning them for line drawings may increase Precision. Experimental results on DISH-HP demonstrate the power of *local* matching. The local region match signals provide evidence to filter out irrelevant diagrams that share similar shapes with the query but differ in detail. It also enables retrieving relevant diagrams that partially match the query. DISH-HP largely outperforms commonly-used kNN-style global retrieval approaches, including state-of-the-art instance retrieval models. The Recall of DISH-HP was not perfect, especially on scale and rotation changes. But it may serve as good starting point for a retrieval pipeline and to generate training data for more advanced ranking models.

6.2 Re-ranking Performance of DISH-Conv

The second experiment investigated DISH-Conv and its variants. DISH-Conv uses learned weights, multi-scale matching, and convolutional features to improve ranking, especially for queries at different scales and rotations. Due to its greater computational cost, DISH-Conv was only tested as a second stage that re-ranks the top N results returned by a first-stage ranker such as DISH-HP. As a reference, we also tested the baseline methods on the re-ranking task.

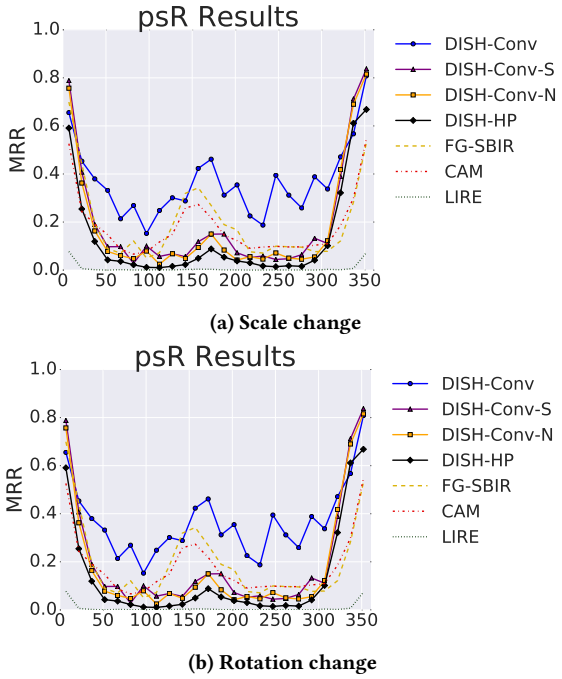
As shown in Table 3, LIRE failed to improve the initial ranking of DISH-HP, but both CAM and FG-SBIR were able to improve it. DISH-Conv greatly improved ranking accuracy. In invariant (psr) and position changed queries, over 80% of the relevant documents were ranked first. On queries with scale (pSr) changes, DISH-Conv is able to find 90% of the relevant documents by rank 10, 28% more than DISH-HP. On queries with scale (pSr) changes, DISH-Conv almost tripled Recall@10 of DISH-HP. Together, they lead to higher performance on the most difficult *PSR* queries.

Sources of effectivenss. The two variants, DISH-Conv-N and DISH-Conv-S, help us to understand the sources of effectiveness.

DISH-Conv-N is DISH-Conv without convolution. It can be viewed as a supervised version of DISH-HP , where the hard histogram is replaced by soft RBF kernels, the weight of the kernels is learned, and the heuristic-based region filter is replaced by an end-to-end trained gating network. DISH-Conv-N outperforms DISH-HP, demonstrating that machine-learned kernel weights and machine-learned gating network are more effective than the heuristics.

DISH-Conv-S uses spatial pooling to generate multi-scale representations and matches two diagrams at multiple scale levels. Compared to DISH-Conv-N that only models single-scale match, the pooling-based multi-scale signals in DISH-Conv-S slightly improved the search accuracy for scale changed queries (pSr). Unexpectedly, the model has very high accuracy on position changes (Psr). When a query changes position, the perceptive field receives different content, and the convolution features changes. Pooling features from adjacent regions produces a descriptor for a larger region and compensates for the position change. The results shows

that matching at multiple scales is not only effective for scale invariance, but also improves position invariance.



DISH-Conv is the most effective model on queries with scale and rotation changes (pSr, psR and PSR). In contrast to DISH-Conv-S which uses simple average pooling to generate features, DISH-Conv learns a matrix transformation of small-region features to larger-region features. The transformation is more powerful in handling complex changes in scale and rotation. Besides, the parameters are *learned* from the training data, so that they are tuned to fit the characteristics of the diagram dataset and the ranking task. The convolution, the cross-scale matching, together with machine-learned weights, make DISH-Conv more accurate and more robust.

6.3 Scale and Rotation Invariance Analysis

DISH-Conv uses convolutions and cross-matching to handle scale and rotation differences between queries and diagrams. An analysis investigates the effectiveness of these components (Figure 4).

Figure 4a shows each model's sensitivity to scale changes in pSr queries. Most models are best when the scale is unchanged (1.0). Ranking accuracy gradually decreases when the query is scaled down or up. DISH-Conv and DISH-Conv-S are best for all scale changes, due to their multi-scale representations and cross-scale matching. DISH-Conv is more robust to extreme scale changes, demonstrating that convolution is more powerful than pooling.

Figure 4b shows each model's sensitivity to rotation changes in psR queries. All models except DISH-Conv have a bow-like curve. Their MRR scores are high when there is no rotation, but drop to near 0 when the query is rotated ± 50 degrees. MRR improves somewhat near 180 degrees rotation because some queries are symmetric (e.g., rectangles); the symmetry effect is more obvious on FG-SBIR and CAM. Among all models, DISH-HP is the least able to handle rotation, and DISH-Conv is the most robust, although there is still a significant impact. Convolutions in DISH-Conv learn feature transformations that compensate somewhat for the rotation changes.

(a) Scale change

(b) Rotation change

Figure 4: Re-ranking accuracy (MRR) for different amounts of change in query scale and rotation.

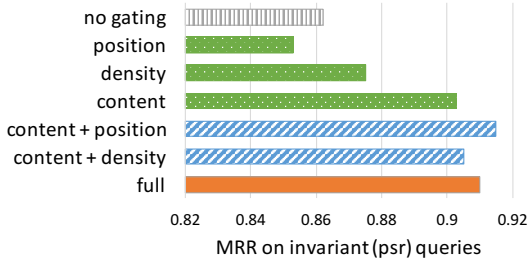


Figure 5: Re-ranking accuracy (MRR) of DISH-Conv on invarinat (psr) queries when gating uses different features.

6.4 Gating Network Analysis

DISH-Conv uses a gating network that estimates the importance of each region based on three types of features: the region's pixel density, estimated by the L2 norm of the feature vector; the region's position, represented by the coordinates of the region center; and the region's content, represented by its feature vector. An ablation study examined the effectiveness of the gating network. Figure 5 compares the accuracy of DISH-Conv with and without the gating network. It also compares gating networks using different types of features.

As shown in Figure 5, the MRR of DISH-Conv drops when the gating network is disabled. Without the gating network, the matches from meaningless areas dominated DISH-Conv's match signals, which produces poor results.

Comparison of gates using position, density, and/or content features indicates that content is the most powerful feature. The content gate learns the importance of a region from its CNN feature vectors, essentially capturing the *meaning* of the region. The position gate predicts a region's importance based on its location in the diagram, assuming that the center of the image is more likely to contain content of interest, which is not necessarily true. Using the position feature alone leads to worse results. The density gate used the L2 norm of the region feature vector, which is similar to the low-density region filter used by DISH-HP. The density gate is moderately better than having no gate. Combining all three types of features (full) provides further improvement, but the best combination omits the density feature, which is subsumed by the content feature.

In summary, identifying important regions and ignoring noisy regions is crucial for matching diagrams. A novel gating network was proposed to detect regions that are unimportant for ranking. Experimental results show that the gating network boosts the ranking accuracy of Local-Conv. The feature ablation study shows that learning to recognize unimportant contents delivers most of the gain, followed by the position of the region within the image.

Table 4: Manual Relevance Assessments statistics

Relevance Judgment Criteria	Avg Doc/Query
3 Same furniture	5.7
2 Likely to be the same furniture	1.3
1 Different, but similar assembly	5.8
0 Not related	63.6

Table 5: Re-ranking accuracy on 50 rotation queries (psR) with manual relevance assessments.

	Auto Labels			Manual Labels		
Method	MRR	R@1	R@10	MRR	R@1	R@10
DISH-HP	0.11	6%	18%	0.17	3%	10%

6.5 Manual Relevance Assessments

The experiments above measure search accuracy using large-scale, auto-generated relevance labels, where a query's source diagram is treated as its only relevant document. The last experiment measures accuracy using a small set of manual relevance judgments.

For each of 50 queries, the top 30 diagrams retrieved by Psr, pSr, and psR query variants were judged. 76 diagrams per query were assessed, on average. Three assessors judged the relevance of each diagram on a scale of $0-3$. Table 4 shows the relevance criteria and distribution. Diagrams with labels of 2 and 3 were considered relevant. On average, a query had 7 relevant diagrams.

These assessments were used to evaluate DISH methods and the best baseline FG-SBIR in the re-ranking setting. We report results for rotation (psR) queries because they differentiate the ranking methods the most. As shown in Table 5, the relative order of the ranking methods using manual labels is consistent with that on auto-generated labels: all DISH-Conv methods improved the initial ranking from DISH-HP; DISH-Conv methods were better than FG-SBIR; and DISH-Conv was most accurate. R@1 and R@10 values are lower for manual labels than for auto labels because there are 7× more relevant documents in this condition. MRR values are higher for manual labels, meaning that some top-ranked documents that are considered non-relevant by the auto labels are actually relevant.

In summary, the relative order of the ranking methods does not change when switching from auto labels to manual labels, validating the conclusions drawn from previous experiments.

7 CONCLUSION

Engineering diagram search has specific characteristics in that diagrams are sparse line drawings that contain visual metadata; the query is matched to a small region of a diagram; and the target part can appear at arbitrary position, scale, and rotation. This paper proposes local matching networks that model the interactions between local regions of the query diagram and the document diagrams, providing multiple and detailed match signals. Novel techniques were developed to address the specific issues in engineering diagrams.

This paper first presents an unsupervised model, DISH-HP. It leverages local region features extracted from the middle layer of a deep convolutional neural network. It calculates the similarity scores between query regions and document regions, and uses histogram pooling to combine evidence. The local match signals allow small differences to be recognized. Experimental results showed that matching local, region-level signals leads to superior performance over several retrieval algorithms based on global, image-level features.

The paper then presents a supervised model, DISH-Conv, to improve the robustness to scale and rotation changes. It is inspired by a state-of-the-art neural text ranking model, Conv-KNRM, which uses convolutional networks to generate n-gram embeddings from word embeddings. DISH-Conv adapts that idea and employs spatial convolutions to generate larger-scale representations from small-scale representations, enabling the query and the document diagrams to match at multiple scales. A novel gating network is proposed to improve the search accuracy by automatically detecting unimportant regions of an image. Experimental results show that DISH-Conv improves the ranking of DISH-HP substantially, especially when the target part appears at a different scale and/or is rotated to a different angle in the document diagram.

Our analysis reveals that the power of DISH-Conv is a combination of its ability to transform features through the convolutions, match at multiple scale levels, and suppress unimportant regions through the gating network. The spatial convolution in DISH-Conv generates multi-scale representations that are able to model changes in scale. The convolution is also able to learn a feature transformation that compensates for moderate changes of rotation. The gating network is able to capture the meaning of a region from its feature vector, and suppresses noisy match signals from unimportant regions. The convolution and the gating network are trained end-to-end so that they automatically learn how to transform features and assign importance for the specific task and dataset.

A pipelined system leverages the advantages of both models. DISH-HP efficiently scans the collection to identify a small set of candidate images. DISH-Conv re-ranks the candidates with less noise and richer match signals, delivering more accurate rankings. Together, DISH-HP and DISH-Conv are able to search a large corpus of engineering diagrams efficiently and effectively.

ABSTRACT

We study how to evaluate Anti-Fingerprinting Privacy Enhancing Technologies (AFPETs). Experimental methods have the advantage of control and precision, and can be applied to new AFPETs that currently lack a user base. Observational methods have the advantage of scale and drawing from the browsers currently in real-world use. We propose a novel combination of these methods, offering the best of both worlds, by applying experimentally created models of a AFPET's behavior to an observational dataset. We apply our evaluation methods to a collection of AFPETs to find the Tor Browser Bundle to be the most effective among them. We further uncover inconsistencies in some AFPETs' behaviors.

CCS CONCEPTS

• **Security and privacy → Pseudonymity, anonymity and untraceability**.

KEYWORDS

Privacy enhancing technologies; website fingerprinting; testing

1 INTRODUCTION

Online data aggregators track consumer activities on the Internet to build behavioral profiles. In addition to using stateful methods, such as cookies, some trackers use stateless tracking mechanisms, also known as browser fingerprinting. A stateless tracker extracts fingerprints from consumers as a collection of several attributes of the browser, operating system, and hardware, typically accessed through Javascript APIs. Fingerprints collected on websites like panopticlick.eff.org and amiunique.org/fp demonstrate that they are sufficiently unique and stable for tracking purposes [15, 36]. The list of attributes that can be used in fingerprints is rapidly increasing [3, 4, 13, 18, 21, 41, 55]. Studies have also uncovered fingerprinting code on popular webpages [3, 4, 18].

Anti-Fingerprinting Privacy Enhancing Technologies (AFPETs) aim to protect consumers against fingerprinting by masking, or spoofing, the values of attributes. Our goal is to find attributes that AFPETs are not masking and to quantify their effects on privacy. We develop a method that compares the trackability of AFPET-modified fingerprints with those of the original fingerprints.

Depending on the goals, AFPET evaluation could depend on the context in which the AFPET is used, accounting for features of other users and non-users, or be a more theoretical assessment of the AFPET's potential, untied to the vagaries of today. For example, if the goal of evaluation is to determine which AFPET to use today, one would want to know how many other users of the AFPET there are since they will form the anonymity set – the group of other users one will blend in with. If instead the goal is to determine which AFPET to fund for further development, the user numbers of today may matter less than the technical or theoretical capabilities of the AFPET. Given that no one AFPET evaluation can match all goals, we will explore points in the space of possible evaluations while focusing more on prospective evaluations.

Methods. First, we consider a more theoretical, experimental analysis that directly looks at an AFPET's ability to mask attributes. This method runs browsers with and without an AFPET installed to determine which attributes the AFPET masks. For this purpose, we develop an experimental framework, PETInspector, which has three components: the *fingerprinting server* (FPServer), which collects fingerprints from visitors, the *client simulator* (ClientSim), which simulates consumers and drives them to FPServer with and without AFPETs, and the *analysis engine* (AnaEng), which compares fingerprints across clients to produce a *mask model* characterizing AFPET behaviors. This tool can be applied to new AFPETs that currently lack a user base. This experimental method does not require access to the source code of AFPETs. However, it does not tell us which attributes are the most important to mask.

Next, we consider a highly context-dependent, observational method. Websites like panopticlick.eff.org and amiunique.org/fp obtain large sets of real-world fingerprints, revealing which are the most trackable (i.e., unique and predictable). In principle, these datasets can be studied to evaluate an AFPET by selecting the fingerprints generated by users of that AFPET and, for each such fingerprint, checking how trackable they are compared to other fingerprints in the dataset. We have implemented the core task of measuring trackablity as a tool, FPInspector, which simulates a simple tracker and computes statistics quantifying anonymity, such as entropy. In practice, however, such observational datasets may contain too few users of an AFPET, especially for new ones, for FPInspector evaluate it. Furthermore, in some cases, it may be difficult to determine which fingerprints correspond to which AFPETs. Thus, utilizing such a dataset requires a more nuanced approach.

Then, we develop a hybrid method combining observational and experimental data to enable the evaluation of AFPETs with low or no usage within the context of browsers used today but without

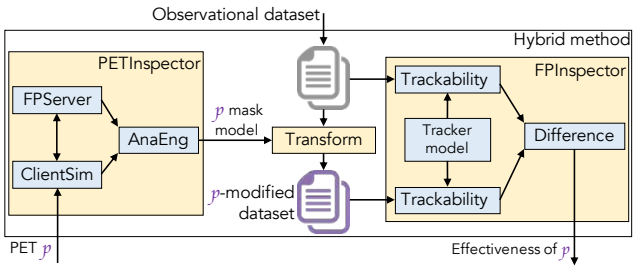

Figure 1: The hybrid AFPET evaluation method takes an observational dataset and a PET, and outputs its effectiveness.

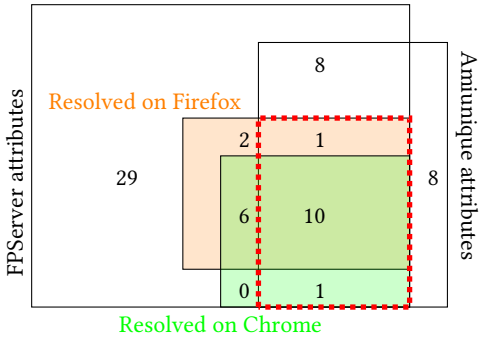

Figure 2: FPServer collects 49 attributes, of which 29 remain unexercised by ClientSim. Amiunique dataset has 28 unique attributes, of which 8 aren't collected by FPServer and 8 are collected but remain unexercised by ClientSim. The red dotted rectangle represents the intersection of attributes exercised by ClientSim and those present in the amiunique dataset, which are used for our hybrid evaluation.

access to the AFPET source code. Our hybrid method combines FPInspector with PETInspector as outlined in Figure 1. It contextualizes the mask model produced by PETInspector by applying it to an observational dataset of real-world fingerprints to produce a counterfactual dataset representing what the browsers would look like to trackers had everyone used the AFPET. By comparing the trackabilities on the two datasets, we evaluate the effectiveness of the AFPET. By parametrically leveraging data from ongoing, large-scale measurement studies, our methods may be adapted for the ever-changing landscape of browsers with little additional work.

Finally, we adjust the hybrid method to take into account the number of users an AFPET has. This shifts the analysis even further in the direction of examining the PET's current abilities.

Results. Using PETInspector, we resolved with high confidence whether 15 AFPETs explicitly claiming to protect against fingerprinting mask 20 attributes of Firefox and 18 attributes of Chrome. We also looked at 11 other popular *blacklisting PETs* (BLPETs), which operate by blacklisting domains known to engage in tracking. While they do not make a claim of protecting against fingerprinting, they should not make matters worse by giving browsers a more unique fingerprint, a property we check them for.

We found that all but the Tor Browser Bundle masked 9 or fewer of the resolved attributes, at least in their default configurations. In particular, we found that Tor left a single attribute, `platform`, unmasked while all others left at least 12 attributes unmasked. PETInspector also uncovered undocumented behaviors and inconsistencies in how some PETs modify various attributes:

- Brave Browser spoofs the `User-Agent` to appear like Chrome, but modifies the `Accept-Language` header, `language` and `plugins` differently than baseline Chrome. This can make Brave users stand out from other Chrome users. We have raised the issue with Brave developers and have received comments from them acknowledging the issue [9, 10].
- While both Privacy Badger and Firefox send the `Dnt` header, only Firefox sets the `doNotTrack` variable in JavaScript's navigator object. As a result, web-services which only use JavaScript to detect the Do Not Track choice will not be able to do so for Privacy Badger users. Furthermore, this inconsistency may make Privacy Badger's users stand out, making them easier to track. We raised this issue with Privacy Badger developers who have since fixed the issue [11].
- HideMyFootprint randomizes the `User-Agent` header, while not modifying the `platform`. This leads to inconsistencies like the `User-Agent` containing *Windows NT 10.0* on a *Linux x86_64* `platform`. Moreover, it sends an additional `Pragma` header, which can make users distinguishable.
- While the Tor Browser Bundle hides the OS by spoofing attributes like `User-Agent` and `cpu class`, one may still infer that information from the `javascript fonts` revealed.

We found 6 AFPETs which masked 4 attributes, but they did not all mask the same set of attributes. To break such ties, we used the hybrid method. We used a pre-existing dataset of over 25,000 real-world fingerprints collected on and provided by the website amiunique.org. [1] Of the 18–20 attributes resolved for each AFPET, only 12 appear in the `amiunique.org` dataset. Figure 2 provides an overview of how we selected attributes for our hybrid evaluation. For these 12 attributes, the hybrid method generates a set of PET-modified fingerprints from the original fingerprints and measures the effectiveness of the 15 AFPETs with FPInspector.

Our hybrid method finds that even with just 12 attributes, 13 AFPETs do not provide much protection over using no PET, decreasing the entropy revealed from about 13 bits without any PET to 11 bits with the AFPET. It finds Tor Browser Bundle (Tor BB) to be most effective, revealing under 3 bits of entropy. Given that some AFPETs only claim to protect a single attribute, these findings do not necessarily show any of them to be broken, but it does provide useful information for users and privacy advocates about their limitations. Furthermore, we found that the AFPET Trace did not mask two attributes that its documentation claimed it did (Table 3).

Recognizing that automation has its limitations, we manually analyzed some of the more interesting findings. We found that some AFPETs performed better when switched out of their default configuration. While we find that some do mask attributes labeled as inconclusive by PETInspector, we did not find any falsely labeled as masked or as unmasked.

[1] Graciously provided by Pierre Laperdrix, one of the creators of amiunique.org.

A source of entropy for Tor BB fingerprints is the revealed screen resolution, which is only partly masked. Tor BB reveals partial information about the screen resolution of its users using a spoofing strategy which depends on the true resolution for usability reasons. We explore a space of alternate spoofing strategies and find some to be just as effective according to our metrics despite being more usable, by utilizing more pixels on average for browsing than Tor.

Interpretation. AFPETs do not claim to protect against all forms of fingerprinting, and, thus, our results should not necessarily be interpreted as finding flaws. Nevertheless, our tool can be useful for AFPET developers. It can test whether they masked the attributes they intended to do so and help ensure that their documentation is correct. Indeed, we found that AFPETs Trace and Tor did not mask all the attributes that their documentation claimed they did.

BLPETs do not claim to protect against fingerprinting, but even they should avoid making browsers more fingerprintable than they already are. For example, we found that Privacy Badger made fingerprinting easier by modifying an attribute in a particular and undocumented way. Despite not making any anti-fingerprinting claims, its developers updated Privacy Badger.

For consumers and their advocates, our results are useful beyond the pre-existing, and sometimes flawed, documentation. In addition to double checking documentation, such consumers may be less concerned with whether PETs meet their specifications than their overall effectiveness, which our tools measure.

Our results are best understood as providing a lower bound on how much room for improvement remains for AFPETs. Our lower bound is sound in that when PETInspector claims that an AFPET leaves an attribute unmasked, it really is not masking it, is not varying the attribute often enough to be effective, or is not masking enough values of the attribute to protect our test browser platforms. Our bound is only a lower bound since, by resolving only the status of 18–20 attributes of each browsing platform, we might label some attributes in need of masking as inconclusive. More attributes can be added to our tools, but the set of possible attributes is open ended and finding platforms that differ in all attributes can be difficult.

Contributions. We make the following main contributions:

- We develop PETInspector to find how 15 AFPETs (and 11 BLPETs) mask 18–20 different attributes. By obtaining a more complete picture of PETs' behaviors, we uncover some inconsistencies and peculiarities (Section 4).
- We develop a hybrid method for evaluating AFPETs from an observational dataset of real-world fingerprints and apply it to evaluate 15 AFPETs. We find Tor BB to be the most effective AFPET among the ones we evaluate (Section 5).
- We adjust the hybrid method to also consider the current number of users each AFPET has (Section 6).
- We explore a space of alternate spoofing strategies for screen resolution by Tor BB and find some which have higher screen utilization than Tor BB, but are just as effective (Section 7).

2 PRIOR WORK

Prior work finds that various attributes are trackable by measuring the uniqueness and predictability of fingerprints collected from real-world browsing platforms [15, 36, 63]. However, few studies evaluate the effectiveness of AFPETs against fingerprinting.

Many prior studies have focused on BLPETs, which use blacklists to block known tracking domains and scripts. Since BLPETs try to prevent the consumer's browser from interacting with trackers, metrics suggestive of successful interactions (e.g., third-party requests sent, cookies placed, etc.) are good indicators of BLPET effectiveness. Studies have evaluated BLPETs by comparing these metrics between browsers with and without the BLPET when visiting popular websites [18, 26, 28, 31, 32, 38, 40, 50]. FPGuard takes a blacklisting strategy to protect against fingerprinting: it uses heuristics to identify fingerprinting domains and blocks them [20]. Gulyás et al. study the tradeoff between a BLPET suppressing some trackers but also leading to the browser having a more unique fingerprint by being a rare browser extension [25].

Most AFPETs protect against fingerprinting by spoofing browser, operating system and hardware characteristics, without blocking specific domains and scripts. AFPETs like the Tor Browser standardize various attribute values [48], whereas others like PriVaricator [45], FP-Block [59], Blink [35], and FPRandom [34] vary them. Metrics for evaluating BLPETs are not able to meaningfully evaluate AFPETs. Some studies have evaluated attribute-varying AFPETs by observing variations in fingerprints when using these AFPETs (e.g., [34, 45]). Vastel et al. look at how AFPETs can introduce inconsistencies between attributes leading to a more unique fingerprint [61]. Our work differs from these and uses a combination of experimental and observational data to more thoroughly evaluate AFPETs.

3 TRACKERS AND PETS

When a user visits a webpage, trackers can have the user's browser execute code that requests information about the user's browsing platform, including their hardware, operating system, and the browser itself. Table 3 provides a list of 49 attributes known to be good candidates for fingerprinting. The tracker can combine multiple attributes $a_1, \ldots, a_n$ to compute a *fingerprint* $id(b) = \langle a_1(b), \ldots, a_n(b) \rangle$ of the browsing platform b where $a_i(b)$ represents the value of attribute a_i for the platform b. A tracker can use fingerprints to identify browsing platforms visiting two websites as being the same one. The more unique the fingerprint is for each user, the fewer false matches the tracker will produce in linking two different users. The more predictable, or stable (ideally, unchanging), the fingerprint is as a user goes from website to website, the fewer matches the tracker will miss.

To protect themselves from fingerprinting, consumers can install AFPETs on their browsing platform to reduce the uniqueness or stability of the platform's fingerprints. Upon installing a PET p, the consumer's browsing platform b is modified to $p(b)$. As a result, the tracker interacts with $p(b)$ and extracts fingerprint $id(p(b))$.

In this study, we look at three types of PETs:

I **Attribute standardizing (AS).** These AFPETs reveal one (full standardization) or one of a small set of possible values (partial standardization) for an attribute. Full standardization makes all AFPET users appear identical, whereas partial standardization makes them appear from a few groups, with respect to that attribute. An AFPET may choose partial over

full standardization if spoofing the attribute value has usability implications.

II **Attribute varying (AV).** These AFPETs vary the value of an attribute so that the values of each user varies across browsing activities. Such variations may affect both the predictability and the uniqueness of the revealed attribute. Laperdrix et al. [34] show that variation AFPETs can vary attributes in a manner that reduces their usability impact.

III **Interaction blocking (IB).** These BLPETs block some or all interactions between the browsing platform and trackers. They rely on a blacklist (e.g., EasyPrivacy) to block interactions matching known tracking patterns. Trackers interacting with browsing platforms with these PETs receive an error message instead of the true fingerprints.

We are primarily interested in evaluating AFPETs that modify the attribute values either by standardizing (I) or varying (II) their values. In some places, we comment on BLPETs that block interactions with known trackers (III). We do so even for BLPETs not claiming to be AFPETs since they are popular, have been the subject of past evaluation studies, have the potential to unintentionally make fingerprints more unique (as we find with Privacy Badger), and can be used as AFPETs. However, we do not directly compare them to the AFPETs since they do not purport to modify any attributes explicitly, and their quality depends upon the quality of their blacklists, necessitating a different form of evaluation.

We leave out of scope PETs that protect against fingerprinting by blocking scripts (e.g., NoScript [29] and ScriptSafe [6]) since they have considerable impact on usability [28]. We also leave out PETs like AdNauseum (adnauseam.io) that do not attempt to prevent tracking but rather to make it pointless by injecting noise into the user's history with fake clicks and website visits.

In this paper, we consider a total of 26 PETs. We assign each PET a unique abbreviation, which we use in some tables. We present the full list of PETs and their abbreviations in Table 1. 23 of the 26 PETs are extensions for Chrome and Firefox, two are full browsers, and one is a browser configuration. 15 of the 26 PETs are AFPETs and purport to either standardize or vary attribute values, while 11 others are popular BLPETs. Some PETs assume mixed strategies.

We went over the documentation of the PETs to uncover how they purport to modify attributes. For all PETs that explicitly document masking an attribute, we place a □ in the corresponding cell in Table 3. Next, we demonstrate how we use our experimental method can check whether the documentation is accurate.

Table 1: List of PETs we study, their abbreviation, and strategy to protection. Most PETs are browser extensions, * indicates full browsers, and ** indicates browser configurations. For AFPETs, we list its number of users.

4 EXPERIMENTAL EVALUATION OF AFPETS

We now consider an experimental, or test-based, approach to AFPET evaluation conducted with artificial users. These artificial users browse on platforms differing in whether they have an AFPET installed. By comparing fingerprints generated by these artificial users, we infer which attributes the AFPET is masking. We use the degree of masking by each AFPET as an evaluation metric.

4.1 Method

Our experimental framework, PETInspector, is composed of three parts. The *client simulator*, ClientSim, creates and drives experimental browsing platforms, with and without various AFPETs installed, to visit a server. The *fingerprinting server*, FPServer, plays the role of an online tracker and collects fingerprints when the browsing platforms, driven by ClientSim, visit it. The *analysis engine*, AnaEng, compares fingerprints across clients to detect whether an AFPET varies, standardizes, or does not mask the value of an attribute. To observe these behaviors, AnaEng compares the value of the attribute on the browsing platform without any AFPET (i.e., on the baseline browser) with the value when an AFPET is installed.

Client Simulator. ClientSim drives simulated clients using browsing platforms with different configurations to visit FPServer. For each base configuration and AFPET, ClientSim simulates a pair of clients only differing on whether the AFPET is installed, to allow the isolation of the AFPET's effects.

We choose the base configurations to exercise a wide range of attribute values in hopes of triggering an AFPET's masking behavior even when the masking is partial. To exercise more platforms than we have access to, ClientSim simulates browsing platforms either locally on a computer or on pre-configured VirtualBox

virtual machines [62]. ClientSim configures different fonts, timezones, languages, and screen properties using OS and browser functionalities. Some attributes directly depend upon hardware (e.g., `max touch points`) or fixed OS libraries (e.g., `math` attributes) preventing their simulation. Avoid altering others due them possibly interfering the operation of PETs (`DNT enabled`, `openDB`, `indexedDB`, two `storage` attributes, and six `header` attributes), being antiqued (`plugins`), or being a function of lower-level attributes (such as `adBlock installed` and `has lied with`).

After setting up a simulated browsing platform, ClientSim drives browser instances on them using the Selenium Webdriver [52] to FPServer. The browser instances interact with FPServer in a specified pattern of reloads and idling to provide insights about the modification behavior of PETs. In hopes of triggering a PET's ability to mask by varying attribute values, ClientSim drives its browsers across various boundaries that may cause the PET to refresh its spoofed value: *reloads* of a single domain, visits to different *domains* (we give FPServer two domain names), and browsing across *sessions*. We define a session to browsing separated by 45 minutes of down time, following Mozilla's definition of a session as a continuous period of user activity in the browser, where successive events are separated by no more than 30 minutes [60].

Fingerprinting Server. FPServer collects attributes collected by the open-source fingerprinting projects FPCentral [33] and Panopticlick [16], often by reusing their code. We list these attributes in the first column of Table 3. Similar to websites like panopticlick.eff.org and amiunique.org/fp, any browser visiting FPServer's domain can view their fingerprint, while FPServer retains a copy.

Analysis Engine. To check for masking by a PET, AnaEng uses both the fingerprints collected by FPServer from the browsers driven by ClientSim and information directly from ClientSim stating which browser used which PETs and in which configurations. Figure 3 provides an overview of AnaEng. In short, the analysis looks for both masking by standardization and by variation. If it detects standardization or variation for an attribute, it models the attribute as masked in the mask model of the PET that it produces. It models an attribute as unmasked if it is able to thoroughly test it and find neither type of masking. The possible results of the analysis are

(1) Inconclusive: cannot test variation due the baseline browser varying the attribute
(2) Masked: detect AFPET-induced variation by seeing variation with the AFPET but not without the AFPET
(3) Masked: detect AFPET-induced standardization by seeing value change in a stable manner from baseline browser to browser with AFPET
(4) Inconclusive: cannot rule out partial standardization due to lack of browsing platforms that differ enough in the attribute
(5) Unmasked: rule out impactful standardization as unlikely

By *impactful* partial standardization, we mean standardization that affects at least a fraction f of the values. In general, ruling out partial standardization with experiments requires testing for all possible attribute values, a prohibitively expensive, if not impossible, task for many attributes. However, AnaEng can, in reasonable time and with reasonable confidence, rule out impactful partial standardization. To do so, AnaEng estimates the probability of seeing at least

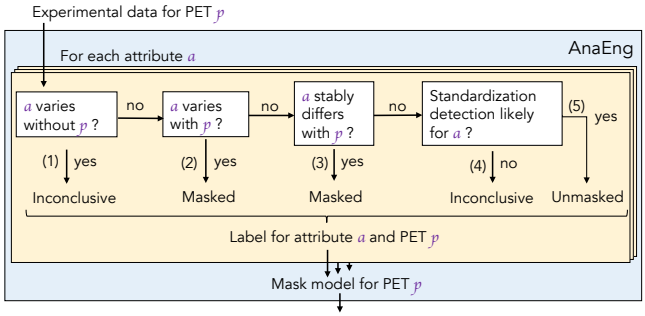

Figure 3: The Analysis Engine (AnaEng) of PETInspector consumes experimental data for a PET and outputs the corresponding mask model.

one changed value given that at least a fraction of them f are being standardized. If this probability is below some threshold α, AnaEng rejects the idea that tool is impactfully standardizing and labels the attribute as unmasked with confidence α. Otherwise, the result is inconclusive since not enough values of the attribute were tested. We use the geometric distribution to estimate likelihood of finding masking given that a fraction f is happening.

4.2 Experiment

Using PETInspector, we performed an initial experiment finding no additional spoofing from AFPETs crossing sessions. Thus, to save time, our main experiment uses only a single session and does not check for the masking of attributes by variation across sessions.

We use ClientSim to simulate six browsing platforms. Three of these are virtual machines running various versions of Linux. We introduce additional changes into these virtual machines to simulate differences in system configurations. Specifically, we install different fonts and browser versions, set up different timezones, and simulate different screen resolutions and languages, The remaining platforms run natively on a Linux desktop, Macbook Pro, and a PC laptop. We perform measurements on Firefox and Chrome browsers. More details on these configurations are in Table 2.

ClientSim drives these experimental browsing platforms to reach FPServer for five reloads of each of the two domain names of FPServer. On each platform, it performs these reloads a total of 28 times: one time each for 26 PETs and one time each for the two baseline browsers. All PETs are left in their default configurations.

4.3 Results

Before commenting on PETs, we make some observations about the baseline browsers. While we did not think of the choice of browsers as affecting the trackability of fingerprints, it turns out that the two browsers have small differences in the attributes shared by them. Aside from the expected difference in the browser name in `User-Agent`, Chrome sets the `cpu class` to *unknown*, the `screen.Depth` to 24, and the `buildID` to *Undefined*, unlike Firefox which reveals different values across browsing platforms. Firefox does not reveal any plugins, while Chrome does, and Chrome's plugins differ across Ubuntu, Debian, and macOS. PETInspector does

Table 2: Configurations of simulated browsing platforms in our main experiment. The last three were regularly used.

#	Type	OS	Addl. Fonts	Resolution	Locale & LANG	Timezone	Browser versions		Notes

not find any baseline browser to vary any attributes itself (outcome (1) in Fig. 3).

Turning to PETs, PETInspector produces Table 3, which displays attributes masked or not by AFPETs. We comment on the BLPETs in text. Among the 15 AFPETs, three (Trace, Privacy Extension, and No Enum. Extensions) do not lead to any detectable masking in their default configurations. The remaining 12 AFPETs mask at least one of the collected attributes.

Our experiment also detects undocumented masking of attributes. For example, while Canvas Defender$_C$, Canvas Defender$_F$, CanvasFingerprintBlock, Glove, and CanvasBlocker claim to spoof only the `canvas fingerprint`, we also find them spoofing `webGL` attributes. Similarly, we find undocumented modifications by Brave, Stop Fingerprinting, and TotalSpoof. We also find inconsistencies in the behavior of Brave, Privacy Badger$_C$, Privacy Badger$_F$, HideMyFootprint, and Tor BB, which we discussed in Section 1.

Among the 11 BLPETs, 4 (Disconnect$_F$, Disconnect$_C$, Ghostery$_C$, and Ghostery$_F$) do not lead to any detectable modifications of attributes, 4 (Adblock Plus$_C$, Adblock Plus$_F$, uBlock Origin$_C$, and uBlock Origin$_F$) modify the attribute `adBlock installed`, and 3 (Privacy Badger$_C$, Privacy Badger$_F$, and Tracking Protection) modify Do Not Track attributes. As discussed in the introduction, these BLPETs are not presented as AFPETs, but their modifications can actually make their users more identifiable. Indeed, Privacy Badger was updated in response to our finding.

4.4 Discussion and Limitations

The ranking above may not be suitable for some evaluation goals. For example, some AFPETs were designed to mask a single attribute and does in fact mask it (e.g., Canvas Defender$_C$). Our findings that such AFPETs (or BLPETs) do not mask all attributes should not be interpreted as the PET having a bug. Nevertheless, consumers and advocates seeking effective PETs may find our results useful.

As mentioned above, we may miss some masking of attributes for not testing values that an AFPET standardizes away. Furthermore, we may not detect an AFPET varying an attribute across a boundary that we do not test. Thus, while we can be sure of masking when we find it, we cannot be sure we have found all masking.

Since FPServer extracts fingerprints using first-party scripts, we do not detect masking that is triggered only for third-party scripts.

To an extent, these limitations can be mitigated with more comprehensive experiments using PETInspector. For example, one can modify FPServer to collect additional attributes in both first-party and third-party contexts. Moreover, one can modify ClientSim to detect variations across other boundaries and use more diverse browsing platforms to be more confident about not missing standardization modifications. We will make PETInspector freely available for more extensive experimentation and further development. Our current evaluations demonstrate the benefits of an experimental evaluation method for AFPETs within the current boundaries.

Our experiments may dispute claimed masking (☒ in Table 3) due to the above limitations rather than documentation making spurious claims. AFPETs may mask more attributes when appropriately configured, but users find it difficult to change defaults [37], suggesting our experiments may capture typical use. Next, we perform a manual analysis to understand the effects of configuration and why our results conflict with some AFPETs' documentation.

4.5 Additional Manual Analysis

To address some of the limitations mentioned above, we manually analyze some AFPETs. Specifically, we analyze AFPETs for which we found no evidence of any masking (Trace, Privacy Extension, No Enum. Extensions) and those which made a claim rejected by PETInspector (Trace, Privacy Extension, Stop Fingerprinting, Tor).

PETInspector rejects two claims of masking by Trace. We could not find the source code for Trace, but we installed the extension and manually examined it. Both the documentation and settings panel show canvas fingerprinting being masked by default, despite our studies concluding the opposite. As far as we can tell, Trace really does not mask this attribute despite claiming to. Since running our tests, Trace has been updated from version 1.0.2 to 1.8.6 and it now randomizes the canvas fingerprinting.

As for masking the user-agent, the settings panel of Trace shows that user-agent randomization is off by default, explaining our finding. Turning it on does randomize the user agent.

All of Privacy Extension's masking abilities are off by default. Turning them on does result in standardizing the two attributes in question: the canvas fingerprint and the user-agent.

To analyze No Enum. Extensions, we examined both its source code and documentation. The documentation of No Enum. Extensions only claims to mask plugins, and we found evidence of plugin masking in No Enum. Extensions's source code. PETInspector was inconclusive for this attribute since it was unable to exercise the plugin list for Firefox due to Firefox making the loading of any plugins a manual process. Thus, this instance does not represent a false negative, and instead represents a failure to find a positive.

Table 3: AFPET masks as purported and observed by PETInspector. □ indicates AFPET's documentation purports that the attribute is masked. The remaining symbols represent the possible outputs of PETInspector: + indicates observed masking, × indicates no masking found even when it is likely to detect it, and · indicates inconclusive results. For the results that we manually double checked, we include the outcome of that check as a superscript. Here, × denotes that the PET really does not mask the attribute, + that it does, ×/+ that it is not masked by default but can be with configuration, and ? that the manual analysis was inconclusive. Not shown are attributes that had all inconclusive results and not purported masking (nothing but ·): DNT enabled, IE addBehavior, adBlock installed, h.Connection, h.Dnt, h.Up.-Ins.-Req., indexedDB, math.acosh(1e300), math.asinh(1), math.atanh(05), math.cbrt(100), math.cosh(10), math.expm1(1), math.log1p(10), math.sinh(1), math.tanh(1), **and** openDB.

We manually tested Stop Fingerprinting and found that, like No Enum. Extensions, it masks plugins despite PETInspector's inconclusive finding. As for the rejected claim of masking javascript fonts, Stop Fingerprinting may be doing something with the fonts, but not enough to defeat the way FPServer fingerprints them.

Examining Tor BB leads us to believe that a recent update (after Version 7.0.11) accidentally affected its masking of the platform attribute. We also find that during the same time frame, cpuclass and h.User-Agent went from being fully masked to partially masked. We found user complaints about this change in version 8.0a10 [7].

We also confirmed that Privacy Badger did not set the doNotTrack field of the navigator object to match the Dnt header. The code was fixed after we notified the developers of the issue [5].

During our manual examinations, we also looked for artifacts introduced by VMs simulating platforms and found none.

5 HYBRID EVALUATION OF AFPETS

Our experimental method provides a model of how various AFPETs mask fingerprints as well a ranking of AFPETs based on the number of attributes they mask. However, it does not consider how important masking each attribute is. We develop a hybrid method that combines the benefits of the experimental method with an observational method. We start by considering a completely observational method and then discuss how combining it with our experimental method allows us to overcome each of their limitations.

5.1 Sampling

We cannot, in practice, see all the world's browsing platforms and instead must work with a sample. The quality of the metrics computed from the sample depends upon both the nature of the metric and the sample. For example, a random sample will provide a reasonable estimation of the entropy (e.g., [47]). However, estimating the proportion of users in small anonymity sets from even a random sample proves difficult since the length of the tail of the distribution may be unclear from a random sample.

Furthermore, in practice, we must approximate truly random samples of browser platforms from available datasets since we cannot force all users to participate. We do so by using a convenience sample provided to us by the `amiunique` website This sample comprises 25,984 real-world fingerprints collected over a period of 30 days (10/02/2017 to 11/02/2017). Each fingerprint has 32 attributes.

Determining the representativeness of this sample is difficult since it can only be compared to other possibly unrepresentative samples. We compare our sample's distributions to GlobalStat's for desktop users [56]. We find that our sample has a higher proportion of Firefox users (42% vs. 12%) and of Linux users (19% vs. 1%).

5.2 Metrics of Trackability

To measure trackability of fingerprints, we build FPInspector, which consumes a dataset and characterizes how trackable its members are. One such characterization is the anonymity set. An *anonymity set* comprises browsing platforms with identical fingerprints that are, thus, indistinguishable from each other. Thus, the smaller and numerous the anonymity sets, the higher the uniqueness. FPInspector implements various proposed functions (in [15, 63]) over the distribution of anonymity sets for measuring uniqueness.

The first metric which we use to measure uniqueness is entropy. For a set of browser platforms $\mathcal{D} = \{b_i\}_i$, such as those using a particular AFPET, let $\mathcal{D}[id(\cdot)]$ denote the multiset of fingerprints $\{id(b_i)\}_i$ where $id(\cdot)$ is the fingerprinting mechanism. The entropy of these fingerprints is given by

$$\mathsf{ent}(\mathcal{D}[id(\cdot)]) = -\sum_{id_k \in \mathcal{D}[id(\cdot)]} \Pr[id_k] \log_2(\Pr[id_k])$$

where $\Pr[id_k]$ is the probability of observing the fingerprint id_k, which we estimate from the frequency of id_k in $\mathcal{D}[id(\cdot)]$. The higher the entropy, the higher the uniqueness of the fingerprints.

FPInspector also measures the proportion of users in anonymity sets of size less than or equal to 1 ($\mathsf{p}_{-\leq 1}$) and 10 ($\mathsf{p}_{-\leq 10}$). These metrics measure the proportion of browsing platforms hiding in anonymity sets of sizes at most 1 and 10. Higher values of these metrics indicate higher uniqueness of the fingerprints.

FPInspector measures effectiveness of a PET p against fingerprinting mechanism $id(\cdot)$ from the dataset of fingerprints $\mathcal{D}[id(\cdot)]$ in terms of a metric f in $\{\mathsf{ent}, \mathsf{p}_{-\leq 1}, \mathsf{p}_{-\leq 10}\}$ as

$$\mathsf{eff}_{\mathsf{f}}(p, id, \mathcal{D}_p, \mathcal{D}_{\bar{p}}) := \mathsf{f}(\mathcal{D}_{\bar{p}}[id(\cdot)]) - \mathsf{f}(\mathcal{D}_p[id(\cdot)]) \quad (1)$$

where $\mathcal{D}_p$ is a subset of $\mathcal{D}$ using the PET and $\mathcal{D}_{\bar{p}}$ is the rest of $\mathcal{D}$.

5.3 Limitations of Observations Alone

In principle, a highly-context dependent, completely observational method could function by comparing the fingerprints produced by users of each AFPET to determine which are the least trackable. In practice, we face difficulties with obtaining a representative sample of AFPET users and determining which users run which AFPETs.

PET determination. Determining PET use from fingerprints not explicitly containing the information is difficult. This limitation can be overcome by a fingerprinting server designed to collect information about PET use. One approach is to ask visitors about their PETs, but users can be unaware of their own browser's configurations. In some cases, PETs have a distinctive fingerprint that gives away their use, but this would only help us with a subset of PETs. Alternatively, fingerprint collection websites can use automated methods to detect browser extension PETs (e.g., [53, 55]). Unfortunately, our observational data lacks this information.

PET sampling. Even with a fingerprinting server collecting PET information, getting a representative sample of real users with AFPETs to visit the website may be difficult, since there are few AFPET users. This is especially true for new and not yet popular AFPETs. Furthermore, users of AFPETs may be systematically different from users without AFPETs, thereby introducing confounding factors influencing the trackability metrics.

Due to these limitations, we cannot apply FPInspector directly to our dataset. Moreover, the PET sampling limitation may prevent application of this method directly to data collected on even fingerprinting servers designed for PET determination. Thus, we instead use FPInspector in a hybrid evaluation method that avoids the PET determination and sampling problems altogether.

5.4 Overcoming Limitations of Observations

To overcome the difficulty of getting a sample $\mathcal{D}_p$ of browser platforms using a PET p, we construct our own from a sample $\mathcal{D}_{\bar{p}}$ of browser platforms not using p. We then provide both to FPInspector, to evaluate the PET p, as show in Figure 1.

This approach requires that we first get a sample of platforms not using p. We start with the `amiunique` dataset. To convert that dataset of fingerprints into one of platforms, we need a mapping of fingerprints to unique browsing platforms. We approximate this mapping using cookie IDs associated with each fingerprint, similarly to Eckersley [15]. In the dataset, 21,395 fingerprints have a cookie associated with them, of which, 18,295 are unique.

To obtain $\mathcal{D}_{\bar{p}}[id(\cdot)]$, we sanitize the dataset by removing fingerprints with obvious signs of PET use, specifically those with JavaScript disabled and illegitimate screen resolutions. Additionally, we only retain fingerprints from desktop browsers (with Windows, Mac, or Linux OSes) since we only study PETs for desktops. These sanitizations leave 9,493 Chrome and 6,516 Firefox browser fingerprints. We find that these fingerprints reveal 13.002 and 12.359 bits

Table 4: Metrics of trackability (from Section 5.2) for AFPETs

PET	ent	$p_{-\leq 1}$	$p_{-\leq 10}$
Chrome PETs

no mask	12.359	0.875	0.96
base mask, No Enum. Extensions	12.177	0.797	0.949
Blend In, TotalSpoof	12.049	0.747	0.936
CanvasBlocker	12.002	0.7	0.941
Blender	11.875	0.678	0.924
Stop Fingerprinting	11.778	0.726	0.919
Canvas Defender$_F$	11.263	0.483	0.833
Tor BB	4.766	0.01	0.038

of entropy for Chrome and Firefox respectively. These and other metrics are presented in Table 4 in the 'no mask' row.

The mask model from the experimental method provides a way to transform these original fingerprints. We apply the mask model $\hat{p}$ of an PET p produced by PETInspector to the sample $\mathcal{D}_{\bar{p}}$ of platforms without a PET to generate a sample of fingerprints $\mathcal{D}_{\hat{p}}[id(\cdot)]$. This generated sample estimates what the original fingerprints would had looked like had the platforms used the PET p. We use FPInspector to calculate the trackability metrics of the modified fingerprints and unmodified fingerprints. By comparing the metrics of the original and $\hat{p}$-modified fingerprints, we estimate the effectiveness of p.

Of the 49 original attributes, PETInspector provides conclusive characterization for 18 attributes on Chrome and 20 attributes on Firefox. Of these, 12 appear in the `amiunique.org` dataset. For a given PET, we mask these 12 attributes according to the model generated by PETInspector and fully mask the remaining 16 attributes for which the experiment is inconclusive. By fully masking inconclusive attributes, we overestimate the effectiveness of PETs. Thus, we generate PET-modified fingerprints (i.e., $\mathcal{D}_{\hat{p}}[id(\cdot)]$) from the original fingerprints to measure the effectiveness of 15 AFPETs.

5.5 Results

We present the trackability metrics from Section 5.2 in Table 4. The original fingerprints reveal 13.002 and 12.359 bits of entropy for Chrome and Firefox respectively. Applying a *base mask* of all inconclusive attributes reduces them to 12.914 and 12.177 bits.

Our evaluations reveal that all AFPETs but Brave and Tor BB reveal over 11 bits of entropy and hence are marginally better than not using any AFPET at all. For these AFPETs, fewer than 20% of the fingerprints are in anonymity sets of size greater than 10. Brave does better, leaking just over 8 bits of entropy and having over 70% of fingerprints in anonymity sets of size greater than 10. Tor BB performs best since it modifies all the 12 attributes we consider.

5.6 Remaining Limitations

While the hybrid method helps us perform a fine-grained evaluation of AFPETs with few users, it inherits some limitations of the methods on which it builds. From the observational method come the limitations that samples may be biased and that no one metric fully captures the quality of an AFPET. From the experimental method, it inherits the approximate nature of mask models.

In particular, our analysis overestimates the effectiveness of all AFPETs, since we assume any modifications of an attribute by an AFPET renders that attribute useless to a tracker. This may not be the case. For example, Brave spoofs the `User-Agent` and the `Accept-Language` headers to different values than Chrome. Similarly, Tor BB also reveals spoofed values of screen resolution.

We can carry out a tighter evaluation by considering a tracker which can take advantage of the spoofed values. This evaluation requires knowledge of how an AFPET spoofs the attribute. For Tor BB, we perform a manual code analysis to determine how exactly Tor BB deals with screen resolution attributes.[2] We rerun the hybrid analysis on a hand crafted mask model capturing this behavior instead of using the rough model produced by PETInspector. This provides a tighter evaluation for Tor BB that will serve as the basis for our analysis in Section 7.

Finally, the above evaluations are performed on the same set of fingerprints and applies the mask to every fingerprint in the dataset, simulating total adoption of the AFPET. This approach is appropriate evaluations with a long-term prospective, such as selecting an AFPET to fund, since a properly promoted AFPET could become nearly universal in the future. However, those looking to select a AFPET for usage today should be concerned with the number of users each AFPET has since it will affect the size of the anonymity set the AFPET produces. In the next section, we consider a modification of the above method for dealing with this issue.

6 ADJUSTING FOR NUMBER OF USERS

To observe the consequences of having user bases of different sizes, we also evaluate the AFPETs taking into account their popularity. Ideally, we would do this by analyzing fingerprints of all the users of an AFPET. However, not having access to this set of fingerprints, we simulate them by drawing random samples of fingerprints from the `amiunique.org` dataset of size equal to the number of AFPET users and estimate uniqueness metrics on the samples.

Table 1 displays the number of users of each AFPET in our list as of Dec. 2017. The popularity of extensions were obtained from the Firefox add-on library [42] and the Chrome extensions webstore [24]. Tor's popularity was obtained from Tor Metrics [58]. For AFPETs with an undisclosed number of users, such as Brave and Tracking Protection, we are unable to perform this evaluation.

We also do not perform these evaluations for AFPETs with a user base greater than 17,109 (like Tor BB, Canvas Defender$_C$ and CanvasBlocker), since we cannot draw a sample from our dataset of sufficient size. Attempting to draw such a sample by allowing the same fingerprint to be sampled multiple times will overestimate the effectiveness of the PET since such repeats will surely be in the same anonymity set even for PETs that do nothing.

PET	#users	ent	$p_{_\leq 1}$	$p_{_\leq 10}$
Chrome PETs				
HideMyFootprint	177.0	7.343	0.901	1.000
Glove	342.0	8.277	0.886	1.000
CanvasFingerprintBlock	7630.0	11.559	0.313	0.899
Firefox PETs				
TotalSpoof	265.0	7.904	0.889	1.000
Blend In	858.0	9.401	0.777	0.983
Stop Fingerprinting	1754.0	9.994	0.641	0.939
Blender	1816.0	10.200	0.614	0.960
Canvas Defender$_F$	5274.0	10.656	0.252	0.845

For all other AFPETs, we compute the mean of the trackability metrics from 100 random samples. Table 5 displays the effectiveness metrics for these AFPETs, sorted according to the entropy. We can see that CanvasFingerprintBlock scores better than HideMyFootprint due to its high popularity, contrary to the original evaluations in Table 4. We also see that the effectiveness of tools with identical effects increases with popularity. For example, TotalSpoof and Blend In both identically modify 12 attributes, but Blend In is more effective than TotalSpoof due to its popularity.

7 APPLICATION: INFORMING AFPET DESIGN

With the ability to accept handcrafted mask models, our hybrid method can help AFPET developers make an informed choice while designing AFPETs. By measuring the effectiveness of hypothetical AFPET designs, developers can compare masking strategies to balance utility with trackability. We carry out such an exploration of alternate designs of Tor BB that mask attributes differently.

Tor BB leaks some information about the screen resolution by only partially standardizing it. Specifically, it resizes new browser windows in quanta (step/bucket sizes) of 200×100 pixels, while capping the window size at 1000×1000 pixels, and uses the client content window size as screen dimensions [48]. As a result all Tor BB users get placed into one of 50 anonymity sets based on the revealed screen dimensions, as long as they do not change the window dimensions manually. We explore the impact of the cap and quanta parameters on the effectiveness of Tor BB.

We use the number of unutilized screen pixels due to a spoofing strategy as a measure of utility loss. We measure two variants: the total number of unutilized pixels (average absolute loss), and the number of unutilized pixels as a percentage of the available pixels (average percentage loss). Increasing the cap parameters and decreasing the quanta parameters reduces this loss.

With the Firefox fingerprints in the `amiunique.org` dataset, we explore parameter settings with the goal of finding a strategy that reduces the utility loss while increasing the effectiveness. We consider alternative cap widths of 1000, 1350, 1550, and 1600 since a higher percentage of fingerprints (25%, 47%, and 51% respectively) have screen widths less than these caps. We retain the cap height of 1000 pixels as more than 50% of the fingerprints remain below that cap. We exhaustively search for all 10,201 quanta in the range 200×100 to 300×200 for all three cap parameters. We set an upper bound of 300×200 as the loss may be too high for low-resolution displays for very high quanta parameters. We find 786 and 291 quanta parameters for cap widths of 1350 and 1550 respectively for which the losses are lower than Tor BB's, but the effectiveness is higher. We display strategies with the least quanta parameters in Table 6. As we increase the cap width to 1600, none of the quanta parameters lead to a higher measure of effectiveness than Tor BB.

Table 6: Comparison of effectiveness and utility-loss of Tor BB's original spoofing strategies with alternate strategies

Cap	Quanta	ent	$p_{_\leq 1}$	$p_{_\leq 10}$	Abs. Loss	% Loss
1000×1000	200×100	2.902	0.001	0.010	870k	50.3%
1350×1000	200×193	2.715	0.001	0.009	729k	42.6%
1350×1000	269×160	2.901	0.000	0.009	728k	42.3%
1550×1000	222×197	2.899	0.000	0.009	666k	40.3%
1550×1000	295×160	2.882	0.000	0.010	636k	37.2%

8 CONCLUSION

We end with some suggestions for AFPET developers and evaluators. We recommend that developers address any attribute that PETInspector flags as unmasked. The entropy results from our hybrid method can aid in determining the order in which to address various unmasked attributes. Given our experimental results, we expect this task will keep the developers of most AFPETs busy. Next, they might want to consider any attributes that PETInspector labeled as inconclusive. After addressing these attributes, they can consider improving how an AFPET spoofs an attribute. As shown in Section 7, not all spoofing is equal. Developers should consider using Tor BB as a starting point for their development and carefully consider the default settings of their AFPET.

The set of fingerprintable attributes are open-ended and will never be fully enumerated, but new attributes can be added to our tools. AFPET evaluators should keep in mind that any one-time evaluation of PETs will quickly become out of date, necessitating the use of automated tools like ours. We encourage developers and advocates (e.g., the EFF) to use automated tools to regularly test the trackability of PETs. Our tool can fill this need, and to this end we open-source the tool here:

ABSTRACT

Heterographic pun plays a critical role in human writing and literature, which usually has a similar sounding or spelling structure. It is important and difficult research to recognize the heterographic pun because of the ambiguity. However, most existing methods for this task only focus on designing features with rule-based or machine learning methods. In this paper, we propose an end-to-end computational approach – Pronunciation Spelling Understanding Gated Attention (PSUGA) network. For pronunciation, we exploit the hierarchical attention model with phoneme embedding. While for spelling, we consider the character-level, word-level, tag-level, position-level and contextual-level embedding with attention model. To deal with the two parts, we present a gated attention mechanism to control the information integration. We have conducted extensive experiments on SemEval2017 task7 and Pun of the Day datasets. Experimental results show that our approach significantly outperforms state-of-the-art methods.

1 Introduction

A pun, also called paronomasia, is a form of word play that suggests two or more meanings by exploiting multiple meanings of a word or by replacing a similar sounding word for an intended humorous or rhetorical effect (Tristan and Mladen, 2016). They are widely used in written and spoken literature, intended as jokes. From Shakespeare's works to modern advertisement catchphrases (Tanaka, 1992), puns have been widely applied as a humorous device. In literature, speeches and slogans, puns are also standard rhetorical ploys where can also be used non-humorously. Both humorous and non-humorous

pun, the special form of ambiguity, have been the theme of extensive and attractive works for creating statements with ambiguous and distinct meanings to arise the attractive effect.

The study of puns recognition can be seen as a respectable research topic in traditional linguistics and the cognitive sciences in Nature Language Processing (NLP). Many scholars study on classifying puns by the semantic relationship between the different meaning (polysemy), or similarly pronounced sound (phonology). For example, Redfern (1987) categorizes pun into homographic pun and heterographic pun, which exploits distinct meanings of the same written word and distinct meanings of the similar spoken word, respectively. There are many relevant research rely on this classification system. Our work also think that a pun is consisted of homographic and heterographic pun.

Homographic pun and heterographic pun both have different meanings to produce a humorous or rhetorical effect. Whereas these two types of puns have own special characteristics.

Exp.1 "Getting rid of your boat for another could cause a whole raft of problems."

A homographic pun is characterized by two or more meanings of a word, each of which leads to a different but valid interpretation. In an example 1 shown above, the word "raft" is the pun word which denoting "raft" as a batch or a type of boat.

Exp.2 "A dentist hates having a bad day at the orifice."

A heterographic pun relies on a different kind of senses between two words which have the similar sound and rhyme, or nearly spelling. In an example 2 shown that the pun word "orifice" has a similarly sounding and spelling word "office", which is associated with the previous word "dentist".

In this study, we focus on heterographic pun, defined as puns containing words that sound identical or similar spell to other words, because these puns widely used everywhere and easily obtain in the current works (Tristan and Mladen, 2016). However, the study of heterographic pun recognition in the exiting works has a challenge because of the confused and ambiguous meanings.

To settle the problem, we propose an automatic computational end-to-end Pronunciation Spelling Understanding Gated Attention network (PSUGA) to recognize heterographic pun. Our model takes pronunciation and spelling into account for heterographic recognition. Based on the experiments, the results show that our work achieves the state-of-the-art performance compared to existing methods, which use manual rules or other machine learning models. Here, our contributions are listed as follows.

(i) We apply the hierarchical attention mechanism to understand the latent semantic phoneme representation by CMU pronunciation dictionary for solving the pronunciation of heterographic pun.

(ii) We propose a neural attention network to learn the spelling relationship by character-level, word-level, tag-level, position-level and contextual embeddings for heterographic pun classification.

(iii) We propose the gated attention strategy to exploit the combination of the pronunciation and spelling which is useful for this task. Experimental results on the datasets of SemEval2017 task 7 and Pun of the Day demonstrate that our method outperforms several strong baselines.

2 Related Work

Puns have been discussed in rhetorical and literary criticism since ancient times and have increasingly become a respectable research topic in recent years. However, it is surprising that puns have attracted little attention for computational linguistics and natural language processing (Tristan and Mladen, 2016). In this section, we will introduce the prior work about puns and recognition methods.

Puns contain semantic ambiguous, sentence pattern, similar sound these own characteristics. Hempelmann (2008) studied the automatic recognition of pun target words and humor text generation. Recently, Miller and Gurevych (2015) proposed methods for homographic pun to detect the ambiguous multiple meanings for the word sense disambiguation. Tristan and Mladen (2016) applied a computational method for the detecting of puns in running text and for the isolation of the intended meanings, and evaluated WSD-inspired systems in a dedicated pun identification task.

Some researchers studying puns tend to have a phonological or syntactic puns rather than semantic puns. Zwicky and Zwicky (1986) provided an analysis of the properties of paronomasia puns, especially with regard to the phonological segments. Binsted et al. (1996) applied the pronounciation dictionary (Robinson 1996) and designed the similar sound rules to generate the word pairs of similar pronounce for puns generation. Kao et al. (2015) proposed a computational model of linguistic humor in puns and two information-theoretic measures, ambiguity and distinctiveness, which derived from a simple model of sentence processing. Aaron et al. (2016) considered the semantic relationship between pun and its phonologically similar target, and leveraged automatically learned phone edit probabilities. N-Hance (Sevgili et al., 2017) assumed every pun has a particularly strong association with exactly one other word in the context, and calculated the PMI between every pair of words. Idiom Savant (Doogan et al, 2017) used Google n-grams, word2vec, and CMU Pronouncing Dictionary to recognize heterographic pun. JU_CSE_NLP (Pramanick and Das, 2017) trained a hidden Markov model and cyclic dependency network, using features from a part-of-speech tagger and a syntactic parser. ECNU (Xiu et al., 2017) applied a supervised approach to pun detection by using WordNet and word2vec embeddings. These above methods mostly design useful features, and adopt rule-based or machine learning methods to recognize the heterographic pun. Here we use an end-to-end computable network for recognizing heterographic pun, combined with CMU pronunciation dictionary and spelling relationship.

Compared with pun recognition, pun generation has attracted little attention in the past decades. Hempelmann et al. (2003) modeled the factors to generate the pun and obtain the

measures for pun evaluation based on the theory. Richie et al. (2005) generated pun based on the analysis of humor language. Hong et al. (2009) used to automatic extract the semantic patterns for puns generation and store the knowledge base in template form by using phonetic and semantic linguistic resources.

Some researchers focus on the application of pun in humor. Yang D et al. (2015) recognized the humor and humor anchor on the Pun of the Day dataset by incongruity, ambiguity, interpersonal effect, and phonetic style these useful semantic features. Taylor and Mazlack (2004) proposed an N-gram method with the syntactic context to detect puns for humorous effect in English jokes. Then Taylor (2009) carried out humor recognition depending on Ontological Semantics in the transforming content. Bertero and Fung (2016) used LSTM model to recognize humor based on the phonetic and textual features with the Big Bang Theory Corpus.

Bahdanau et al. (2014) proposed the attention mechanism to select the reference words in an initial language before translating other language for solving the machine translation problem. Yang et al. (2016) applied attention mechanism to settle the document-level classification. There are also some NLP tasks which employing attention mechanism, including machine comprehension (Seo et al., 2017; Yu et al., 2018), text classification (Du et al., 2017; Tan et al., 2018; Shen et al., 2018; Xu et al., 2018; Shen et al., 2018), question answering (Lu et al., 2016; Gui et al., 2017), generation (Zhang et al., 2018; Kim et al., 2018; Fan et al., 2018). In conclusion, attention model can enable to mining the latent and semantic information for improving the performance of NLP tasks.

Hence, we propose an end-to-end approach Pronunciation Spelling Understanding Gated Attention network (PSUGA) for recognizing heterographic pun, combined with CMU pronunciation dictionary, different levels of embedding and attention mechanism.

3 Methods

In this section, we propose our model as Pronunciation Spelling Understanding Gated Attention network (PSUGA). This model can improve the performance by considering both the phonological semantic representation and spelling relationship with character-level, word-level, tag-level, positon-level and contextual embeddings for heterographic puns recognition.

The overall architecture of our model is shown in Figure 1. It consists of two main components: a hierarchical attention convolutional neural network (CNN) as Pronunciation Understanding network, and a multi-level embedding attention network as Spelling Understanding network for text. These two components are combined by a gated attention strategy to recognize the heterographic pun. We describe the details of these two components in the following subsections.

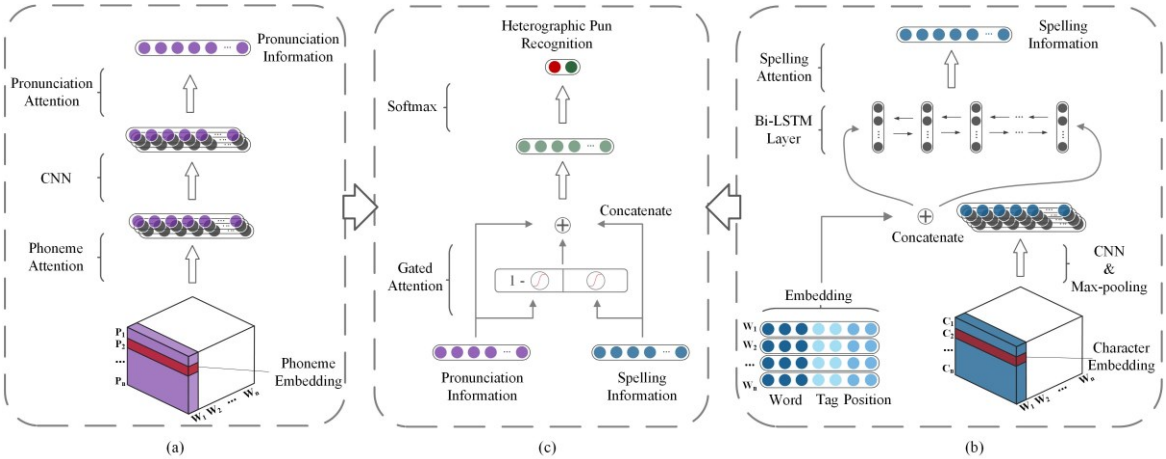

Figure 1: The Framework of Pronunciation Spelling Understanding Gated Attention Network (PSUGA)

3.1 Pronunciation Understanding Network(PUN)

Heterographic pun are mostly fabricated by replacing phonetically similar words. For example, "*What did the grape when it got stepped on? Nothing but it let out a little whine.*" The pun word is "whine", while the similar pronunciation word is "wine" which is associated with the previous word "grape". This example illustrates that one of the main challenges for heteographic pun recognition is identifying multi word expressions between the phonetically similar words.

In order to obtain phoneme representation, we introduce CMU pronouncing dictionary[1] (CMUdict), which developed by Carnegie Mellon University for designing speech synthesizer. It contains 134000 entries. Each entry is pronounced by Arpabet, which is composed of 23 vowels and 31 consonants. For example, the word "Hello" is pronounced as "HH AHO L OW1", where the number indicates stress.

A word can contain a number of phonetic symbols in CMUdict. We use all the pronunciation of an entry for the

[1] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

speech extension, and match any pronunciation as the speech extension of a word. There are two types of speech extensions: the same pronunciation and the similar pronunciation. The former is to look up the word of same sound with this entry in CMUdict, while the latter is to make statistics on pronunciation substitution between original word and target word. Here, we apply the substitution matrix between vowels and vowels, consonants and consonants proposed by Jaech et al. (2016). If the pronunciation is found in CMUdict after phoneme substitution, it can be used as the speech extensions of the original word.

Phoneme Embedding Layer. Phoneme embedding layer is responsible for mapping each word to a high-dimensional vector space. Let $\{x_1,..., x_M\}$ represents the words in the input sentence, where $x_i=\{p_1,...,p_N\}$ represents the phonemes of the word x_i and $p_N \in R^d$ is the d dimensional vector of the N-th phoneme in the target word x_i.

Phoneme Attention Mechanism. Traditional model cannot capture the important parts in sentences. In order to address this problem, we design an attention mechanism that enables model to concentrate on salient phonemes with respect to a specific word. To make full use of pronunciation information, this model uses the phoneme embedding as input to extract phoneme-specific attention signal. The formulas are as follows.

$$u_t = \tanh(w \cdot p_a + b)$$

$$\alpha_{ti} = \frac{\exp(u_{pi}^T p_{vi})}{\sum_i \exp(u_{pi}^T p_{vi})} \quad (1)$$

$$h_t = \sum_i \alpha_{pi} p_{ti}$$

where p_t is the phoneme embedding, p_a and p_v are the weighted matrices in the training process, h_t is the phoneme vector after encoding as input of phoneme embedding layer.

Convolutional Layer. A convolution layer is first used to extract local n-gram features. It involves a filter $w \in R^{ld}$, which is applied to a window of l words to produce a new feature. For example, a window of words $h_{i:\, i+l-1}$ generates the feature map ct as follows,

$$c_t = f(w^{\circ} h_{i:i+l-1} + b) \quad (2)$$

where f is ReLU function, w and b denote the weight matrix and bias respectively, $^{\circ}$ is a convolutional operator which can be considered as 1D inputs to the CNN, l is the length of the filter, h is the phoneme vector after phoneme attention layer, d is the dimension of the phoneme vector, d_l is the dimension of the feature map c_t.

Pronunciation Attention Mechanism. We also apply an attention mechanism, which drives the model to discover the heterographic pun and use the feature map as input to extract pun-specific attention signal. The formulas are as follows.

$$u_o = \tanh(w \cdot c_a + b)$$

$$\alpha_o = \frac{\exp(u_{ci}^T c_{vi})}{\sum_i \exp(u_{ci}^T c_{vi})} \quad (3)$$

$$r_o = \sum_i \alpha_{ci}\, c_{ti}$$

where c_t is the convolutional feature map, c_a and c_v are the weighted matrices in the training process, r_o is the pronuncation understanding vector after encoding, the dimension of r_o is d_l.

3.2 Spelling Understanding Network(SUN)

Heterographic pun can rely on spelling to create the ambiguous effect. For example, "*When the church bought gas for their annual barbecue, proceeds went from the sacred to the propane.*" This pun exploits the spelling similarity between the surface sign "propane" and the latent target "profane".

This task has some challenges, in particular mapping clever near spelling into the intended form. For example, "Tom Swify" (Lessard and Levison, 1992) is one type of pun often found in the data set. Meanwhile, a large of puns is descriptions of things that have been seen and heard in the past. Moreover, heterographic pun is related with the part of speech and position. Miller points out the candidate pun words mainly consist of nouns, verbs, adjectives and adverbs in each pun at the end of the sentence. Our model introduces the useful information as different levels of embedding in the Spelling Understanding Network.

Character Embedding Layer. Our model accepts a sequence of encoded characters as input following Zhang et al. (2015). The encoding is prescribing an alphabet for the input language, and then quantizes each character according to 1-of-m encoding. The alphabet consists of 70 characters, including 26 English letters, 10 digits, 33 other characters and the new line character.

Character embedding layer is responsible for mapping each word to a high-dimensional vector space. Let $\{x_1,..., x_M\}$ represent the words in the input sentence. Following Kim (2014), we obtain the character-level embedding of each word for the intended form with heteographic pun by using Convolutional Neural Networks (CNN). Characters are embedded into vectors, which can be considered as 1D inputs to the CNN model, and the size is the input channel size of CNN model. Then the outputs of the CNN are max-pooled to get a fixed-size vector for each word, where the dimension of outputs is d_c.

Word Embedding Layer. Word embedding layer also maps each word to a high-dimensional vector space for the latent semantic representation. Here we use pre-trained word vectors, GloVe (Pennington et al., 2014) to obtain the fixed word embedding of each word for recognizing heterographic puns. The dimension of GloVe is d_w.

Tag Embedding Layer. Part of speech information is important clue for heterographic pun recognition. Here we define five types of tags: noun, verb, adjective, adverb and other. Tag embedding layer is also capable for representing each word to a high-dimensional semantic vector space. The dimension of tag embedding is d_t.

Position Embedding Layer. Position information can represent the distance for recognizing heterographic pun. Position embedding layer is also able to represent each term into a high-dimensional semantic vector space. The dimension of tag embedding is d_p.

The concatenation of the character-level, word-level, tag-level and position-level embedding vectors is pass to a concatenate operation. The output vector is $Q \in R^{(d_c+d_w+d_t+d_p)\times M}$, where the dimension is $(d_c+d_w+d_t+d_p)$.

Contextual Embedding Layer. We leverage a Long Short-Term Memory Network (LSTM) (Hochreiter and Schmidhuber, 1997) on top of the embeddings provided by the preceding layers to model the temporal interactions between words. LSTM was proposed by Hochreiter and Schmiduber (1997), which had been widely adopted for text processing. There are three gates and one cell in LSTM: an input gate i_t, a forget gate f_t, an output gate o_t and a memory cell c_t. They are all vector in $\mathbb{R}^d$. The equations of transition are:

$$\begin{aligned} i_t &= \sigma(W_i x_t + U_i h_{t-1} + V_i c_{t-1}) \\ f_t &= \sigma(W_f x_t + U_f h_{t-1} + V_f c_{t-1}) \\ o_t &= \sigma(W_o x_t + U_o h_{t-1} + V_o c_{t-1}) \\ \tilde{c_t} &= \tanh(W_c x_t + U_c h_{t-1}) \\ c_t &= f_t \odot c_{t-1} + i_t \odot \tilde{c_t} \\ h_t &= o_t \odot \tanh(c_t) \end{aligned} \quad (4)$$

where x_t is an input vector at the current time step,σ is the sigmoid function and $\odot$ is the element-wise multiplication operation, $W_{\{i,f,o,c\}}, U_{\{i,f,o,c\}}, V_{\{i,f,o,c\}}$ are learned weight parameters, h_t is the hidden state vector. In LSTM, the hidden state h_t only encodes the front context in a forward direction but not consider the backward context.

We apply a LSTM in both directions, and concatenate the outputs of the two LSTMs (Bi-LSTM) by Graves et al. (2013) to better learn the context with heterographic pun. It has a forward LSTM $\overrightarrow{h}$ and a backward LSTM $\overleftarrow{h}$ to concatenate the hidden states of two LSTMs as the representation of the corresponding word. By doing this, the forward and backward contexts can take into account simultaneously.

Hence, we obtain $E \in R^{2d_e \times M}$ from the input concatenation of the character, word, tag and position vectors Q, where e is the neural units of LSTM model. Note that each column vector of E is 2de-dimensional because the outputs concatenate the forward and backward LSTMs, each with d_u dimensional output.

Spelling Attention Mechanism. In order to discover the important information in spelling understanding, we design an attention mechanism, which enables model to concentrate on salient spelling. To make full use of spelling information, this model uses the contextual embedding as input to extract spelling-specific attention signal. The formulas are as follows.

$$u_f = \tanh(w \cdot e_a + b)$$

$$\alpha_{fi} = \frac{\exp(u_{ei}^T e_{vi})}{\sum_i \exp(u_{ei}^T e_{vi})} \quad (5)$$

$$s_f = \sum_i \alpha_{ei} e_{fi}$$

where e_f is the contextual embedding combining of character-level, word-level and tag-level embeddings, e_a and e_v are the weighted matrices in the training process, s_f is the spelling vector after encoding as the input of contextual embedding layer, the dimension of s_f is $2d_e$.

Gated Attention Mechanism. After learning the pronunciation understanding and spelling understanding networks, the next step is to combine them to get the integrated information. We carry out two strategies as following.

ST1: Averaged Aggregation strategy. We assume that the information of pronunciation part and spelling part are of same importance. The integrated information is computed as:

$$R_{st1} = \alpha * r_o + (1 - \alpha) * s_f \quad (6)$$

where α is 0.5, the dimension of the attention gate is same as r_o and s_f.

ST2: Weighted Aggregation strategy. We assume that the pronunciation information and spelling information are of different importance. We leverage gated attention to model the confidence of clues provided by the two parts. The value of the attention gate is computed as:

$$g = \sigma(w[r_o; s_f] + b) \quad (7)$$

where w is the weight matrix and b is the bias term, σ is the sigmoid function accepting vector as input.

We use 1-g and g as the combination weights of pronunciation side and spelling side to assemble r_o and s_f. Here the attention gate can be seen as a sentinel to control information combination between pronunciation part and spelling part. Note that the dimension of the attention gate is same as r_o and s_f, and the integrated information is computed by weighted sum as:

$$R_{st2} = (g^{\circ} r_o) + ((1 - g)^{\circ} s_f) \quad (8)$$

where $^{\circ}$ stands for element-wise multiplication operation, g is the combination weight, R_{st2} represents the final integrated information of various parts.

Output Layer. Follow previous work, we formulate heteographic pun recognition as a classification problem. In the output layer, we combine r_o, s_f, and R_{st2} as input to a softmax classifier:

$$z_{out} = \text{Softmax}(W \cdot [r_o; s_f; R_{st2}] + b) \quad (9)$$

where $z_{out} \in R^C$ is the vector of predicted probability for heterographic pun. Here C is the number of classes of pun labels, W and b are parameters of the classification layer, activation function is softmax.

3.3 Model Training

Here we introduce the learning and optimization details of our framework. The model can be trained in an end-to-end way by backpropagation, where objective function (loss function) is the cross-entropy loss. Here y is the target distribution and $\hat{y}$ is the predicted distribution. The goal of training model is to minimize the loss function between y and $\hat{y}$ for all examples. The formula is as following.

$$\text{loss}(\theta) = -\sum_i \sum_j y_i^j \log \hat{y}_i^j + \lambda \|\theta\|^2 \quad (10)$$

where i is the index of sentence, j is the index of class, λ is the regularization parameter and θ indicates all parameters.

For optimization method, we adopt mini-batch stochastic gradient descent (SGD) to minimize the objective function. Meanwhile, we add dropout strategy to prevent the co-adaptation of the parameters to settle the overfitting problem.

4 Experiments

In this section, we first introduce the dataset and evaluation metrics. Then we examine the performance of our PSUGA model comparison with existing methods. Finally, we give the detailed analysis of our proposed model.

4.1 Dataset and Evaluation Metrics

We conduct experiments on the widely used Pun of the Day[2] and SemEval2017 Task7[3] dataset.

Pun of the Day. This corpus only contains pun content in the beginning. Then it collects the negative samples from Yahoo!Answer, AP News, New York Times and Proverb to balance the distribution of positive and negative samples for the domain discrepancy.

SemEval2017 Task7. This corpus includes homographic and heterographic pun for recognizing and interpreting pun. We mainly focus on heterographic pun detection in pronunciation and spelling. Each text includes at least one pun. Table 1 shows a detailed statistical distribution of our datasets.

Table 1: Statistics on SemEval2017 Task7 and Pun of the Day.

Dataset	Positive	Negative
Task 7 (Heterographic Pun)	1271	509
Task 7 (Homographic Pun)	1607	643
Pun of the Day	2423	2403

We apply the following standard criteria precision, recall, accuracy and F1-score for evaluation, which also adopted as metrics in SemEval2017 task7 for heterographic pun recognition.

Training Details. In our experiments, our model is tuned with 5-fold cross validation. We apply the GloVe embedding (Pennington et al., 2014) and the dimension is 100. The size of units in LSTM is 100 and dropout is 0.5. We use learning rate decay and early stop in the training process.

4.2 Comparison with Existing Methods

We compare our model with many state-of-the-art methods as follows. The good performing models in SemEval2017 task7 are N-Hance, Idiom Savant, JU_CSE_NLP and ECNU (Miller et al., 2017).

- CNN: CNN without Pronunciation Spelling Understanding Gated Attention network.
- LSTM: LSTM without Pronunciation Spelling Understanding Gated Attention network.
- Bi-LSTM: Bi-LSTM without Pronunciation Spelling Understanding Gated Attention network.
- Bi-LSTM-Attention: Bi-LSTM with single attention mechanism.
- N-Hance (Sevgili et al., 2017): N-Hance system calculates the PMI between every pair of words and uses a certain threshold method to distinguish the pun.
- Idiom Savant (Doogan et al., 2017): This method uses Google n-grams, word2vec, and CMU Pronunciation Dictionary to recognize heterographic pun.
- JU_CSE_NLP (Pramanick and Das, 2017): It trains a hidden Markov and cyclic dependency network, using features from a part-of-speech tagger and syntactic parser.
- ECNU (Xiu et al., 2017): It applies a supervised machine learning approach to detect pun by using WordNet and word2vec embedding.
- PSUGA: Here we both consider the Pronunciation Understanding with hierarchical attention mechanism and phoneme embedding and Spelling Understanding with different level embeddings. They are concatenated by the gated attention mechanism.

The performance is shown in Table 2. Our PSUGA model uses Pun of the Day as the training set to obtain all the parameters, and test in the SemEval2017 task7 dataset for hetegraphic pun recognition. From the results, we have several observations that:

Table 2: Performance of all the methods.

Models	P(%)	R(%)	A(%)	F1(%)
CNN	81.57	80.73	78.61	81.15
LSTM	82.42	81.56	80.61	81.99
Bi-LSTM	82.71	82.34	80.82	82.52
CNN-Attention	81.98	81.26	79.44	81.62
Bi-LSTM-Attention	83.49	82.71	81.30	83.10
N-Hance	77.25	93.00	75.45	84.40
Idiom Savant	87.04	81.90	78.37	84.39
JU_CSE_NLP	73.67	94.02	71.74	82.61
ECNU	78.07	67.61	63.33	72.47
PSUGA	87.92	85.04	82.91	86.46

(1) LSTM has the better performance for heterographic pun recognition compared with CNN (81.99% vs. 81.15%). It shows that LSTM is able to find the global useful features for classification than CNN model. Meanwhile Bi-LSTM outperforms LSTM (82.52% vs. 81.99%), which demonstrated the two parallels of Bi-LSTM has ability to learn more context information.

[2] Pun of the Day: http://www.punoftheday.com/

[3] SemEval2017 Task7:http://alt.qcri.org/semeval2017/task7/

(2) Bi-LSTM-Attention performs slightly better than Bi-LSTM (83.10 % vs. 82.52%). Meanwhile CNN-Attention outperforms CNN (81.62 % vs. 81.15%). It shows that the attention mechanism can capture the semantic important parts to recognize heterographic pun. As we know, attention mechanism enables to improve the performance of NLP tasks.

(3) Among all the approaches, our method behaves best. It achieves the best performance (86.46% of F1) on SemEval2017 task7 and beats the best reported approach N-Hance by 2.06% on F1. It shows that the pronunciation information, spelling information and gated attention mechanism can largely affect the performance for this task.

(4) Compared with other methods, our model tends to achieve the higher precise score and accuracy score but lower recall. We argue it is the different types of additional information, which causes this phenomenon. Our model is able to learn pronunciation and spelling features, and apply the attention mechanism for providing more coherent and related clues. While for rule based methods, they usually need to fit the pun pattern by heuristic rules for obtaining high recall compared with our model.

4.3 Detailed Analysis

We conduct extra experiments to do detailed analysis as following.

4.3.1 Analysis of PSUGA model . In this subsection, we design a series of models to verify the effectiveness of our PSUGA model. First, we do not introduce the pronunciation, spelling and attention mechanism. We design N-Pron-N-Sp model which only using Bi-LSTM for recognizing heterographic pun. Then we implement our model Y-Pron-N-Sp (PUN), which considers pronunciation embedding and hierarchical attention mechanism based on CNN. Next, we design N-Pron-Y-Sp (SUN) model that employing character-level, word-level, tag-level, position-level and contextual-level embeddings to learn the spelling information based on Bi-LSTM and attention model. Then, we design our model Y-Pron-Y-Sp (PSUGA). Table 3 shows the performance of all the models.

Table 3: Analysis of the PSUGA model.

Models	P(%)	R(%)	A(%)	F1(%)
N-Pron-N-Sp	82.71	82.34	80.82	82.52
Y-Pron-N-Sp (PUN)	83.94	83.13	81.74	83.53
N-Pron-Y-Sp (SUN)	85.26	83.92	82.33	84.58
Y-Pron-Y-Sp (PSUGA)	87.92	85.04	82.91	86.46

(1) From Table 3, we can see that N-Pron-N-Sp model achieves the worse performance, which justifies the intuition of exploiting the pronunciation information, spelling information and gated attention mechanism to recognize the heterographic pun.

(2) For Y-Pron-N-Sp and N-Pron-Y-Sp model, they both outperform N-Pron-N-Sp and underperform Y-Pro-Y-Sp. It proves the effectiveness and necessity of the pronunciation part, spelling part, and the gated attention mechanism.

(3) Among all the models, Y-Pron-Y-Sp (PSUGA) beats the three baselines and achieves the best performance. The reason is that our model considers the hierarchical attention mechanism with CMU pronounce embedding, different level of embeddings with spelling information, and effective gated attention mechanism.

4.3.2 Impact of Feature Combinations . In this section, we exploit the effects of feature combinations. The experiments are conducted in the same setting. Results are show in table 4:

According to the results, we find that: (1) Phoneme embedding provides complement improvement for understanding the pronunciation information. (2) Character embedding is effective for understanding spelling. It proves that "Tome Swify", "-ed" these structures can discover the heterogarphic pun. (3) Tag embedding can improve the performance because the part of speech information is useful for this task. (4) While the effectiveness of position embedding is low. An intuition explanation is that when using Bi-LSTM to represent sentence, position information might have been encoded by some extent to the distributed representations for reducing the effect.

Table 4: Performance on Features Combination

Models	Features	F1(%)
PUN	Word Embedding	81.62
	Phoneme Embedding	83.53
SUN	Word Embedding	83.10
	+Character Embedding	83.82
	+ Tag Embedding	83.56
	+Position Embedding	83.37
	+Contextual Embedding	84.09
	All	84.58

4.3.3 Impact of Different Combination Strategies . We come up with the single model and combination model to exploit the effects of different attention strategies. Single model is the basic model to introduce the Pronunciation Understanding network (PUN) and Spelling Understanding network (SUN). Combination model is to assemble PUN and SUN with different strategies. Highway network which proposed by Srivastava et al. (2015) is an effective combination network. ST1 and ST2 are two attention strategies have been described in Section 3.2. Results are shown in table 5.

We find that: (1) all the combination models best the single model PUN and SUN, which justifies the intuition of combination strategy to recognize heterographic pun. (2) Among the combination models, both ST1 and ST2 achieve better results than concatenate and highway. It shows that the attention combination strategy can improve the performance for this task. (3) Besides, ST2 beats ST1 by a large margin (0.89% on F1), showing the advantages of using gated attention strategy to assemble information.

Table 5: Performance on Different Combination Strategies

Models		F1(%)
Single	PUN	83.53
	SUN	84.58
Combination	PSUGA with concatenate	85.09
	PSUGA with highway	85.42
	PSUGA with ST1	85.57
	PSUGA with ST2	86.46

4.3.4 Attention Visualization . Attention weights of two examples are visualized in Figure 2.

In Exp.1, "dentist", "hates" and "orifice" are of higher attention weights, which implies a pun related to part of speech and position. The weight of gated attention strategy is high for spelling understanding, which shows "orifice" and "office" has much similar spelling. In Exp.2, "grape" and "whine" are the words with much attraction in this sentence. The attention weight of pronunciation understanding is high, which implies pronunciation information can capture the semantic learning between "whine" and "wine".

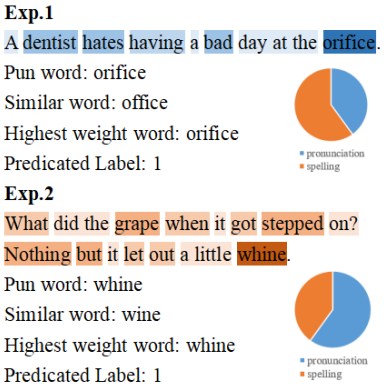

Figure 2: Attention visualization. The word is more important if the color is darker. The pie chart indicates the average value of the gated attention mechanism.

4.3.5 Error Analysis . We also analyze the sentence where our model failed to predict the correct labels of heterographic pun.

Exp.3 When the church bought gas for their annual barbecue, proceeds went from the sacred to the propane.

For example, the true pun label is "negative", but our model predicted its label as "positive". For predicting the label, ambiguity is the main reasons affected the performance. It needs deep semantic analysis of the sentence to identify the ambiguity out. Meanwhile, some background knowledge would be required to predict the label correctly.

5 Conclusion and Future Work

In conclusion, we propose an automatic computational PSUGA model combined with Pronunciation-based hierarchical attention mechanism, Spelling-based different levels embeddings and gated attention strategy to settle with confused and ambiguous meaning. Experimental results show that our method achieves significant improvement over exiting methods and sets a new state-of-the-art performance.

In future work, we would like to find an appropriate way in incorporation the external background knowledge for recognizing the heterographic pun. We also focus on deep semantic analysis, interpretation and generation with heterographic pun. Those are all promising jobs we can pursue in the future.

ABSTRACT

In this paper, we study the efficacy of login challenges at preventing account takeover, as well as evaluate the amount of friction these challenges create for normal users. These secondary authentication factors—presently deployed at Google, Microsoft, and other major identity providers as part of risk-aware authentication—trigger in response to a suspicious login or account recovery attempt. Using Google as a case study, we evaluate the effectiveness of fourteen device-based, delegation-based, knowledge-based, and resource-based challenges at preventing over 350,000 real-world hijacking attempts stemming from automated bots, phishers, and targeted attackers. We show that knowledge-based challenges prevent as few as 10% of hijacking attempts rooted in phishing and 73% of automated hijacking attempts. Device-based challenges provide the best protection, blocking over 94% of hijacking attempts rooted in phishing and 100% of automated hijacking attempts. We evaluate the usability limitations of each challenge based on a sample of 1.2M legitimate users. Our results illustrate that login challenges act as an important barrier to hijacking, but that friction in the process leads to 52% of legitimate users failing to sign-in—though 97% of users eventually access their account in a short period.

1 INTRODUCTION

In response to the threat of wide-scale password theft and account takeover [22], identity providers have re-framed password-only authentication from a binary task of validating password correctness into *risk-aware authentication* [19]. This approach incorporates multiple passive authentication signals with layered proofs of identity. For example, Freeman et al. developed a statistical model of a user's geolocation, browser configuration, and access patterns to detect aberrant login attempts [10]. Google and Microsoft actively deploy similar systems that judge IP address reputation, device reputation, and automation patterns [18, 23]. Of course, with any risk analysis scheme there exists a chance for false positives as users travel and acquire new devices, and networks churn due to DHCP lease expiration. As such, outright blocking any suspicious sign-in would lock a significant volume of legitimate users out of their accounts.

In order to differentiate hijackers from legitimate account holders in edge cases, risk-aware authentication triggers a *challenge* to act as a second proof of identity. Challenges can take many forms: proof of access to a registered device, proof of access to a backup account, knowledge of a shared secret (e.g., a security question), or merely proof of access to a scarce resource (e.g., a CAPTCHA). This layered authentication approach is distinct from two-factor authentication as challenges appear dynamically in response to a perceived threat, thus reducing overall friction on every user sign-in. Additionally, challenges scale to every user by adapting to the security posture of each account, taking advantage of recovery accounts or trusted devices when available. While ideal from a deployment standpoint, it remains unclear how well these varied challenges protect against hijacking or what friction they create for legitimate account holders.

In this paper, we evaluate the security and usability trade-offs of fourteen challenges based on their real-world performance. We begin by building a ground truth corpus of over 350,000 hijacking attempts from increasingly sophisticated actors including automated bots, phishers, and targeted attackers. Then, using login traces from Google, we examine whether risk-aware authentication triggered a challenge for these hijacking attempts, what challenge the algorithm selected, and ultimately whether the hijacker was able to access the account. Additionally, we isolate 1.2 million challenges solved by legitimate users to measure how often challenges temporarily locked out account holders. Critically, our evaluation approach is independent of Google's risk analysis techniques and generalizes to any identity provider.

Our analysis reveals that even weak, knowledge-based challenges can offer hijacking protections against automation to billions of users without requiring any enrollment. That said, the security posture of users plays an important role in protecting against more sophisticated attacks. Users that established a trusted device or a delegated recovery account received up to 10 times better protections against phishing, and to a lesser extent, targeted attacks. We argue that risk-aware authentication and challenges can help extend the viability of passwords in the interim as the community

considers alternative forms of authentication. For at-risk users looking to mitigate the risk of remote hijacking entirely, we emphasize that security keys offer the best immediate solution.

We summarize our key findings as follows:

- Knowledge-based challenges, such as recalling a secondary email address, prevented over 73% of automated hijacking attempts but only 10% of attacks rooted in phishing.
- On-device prompts, like those shown during two-factor authentication, provide the strongest protection. They blocked 99% of attacks rooted in phishing and 90% of targeted attacks.
- SMS-based challenges provided weaker protections, preventing only 96% of attacks rooted in phishing and 76% of targeted attacks.
- We show that risk-aware authentication in aggregate prevented over 99.99% of automated hijacking attempts and over 92% of attacks rooted in phishing.
- Despite low per-challenge pass rates by legitimate users (13–64% depending on the challenge), over 97% of users gained access to their account within a short period of seeing a challenge. This figure is comparable to password-only authentication.

2 LOGIN & RECOVERY CHALLENGES

Before diving into our study, we outline the fourteen challenges currently deployed at Google that can be triggered at login or during account recovery. We categorize these challenges into four classes as shown in Table 1. While our study focuses on empirical measures of performance, we also frame each challenge's trade-offs between memorability, ease of use, and susceptibility to attacks according to the criteria set down by Bonneau et al. for evaluating web authentication schemes [3]. We extend this taxonomy to include five new criteria. *Frictionless setup*—the challenge does not require a pre-established secret with an identity provider. *No additional network access*—there is no need for a cellular or other network connection. *Resilient to third-party leaks*—the challenge does not involve data that might be revealed by a breach. *Not publicly searchable*—the challenge cannot be gleaned from public information. And lastly *Affinity to user*—the challenge establishes some relationship to a user, rather than just a hard to acquire resource. We discuss each class of challenge according to this criteria and how Google opts to elect one challenge over another during risk analysis.

2.1 Types of challenges

Device-based Challenges. Device-based challenges leverage the ubiquity of mobile devices to establish a second authentication factor for users or, less frequently, access to a hardware security token. For users with mobile devices, identity providers can leverage one-time pads (e.g., a 6-8 digit code that users re-type) generated by an app like Google Authenticator [16] or Duo [7] or via the phone's operating system [11]. Both can operate offline by using a synchronized key between a server and device. Additional delivery mechanisms include on-device prompts where a user clicks "Yes" to confirm a sign-in attempt [7, 13] or SMS where a user re-types a numeric code texted to their device. Both of these require additional network access.

As detailed in Table 1, the primary usability concern of device-based challenges is both access to a mobile device or phone number and the willingness of users to proactively associate these with their account. Sharing a phone number incurs at least some friction in terms of setup, while registering a device or authenticator app requires even more steps. Additionally, while the time-sensitive nature of device challenges obviates some classes of attacks, they are nevertheless vulnerable to man-in-the-middle attacks such as inline phishing. This stems from the inability of apps that generate a code to observe the domain a victim is visiting, something U2F security keys solve. Theft of mobile devices is another risk as it both locks the victim out of their account and gives attackers access to OTP codes. Requiring a PIN or password to access the device partially mitigates this threat.

Delegation-based Challenges. Delegation-based challenges rely on a secondary identity provider to serve as an authority for establishing trust with a user. At Google, this involves sending a one-time code to a secondary email address. Other alternatives include Facebook's delegated recovery [9] where Facebook provides a break-glass, pre-registered secret token that users can employ in lieu of a password at the other identity provider. These schemes require memorizing a username and password for the delegated identity provider. As a single identity (and thus password) can span multiple other providers, we consider backup emails to be partially memorywise effortless. Compared to device-based challenges, these schemes are susceptible to stepping-stone attacks, phishing, or brute force guessing of the secondary account's password, where security is only as strong as the weakest link in the identity chain.

Knowledge-based Challenges. This class of challenges relies on establishing a shared secret with users either at registration time or as the result of actions on a service. Examples include answering security questions, or providing a recovery email or phone number (where no challenge code is sent). Alternatively, identity providers may probe information that a user implicitly provided, such as where the user commonly logs in from or the date they first created an account. Finally, while not presently deployed at Google, challenges may cover a history of the user's interactions, such as selecting the names or faces of contacts the user recently communicated with among decoy contacts [8].

Some knowledge-based schemes provide a frictionless account creation process, but then force users to recall potentially non-obvious interactions in the future. We consider re-usable secrets, such as an email or phone number, to be partially frictionless to establish. Knowledge-based challenges are also vulnerable to any form of observation, including third-party leaks or search indexing, and even fail to protect against throttled guessing when the solution space is biased towards common answers [2]. Nevertheless, these challenges are the only fallback mechanism for establishing some proof of identity when users refuse requests to establish device-based or delegation-based backups.

Resource-based Challenges. Resource challenges do not attempt to establish a proof of identity with users. Instead, they offer a hurdle to prevent automation. These challenges include confirming access to any phone number or (secondary) email address. As such, the primary goal is to restrict throttled guessing. However, attackers

Table 1: Challenges presently deployed at Google, broken down by their usability and security concerns. Challenges may appear in multiple contexts: at login due to a suspicious sign-in attempt (L), during recovery when a user forgets their passwords (R), or as a second-factor for accounts with 2FA enabled (S). We indicate fulfillment of a property with a filled circle (●) and partial fulfillment with a half circle (◐). We refer readers to Bonneau et al. for a detailed description of each criteria [3].

can farm these challenges out to unsuspecting users or rely on compromised resources including phones or email accounts.

2.2 Challenge Selection in Practice

Challenge selection at Google is a function of both security posture and context. In the event of a suspicious sign-in attempt, Google's risk analysis engine selects the strongest challenge that an account's legitimate owner should ideally be able to solve. For accounts with an associated device or phone number, the risk engine exclusively allows device-based challenges[1]. Absent a device, the engine falls back to delegation-based challenges, then knowledge-based challenges, and ultimately additional resource challenges. As such, even though a hijacker may know a victim's phone number or backup email, the risk engine will only present such a challenge if no stronger option exists. We present a sample challenge served by Google in Figure 1. Failing a challenge does not allow an actor to subsequently select a weaker class of challenge; for legitimate users, this may mean account lockout until the user can regain access to a trusted network or device. This lock out friction mitigates the risk of downgrade attacks influencing the challenge selection process towards weaker challenges.

While we primarily focus on challenges shown during login and account recovery in this study, we also consider the usability and security of two-factor authentication. We provide a detailed breakdown in Table 1 of the contexts where a challenge may appear. Two-factor authentication always involves a phone or security key to solve a device-based challenge. During recovery, Google, in some cases, might allow users to solve weaker challenges such as providing an account's creation date or confirming access to any email account[2]. The recovery flow mitigates the hijacking risk of such knowledge-based challenges by requiring users to solve multiple, successive challenges and by blocking recovery attempts from devices or networks deemed as high-risk. As with login challenges, Google's recovery process elects the strongest challenge available based on the pre-negotiated secrets and recovery options established by an account holder.

3 DATASETS

In order to evaluate the security and usability of challenges in practice, we had to overcome two hurdles: (1) obtaining a dataset of challenges that hijackers attempted without our findings being biased by Google's risk detection; (2) obtaining a dataset of challenges served to legitimate users where memorability, misplaced devices, and an incentive to access to the account were all in play. We describe our approach to constructing each dataset below and the

[1]The risk engine also makes a judgment to the "liveness" of the device or phone number. This is why phone numbers can be part of an SMS challenge as well as a knowledge challenge. The process for determining liveness is beyond the scope of this paper.

[2]Only for accounts with no two-factor authentication enabled.

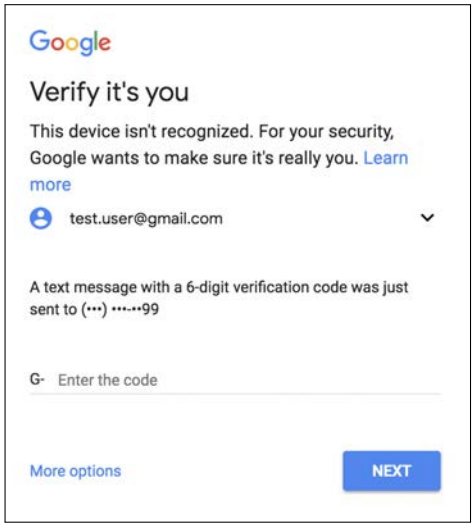

Figure 1: Sample challenge deployed as part of Google's risk engine for login and account recovery. The example shown requests that an account holder confirm an OTP sent via SMS.

Table 2: Datasets for studying usability and security performance for challenges.

ethical considerations involved. We provide a high-level overview of the resulting datasets in Table 2.

3.1 Security Datasets

For our study, we leverage three existing threat intelligence feeds that contain credentials stolen by automated bots, phishers, and targeted attackers. We retroactively joined these with records of logins to Google from February 23, 2018–May 31, 2018. For each login, we isolated sign-in attempts from hijackers (described below) and ultimately output whether Google's risk engine served a challenge in response to the hijacking attempt. Our resulting dataset consists of the type of challenge served and one of four outcomes: *passed* indicating the attacker supplied the correct challenge response, *failed* indicating an incorrect response, *skipped* indicating the attacker opted to try and solve an alternative challenge, or *abandoned* indicating the attacker exited the login flow and never supplied a solution.

3.1.1 Challenges to Automated Bots. Automated bots rely on third-party data breaches and brute force password guessing in an attempt to access millions of accounts every day. To detect this activity, Google scores every login using its passive reCAPTCHA system to identify bot activity [12]. We sampled a total of 300,000 login attempts flagged as bot activity, where the target account displayed previous organic sign-in activity (e.g., not a fake account). We manually evaluated metadata for 100 of these sessions and found all were indeed hijacking attempts. We then examined whether Google's risk engine triggered an accompanying challenge for each login. This occurred in every login attempt, resulting in a final dataset of 300,000 challenges. We caution that some bots may only be engaged in checking password validity and not attempt to solve a challenge. As such, we likely underestimate the capabilities of bots to automatically solve challenges. Furthermore, as bot detection plays a role in risk analysis, any estimate of overall hijacking protection provided against bots may be biased towards the types of bots that reCAPTCHA can identify.

3.1.2 Challenges to Phishers. Phishers harvest usernames and passwords, but also additional personal information including IP addresses and phone numbers in an attempt to bypass challenges [5]. Using data from Thomas et al. [22], we collected a sample of 400,000 Google accounts that had their valid password stolen between February 23–May 21, 2018. We then retroactively analyzed all Google sign-in attempts to these accounts during the same period. Only 20.4% of these accounts had any new sign-in activity, indicating phishers either waited on the stolen credentials or that another service may have been the target of interest. For accounts with some sign-in activity, we clustered each login in an effort to identify a single attacker accessing multiple phished accounts. The features we use for clustering are sensitive, but the overall technique identifies hijackers that re-use automation tools or resources when logging in. We note this clustering is independent of risk analysis and thus should not introduce any bias. In total, clustering identified 81,450 sessions as potential hijacking attempts. We manually evaluated metadata for 100 of these sessions and found all were indeed hijacking.

For each login attempt, we then examined whether Google's risk analysis engine triggered a challenge. In total, we identified 50,867 challenges served to phishers. In each case, the risk analysis engine triggered on a suspicious sign-in from a new country previously unassociated with the victim's account. The absence of a challenge in some cases stems from incorrect passwords (the login is rejected and no challenge shown) and because risk analysis will not trigger on repeated, successful accesses (if a phisher successfully accesses the account once, they will not be challenged in the future). We reiterate this analysis was retroactive; there were no additional protections we could provide to the victims at the time of the hijacker's sign-in attempt. In the course of our investigation, if we identified a successfully hijacked account, we forced the account into recovery thus blocking any further access by hijackers.

3.1.3 Challenges to Targeted Attackers. Our last security dataset consists of 214 Google accounts previously identified as victims of targeted attacks between February 23–May 21, 2018 [20]. We lack context for the attack techniques involved in every case, but many relate to spear phishing. We retroactively analyzed each account to isolate the hijacker's attempted login. From this, we identified 453 challenges that Google's risk engine served to attackers. As with phishing, this retroactive analysis precludes the possibility of providing any additional defense to victims at the time of hijacking. In the course of our investigation, if we identified a successfully hijacked account, we forced the account into recovery thus blocking any further access by hijackers.

3.2 Usability Datasets

In order to capture a spectrum of users and contexts, we developed four datasets of challenges to legitimate account holders: challenges to sign-ins from a familiar device or network (via an active experiment), organic challenges shown to sign-ins from an unfamiliar device or network, challenges shown during two-factor authentication, and challenges served during account recovery. As with our security dataset, we ultimately obtain only the type of challenge served and the resulting outcome.

3.2.1 Challenges to Familiar Devices & Networks. In order to gather a sample of challenges solved exclusively by legitimate users, we ran an experiment where we augmented Google's sign-in flow to challenge a random sample of user logins from familiar devices or networks. In the normal course of risk-based authentication, Google would not challenge these logins. We ran our experiment from June 19, 2017–August 15, 2017 and collected a total of 300,000 challenges and responses. We selected the challenge displayed randomly from a set of 9 available challenges.[3]

We ameliorated any risk of lock out by introducing a "Skip" button after a delay of 5 seconds which allowed users to bypass the experiment and continue to their account. Similarly, we allowed users to access their account regardless of the correctness of their response to the challenge. While this may skew results, ethically it presents the least friction to users. We caution that pass rates are thus likely lower than in practice.

3.2.2 Challenges to Low-risk New Devices & Networks. Given the bias of our previous experiment, we also consider a second set of organic challenges and responses served to a random sample of 300,000 user logins from February 23, 2018–May 31, 2018. Google's risk-analysis triggered these challenges due to users signing in from unfamiliar devices and networks, but considered them low risk as there were no other signs of automation or known hijacking access patterns. While the majority of such logins belong to legitimate users—risk analysis is biased towards false positives that lead to friction rather than false negatives that lead to hijacking—it may be that the dataset contains some hijacking attempts. We cannot empirically evaluate how many hijackings appear in this dataset due to a lack of supplementary signals.

3.2.3 Account Recovery Challenges to Familiar Devices & Networks. Account recovery captures users in moments where they have forgotten their password and potentially any other pre-shared secrets. To measure this effect on challenge pass rates, we randomly sampled 300,000 challenges shown organically as part of Google's account recovery flow from February 23, 2018–March 22, 2018. We limit our selection to flows initiated by users from familiar devices and networks to minimize any risk of including hijacker activity.

3.2.4 Two-factor Authentication Challenges to Familiar Devices & Networks. On the other end of the spectrum, users with two-factor authentication are primed to expect a challenge and to have a device on-hand. We randomly sampled 300,000 device-based challenges from February 23, 2018–March 22, 2018 for users with two-factor authentication enabled. We restrict our selection to sign-ins from familiar devices and networks to minimize any risk of including hijacker activity.

3.3 Ethics

Our in situ measurement of challenges raises a number of ethical concerns. While Google does not require IRB approval, we still took care to design our data collection to never capture sensitive private or identifying information related to the legitimate account holders under analysis. Our controlled experiment—the only instance where we introduce new challenges—also minimized any risk of account lock out. When analyzing hijacking attempts, our signals either derive from existing user protections or from auxiliary annotations that preclude real-time usage as a protection. As such, while we may learn of a successful hijacking, it is always after-the-fact. In those cases, we force the affected account into recovery in order to prevent any further damage by hijackers.

3.4 Limitations

Our security dataset is biased towards the class of bots, phishers, and targeted attackers for which we have threat intelligence and thus not a true random sample. Additionally, as attacks and capabilities may evolve over time, our measurements capture only a current snapshot of the effectiveness of challenges at preventing hijacking. Furthermore, as our experiment is in situ, we do not control the challenges these attackers receive. This may result in smaller samples for one type of challenge as compared to another. For example, if a victim has a device associated with their account it precludes showing any other class of challenges. We provide error margins on all measurements to account for small sample sizes. Finally, while we randomly sample Google's entire global user base to assess usability, in practice challenge solution rates likely differ by region. As such, any overall overall passrate statistics will be biased towards the underlying demographic and device accessibility distribution of Google's users.

4 THE SECURITY OF CHALLENGES

We begin our analysis by assessing the performance of individual challenges and ultimately the hijacking risk posed by bots, phishing, and targeted attacks. Our results illustrate that device-based and delegation-based challenges—despite their known limitations—protect against 100% of automated bots and over 92% of attacks rooted in phishing. Furthermore, we show that certain device-based and knowledge-based challenges outperform their category peers. Identity providers should prioritize these challenges when available.

[3]The experiment excludes challenges shown only during recovery or that require two factor authentication via an app or security key.

Category	Challenge	Prevention rate			Skip rate		
		Bot	*Phishing*	*Targeted*	*Bot*	*Phishing*	*Targeted*
Device-based	Authenticator OTP	100% ± 3%	94% ± 7%	–	0% ± 3%	38% ± 7%	–

Table 3: Hijacking attempts from bots, phishers, and targeted attackers prevented by login or recovery challenges along with error margins for 95% confidence intervals. Device-based challenges prevent 94% of attacks rooted in phishing and 76% of targeted attacks.

4.1 Prevention rate per challenge

The primary security metric for any challenge is whether the information requested cannot be produced by a hijacker. Rogue sources of challenge solutions may come from third-party breaches, phishing, or other forms of observation such as malware on a victim's device. We measure a challenge's prevention rate as:

$$1 - \frac{passed\ challenges}{total\ challenges}$$

We provide a breakdown of prevention rates per challenge and class of attack in Table 3. We omit statistics in scenarios where we have fewer than 10 samples. We include error margins for 95% confidence intervals.

Automated Bots. We find that bots failed to solve 100% of device-based and delegation-based challenges in our sample. This indicates that automation tools lack both real-time access to OTPs and stepping-stone access to the target's secondary accounts. Similarly, bots appear to lack access to expensive-to-scale resources such as phone numbers for receiving an SMS challenge, failing 100% of such challenges. Knowledge-based challenges posed the only hijacking risk, with bots solving 27% of challenges asking for a pre-registered recovery emails. This likely stems from third-party breaches revealing billions of email records and potential recovery details [22]. In the same vein however, these bots do not appear to have access to prior login locations or phone numbers. We note that we cannot calculate the prevention rate of three challenges as they only appear in a recovery context where bots are outright blocked.[4] Our results illustrate that while third-party breach data may be readily available in underground communities, we do not observe its widespread use in hijacking attempts beyond access to valid passwords and secondary identities.

[4]Bots are not exclusively blocked from login in the unlikely event of a false positive, which might otherwise lock a legitimate user out.

Phishing. We find that no single category of challenges is immune to hijacking attempts rooted in phishing. Device-based challenges provided the strongest protection, preventing 94–100% of attacks in our sample. The presence of any successful hijackings indicates that a fraction of attackers can relay OTP codes (or have users click a prompt) within the challenge's freshness window. Given the remote nature of attackers, we believe this likely results from attackers coercing users through a man-in-the-middle attack. Zooming in, we find that phishers correctly solved 4% of SMS challenges compared to 1% of on-device prompts. We believe this statistically significant difference ($p < 0.0001$) results from the context that account holders have about the source of a sign-in. If a user enters their credentials into a man-in-the-middle phishing page, an SMS challenge relays only an OTP code with no additional information. In comparison, an on-device prompt reveals the device type (e.g., phone, desktop), operating system, and geolocation of the phisher who initiated the sign-in attempt. Account holders can use this information to then block the hijacking attempt. Alternatively, it is possible that attackers deceive cellular providers into handing over control of the victim's phone number. There is no equivalent remote attack on device prompts. Further, because there is no overhead for offline codes, the freshness window can be much shorter than for SMS codes. Offline codes from apps are refreshed every 30-60 seconds, whereas SMS based codes may be valid for hours or even days. These longer windows may be another reason that SMS challenges are more susceptible to phishing. In order to avoid all phishing risks, security keys provide the best protection, blocking 100% of attacks in our dataset.

Our phishing dataset also quantifies the risk of relying on secondary identity providers. Here, we find that phishers supplied proof of access to a backup email 8% of the time. Two possible explanations exist: hijackers either phished the OTP code from victims via a man-in-the-middle attack just as they did with device-based challenges, or the attackers had direct access to the backup account. If OTP phishing were the sole technique, we might expect similar prevention rates as OTP codes delivered via SMS (or

Challenge	Incorrect solution rate		
	Bot	*Phishing*	*Targeted*
Account creation date	–	70% ± 10%	–
Known pre-registered email	69% ± 3%	30% ± 3%	50% ± 40%
Known pre-registered phone	–	8% ± 3%	8% ± 27%
Last login location	–	8% ± 3%	–
Printed backup code	–	–	–
Security question	–	78% ± 7%	–

Table 4: Frequency that attackers supply incorrect solutions to challenges, exclusively for knowledge-based challenges.

even higher rates, due to users forgetting their backup account's password). Instead, the lower prevention rates for backup emails suggests that some hijackers have stepping-stone access to backup accounts, reducing the security of the overall scheme to that of the weakest trusted identity provider. Given the propensity of bots to also know a victim's backup email address, we believe it likely this access derives from third-party breaches.

Finally, we find that challenges asking for a user's phone number and last login location prevented only 10–26% of hijacking attempts. This information is likely stolen directly from users via a phishing page, something observed by Thomas et al. in their analysis of phishing kits [22]. We find that challenges asking for an account's creation date, backup email, and security questions prevented 68–93% of hijacking attempts. Security here stems from the inability of victims to recall the correct challenge solution and supply it to the phishing prompt. To illustrate this, we calculate the frequency that hijackers provided an incorrect solution for knowledge-based challenge:

$$1 - \frac{passed\ challenges}{total\ challenges - abandoned - skipped}$$

This metric differs from a challenge's prevention rate as we exclude samples where an attacker fails to provide any solution (e.g., they skip or abandon the challenge). As detailed in Table 4, we find that attackers provided an incorrect solution for a victim's account creation date in 70% of cases and an incorrect solution for a victim's security question in 78% of cases. In contrast, attackers supplied an incorrect phone number and login location for only 8% of such challenges. We confirm issues with memorability in non-phishing contexts later in Section 5.

Targeted Attacks. Our sample of targeted attacks emphasizes the weakness of mobile device-based challenges as a protection against concerted adversaries. We find that SMS challenges blocked only 76% of attacks and that device prompts blocked 90% of attacks. The security of device prompts over SMS is statistically significant ($p < 0.002$). Compared to large-scale phishing, targeted attackers are more adept at stealing SMS OTP codes, likely due to more sophisticated tools and more time available to expend per victim, perhaps employing social engineering as descried by Siadati et al. [21]. Our sample size for knowledge-based challenges is too limited to draw conclusions, but we argue such challenges are unlikely to perform any better against a targeted attacker than in the phishing context where memorability is also a factor. While not shown in Table 3, our sample also includes two targeted attacks on accounts with security keys. The second-factor prevented both attacks. This reiterates the importance of domain validation as part of two-factor authentication rather than just proof of access to a physical resource.

4.2 Overall hijacking prevention

While our focus thus far has been on per-challenge prevention rates, in practice, the protection provided by risk analysis is a holistic function of each user's security posture and the frequency of repeated hijacking attempts. We capture this by measuring the fraction of users in our dataset with any successful sign-in from a hijacker. This includes accounts that never received a challenge, or where multiple challenges may have been involved. As our bot dataset includes only a sample of 300K sign-in attempts, we rely on a separate snapshot of all bot sign-in attempts over a month long window. We find that Google's risk analysis engine blocked over 99.99% of automated hijacking attempts by bots and 92% of attacks rooted in phishing. For targeted attacks, we believe protection is better measured by the number of hijacking attempts by attackers—effectively the window in which an identity provider can trigger more rigorous protections. Successful attacks involved 1–9 challenges, while failed attacks involved 1–12 challenges before the attackers abandoned their efforts. We provide only ranges due to the qualitative nature of the sample (N=214) involved.

5 USABILITY OF CHALLENGES

Layered authentication schemes are counterproductive if legitimate users are unable to access their account from new devices and locations. We measure the friction introduced by each challenge in terms of whether users skip, abandon, or provide incorrect solutions to challenges. We also consider whether, despite failing a challenge, users ultimately retry and gain access to their account. Our results indicate that over 97.3% of users can navigate challenges successfully. For comparison, 95.8% of users can navigate password-only authentication according to the same metric.

5.1 Pass rate per login challenge

In the inverse of the security context, our primary metric for usability is whether legitimate account holders can correctly solve a login challenge, thus avoiding account lockout. We consider two sets of users: those logging in from a familiar device or network and those logging in from a new device and network (which as discussed in Section 3, may include hijacking attempts). For each dataset we measure the overall pass rate per challenge as:

$$\frac{passed\ challenges}{total\ challenges}$$

This metric includes multiple failure modes: users providing an incorrect solution to a challenge, users skipping a challenge in favor of an alternative, and users abandoning a sign-in attempt entirely. To isolate issues related to memorability or mistyping, we calculate the adjusted pass rate per challenge as:

$$\frac{passed\ challenges}{total\ challenges - abandoned - skipped}$$

Category	Challenge	Pass rate		Skip rate		Abandon rate		Adjusted pass rate	
		Familiar	*Unfamiliar*	*Familiar*	*Unfamiliar*	*Familiar*	*Unfamiliar*	*Familiar*	*Unfamiliar*
Device-based	Device Prompt	35%	38%	16%	30%	44%	23%	93%	87%
	Device SMS OTP	45%	62%	28%	12%	25%	20%	98%	93%
	Device Settings OTP	13%	9%	16%	34%	64%	48%	72% ± 1%	56% ± 2%
Delegation-based	OTP to backup email	22%	5%	18%	1%	56%	92%	90% ± 1%	94% ± 3%
Knowledge-based	Known pre-reg. email	48%	66%	6%	8%	35%	14%	83%	86%
	Known pre-reg. phone	64%	65%	5%	10%	27%	13%	96%	86%
	Last login location	62%	77% ± 7%	5%	5% ± 7%	23%	7% ± 7%	88% ± 1%	89% ± 7%
	Security question	37%	48% ± 1%	18%	23% ± 1%	33%	13% ± 1%	78%	77% ± 1%
Additional resource	OTP to any phone	43%	42%	9%	17%	45%	34%	96% ± 1%	92%

Table 5: Usability of individual challenges as assessed by their overall pass rates and detailed failure modes including users skipping, abandoning, or incorrectly answering a challenge.

We isolate the other failure modes by calculating the skip rate and abandon rate per challenge. We present our results in Table 5. Unless otherwise noted, all error margins are within 1% at a 95% confidence interval. We note that challenges related to Google's Authenticator app, security keys, account creation time, and proof of access to any email address are not present as they appear exclusively during two-factor authentication and recovery.

Familiar Device & Network. We find that ready access to a trusted mobile device proved challenging for most users. Only 35% of users successfully responded to an on-device prompt and another 45% successfully provided an SMS OTP. Asking users to access their device settings and supply an OTP code proved even more challenging, with only 13% of users passing the challenge. When confronted with a device-based challenge, 25–64% of users outright abandoned the sign-in attempt while another 16–28% opted to solve an alternative challenge. These failure modes highlight the friction introduced by requiring "something you have" for authentication, despite the ubiquity of mobile devices. All of these device-based methods also rely on action flows that users may never have previously encountered. If we isolate challenges solely to those where users attempted to provide a solution, we find that 93% correctly clicked "Yes" to the on-device prompt and 98% supplied the correct SMS code. In aggregate, our findings illustrate that while device-based security challenges provide the best security, there is a non-negligible risk that users may not have immediate access to their device.

OTP codes sent to a backup email had the second lowest pass rate at 22%. Users abandoned a majority of these–56%–either due to an inability to remember their alternative email and password or the overhead involved. We expect that these rates would be higher for service providers that, unlike Google, are not major email providers. Many users have one primary email address that serves as the backup and recovery mechanism for other web services, and many users use Gmail accounts for this, so we might expect that they have difficulty remembering the credentials to an account they do not necessarily use every day. It's possible that a significant fraction of the accounts in our sample are such accounts. Adjusted pass rates of 90% indicate that users had a harder time copying the supplied code, possibly due to having to memorize the code while switching between browser tabs. In comparison, SMS OTPs had higher adjusted pass rates at 98% likely due to having a second screen.

Knowledge-based challenges exhibited the lowest degree of user friction, with pass rates ranging from 37–64%. If we isolate our analysis solely to memorability, we find that users correctly recalled their phone number 96% of the time and their last login location 88% of the time. Secret questions proved the most difficult for users, with users opting to skip them three times more than other knowledge-based challenges and providing a correct solution in only 78% of cases. As previously noted by Bonneau et al., users provide fake responses to security questions which decreases their recall at a later time [2]. Taken as a whole, knowledge-based challenges provide the best overall usability—though at the expense of failing to prevent over 74% of phishing attacks. These trade-offs highlight the decision identity providers must make when determining whether to minimize hijacking or account lockout.

We find that challenges which require only a single, re-usable secret with nothing to carry such as a phone number or email address provide the best memorability and usability. Users struggle with more complex pre-shared secrets such as passwords at secondary verifiers or security questions. These basic knowledge challenges, though simple for users, are also the easiest for attackers to bypass. In contrast, device-based challenges exhibit slightly higher user friction while providing better security protections.

Unfamiliar Device & Network. Compared to familiar devices and networks, users logging in from unfamiliar devices and networks exhibited 0.3–28% higher overall pass rates with the exception of only three challenges as shown in Table 5. We believe this stems from users having both a higher incentive to gain access from their new device and more context for why a challenge occurred. For example, we find users were 20–209% less likely to abandon a challenge. Skip rates were 4–42% higher, indicating users attempted to navigate towards a challenge they could solve. If we isolate our analysis to issues of memorability, we find that users exhibited lower adjusted pass rates for all device-based challenges and resource-based challenges and similar adjusted pass rates for all knowledge-based challenges (with the exception of their phone number). Interpreting these results, we believe that the lower adjusted pass rates for device-based challenges stems from the same place as the lower abandonment rate—users who would otherwise

Table 6: Variations in usability across contexts for two-factor authentication, login challenges, and account recovery. Two-factor authentication users have a higher likelihood of carrying a device, while users in recovery struggle more with knowledge-based challenges.

have abandoned the challenge in our familiar device and network experiment are instead attempting to solve it. Additionally, this dataset likely includes some hijacking activity, pulling down aggregate adjusted pass rates. As such, when interpreting usability, we believe pass rates for both our familiar and unfamiliar context datasets represent a lower bound.

5.2 Spectrum of preparedness

Beyond risk analysis at login, challenges also appear in two-factor authentication and account recovery. Combined, these three contexts form a spectrum of preparedness from users who are primed to expect a challenge to users in a forgetful frame of mind. We examine how these contexts influence overall pass rates and memorability in Table 6.

Users enrolled in two-factor authentication had access to their security key for 67% of sign-in attempts, while another 75–82% had access to their mobile device. These pass rates, while roughly twice as high as the login challenge context, illustrate the limitation of expecting users to have a device on hand. At the other end of the preparedness spectrum, we find that device-based challenges displayed during account recovery exhibited pass rates roughly in line with login challenges. Taken as a whole, while improving user familiarity with SMS OTPs or on-device prompts may help increase their pass rate, device accessibility will cause at least a quarter of users to fail such challenges.

Unfortunately, users who struggled to remember their password were equally likely to struggle with accessing their backup account. We find users passed only 22% of delegation-based challenges during recovery, in line with the pass rates of users in a login challenge context.

Finally, knowledge-based challenges proved even more challenging for users in a recovery context. Here, only 13% of users passed a challenge for their account creation date and 22% their security question. Even when we restrict failures to memory alone, we find adjusted pass rates for both challenges fall below 38%. Users were more apt to produce their phone number–succeeding 61% of the time–at rates in line with users in a login challenge context. Printed backup codes also proved difficult to locate, with only 7% of users passing the challenge during recovery. In contrast, two-factor authentication users who selected to submit a code ultimately succeeded in 48% of cases. Our results highlight how recovery introduces even more usability challenges than a login challenge context. Given the issues of memorization at play, we argue that associating a phone number with an account presents the best path towards helping users who forget their password—though this fails to mitigate the risk of phishing without also requiring an SMS OTP code.

5.3 Overall success rate

While exploring challenges in isolation lets us reason about factors that influence usability, the most critical metric for any layered authentication scheme is whether users can solve at least one available challenge and thus access their account. Here, we examine *all* sign-in attempts to Google over a one month period to determine (1) whether users succeeded in logging in during a single challenged session, and (2) whether any user who failed a challenge ultimately succeeded in accessing their account within one week.[5] For this computation, we segment users into three groups: those with two-factor authentication enabled and accessing their account from a familiar device or network; those attempting to recover access to their account from a familiar device or network; and users signing in from an unfamiliar device and network. We note that we lack an equivalent experiment for login challenges to users signing in from a familiar device or network as this scenario never occurs in situ. For comparison, we also calculate the success rate of password-only authentication for users signing in from familiar devices or networks.

[5]We are unable to provide more granular results due to the computation and anonymization involved.

Source of initial failure	Success rate	
	Same session	*Within one week*
Two-factor authentication	88.2%	98.4%
Login challenge,	47.8%	97.3%
Login challenge, device-based	59.3%	97.9%
Account recovery	49.7%	93.8%
Account recovery, device-based	46.6%	94.6%
Password-only	89.5%	95.8%

Table 7: Success rates of users who fail a challenge to gain access to their account within one week. Login challenges and two-factor authentication exhibit less user friction than passwords.

We caution that overall success rate does not equate to lockout as some users may infrequently access their account. Likewise, for login challenges, hijacking activity will depress per-session success rates.

We present our results in Table 7. We find that two-factor authentication exhibits similar user friction compared to password-only authentication. This holds both per-session and overall. Conversely, just 47.8% of challenged sign-ins result in success, with similar rates of 49.7% for account recovery. However, over the course of a week, users have an opportunity to regain access to a familiar device or network and thus eventually access their account. If we isolate our analysis to device-based challenges only, we find that success rates increased for login challenges, but decrease slightly for users attempting to recover their accounts.

These results illustrate that inherent trade-off of login challenges. Identity providers can significantly reduce the risk of hijacking, but the resulting friction increases the risk of account lockout. However, by allowing users to re-try or to find a trusted device or network, users can eventually access their account at rates similar to password-only authentication. The significantly higher success rate of two-factor authentication indicates that education and habituation play a major role in reducing lock out risks.

6 RELATED WORK

Numerous studies have explored knowledge-based challenges in isolation from a usability perspective. Bonneau et al. extensively examined issues with secret questions as secondary authentication measures [2]. They found that users do not answer questions truthfully—with a mind to increase their own security. Consequently, the authors found users were unable to recall their answers during recovery. Similarly, Jakobsson et al. showed that security questions are more effective when responses are restricted to boolean values rather than free-form responses [15]. While improvements to knowledge-based questions in general help to reduce the risk of lockout, our results emphasize that this class of challenges provides only limited protection against phishing and targeted attacks. However, they do provide value against automated attacks and thus there is merit to exploring usability improvements.

Given the push towards two-factor authentication, recent studies have also explored usability challenges with security keys. Das et al. examined barriers to security key adoption and found users were most concerned with losing their second factor and did not feel they needed the extra layer of security [6]. Lang et al. explored security keys and device OTPs from a practical deployment standpoint and found keys provided both better security and reduced the time that users spent authenticating [17]. We believe that on-device prompts can similarly provide a more seamless authentication experience compared to copying an SMS code, though at present SMS is a more familiar experience for most users. In a similar vein, Siadati et al. examined the phishability of SMS codes and found they could socially engineer 50% of participants into handing over an OTP code [21]. With improvements to warning language included in the text of the SMS, only 8% of participants handed over their OTP code.

Finally, in terms of potential new forms of challenges, research has recently started to explore social challenges. Alomar et al. provide an overview of proposals in this space and potential trade-offs [1]. Brainard et al. proposed vouching by a single additional party [4], where authentication becomes a transitive property. Alternatively, Jain et al. proposed asking users to identify recent activity from friends or to identify a list of friends—more akin to knowledge-based challenges [14]. We are unaware of any large-scale deployments of such schemes, but our taxonomy is comprehensive enough to capture the challenges in this space.

7 CONCLUSION

While the quest to replace passwords continues, authentication challenges offer an effective barrier against remote hijacking threats rooted in password theft. From a practical standpoint, we found that challenges, in conjunction with risk-aware authentication, blocked over 99.99% of automated hijacking attempts and 92% of attacks rooted in phishing at Google. These protections come at a cost of increased failed sign-in attempts from legitimate users, but with eventual success rates at levels similar to password-only authentication. We caution our metrics represent a current snapshot of an arms race. But unlike many cybercrime threats, users can take simple proactive steps to dramatically increase their security. Users who associate a device with their account can reduce their phishing risk by up to 99%. This approach provides similar levels of protection to two-factor authentication while removing the requirement of always having a device on-hand. However, as our data showed, risk-aware authentication cannot reliably protect against repeated, targeted hijacking attempts that involve social engineering. Here, security keys provide the only 100% guarantee of protection against remote password theft. By providing risk-aware authentication as a default protection and security keys as opt-in, users can choose the security and usability trade-off that best works for them.

ABSTRACT

RNN models have achieved the state-of-the-art performance in a wide range of text mining tasks. However, these models are often regarded as black-boxes and are criticized due to the lack of interpretability. In this paper, we enhance the interpretability of RNNs by providing interpretable rationales for RNN predictions. Nevertheless, interpreting RNNs is a challenging problem. Firstly, unlike existing methods that rely on local approximation, we aim to provide rationales that are more faithful to the decision making process of RNN models. Secondly, a flexible interpretation method should be able to assign contribution scores to text segments of varying lengths, instead of only to individual words. To tackle these challenges, we propose a novel attribution method, called REAT, to provide interpretations to RNN predictions. REAT decomposes the final prediction of a RNN into additive contribution of each word in the input text. This additive decomposition enables REAT to further obtain phrase-level attribution scores. In addition, REAT is generally applicable to various RNN architectures, including GRU, LSTM and their bidirectional versions. Experimental results demonstrate the faithfulness and interpretability of the proposed attribution method. Comprehensive analysis shows that our attribution method could unveil the useful linguistic knowledge captured by RNNs. Some analysis further demonstrates our method could be utilized as a debugging tool to examine the vulnerability and failure reasons of RNNs, which may lead to several promising future directions to promote generalization ability of RNNs.

1 INTRODUCTION

The RNNs, such as LSTM [14] and GRU [5], have achieved the state-of-the-art performance in a variety of text classification tasks. These deep text classification models have became increasingly deployed in different web applications, including sentiment classification [42], named entities recognition [32], textual entailment [4], etc. Despite the superior performance, RNNs are often criticized by their lack of interpretability, and are often treated as black-boxes [21]. The lack of understanding of the mechanism behind RNN predictions not only reduces the acceptance from end-users towards the deployed predictors, but also limits ability of system developers in diagnosing the model, searching the reasons for wrong predictions, and improving the model architectures. Therefore, it is highly desirable to explore the interpretability of RNNs, so as to provide insight of how they process text inputs and make inferences therefrom.

It is possible to provide interpretability for RNNs from two perspectives: adding interpretable components to RNN models or performing post-hoc attribution [9]. The former category integrates interpretability directly into the structure of deep models, and usually resorts to attention mechanism [20, 44]. However, the attention components only provide an indirect indicator of contribution scores. For classification tasks, it is not clear which specific class these attention weights contribute to [27]. In contrast, the philosophy of post-hoc attribution is to provide interpretation to predictions made by a pre-trained black-box model without any architectural modification. Post-hoc attribution aims to attribute the prediction of a model to its input features, e.g., words in a text classification task, and produce a heatmap as interpretation, indicating the contribution of each feature to a particular class of interest. In this paper, we follow the post-hoc attribution strategy, as it could provide understandable rationale to the given predicted label from the model while keeping the underlying model status intact.

Although post-hoc attribution has been extensively studied for understanding MLP and CNNs [10], attribution for RNN predictions is still a technically challenging problem. First, one challenge lies in how to guarantee that the interpretations are indeed faithful to the original model. Many previous attribution work, including back-propagation based methods [7, 13], perturbation based methods [16, 19], and local approximation based methods [35, 36], all follow the philosophy of *local interpretation*. That is, they generate interpretable approximation of the original model around the neighborhood of a given prediction to be explained. However, it is not guaranteed that the generated interpretations accurately reflect the decision making process of the original model [6, 12]. In this case, it is hard to tell whether an unexpected interpretation is caused by misbehavior of the model or limitation of the attribution method. Second, it is challenging to develop a flexible attribution method which could generate attribution scores to text

segments (e.g., phrases) of varying lengths. Prior work for RNNs attribution mainly focuses on identifying *word-level contribution scores* [7, 35, 41], which assigns a real-value score for each of the words, indicating the extent to which it contributes to a particular prediction. However, word-level attributions fail to explain why RNNs are successful to process sequences where the order of the data entries matters. Consider an example of sentence sentiment analysis, "I do not dislike cabin cruisers." expresses a neutral opinion. Word-level attribution methods may accurately identify that the word "dislike" has a negative contribution for this prediction, but they fail to capture that the negation word "not" has shifted its polarity and the word combinations "not dislike" have a positive impact for model prediction.

In this paper, we propose a decomposition based attribution method, called REAT (REcurrent ATtribution Method), to provide interpretation for given predictions made by a RNN in a faithful and flexible manner. Through modeling the information flowing process of the hidden state vectors in RNN models, REAT could decompose the final prediction of a RNN into additive contribution of each word in the input text. Since REAT is constructed by directly leveraging the information propagation process from hidden state vectors to the output layer, it enjoys the benefit of high faithfulness to the original RNN model. This method not only can quantify the contribution of each individual word to a prediction, but also could naturally be applied to identify the contribution of word sequences. It thus enables the illumination of how RNNs make use of sequential information, as well as how they capture long-term dependencies. In addition, REAT is widely applicable to different recurrent architectures, including LSTMs and GRUs, and their bidirectional versions. Furthermore, based on the observation that language usually exhibits hierarchical structures, we expand REAT to a hierarchical attribution method, to represent the contributions at different levels of granularity. The major contributions of this paper are summarized as follows:

- We propose a RNN attribution method based on additive decomposition, called REAT, which could provide both word-level and phrase-level attribution scores.
- REAT is applicable to different RNN architectures. We demonstrate its applicability to three standard RNN architectures, including GRU, LSTM and Bidirectional GRU.
- Experimental results on two sentiment analysis datasets validate the faithfulness and interpretability of the proposed method.
- We demonstrate that REAT could be utilized as a debugging tool to analyze the useful linguistic knowledge captured by RNNs and examine the vulnerability and failure reasons of RNNs.

2 PRELIMINARIES

In this section, we start by introducing post-hoc attribution that serves as the basic attribution scheme in this paper. Then we introduce three representative RNN architectures as well as the output layer which transforms the hidden state into probability output.

2.1 Post-hoc Attribution

Notations: Consider a typical multi-class text classification task, a RNN-based classification model can be denoted as $f : X \rightarrow Y$, where X is the text space, and $Y = \{1, ..., C\}$ denotes the set of output classes. The RNN model accepts an instance $\mathbf{x} \in X$ as input, and maps it to an output class: $f(\mathbf{x}) = c \in Y$. Assume the input is composed of a sequence of T words: $\mathbf{x} = \{x_1, ..., x_T\}$ and each word $x_t \in \mathbb{R}^d$ denotes the embedding representation of the t-th word. The high level idea of post-hoc attribution is to attribute the prediction $f(\mathbf{x})$ of a RNN model to its input features $\mathbf{x}$ and output a heatmap indicating the contribution of each feature $x_t \in \mathbf{x}$ to a particular class of interest c. Specifically, we target to generate attributions for a RNN prediction which is specified as follows:

Phrase-level Attribution: We first partition the input text into meaningful phrases (coherent pieces of text) and then attach an attribution score to each individual phrase. Given one index phrase as query. The index set of a phrase that we want to calculate its attribution score is denoted as: $A = \{q, ...r\}$ where $1 \leq q \leq r \leq T$. We indicate the attribution score for the targeting phrase as $S(\mathbf{x}_A)$.

2.2 RNN Architectures

RNNs come in many variants with different architectures, which results in different mapping functions f. In this paper, we discuss three representative RNN architectures that are fundamental and have been widely used in many applications. The common formulations in different RNN architectures motivate the design of our interpretation approach.

LSTM: In a Vanilla RNN, at any time step in a sequence, the hidden state h_t is calculated based on its previous hidden state h_{t-1} and the current input vector x_t:

$$h_t = \tanh(W_{hx}x_t + W_{hh}h_{t-1} + b_h). \tag{1}$$

Comparing to the Vanilla RNN, LSTM makes two major changes. Firstly, LSTM introduces a cell state c_t that serves as an explicit memory. Secondly, instead of simply updating the hidden state h_t in Eq. (1), LSTM uses three gates: input gate i_t, forget gate f_t, and output gate o_t to update the hidden state h_t.

$$\begin{aligned} i_t &= \sigma(W_{ix}x_t + W_{ih}h_{t-1} + b_i) \\ f_t &= \sigma(W_{fx}x_t + W_{fh}h_{t-1} + b_f) \\ o_t &= \sigma(W_{ox}x_t + W_{oh}h_{t-1} + b_o) \\ g_t &= \tanh(W_{gx}x_t + W_{gh}h_{t-1} + b_g) \\ c_t &= f_t \odot c_{t-1} + i_t \odot g_t \\ h_t &= o_t \odot \tanh(c_t). \end{aligned} \tag{2}$$

where each W and b represent weight matrix and bias vector respectively, and $\odot$ denotes element-wise multiplication.

GRU: GRU makes some slight modifications on the basis of LSTM. It only has two gates, i.e., reset gate r_t and update gate u_t. Besides, it merges the cell state and hidden state into a single hidden state h_t. The updating rule of hidden state is denoted as follows.

$$\begin{aligned} r_t &= \sigma(W_{rx}x_t + W_{rh}h_{t-1} + b_r) \\ u_t &= \sigma(W_{ux}x_t + W_{uh}h_{t-1} + b_u) \\ g_t &= \tanh(W_{gx}x_t + r_t \odot W_{gh}h_{t-1} + b_g) \\ h_t &= u_t \odot h_{t-1} + (1 - u_t) \odot g_t. \end{aligned} \tag{3}$$

Bidirectional GRU: This model is constructed by putting two independent GRUs together. The word sequences are fed into one GRU in normal time order, and in reverse time order into another. For each network, the hidden state is updated using the same rule as

Eq. (3). For the sake of brevity, we use subscripts n and r to represent the *normal* and *reverse* network respectively. For classification tasks, the final hidden vector fed into the output layer is constructed by concatenating the hidden vector at time step T for the normal GRU and the hidden vector at time step 1 for the reverse one:

$$h = h_{T,n} \oplus h_{1,r}, \tag{4}$$

where symbol $\oplus$ denotes concatenation operation of two vectors. Both $h_{T,n}$ and $h_{1,r}$ contain the information of the whole text. Hidden state $h_{T,n}$ encodes the information of the normal text (from x_1 to x_T), while $h_{1,r}$ captures the information in the inverse text (from x_T to x_1). In the remaining part of this paper, we use BiGRU to denote Bidirectional GRU.

2.3 RNN Output Layer

To serve the purpose of multi-class text classification, a discriminative layer is added after the activation vector h_T of the last hidden layer at time step T. This layer takes the hidden state h_T as input and turns it into a logit vector z using a weight matrix W:

$$z = Wh_T, \tag{5}$$

and then produces the class probabilities using a softmax layer which converts the logit z_c for a class c into a probability y_c, by comparing it with other logit values:

$$y_c = \text{softmax}(z)_c = \frac{\exp(z_c)}{\sum_{k=1}^{C} \exp(z_k)}. \tag{6}$$

3 METHODOLOGY

In this section, we introduce the proposed attribution method for explaining RNN predictions. We first present a general method for phrase-level RNN prediction attribution, and then apply it to three widely used RNN architectures. Finally, we expand the method to enable hierarchical attribution schemes.

3.1 Phrase-level Attribution Method for Recurrent Models

3.1.1 A Naive Attribution Approach. From the last section, we know that RNNs possess a series of hidden state vectors $\{h_t\}_{t=1,\ldots,T}$, where each vector h_t stores information about the past input blocks, ranging from time step 1 to t. A crucial property of the hidden state vector is that it is updated from time step to time step. Knowing how much information is accumulated at each time step enables us to derive the contribution of that time step towards the final prediction. Intuitively, we denote the response of the RNN model to word $\mathbf{x}_t$, and thereby the information gained at step t, as follows:

$$\tilde{h}_t = g(\mathbf{x}_t) = h_t - h_{t-1}. \tag{7}$$

In this way, we can consider the final hidden state vector h_T to contain information accumulated at T time steps, denoted as: $h_T = \sum_{t=1}^{T} \tilde{h}_t = \sum_{t=1}^{T} (h_t - h_{t-1})$. Then, we can decompose the logit z_c (see Eq. (5)) for target class c using a sequence of factors:

$$z_c = W_c h_T = \sum_{t=1}^{T} W_c (h_t - h_{t-1}). \tag{8}$$

It can be treated as the additive contribution of each word in the input $\mathbf{x}$ to the output logit (unnormalized output probability) of class c. Therefore, the contribution of word $\mathbf{x}_t$ towards the logit z_c can be calculated as:

$$S(\mathbf{x}_t) = W_c (h_t - h_{t-1}). \tag{9}$$

However, this decomposition has a severe shortcoming. The underlying assumption of this formulation is that all evidence accumulated up to time step $t-1$ has been transferred to time t. This violates the updating rules of all the three architectures listed in Sec. 2.2. Actually, it fails to take into consideration the forgetting mechanism of RNNs. For example, both LSTM and GRU have explicit gates to model the forgetting and remembering mechanism, which serves the purpose of controlling information flow and calculating how much proportion of information derived from previous time steps should be kept.

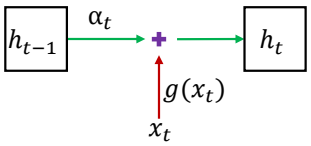

Figure 1: An illustration of the summarized updating rule for the RNN hidden state vectors.

3.1.2 The Proposed Recurrent Attribution Method (REAT). Many variants of RNNs share a similar form of hidden state updates. We summarize a common rule which can be applied to different recurrent network architectures, as illustrated in Fig. 1. The rule maintains a hidden state h_t which summarizes information for past sequences. Also, at each time step t, the hidden state is updated using the following equation:

$$h_t = \alpha_t \odot h_{t-1} + \tilde{h}_t, \tag{10}$$

where $\alpha_t \in [0,1]^{d'}$ so that only partial evidence obtained by RNN from previous $t-1$ steps is brought to the time step t. Here d' is the dimension of hidden state vectors. A higher value of α means that the RNN model preserves more important information from previous time steps. Here $\tilde{h}_t = g(\mathbf{x}_t)$ denotes the evidence that a RNN obtains at time step t, but note that it is no longer defined as in Eq. (7). Some RNN architectures obey this rule exactly, like GRU, while some other architectures follow this rule approximately, such as LSTM. Based on this hidden state updating rule, we can iteratively trace back the generation of h_T and decompose the logit value z_c into the following form:

$$z_c = W_c h_T = \sum_{t=1}^{T} W_c (\tilde{h}_t \odot \prod_{k=t+1}^{T} \alpha_k). \tag{11}$$

Replacing each $\tilde{h}_t$ with $h_t - \alpha_t \odot h_{t-1}$, we can reformulate the additive decomposition as:

$$z_c = \sum_{t=1}^{T} W_c [(h_t - \alpha_t \odot h_{t-1}) \odot \prod_{k=t+1}^{T} \alpha_k]. \tag{12}$$

The main benefit of Eq. (12) comparing to Eq. (11) is that we do not need to know the exact form of $\tilde{h}_t$. Merely knowing the hidden state vector h_t and the updating parameter vector α_t will be sufficient to derive the decomposition. Eq. (12) can be considered as the additive

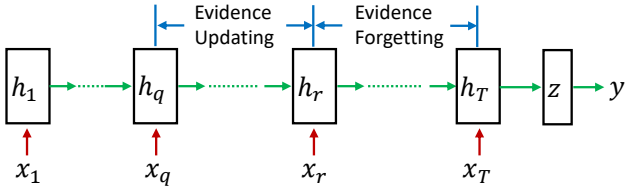

Figure 2: An illustration of the proposed method.

contribution of each word $\mathbf{x}_t$ towards the logit z_c, which is the unnormalized probability for target class c. By taking out the term relevant to time step t, we can derive the contribution value for a single word $\mathbf{x}_t$ at the current time step:

$$S(\mathbf{x}_t) = W_c[\underbrace{(h_t - \alpha_t \odot h_{t-1})}_{Updating} \odot \underbrace{\prod_{k=t+1}^{T} \alpha_k}_{Forgetting}]. \tag{13}$$

The above formulation within the square brackets is the element-wise multiplication of two terms. The left term denotes the updating evidence from time $t-1$ to t, i.e., the contribution to class c by the input word $\mathbf{x}_t$. The right term represents the forgetting mechanism of RNN. The evidence that a RNN has gathered at time step t gradually diminishes as the time increases from $t+1$ to the final time step T. That is to say, only part of the updating evidence will have impacts on the classification task at time step T.

Based on the word-level additive attribution formulation in Eq. (13), we can conveniently derive the phrase-level attribution. For a phrase $\mathbf{x}_A$, where $A = \{q, ...r\}$, $1 \le q \le r \le T$, its attribution score $S(\mathbf{x}_A)$ can be denoted as:

$$S(\mathbf{x}_A) = W_c[\underbrace{(h_r - \prod_{j=q}^{r} \alpha_j \odot h_{q-1})}_{Updating} \odot \underbrace{\prod_{k=r+1}^{T} \alpha_k}_{Forgetting}]. \tag{14}$$

Similar to word-level attribution, phrase-level attribution $S(\mathbf{x}_A)$ also contains two terms. The left term within the square brackets in Eq. (14) represents the updating evidence from time step $q-1$ to time r, while the right term denotes how much percentage of the evidence has been forgotten from time $r+1$ to T. We illustrate this process in Fig. 2. It is worth noting that the key component here to derive phrase-level attribution score for a RNN classifier is to obtain the hidden state vectors and the updating vectors. Usually, only one feed forward operation is needed to derive phrase-level attribution score, which can be implemented efficiently.

3.2 Applications to Specific Architectures

In this section, we apply the proposed idea to three standard RNN architectures, including LSTM, GRU and BiGRU.

3.2.1 GRU Attribution. The hidden state vector updating rule for GRU is written as:

$$h_t = u_t \odot h_{t-1} + (1 - u_t) \odot g_t, \tag{15}$$

which conforms with the paradigm in Eq. (10). Therefore, for a phrase $\mathbf{x}_A$, where $A = \{q, ...r\}$, $1 \le q \le r \le T$, we can directly replace α_t in Eq. (14) with the updating gate vector u_t of the GRU model, and obtain the phrase-level attribution score $S(\mathbf{x}_A)$:

$$S(\mathbf{x}_A) = W_c[(h_r - \prod_{j=q}^{r} u_j \odot h_{q-1}) \odot \prod_{k=r+1}^{T} u_k]. \tag{16}$$

3.2.2 LSTM Attribution. Although it is difficult to directly match the LSTM updating rule of hidden state h_t in Eq. (2) to the paradigm in Eq. (10), the update of the cell state c_t adheres to the expected updating format in Eq. (10). It is denoted as: $c_t = f_t \odot c_{t-1} + i_t \odot g_t$, where f_t is the forgetting gate of LSTM.

Based on the updating rule from the cell state c_t to hidden state: $h_t = o_t \odot tanh(c_t)$, approximately we can obtain:

$$c_t \sim \frac{h_t}{o_t}, \tag{17}$$

where the right term is a element-wise division. Thus we approximate the updating rule of the hidden state vector for LSTM as below:

$$h_t = \frac{f_t \odot o_t}{o_{t-1}} \odot h_{t-1} + \tilde{h}_t. \tag{18}$$

Then, we can further decompose the final hidden state vector h_T into the following formulation:

$$h_T = \sum_{t=1}^{T} (h_t - \frac{f_t \odot o_t}{o_{t-1}} \odot h_{t-1})) \odot \prod_{k=t+1}^{T} \frac{f_k \odot o_k}{o_{k-1}}. \tag{19}$$

For a phrase $\mathbf{x}_A$, where $A = \{q, ...r\}$, $1 \le q \le r \le T$, we can obtain the attribution score $S(\mathbf{x}_A)$:

$$S(\mathbf{x}_A) = W_c[(h_r - \prod_{j=q}^{r} \frac{f_j \odot o_j}{o_{j-1}} \odot h_{q-1}) \odot \prod_{k=r+1}^{T} \frac{f_k \odot o_k}{o_{k-1}}]. \tag{20}$$

3.2.3 BiGRU Attribution. In this section, we illustrate how the proposed method can be applied to bidirectional architectures. The last hidden state $h_{T,n}$ at time step T of the normal GRU uses the identical decomposition as in Sec. 3.2.1. As for the reverse GRU, we use the hidden state vector at time step 1 in order to capture the information from 1 to T, which can be decomposed as follows:

$$h_{1,r} = \sum_{t=1}^{T} (h_{t,r} - u_{t,r} \odot h_{t+1,r}) \odot \prod_{k=1}^{t-1} u_{k,r}. \tag{21}$$

Recall that the final hidden vector fed into the classification layer is the concatenation of the hidden vector at time step T for the normal GRU and the hidden vector at time step 1 for the reverse GRU, i.e., $h = h_{T,n} \oplus h_{1,r}$. As such, the logit value is computed as $z_c = W_c(h_{T,n} \oplus h_{1,r})$. To obtain the attribution score for a phrase $\mathbf{x}_A$, where $A = \{q, ...r\}$, we first calculate the updated hidden evidence for the normal network and the reverse network respectively. We then concatenate these two updated hidden evidence, and multiply it with W_c to produce the contribution scores.

$$\begin{aligned} S(\mathbf{x}_A) = & W_c[((h_{r,n} - \prod_{j=q}^{r} u_{j,n} \odot h_{q-1,n}) \odot \prod_{k=r+1}^{T} u_{k,n}) \oplus \\ & ((h_{q,r} - \prod_{j=q}^{r} u_{j,r} \odot h_{r+1,r}) \odot \prod_{k=1}^{q-1} u_{k,r})]. \end{aligned} \tag{22}$$

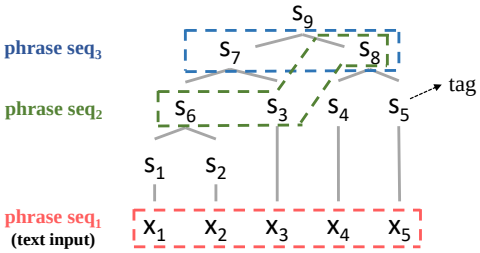

Figure 3: The proposed phrase-based attribution method is naturally compatible with sentence parsing.

Noun chunks	$< DET >?(< NOUN > + < ADP\|CONJ >)* < NOUN > +$

Table 1: Regular expression matching.

3.3 Automatic Attribution Generation

The developed method so far can only calculate the contribution score of a phrase whose beginning and ending in $\mathbf{x}$ are already specified. A natural question that arises is: how to comprehensively analyze and combine the contributions of different parts of an input text, so as to explain the response of RNNs spanning on the whole text. A naive way is to exhaustively select phrases of different length and starting points, and compute their contribution scores respectively. However, such search scheme will span over a lot of redundant and trivially overlapping text segments. In this case, the redundant amount of interpretation information may be overwhelming to users. Traditional word-level interpretation can be seen as a special case of our method by simply setting the phrase length as one, but its flexibility is limited.

To design an interpretation scheme with both desirable understandability and flexibility, we apply text parsing into the attribution method. The general idea is illustrated in Fig. 3. The parse tree is derived from certain existing text parsing algorithm. Here $\mathbf{x}_n$ denotes a word, and $\mathbf{s}_i$ denotes a non-terminal symbol (i.e., a POS tag or a phrase type). Our attribution method will be applied to each of the selected phrase sequences. The phrases within each sequence are semantically meaningful and mutually non-overlapping. In this way, we obtain interpretation of different granularity on a sentence. The interpretation is thus more compatible with the cognition habits of human.

In this work, we partition sentences using regular expression matching [25] to divide each sentence into meaningful phrases. Specifically, we use two regular expressions shown in Tab. 1 to partition the sentence into continuous noun and verb chunks. Take the sentence "The movie does n't serve up lot of laughs." for example. A middle-level phrase sequence obtained from parsing could be "{The movie} {does n't serve up} {lot of laughs}.", which correspond to noun chunk, verb chunk, and noun chunk respectively. Then we feed the sentence into the RNN and the attribution method. The output is a sequence of phrases along with corresponding attribution scores, capturing the most significant phrases contributing to the network prediction during the prediction lifetime. In practice, each original text may end up with 2 (word-level and phrase-level) or 3 (word-level, phrase-level, and clause-level, where clause denotes part of a sentence or a complete sentence containing a verb) hierarchies, and users can obtain a hierarchical interpretation of the prediction.

4 EXPERIMENTS

In this section, we present the experimental results in order to answer the following research questions (**RQ**s).

- **RQ1** - Does the generated attribution faithfully reflect how the original RNN model makes predictions?
- **RQ2** - Does the proposed RNN attribution method outperform alternative approaches in terms of interpretability?
- **RQ3** - Could hierarchical interpretation comprehensively capture the evidences for prediction at different levels of granularity?
- **RQ4** - How to use the proposed attribution method to analyze the useful insights captured by RNNs?
- **RQ5** - How to use the proposed attribution method to analyze the misbehavior of RNNs and ultimately promote RNNs' generalization capability?

4.1 Datasets

We conduct our experiments on two publicly available sentiment analysis datasets, whose statistics are shown in Tab. 2.

Stanford Sentiment Treebank 2 (SST2) [39] - It contains 2 classes (negative and positive). The numbers of instances for training set, development set and test set are 6920, 872, and 1821 respectively.

Yelp Polarity (Yelp) [46] - It consists of reviews originally extracted from the Yelp Dataset Challenge 2015 data. Zhang et al. [46] constructed the Yelp reviews polarity dataset by considering stars 1 and 2 as negative, and considering 4 and 5 as positive. The numbers of instances for training set and test set are 560,000 and 38,000 respectively. We use a subset of this dataset by filtering out texts whose length is larger than 40, and then randomly select part of the samples from the training set as development set. Ultimately, the dataset contains 80000, 1999, and 5492 instances for training, development, and test set respectively, with each polarity occupying around half of the instances in each set.

4.2 Experimental Setup

For each classification model used in our experiments, it contains a word embedding layer to transform words to fixed length representation vectors, a recurrent network layer to transform word embeddings to hidden state vectors, and a classification layer for output. Specifically, the pre-trained 300-dimensional word2vec word embedding [25] is utilized to initialize the embedding layer. For those words that do not exist in word2vec, we initialize their embedding vectors with some random values. The dimension of hidden state vectors is 150 for both LSTM and GRU, and 300 for BiGRU. The classification layer is composed of a dense layer and a softmax nonlinear transformation. The Adam optimizer [18] is utilized to optimize these models and the learning rate is fixed to 10^{-3}. We train each model for 20 epoches and select the one with the best performance on the development set. Note that we freeze the embedding layer when training all models on SST2, while fine-tune the embedding parameters when training on Yelp. Empirical results show that this can lead to better prediction performance for models on both datasets. We evaluate the test accuracy with the best performing model on the development set, and the performance statistics on SST2 and Yelp dataset are reported on Tab. 3.

4.3 Baseline Methods

We evaluate the proposed REAT method by comparing it with five baseline approaches.

- **Vanilla gradient (VanillaGrad)** [13]: Compute gradients of the output prediction with respect to individual entries in word embedding vectors, and use the L2 norm to reduce each vector of the gradients to a single attribution value, representing the contribution of each single word.
- **Integrated gradient (InteGrad)** [41]: Integrate all Vanilla gradients using a linear interpolation between a baseline input and the original input. Here the baseline input are sentences whose word embedding values are all set to zeros.
- **Gradient times input (GradInput)** [7]: First calculate the gradient of the output with respect to word embedding, and then use dot product of the gradient vector and word embedding vector as the contribution score for a word.
- **LIME** [35]: A model-agnostic interpretation method. It approximates the behavior of a RNN in the neighborhood of a given input using an interpretable white-box model. Here, the interpretable model is a sparse linear model.
- **NaiveREAT**: A simplified variant of the proposed method, as introduced in Sec. 3.1.1. The attribution score for a single word is calculated using Eq. (9).

It is worth noting that except NaiveREAT, the other four baseline methods could only derive word-level contribution scores. To get phrase-level or sentence-level contribution scores, we sum up the scores of all word within a phrase or a sentence.

4.4 Attribution Faithfulness Evaluation

In this section, we evaluate the faithfulness of the attribution methods with respect to the target RNN models. We want to assess whether the attribution results correctly reflect the prediction behavior of RNNs. In general, the faithfulness of an attribution method is evaluated by deleting the sentence of the highest contribution score and observing the prediction changes of the target RNNs [29]. Specifically, the attribution method first produces contribution scores for sentences in the text. Then, it is expected that once the most important sentence is deleted, it will cause the probability value to significantly drop for the target class. Here we define faithfulness score as the metric:

$$S_{\text{faithfulness}} = \frac{1}{N}\sum_{i=1}^{N}(y(\mathbf{x}^{(i)}) - y(\mathbf{x}^{(i)}_{\setminus A})), \tag{23}$$

where A denotes the sentence identified as the most predictive for a prediction, and N is the total number of texts in the dataset. An advantage of this metric is that no knowledge is required of ground truth labels. Theoretically this metric can also be utilized to evaluate word-level and phrase-level attributions. However, empirically, we find some irrelevant words or phrases could also lead to big probability drop, because they cause grammar or syntactic errors instead of really changing the semantics [26, 37]. Therefore, we only use this metric in sentence-level attribution scenarios.

Models	GRU	LSTM	BiGRU
VanillaGrad	0.272	0.243	0.068
InteGrad	0.255	0.253	0.113
GradInput	0.301	0.199	0.178
Lime	0.209	0.188	0.092
NaiveREAT	0.213	0.207	0.114
REAT	**0.311**	**0.318**	**0.196**

Table 4: Comparison about attribution faithfulness between our method and the baseline methods.

We search in SST2 dataset for texts that contain two sentences and use the word "but" as conjunction, and obtain a set with 142 texts. The faithfulness scores for different attribution methods on SST2 dataset are reported in Tab. 4. The proposed method consistently outperforms the baseline methods for all the three architectures. This result demonstrates two advantages of REAT: (1) the generated interpretations are highly faithful to original RNN, (2) the generated phrase-level interpretations are accurate. Since the NaiveREAT method does not consider the forgetting mechanism, it may assign false positive contribution scores for the first sentence in the testing texts. As a result, it is not faithful to the target model and achieves relatively low faithfulness score comparing to REAT. Besides, for the other baseline methods, they can only output word-level attribution scores. Since the word-level scores are not sufficiently faithful to the target model, the sentence-level scores calculated by summing up the word-level scores will further deviate from the prediction of the target RNN model. As a result, these methods have only limited faithfulness performance.

4.5 Attribution Interpretability Evaluation

We evaluate the interpretability of the proposed method to show whether the generated interpretations are reasonable from some fundamental perspectives of human comprehension. We only search for texts that contain both positive adjective words and negative adjective words with obvious sentiment bias. The searching criterion is whether a word belongs to the human annotated lists containing

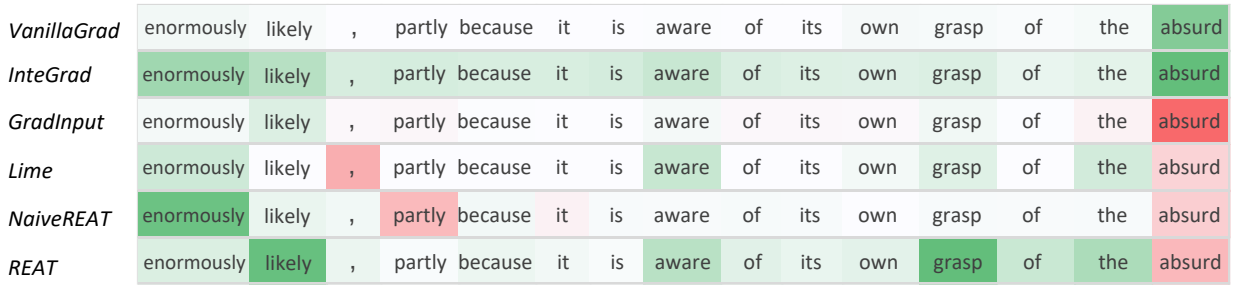

Figure 4: Word-level attribution heatmaps comparing with baseline methods, for a GRU prediction with 99.2% confidence as positive sentiment. Green and red color denote positive and negative contribution of a word to the prediction, respectively.

	SST2			Yelp		
Models	GRU	LSTM	BiGRU	GRU	LSTM	BiGRU
VanillaGrad	41.0	42.3	26.9	57.6	44.4	38.4
InteGrad	44.9	52.6	42.3	58.6	42.4	33.3
GradInput	84.6	80.8	85.9	84.8	82.8	90.9
Lime	73.1	80.8	73.1	74.7	77.8	80.8
NaiveREAT	79.5	87.2	**92.3**	55.6	83.8	86.9
REAT	**85.9**	**89.7**	88.5	**87.9**	**83.8**	**92.9**

Table 5: Interpretability statistical comparison (in percent) of our method with baseline RNN attribution methods.

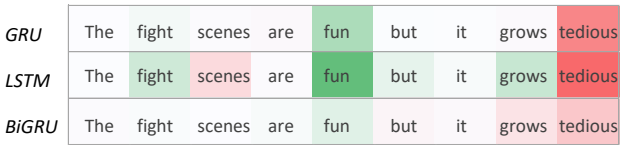

Figure 5: Word-level attribution heatmaps for 3 RNN architectures. Green and red color denote positive and negative contribution of a word to the prediction, respectively.

both positive words[1] and negative words[2] [22]. We obtain a testing set with 78 and 99 samples from SST2 and Yelp respectively. Then we generate a attribution score after feeding each text sample to a RNN, and evaluate the consistency of attribution with human annotations. Here, we focus on analyzing the attribution scores of these words for the positive sentiment side for all testing texts. The interpretation is considered to be a match if the attribution scores for positive words are lager than negative words, otherwise it is treated as a mismatch. Take text "It is ridiculous, of course but it is also refreshing" for example, if the attribution method assigns a higher contribution score to positive word "refreshing" comparing to negative word "ridiculous", we consider it as a match. The final interpretability score is judged by the ratio of matched cases:

$$S_{\text{interpretability}} = \frac{\#\text{match}}{\#\text{match} + \#\text{mismatch}}. \tag{24}$$

We compare the interpretability score of the proposed method with baseline methods on three RNN architectures over SST2 and Yelp dataset. The results are presented in Tab. 5. The proposed method ranks highest for five tasks among all six classification tasks. We observe that the interpretability scores for the NaiveREAT method, which is introduced in Sec. 3.1.1, are unstable across different models and datasets, partly due to the reason that it is not faithful to the original recurrent model. Sometimes, NaiveREAT could accurately capture the contribution score for strong sentiment word, such as for BiGRU prediction on SST2. In other cases, it may assign some false positive and false negative attribution values, leading to lower interpretability scores. Another interesting finding is that the interpretability of InteGrad does not outperform VanillaGrad consistently on all cases. Besides, GradInput yields consistently better performance comparing to VanillaGrad.

4.6 Qualitative Evaluation via Case Studies

We provide several case studies to qualitatively check the effectiveness of the proposed method using heatmaps shown from Fig. 4 to Fig. 6. We use green color to denote positive contribution and red color for negative contribution. Deeper color means higher contribution to the prediction.

4.6.1 Visualization Comparisons with Baseline Methods. We present attribution visualization for a prediction made by GRU with 99.2% confidence for positive sentiment, and compare it with the baseline attribution methods. The results are shown in Fig. 4. The heatmap shows that REAT not only identifies that words "enormously", "likely", "aware", "grasp" have positive contribution for the prediction, but also captures that "absurd" has negative contribution. It is consistent with human comprehension towards this sentence. In contrast, VanillaGrad and InteGrad fail to attribute the negative word; GradInput fails to identify the words that strongly and positively contribute to the prediction, thus can not explain why GRU gives such a high positive prediction score to this text. Also, LIME and NaiveREAT generate some noisy negative scores for irrelevant words, such as "partly", "it" and ",".

4.6.2 Visualizations Under Different RNN Architectures. We compare the word-level attribution results of three RNN architectures. For a given text "The fight scenes are fun but it grows tedious", GRU, LSTM and BiGRU give positive prediction (51.6% confidence), positive prediction (96.2% confidence), and negative prediction (62.7%

[1]https://gist.github.com/mkulakowski2/4289437
[2]https://gist.github.com/mkulakowski2/4289441

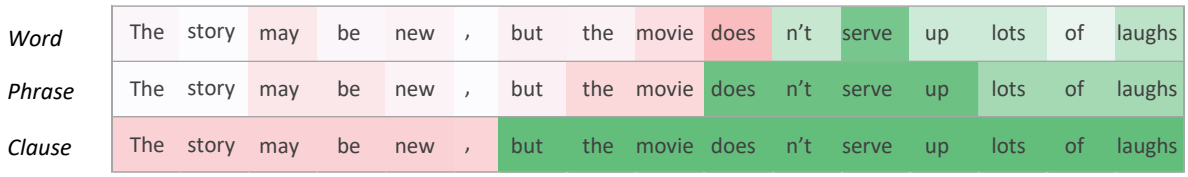

Figure 6: Visualization heatmaps for hierarchical attribution. Green and red color denote positive and negative contribution of a word to the prediction, respectively.

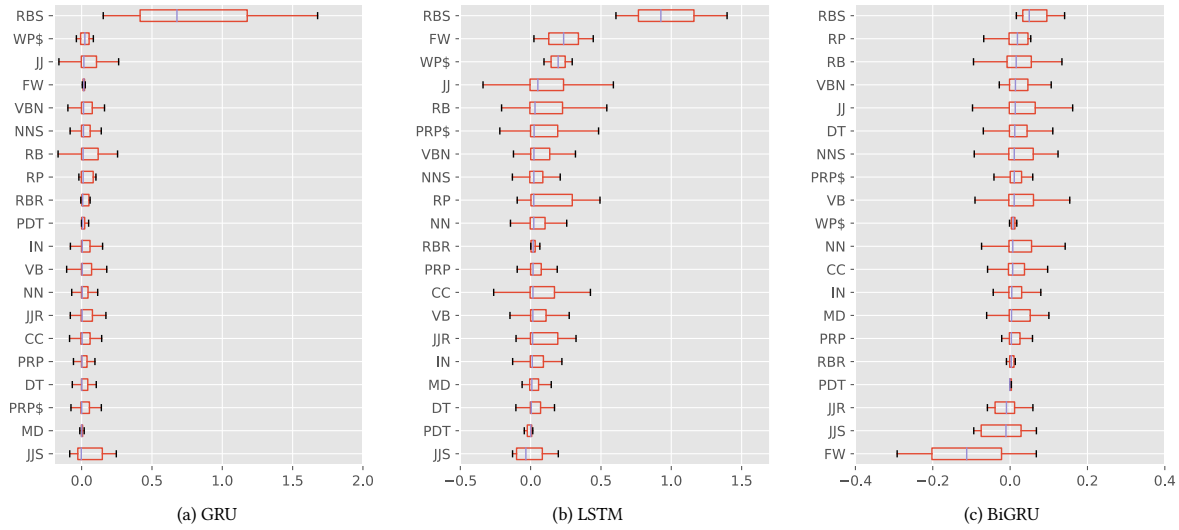
confidence), respectively. We display the attribution heatmaps for positive prediction for all three architectures in Fig. 5. GRU gives nearly the same absolute value of attribution score for "fun" and "tedious". LSTM attributes more words positive contributions than negative words, while BiGRU gives more words negative contribution scores. These attribution heatmaps well reflect the prediction scores, which thus indicates that the interpretations could give users understandable rationale for the predictions.

4.6.3 Visualization for Hierarchical Attribution. We also give the visualization heatmaps of hierarchical attributions in Fig. 6. In this case, we show the attribution scores of a negative sentiment prediction with 99.46% confidence from a LSTM model. For the word-level attribution, "does" has a negative contribution for the prediction, while the combination "does n't serve up" will have a strong positive contribution for the prediction. The clause-level attribution shows that the first clause has a relatively small negative contribution for prediction, while the second clause has a strong positive contribution for prediction. This hierarchical attention thus could represent the contributions at different levels of granularity.

4.7 Linguistic Patterns Analysis

In this section, we apply REAT to analyze the linguistic patterns, in order to comprehend what kind of linguistic knowledge in natural language has been captured by RNNs. We aim to understand whether the linguistic patterns learned are consistent with human cognition. Overall, the analysis of linguistic patterns is implemented by obtaining the contribution score distributions for different syntactic categories. We first tag each word in a text into different part-of-speech (POS) categories. Here, the tagging is performed using the NLTK package[3]. We then proceed by feeding that text to the RNN model and use REAT to generate the contribution score for each word. For each text, the class of interest is its prediction label generated by the RNN model. After that, we summarize the contribution scores for each syntactic category by averaging the scores for all words in that category contained in the dataset.



We employ the SST2 test set to analyze linguistic patterns for the three RNN architectures, and use boxplot to illustrate the distribution patterns, as illustrated in Fig. 7. Note that we rank different categories according to the median value. Besides, we combine different verb forms (e.g., past tense and present tense) to a single one, since we observe these verb variants have similar distribution patterns. Also, to capture the primary contribution of each POS category towards the prediction, we omit the outlier points when drawing the boxplot, i.e., those data points that are located outside the fences of the boxplot. An interesting discovery from the boxplots is that, the RBS category, which denotes superlative adverb such as "best" and "most", achieves the highest median value on all three RNN architectures. This is consistent with our human cognition since we indeed rely on these superlative words to express strong emotions. Besides, the adjective category (JJ) ranks relatively high among all the three architectures. The noun category (NN) has a near-zero median for all three architectures. It indicates that these recurrent models are more sensitive to adjectives than nouns, which also makes sense to common cognition habits. In addition, we can observe that the attribution score distribution patterns are similar between GRU and LSTM, while they are very distinct from that of BiGRU. This is partly due to the reason that BiGRU has a bidirectional structure, which will make it use different evidence in making predictions. These findings demonstrate that these RNNs have learned some useful patterns and pay special attention to words that well represent the underlying task.

4.8 Model Misbehavior Analysis

In this section, we apply REAT as a debugging tool to analyze the misbehavior of RNNs. This is motivated by the observation that RNN models may not always meet the expectations of humans, since their performances are still not perfect (see Tab. 3). In this case, the attribution method can be utilized as the tool to analyze their vulnerability and reason the failure cases.

4.8.1 Attribution-based Failure Case Debugging. We use a sample text in the SST2 test set to illustrate this process. The LSTM gives a 99.97% negative sentiment prediction for a text "Schweiger is talented and terribly charismatic, qualities essential to both movie stars and social anarchists". However, this prediction makes no sense to humans, since it is in fact a strong positive sentiment text. Using the proposed attribution method, we find that "terribly" makes the highest contribution for this negative prediction. One possible explanation is that the LSTM model only captures the meaning similar to "terrible", and ignores its other meanings relevant to "extremely", since "terribly" is a polysemant. To validate this hypothesis, we further generate the attribution score distribution for two words "terrible" and "terribly" (see Fig. 8), and find that these two words have consistently negative contribution for positive sentiment. It comes as no surprise, since we use pre-trained word2vec as word embeddings, which are fixed and context-free representations and are limited in performance. Besides, the training set only contains a limited number of apperances of "terribly".

(a) GRU (b) LSTM (c) BiGRU

Figure 7: POS category score distributions of three RNN architectures. The x axis denotes attribution scores.

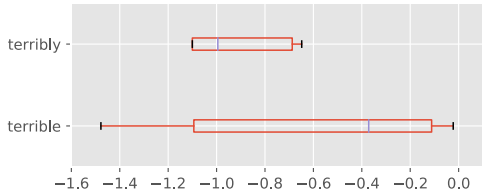

Figure 8: Attribution score distribution for two words.

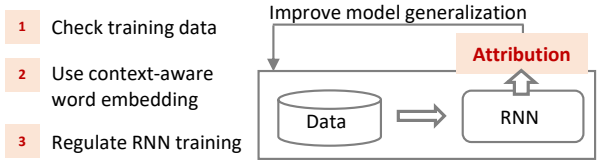

Figure 9: Utilizing attribution to improve models.

This makes the model fail to learn language polysemy and capture the context dependent meaning of "terribly".

4.8.2 Attribution-based Adversarial Attack. Based on the above attribution analysis, we can perform adversarial attacks using interpretable perturbation. Recent work shows that DNNs are fragile, where a small perturbation could dramatically change their prediction results [11, 24, 30]. We change the word "terribly" to its synonyms "extremely" and "very", as shown in Tab. 6. As the result, the prediction for this text shifts from strong negative to strong positive for both conditions, even though the real meaning of the original text is unchanged. Beside this example, such adversarial attack finding applies to other texts in SST2 dataset. We search for texts in test set of SST2, which contain word "extremely" and are originally assigned positive predictions by the LSTM classifier. We change the word "extremely" in the original text to "terribly", as can be seen in Tab. 7. Although the modified texts are semantically identical to our humans, both predictions of these two samples switch from strong positive to strong negative, demonstrating to some extent the vulnerability of this LSTM classifier.

4.8.3 Discussion of Attribution-based Model Generalization Enhancement. The derived attribution method can also be employed to promote the generalization performance of RNN classifiers. Although all the three pretrained RNN classifiers could achieve 100% accuracy on training set of SST2, all of their accuracy on the test set are below 82%. This big gap indicates that the RNN classifiers have overfitted to the training set and may have memorized the artifacts and biases that widely exist in texts. Through examining the failure reasons using the the proposed attribution method, or through attacking the RNN classifiers using attribution-based adversarial samples, we could identify the problem of the RNN classifier. We further propose three directions to promote the generalization ability of RNN classifiers, from the perspective of the training data, word embedding or recurrent model, respectively, as illustrated in Fig. 9. First, if attribution statistic analysis shows that the RNN has learned lots of bias from the training data, then we can check the training data to reduce the data imbalance or data leaking problem to make sure the training data is less biased. Second, if attribution analysis tell us that trained RNN cannot capture context dependent meanings of words, then we can replace context-free and fixed word embeddings, such as word2vec [25] and GloVe [31], to context-aware embeddings, such as the recently proposed ELMo [33], ULMFiT [15] and BERT [8]. Third, if the attribution analysis indicates that the RNN heavily relies on superficial correlations in the training data, then we can add a regularizer to regulate the training behavior of the original RNN model. Bridging attribution with improving model generalization is a challenging topic, which is beyond the length of this paper and will be further investigated in our future research.

	Text	Prediction
Original	Schweiger is talented and terribly charismatic, qualities essential to both movie stars and social anarchists.	Negative (99.97%)
Adversarial	Schweiger is talented and extremely charismatic, qualities essential to both movie stars and social anarchists.	Positive (81.29%)
Adversarial	Schweiger is talented and very charismatic, qualities essential to both movie stars and social anarchists.	Positive (99.53%)

Table 6: Interpretable adversarial attack for a LSTM classifier based on attribution.

	Text	Prediction
Original	Occasionally melodramatic, it 's also extremely effective.	Positive (99.74%)
Adversarial	Occasionally melodramatic, it 's also terribly effective.	Negative (99.00%)
Original	Extremely well acted by the four primary actors, this is a seriously intended movie that is not easily forgotten.	Positive (99.98%)
Adversarial	Terribly well acted by the four primary actors, this is a seriously intended movie that is not easily forgotten.	Negative (87.70%)

5 RELATED WORK

Interpretable machine learning is a research topic covering a wide range of directions [3, 9, 17, 23, 43, 45]. In this section, we focus on post-hoc and local interpretation methods which are most relevant to ours and briefly review methods that could provide interpretations for RNN predictions. These attribution methods can be further classified into the following three main categories.

Back-propagation Based Methods This line of work calculates the gradient or its variants of the output with respect to the input, for a particular class of interest, using back-propagation to derive the contribution of words. The philosophy is to identify the words whose variation will most significantly lead to the change of output probability. In the simplest case, the gradient signal is back-propagated, which is first proposed in CNN image classification [38] and later introduced to provide attribution for text classification in NLP. In NLP, gradients are computed with respect to individual entries in word embedding vectors, and then the L2 norm [13] or the dot product of the gradient and the word embedding [7] is calculated to reduce the gradient vector to a scalar, representing the contribution of a single word. Besides gradient signal, some work proposes to back-propagate different signals to the input, such as the relevance of the final prediction score through each layer of the network onto the input layer [1, 2], or only considering the positive gradient signals in the back-propagation process [40].

Perturbation Based Methods The motivation of perturbation based methods is that the most important word for a prediction, once perturbed, will cause the largest probability drop of the output for the target class. We can implement the perturbation in two ways: omission [16, 19] and occlusion [34]. For omission, the word is deleted directly [16]. As for occlusion, the word is replaced with a baseline input. Here, a zero-valued word embedding is utilized [34]. However, both omission and occlusion could make the sentence nonsensical. Since word order is an essential factor of RNN predictions, either omission or occlusion can destroy the word order and thus may trigger the adversarial side of RNN. Therefore, it cannot guarantee that it is meaningful interpretations.

Local Approximation Based Methods These methods are based on the assumption that behaviors of a complex and opaque model around the neighborhood of a given input can be approximated by a simple and interpretable white-box model [35]. A sparse linear model, for example, can be utilized as the locally interpretable model and the weight vector of the linear model is used as the contribution score for a RNN prediction. Sometimes, even the local behavior of a complex model can be extremely non-linear, where linear explanation could lead to poor performance. Therefore, models that are able to capture the non-linear relationship are utilized as the local approximation model. For example, a local attribution method can be designed using if-then rules [36]. Experimental results demonstrate that the generated rules could be utilized to explain both the current instance and some other relevant instances.

The most similar work to ours are two decomposition based methods [27, 28]. However, their work are exclusively designed for LSTM, while our attribution method is widely applicable to different recurrent neural network architectures.

6 CONCLUSION

We propose a new RNN attribution method, called REAT, to provide interpretations for RNN predictions. REAT decomposes the prediction of a RNN as the additive contribution of each words in the input text, in order to faithfully calculate the response of RNN to the input. REAT could also generate phrase-level attribution scores, which can be combined with syntactic parsing algorithms towards attribution at varying granularity. We apply REAT to three standard RNN architectures, including GRU, LSTM and BiGRU. Empirical results on two sentiment analysis datasets validate that interpretations generated by REAT are both interpretable to humans and faithful to the original RNN classifier. We further demonstrate that REAT can reveal the useful linguistic patterns learned by RNNs. In addition, we find that RNN models sometimes capture biases in the training data, which causes them to be vulnerable to adversarial attacks. Leveraging the debugging ability provided by REAT, we are able to identify the problems of RNN, and point out several promising directions to improve RNN's generalization ability. This is a challenging topic and will be investigated in our future research.

ABSTRACT

Recent interest in graph embedding methods has focused on learning a single representation for each node in the graph. But can nodes really be best described by a single vector representation? In this work, we propose a method for learning multiple representations of the nodes in a graph (e.g., the users of a social network). Based on a principled decomposition of the ego-network, each representation encodes the role of the node in a different local community in which the nodes participate. These representations allow for improved reconstruction of the nuanced relationships that occur in the graph – a phenomenon that we illustrate through state-of-the-art results on link prediction tasks on a variety of graphs, reducing the error by up to 90%. In addition, we show that these embeddings allow for effective visual analysis of the learned community structure.

1 INTRODUCTION

Learning embedded representations of graphs is a recent and very active area [2, 14, 25, 37, 38, 44]. In a nutshell, an embedding algorithm learns a latent vector representation that maps each vertex v in the graph G to a *single* d dimensional vector. This area has found strong applications, as the embedding representation of nodes leads to improved results in data mining and machine learning tasks, such as node classification [37], user profiling [39], ranking [26], and link prediction [2, 25]. In virtually all cases, the crucial assumption of the embedding methods developed so far is that a *single* embedding vector has to be learned for each node in the graph. Thus, the embedding method can be said to seek to identify the single role or position of each node in the geometry of the graph.

This observation allows us to draw a historical parallel between the very recent research area of graph embedding and the more established field of community detection or graph clustering [22, 24]. Detecting clusters[1] in real world networks is a central topic in computer science, which has an extensive literature. At the beginning of its development, graph clustering has focused mostly on the study of non-overlapping clustering methods [24, 43]. In such methods, each node is assigned to a *single* cluster or community. While the problem of non-overlapping clustering is better understood and has found strong applications and theoretical results, recently, much attention has been devoted to developing *overlapping* clustering methods [16, 20, 40], where each node is allowed to participate in multiple communities. This interest in overlapping comunities is motivated by a number of recent observations of real world networks [1, 16, 19, 29, 30] that show a lack of clear (non-overlapping) community structure.

These findings motivate the following research question: can embedding methods benefit from the awareness of the overlapping clustering structure of real graphs? In particular, can we develop methods where nodes are embedded in multiple vectors, representing their participation in different communities?

In this paper, we provide positive results for these two questions. We develop Splitter, an unsupervised embedding method that allows nodes in a graph to have multiple embeddings to better encode their participation in multiple overlapping communities. Our method is based on recent developments in ego-net analysis, in particular, in overlapping clustering algorithms based on ego-network partitioning [20]. More precisely, we exploit the observation in [16, 19, 20, 40] that cluster structure is easier to identify at the local level. Intuitively, this happens because each node interacts with a given neighbor in usually a single context (even if it is part of many different commmunities in total).

Splitter extends this idea to the case of node embeddings. In particular, we exploit the *persona graph* concept defined by Epasto et al. [20]. This method, given a graph G, creates a new graph G_P (called the persona graph of G), where each node u in G is represented by a series of replicas. These replica nodes, (called the *persona*(s) of u) in G_P, represents an instantiation of the node u in the local community to which it belongs. The method was originally introduced to obtain overlapping clusters. In this paper, we instead show that ego-net based techniques can lead to improvements in

[1]Note that in the paper, we use the terms "cluster" and "community" interchangeably.

embedding methods as well. In particular, we demonstrate that a natural embedding method based on the persona graph outperforms many embedding baselines in the task of link prediction.

To summarize, the contributions of this paper are as follows:

(1) We introduce Splitter, a novel graph embedding method that embeds each node in the graph into multiple embedding vectors, which is based on the analysis of the overlapping structure of communities in real networks.
(2) Our method adds a novel graph regularization constraint to the optimization that enforces consistency of the multiple learned representations for each node.
(3) The method automatically determines the number of embeddings used for each node depending on a principled analysis of the local neighborhood of the node. This does not require the user to specify the number of embeddings as a parameter.
(4) We show experimentally strong improvements over several embedding baselines for the important task of link prediction.
(5) We show how our method enables visual discovery of community membership for nodes that are part of multiple social groups.

2 METHOD

In this section we describe Splitter, our proposed method for learning multiple community-aware representations for a node. First, we start with a review of the preliminaries necessary to understand the work in Section 2.1. Next, in Section 2.2 we discuss our extension for learning multiple node representations. Then we introduce Splitter in Section 2.3, and close with discussing some details of the optimization in Section 2.4.

2.1 Preliminaries

Our method builds upon recent work related to node decomposition [20], and learning node representations with neural networks [35, 37, 38]. Here we describe the basics of both methods.

2.1.1 Notation. We begin with some notation. Let $G = (V, E)$ be an undirected graph[2] consisting of a set V of nodes and a set $E \subset V \times V$ of edges. Let $G[U] = (U, E \cap U \times U)$ be the induced graph of a subset of G's nodes, $U \subset V$. Given a node $u \in V$, we denote its neighborhood as the set of nodes connected to it $N_u = \{v; (u, v) \in E\}$, and its *ego-network* (or ego-net) as the graph induced on the neighborhood $G[N_u]$. We note that the ego-net of u does not include the node u itself in this definition. Finally, let $\mathcal{A}$ be a *non-overlapping clustering* algorithm that given G as an input, returns a partition $\mathcal{A}(G) = (V_1, \ldots, V_t)$ of the vertices V into t disjoint sets (let $\mathrm{np}_{\mathcal{A}}(G) = t$ denote the number of partitions in output.).

2.1.2 Persona Decomposition. The topic of community detection and graph clustering has been of great interest to the community over the last several decades. While much work has focused on finding large clusters, it has been noted that while the community detection problem is hard at scale (the *macroscopic* level), it is relatively trivial when viewed locally (the *microscopic* level) [17, 19]. Using this intuition, a recent proposal from Epasto et al. [20] uses the clusters found in the ego-network of a node (its neighbors and their induced subgraph) as the basis to define a new graph, the *persona graph*, G_P. The nodes in this new graph, which are called *personas*, divide the interactions of each original node in G into several semantic subgroups, which capture different components (or senses) of its network behavior.

More formally, let us assume that we are given a graph G and a clustering algorithm $\mathcal{A}$. The persona decomposition (as proposed in [20]) employs the following algorithm PersonaGraph$(G, \mathcal{A})$ to transform G to its persona graph G_P:

(1) For each node $u \in V$, we use the clustering algorithm $\mathcal{A}$ to partition the ego-net of u. Let $\mathcal{A}(G[N_u]) = \{N_u^1, N_u^2, \ldots, N_u^{t_u}\}$, where $t_u = \mathrm{np}_{\mathcal{A}}(G[N_u])$.
(2) Create a set V' of personas. Each node v_o in V will correspond to t_{v_o} personas (the number of splits of the ego-net of v_o) in V_P, denoted by v_i for $i = 1, \ldots, t_{v_o}$.
(3) Add edges between personas. If $(u, v) \in E$, $v \in N_u^i$ and $u \in N_v^j$, then add an edge (u_i, v_j) to E_P.

After using this procedure, one obtains the persona graph G_P which has some interesting properties. First, every node in G_P is a node from the original graph, split into one or more personas. However, there is no additional connectivity information – the number of edges in G_P is equal to the number of edges in the persona graph. This means that the space required to store G_P is (almost) the same as the original graph. Second, each node in the original graph can be mapped to its corresponding persona(s). However, the community structure of G_P can be wildly different from the original graph. Standard clustering methods, when run on G_P instead genereate overlapping clusterings of G. This phenomena of exposing differing clustering information is visualized further in Section 4.

2.1.3 Graph Embedding. Before introducing our method for learning multiple embeddings for each node, we first review the standard setting of network representation learning, in which a single embedding is learned for each node. The purpose of network embedding is to learn a mapping $\Phi\colon v \in V \mapsto \mathbb{R}^{|V| \times d}$, which encodes the latent structural role of a node in the graph. This, in practice, can be achieved by representing the mapping Φ as a $|V| \times d$ matrix of free parameters that are learned by solving an optimization problem. Perozzi et al. [37] first introduced a modeling of the vertex representation that encodes the node as a function of its co-occurrences with other nodes in short truncated random walks.

More precisely, the method consists of performing multiple random walks over the social graph from each node. The sequences of these walks are then used to extract the co-occurrences of nodes in short sub-windows. These co-occurrences capture the diffusion in the neighborhood around each vertex in the graph, and explore the local community structure around a node. More concretely, the goal of the embedding method is to learn a representation that enables an estimate of the likelihood of a vertex v_i co-occurring with other nodes in the sub-window of a short random walk:

$$\Pr\Big(v_i \mid \big(\Phi(v_1), \Phi(v_2), \cdots, \Phi(v_{i-1})\big)\Big) \tag{1}$$

[2]The method can be also defined for directed graphs in the obvious way; however, we describe it for undirected graphs for simplicity

Notice that the exact computation of this conditional probability is computationally expensive for increasing lengths of the random walks, so DeepWalk uses two techniques to address this challenge. First, the order of the neighboring vertices is ignored. Second, the method reverses the learning task; instead of predicting a missing vertex using the context, it addresses the opposite problem of predicting its local structure using the vertex itself.

These modifications result in the following optimization problem for computing the vertex representations of each node in DeepWalk:

$$\underset{\Phi}{\text{minimize}} \quad -\log \Pr\left(\{v_{i-w}, \cdots, v_{i+w}\} \setminus v_i \mid \Phi(v_i)\right) \tag{2}$$

In the DeepWalk [37] model, the probability of a node v_i co-occurring with v_j is estimated by using a softmax to map the pairwise similarity to a probability space,

$$Pr(v_i|v_j) = \frac{exp(\Phi(v_i) \cdot \Phi'(v_j))}{\sum_{j \in \mathcal{V}} exp(\Phi(v_i) \cdot \Phi'(v_j)} \tag{3}$$

Where $\Phi'(v_i)$ and $\Phi'(v_j)$ represent the "input" and "output" embeddings for node v_i and v_j respectively [34].

2.2 Learning Multiple Node Representations

As discussed so far, network representation learning seeks to learn a function that maps each node to its own representation. Here, we discuss our modifications that were made in light of the fact that we wish to learn one or more representation for each node.

Using the persona decomposition discussed in Section 2.1.2, we can convert the input graph G into the persona graph G_P. From here, it seems like a straightforward application of existing methods to learn one representation for each node $v \in |V_P|$, and as such, learn one or more representation for each original node $u \in |V|$. Unfortunately, this is not the case. The strength of the persona decomposition is also a weakness - it can create a graph that is quite different from that of the original input. In fact, the persona graph can be so different that it may consist of many disconnected components, even if the original graph was connected! Thus, these disconnected components can cause difficulties for representation learning methods. To address these challenges, we propose two improvements to the learning algorithm.

First, we propose adding a constraint, that the persona representations be able to predict their original node in addition to predicting the personas around it in G_P. Specifically, given a persona v_i, we propose to require its representation include a dependency on the node v_o in the original graph G:

$$\Pr\left(v_o \mid \Phi_{G_P}(v_i)\right). \tag{4}$$

To control the strength of our graph regularization, we introduce the parameter λ, which combines with Eq. (2) to yield the following optimization problem:

$$\begin{aligned}\underset{\Phi_{G_P}}{\text{minimize}} \quad & -\log \Pr\left(\{v_{i-w}, \cdots, v_{i+w}\} \setminus v_i \mid \Phi_{G_P}(v_i)\right) \\ & -\lambda \log \Pr\left(v_o \mid \Phi_{G_P}(v_i)\right).\end{aligned} \tag{5}$$

Put another way, this change to the optimization enforces that there are invisible edges to each persona's parent, informing the learning process and regularizing the degree to which the persona representations can deviate. This effectively lets the model reason about the different connected components that may exist after the persona transformation. We note that in practice, we achieved good results on all graphs we considered by simply setting $\lambda = 0.1$.

Secondly, we propose to also make the representation $\Phi_{G_P}(v)$ of a node v's personas depend on its original representation $\Phi_G(v)$ as a prior via initialization. Initializing all personas to the same position in $\mathbb{R}^d$, combined with the regularization term from Eq. (5), constrains the persona embeddings to behave like cohesive parts of a single entity. We note that this does not mean that all of a node's personas end up in the same position at the end of the optimization! Instead, we find that personas with similar roles stay close together, while personas with different roles separate. This is discussed further in Section 4.2, where we examine a visualization of Splitter embeddings. Finally, there is an additional benefit of using the representation of the original graph Φ_G as an initialization – it can help avoid potentially bad random initializations, which can lower task performance [14].

Inference with Multiple Representations. Notice that our method outputs multiple embeddings for each node. To do inference of node features or to predict edges between nodes, one can use standard ML methods to learn a function of the multiple embeddings of each node (or pair of nodes). However, basic aggregations can work too. In our experiments with link prediction, we simply use the maximum dot product over all pairs of embeddings of u and v to predict the likelihood of the pair of nodes being connected.

2.3 Splitter

Using the ideas discussed so far, we present the details of our approach.

2.3.1 Parameters. In addition to an undirected graph $G(V, E)$, the clustering algorithm $\mathcal{A}$ used to obtain the persona graph, as well as the dimensionality of the representations d, our algorithm uses a number of parameters that control the embedding learning process. The first group of parameters deal with sampling G, an essential part of any graph embedding process. Without loss of generality, we describe the parameters to control the sampling process in the notation of Perozzi et. al [37]. Briefly, they are w, the window size to slide over the random walk, t, the length of the random walk to sample from each vertex, and γ the number of walks per vertex. We emphasize that our approach is not limited to simple uniform random walk sampling - any of the more recently proposed graph sampling strategies [25, 35, 38] can be applied in the Splitter model.

The next group of parameters control the optimization. The parameter α controls the learning rate for stochastic gradient descent, and λ effects how strongly the original graph representation regularizes the persona learning.

Finally, an embedding function EmbedFn is used to learn a representation Φ_G of the nodes in the original graph. In order to use the learning algorithm that we specify, this embedding method simply needs to produce representations where the dot-product between vectors encodes the similarity between nodes. The most popular graph embedding methods meet this criteria, including DeepWalk [37], LINE [44], and node2vec [25].

Algorithm 1 SPLITTER. Our method for learning multiple representations of nodes in a graph

Input:
$G(V, E)$, a graph
w, window size
d, embedding size
γ, walks per vertex
t, walk length
α, learning rate
λ, graph regularization coefficient
$\mathcal{A}$, clustering algorithm for the ego-nets
EMBEDFN, a graph embedding method which uses the dot-product similarity (e.g. DeepWalk, node2vec)

Output:
Φ_{G_P} a matrix with one or more representations for each node
$P2N$, a mapping of the rows of Φ_{G_P} to V (the original nodes)

1: **function** SPLITTER(G, EMBEDFN)
2: $G_P \leftarrow$ PERSONAGRAPH$(G, \mathcal{A})$ ▷ Create the persona graph G_P of G using clustering algorithm $\mathcal{A}$ and method in [20].
3: $P2N \leftarrow \emptyset$
4: $\Phi_G \leftarrow$ EMBEDFN(G, w, d, γ, t) ▷ Embed original graph
5: **for each** $v_o \in V$ **do**
6: **for each** $v_j \in$ personas of v_o **do**
7: $\Phi_{G_P}(v_j) \leftarrow \Phi_G(v_o)$ ▷ Initialize j-th persona of v_o
8: $P2N(v_j) \leftarrow v_o$
9: **for** $i = 0$ to γ **do**
10: $O = \text{Shuffle}(V_{G_P})$
11: **for each** $v_i \in O$ **do**
12: $\mathcal{W}_{v_i} = RandomWalk(G_P, v_i, t)$
13: **for each** $v_j \in \mathcal{W}_{v_i}$ **do**
14: **for each** $u_k \in \mathcal{W}_{v_i}[j - w : j + w]$ **do**
15: $J_{G_P}(\Phi_{G_P})_= - \log \Pr(u_k \mid \Phi(v_j))$
16: $J_G(\Phi_{G_P})_= - \log \Pr(P2N(v_j) \mid \Phi(v_j))$
17: $\Phi_{G_P} = \Phi_{G_P} - \alpha * \left(\frac{\partial J_{G_P}}{\partial \Phi_{G_P}} + \lambda \frac{\partial J_G}{\partial \Phi_{G_P}} \right)$
18: **return** Φ_{G_P}, $P2N$

2.3.2 Algorithm. Here, we describe our full algorithm, shown in Algorithm 1 in detail. Lines 2-4 initialize the data structures, create the persona graph, and learn the embedding of the underlying graph. We note that not all of the nodes will necessarily be split; this will depend on each ego-net's structure, as described in Section 2.1.2. Lines 5-8 use the persona graph to initialize the persona representations Φ_{G_P}. The remainder of the algorithm (lines 9-17) details how the persona representations are learned. Line 12 generates the random walks to sample the context of each vertex. WLOG can be graph samples generated in any meaningful way - including uniform random walks [37], skipped random walks [38], or random walks with backtrack [25]. Line 15 calculates the loss due to nodes in the persona graph (how well the persona representation of Φ_{v_j} is able to predict the observed node u_k). Line 16 computes the loss due to the graph regularization (how well the persona representation Φ_{v_j} is able to predict its corresponding original node). Finally, line 18 returns the induced representations Φ_{G_P} and their mapping back to the original nodes $P2N$.

Complexity. The complexity of the algorithm is dominated by two major steps: creating the persona graph and the Skip-gram model learning. Both parts have been analyzed in previous works [14, 20], so we report briefly on the complexity of our algorithm here. Suppose the clustering algorithm $\mathcal{A}$ used on the ego-nets has a complexity of $T(m')$ for analyzing an ego-net of m' edges. Further, suppose the original graph has $\mathcal{T}$ triangles. As such, the persona creation method has a total running time $O(\mathcal{T} + m + \sqrt{m}T(m))$. Moreover, as a worst case, $\mathcal{T} = O(m^{3/2})$ the complexity is $O(m^{3/2} + \sqrt{m}T(m))$. Suppose, for instance, that a linear time clustering algorithm is used; then, the total cost of this phase as a worst case is $O(m^{3/2})$. However, as observed before [20], the algorithm scales much better in practice than this pessimistic bound because the number of triangles is usually much smaller than $m^{3/2}$. The embedding method for a graph of n' total nodes in the persona graph has instead a complexity $O(n'\gamma t w d \log(n')))$, as shown in [14], where d is the number of dimensions, t is the walk length size, w is the window size and γ is the number of random walks used. Notice, that $n' \in O(m)$, as each node u can have at most $O(deg(u))$ persona nodes, so the worst case complexity is: $O(m^{3/2} + \sqrt{m}T(m) + m\gamma t w(d + d\log(m)))$.

2.4 Optimization

As detailed in [37], using representations to predict the probability of nodes (Line 15-16, Algorithm 1) is computationally expensive. To deal with this, we use the hierarchical softmax [34] to calculate these probabilities more efficiently. For completeness's sake, we remark that an alternative optimization strategy exists (using noise contrastive estimation [34]).

Thus, our model parameter set includes both Φ_{G_P} and T, the parameters used internally by the tree in the hierarchical softmax. Further, we use the back-propagation algorithm to estimate the derivatives in lines 15-16, and a stochastic gradient descent (SGD) to optimize the model's parameters. The initial learning rate α for SGD is set to 0.025 at the beginning of the training and then decreased linearly with the number of nodes we have seen so far. Additionally, the parameter λ regularizes the persona embeddings by how much they deviate from the node's original representation.

3 TASK: LINK PREDICTION

In this section, we study how the SPLITTER model proposed so far can be used for the task of link prediction – judging the strength of a potential relationship between the two nodes. We focus on this fundamental application task for the following reasons.

First, we are interested in developing new models that can capture the variation of social behaviors that are expressed in real-world social networks (such as membership in multiple communities). Several recent works suggest that link prediction (or *network reconstruction*) [2, 50] is the best way to analyze an unsupervised network embedding's performance, as it is a primary task (unlike node classification - a secondary task that involves a labeling process that may be uncorrelated with the graph itself). Second, there are several important industrial applications of link prediction on

real networks (e.g. friend suggestion on a social network, product recommendation on an e-commerce site, et cera).

Finally, this task highlights a particular strength of our method. Splitter's ability to model the differing components of a node's social profile (its *personas*) make it especially suitable for the task of link prediction. This addresses a fundamental weakness of most node embedding methods, which effectively treat a node's representation as an average of its multiple senses – a representation that may not make sense in continuous space. Unlike previous work utilizing community information in embeddings [12, 47, 51], we aim to expose the nuanced relationships in a network by sub-dividing the nodes (not the macro-scale community relationships found by joining nodes together).

3.1 Experimental Design

3.1.1 Datasets. We test our Splitter method as well as other baselines on a dataset of five directed and undirected graphs. Our datasets are all publicly available: PPI is introduced [25, 42], while the other datasets are from Stanford SNAP library [28]. For each dataset, in accordance with the standard methodology used in the literature [2, 25], we use the largest weakly connected component of the original graph. We now provide statistics for our dataset.

Directed graphs:

(1) **soc-epinions**: A social network $|V| = 75,877$ and $|E| = 508,836$. Edges represent who trusts whom in the opinion-trust dataset of Epinions.

(2) **wiki-vote**: A voting network $|V| = 7,066$ and $|E| = 103,663$. Nodes are Wikipedia editors. Each directed edges represents a vote for allowing another user becoming an administrator.

Undirected graphs:

(1) **ca-HepTh**: Arxiv's co-author network of High Energy Physics Theory $|V| = 9,877$ and $|E| = 25,998$. Each edge represents co-authorship between two author nodes.

(2) **ca-AstroPh**: Arxiv's co-author network of Astrophysics, $|V| = 17,903$ and $|E| = 197,031$. Each edge represents co-authorship between two author nodes.

(3) **PPI**: Protein-protein interaction graph, $|V| = 3,852$ and $|E| = 20,881$. This represents a natural dataset, where each node is a protein and there is an edge betwen two proteins if they interact (more details in [25]).

3.2 Task

The Link Prediction task follows the methodology introduced in [2, 25], which we briefly detail here. First, the input graph is split into two edge sets, E_{train} and E_{test}, of equal size. The test edges are removed uniformly at random, with the restriction that they do not disconnect the graph. E_{test} is then used as positive examples for a classification task. A corresponding equal sized set of non-existent (random) edges are generated to use as negative examples for testing. The baseline methods are providing the training edges as input, which they use to learn a similarity model (embedded or otherwise). The performance of each method is then measured by ranking the removed edges. Specifically, for each method, we report the ROC-AUC.

3.3 Methods

Here we describe the numerous baseline methods we tested against, including both traditional non-embedding baselines (such as common neighbors) and several embedding baselines. We also detail the application of Splitter's multiple representations of this task.

Non-embedding Baselines: Here, we report standard methods for link prediction that are solely based on the analysis of the adjacency matrix of the graph and in particular, on the immediate neighborhood of the nodes in the graph. These methods take into input E_{train} during inference. Thus, we denote $N(u)$ as the neighbors of u observed in E_{train}. For directed graphs, $N(u)$ only refers to the outgoing edges. In the non-embedding baseline considered, we score an edge (u, v) as a $g(u, v)$, which is a function of $N(u)$ and $N(v)$ only. We consider the following baselines:

(1) **Jaccard Coefficient (J.C.) :**

$$g(u, v) = \frac{|N(u) \cap N(v)|}{|N(u) \cup N(v)|}$$

(2) **Common Neighbors (C.N.):**

$$g(u, v) = |N(u) \cap N(v)|$$

(3) **Adamic Adar (A.A.):**

$$g(u, v) = \sum_{x \in N(u) \cap N(v)} \frac{1}{\log(|N(x)|)}$$

We apply these methods to both the original graph and the persona graph. For the persona graph, we follow a technique similar to our Splitter method to extract a single score from the pairwise similarity (say Jaccard Coefficient) of the multiple persona nodes of a pair of nodes u,v. We also define the Jaccard Coefficient of u, v in the persona graph as the maximum Jaccard Coefficient of a persona node of u and a persona node of v in the persona graph. Similarly, we define the baselines Common Neighbors and Adamic Adar in the persona graph. We report results for using the maximum as aggregation function consistently with our Splitter method, but we experimented as well with many other functions, such as the minimum and the mean and we observed the maximum to perform best.

Embedding Baselines: We also consider the following embedding baselines. These methods take as input E_{train} to learn embedding $\Phi_G(u)$ for every graph node u. During inference, then only the learned embedding are used but *not* the original graph. We compare against these state-of-the-art embedding methods:

(1) Laplacian **EigenMaps** [6] determines the lowest eigenvectors of the graph Laplacian matrix.

(2) **node2vec** [25] learns the embedding by performing random walks on the training edges E_{train} and learning a minimizing skipgram objective (Equation 3).

(3) **DNGR** [11] performs a non-linear (i.e. deep) node embeddings passing a "smoothed" adjancency matrix through a deep auto-encoder. The "smoothing" (called Random Surfing) an alternative to random walks, which effectively has a different context weight from node2vec.

(4) **Asymmetric** [2] is a recent method that learns embeddings by explicitly modeling the edges that appear in the graph.

Table 1: We report the ROC-AUC for a link prediction task performed using an ablation test. The columns J.C., C.N. and A.A. stand for the baselines jaccard coefficient, common neighbors and adamic-adar, respectively. The rows represents the datasets (directed and undirected) while the columns represent the methods compared. We compare our Splitter method with three non-embeddings methods (applied to both the original and persona graph) as well four embeddings baselines. For the embedding methods we report results using dimensionality $\{8, 16, 32, 64, 128\}$. We report in bold the highest AUC-ROC for each dimension and dataset. Notice that for Splitter the dimension refers to the size of the embedding of each persona node (i.e. the total embedding size of each node is larger). The next table reports results at parity of space. Results with † indicate lack of completion. We used a machine with 32 GB ram.

Dataset	Avg. Personas per Node $\bar{p}$
soc-epinions	3.03
wiki-vote	4.00
ca-HepTh	2.39
ca-AstroPh	2.53
ppi	4.97

Table 2: Average number of persona nodes per node in original graph.

We compare against the most similar model proposed in the work, the shallow asymmetric model.

(5) **M-NMF** [47] uses a modularity based community detection model to jointly optimize the embedding and community assignment of each node. Unlike Splitter, this method assigns each node to one community, and is based on joining nodes together (not splitting them apart).

We run each of these methods with their suggested default parameters.[3]

During inference with the baselines, we use the embedding of a pair of node u and v to rank the likelihood of the link u, v formed by employing a scoring function that takes in the input the embeddings of the two nodes. To do so, for consistency with previous work, we used the same methodology of [2], which we summarize here. Let Y_u and Y_v be, respectively, the embeddings of u and v. The edge scoring function is defined as follows: for **EigenMaps**,

[3]In order to advance the field, and ensure the reproducibility of our method, we are releasing an implementation of Splitter at https://github.com/google-research/google-research/tree/master/graph_embedding/persona.

it is $-||Y_u - Y_v||$; for **node2vec**, we use the off-shelve binary classification LogisticRegression algorithm of sklearn to lean a model over the Hadamard product of the embeddings of the two nodes; for **DNGR**, we use the bottleneck layer values as the embeddings and the dot product as similarity; for **Asymmetric**, we use the dot product; and for **M-NMF**, similarly to node2vec, we train a model on the Hadamard product of the embeddings.

Our Method (Splitter): In order to use Splitter for link prediction, we need a method to calculate a single similarity score between two nodes (u,v) in the original graph G, each of which may have multiple persona representations. Specifically, as the Splitter embedding model uses the dot-product to encode the similarity between the two node's representations, we need a method to extract a single score from the pairwise similarity of the (potentially) multiple persona nodes. Similar to applying non-embedding baselines to the persona graph, we experimented with a number of aggregation functions (including *min*, *max*, *mean*, etc). The highest performing aggregation function was the maximum, so we define the similarity between the two nodes in G to be the maximum dot-product between any of their constituent personas in G_P.

For learning embeddings with Splitter, we set the random walk length $t = 40$, number of walks per node $\gamma = 10$, and the window size $w = 5$, the initial learning rate $\alpha = 0.025$, and the graph regularization coefficient $\lambda = 0.1$. For EmbedFn, we used node2vec with random walk parameters ($p = q = 1$) which is equivalent to DeepWalk.

3.4 Experimental Results

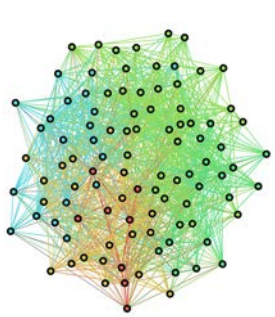
In the following table, we report the experimental comparison of Splitter with several embedding and non-embedding baselines. For each experiment, we report the AUC-ROC in a link prediction task performed using an ablation test described in Section 3.2. For consistency of comparison, we use the experimental settings (datasets and training/testing splits) of [2] for the baselines. Hence, the baselinesâĂŹ numbers are the same of [2] and are reported for completeness.

We first report in Table 1 the results of Splitter with several dimensionality settings. All results involving Splitter or the adjacency matrix on persona graph baseline uses the connected component method for ego-net clustering. We chose the connected component algorithm for easy replication of the results because it performs very well, as well as due to its previous use in ego-net clustering [20, 40]. In particular [20], showed theoretical results in a graph model for the connected component method at ego-net level.

We first take a look at the adjacency matrix baselines. Here, we consider both the vanilla version of the well-known baselines in the original graph, as well as the application of such baselines on the persona pre-processed graph (with a methodology similar to Splitter, as described above). We observe that simply applying the persona preprocessing to the standard baselines does not consistently improve the results over using them in the original graph. In particular, we only observe improvements in two of the five graphs we analyzed, while sometimes, we see even strong losses in applying this simple pre-processing, especially for our sparsest graphs, such as ca-HepTh. This confirms that the gains observed in our Splitter do not come merely from the pre-possessing.

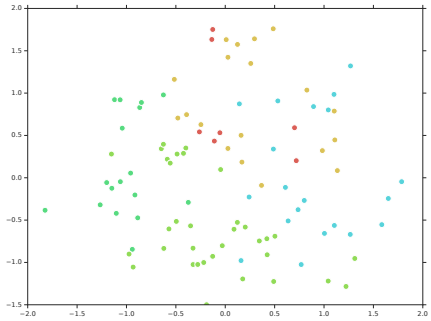
Now, we consider the embedding methods. In this table, to gain an understanding of Splitter embeddings, we compare different sizes of Splitter embeddings (per persona node) with same size embeddings of other methods (per node). Before delving into the results, a note is important; since each node can have multiple persona embeddings, the total embedding size of Splitter (for the same dimension) can be larger than that of another standard embedding method. For this reason, we will later compare the results at same total embedding size. First, we observe in Table 1 that at the same level of dimensionality, Splitter always outperforms all other baselines. The improvement is particularly significant in the largest graph *epinions* where our method using size 8 embeddings improves AUC-ROC by a factor of 40% (reduction in error of 90%) even when compared with the best baseline with 128 dimensions. Similarly, our method achieves close to optimal performances in two of the other largest graphs, wiki-vote and ca-AstroPh.

As we have mentioned before, our method embeds each node into multiple embeddings (one for each persona node), so for a given dimension d of the embedding, the average embedding size per node is given by $d\bar{p}$, where $\bar{p}$ is the average number of personas per nodes (i.e. the average number of ego-net clusters per node) in the graph. We report the average number of persona nodes for all the graphs in our datasets in Table 2. As we notice, the average number of persona nodes is between 2 and 5 in our datasets (using the connected component ego-network splitting algorithm). We report in Table 3 a different look at the previous results. This time, we compare Splitter's AUC-ROC to other embeddings, allowing for the same (or higher) total embedding space. In our example in Table 3, we fix $d = 16$ for the Splitter method and then we compute the effective average embedding size for each dataset ($\bar{p}16$). Thereafter, we compare our results with the best result for each baseline that uses approximately $16\bar{p}$ dimensions (for fairness of comparison, we actually round $16\bar{p}$ to the next power of 2 and always allow more space for the other methods vs our method). Thus, it is possible to observe that the AUC-ROC of Splitter is higher than that of every other baseline using about $16\bar{p}$ dimensions for all datasets, except once (in ca-HepTh, M-NMF is better, and we observe this is the sparsest graph). This confirms that the method improves over the baselines even after accounting for the increased space due to the presence of multiple embeddings for nodes. We observe the same results for other d besides $d = 16$.



4 TASK: VISUALIZATION

4.1 Synthetic graphs



To gain insight on how our embedding method framework operates, we first provide a visualization of a small synthetic graph. The methodology we use is similar to that of [20], which we report for completeness. We created a random graph with planted overlapping communities using the Lanchinetti et al [27] model. We chose this model for consistency with previous ego-net based works [16, 20] and because the model replicates several properties of real-world graphs, such as power law distribution of degrees, varying community sizes and the membership of nodes in varying community numbers. The graph contains 100 nodes and has 9 highly overlapping ground-truth communities.

Dataset	$d_{max} = 16\bar{p}$	Best EigenMaps	Best Node2Vec	Best DNGR	Best Asymmetric	Best M-NMF	Splitter $d = 16$
soc-epinions	48.5	†	0.726	†	0.700	†	**0.974**
wiki-vote	64.0	0.613	0.643	0.630	0.702	0.932	**0.952**
ca-HepTh	38.2	0.802	0.886	0.868	0.885	**0.912**	0.897
ca-AstroPh	40.5	0.824	0.934	0.939	0.942	0.966	**0.972**
ppi	79.5	0.737	0.733	0.769	0.813	0.840	**0.869**

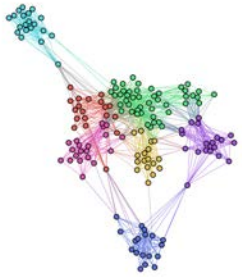


Table 3: AUC-ROC of Splitter with $d = 16$ compared with best baseline allowed larger total embedding space (at approximate space parity).

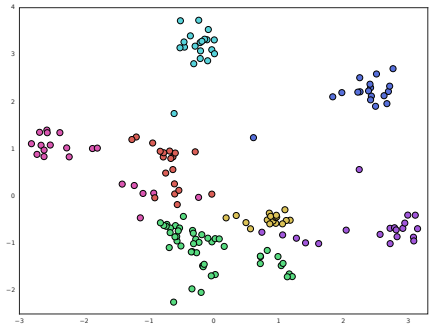

(a) Original Graph

(b) Original Graph Embedding – using M-NMF

(c) Persona Graph

(d) Persona Graph Embedding – using Splitter

Figure 1: Original graph and Persona graph with corresponding embeddings. Notice how the persona graph community structure is clearer than the one in the original graph and this corresponds to more separated embeddings. The colors in the original and persona graph corresponds to community found by a modularity based algorithm. Left side pictures are used with permission from Epasto et al. [20]. (best viewed in color)

We show the results of the visualization in Figure 1. First in Figure 1a and Figure 1c we show a force-directed layout of the original graph and the corresponding persona graph (using Gephi [5] with the same visualization settings). The node coloring corresponds to the discovered communities using a non-overlapping community detection that optimizes modularity [7]. As observed by Epasto et al. [20] on this dataset, the persona graph has a much clearer community structure, finding 8 of the 9 overlapping communities (only 5 communties around found in the original graph).

We now turn our attention to the embeddings output by our method. In Figure 1b, we show a 2D embedding obtained using M-NMF [47] with default settings on the original graph, while in Figure 1d, we show a 2D embedding obtained by our method. As such, it is possible to appreciate how the Splitter embeddings more clearly identify the community structure, as the eight communities found are better separated. In contrast, the M-NMF embeddings do not show a clear separation for this graph, which has highly overlapping communities.

4.2 DBLP Co-Authorship Graph

We then turn our attention to a real-world co-authorship graph using DBLP data. The `4area` graph contains co-authorship relationships extracted from papers in 4 areas of study: Data Mining, Machine Learning, Databases, and Information Retrieval [36]. It is possible to see in Figure 2a and Figure 2b, respectively, a plot of node2vec embeddings and of Splitter embeddings. Notice how in Figure 2b there are 4 areas more or less separated that upon inspection, corresponds to the 4 different fields. A similar observation is

(a) Node2vec – Highlighted Author

(b) Splitter Embeddings – Highlighted Author

Figure 2: Comparison of embedding visualization of a node2vec and Splitter in a DBLP co-authorship graph containing authors from 4 main areas: Data Mining, Machine Learning, Data Base and Information Retrieval. It is possible to observe how the 4 areas correspond to (more or less) well separated regions in the space in both embedding methods. However, standard embeddings force each author that participates in multiple communities to be represented in a single point, while the persona methods allow author-nodes to be represented by multiple embeddings. We show one such embedding for a prolific author with contributions in both the Data Mining and Machine Learning community. Notice how the node2vec embedding results in the author being embedding in the data mining region only (this is best viewed in color).

possible for Figure 2a, representing node2vec embeddings. The key observation in this application scenario is that many authors (in particular the most prolific ones) can contribute to more than one area of study or more than one subarea. However, standard embedding methods force each node to be embedded in only one point in the space, while the Splitter method allows to represent a node as a combination of embeddings (in this setting, we obtain 1.58 personas per node on average). In the Figures 2a and 2b, respectively, we highlight the embeddings learned for one such prolific author, `Jure Leskovec`. Note how this author has one single embedding obtained by node2vec, and multiple embeddings given in output by Splitter. Upon inspection, we observe that the author is embedded in a data mining region by node2vec, surrounded by other prominent authors in Data Mining, such as `Christos Faloutsos`.

However, when observing the representations learned through our Splitter method, we see that this author has a number of persona representations. Moreover, many of the personas reflect different sub-groups of coauthors in Data Mining that our node (e.g. one persona corresponds to co-authorship with other students while at CMU). These personas encode significant portions of the 'average' or 'global' position, which is captured by node2vec. Nevertheless, we also see that a persona ((Jure Leskovec|4)) is now present in the Machine Learning cluster. This illustrates how the representations from Splitter allows the node to span both the Data Mining and Machine Learning region of the space, better characterizing the contributions of the node. Similar observations hold for other authors.

5 RELATED WORK

Our work bridges two very active areas of research: ego-net analysis and graph embeddings. As these are vast and fast growing, we will restrict ourselves to reviewing only the most closely related papers in these two areas.

5.1 Graph embedding

These methods learn one embedding per graph node, with an objective that maximizes (minimizes) the product (distance) of node embeddings if they are 'close' in the input graph. These are most related to our work. In fact, our work builds on the approach introduced by DeepWalk [37], which learns node embeddings using simulated random walks. This idea has been extended to consider node embeddings learned on different variations of random walks [25], as well as other graph similarity measures [45], other loss functions [8], or additional information such as edge labels [15]. These node embeddings have been used as features for various tasks on networks, such as node classification [37], user profiling [39], and link prediction [2, 25, 50]. More recent work in the area has examined preserving the structural roles of nodes in a network [41, 46], learning embeddings for a graph kernel [4], or proposing attention methods to automatically learn the model's hyperparameters [3]. For more information on node embedding, we direct the reader to a recent survey [13].

Moreover, most node embedding methods focus on only learning one representation for each node in the graph. Walklets [38] decompose the hierarchy of relationships exposed in a random walk into a family of related embeddings. However, this is distinctly different from our work, as each node is represented exactly once at each

level of the hierarchy. In addition, the representations are learned independently from each other. HARP [14] is a meta-approach for finding good initializations for embedding algorithms. As a by-product, it produces a series of representations that encode a hierarchical clustering. A number of other works focus on learning community representations, or using communities to inform the node embedding process [12, 47, 51]. Unlike these works, which focus on aggregating nodes into *less* representations, we focus on *dividing* nodes into more representations. This allows our approach, Splitter, to more easily represent prolific nodes that may have overlapping community membership.

5.2 Ego-net analysis

Our work is most closely related to the line of research in social network analysis based on ego-net clustering. From their introduction by Freeman [23] in 1982, ego-nets or ego-networks are a mainstay of social-network analysis [9, 18, 21, 48]. Rees and Gallagher [40] jump-started a rich stream of works [16, 19, 20] that exploit ego-network level clusters to extract important structural information on communities [22], to which a node belongs. They proposed to partition nodes' ego-net-minus-ego graphs in their connected components to find a global overlapping clustering of the graph. Coscia et al. [16] improved over their clustering method by proposing to use a more sophisticated label propagation ego-net partitioning technique. Several authors have since built on such a line of work to improve the scalability and accuracy of ego-net based clustering [10, 19, 20, 33, 33], while others have designed ego-net analysis methods that tackle user metadata on top of the ego-net connectivity [31, 32, 49].

Mostly related to our work is the recent paper by Epasto el al. [20], where they introduce the persona graph method for overlapping clustering. They present a scalable overlapping clustering algorithm based on a local ego-net partition. Their algorithm first creates the ego-nets of all nodes and partition them (in parallel) using any non-overlapping algorithm. These ego-net level partitions are then used to create the persona graph, which is described in more detail in this paper, as this is the basis of our embedding methods. Then, the persona graph is partitioned with another parallel clustering algorithm to obtain overlapping clusters in the original graph.

6 CONCLUSIONS

We introduced Splitter, a novel graph embedding method that builds on recent advances in ego-network analysis and overlapping clustering. In particular, we exploited the recently introduced persona graph decomposition to develop an embedding algorithm that represents nodes in the graph with multiple vectors in a principled way. Our experimental analysis shows strong improvements for the tasks of link prediction and visual discovery and exploration of the community membership of nodes.

Our method draws a connection between the rich and well-studied field of overlapping community detection and the more recent one of graph embedding which we believe may result in further research results. As future work we want to explore more in this direction, focusing on the following challenges: (1) exploiting embeddings for overlapping clustering; (2) studying the effect of this method on web-scale datasets; (3) developing theoretical results on this method; (4) applying our embeddings for classification and semi-supervised learning tasks; and (5) developing the study of learning polysemous node embeddings.

ABSTRACT

Motivated by the increasing need to preserve privacy in digital devices, we introduce the *on-device public-private* model of computation. Our motivation comes from social-network based recommender systems in which the users want to receive recommendations based on the information available on their devices, as well as the suggestions of their social contacts, without sharing such information or contacts with the central recommendation system. Our model allows us to solve many algorithmic problems while providing absolute (deterministic) guarantees of the privacy of on-device data and the user's contacts. In fact, we ensure that the private data and private contacts are never revealed to the central system. Our restrictive model of computation presents several interesting algorithmic challenges because any computation based on private information and contacts must be performed on local devices of limited capabilities. Despite these challenges, under realistic assumptions of inter-device communication, we show several efficient algorithms for fundamental data mining and machine learning problems, ranging from k-means clustering to heavy hitters. We complement this analysis with strong impossibility results for efficient private algorithms without allowing inter-device communication. In our experimental evaluation, we show that our private algorithms provide results almost as accurate as those of the non-private ones while speeding up the on-device computations by orders of magnitude.

1 INTRODUCTION

Digital devices play a significant role in the lives of their users through the connections they provide, the information they assist in consuming, and the online purchases they enable. The wealth of information on such devices (contacts, purchases, etc.) can be potentially used to provide their owner with ever-improving services and a better user experience, but *only* if the user's privacy is respected. Providing the users with useful services while also respecting their privacy is the holy grail of data mining and machine learning and a fundamental endeavor in the research community and in the industry [1, 15, 21–23, 27, 48].

Consider the case of a standard recommender system, such as a service that suggests books to read. The system has a central recommendation provider. The user logs into the system and volunteers her ratings for the books already read and, in exchange, receives suggestions for new books to read. Now, assume that the user would like to receive suggestions based on the books read by her close friends (perhaps the contacts in her mobile phone). In a standard centralized system [12], to obtain such social recommendations, the user needs to authorize access to her list of contacts on the phone.

This has obvious limitations. The user might want to share the book reviews online and with her friends, but at the same time she might not want to share the contact list to the system. The standard centralized system architecture does not allow such a use case, because all the data necessary to solve the task of obtaining the reviews (i.e., the book ratings and the social graph) must be stored and processed in a centralized system.

In this paper, we begin the study of a new model of computation that we call the *On-Device Public-Private* model. This model allows the user to employ all the information available on her device, as well as the user's social contacts, without sharing them with the central system. In particular, we show how to solve several machine learning and data mining problems, in this model, without having to move any private data to the central system and without having to reveal the private connections in the social graph. Our method provides absolute deterministic guarantees of privacy, as no information based on the private data or the private contacts of the user is shared with the central authority.

This model is along the lines of other privacy-preserving schemes that are actively studied and that are reviewed in related workâĂŤfor instance, differential privacy [1, 22–24], federated learning [38], and the recent public-private data models [7, 15]. All these methods allow strong privacy guarantees, and may complement ours, but we observe that they do not directly model the social-graph-based information or they involve a setting where private data or some information based on it may still need to be collected by the central

authority (although in an anonymized or aggregated form). We seek to study a model that allows general algorithmic problems to be solved while harnessing the social network of the users. Our model can be seen as an extension to the recent public-private graph model [15], along the lines of on-device learning settings in which our model, contrary to the public-private graph model, does not require any private information to be shared with the central system, and it also allows metadata on nodes of the network to address applications beyond graph analysis. Finally, we show how to achieve this without relying on insertion of noise to obfuscate the output, which might partially degrade it, while achieving, by design, an even stronger notion of privacy: private data is only used to provide outputs to the data owner.

Our restrictive model of computation presents several interesting algorithmic challenges: since no private information is shared, all computations based on private data must be performed on local devices of limited capabilities. Despite these challenges, we show efficient algorithms in our model for fundamental data mining and machine learning problems, ranging from clustering to recommendation system applications.

In a nutshell, our model works as follows: we allow the user to specify an arbitrary partitioning of the local device data as public or private. Moreover, the user is allowed to specify some contacts as private or public. Only the public data and the public contacts are shared to the central system in accordance with the choice of the user. Then, the user wants to obtain some information (e.g., the results of a recommendation system algorithm) on a dataset consisting of all the data to which the user has access (i.e., her private data, all her contacts whether private or public, as well as all the public information available in the system). All of this must be achieved without revealing the private data and the private contacts to the central authority. We present a formal summary of these results in section 3 after defining necessary preliminaries.

Under the realistic assumption of a limited amount of communication among private contacts, we show positive results for addressing general algorithmic problems with applications in areas including social-network-based recommender systems [42, 46]. We stress that our model, contrary to previous work [15], is not restricted to graph-based problems. In fact, we show results on general machine learning and data mining problems, finding heavy hitter [33] and solving clustering problems (like k-medians, k-means and k-centers) [11, 29].

To further motivate the model, we study a more restrictive case in which the devices cannot communicate directly with each other. In this *no-inter-communication* scenario, we show strong impossibility results for many problems of practical interest, including approximating the distance of users in social networks or counting the connected components of the graph. These impossibility results, in turn, motivate our model that allows minimal communication among devices. On the positive side, we show that, informally, even in this restrictive case, any problem that allows a streaming algorithm with a limited amount of space can be solved efficiently.

The rest of the paper proceeds as follows. In section 2, we introduce our models and review the prior public-private graph models. Then, in section 3, we present our main theoretical results for our model. Next, in section 4, we show empirical evaluation of algorithms in our model. In section 5, we review related work, and finally, in section 6, we present our conclusions.

2 ON-DEVICE PUBLIC-PRIVATE MODEL OF COMPUTATION

In this section, we formally define the *on-device public-private model* of computation. Before defining the model, we review the *public-private graph* model, which was introduced by Chierichetti et al. [15], to which we refer as *centralized* public-private model to distinguish it from the *on-device* version we introduce.

Centralized model. In the (centralized) public-private model of computation, we have a graph $G = (V, E)$, called the *public* graph, where V is the set of nodes representing users of a system and E is the set of public edges connecting them. Let $n = |V|$ and $m = |E|$. Then, for each node $u \in V$, we have an associated *private* graph $G_u = (\{u\} \cup V_u, E_u)$, over the set of nodes $V_u = \{v_1, \ldots, v_k\} \subseteq V$ representing the private edges of the node. Throughout the paper, we assume that the public and private graphs are undirected, unweighted graphs, but the model can be defined [15] in the obvious way for general graphs. We also focus on the most studied instance of the model (known as the star case) where the set E_u consists of a star centered in u (i.e., $E_u = \{u\} \times V_u$), which represents the private neighbors of the node u.

In the centralized public-private model of computation, we have a graph problem to solve (e.g., determining the connected components of the graph) and want to output efficiently the solution for the problem for the graph visible to any arbitrary user u (i.e., the public-private graph of node u, $G \cup G_u$) after performing some efficient preprocessing of the public graph G computed by a central machine. More precisely, let P be the preprocessing algorithm. Ideally, we want P to analyze the public graph G in a time that is polynomial in its size (i.e., $O(\text{poly}(n + m))$), and to output a space-efficient *synopsis* $P(G)$ of the public graph with space $\tilde{O}(n)$.[1] Then, the aim of the query algorithm is to take in input for node u the private graph G_u and to output the solution of the problem for $G \cup G_u$ by using the synopsis $P(G)$, in time and space that is ideally near-linear in $|E_u|$ and poly-log(n). Crucially, we observe that this model assumes that the query algorithm can access the entire synopsis by making queries to it that depend on the private data. Implicitly, this means that the private graph (or some information based on it) resides in the central machine.

On-device model. Motivated by the problem of social-network-based recommendations, in this paper we refine the previous model to enforce that each private graph G_u is stored exclusively on the device owned by the agent u to protect her privacy. We assume that private edges of E_u represent reciprocal private connections of the user u (i.e., $v \in E_u$ implies that $u \in E_v$ and that u and v know each other and they want their connection to be private to them and not shared to the central authority or any other user). Hence, contrary to the centralized model, the query algorithm must be executed on a device of limited computation power and (crucially) cannot make queries to the central machine that depend on the private edges, as this would reveal the private connections to the shared machine.

[1] we use $\tilde{O}(\cdot)$ to neglect polylogarithmic factors.

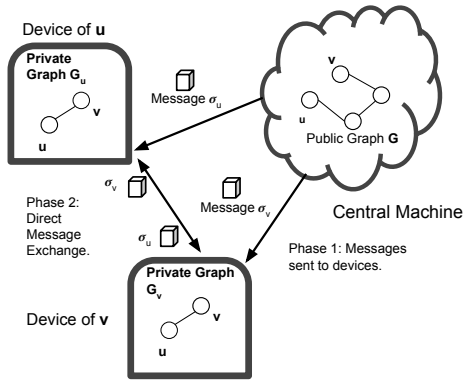

Figure 1: Description of the on-device public private model of computation

To model this, we assume, as in the previous model, that a central machine with high computational power can preprocess the public graph G in polynomial time. Then, contrary to the previous model, we assume that the query algorithm for $G \cup G_u$ is run on the private device of u that is not capable of storing the whole public graph. Indeed, as the complete graph might be large, we restrict the computation power (both space and running time) on each device to be sublinear in the size of the public graph $o(n + m)$, preferably poly-logarithmic in n, and polynomial in the size of the private graph, ideally $\tilde{O}(E_u)$. As this rules out the possibility for the device to store a synopsis of G of size $\Theta(n)$, we allow the device to communicate with the central machine and to the other private neighbors' devices with small-size messages.

The on-device communication protocol. More formally, in the on-device model, we assume that the central machine, after preprocessing the public graph G, sends a single message σ_u to the device corresponding to the node u of (ideally) poly-log(n) bits (we refer to Figure 1 for a pictorial description of the model). No other communication is allowed with the central machine from the device thereafter. Indeed, the shared machine has no information about the private graph G_u, and σ_u just depends on the public graph G and node u, thus preserving completely the privacy of the private contacts in G_u. Next, the device of u is allowed to directly query the device of each private neighbor $v \in E_u$ to receive the *same* message σ_v sent to v by the central machine. We observe that this communication does not involve the central authority and so does not leak any information to it. We also observe that the messages exchanged between a pair of private contacts do not contain private information (as they are obtained from the public machine and shared verbatim with the private contact), so no leakage is possible. Finally, after this exchange, the query algorithm on the device uses the messages received *only* to solve the problem.

For instance, in our book recommendation system example in the introduction, v might be a contact of u in u's favoring secure messaging app.[2] User u may obtain σ_v using the same messaging app to contact v, without thus sharing the app contact list to the book recommendation system provider. Then, u will use the messages received to compute the recommendations on her device.

Guarantees. Notice that, in this model, we protect *by design* all private information from being known by the central authority, as it is never reported to it. Notice, also, that nodes do not share private data with their neighbors (the messages exchanged contain only public data processed by the central machine). Thus, no leakage is possible from neighbors, by design, under the assumptions that the devices are able to establish a trusted connection with their private contacts, and the private contacts will not leak the existence of their connection to others. Notice that even if a private neighbor were to collude with the central machine, the only information that could be obtained by the machine would be the existence of the connection with that neighbor.

Alternative models without communication or a centralized system. Our model requires a single round of small-sized communication among private contacts. This assumption is indeed necessary to solve many important problems, as, in section 3.8, we show strong impossibility results in a model with no-inter-communication between devices. Finally, we observe that the protocol could be simulated without a central authority, if computational constraints were not present, but that would require to process all public data on the user's devices, which is not feasible for large-scale systems.

Metadata. So far, we have described a model which, as in [15], only involves graph information. Recently, another model has been defined that allows public-private (problem-specific) data associated with users as the public-private framework of data summarization [39]. In our on-device framework, as well, we allow both graph data and non-graph metadata on nodes. We assume that each node has a problem-specific public metadata S_u^P that can be shared publicly to everyone and a problem-specific private metadata S_u^V that is only available to u. This allows us to address non-graph-related problems such as clustering and heavy hitters, as we show in our paper. Similar to the graph information, the public metadata can be stored in the central machine, while the private metadata must be processed locally. We observe that more sophisticated access controls (who-can-access-what) can be defined, but we leave this to a future work. To handle the metadata, we seek algorithms that use polynomial time and space in the size of all public data for preprocessing and linear time in the private data of a user for the query algorithm.

3 ALGORITHMIC RESULTS FOR THE ON-DEVICE MODEL

In this section, we report our main algorithmic results. First, we study formally the relationships between the centralized and the on-device model in Section 3.1. Then, we show novel algorithmic results for the heavy hitters problem and k-clustering problem. Finally, we show impossibility results when the devices are not allowed to communicate between private contacts.

[2] In our model we abstract away the details of the communication protocols involved. We only assume that there is a way for the devices to obtain small messages from their private contacts without involving the central authority providing the recommendation system.

3.1 Relationships between the models

Before introducing our main novel algorithmic results, as a warm-up, we present a few basic lemmas to clarify the relationships between the on-device and the centralized model for graph algorithms. In the on-device model, we define Σ as the maximum size of a message exchanged in the protocol, while in the centralized algorithm, we define $|P(G)|$ as the size of the preprocessing synopsis obtained.

First, we prove that the on-device model is at least as hard as the centralized model, because any on-device algorithm can be implemented in the centralized setting.

Lemma 1. *Any on-device public-private graph algorithm with polynomial time preprocessing, $\Sigma \in \tilde{O}(1)$ message size and $\tilde{O}(|E_u|)$ query time, can be implemented in the centralized public-private graph model with polynomial time preprocessing, $|P(G)| \in \tilde{O}(n)$ preprocessing space and $\tilde{O}(|E_u|)$ query time.*

Proof. It is easy to observe that using the central machine, one can simulate the on-device protocol by storing in the synopsis all the messages sent to the nodes and reading them from memory during query time. The total space for the preprocessing is hence $O(n\Sigma)$, while the preprocessing time is clearly polynomial. At query time, the central machine reads the $\tilde{O}(|E_u|)$ messages "sent" to u and simulates the on-device query algorithm in $\tilde{O}(|E_u|)$ time. □

Another simple lemma shows that the contrary is not always true: the on-device mode is *strictly* harder.

Lemma 2. *There exist problems that admit a $|P(G)| \in O(n)$ preprocessing space in the centralized model and for which there is no $o(n)$ message size algorithm in the on-device public-private model.*

The proof is omitted for lack of space, but it is based on standard results in communication theory. All omitted proofs are deferred to the extended version of the paper.

Despite the on-device model being generally harder, we now show that for a significant class of centralized public-private graph algorithms, there is an immediate reduction to the on-device model.

Lemma 3. *Suppose for a given problem there exists a centralized public-private algorithm with synopsis $P(G)$ decomposable in n data-structures, $P(G)_u$ for $u \in V$ such that $|P(G)_u| \in \tilde{O}(1)$ and such that the query algorithm for node u solves the problem in $\tilde{O}(|E_u|)$ time by having access only to $P(G)_u$ and $P(G)_v$ for $v \in E_u$. Then, there exists a $\Sigma \in \tilde{O}(1)$ message size and $\tilde{O}(|E_u|)$ query time algorithm in the on-device model.*

Proof. We observe that the reduction is immediate because the central machine can send message $\sigma_u := P(G)_u$ with space $\tilde{O}(1)$ to each node u, and then the devices can implement the query algorithm using only the messages received from the central machine and their private contacts. □

The previous reductions yield directly algorithms in the on-device model for many problems already studied in the centralized model such as counting the number of connected components, estimating the size of the reachability set of a user, and several centrality estimations (we refer the reader to [15] for details) when the centralized public-private algorithm defined therein has the property required by Lemma 3. Conversely, we observe that this property does not hold for many important algorithms defined in centralized settings, including approximating shortest path distances between nodes u and v and estimating several notions of node similarities between them, because such algorithms require arbitrary access to the centralized synopsis. In particular, the central machine needs to be informed about the node v queried from u. Solving these problems while protecting the privacy of the query in our restrictive model is an interesting open problem.

3.2 Problems addressed

We now introduce our main algorithmic contributions in which we study a class of problems related to recommendation systems in the on-device public-private model. In a social-network recommendation system, there is a set of arbitrary items $\mathcal{S}$ and a graph indicating the social network. We assume the social graph includes a public part G and a private graph G_u for each node u as described above. For each vertex u, we have a set $S_u^P \subseteq \mathcal{S}$ of public items and a set $S_u^V \subseteq \mathcal{S}$ of private items, respectively, that u likes.

We model the problem of implementing a social recommendation system that, given the information in the neighborhood reachable within distance d of a vertex u in the graph visible to u, $G \cup G_u$, returns a subset of items I, with $|I| = k$ to recommend to u. More formally, for a graph $\mathcal{G}$, we let $N_u^d(\mathcal{G})$ be the set of vertices reachable from u within a distance at most d on graph $\mathcal{G}$. We let

$$S_u^d(\mathcal{G}) = S_u^V \cup \bigcup_{v \in N_u^d(\mathcal{G})} S_v^P$$

be the set of items visible to u in $\mathcal{G}$ (i.e., the private items of u plus all public items of nodes reachable from u at distance less than d in the graph $\mathcal{G}$). We will drop $\mathcal{G}$ when we refer to the public graph G. In particular, in our on-device model, we want to approximate the output of certain functions specifying relevant items over the set $S_u^d(G \cup G_u)$ to recommend. We show results for the following problems.

Uniform recommendation function. A uniform recommendation function is a randomized function that returns a subset of items uniformly at random without replacement from $S_u^d(G \cup G_u)$.

Linear recommendation function. Fix a node u, let S_v be $S_v := S_v^P$ for $v \neq u$ and $S_u := S_u^V \cup S_u^P$ for u. Notice that $S_u^d(G \cup G_u) = \bigcup_{v \in N_u^d(G \cup G_u)} S_v$. For a fixed u, item $i \in \mathcal{S}$, and distance d, we define $C_u^i(G \cup G_u)$ as the number of distinct nodes $v \in N_u^d(G \cup G_u)$ for each i that appears in the set S_v defined above. A linear recommendation function is a randomized function that returns a subset of k items I, where the items in I are chosen from $S_u^d(G \cup G_u)$ without replacement with probability proportional to $C_u^i(G \cup G_u)$.

Heavy hitter. Let M be a multiset of $\mathcal{S}$, i.e., a set of items with repetitions. For parameters ϵ and κ, heavy hitter is a function that returns a subset of items I from a multiset M with two properties. 1) I contains all items that appear in at least $\frac{|M|}{\kappa}$ times in M where $|M|$ is the total number of items counting repetitions; and 2) each item $i \in I$ appears at least $\frac{|M|}{\kappa} - \epsilon$ times in M.

For a node u and distance d, we let M be the multiset that contains the union (with repetitions) of S_v for distinct $v \in N_u^d(G \cup G_u)$ (i.e.,

Algorithm 1: General Algorithm.

Output: Output k items for each node u

Pre-processing on central machine using G, $\forall_{u\in V} S_u^P$.
for all $u \in V$, for $d' \le d$ **do**
  Let $\bar{S}_u^{d'}(G) := \bigcup_{v\in N_u^d(G)} S_v^P$.
  Compute $I_u^{d'} := sketch(\bar{S}_u^{d'}(G))$.
  Send to u, $\sigma_u := (I_u^{d-1}, I_u^d)$.
Query algorithm on u's device using G_u, S_u^V.
Receive σ_u from central machine.
Send σ_u to v and receive σ_v from v for all $v \in E_u$.
Compute $I_u^V := sketch(S_u^V)$.
Compose sketches I_u^V, I_v^{d-1} for $v \in E_u$, and I_u^d to obtain sketch I_u.
Extract k items from I_u.

all items visible to u counted with the number of users liked by them). We seek to find all heavy hitters as defined above.

k-Clustering. In this case, each item in $\mathcal{S}$ represents a point in an arbitrary metric space, and the goal is to pick a set of k points $r_1, \ldots, r_k$ that minimizes the cost function.

$$\Big(\sum_{s\in S_u^d(G\cup G_u)} \min_{j=1}^{k} \mathrm{dist}(r_j, s)^\rho \Big)^{1/\rho},$$

for a particular fixed ρ. $\rho = 1$ corresponds to k-median, $\rho = 2$ to k-means and $\rho \to \infty$ to k-center.

In the next sections, we show algorithms with provable theoretical guarantees for all these problems in our model.

3.3 General algorithmic approach

The general approach of our algorithms (reported in Algorithm 1) for the previously mentioned problems is to define a composable sketch function *sketch* over sets of items such that 1) from $sketch(A)$, one can extract k items, approximately solving the problem; 2) $sketch(A)$ has small space $\tilde{O}(k)$; and 3) the sketches computed over two (possibly overlapping) sets of items A and B can be computed easily by composing $sketch(A)$ and $sketch(B)$. Assume that such a function exists; we will use it to compute a sketch $I_u^{d'}$ for the items in the neighborhood at distance at most d' from a node u on the public graph G over the public items S_u^P for all $u \in V$. These sketches will be computed over the public data in the centralized machine in the preprocessing phase for all integers $1 \le d' \le d$ using the public graph G and the public items S_u^P for all $u \in V$. We will send to each individual node u, as the message σ_u, the sketches for the greatest two distances (i.e., $\sigma_u := (I_u^{d-1}, I_u^d)$). Then, the nodes will share the message received from the central machine with their private neighbors and collect their messages. In the query phase, node u will compose: the sketch I_u^d and the sketches $I_v^{d-1} \forall v \in |E_u|$ received, as well as the sketch computed over the private local items S_u^V, to obtain a sketch I_u and to extract from it the recommendations.

Given this general framework, for each specific problem, we only need to show how the preprocessing phase obtains the sketches $I_u^{d'}$ efficiently, how they can be composed, and how to extract the solution from the sketch.

Algorithm 2: Algorithm for uniform recommendation function.

Input: G, $\forall_{u\in V}(S_u^P, S_u^V, G_u)$, d, k, a hash function $h(.)$
Output: Output k uniform sample items for each node u

Obtaining $I^{d'}$'s during preprocessing
For $d' = 0$
for all $u \in V$ **do**
  Sort items in $i \in S_u^P$ based on hash $h(i)$ and let I_u^0 be the first k items by $h(\cdot)$.
for $d' \in \{1 \cdots d\}$ for $u \in V$ **do**
  Let $\hat{I}_u^{d'}$ be the union of $I_u^{d'-1} \cup \bigcup_{v\in N(u)} I_v^{d'-1}$ where $N(u)$ is refers to graph G.
  Sort items in $\hat{I}_u^{d'}$ based on $h(i)$ and let $I_u^{d'}$ be the first k items.
Query algorithm on u's device using same $h(\cdot)$ function.
Let I_u^V be the top k items by $h(\cdot)$ in S_u^V.
Compute $\hat{I}_u$ as union of I_u^V, I_v^{d-1} for $v \in E_u$, and I_u^d.
Extract k items from $\hat{I}_u$ by $h(\cdot)$.

3.4 Uniform recommendation function

We define the sketch for the uniform case. We start with a simple sketching algorithm that does not work. Let us assume the public server defines as sketch I_u^d of uniform and independent sample of items from S_u^d. Suppose u has two neighbors, v' and v''. Let item $i \in S_{v'}^d$, $i \in S_{v''}^d$, and $i' \in S_{v'}^d$, but $i' \notin S_{v''}^d$. In this case, the probability that i exists in either one of the samples of v' or v'' is more than the probability for element i', which is not desired because it does not allow a simple combination of the two samples.

To resolve this issue, we assume that there exists a k-min-wise independent uniform hash function $h : \mathcal{S} \to [0, 1]$ from the items to $[0, 1]$. We assume that the function has shared random seeds that are available to all devices and the central machine (i.e., we can compute it consistently in every device). The algorithm is reported in Algorithm 2, in which we report only the details missing from the general Algorithm 1. To sketch a set of items S, we hash the items in S and keep the k items with minimum values. Two sketches for sets A, B can be easily composed because one can sort the items in $A \cup B$ and return the top k by h. Algorithm 2 shows how to use this property to iteratively construct $I_u^{d'}$ for all nodes based on $I_u^{d'}$ and how to initialize I_u^0, which is the sketch of S_u^P. Then, $I_u^{d'}$ is obtained by combining the sketches of $I_v^{d'-1}$ for the public neighbors of u and the previous sketch $I_u^{d'-1}$ of u. Finally, the last two sketches for d and $d-1$ are sent to each device. To construct uniform recommendations, for any v in the private neighborhood of u, we query v to obtain I_v^{d-1}, construct $\cup_{v'\in E_u\cup G_v} I_{v'}^{d-1} \cup I_u^d$, and compose it with the sketch of the private items in u. Finally, we recommend the k items with minimum hash value from the combined sketch.

The following lemma can be shown.

Theorem 4. *Algorithm 2 obtains k uniform recommendations without replacement for each node in the on-device model with total preprocessing time $\tilde{O}\left(\sum_u |S_u^P| + kd(m+n)\right)$ using $\tilde{O}(k)$ space messages and $\tilde{O}\left(|S_u^V| + k|E_u|\right)$ query time.*

We observe that one could use l_0 sketches [30] on each vertex to provide a uniform recommendation function. However, l_0 samplers

provide independent samples (i.e., with replacements). This can be resolved by using more sketches on each vertex and removing duplicated items, but l_0 samplers are designed to handle deletions of items as well, which is not necessary here.

3.5 Linear recommendation function

In this subsection, we provide a simple technique to recommend k items without replacement from $S_u^d(G \cup G_u)$ with probability proportional to $C_u^i(G \cup G_u)$.

First, we give a simple example to show that unlike the uniform sampling case, several copies of independent samplers are not useful to solve the problem efficiently. Suppose we have only items i and i', and $C_u^i(G \cup G_u) = n$ and $C_u^{i'}(G \cup G_u) = 1$. Note that any sampler that samples 2 items without replacement reports both i and i'. However, sampling one item gives i with probability $\frac{n}{n+1}$, and i' with probability $\frac{1}{n+1}$. Hence, in expectations, we need to make $O(n)$ linear samples with replacement to observe i' once, which is not desirable.

Here again, we use k-min-wise hash functions with shared random bits in a similar fashion to Algorithm 2. The key difference with the algorithm is in the sketch method, which instead of hashing items $\mathcal{S}$ to $[0, 1]$, it hashes pairs of items (i, u) to $[0, 1]$, where i is an item and u is a vertex containing i in its items. We first focus on the preprocessing. For each vertex u, we define $T_u^{d'} = \{(v, i) | v \in N_v^{d'}(G)$ and $i \in S_v^P\}$. We define the sketch $I_u^{d'}$ to be the set of k pairs in $T_u^{d'}$ with minimum hash values and with distinct items (i.e., when an item appears several times, we only keep the pair with lowest hash value for that item). It is easy to see that such sketches can be computed iteratively as in the uniform case. Notice also that at query time for node u, by having access to I_u^d, I_v^{d-1} for $v \in E_u$ and S_u^V, one can construct in the same way a sketch for $S_u^d(G \cup G_u) = \cup_{v \in N_u^d(G \cup G_u)} S_v$, where S_v is defined as $S_v := S_v^P$ for $v \neq u$ and $S_u = S_u^P \cup S_u^V$.

To construct the linear recommendations, we recommend the k distinct items with minimum hash values in the combined sketch of $S_u^d(G \cup G_u)$. Notice that the recommended set is equivalent to the set of the k distinct items with minimum hash values in $T_u^d(G \cup G_u) = \{(v, i) | v \in N_u^d(G \cup G_u)$ and $i \in S_v\}$. Hence, the probability that a pair corresponding to an item i has the minimum hash value is proportional to its frequency C_u^i as desired. After removing the pairs corresponding to the first item, the same argument holds for the second item, and so on. This allows the following theorem to be shown.

Theorem 5. *The previous algorithm obtains k linear recommendations without replacement for each node in the on-device model with total preprocessing time $\tilde{O}\left(\sum_u |S_u^P| + kd(m+n)\right)$ using $\tilde{O}(k)$ space messages and $\tilde{O}\left(|S_u^V| + k|E_u|\right)$ query time.*

3.6 Heavy Hitters

In this subsection, we provide a technique to recommend heavy hitters. Fix a probability $0 < \delta < 1$. Let $s = |\mathcal{S}|$ be the total number of items. We use a similar technique to the linear case, except that we use $H = 12 \log \frac{2s}{\delta} \epsilon^{-2}$ fully independent hash functions. As in the linear recommendations case, each hash function maps a pair (u, i) of user and item to $[0, 1]$. The sketch I_u^d keeps H pairs, one per function, such that for each function, the pair stored is the one with minimum hash value over the items inserted in the sketch. It can be observed that the sketch is composable. The construction of the sketches in the pre-processing and query time is the same as in the linear case. It can be noted that the final sketch I_u^d constructed at query time is a list of $\frac{12 \log \frac{2s}{\delta}}{\epsilon^2}$ items sampled independently, this time with replacement, from $N_u^d(G \cup G_u)$ with probability proportional to $C_u^d(G \cup G_u)$. We recommend an item if and only if it appears at least $\left(\frac{1}{\kappa} - \frac{\epsilon}{2}\right) \frac{12 \log \frac{2s}{\delta}}{\epsilon^2}$ times in the list I_u^d.

Given the result in Theorem 5, the proof can be adapted to show the following bound on the running time and message space.

Lemma 6. *The previous algorithm obtains runs in the on-device model with total pre-processing time $\tilde{O}\left(\sum_u |S_u^P| H + d(m+n)H\right)$ using $\tilde{O}(H)$ space messages and $\tilde{O}\left(|S_u^V| H + |E_u| H\right)$ query time.*

With a little more work, we can also show the following lemma.

Lemma 7. *The algorithm defined above returns the heavy hitter items in the neighborhood of u, with probability $1 - \delta$.*

3.7 k-clustering

Our algorithm in this section is based on the notion of composable core-sets [11]. Bateni et al. [11] show that given a linear space α-approximation algorithm for k-clustering problem for a fixed ρ norm (e.g., $\rho = 1$ for k-median, $\rho = 2$ for k-means, $\rho = \infty$ for k-center), the following procedure provides an $O(\alpha)$-approximate solution of the problem. Arbitrarily decompose the points into *disjoint* sets $U_1, \cdots, U_t$. Inside each set U_i select an approximate solution of size $\tilde{\Theta}(k)$. We call these points representatives. Then, for each point in U_i that is not a representative we move it to the location of the closest representative point in U_i. Now one can represent the new dataset by distinct point locations and their multiplicities, which are composable core-sets. Then, combine the composable core-sets and solve the problem on the new dataset. This is known to provide a $O(\alpha)$-approximation. Notice that the challenge to applying this method to our case is that the points in the sets S_u^P, S_u^V for $u \in V$ are not necessarily disjoint. We show, nevertheless, how to use this technique in our case.

Similar to the technique in previous sections, for each node u we keep a composable core-set of the points in $\bigcup_{v \in N_u^{d'}(G)} S_v^P$ for $d' = d$ and $d' = d - 1$, for each node. We do this, in this section, by first running a BFS search from each node u, gathering the points in S_v^P for $v \in N_u^{d'}(G)$, and finding the corresponding core-sets $I_u^{d'}$ as in [11]. Note that this preprocessing step can be implemented in $\tilde{O}(k|V|)$ space and polynomial time. Then, u receives I_v^{d-1} from each vertex v in its private neighborhood. Node u merges the userâĂŹs core-set I_u^d and the core-sets from private neighbors I_v^{d-1} and solves the problem. Note that core-sets I_v^{d-1} correspond to not necessarily disjoint sets. However, each point appears at most $|E_u| + 1$ times in these core-sets, where $|E_u|$ is the number of private neighbors of u. Therefore, we can show that our approximation factor is increased by a factor of at most $|E_u| + 1$. This implies the following theorem, where, as in [11], we assume there is a polynomial time, linear

space, α-approximation algorithm *Alg* for k-clustering in the norm ρ.

THEOREM 8. *The previous algorithm obtains a $O(\alpha|E_u|)$-approximate k-clustering in the norm ρ, for each node u, in the on-device model with polynomial time preprocessing, using $\tilde{O}(k)$ space messages, and using query time polynomial in $|S_u^V|$, k and $|E_u|$, as desired.*

Specifically, the total pre-processing time is

$$\tilde{O}\left(\sum_u f\left(\left|\bigcup_{v\in N_u^{d'}(G)} S_v^P\right|\right) + m + \sum_u \sum_{v\in N_u^d(G)} \left|S_u^P\right|\right)$$

and query time is $\tilde{O}\left(f\left(\left|S_u^V\right| + k|E_u|\right)\right)$, where $f(.)$ indicates the running time of the offline algorithm *Alg*.

The increase $|E_u|$ in the approximation factor in the previous algorithm is due to the possibility of items appearing in multiple core-sets. In the next subsection we provide a sketching technique that allows us to reduce the weight of the duplicated points from the core-sets. By applying this sketching, our algorithm is (approximately) using the true weight of the points in the core-set. While this heuristic does not improve the approximation factor in the worst case, this theoretically sound heuristic improves the results in practice.

3.7.1 Removing duplicated items. As we mentioned earlier in this subsection, composable core-sets are designed to work with disjoint sets (i.e., a decomposition of the input set). However, in the case of our application, if a vertex v is reachable from two private neighbors of u (via distance less than d), the items (i.e., points) of v appear in both of these neighbors. Hence, we double count the weight of these items on the representative items. If we could explicitly keep the set of the items assigned to the representative items (which we refer to as $A_1, \ldots, A_t$ for simplicity of notation), we could directly indicate the duplicated items and remove their weights from the representative items. However, this might not be practical due to the large size of these sets. In this subsection we provide a technique to sketch these sets such that we can remove the weight of the duplicated items fairly accurately (i.e., with an ϵ error) using a smaller memory.

Next, we provide our tool to deal with sets that are not disjoint for composable core-sets. This tool might be of independent interest.

Let A be a collection of items and let $A_1, \ldots, A_t \subseteq A$ be a collection of subsets of A. Without loss of generality, we assume $|A_1| \geq |A_2| \geq \cdots \geq |A_t|$. Let Δ be an upper bound on the number sets that contain a, for any arbitrary $a \in A$. Let $h(.)$ be a universally shared hash function that hashes $A \to [0,1]$ uniformly at random. We let $\hat{A}_i$ be the subset of A_i with hash value at most $\lambda_i = \frac{6\log(\delta t)\Delta^2}{\epsilon^2}\frac{1}{|A_i|}$. Note that we have $E[|\hat{A}_i|] = |A_i|\frac{6\log(\delta t)\Delta^2}{\epsilon^2}\frac{1}{|A_i|} = \frac{6\log(\delta t)\Delta^2}{\epsilon^2} \in \tilde{O}(\Delta^2)$.

For $i \in \{1, \ldots, t\}$ we define $B_i = \left\{a \middle| a \in A_t \& \nexists_{j>i} a \in A_j\right\}$. This intuitively says that to construct B_is from A_is, we remove duplicated items from the larger sets and keep them in the smaller ones. Similarly, for $i \in \{1, \ldots, t\}$ we define $\hat{B}_i = \left\{a \middle| a \in \hat{A}_t \& \nexists_{j>i} a \in \hat{A}_j\right\}$.

LEMMA 9. *With probability at least $1 - \delta^{-1}$, simultaneously, for all $i \in \{1, \ldots, t\}$ we have*

$$\left||B_i| - \frac{1}{\lambda_i}|\hat{B}_i|\right| \leq \epsilon\frac{|A_i|}{\Delta}.$$

The proof is omitted for lack of space.

3.8 Hardness results for no-inter-communication models

To motivate our model, here we consider a more restrictive case where we do not allow the nodes to exchange the messages σ's with their private contacts. Hence, after the message σ_u is received, the query algorithm has to solve the problem based exclusively on the local private graph G_u and the message σ_u. We call this model *no-inter-communication* model.

We show that it is impossible to solve several basic graph problems in the *no-inter-communication* public-private model, which motivates our more general model and distinguishes the computation power of these two models. We summarize our negative results in the following theorem.

THEOREM 10. *It is information-theoretically impossible to solve the following problems in the* no-inter-communication *public-private model using $o(n)$ size messages:*

- *Approximate the distance of u and v.*
- *Decide if u is connected to v.*
- *Approximate the number of connected components.*

The full proof of all the results is available in the full version. For lack of space, here we describe the intuition behind them. Our hardness results are based on two-party communication complexity techniques. Note that we provide information-theoretic hardness, and hence we do not require computational complexity assumptions like $P \neq NP$.

We use the hardness of the indexing problem [32] and set disjointness [31, 44]. In the indexing problem, we have two parties: namely, Alice and Bob. Alice holds a subset $A \subseteq \{1, 2, \ldots, n\}$ and Bob holds an element a. The goal is for Bob to detect whether or not $a \in A$, using a one-way communication link from Alice to Bob. It is known that $\Omega(n)$ bits of communication are required to solve this problem.

In the set disjointness problem as well, we have two parties, Alice and Bob, each holding a subset of $\{1, 2, \ldots, n\}$. Say Alice holds A and Bob holds B. The goal here is to detect whether or not $A \cap B = \emptyset$, using a two-way communication link. This problem requires $\Omega(n)$ bits of communication as well.

To prove the above theorem, let us define the reachability problem as follow. We have a network G with a vertex r indicated as the root. A vertex v is reachable if there is a path from v to the root. Indeed, the goal is to detect whether each vertex is reachable. The next theorem shows the hardness of solving the reachability problem in the *no-inter-communication* model.

LEMMA 11. *It is not possible to solve the reachability problem in the* no-inter-communication *model using $o(n)$ size messages to the device.*

Next we show the hardness of counting the number of connected components.

Lemma 12. *Let $\epsilon \in (0,1]$ be an arbitrary small constant. It is not possible to approximate the number of connected components with an approximation factor ϵ in the* no-inter-communication *model using $o(n)$ communication with each device.*

Let us define the delay approximation problem as follows. We have an undirected unweighted network G with a vertex r indicated as the root. The delay of a vertex v is equal to the length of the shortest path between v and the root. The delay approximation problem is to approximate the length of the shortest path between each vertex and the root. The next theorem shows the hardness of delay approximation in the *no-inter-communication* model.

Lemma 13. *It is not possible to solve the delay approximation problem with an approximation factor $\omega(\frac{1}{n})$ in the* no-inter-communication *model using $o(n)$ communication with each local device.*

Positive results. Despite the strong impossibility results presented above, we show a reduction from the popular class of streaming algorithms (with $\tilde{O}(1)$ space). This result translates any streaming algorithm to a *no-inter-communication* on-device public-private algorithm and directly provides a few basic algorithms for the *no-inter-communication* model.

Theorem 14. *Consider a problem that admits an (insertion-only) streaming algorithm with $\tilde{O}(1)$ space, T_0 update time per element inserted, and T_1 query time. The problem can be solved in the* no-inter-communication *public-private setting using $\tilde{O}(1)$ message space and $\tilde{O}(|E_u|T_0 + T_1)$ query time.*

One application of this theorem is to estimate the size of the maximum matching in planar graphs (and bounded arboricity graphs). This can be done with $\tilde{O}(1)$ space, $\tilde{O}(1)$ update time, and $\tilde{O}(1)$ query time [37]. In fact, none of the other results presented in this paper can be derived from this theorem.

4 EXPERIMENTS

In this section, we empirically evaluate the efficiency of our algorithms in the on-device public-private model. For experimentation purposes, to ensure replicability of the results, and for privacy reasons, we exclusively use public-available data for all our experiments. All our datasets are obtained from the Stanford's SNAP dataset (http://snap.stanford.edu/data) or from the DBLP public data repository of computer science publication records (https://dblp.uni-trier.de/). Of course, these datasets do not contain private data, so as in previous works [15, 39], we simulate the public-private data split in our dataset. We first describe the datasets used and then show how we simulated the public-private data split.

Uniform sampling, linear sampling, and heavy hitter. To evaluate our algorithms for uniform sampling, linear sampling, and heavy hitters, we use three datasets, referred to as `dblp`, `foods` [35], and `movies` [35]. From these three datasets we extract a collection of user-user relationships (representing the social network of the users) and a collection of user-item pairs (representing the items associated to each user). We first present statistics on these datasets.

- `dblp` contains 1.1×10^6 nodes 8.6×10^6 links and 8.1×10^3 distinct items (for 3.5×10^6 total user-items relationships)
- `foods` contains 2.1×10^5 nodes 1.8×10^7 links and 6.8×10^4 distinct items (for 4.7×10^5 total user-items relationships).
- `movies` contains 9.4×10^5 nodes 1.7×10^8 links and 2.4×10^5 distinct items (for 6.7×10^6 total user-items relationships).

For `dblp` the nodes are authors, and the items associated with a node correspond to the venues in which the author published. The social graph instead represents co-authorship relationships among nodes. For `foods` and `movies`, the nodes are users in a recommender system (see [35] for more details), while the user-items relationships represent the objects each user reviewed. The edges in the social network represent co-reviewing relationships.

k-Clustering. To evaluate our algorithms for the k-clustering problem instead we use a dataset where items are associated with a point in a metric space. We use the `gowalla` dataset [16] which contains 2.0×10^5 nodes 9.5×10^5 links and a total of 6.4×10^6 distinct items. The items represent check-ins corresponding to 2d location data. We use $\rho = \infty$ for the norm, corresponding to the well studied k-center problem. The edges in this dataset are the social connections among users.

Simulating the public-private graphs. To obtain examples of public-private graphs as in [15, 39] we mark independently and uniformly a fraction p of the edges in each dataset as private and remove them from the public graph G while adding each private edge u, v to the private graphs G_u and G_v. We use $p = 1/2$ in the experiments reported, but this coefficient does not qualitatively affect the results obtained. As the most salient aspect of the model is the sketching of the public data in the preprocessing phase we mark all items as public in our experiments, again this does not qualitatively affect the results significantly.

4.1 Results for uniform sampling, linear sampling, and heavy hitter

Here we experiment with our algorithms for uniform sampling, linear sampling, and heavy hitter. In this setting, we use $d = 2$ and $d = 3$ for the radius of the neighborhood around a node for which we extract the suggestions. We chose this range as it is large enough to be algorithmically challenging but not so large that it results in little variability between node suggestions (it is well known that most nodes are at distance 4 to 5 from each other [8, 34]). We experiment with the recommendation number k in the range $[1, 10]$. For heavy hitter we set $\kappa = k$, $\epsilon = \frac{1}{2k}$, and probability of success to 90% (i.e, we upper bound the number of recommendations by k). For stability of the results, when we report the running time, we show the mean of 100 independent executions.

Recall that our aim is to provide to node u suggestions from $S_u^d(G \cup G_u) = S_u^V \cup \bigcup_{v \in N_u^d(G \cup G_u)} S_v^P$ according to the definitions of the specific problem (uniform sampling, linear sampling, and heavy hitter). Notice that our on-device algorithms for uniform sampling and linear sampling are guaranteed to have the same output of a centralized algorithm that analyzes all the data (private and public) in $S_u^d(G \cup G_u)$ and then computes the suggestions. Moreover, our on-device algorithm for heavy hitters has the same output (and hence accuracy) of the centralized sketch-based algorithm running on all the data in $S_u^d(G \cup G_u)$. As such, in our experiments for these problems, we focus on the efficiency of the algorithms. Our main aim is to show that executing the query algorithm for a single

node is highly efficient and can be performed on an inexpensive device. In particular, we seek to show that our preprocessing allows the query time to be much faster than without preprocessing the data. To show this, we make the conservative comparison of the running time of our query algorithm, executed for one node u, with an algorithm that simply loads in memory all data in $S_u^d(G \cup G_u)$ (which is much faster than an algorithm computing the suggestions). This will show the gains that come from the preprocessing. Also, we show the preprocessing algorithm running time to evaluate its scalability in a centralized system. For ease of comparison of the preprocessing and query algorithm running times, we ran all our algorithms (preprocessing and query) as a standard sequential single-core job on the same machine (we used an Intel Xeon CPU E5-1650 v4 with 6 cores at 3.60 GHz, running Debian). Each job uses a single core, but we observe that the preprocessing algorithms lead to an obvious distributed implementation. We observe for the query algorithms very little memory use (less than 1 MB for the data storage), while the preprocessing used less than 10 GB of RAM.

(a) `movies` preprocessing time

(b) `movies` query time

Figure 2: Running time of the preprocessing and query algorithm for heavy hitter.

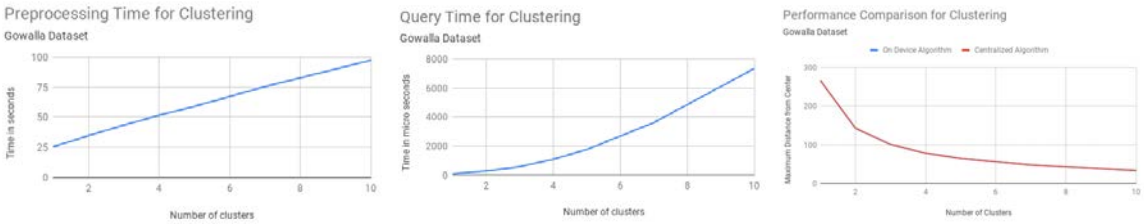
Preprocessing. We report the running time of our preprocessing algorithms in Figures 2a for the heavy hitter case in `movies`. We omit the figures for the uniform and linear sampling case for lack of space as well as the figures for `dblp`, `foods`. The results are qualitatively similar in all datasets and problems more details are deferred to the full version of the paper.

From the charts, we can make the following observations. Note that as expected, the number of recommendations has only an almost-linear effect on the preprocessing time. The radius d has also a moderate effect on the preprocessing time.

Query time. We now focus on the query time, which is reported in Figure 2b for heavy hitter in `movies` (results for linear and uniform sampling and for other datasets are omitted for lack of space, but are qualitatively very similar). Here we can observe that the diameter, as expected, does not affect the query time. As expected, increasing the number of recommendations has a linear effect on the query time. We observe running times that range from 0.5 to 2.00 milliseconds per query in heavy hitter for the movies dataset (see Figure 2b), showing great efficiency.

Recall that to show a conservative estimate of the speedup of the running time of our query algorithm due to the preprocessing, we compare its mean running time (over 100 random nodes u) with the mean running time of an algorithm that simply loads in memory all data in $S_u^d(G \cup G_u)$. Our experiments for linear sampling, uniform sampling, and heavy hitter shows that the query time for `dblp` obtains a speedup of a factor 10 to 100 for $d = 2$ and a factor 100 to 1000 for $d = 3$ by the preprocessing. Similarly, for `foods` we see a factor 20 to 200 for $d = 2$ and a factor 400 to 4000 for $d = 3$ and for `movies` a factor 200 to 2000 for $d = 2$ and a factor 15000 to 150000 for $d = 3$.

4.2 Results for clustering



In this section, we show similar experimental results for our algorithm for k-center (i.e., k-clustering with $\rho = \infty$) in the `gowalla` dataset. We set the number of points in the core-set to be k and we set the de-duplication method to use $E[|\hat{A}_i|] = 10|A_i|$. As clustering algorithm, to obtain the core-sets we use the standard k-center greedy algorithm. The running times are reported in Figure 3a and Figure 3b for preprocessing and query algorithm, respectively, for $d = 2$ and $k \in [1, 10]$ clusters. The preprocessing time is again linearly related to k. The average running time per query is less than 9 milliseconds. Here we observe that the running time has a more than linear relationship with k but still is extremely fast for all k. Again, as a benchmark, we compare the running times of the query algorithm with a centralized algorithm: gathering the items on a 2-neighborhood of the query node, we run the same greedy k-center algorithm and observe an increase in speed from a factor of 38 to a factor of 700 times for $d = 2$. Again, this confirms that the preprocessing improves performances significantly.

Then, in Figure 3c, we evaluated the cost of the clustering solution obtained by our algorithm (using the point de-duplication technique) and the cost obtained by a centralized clustering algorithm that runs over the correct dataset without duplicates. We recall that the issue with the composability of the sketches is that the points in the sketches for the private neighbors are not disjoint (notice that this is true even if each user has distinct points, because the sketches include points at distance 2 from the neighbor). For this reason, we introduced a sketching technique to estimate the correct multiplicity of the points in the core-sets. As it is possible to see in the figure, the two lines are almost coincident. In fact, we observe less than 1% variation in the cost of the two solutions, confirming the accuracy of the method beyond the worst case guarantees in this dataset.

5 RELATED WORK

Related work to our paper spans a variety of areas, so we will focus only on the most directly related ones.

Our paper is motivated by the importance of preserving privacy in social-network-based systems. This area has attracted significant attention [21, 26, 27, 48]. Several authors describe attacks and remedies to potential attacks on social-networks' privacy [9,

(a) `gowalla` preprocessing time **(b) `gowalla` query time** **(c) `gowalla` clustering solution cost**

Figure 3: Running time of the preprocessing and query algorithm for clustering and cost of the clustering solution.

47, 48]. Users are increasingly interested in privacy controls of social-network data as Dey et al. [21] observe.

Private-public data model. This interest has motivated many privacy-preserving frameworks in the past. The one most related to our work is the public-private graph framework [15] described in section 2. Chierichetti et al. [15] show how the framework allows multiple graph problems to be solved, including connected components, all-pair distance estimation [19], node similarity scores as social affinity [41], correlation clustering [10], shortest paths [20], and Personalized PageRank computation [25]. Notice that Chierichetti et al. [15] do not explicitly address the issue of keeping the user's private data on the device of limited capacity because it models a centralized setting.

The original framework was defined for graph problems only, however, other non-graph problems have been studied such as the data summarization framework [39], where users possess both private and public data and one wants to summarize the data for personalized recommender systems. The authors show succinct summaries for optimizing submodular user utility functions. Similarly, Archer et al. [7] study indexing problems in public-private graphs, where one wants to retrieve nodes visible to a user. Neither Mirzasoleiman et al. [39] nor Archer et al. [7] define explicitly a notion of on-device computation.

Other privacy-preserving learning models. Related to ours is the rich area of research on differential privacy [1, 22, 23]. Differential privacy was originally proposed as a model for preventing leakage of individuals' information from the output of a computation over private databases. In a nutshell, a differentially private algorithm is guaranteed to have an output that is mostly unaffected by the data of any given user, in a strong probabilistic sense. This strong constraint limits the information over the private data that an attacker can learn. This method has found wide adoption in many areas of computer science, including deep learning [1], for its theoretical elegance and its strong guarantees.

The original applications of differential privacy were in centralized settings, but recently, several studies have used it to protect communication of on-device data to a central authority. An example is Qin et al. [43], who address recommender system problems using differential privacy in a setting not involving social-graph-based information (unlike our paper). More generally, the local differential privacy [24] technique consisting of perturbing local information before sending it to the central authority has received wide attention because it allows the computation of aggregate statistics over user data.

Another related topic is the setting of federated learning [38]. In a federated learning scenario, the users of a system want to optimize a shared machine learning model (e.g., training a single model for all users, using their own private on-device data in a distributed setting without sharing it to the central machine). In this setting, several works [14, 38] show strong theoretical guarantees of privacy based on differential privacy and sophisticated cryptographic protocols [14]. We observe that the setting is different from ours because it does not directly model social-graph-based information, and it focuses on the problem of using every user's data to improve machine learning models for all users.

Contrary to previous work, in our on-device framework, we do not rely directly on differential privacy techniques, as we guarantee, by design, an even stronger notion of privacy because private data is only used to provide output to the data owner. We also observe that our model does not require the insertion of noise in the output, the estimation of output sensitivity [23], or the use of specific cryptographic protocols. However, we believe that the wealth of theoretical results on differential privacy, federated learning, and other areas conceivably can be used to address a wide class of problems in variants of our model, an effort that we leave as an open problem.

Algorithmic problems addressed in our work. Our paper addresses several algorithmic problems in heavy hitters [33] and clustering [4, 29], both of which have a vast literature. Related to our algorithmic techniques is the area of streaming algorithms and streaming data analysis [30, 36, 45]. In particular, we use extensively techniques from sketching [5, 6] that have found applications in graph problems [13, 17, 18, 36, 40]. Particularly related are the notions of composable sketches, which are also related to the concept of composable core-sets [3, 28], mergeable summaries [2], and mapping core-sets for clustering [11].

Finally, to obtain our impossibility results, we use a few important results such as [31, 32, 44].

6 CONCLUSIONS

We introduce a new model for addressing several computational problems while providing strong privacy guarantees for the data and contacts present on a user's device. We believe that our paper further shows how techniques from streaming and sketching can

be used for privacy-preserving computations in on-device computations. As a future work, we would like to further explore the connection of the area of streaming and privacy to address more problems in the on-device public-private model. Also, an interesting area of study is the use of differential-privacy methods in this model.

Acknowledgments. We thank Flavio Chierichetti, Ravi Kumar and Silvio Lattanzi for their work on the public-private graph model that inspired this work.

ABSTRACT

In recent years, Graph Neural Networks (GNNs), which can naturally integrate node information and topological structure, have been demonstrated to be powerful in learning on graph data. These advantages of GNNs provide great potential to advance social recommendation since data in social recommender systems can be represented as user-user social graph and user-item graph; and learning latent factors of users and items is the key. However, building social recommender systems based on GNNs faces challenges. For example, the user-item graph encodes both interactions and their associated opinions; social relations have heterogeneous strengths; users involve in two graphs (e.g., the user-user social graph and the user-item graph). To address the three aforementioned challenges simultaneously, in this paper, we present a novel graph neural network framework **(GraphRec)** for social recommendations. In particular, we provide a principled approach to jointly capture interactions and opinions in the user-item graph and propose the framework GraphRec, which coherently models two graphs and heterogeneous strengths. Extensive experiments on two real-world datasets demonstrate the effectiveness of the proposed framework GraphRec.

1 INTRODUCTION

The exploitation of social relations for recommender systems has attracted increasing attention in recent years [18, 28, 30]. These social recommender systems have been developed based on the phenomenon that users usually acquire and disseminate information through those around them, such as classmates, friends, or colleagues, implying that the underlying social relations of users can play a significant role in helping them filter information [23]. Hence, social relations have been proven to be helpful in boosting the recommendation performance [8, 29].

Recent years have witnessed great developments in deep neural network techniques for graph data [15]. These deep neural network architectures are known as Graph Neural Networks (GNNs) [5, 10, 19], which have been proposed to learn meaningful representations for graph data. Their main idea is how to iteratively aggregate feature information from local graph neighborhoods using neural networks. Meanwhile, node information can be propagated through a graph after transformation and aggregation. Hence, GNNs naturally integrate the node information as well as the topological structure and have been demonstrated to be powerful in representation learning [5, 7, 15]. On the other hand, data in social recommendation can be represented as graph data with two graphs. As demonstrated in Figure 1, these two graphs include a social graph denoting the relationships between users, and a user-item graph denoting interactions between users and items. Users are simultaneously involved in both graphs, who can bridge them. Moreover, the natural way of social recommendation is to incorporate the social network information into user and item latent factors learning [37]. Learning representations of items and users is the key to build social recommender systems. Thus, given their advantages, GNNs provide unprecedented opportunities to advance social recommendation.

Meanwhile, building social recommender systems based on GNNs faces challenges. The social graph and the user-item graph in a social recommender system provide information about users from different perspectives. It is important to aggregate information

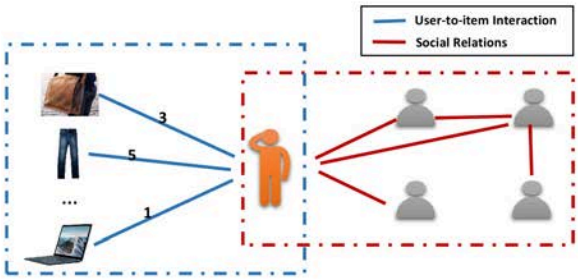

Figure 1: Graph Data in Social Recommendation. It contains two graphs including the user-item graph (left part) and the user-user social graph (right part). Note that the number on the edges of the user-item graph denotes the opinions (or rating score) of users on the items via the interactions.

from both graphs to learn better user representations. Thus, the first challenge is how to inherently combine these two graphs. Moreover, the user-item graph not only contains interactions between users and items but also includes users' opinions on items. For example, as shown in Figure 1, the user interacts with the items of "trousers" and "laptop"; and the user likes "trousers" while disliking "laptop". Therefore, the second challenge is how to capture interactions and opinions between users and items jointly. In addition, the low cost of link formation in online worlds can result in networks with varied tie strengths (e.g., strong and weak ties are mixed together) [36]. Users are likely to share more similar tastes with strong ties than weak ties. Considering social relations equally could lead to degradation in recommendation performance. Hence, the third challenge is how to distinguish social relations with heterogeneous strengths.

In this paper, we aim to build social recommender systems based on graph neural networks. Specially, we propose a novel graph neural network **GraphRec** for social recommendations, which can address three aforementioned challenges simultaneously. Our major contributions are summarized as follows:

- We propose a novel graph neural network GraphRec, which can model graph data in social recommendations coherently;
- We provide a principled approach to jointly capture interactions and opinions in the user-item graph;
- We introduce a method to consider heterogeneous strengths of social relations mathematically; and
- We demonstrate the effectiveness of the proposed framework on various real-world datasets.

The remainder of this paper is organized as follows. We introduce the proposed framework in Section 2. In Section 3, we conduct experiments on two real-world datasets to illustrate the effectiveness of the proposed method. In Section 4, we review work related to our framework. Finally, we conclude our work with future directions in Section 5.

2 THE PROPOSED FRAMEWORK

In this section, we will first introduce the definitions and notations used in this paper, next give an overview about the proposed framework, then detail each model component and finally discuss how to learn the model parameters.

Table 1: Notation

Symbols	Definitions and Descriptions
r_{ij}	The rating value of item v_j by user u_i
$\mathbf{q}_j$	The embedding of item v_j
$\mathbf{p}_i$	The embedding of user u_i
$\mathbf{e}_r$	The opinion embedding for the rating level r, such as 5-star rating, $r \in \{1, 2, 3, 4, 5\}$
d	The length of embedding vector
$C(i)$	The set of items which user u_i interacted with
$N(i)$	The set of social friends who user u_i directly connected with
$B(j)$	The set of users who have interacted the item v_j
$\mathbf{h}_i^I$	The item-space user latent factor from item set $C(i)$ of user u_i
$\mathbf{h}_i^S$	The social-space user latent factor from the social friends $N(i)$ of user u_i
$\mathbf{h}_i$	The user latent factor of user u_i, combining from item space $\mathbf{h}_i^I$ and social space $\mathbf{h}_i^S$
$\mathbf{x}_{ia}$	The opinion-aware interaction representation of item v_a for user u_i
$\mathbf{f}_{jt}$	The opinion-aware interaction representation of user u_t for item v_j
$\mathbf{z}_j$	The item latent factor of item v_j
α_{ia}	The item attention of item v_a in contributing to $\mathbf{h}_i^I$
β_{io}	The social attention of neighboring user u_o in contributing to $\mathbf{h}_i^S$
μ_{jt}	The user attention of user u_t in contributing to $\mathbf{z}_j$
r'_{ij}	The predicted rating value of item v_j by user u_i
$\oplus$	The concatenation operator of two vectors
T	The user-user social graph
R	The user-item rating matrix (user-item graph)
W, **b**	The weight and bias in neural network

2.1 Definitions and Notations

Let $U = \{u_1, u_2, ..., u_n\}$ and $V = \{v_1, v_2, ..., v_m\}$ be the sets of users and items respectively, where n is the number of users, and m is the number of items. We assume that $\mathbf{R} \in \mathbb{R}^{n \times m}$ is the user-item rating matrix, which is also called the user-item graph. If u_i gives a rating to v_j, r_{ij} is the rating score, otherwise we employ 0 to represent the unknown rating from u_i to v_j, i.e., $r_{ij} = 0$. The observed rating score r_{ij} can be seen as user u_i's opinion on the item v_j. Let $\mathcal{O} = \left\{\left\langle u_i, v_j \right\rangle | r_{ij} \neq 0\right\}$ be the set of known ratings and $\mathcal{T} = \left\{\left\langle u_i, v_j \right\rangle | r_{ij} = 0\right\}$ be the set of unknown ratings. Let $N(i)$ be the set of users whom u_i directly connected with, $C(i)$ be the set of items which u_i have interacted with, and $B(j)$ be the set of users who have interacted with v_j. In addition, users can establish social relations to each other. We use $\mathrm{T} \in \mathbb{R}^{n \times n}$ to denote the user-user social graph, where $\mathrm{T}_{ij} = 1$ if u_j has a relation to u_i and zero otherwise. Given the user-item graph **R** and social graph T, we aim

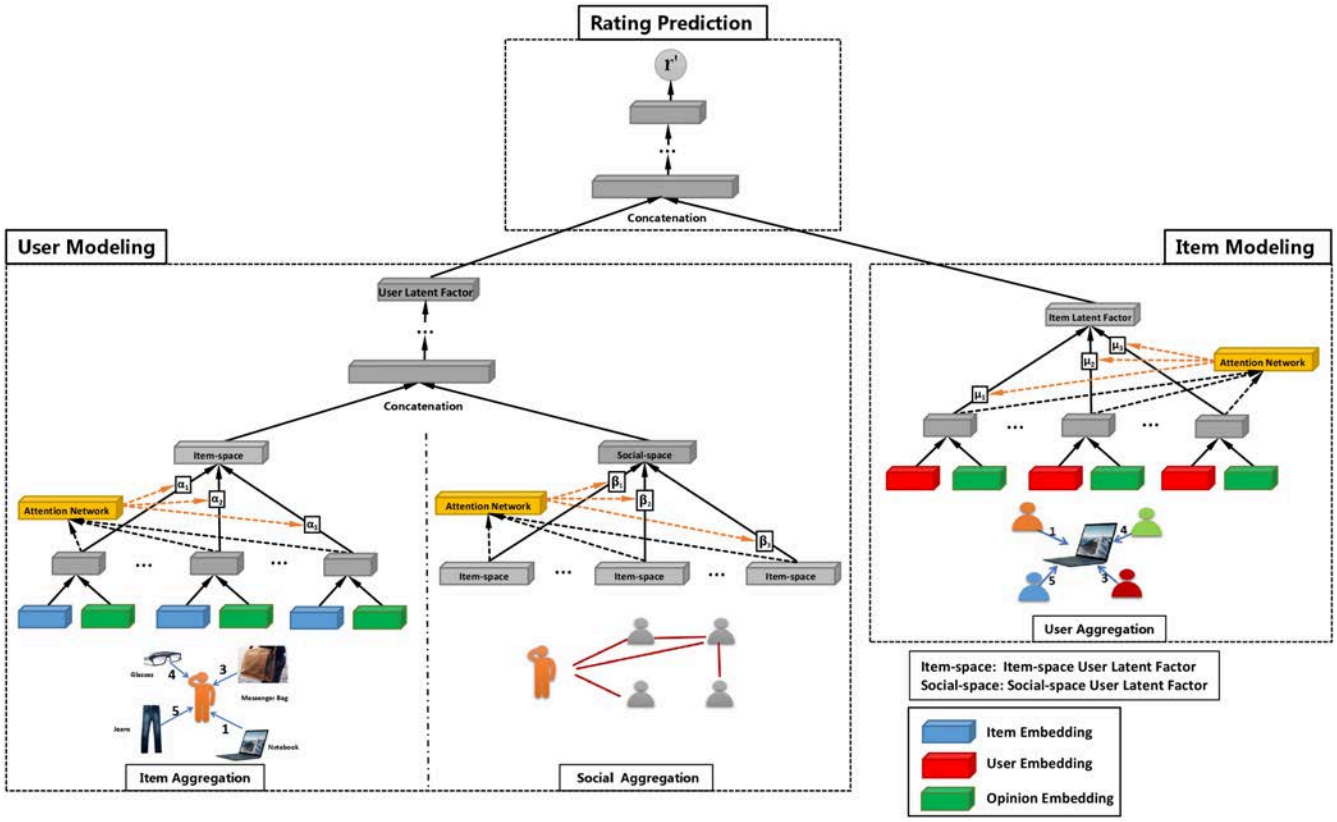

Figure 2: The overall architecture of the proposed model. It contains three major components: user modeling, item modeling, and rating prediction.

to predict the missing rating value in $\mathbf{R}$. Following [11], we use an embedding vector $\mathbf{p}_i \in \mathbb{R}^d$ to denote a user u_i and an embedding vector $\mathbf{q}_j \in \mathbb{R}^d$ to represent an item v_j, where d is the length of embedding vector. More details will be provided about these embedding vectors in the following subsections. The mathematical notations used in this paper are summarized in Table 1.

2.2 An Overview of the Proposed Framework

The architecture of the proposed model is shown in Figure 2. The model consists of three components: user modeling, item modeling, and rating prediction. The first component is user modeling, which is to learn latent factors of users. As data in social recommender systems includes two different graphs, i.e., a social graph and a user-item graph, we are provided with a great opportunity to learn user representations from different perspectives. Therefore, two aggregations are introduced to respectively process these two different graphs. One is item aggregation, which can be utilized to understand users via interactions between users and items in the user-item graph (or item-space). The other is social aggregation, the relationship between users in the social graph, which can help model users from the social perspective (or social-space). Then, it is intuitive to obtain user latent factors by combining information from both item space and social space. The second component is item modeling, which is to learn latent factors of items. In order to consider both interactions and opinions in the user-item graph, we introduce user aggregation, which is to aggregate users' opinions in item modeling. The third component is to learn model parameters via prediction by integrating user and item modeling components. Next, we will detail each model component.

2.3 User Modeling

User modeling aims to learn user latent factors, denoted as $\mathbf{h}_i \in \mathbb{R}^d$ for user u_i. The challenge is how to inherently combine the user-item graph and social graph. To address this challenge, we first use two types of aggregation to learn factors from two graphs, as shown in the left part in Figure 2. The first aggregation, denoted as item aggregation, is utilized to learn item-space user latent factor $\mathbf{h}_i^I \in \mathbb{R}^d$ from the user-item graph. The second aggregation is social aggregation where social-space user latent factor $\mathbf{h}_i^S \in \mathbb{R}^d$ is learned from the social graph. Then, these two factors are combined together to form the final user latent factors $\mathbf{h}_i$. Next, we will introduce item aggregation, social aggregation and how to combine user latent factors from both item-space and social-space.

Item Aggregation. As user-item graph contains not only interactions between users and items but also users' opinions (or rating scores) on items, we provide a principled approach to jointly capture interactions and opinions in the user-item graph for

learning item-space user latent factors $\mathbf{h}_i^I$, which is used to model user latent factor via interactions in the user-item graph.

The purpose of item aggregation is to learn item-space user latent factor $\mathbf{h}_i^I$ by considering items a user u_i has interacted with and users' opinions on these items. To mathematically represent this aggregation, we use the following function as:

$$\mathbf{h}_i^I = \sigma(\mathbf{W} \cdot Aggre_{items}(\{\mathbf{x}_{ia}, \forall a \in C(i)\}) + \mathbf{b}) \tag{1}$$

where $C(i)$ is the set of items user u_i has interacted with (or u_i's neighbors in the user-item graph), $\mathbf{x}_{ia}$ is a representation vector to denote opinion-aware interaction between u_i and an item v_a, and $Aggre_{items}$ is the items aggregation function. In addition, σ denotes non-linear activation function (i.e., a rectified linear unit), and $\mathbf{W}$ and $\mathbf{b}$ are the weight and bias of a neural network. Next we will discuss how to define opinion-aware interaction representation $\mathbf{x}_{ia}$ and the aggregation function $Aggre_{items}$.

A user can express his/her opinions (or rating scores), denoted as r, to items during user-item interactions. These opinions on items can capture users' preferences on items, which can help model item-space user latent factors. To model opinions, for each type of opinions r, we introduce an opinion embedding vector $\mathbf{e}_r \in \mathbb{R}^d$ that denotes each opinion r as a dense vector representation. For example, in a 5-star rating system, for each $r \in \{1, 2, 3, 4, 5\}$, we introduce an embedding vector $\mathbf{e}_r$. For an interaction between user u_i and item v_a with opinion r, we model opinion-aware interaction representation $\mathbf{x}_{ia}$ as a combination of item embedding $\mathbf{q}_a$ and opinion embedding $\mathbf{e}_r$ via a Multi-Layer Perceptron (MLP). It can be denoted as g_v to fuse the interaction information with the opinion information as shown in Figure 2. The MLP takes the concatenation of item embedding $\mathbf{q}_a$ and its opinion embedding $\mathbf{e}_r$ as input. The output of MLP is the opinion-aware representation of the interaction between u_i and v_a, $\mathbf{x}_{ia}$, as follows:

$$\mathbf{x}_{ia} = g_v([\mathbf{q}_a \oplus \mathbf{e}_r]) \tag{2}$$

where $\oplus$ denotes the concatenation operation between two vectors.

One popular aggregation function for $Aggre_{items}$ is the mean operator where we take the element-wise mean of the vectors in $\{\mathbf{x}_{ia}, \forall a \in C(i)\}$. This mean-based aggregator is a linear approximation of a localized spectral convolution [15], as the following function:

$$\mathbf{h}_i^I = \sigma(\mathbf{W} \cdot \left\{ \sum_{a \in C(i)} \alpha_i \mathbf{x}_{ia} \right\} + \mathbf{b}) \tag{3}$$

where α_i is fixed to $\frac{1}{|C(i)|}$ for all items in the mean-based aggregator. It assumes that all interactions contribute equally to understand the user u_i. However, this may not be optimal, due to the fact that the influence of interactions on users may vary dramatically. Hence, we should allow interactions to contribute differently to a user's latent factor by assigning each interaction a weight.

To alleviate the limitation of mean-based aggregator, inspired by attention mechanisms [3, 38], an intuitive solution is to tweak α_i to be aware of the target user u_i, i.e., assigning an individualized weight for each (v_a, u_i) pair,

$$\mathbf{h}_i^I = \sigma(\mathbf{W} \cdot \left\{ \sum_{a \in C(i)} \alpha_{ia} \mathbf{x}_{ia} \right\} + \mathbf{b}) \tag{4}$$

where α_{ia} denotes the attention weight of the interaction with v_a in contributing to user u_i's item-space latent factor when characterizing user u_i's preference from the interaction history $C(i)$. Specially, we parameterize the *item attention* α_{ia} with a two-layer neural network, which we call as the *attention network*. The input to the attention network is the opinion-aware representation $\mathbf{x}_{ia}$ of the interaction and the target user u_i's embedding $\mathbf{p}_i$. Formally, the attention network is defined as,

$$\alpha_{ia}^* = \mathbf{w}_2^T \cdot \sigma(\mathbf{W}_1 \cdot [\mathbf{x}_{ia} \oplus \mathbf{p}_i] + \mathbf{b}_1) + b_2 \tag{5}$$

The final attention weights are obtained by normalizing the above attentive scores using Softmax function, which can be interpreted as the contribution of the interaction to the item-space user latent factor of user u_i as:

$$\alpha_{ia} = \frac{exp(\alpha_{ia}^*)}{\sum_{a \in C(i)} exp(\alpha_{ia}^*)} \tag{6}$$

Social Aggregation. Due to the social correlation theories [20, 21], a user's preference is similar to or influenced by his/her directly connected social friends. We should incorporate social information to further model user latent factors. Meanwhile, tie strengths between users can further influence users' behaviors from the social graph. In other words, the learning of social-space user latent factors should consider heterogeneous strengths of social relations. Therefore, we introduce an attention mechanism to select social friends that are representative to characterize users social information and then aggregate their information.

In order to represent user latent factors from this social perspective, we propose social-space user latent factors, which is to aggregate the item-space user latent factors of neighboring users from the social graph. Specially, the social-space user latent factor of u_i, $\mathbf{h}_i^S$, is to aggregate the item-space user latent factors of users in u_i's neighbors $N(i)$, as the follows:

$$\mathbf{h}_i^S = \sigma(\mathbf{W} \cdot Aggre_{neigbhors}(\left\{\mathbf{h}_o^I, \forall o \in N(i)\right\}) + \mathbf{b}) \tag{7}$$

where $Aggre_{neigbhors}$ denotes the aggregation function on user's neighbors.

One natural aggregation function for $Aggre_{neigbhors}$ is also the mean operator which take the element-wise mean of the vectors in $\left\{\mathbf{h}_o^I, \forall o \in N(i)\right\}$, as the following function:

$$\mathbf{h}_i^S = \sigma(\mathbf{W} \cdot \left\{ \sum_{o \in N(i)} \beta_i \mathbf{h}_o^I \right\} + \mathbf{b}) \tag{8}$$

where β_i is fixed to $\frac{1}{|N(i)|}$ for all neighbors for the mean-based aggregator. It assumes that all neighbors contribute equally to the representation of user u_i. However, as mentioned before, strong and weak ties are mixed together in a social network, and users are likely to share more similar tastes with strong ties than weak ties. Thus, we perform an attention mechanism with a two-layer neural network to extract these users that are important to influence u_i, and model their tie strengths, by relating *social attention* β_{io} with

$\mathbf{h}_o^I$ and the target user embedding $\mathbf{p}_i$, as below,

$$\mathbf{h}_i^S = \sigma(\mathbf{W} \cdot \left\{ \sum_{o \in N(i)} \beta_{io} \mathbf{h}_o^I \right\} + \mathbf{b}) \tag{9}$$

$$\beta_{io}^* = \mathbf{w}_2^T \cdot \sigma(\mathbf{W}_1 \cdot [\mathbf{h}_o^I \oplus \mathbf{p}_i] + \mathbf{b}_1) + b_2 \tag{10}$$

$$\beta_{io} = \frac{exp(\beta_{io}^*)}{\sum_{o \in N(i)} exp(\beta_{io}^*)} \tag{11}$$

where the β_{io} can be seen as the strengths between users.

Learning User Latent Factor. In order to learn better user latent factors, item-space user latent factors and social-space user latent factors are needed to be considered together, since the social graph and the user-item graph provide information about users from different perspectives. We propose to combine these two latent factors to the final user latent factor via a standard MLP where the item-space user latent factor $\mathbf{h}_i^I$ and the social-space user latent factor $\mathbf{h}_i^S$ are concatenated before feeding into MLP. Formally, the user latent factor $\mathbf{h}_i$ is defined as,

$$\mathbf{c}_1 = \left[\mathbf{h}_i^I \oplus \mathbf{h}_i^S \right] \tag{12}$$

$$\mathbf{c}_2 = \sigma(\mathbf{W}_2 \cdot \mathbf{c}_1 + \mathbf{b}_2) \tag{13}$$

$$\cdots$$

$$\mathbf{h}_i = \sigma(\mathbf{W}_l \cdot \mathbf{c}_{l-1} + \mathbf{b}_l) \tag{14}$$

where l is the index of a hidden layer.

2.4 Item Modeling

As shown in the right part of Figure 2, item modeling is used to learn item latent factor, denoted as $\mathbf{z}_j$, for the item v_j by user aggregation. Items are associated with the user-item graph, which contains interactions as well as user's opinions. Therefore, interactions and opinions in the user-item graph should be jointly captured to further learn item latent factors.

User Aggregation. Likewise, we use a similar method as learning item-space user latent factors via item aggregation. For each item v_j, we need to aggregate information from the set of users who have interacted with v_j, denoted as $B(j)$.

Even for the same item, users might express different opinions during user-item interactions. These opinions from different users can capture the characteristics of the same item in different ways provided by users, which can help model item latent factors. For an interaction from u_t to v_j with opinion r, we introduce an opinion-aware interaction user representation $\mathbf{f}_{jt}$, which is obtained from the basic user embedding $\mathbf{p}_t$ and opinion embedding $\mathbf{e}_r$ via a MLP, denoted as g_u. g_u is to fuse the interaction information with the opinion information, as shown in Figure 2:

$$\mathbf{f}_{jt} = g_u([\mathbf{p}_t \oplus \mathbf{e}_r]) \tag{15}$$

Then, to learn item latent factor $\mathbf{z}_j$, we also propose to aggregate opinion-aware interaction representation of users in $B(j)$ for item v_j. The users aggregation function is denoted as $Aggre_{users}$, which is to aggregate opinion-aware interaction representation of users in $\left\{ \mathbf{f}_{jt}, \forall t \in B(j) \right\}$ as:

$$\mathbf{z}_j = \sigma(\mathbf{W} \cdot Aggre_{users}(\left\{ \mathbf{f}_{jt}, \forall t \in B(j) \right\}) + \mathbf{b}) \tag{16}$$

In addition, we introduce an attention mechanism to differentiate the importance weight μ_{jt} of users with a two-layer neural attention network, taking $\mathbf{f}_{jt}$ and $\mathbf{q}_j$ as the input,

$$\mathbf{z}_j = \sigma(\mathbf{W} \cdot \left\{ \sum_{t \in B(j)} \mu_{jt} \mathbf{f}_{jt} \right\} + \mathbf{b}) \tag{17}$$

$$\mu_{jt}^* = \mathbf{w}_2^T \cdot \sigma(\mathbf{W}_1 \cdot [\mathbf{f}_{jt} \oplus \mathbf{q}_j] + \mathbf{b}_1) + b_2 \tag{18}$$

$$\mu_{jt} = \frac{exp(\mu_{jt}^*)}{\sum_{t \in B_{(j)}} exp(\mu_{jt}^*)} \tag{19}$$

This *user attention* μ_{jt} is to capture heterogeneous influence from user-item interactions on learning item latent factor.

2.5 Rating Prediction

In this subsection, we will design recommendation tasks to learn model parameters. There are various recommendation tasks such as item ranking and rating prediction. In this work, we apply the proposed GraphRec model for the recommendation task of rating prediction. With the latent factors of users and items (i.e., $\mathbf{h}_i$ and $\mathbf{z}_j$), we can first concatenate them $\left[\mathbf{h}_i \oplus \mathbf{z}_j \right]$ and then feed it into MLP for rating prediction as:

$$\mathbf{g}_1 = \left[\mathbf{h}_i \oplus \mathbf{z}_j \right] \tag{20}$$

$$\mathbf{g}_2 = \sigma(\mathbf{W}_2 \cdot \mathbf{g}_1 + \mathbf{b}_2) \tag{21}$$

$$\cdots$$

$$\mathbf{g}_{l-1} = \sigma(\mathbf{W}_l \cdot \mathbf{g}_{l-1} + \mathbf{b}_l) \tag{22}$$

$$r'_{ij} = \mathbf{w}^T \cdot \mathbf{g}_{l-1} \tag{23}$$

where l is the index of a hidden layer, and r'_{ij} is the predicted rating from u_i to v_j.

2.6 Model Training

To estimate model parameters of GraphRec, we need to specify an objective function to optimize. Since the task we focus on in this work is rating prediction, a commonly used objective function is formulated as,

$$Loss = \frac{1}{2\,|O|} \sum_{i,j \in O} (r'_{ij} - r_{ij})^2 \tag{24}$$

where $|O|$ is the number of observed ratings , and r_{ij} is the ground truth rating assigned by the user i on the item j.

To optimize the objective function, we adopt the RMSprop [31] as the optimizer in our implementation, rather than the vanilla SGD. At each time, it randomly selects a training instance and updates each model parameter towards the direction of its negative gradient. There are three embedding in our model, including item embedding $\mathbf{q}_j$, user embedding $\mathbf{p}_i$, and opinion embedding $\mathbf{e}_r$. They are randomly initialized and jointly learned during the training stage. We do not use one-hot vectors to represent each user and item, since the raw features are very large and highly sparse. By embedding high-dimensional sparse features into a low-dimensional latent space, the model can be easy to train [11]. Opinion embedding matrix $\mathbf{e}$ depends on the rating scale of the system. For example, for a 5-star rating system, opinion embedding

matrix **e** contains 5 different embedding vectors to denote scores in {1, 2, 3, 4, 5}. Overfitting is a perpetual problem in optimizing deep neural network models. To alleviate this issue, the dropout strategy [26] has been applied to our model. The idea of dropout is to randomly drop some neurons during the training process. When updating parameters, only part of them will be updated. Moreover, as dropout is disabled during testing, the whole network is used for prediction.

3 EXPERIMENT

3.1 Experimental Settings

3.1.1 Datasets. In our experiments, we choose two representative datasets Ciao and Epinions[1], which are taken from popular social networking websites Ciao (http://www.ciao.co.uk) and Epinions (www.epinions.com). Each social networking service allows users to rate items, browse/write reviews, and add friends to their 'Circle of Trust'. Hence, they provide a large amount of rating information and social information. The ratings scale is from 1 to 5. We randomly initialize opinion embedding with 5 different embedding vectors based on 5 scores in {1, 2, 3, 4, 5}. The statistics of these two datasets are presented in Table 2.

Table 2: Statistics of the datasets

Dataset	Ciao	Epinions
# of Users	7,317	18,088
# of Items	10,4975	261,649
# of Ratings	283,319	764,352
# of Density (Ratings)	0.0368%	0.0161%
# of Social Connections	111,781	355,813
# of Density (Social Relations)	0.2087%	0.1087%

3.1.2 Evaluation Metrics. In order to evaluate the quality of the recommendation algorithms, two popular metrics are adopted to evaluate the predictive accuracy, namely Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) [34]. Smaller values of MAE and RMSE indicate better predictive accuracy. Note that small improvement in RMSE or MAE terms can have a significant impact on the quality of the top-few recommendations [16].

3.1.3 Baselines. To evaluate the performance, we compared our GraphRec with three groups of methods including traditional recommender systems, traditional social recommender systems, and deep neural network based recommender systems. For each group, we select representative baselines and below we will detail them.

- **PMF** [24]: **P**robabilistic **M**atrix **F**actorization utilizes user-item rating matrix only and models latent factors of users and items by Gaussian distributions.
- **SoRec** [17]: **So**cial **Rec**ommendation performs co-factorization on the user-item rating matrix and user-user social relations matrix.
- **SoReg** [18]: **So**cial **Reg**ularization models social network information as regularization terms to constrain the matrix factorization framework.
- **SocialMF** [13]: It considers the trust information and propagation of trust information into the matrix factorization model for recommender systems.
- **TrustMF** [37]: This method adopts matrix factorization technique that maps users into two low-dimensional spaces: truster space and trustee space, by factorizing trust networks according to the directional property of trust.
- **NeuMF** [11]: This method is a state-of-the-art matrix factorization model with neural network architecture. The original implementation is for recommendation ranking task and we adjust its loss to the squared loss for rating prediction.
- **DeepSoR** [8]: This model employs a deep neural network to learn representations of each user from social relations, and to integrate into probabilistic matrix factorization for rating prediction.
- **GCMC+SN** [1]: This model is a state-of-the-art recommender system with graph neural network architecture. In order to incorporate social network information into GCMC, we utilize the *node2vec* [9] to generate user embedding as user side information, instead of using the raw feature social connections ($T \in \mathbb{R}^{n \times n}$) directly. The reason is that the raw feature input vectors is highly sparse and high-dimensional. Using the network embedding techniques can help compress the raw input feature vector to a low-dimensional and dense vector, then the model can be easy to train.

PMF and NeuMF are pure collaborative filtering model without social network information for rating prediction, while the others are social recommendation. Besides, we compared GraphRec with two state-of-the-art neural network based social recommender systems, i.e., DeepSoR and GCMC+SN.

3.1.4 Parameter Settings. We implemented our proposed method on the basis of Pytorch[2], a well-known Python library for neural networks. For each dataset, we used $x\%$ as a training set to learning parameters, $(1-x\%)/2$ as a validation set to tune hyper-parameters, and $(1-x\%)/2$ as a testing set for the final performance comparison, where x was varied as $\{80\%, 60\%\}$. For the embedding size d, we tested the value of [8, 16, 32, 64, 128, 256]. The batch size and learning rate was searched in [32, 64, 128, 512] and [0.0005, 0.001, 0.005, 0.01, 0.05, 0.1], respectively. Moreover, we empirically set the size of the hidden layer the same as the embedding size and the activation function as ReLU. Without special mention, we employed three hidden layers for all the neural components. The early stopping strategy was performed, where we stopped training if the RMSE on validation set increased for 5 successive epochs. For all neural network methods, we randomly initialized model parameters with a Gaussian distribution, where the mean and standard deviation is 0 and 0.1, respectively. The parameters for the baseline algorithms were initialized as in the corresponding papers and were then carefully tuned to achieve optimal performance.

3.2 Performance Comparison of Recommender Systems

We first compare the recommendation performance of all methods. Table 3 shows the overall rating prediction error $w.r.t.$ RMSE and

[1] http://www.cse.msu.edu/~tangjili/index.html

[2] https://pytorch.org/

Table 3: Performance comparison of different recommender systems

Training	Metrics	Algorithms								
		PMF	SoRec	SoReg	SocialMF	TrustMF	NeuMF	DeepSoR	GCMC+SN	**GraphRec**
Ciao (60%)	MAE	0.952	0.8489	0.8987	0.8353	0.7681	0.8251	0.7813	0.7697	0.7540
	RMSE	1.1967	1.0738	1.0947	1.0592	1.0543	1.0824	1.0437	1.0221	1.0093
Ciao (80%)	MAE	0.9021	0.8410	0.8611	0.8270	0.7690	0.8062	0.7739	0.7526	0.7387
	RMSE	1.1238	1.0652	1.0848	1.0501	1.0479	1.0617	1.0316	0.9931	0.9794
Epinions (60%)	MAE	1.0211	0.9086	0.9412	0.8965	0.8550	0.9097	0.8520	0.8602	0.8441
	RMSE	1.2739	1.1563	1.1936	1.1410	1.1505	1.1645	1.1135	1.1004	1.0878
Epinions (80%)	MAE	0.9952	0.8961	0.9119	0.8837	0.8410	0.9072	0.8383	0.8590	0.8168
	RMSE	1.2128	1.1437	1.1703	1.1328	1.1395	1.1476	1.0972	1.0711	1.0631

MAE among the recommendation methods on Ciao and Epinions datasets. We have the following main findings:

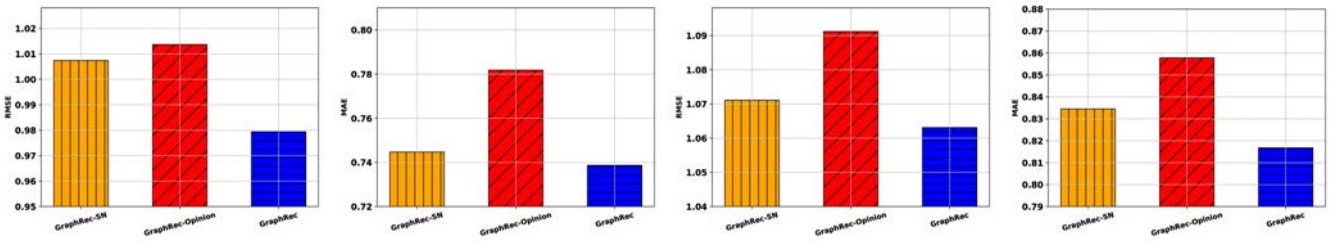
- SoRec, SoReg, SocialMF, and TrustMF always outperform PMF. All of these methods are based on matrix factorization. SoRec, SoReg, SocialMF, and TrustMF leverage both the rating and social network information; while PMF only uses the rating information. These results support that social network information is complementary to rating information for recommendations.
- NeuMF obtains much better performance than PMF. Both methods only utilize the rating information. However, NeuMF is based on neural network architecture, which suggests the power of neural network models in recommender systems.
- DeepSoR and GCMC+SN perform better than SoRec, SoReg, SocialMF, and TrustMF. All of them take advantage of both rating and social network information. However, DeepSoR and GCMC+SN are based on neural network architectures, which further indicate the power of neural network models in recommendations.
- Among baselines, GCMC+SN shows quite strong performance. It implies that the GNNs are powerful in representation learning for graph data, since it naturally integrates the node information as well as topological structure.
- Our method GraphRec consistently outperforms all the baseline methods. Compared to DeepSoR and GCMC+SN, our model provides advanced model components to integrate rating and social network information. In addition, our model provides a way to consider both interactions and opinions in the user-item graph. We will provide further investigations to better understand the contributions of model components to the proposed framework in the following subsection.

To sum up, the comparison results suggest (1) social network information is helpful for recommendations; (2) neural network models can boost recommendation performance and (3) the proposed framework outperforms representative baselines.

3.3 Model Analysis

In this subsection, we study the impact of model components and model hyper-parameters.

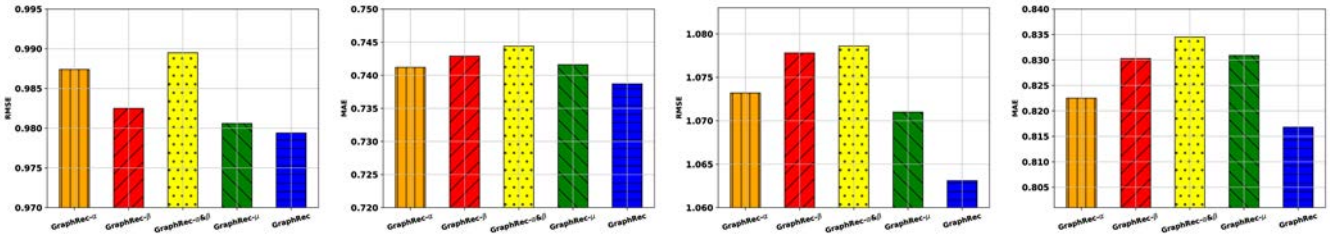
3.3.1 Effect of Social Network and User Opinions. In the last subsection, we have demonstrated the effectiveness of the proposed framework. The proposed framework provides model components to (1) integrate social network information and (2) incorporate users' opinions about the interactions with items. To understand the working of GraphRec, we compare GraphRec with its two variants: GraphRec-SN, and GraphRec-Opinion. These two variants are defined in the following:



- GraphRec-SN: The social network information of GraphRec is removed . This variant only uses the item-space user latent factor $\mathbf{h}_i^I$ to represent user latent factors $\mathbf{h}_i$; while ignoring the social-space user latent factors $\mathbf{h}_i^S$.
- GraphRec-Opinion: For learning item-space user latent factor and item latent factor, the opinion embedding is removed during learning $\mathbf{x}_{ia}$ and $\mathbf{f}_{jt}$. This variant ignores the users' opinion on the user-item interactions.

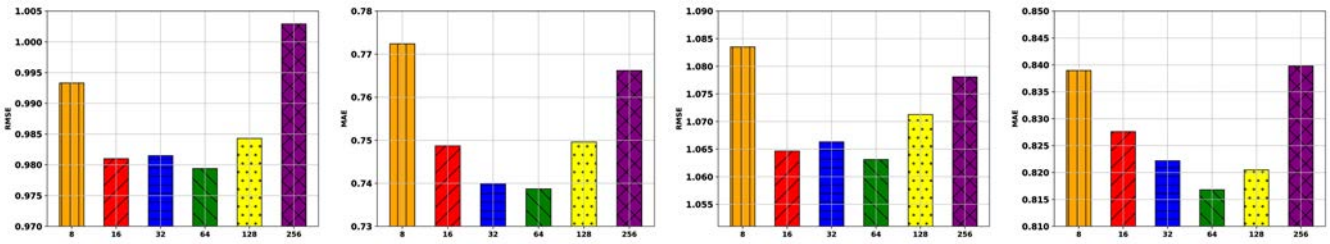
The performance of GraphRec and its variants on Ciao and Epinions are given in Figure 3. From the results, we have the following findings:

- **Social Network Information.** We now focus on analyzing the effectiveness of social network information. GraphRec-SN performs worse than GraphRec. It verifies that social network information is important to learn user latent factors and boost the recommendation performance.
- **Opinions in Interaction.** We can see that without opinion information, the performance of rating prediction is deteriorated significantly. For example, on average, the relative reduction on Ciao and Epinions is 3.50% and 2.64% on RMSE metric, and 5.84% and 5.02% on MAE metric, respectively. It justifies our assumption that opinions on user-item interactions have informative information that can help to learn user or item latent factors and improve the performance of recommendation.



3.3.2 Effect of Attention Mechanisms. To get a better understanding of the proposed GraphRec model, we further evaluate the key components of GraphRec - *Attention mechanisms*. There are three different attention mechanisms during aggregation, including item attention α, social attention β, and user attention μ. We compare GraphRec with its four variants: GraphRec-α, GraphRec-β, GraphRec-$\alpha\&\beta$, and GraphRec-μ. These four variants are defined in the following:

- GraphRec-α: The item attention α of GraphRec is eliminated during aggregating the opinion-aware interaction representation of items. This variant employs the mean-based aggregation function on item aggregation for modeling item-space user latent factors.



(a) Ciao-RMSE (b) Ciao-MAE (c) Epinions-RMSE (d) Epinions-MAE

Figure 3: Effect of social network and user opinions on Ciao and Epinions datasets.

(a) Ciao-RMSE (b) Ciao-MAE (c) Epinions-RMSE (d) Epinions-MAE

Figure 4: Effect of attention mechanisms on Ciao and Epinions datasets.

(a) Ciao-RMSE (b) Ciao-MAE (c) Epinions-RMSE (d) Epinions-MAE

Figure 5: Effect of embedding size on Ciao and Epinions datasets.

- GraphRec-β: The social attention α is to model users' tie strengths. The social attention α of GraphRec in this variant is eliminated during aggregating user's neighbors. This variant employs the mean-based aggregation function on social aggregation for modeling social-space user latent factors.
- GraphRec-$\alpha\&\beta$: This variant eliminates two attention mechanisms (item attention α and social attention β) on item aggregation and social aggregation for modeling user latent factors.
- GraphRec-μ: The user attention μ of GraphRec is eliminated during aggregating opinion-aware interaction user representation. This variant employs the mean-based aggregation function on user aggregation for modeling item latent factors.

The results of different attention mechanisms on GraphRec are shown in Figure 4. From the results, we have the following findings,

- Not all interacted items (purchased history) of one user contribute equally to the item-space user latent factor, and not all interacted users (buyers) have the same importance to learning item latent factor. Based on these assumptions, our model considers these difference among users and items by using two different attention mechanisms (α and μ). From the results, we can observe that GraphRec-α and GraphRec-μ obtain worse performance than GraphRec. These results demonstrate the benefits of the attention mechanisms on item aggregation and user aggregation.
- As mentioned before, users are likely to share more similar tastes with strong ties than weak ties. The attention mechanism β at social aggregation considers heterogeneous

strengths of social relations. When the attention mechanism β is removed, the performance of GraphRec-β is dropped significantly. It justifies our assumption that during social aggregation, different social friends should have different influence for learning social-space user latent factor. It's important to distinguish social relations with heterogeneous strengths.

To sum up, GraphRec can capture the heterogeneity in aggregation operations of the proposed framework via attention mechanisms, which can boost the recommendation performance.

3.3.3 Effect of Embedding Size. In this subsection, to analyze the effect of embedding size of user embedding $\mathbf{p}$, item embedding $\mathbf{q}$, and opinion embedding $\mathbf{e}$, on the performance of our model.

Figure 5 presents the performance comparison $w.r.t.$ the length of embedding of our proposed model on Ciao and Epinions datasets. In general, with the increase of the embedding size, the performance first increases and then decreases. When increasing the embedding size from 8 to 64 can improve the performance significantly. However, with the embedding size of 256, GraphRec degrades the performance. It demonstrates that using a large number of the embedding size has powerful representation. Nevertheless, if the length of embedding is too large, the complexity of our model will significantly increase. Therefore, we need to find a proper length of embedding in order to balance the trade-off between the performance and the complexity.

4 RELATED WORK

In this section, we briefly review some related work about social recommendation, deep neural network techniques employed for recommendation, and the advanced graph neural networks.

Exploiting social relations for recommendations has attracted significant attention in recent years [27, 28, 37]. One common assumption about these models is that a user's preference is similar to or influenced by the people around him/her (nearest neighbours), which can be proven by social correlation theories [20, 21]. Along with this line, SoRec [17] proposed a co-factorization method, which shares a common latent user-feature matrix factorized by ratings and by social relations. TrustMF [37] modeled mutual influence between users, and mapped users into two low-dimensional spaces: truster space and trustee space, by factorizing social trust networks. SoDimRec [30] first adopted a community detection algorithm to partition users into several clusters, and then exploited the heterogeneity of social relations and weak dependency connections for recommendation. Comprehensive overviews on social recommender systems can be found in surveys [29].

In recent years, deep neural network models had a great impact on learning effective feature representations in various fields, such as speech recognition [12], Computer Vision (CV) [14] and Natural Language Processing (NLP) [4]. Some recent efforts have applied deep neural networks to recommendation tasks and shown promising results [41], but most of them used deep neural networks to model audio features of music [32], textual description of items [3, 33], and visual content of images [40]. Besides, NeuMF [11] presented a Neural Collaborative Filtering framework to learn the non-linear interactions between users and items.

However, the application of deep neural network in social recommender systems is rare until very recently. In particular, NSCR [35] extended the NeuMF [11] model to cross-domain social recommendations, i.e., recommending items of information domains to potential users of social networks, and presented a neural social collaborative ranking recommender system. However, the limitation is NSCR requires users with one or more social networks accounts (e.g., Facebook, Twitter, Instagram), which limits the data collections and its applications in practice. SMR-MNRL [42] developed social-aware movie recommendation in social media from the viewpoint of learning a multimodal heterogeneous network representation for ranking. They exploited the recurrent neural network and convolutional neural network to learn the representation of movies' textual description and poster image, and adopted a random-walk based learning method into multimodal neural networks. In all these works [35] [42], they addressed the task of cross-domain social recommendations for ranking metric, which is different from traditional social recommender systems.

Most related to our task with neural networks includes DLMF [6] and DeepSoR [8]. DLMF [6] used auto-encoder on ratings to learn representation for initializing an existing matrix factorization. A two-phase trust-aware recommendation process is proposed to utilize deep neural networks in matrix factorization's initialization and to synthesize the user's interests and their trust friends' interests together with the impact of community effect based on matrix factorization for recommendations. DeepSoR [8] integrated neural networks for user's social relations into probabilistic matrix factorization. They first represented users using pre-trained node embedding technique, and further exploited k-nearest neighbors to bridge user embedding features and neural network.

More recently, Graph Neural Networks (GNNs) have been proven to be capable of learning on graph structure data [2, 5, 7, 15, 25]. In the task of recommender systems, the user-item interaction contains the ratings on items by users, which is a typical graph data. Therefore, GNNs have been proposed to solve the recommendation problem [1, 22, 39]. sRMGCNN [22] adopted GNNs to extract graph embeddings for users and items, and then combined with recurrent neural network to perform a diffusion process. GCMC [1] proposed a graph auto-encoder framework, which produced latent features of users and items through a form of differentiable message passing on the user-item graph. PinSage [39] proposed a random-walk graph neural network to learn embedding for nodes in web-scale graphs. Despite the compelling success achieved by previous work, little attention has been paid to social recommendation with GNNs. In this paper, we propose a graph neural network for social recommendation to fill this gap.

5 CONCLUSION AND FUTURE WORK

We have presented a Graph Network model (GraphRec) to model social recommendation for rating prediction. Particularly, we provide a principled approach to jointly capture interactions and opinions in the user-item graph. Our experiments reveal that the opinion information plays a crucial role in the improvement of our model performance. In addition, our GraphRec can differentiate the ties strengths by considering heterogeneous strengths of social

relations. Experimental results on two real-world datasets show that GraphRec can outperform state-of-the-art baselines.

Currently we only incorporate the social graph into recommendation, while many real-world industries are associated rich other side information on users as well as items. For example, users and items are associated with rich attributes. Therefore, exploring graph neural networks for recommendation with attributes would be an interesting future direction. Beyond that, now we consider both rating and social information static. However, rating and social information are naturally dynamic. Hence, we will consider building dynamic graph neural networks for social recommendations with dynamic.

ABSTRACT

Representing words as embeddings in a continuous vector space has been proven to be successful in improving the performance in many natural language processing (NLP) tasks. Beyond the traditional methods that learn the embeddings from large text corpora, ensemble methods have been proposed to leverage the merits from pre-trained word embeddings as well as external semantic sources. In this paper, we propose a knowledge-enhanced ensemble method to combine both knowledge graphs and pre-trained word embedding models. Specifically, we interpret relations in knowledge graphs as linear translation from one word to another. We also propose a novel weighting scheme to further distinguish edges in the knowledge graph with same type of relation. Extensive experiments demonstrate that our proposed method is up to 20% times better than state-of-the-art in word analogy task and up to 16% times better than state-of-the-art in word similarity task.

1 INTRODUCTION

Word embeddings are low dimensional distributed representations of words in a real-valued vector space. As they are both compact and informative, word embeddings have proven to be effective in improving the performance in many natural language processing (NLP) tasks, e.g., named entity recognition (NER) [32], POS tagging [26] and information retrieval [30]. Most of the existing methods for learning word embeddings are trained on large unlabeled text corpora and many pre-trained word embeddings are available online. Mikolov et al. [18] learn the continuous bag-of-words (CBOW) and Skip-Gram embeddings from Google News corpus. The training objective of CBOW is to combine the embeddings of context words to predict the target word, while Skip-Gram is to use the embedding of each target word to predict its context words. Pennington et al. [24] learn the GloVe embedding set from the common crawled web data. The training objective of GloVe is to let the dot product of the embeddings of two words approximately equal to the logarithm of the count of their co-occurrences.

As word embeddings learned by different methods often capture different statistics from different corpora and these corpora are usually not available publicly, a natural idea for gathering the merits from multiple pre-trained word embeddings is to learn an ensemble model taking the statistics from them. Muromagi et al. [22] propose to combine several word embedding models into a unified one. They prove that an ensemble model can not only cancels out random noise of individual models but also reinforces co-occurrence patterns in the input models. However, the above models are totally context-based and ignore the common sense relations between two words within the embeddings. As a result, these models are incapable of capturing semantic relatedness of words if they do not appear in similar context.

Several studies [3, 7, 28, 34, 36] have been proposed to incorporate external semantic sources. Knowledge graphs, such as WordNet [19] and ConceptNet [29], are considered as one of the most important semantic sources for improving word embeddings. A knowledge graph is a directed graph and can be represented by a set of (entity, *relation*, entity) tuples. Faruqui et al. [7] propose a "retrofitting" method to leverage the synonym, hypernym, hyponym and paraphrase relations in WordNet to learn the ensemble embeddings. Robert et al. [28] propose a more general method "ConceptNet-Numberbatch (CN)" to support other types of relations in ConceptNet. However, these methods underlook the importance of the relations and consider two words are related if they are connected by any relation in the knowledge graph. For instance, relations *EatenBy* and *Hit* in tuples (apple, *EatenBy*, man) and (apple, *Hit*, man) are viewed as equivalent.

In this paper, we propose a knowledge-enhanced ensemble learning model called *RA-Retrofit* for word embeddings. The proposed model is able to leverage all semantic information provided by knowledge graphs as well as the pre-trained word embedding models. Firstly, to use the semantic information provided by knowledge graph, inspired by the efforts on multi-relational data embedding

[1], we learn embeddings for both nodes (each node represents a word) and edges (each edge represents the relation between two words) in the knowledge graph. The embedding of an edge is interpreted as linear translation from the source word to the target word. In the previous example, the embedding of "man" can be calculated by simply adding the embeddings of word "apple" and relation *EatenBy*. Different from [1], we propose a novel scheme to assign weights to the edges in the loss function. We compute the weight for each edge based on the relevance between the two words connected by the edge: a larger weight for two close related words. For example, we give higher weights for (Internet, *RelatedTo*, Computer) than for (Multipart, *RelatedTo*, Computer) because "Computer" is more related to "Internet" than "Multipart". Secondly, to preserve the information from both the input models and knowledge graphs in the ensemble word embeddings, we propose a joint learning method that minimizes (1) the training loss of the knowledge graph embeddings at the same time. Additionally, we show that *RA-Retrofit* is more general than several existing embedding methods through a theoretical analysis and (2) the difference between the pre-trained word embeddings and the linear projection of the ensemble word embeddings.

In summary, this paper has the following contributions.

- We propose a knowledge-enhanced method to incorporate common sense knowledge into pre-trained embeddings. We learn embeddings for both words and their relations in the knowledge graph and represent the relations as linear translation between the embedding vectors of words. Additionally, we propose a novel weighting scheme for different edges in knowledge graphs by considering the relatedness of the two words of the edge in terms of neighborhood similarity.
- We propose an effective joint learning algorithm that minimizes two losses simultaneously - (1) the loss of acquiring a word's representation vector via relation translation and (2) the loss of recovering the pre-trained word embeddings through linear projection of the ensemble embedding.
- We establish a thorough theoretical analysis to show that several embedding models are restricted version of the RA-Retrofit model proposed in this paper.
- We conduct extensive experiments to show the superiority of the proposed ensemble learning method. Our method significantly outperforms individual pre-training word embeddings (word2vec [18] and Glove [24]) and the state-of-the-art ensemble methods (CN [28] and Meta-Embedding [35]) in both word analogy and word similarity tasks.

2 RELATED WORKS

Our work is related to *word embedding*, *ensemble method*, and *knowledge graph embedding*. We relate research in these areas in turn.

2.1 Word Embedding

Learning word embeddings has been an active research problem for the past couple of years. A host of approaches has been proposed and they have been shown to be successful in improving and simplifying many natural language applications. Most of these word embeddings are trained on large unlabeled text corpora. Continuous bag-of-words (CBOW) and Skip-Gram [18] are two typical embedding methods that either use the context words to predict the target word or vice-versa. GloVe [24] is another unsupervised learning algorithm for learning word embeddings based on context words. It is trained with global word co-occurrence counts and learns a set of word embeddings such that the dot product of the embeddings of two words is approximately equal to the logarithm of their co-occurrence count. The above word embedding methods learn two vectors for each word – a representation vector for the word acting as a target word and a context vector for the word acting as a context word. Usually, only the representation vectors are used for computing similarity.

Different from our proposed approach, the above word embedding models learn the representation only from text corpora. In our proposed approach, we incorporate knowledge graph into our ensemble model. We use the relations in knowledge graph to refine the word embeddings.

2.2 Ensemble Method

Motivated by the fact that different word embedding are trained on different corpora and these corpora are often not publicly available, a group of ensemble methods has been proposed to combine these pre-trained word embeddings. They can be categorized into two types.

The first type of ensemble methods [11, 15, 31, 32, 35] aims to combine multiple embeddings to generate an ensemble embedding with better quality. For instance, Tsuboi et al. [31] incorporate word2vec and GloVe embeddings into a POS tagging system and show that the ensemble model outperforms both individual models. Turian et al. [32] show that the ensemble model that combines CW embeddings [5] and HLBL embeddings [21] outperforms the individual models in natural language applications like named entity recognition and chunking. Luo et al. [15] train the CBOW model with three datasets and propose an ensemble model to combine the word embeddings learned from the three datasets. They show that the ensemble model achieves better performance than using a single word embedding. Hill et al. [11] propose an ensemble method based on machine translation. Yin et al. [35] propose an ensemble approach of combining different public embedding sets to learn meta-embeddings. They show that the meta-embeddings achieve better performance in word similarity and word analogy tasks compared to individual models. These approaches do not incorporate external semantic resources, and thus they are different from our proposed model.

The second type of ensemble methods incorporates external semantic resources to improve word embeddings [7, 28, 36]. One of the most famous semantic resources is knowledge graph, including, but not limited to PPDB [9], WordNet [19] and ConceptNet [28]. The second type of ensemble methods can be further divided into two categories. In the first category, the ensemble methods use semantic resources as a feature when learning the word embeddings [3, 34, 36]. Yu et al. [36] propose a new training objective for learning word embeddings that incorporates prior knowledge. The model extends the objective of word2vec [18] to take prior knowledge about synonyms from semantic resources into account. In the second category, the ensemble methods retrofit the semantic resources into existing word embeddings [7, 28]. Faruqui et al.

[7] introduce a technique known as "retrofitting", which combines embeddings learned from the existing corpus with a source of structured connections between words. Robert et al. [28] modify the retrofitting algorithm, making it not depending on the row order of its input matrix, and allowing it to propagate over the union of the vocabularies. These approaches differ from our proposed model in the aspect that they disregard the types of the relations in the knowledge graph. In contrast, the proposed model interprets relation as linear translation from a word to the other.

2.3 Knowledge graph embedding

The proposed model is also related to knowledge graph embedding. Various types of representation learning methods have been proposed to embed entities and relationships of knowledge graphs into low dimensional vector spaces. Given the representation vectors of entities and relations, these methods define a scoring function on each fact to measure its plausibility. For example, given two entity vectors, the model of Neural Tensor Network [27] represents each relation as a bilinear tensor operator followed by a linear matrix operator. The model of TransE [1], on the other hand, represents each relation as a single vector that linearly interacts with the entity vectors. Likewise, variations on entity representations also exist. RESCAL [23] models triples through bilinear operations over entity and relation representations.

Recently, more and more researchers have started to represent a graph as a document. These approaches sample sequences of nodes from the underlying graph and turn a graph into an ordered sequence of nodes. For example, DeepWalk [25] shows that the distribution of nodes appearing in short random walks is similar to the distribution of words in natural language and employes Skip-Gram to learn the representations of nodes. Node2vec [10] defines a flexible notion of a node's network neighborhood and design a biased random walk procedure. KGloVe [4] presents an approach in that exploits global patterns for creating vector space embeddings, which is inspired by the GloVe model.

Since the adjacency matrix of a knowledge graph is sparse [13], the entity embeddings learned from a knowledge graph cannot provide enough information. In the proposed method, we view the pre-trained word embeddings as distinct descriptions of words and combine it with the entity embeddings.

3 METHOD

In this section, we present an ensemble model that combines pre-trained word embedding models and knowledge graphs. Important notations are summarized in Table 1.

3.1 Problem Formulation

In this subsection we formulate the problem to be investigated. We start with some basic definitions.

Definition 3.1. (**Word Embedding Matrix**): Let V be a vocabulary of words. A word embedding matrix $W \in \mathbb{R}^{|V| \times d}$ contains d-dimensional continuous representation for each word in V. Each row w_v in W is the representation vector for word $v \in V$.

Definition 3.2. (**Knowledge Graph**): A knowledge graph $G(V, E)$ is a directed graph, where V is the set of nodes, or equivalently the vocabulary of words, and E is the set of edges. Each edge in E connects a source word $v \in V$ with target word $u \in V$ via a relation type r. Each edge in E is denoted as a tuple $e = (v, r, u)$, where $v, u \in V$, and $r \in R$ is a type of relation.

Table 1: Notations

Notation	Description
$w_v^i \in \mathbb{R}^{d_i}$	pre-trained word embedding for word v in model i
V	vocabulary
R	relation set
d_i	dimension of the i-th pre-trained word embeddings
$G(V, E)$	knowledge graph G with entity set V and edge set E
(v, r, u)	an edge in E specifying relation r between two words $v, u \in V$
$q_r \in \mathbb{R}^d$	d-dimensional embedding for relation r
$y_v \in \mathbb{R}^d$	the target d-dimensional ensemble word embedding for word v

Consider t pre-trained word embedding matrices $W^1, \ldots, W^t$ and a knowledge graph G on a global vocabulary V, we aim to train (1) an ensemble word embedding matrix Y, where each row $y_v \in \mathbb{R}^d$ is the d-dimensional representation vector for $v \in V$, and (2) the representation vector $q_r \in \mathbb{R}^d$ for each relation $r \in R$.

3.2 Overview

We propose an ensemble model to combine the linguistic information in a set of t pre-trained word embedding models and knowledge graphs. The learning objective of our ensemble model is twofold: (1) To leverage the knowledge graph, the representation vector y_v for word v should be close to the addition of the representation vector of its related word and the relation that connects the two words. (2) To leverage the t word embedding models, the representation vector y_v for word v in the target model should be close to its representation vector w_v^i in the pre-trained word embedding models via linear projection.

To achieve the learning objectives, we first introduce learning from knowledge graph (3.3) and learning from word embedding models (3.4) separately. Then we introduce the weighted global objective function for our ensemble model (3.5), and the corresponding weighting scheme by considering the relevance strength of each edge in the knowledge graph (3.6). To minimize the objective function, we also propose the positive and negative sampling methods (3.7). We elaborate on these issues in turn in the subsequent subsections.

3.3 Learning from Knowledge Graphs

The edges in the knowledge graph reveal a lot of syntactic and semantic relations between the words. A host of work has been proposed to leverage the information in the knowledge graph to improve the word embedding models. Faruqui et al. [7] introduce the "retrofitting" procedure, which refines dense matrices of embeddings to take into account external knowledge from a sparse semantic network. Robert et al. [28] improve the retrofitting algorithm by making it not depending on the row order of its input

matrix and allowing it to propagate over the union of the vocabularies. Both methods define the dissimilarity between two words in the Euclidean space, i.e., dissimilarity between two words is the Euclidean distance between the representation vectors of the two words in the edge. Specifically, given an edge (u, r, v) from the knowledge graph, the dissimilarity between u and v is defined as

$$\phi(u, v) = \| y_u - y_v \|, \tag{1}$$

where y_u and y_v are the learned representation vectors for u and v, respectively.

By using the Euclidean distance, it can bring the embeddings of two similar words closer to each other. However, this dissimilarity measure disregards the types of the relation in the edge. For instance, (obscurity, *RelatedTo*, darkness) and (sleeping, *HasPrerequisite*, darkness) are two edges in the knowledge graph. Though "obscurity" and "sleeping" are both connected to "darkness", they are connected by different types of edges. Apparently, it is not reasonable to encourage the embedding vectors of "obscurity" and "sleeping" to be close to each other.

How can we leverage the type of the relation while we are learning from knowledge graph? To answer the question, we first think about *discovering analogical relations*, which is one of the most popular benchmarks for word embeddings. This task, which is first proposed in [18], shows that the proportional analogies (A is to B as C is to D) can be solved by finding the vector closest to the hypothetical vector calculated as $w_C - w_A + w_B$, e.g. vec("king") - vec("man") + vec("woman") $\approxeq$ vec("queen"). In knowledge graph, proportional analogy (A is to B as C is to D) is relationally equal to edges (A, r, B) and (C, r, D) having the same type of relation. Hence, it is a natural idea to interpret an edge as linear translation operating on the embeddings of the two words. Specifically, given an edge (u, r, v), we represent the relation r with a vector based on its type. The embedding vector of v should be close to the addition of the embeddings of u and r. Therefore, we define the following function to evaluate the dissimilarity for an edge:

$$\phi(u, r, v) = \| y_u + q_r - y_v \|, \tag{2}$$

where y_u and y_v are the learned representation vectors for u and v, respectively, and q_r is the embeddings for relation r. Given two edges (A, r, B) and (C, r, D) from the knowledge graph, Equation 2 encourages the representation vector $y_v = w_D$ (w_B) to be close to the addition of $y_u = w_C$ and q_r (w_A and q_r). Hence, $w_B - w_A + w_C$ will be close to w_D.

In fact, the idea of interpreting edges as translation operating on vectors of nodes has been investigated by efforts on multi-relational data embedding [1], where a model called TransE is proposed to embed entities and relationships of multi-relational data into vectors. Since the TransE model is designed for multi-relational data embedding, we also combine it with other word embedding models to make it suitable for word embedding problem, denoted by TransE+. We will show in Section 5 that the ensemble model proposed in this paper outperforms both TransE and TransE+ in all tasks.

Let (u, r, v) be a positive edge, i.e., a real edge from E. Let (u', r, v') be a negative edge, i.e., (u', r, v') does not exists in E. In order to learn from knowledge graph, we minimize a weighted margin-based ranking criterion over the edges in the knowledge graph:

$$\mathcal{L}_1(u, u', v, v', r) = \mathcal{W}(u, r, v) \max\{m + \phi(u, r, v) - \phi(u', r, v'), 0\}, \tag{3}$$

where m is the margin, $\phi(\cdot)$ is the score function defined in Equation 2, and $\mathcal{W}(u, r, b)$ is the weight of an edge (to be discussed in section 3.6). The intuition is that the dissimilarity of positive edges should be smaller than the negative ones.

3.4 Learning from Word Embedding Models

We consider t word embedding models that are trained with different algorithms and corpora. They can be viewed as distinct descriptions of words. In this section, we first present how to pre-process these word embedding models. Then we present how to learn from these word embedding models.

3.4.1 Aligning Vocabularies. Different word embeddings are trained with different corpora. Moreover, these models apply different pre-processing steps to produce their own vocabularies. For instance, word2vec [18] joins multi-word phrases with underscores while GloVe [24] does not. These pre-processing steps produce different vocabularies for each model. We can combine these models only if their vocabularies are aligned. We next present a unified pre-processing procedure that combines all the pre-processing steps that the word embedding models apply.

The unified pre-processing includes five steps: tokenizing text to separate words from punctuation, joining multi-word phrases with underscores, removing a small list of stopwords from multi-word phrases, folding the text to lowercase, and replacing multiple digits with the character '#'.

This pre-processing procedure is a many-to-one procedure. For instance, "When", "WHEN", and "when" are all in the vocabulary of word2vec. Each of the three terms corresponds a pre-trained representation vector. After the unified pre-processing procedure, they are all transformed to "when" in the new vocabulary. In this case, the term "when" in the new vocabulary is associated with three pre-trained representation vectors. As a result, we need to merge the associated pre-trained vectors for the transformed terms. In this paper, we follow the strategy proposed in a previous work [28] to merge the associated representation vectors by computing a weighted average based on terms' frequencies. Specifically, for a pre-trained word embedding model W, let $v_1, \ldots, v_k$ be the set of terms that will be transformed to a term v after the unified pre-processing step. The merged representation vector for term v is defined as

$$w'_v = \sum_{j=1}^{k} freq(v_j) w_{v_j} \tag{4}$$

where w'_v is the merged representation vector for v, and w_{v_j} is the representation vector of v_i in the pre-trained embedding matrix, and $freq(v_j)$ is the frequency of v_j

In the remaining of the paper, we assume the vocabularies of all pre-trained word embedding models have been aligned. With a slight abuse of notation, we still use w^i_v to denote the merged representation vector of term v in model W^i.

3.4.2 Learning from Pre-trained Word Embedding Models. Given a word $v \in V$ and t word embedding models $W^1, \ldots, W^t$, we use a

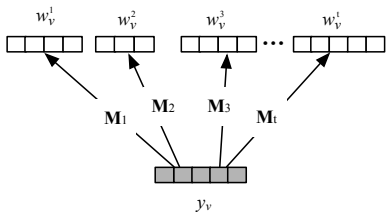

Figure 1: Network for Combining Pre-trained Embeddings

simple neural network to learn the ensemble embeddings, as shown in Figure 1. Let Y be the ensemble embedding model. We define a projection from space Y to space W^i, $i \in [1, t]$ as follows:

$$\hat{w}_v^i = \mathbf{M}_i y_v, \tag{5}$$

where $y_v \in \mathbb{R}^d$ is the embedding of word $v \in V$, $\hat{w}_v^i \in \mathbb{R}^{d_i}$ is the predicted embedding vector of v in W^i and d_i is the dimension of the representation vectors in model W^i, $\mathbf{M}_i \in \mathbb{R}^{d_i \times d}$ is the transformation matrix.

The predicted embedding vector $\hat{w}_v^i$ of word v should be close to the embedding vector w_v^i in model W^i. Thus, we define the objective function for a word v as:

$$\begin{aligned} \mathcal{L}_2(v) &= \sum_{i=1}^{t} \parallel \hat{w}_v^i - w_v^i \parallel \\ &= \sum_{i=1}^{t} \parallel \mathbf{M}_i y_v - w_v^i \parallel, \end{aligned} \tag{6}$$

The intuition behind Equation 6 is that we treat each individual embedding vector as a projection of the ensemble embedding vector. An individual embedding is a description of the word based on the corpus and the model that were used to create it. The ensemble embedding model tries to recover a more comprehensive description of the word when it is trained to predict the individual descriptions.

3.5 Global Objective Function

Now we proceed to give the global objective function. The global objective function is the linear combination of the two aforementioned objective functions, which is defined as follows:

$$\begin{aligned} \mathcal{L}(u, u', v, v', r) =& \mathcal{L}_1(u, u', v, v', r) + \mu \sum_{s \in \{u, u', v, v'\}} \mathcal{L}_2(s) \\ &+ \eta_1 \parallel \Theta_1 \parallel + \eta_2 \parallel \Theta_2 \parallel, \end{aligned} \tag{7}$$

where μ is a parameter to balance the two aforementioned loss functions, $\Theta_1 = \{ y_u, y_{u'}, y_v, y_{v'}, q_r \}$ is the set of embedding vectors of words u, u', v, v' and relation r, $\Theta_2 = \{\mathbf{M}_1, \ldots, \mathbf{M}_t\}$ is the set of transformation matrices that are defined to project the embedding vector in the ensemble model to the space of each individual embedding model.

In the global objective function, the first term $\mathcal{L}_1(u, u', v, v', r)$ makes the ensemble model to learn the information from knowledge graphs. The second term $\mathcal{L}_2(s)$ allows the ensemble model to capture the information in each individual embedding model. The last two terms are L2 regularization to avoid over-fitting, and $\eta_1 > 0$ and $\eta_2 > 0$ are the regularization coefficients.

Algorithm 1 Learning Ensemble Model

Input: Knowledge graph $G = (V, E)$, pre-trained embedding models $W^1, \ldots, W^t$, learning rate γ, ensemble embedding dimension d, component weight μ, η_1, η_2
Output: Ensemble embedding for each words $i \in V$ and relation $r \in R$; transformation parameters $\mathbf{M}_1, \ldots, \mathbf{M}_t$
Initialize ensemble embedding for each $i \in V$, $r \in R$ and parameters $\mathbf{M}_1, \ldots, \mathbf{M}_t$ with uniform distribution $(-\frac{1}{d}, \frac{1}{d})$
repeat
  for $(u, r, v) \in E$ **do**
    $P_N \leftarrow \emptyset$
    for k steps **do**
      $(u', r, v') \leftarrow$ Sample a negative edge
      $P_N \leftarrow (u', r, v')$
    end for
    Extract embeddings of all words in positive and negative edges from $W^1, \ldots, W^t$
    Compute loss function $\mathcal{L}$
    Update gradient $\Theta \leftarrow \Theta + \gamma \frac{\partial}{\partial \Theta} \mathcal{L}$
    Normalize word embeddings
  end for
until *convergence*

The optimization is carried out by stochastic gradient descent. In each step, we update all parameters $\Theta = \Theta_1 \cup \Theta_2$ by calculating the gradient:

$$\Theta \leftarrow \Theta + \gamma \frac{\partial}{\partial \Theta} \mathcal{L}, \tag{8}$$

where γ is the learning rate and $\frac{\partial}{\partial \Theta}$ indicates the gradient of parameters Θ. Finally, we normalize the embedding vectors for word v in the ensemble model Y:

$$\hat{y}_v = \frac{y_v}{max(\parallel y_v \parallel, 1)}. \tag{9}$$

The detailed optimization procedure of ensemble approach is summarized in Algorithm 1. All embedding vectors in the ensemble model are first randomly initialized. At each main iteration of the algorithm, the embedding vectors of the words are first normalized. For each positive edge in the knowledge graph, we first generate k negative edges. We utilize a list P_N to store all negative edges. Then for each individual word embedding model W^i, we extract the pre-trained embedding vectors for the words in the positive and negative edges. After that, we compute the loss function. The parameters are then updated by taking a gradient step with constant learning rate. The algorithm is stopped based on its performance on a validation set.

We also consider the out-of-vocabulary (OOV) words in the vocabulary union i.e., words that not covered by vocabulary intersection. For the words not appearing in the pre-trained embedding model, we initialize the OOV embeddings randomly and use the same mapping formula as for RA-retrofit to connect a ensemble embedding with the pre-trained embeddings. Both ensemble embedding and initialized OOV embeddings are updated during training. For the words not appearing in the graph model, we use equation 6 to learn the ensemble embeddings.

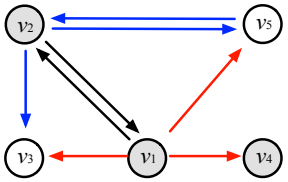

Figure 2: An example of knowledge graph

3.6 Weighting Scheme for an Edge

The relevances between the words of the two edges may be different even if they have same type of relation. For example, although edges (Internet, *RelatedTo*, Computer) and (Multipart, *RelatedTo*, Computer) have the same relation "RelatedTo", the relevance between the words "Internet" and "Computer" should be higher than that between words "Multipart" and "Computer". Intuitively, given an edge (u, r, v) from the knowledge graph, the relevance between words u and v is not only dependent on the type of relation r, but also dependent on the two words themselves. We have shown that we use a representation vector q_r to capture the relation r between two words. We next present how to capture the relevance between the two words in an edge.

Some prior work proposes to use manually defined constraints to distinguish the relevance between the words. For example, Ding et al. [6] propose to impose non-negativity constraints on vector representations, in which only positive samples will be used to learn the representations. Their approach has many limitations. First, it requires expertise to define the most appropriate constraint. Second, it is difficult to compare the relevance between words, especially when the number of words is large. Third, the relevance defined in their approach is highly subjective.

To solve this problem, we propose a method to compute the weight for each edge. Firstly, we define the neighbors of a word v in a knowledge graph as the words that can be connected with v via any relation r. Intuitively, if two words share more common neighbors, they are more likely to be highly relevant. Figure 2 shows an example of the knowledge graph. It can be seen in Figure 2 that v_1 shares more common neighbors with v_2 than with v_4. Specifically, the common neighbors of v_1 and v_2 are v_3 and v_5, while v_1 and v_4 have no common neighbors. Hence, v_1 and v_2 is likely to be more relevant.

Given a word v, let v^N be the set of neighbors of v. We define the weight of an edge (u, r, v) as the Jaccard similarity between the neighbors of u and v:

$$\mathcal{W}(u, r, v) = \epsilon_1 + \frac{|u^N \cap v^N|}{|u^N \cup v^N| + \epsilon_2}, \tag{10}$$

where $\epsilon_2 = 0.001$ is used to prevent division by zero, ϵ_1 is equal to the average value of $|u^N \cap v^N|/(|u^N \cup v^N| + \epsilon_2)$ in all edges such that the weight of an edge is always larger than 0.

3.7 Positive and Negative Sampling

The most frequent words can easily occur hundreds of millions of times. Such words usually provide less information value than the rare words. To counter the imbalance between the rare and frequent words, Mikolov et al. [18] use a simple subsampling approach: Each word v in the training set is discarded with probability computed by the equation:

$$P(v) = 1 - \sqrt{\frac{s}{f(v)}}, \tag{11}$$

where $f(v)$ is the frequency of word v and s is a chosen threshold.

In this paper, we extend the probability equation for edges in the knowledge graph. Given an edge (u, r, v), we define a combine frequency $f(u, v)$ over the corresponding frequency $f(u)$ and $f(v)$. We consider several choices for the combining operator which are summarized in Table 2. We define the subsampling formula for each edge as following:

$$P((u, r, v)) = 1 - \sqrt{\frac{s}{g(u, v)}}, \tag{12}$$

where $g(u, v)$ is the combined frequency of edge (u, r, v) (all combined frequencies are normalized to the interval $[0, 1]$) and s is a chosen threshold (we define $s = 1 \times 10^{-5}$ in this paper).

We next present the negative sampling technique to construct negative edges. Negative sampling assumes that two random words from the vocabulary V should be unrelated with high probability. Given an edge (u, r, v), we generate a set $E'_{(u,r,v)}$ of k negative edges by replacing either u or v by a random word v' from vocabulary V excluding u and v.

$$E'_{(u,r,v)} = \{(u, r, v')|v' \in V \setminus \{u, v\}\} \cup \{(u', r, v)|u' \in V \setminus \{u, v\}\} \tag{13}$$

Table 2: Combining operator $g(u, v)$ for u and v

Id	Operator	Definition
1	Average	$g(u, v) = \frac{f(u)+f(v)}{2}$
2	Max value	$g(u, v) = max(f(u), f(v))$
3	Geometric mean	$g(u, v) = \sqrt{f(u) \times f(v)}$

4 RELATIONSHIP TO OTHER MODELS

In the following we provide a unified view of several embedding models, by showing that they are restricted versions under our framework.

4.1 ConceptNet-Numberbath (CN)

Given an edge (u, r, v), the CN model [28] encourages the embedding vector of u to be close to both the pre-trained embedding vector of u and the embedding vector of its neighbor v. The objective of CN is to minimize:

$$\mathcal{L}_{cn}(u) = \alpha \parallel y_u - w_u \parallel + \beta_{u,v} \parallel y_u - y_v \parallel, \tag{14}$$

where w_u is pre-trained embedding vector of u, y_u and y_v are the embedding vectors of u and v in the ensemble model, respectively.

Proposition 1. CN can be fully recovered by RA-Retrofit embedding when $m = 0$, $\mathcal{W}(u, r, v) = 2\beta_{u,v}$, $t = 1$, $\alpha = \mu$, $\mathbf{M}$ is identity matrix, the number of negative samples $N_s = 0$, and remove the relation embedding q_r and regularization terms.

Proof. For each edge (u, r, v) from the knowledge graph, we remove the regularization terms and set $m = 0, N_s = 0, \mathcal{W}(u, r, v) =$

$2\beta_{u,v}$ and $t = 1$. We can get the objective function of RA-Retrofit as

$$\begin{aligned}\mathcal{L}(u,v,r) =& \mathcal{L}_1(u,v,r) + \mu\mathcal{L}_2(u) + \mu\mathcal{L}_2(v)\\ =& \mathcal{W}(u,r,v)\max\{\phi(u,r,v),0\} + \mu\mathcal{L}_2(u) + \mu\mathcal{L}_2(v)\\ =& 2\beta_{u,v} \parallel y_u + q_r - y_v \parallel + \mu \parallel \mathbf{M}y_u - w_u \parallel\\ &+ \mu||\mathbf{M}y_u - w_v||.\end{aligned} \tag{15}$$

By removing the relation embedding q_r, the objective function $\mathcal{L}$ can be rewrite as

$$\mathcal{L}(u,v) = 2\beta_{u,v} \parallel y_u - y_v \parallel + \mu \parallel y_u - w_u \parallel + \mu \parallel y_v - w_v \parallel . \tag{16}$$

The objective of an edge (u,r,v) to be minimized in CN can be viewed as the addition of the objective functions for u and v:

$$\begin{aligned}\mathcal{L}_{cn}(u,v) =& \mathcal{L}_{cn}(u) + \mathcal{L}_{cn}(v)\\ =& \alpha \parallel y_u - w_u \parallel + \beta_{u,v} \parallel y_u - y_v \parallel + \alpha \parallel y_v - w_v \parallel\\ &+ \beta_{u,v} \parallel y_v - y_u \parallel\\ =& \alpha \parallel y_u - w_u \parallel + 2\beta_{u,v} \parallel y_u - y_v \parallel + \alpha \parallel y_v - w_v \parallel .\end{aligned} \tag{17}$$

When $\alpha = \mu$, this function can be fully recovered by the proposed model. □

4.2 Meta-Embedding (MetaE)

MetaE [35] leverages multiple word embedding models and defines the objective function as:

$$\sum_{k=1}^{t} f_m(\parallel \mathbf{M}_k y_v - w_v^k \parallel + \gamma \parallel \mathbf{M}_k \parallel), \tag{18}$$

where y_v is the learned embedding of word $v \in V$, w_v^k is the embedding of word v in pre-trained embedding model W^k, $\mathbf{M}_k$ is transformation matrix.

Proposition 2. MetaE can be fully recovered by RA-Retrofit embeddings when $\mathcal{W}(u,r,v) = 0$, $f_m = \mu$, $\eta_1 = 0$ and $\eta_2 = f_m \times \gamma$.

Proof. When $\mathcal{W}(u,r,v) = 0$, the objective function of RA-Retrofit can be reduced to

$$\mathcal{L}(u,v) = \mu\mathcal{L}_2(u) + \eta_1 \parallel \Theta_1 \parallel + \eta_2 \parallel \Theta_2 \parallel . \tag{19}$$

For each word v in the edge, the objective of RA-Retrofit to be minimized can be reduced to

$$\begin{aligned}\mathcal{L}(v) =& \mu\mathcal{L}_2(v) + \eta_1 \parallel \Theta_1 \parallel + \eta_2 \parallel \Theta_2 \parallel\\ =& \mu \sum_{k=1}^{t} \parallel \mathbf{M}_k y_v - w_v^k \parallel + \eta_1 \parallel y_v \parallel + \eta_2 \sum_{k=1}^{t} \parallel \mathbf{M}_k \parallel .\end{aligned} \tag{20}$$

When $f_m = \mu$, $\eta_1 = 0$, $\eta_2 = f_m \times \gamma$, the proposed model can recover the meta-embed model. □

4.3 Translating Embeddings (TransE)

TransE [1] is a knowledge graph embedding model. The objective of the TransE is to minimize:

$$\begin{aligned}&\max\{m + \phi(u,r,v) - \phi'(u',r,v'), 0\}\\ &s.t. \quad \phi(u,r,v) = \parallel y_u + q_r - y_v \parallel,\end{aligned} \tag{21}$$

where where y_u and y_v are the learned representation vectors for u and v, respectively, q_r is the embeddings for relation r, $\phi(u,r,v)$ and $\phi'(u',r,v')$ are the scores for positive and negative edges, respectively.

Proposition 3. TransE can be fully recovered by RA-Retrofit when $\mu = \eta_1 = \eta_2 = 0$ and $\mathcal{W}(u,r,v) = 1$.

Proof. It is easy to verify that RA-Retrofit can recover TransE if we set $\mathcal{W}(u,r,v) = 1$ and $\mu = \eta_1 = \eta_2 = 0$. □

5 EXPERIMENTAL STUDY

In this section, we first describe the datasets that are used in the experimental study. Then we present the settings of our experiments. Finally, we investigate the performance of the evaluated methods. All the experiments are done on a computer having Intel(R) Core(TM) i7-6700 CPU @3.40 GHz processor, 6 GB RAM, and running Ubuntu 16.04. Our source codes will be released at https://github.com/fanglanting/RA-retrofit.

5.1 Datasets

We use GloVe[1] and word2vec[2] as the pre-trained embedding vectors for learning. We use ConceptNet (CNet)[3], PPDB[4] and WordNet (WNet)[5] as the knowledge graphs for retrofitting.

5.1.1 Pre-trained embeddings. **Glove** consists of 300 dimensional embedding vectors for 1.9 million words. These vectors were trained on 6 billion words from Wikipedia and English Gigaword. **Word2vec** are trained on 100 billion words of Google news dataset and are of length 300. It consists of embedding vectors for 3 million words.

5.1.2 Knowledge graphs. **CNet** originated as a machine-parsed version of the early crowd-sourcing project called Open Mind Common Sense, and has expanded to include several other data sources. It is a graph whose edges express common sense relationships between two short phrases or words, known as concepts. The edges are labeled from a defined set of relations, such as IsA, HasA, or UsedFor, expressing what relationship holds between the concepts. It contains a total of 2.8 millions of edges, in which 842, 194 edges remain after filtering out the edges whose words do not appear in the vocabularies of both word2vec and GloVe.

PPDB is another resource that is useful for learning about word similarity. It lists pairs of words that are translated to the same word in parallel corpora. Most of its edges are labeled with "Equivalent" and a small part is labeled with other types such as "OtherRelated" and "ForwardEntailment". It contains a total of 7.4 million edges for English language, in which 6 million edges remain in our experiments.

WNet is a lexical database for English. It groups English words into sets of synonyms called synsets, and records a number of relations among these synsets. It explicitly relates concepts with semantically aligned relations such as "hypernyms" and "hyponyms". For example, the word dog is a synonym of canine, a hypernym of puppy and a hyponym of animal. It contains a total of 843, 856 edges, in which 688, 147 edges remain in our experiments.

5.2 Evaluated Methods

We evaluate three types of methods in our experimental study: individual embedding models, ensemble models, and RA-Retrofit model.

Individual embedding models. In the first type of methods, we evaluate the performance of three well-known embedding models: **GloVe** [24], word2vec [18], denoted by **W2V**, and **TransE** [1]. We use the pre-trained vectors for GloVe and word2vec that are published online. We combine CNet, PPDB and WNet as the knowledge graph to train the TransE embeddings.

Ensemble models. In the second type of methods, we consider two state-of-the-art ensemble models **CN** [28] and **MetaE** [35]. We use the published pre-trained vectors for CN directly. We train MetaE to combine word2vec and GloVe with the suggested hyper-parameters [35]. In addition, we adapt the TransE model, denoted by **TransE+**, to make it suitable for embedding words into vector space. Specifically, **TransE+** uses TransE, word2vec and GloVe as the pre-trained embeddings models, and use Eq. (6) to learn the ensemble embedding.

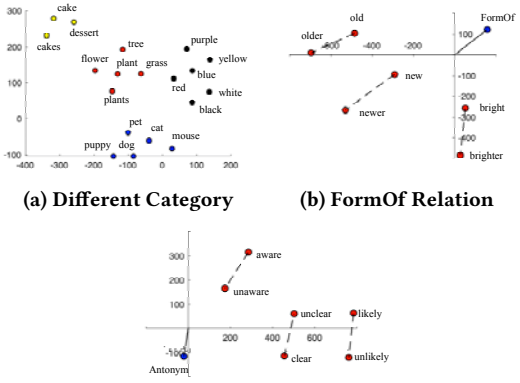
RA-Retrofit model. In the third type of methods, we evaluate the proposed RA-Retrofit model by varying the components in the model. Recall that the RA-Retrofit model combines knowledge graph and pre-trained word embeddings to learn the ensemble model. We vary the knowledge graphs and the pre-trained word embedding models that RA-Retrofit uses and get different variations of RA-Retrofit model. All these variations of RA-Retrofit models are trained by back-propagation with mini-batches. In the experiments, we set the hyper-parameters margin ridge m as 1, parameters μ as 0.01, η_1 and η_2 as 5×10^{-5}, learning rate γ as 0.02, the number of negative samples as 5 and iteration epoch as 100. When retrofitting a single knowledge graph, we set the batch size as 128. When retrofitting multiple knowledge graphs, we set the batch size as 256. In the subsampling process, we use geometric mean as the combine operator.

5.3 Evaluation Tasks

We conduct experiments on three tasks, word visualization, word similarity and word analogy to evaluate the performance of the proposed ensemble model.

The word anology task consists of questions like, "a is to b as u is to ?". In our experimental study, we use the state-of-the-art Google analogy test set [6]. Note that not all questions in the test set are covered by vocabularies of the embedding models. We filter out the uncovered questions and use 17,809 remaining questions in the test set. These questions are divided into two subsets: a semantic subset of size 8,733 and a syntactic subset of size 9,076. Given three words a, b, and u, we find the optimal word v for the analogy "a is to b as u is to v" by using the 3CosMul function [14] defined as follows:

$$v = \arg\max_{y_v} \frac{(\cos(y_v, y_b) + 1) \cdot (\cos(y_v, y_u) + 1)}{2(\cos(y_v, y_a) + 1) + 0.004} \tag{22}$$



where y_a, y_b, y_u and y_v are the embeddings of word a, b, u and v.

In the word similarity task, we use the following word-similarity gold standards: WordSim-353 (WS353) [8], The Stanford Rare Words (RW) [16], MC-30 (MC) [20], MEN-3000 (MEN) [2] and Stanford Contextual Word Similarity (SCWS) [12]. Each test set contains pairs of words together with their human-assigned similarity scores. We only consider the pairs of words that are also in the vocabularies of the elvauated models. The test set WS353, RW, MC, MEN, and SCWS contains 353, 1707, 30, 3000, and 1971 valid pairs, respectively. For each test set, we calculate cosine similarity between the vectors of two words, and report Spearman's rank correlation coefficient [33] between the rankings produced by our model against the human rankings:

$$\rho = 1 - \frac{6 \sum_{i=1}^{N} \Delta_i^2}{N(N^2 - 1)}, \tag{23}$$

where Δ_i is the difference between the two ranks of each observation and N is the number of observations.

(a) Different Category (b) FormOf Relation

(c) Antonym Relation

Figure 3: Visualization of word embeddings by t-SNE

5.4 Word Visualization

An intuitive way to understand the performance of a word embedding model is to visualize the embedding vectors. This task allows us to make qualitative assessment of the learned word embeddings.

We project word emebeddings into a 2-dimensional space using the t-SNE toolbox [17], as shown in Figure 3 (a). We can observe from Figure 3 (a) that words sharing similar semantics are closer to each other in the 2-dimensional space than the other words. For example, the words at the right side of Figure 3 (a) are all about color, while the words at the bottom are all related to animal.

To evaluate the analogy feature of the RA-Retrofit embeddings, we randomly select three edges with "FormOf" relation and three edges with "Antonym" relation from the knowledge graphs. Relation "FormOf" represents *A is an inflected form of B and B is the root word of A*. Relation "Antonym" represents *A and B are opposites in some relevant way*. We project the embedding vectors of words and relations in the edges into the 2-dimensional space. The embeddings of the selected edges are reported in Figure 3 (b) and Figure 3 (c). These results show that the embeddings can capture the analogy relationships between the words, i.e. A is to B as C is to D. For instance, vec("aware")-vec("unaware") is similar to vec("likely")-vec("unlikely"). Moreover, we observe that the embedding vector of a relation is similar to the subtraction between the embedding vectors of the two words. For instance, vec("aware")-vec("unaware") is similar to vec("'Antonym").

Table 3: Results on word analogy tasks. If a result is the best result in a block and better than all models in "Ind", then it is bolded. The best result for each benchmark is marked with †.

	Model	Semantic	Syntactic	Full
Ind	W2V	75.51	72.73	74.09
	GloVe	81.17	70.81	75.89

5.5 Word Analogy

We next conduct experiments to evaluate the capability of the proposed model for semantic deduction with the word analogy task [18].

Table 3 reports the performance of each model in word analogy tasks. Block "Ind" lists the performance of individual embedding models W2V, GloVe and TransE. Block "Ens" lists the performance of state-of-the-art ensemble models CN, MetaE and TransE+. Block "RA-Retrofit" lists all the variations of the proposed RA-Retrofit models. Specifically, we use GloVe, W2V, and both GloVe and W2V as the pre-trained word embeddings for the RA-Retrofit model, respectively. We vary the knowledge graphs by using PPDB, WNet, CNet, and all three graphs (All).

From block "Ind" and "Ens", we observe that the analogy test accuracy of CN is comparable with W2V and GloVe in the full test set. This is because CN does not utilize the relation information, which is very important to analogy tasks. On the contrary, MetaE outperforms W2V and GloVe w.r.t. analogy test accuracy in the full test set. The results show that combing multiple embeddings can generate an ensemble embedding that contains more analogy information. Moreover, we observe that TransE has the worst accuracy compared with other methods. This is because the semantic information contained in knowledge graphs is not enough for word embeddings. When combined with pre-trained embeddings, TransE+ achieves a better accuracy than the other individual models or state-of-the-art ensemble models.

When the RA-Retrofit model is trained with GloVe or with W2V, we observe that combining knowledge graphs can improve the accuracy compared with each individual embedding model. Among the knowledge graphs, CNet achieves the best increase in the accuracy. This is because CNet contains more edges than WNet, and more relation categories than PPDB (CNet has 37 categories of relations, while PPDB has 6 categories).

When the RA-Retrofit model is trained with both GloVe and W2V, we observe that using all knowledge graphs achieves the best performance. This full model is 20% times better than CN in semantic test set, and 11% times better than W2V, 8% times better than GloVe, 11% times better than MetaE and 6% times better than TransE+ in the full test set.

Based on the observations, we conclude that the word representations generated by the RA-Retrofit model achieves the best performance in the word analogy task.

5.6 Word Similarity

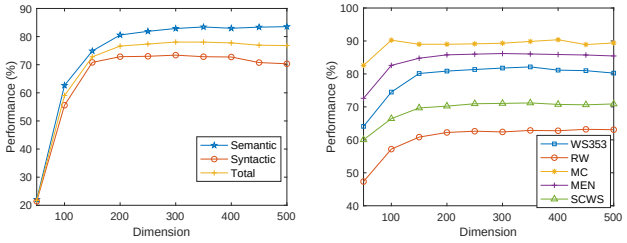
Table 4 reports the empirical results on the word similarity task. We observe that the full RA-Retrofit model (trained with both pre-trained word embeddings and all knowledge graphs) outperforms all individual word embedding models. For instance, the full model is 16% times better than W2V and 7% times better than GloVe in WS353. Additionally, the full RA-Retrofit model performs better than ensemble models MetaE and TransE+. Although CN model generates competitive results compared with the proposed model, its analogy results are much worse than the proposed model. These results show that the proposed model can improve the performance of the word embedding not only at the analogy tasks but also at the word similarity tasks.

According to the results, we conclude that the proposed RA-Retrofit model is capable to generate high quality word embeddings compared with state-of-the-art methods.

Table 5: The effects of various modifications to the RA-Retrofit. Bold indicates the best result.

Model	Semantic	Syntactic	Total
RA-Retrofit-SVD	84.44	77.10	80.70
RA-Retrofit-unweighted	85.17	76.83	80.92
RA-Retrofit-Avg	85.15	77.58	81.29
RA-Retrofit-Max	84.47	78.24	81.30
RA-Retrofit-LogLoss	78.82	70.42	74.54
RA-Retrofit	**85.51**	**78.46**	**81.92**

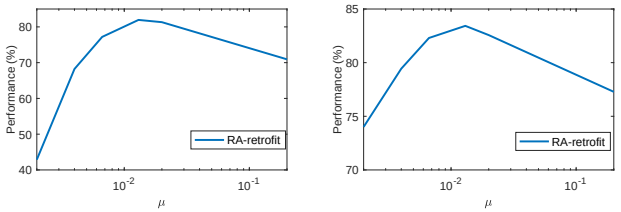
5.7 Miscellaneous



5.7.1 Ablation study for the RA-Retrofit model. We first conduct a set of experiments to justify the design of RA-Retrofit model by varying the components.

Effectiveness of transformation matrix. When learning from pre-trained word embeddings, we use a transformation matrix to project the ensemble embedding of a word such that the projection should be close to the word's pre-trained embedding vector. In this set of experiments, we modify the RA-Retrofit by replacing the transformation matrix with singular value decomposition (SVD). Specifically, we first concatenate the GloVe (300-dimensional) and word2vec (300-dimensional) vectors into 600-dimensional vectors. We then discount redundancy between its features by transforming these 600-dimensional vectors to 300-dimensional vectors with SVD. We encourage the ensemble embedding vector to be close to the decomposed vector. We refer to this modification as *RA-Retrofit-SVD*. The first row in Table 5 reports the accuracy of *RA-Retrofit-SVD*. We observe that using transformation matrix achieves better accuracy than using SVD.

Effectiveness of weight. As discussed in Section 3.6, we propose a scheme to assign weights to each edge. In this set of experiments, we modify the RA-Retrofit by using unweighted global loss to show the effectiveness of our weighting scheme. The modification is referred to as *RA-Retrofit-unweighted* and its accuracy is reported in the second row of Table 5. The results show that the weighting scheme improves the accuracy of the proposed model.



Effectiveness of combining operator. Recall that we discussed subsampling technique in Section 3.7, where we propose several combining operator to combine frequency of an edge. In this set of experiments, we replace the geometric mean in RA-Retrofit with *average* and *max*, respectively. The modifications are referred to as *RA-Retrofit-Avg* and *RA-Retrofit-Max*. The third and fourth rows in Table 5 report the accuracies of the two modifications. We observe that the RA-Retrofit model achieves the best performance when geometric mean is used as the combining operator.

Effectiveness of $\mathcal{L}_1$. As discussed in Section 3.3, we use margin-based ranking criterion to learn the information in the knowledge graphs. Another popular criterion that is often used to learn the knowledge graph embeddings is logistic loss. We modify the RA-Retrofit by changing the margin-based ranking criterion to logistic loss. The modification is referred to as *RA-Retrofit-LogLoss* and its accuracy is reported in the fifth row in Table 5. We observe that the performance drops rapidly. This is because the margin-based ranking criterion tend to assign low scores to positive edges and high scores to negative edges, which makes the learned representations more reasonable.

Figure 4: Effect of Dimensions

(a) Word Analogy (Full) **(b) Word Similarity (WS353)**

Figure 5: Effect of parameter μ

5.7.2 Effects of dimensions and hyper-parameter μ. Figure 4 shows the effects of dimensionality $d \in [50, 500]$ for RA-Retrofit. There are no big differences in the word analogy and similarity tasks when the dimension d is high enough, roughly in the interval $[300, 500]$. In summary, as long as d is chosen to be large enough, the performance of the proposed model is robust.

Figure 5 demonstrates how hype-parameter $\mu \in [0.002, 0.2]$ affects RA-Retrofit in word similarity and word analogy tasks. We observe that the its performance degrades when the value of μ is either too small or too large. The best performance is obtained when μ is set to a value between 0.007 and 0.04. When μ is too small, the result is similar to only using the knowledge graph. When μ is too large, the result is similar to only using the pre-trained word embeddings. This experiment justifies that both knowledge graph and pre-trained word embeddings actually help improving word similarity computation and word analogy.

6 CONCLUSION

In this paper, we proposed a knowledge-enhanced ensemble learning method named RA-Retrofit for word embeddings. RA-Retrofit integrates common sense knowledge into an ensemble model of pre-trained distributional word embeddings to learn high quality word embeddings that is suitable for both word similarity and analogy. Our contributions include a method for translating embedding, equipped by a novel edge weighting scheme for knowledge graph, a joint learning method for optimizing both objectives from knowledge graph and pre-trained embeddings, and a thorough theoretical analysis among RA-Retrofit and other ensemble methods. Extensive experiments demonstrate that our proposed method is up to 20% times better than CN in word analogy task and up to 16% times better than W2V in word similarity task.

ABSTRACT

Entity linking is the task of aligning mentions to corresponding entities in a given knowledge base. Previous studies have highlighted the necessity for entity linking systems to capture the global coherence. However, there are two common weaknesses in previous global models. First, most of them calculate the pairwise scores between all candidate entities and select the most relevant group of entities as the final result. In this process, the consistency among wrong entities as well as that among right ones are involved, which may introduce noise data and increase the model complexity. Second, the cues of previously disambiguated entities, which could contribute to the disambiguation of the subsequent mentions, are usually ignored by previous models. To address these problems, we convert the global linking into a sequence decision problem and propose a reinforcement learning model which makes decisions from a global perspective. Our model makes full use of the previous referred entities and explores the long-term influence of current selection on subsequent decisions. We conduct experiments on different types of datasets, the results show that our model outperforms state-of-the-art systems and has better generalization performance.

1 INTRODUCTION

Entity Linking (EL), which is also called Entity Disambiguation (ED), is the task of mapping mentions in text to corresponding entities in a given knowledge Base (KB). This task is an important and challenging stage in text understanding because mentions are usually ambiguous, i.e., different named entities may share the same surface form and the same entity may have multiple aliases. EL is key for information retrieval (IE) and has many applications, such as knowledge base population (KBP), question answering (QA), etc.

Existing EL methods can be divided into two categories: local model and global model. Local models concern mainly on contextual words surrounding the mentions, where mentions are disambiguated independently. These methods are not work well when the context information is not rich enough. Global models take into account the topical coherence among the referred entities within the same document, where mentions are disambiguated jointly. Most of previous global models [14, 27, 37] calculate the pairwise scores between all candidate entities and select the most relevant group of entities. However, the consistency among wrong entities as well as that among right ones are involved, which not only increases the model complexity but also introduces some noises. For example, in Figure 1, there are three mentions "France", "Croatia" and "2018 World Cup", and each mention has three candidate entities. Here, "France" may refer to *French Republic*, *France national basketball team* or *France national football team* in KB. It is difficult to disambiguate using local models, due to the scarce common information in the contextual words of "France" and the descriptions of its candidate entities. Besides, the topical coherence among the wrong entities related to *basketball team* (linked by an orange dashed line) may make the global models mistakenly refer "France" to *France national basketball team*. So, how to solve these problems?

We note that, mentions in text usually have different disambiguation difficulty according to the quality of contextual information and the topical coherence. Intuitively, if we start with mentions that are easier to disambiguate and gain correct results, it will be effective to utilize information provided by previously referred entities to disambiguate subsequent mentions. In the above example, it is much easier to map "2018 World Cup" to *2018 FIFA World Cup*

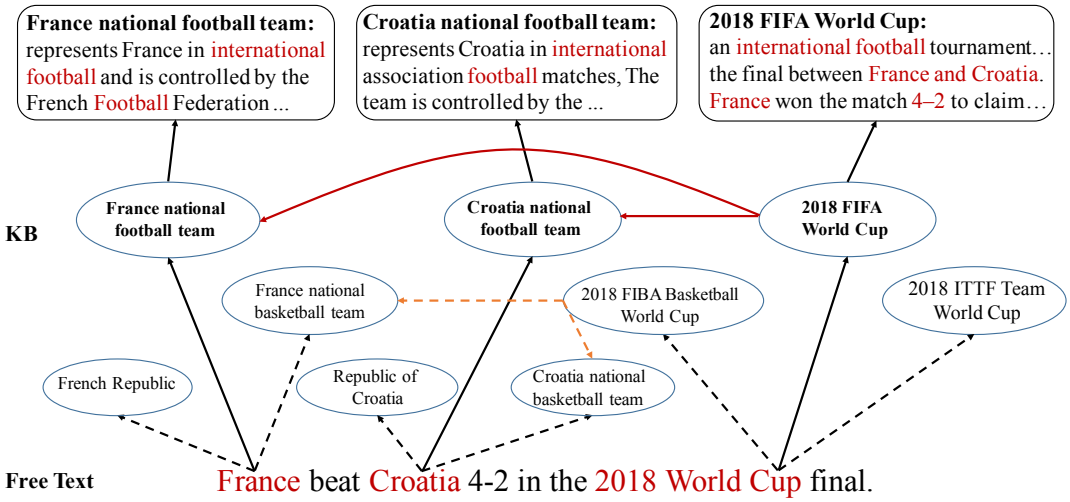

Figure 1: Illustration of mentions in the free text and their candidate entities in the knowledge base. Solid black lines point to the correct target entities corresponding to the mentions and to the descriptions of these correct target entities. Solid red lines indicate the consistency between correct target entities and the orange dashed lines denote the consistency between wrong candidate entities.

based on their common contextual words "France", "Croatia", "4-2". Then, it is obvious that "France" and "Croatia" should be referred to the national football team because football-related terms are mentioned many times in the description of *2018 FIFA World Cup*.

Inspired by this intuition, we design the solution with three principles: (i) utilizing local features to rank the mentions in text and deal with them in a sequence manner; (ii) utilizing the information of previously referred entities for the subsequent entity disambiguation; (iii) making decisions from a global perspective to avoid the error propagation if the previous decision is wrong.

In order to achieve these aims, we consider global EL as a sequence decision problem and propose a deep reinforcement learning (RL) based model, RLEL for short, which consists of three modules: Local Encoder, Global Encoder and Entity Selector. For each mention and its candidate entities, Local Encoder encodes the local features to obtain their latent vector representations. Then, the mentions are ranked according to their disambiguation difficulty, which is measured by the learned vector representations. In order to enforce global coherence between mentions, Global Encoder encodes the local representations of mention-entity pairs in a sequential manner via a LSTM network, which maintains a long-term memory on features of entities which has been selected in previous states. Entity Selector uses a policy network to choose the target entities from the candidate set. For a single disambiguation decision, the policy network not only considers the pairs of current mention-entity representations, but also concerns the features of referred entities in the previous states which is pursued by the Global Encoder. In this way, Entity Selector is able to take actions based on the current state and previous ones. When eliminating the ambiguity of all mentions in the sequence, delayed rewards are used to adjust its policy in order to gain an optimized global decision.

Deep RL model, which learns to directly optimize the overall evaluation metrics, works much better than models which learn with loss functions that just evaluate a particular single decision. By this property, RL has been successfully used in many NLP tasks, such as information retrieval [28], dialogue system [10] and relation classification [12], etc. To the best of our knowledge, we are the first to design a RL model for global entity linking. And in this paper, our RL model is able to produce more accurate results by exploring the long-term influence of independent decisions and encoding the entities disambiguated in previous states.

In summary, the main contributions of our paper mainly include following aspects:

- We are the first to consider EL as a sequence decision problem and innovatively utilize a deep reinforcement learning model in this task.
- The proposed model takes into account both local context and global coherence. In the process of global disambiguation, we make full use of the previous selected entity information and make decisions from a global perspective.
- We evaluate our model on several benchmark datasets and the experimental results show that our model achieves significant improvements over the state-of-the-art methods.

2 METHODOLOGY

The overall structure of our RLEL model is shown in Figure 2. The proposed framework mainly includes three parts: Local Encoder which encodes local features of mentions and their candidate entities, Global Encoder which encodes the global coherence of mentions in a sequence manner and Entity Selector which selects an entity from the candidate set. In the training process, Local Encoder is trained independently because its output is just used as the input of Entity Selector. Entity Selector and Global Encoder are

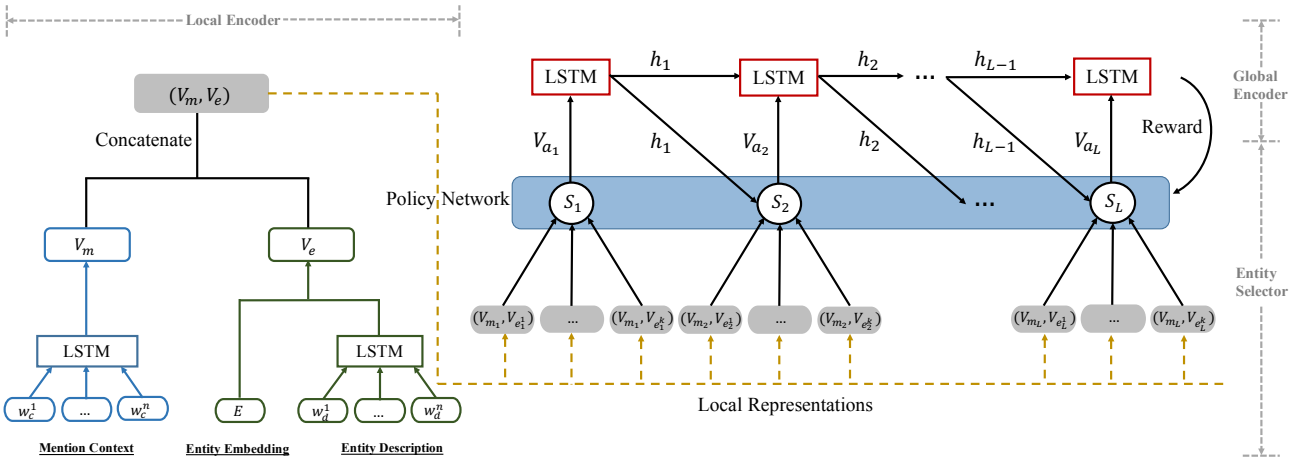

Figure 2: The overall structure of our RLEL model. It contains three parts: Local Encoder, Global Encoder and Entity Selector. In this framework, $(V_{m_t}, V_{e_t^k})$ denotes the concatenation of the mention context vector V_{m_t} and one candidate entity vector $V_{e_t^k}$. The policy network selects one entity from the candidate set, and V_{a_t} denotes the concatenation of the mention context vector V_{m_t} and the selected entity vector $V_{e_t^*}$. h_t represents the hidden status of V_{a_t}, and it will be fed into S_{t+1}.

trained jointly, because these two modules interact on each other. In the following, we will introduce the technical details of these modules.

2.1 Preliminaries

Before introducing our model, we firstly define the entity linking task. Formally, given a document D with a set of mentions $M = \{m_1, m_2, ..., m_k\}$, each mention $m_t \in D$ has a set of candidate entities $C_{m_t} = \{e_t^1, e_t^2, ..., e_t^n\}$. The task of entity linking is to map each mention m_t to its corresponding correct target entity e_t^+ or return "NIL" if there is no correct target entity in the knowledge base. Before selecting the target entity, we need to generate a certain number of candidate entities for model selection.

Inspired by the previous works [29, 31, 42], we use the mention's redirect and disambiguation pages in Wikipedia to generate candidate sets. For those mentions without corresponding disambiguation pages, we use its n-grams to retrieve the candidates [31]. In most cases, the disambiguation page contains many, sometimes even hundreds of entities. To optimize the model's memory and avoid unnecessary calculations, the candidate sets need to be filtered [1, 14, 37]. Here we utilize the XGBoost model [3] as an entity ranker, in which the useful features can be divided into two aspects, the one is string similarity such as the Jaro-Winkler distance between the entity title and the mention, the other is semantic similarity such as the cosine distance between the mention context representation and the entity embedding. Furthermore, we also use the statistical features based on the pageview and hyperlinks in Wikipedia. Empirically, we get the pageview of the candidate entities from the Wikipedia Tool Labs[1] which counts the number of visits on each entity page in Wikipedia. After ranking the candidates based on above features, we take the top k entities as final candidate set for each mention.

[1]The url of the website is: https://tools.wmflabs.org/pageviews/

2.2 Local Encoder

Given a mention m_t and the corresponding candidate set $\{e_t^1, e_t^2, ..., e_t^k\}$, we aim to get their local representation based on the mention context and the candidate entity description. For each mention, we firstly select its n surrounding words, and represent them as word embedding using a pre-trained lookup table [24]. Then, we use Long Short-Term Memory (LSTM) networks to encode the contextual word sequence $\{w_c^1, w_c^2, ..., w_c^n\}$ as a fixed-size vector V_{m_t}. The description of entity is encoded as $D_{e_t^i}$ in the same way. Apart from the description of entity, there are many other valuable information in the knowledge base. To make full use of these information, many researchers trained entity embeddings by combining the description, category, and relationship of entities. As shown in [14], entity embeddings compress the semantic meaning of entities and drastically reduce the need for manually designed features or co-occurrence statistics. Therefore, we use the pre-trained entity embedding $E_{e_t^i}$ and concatenate it with the description vector $D_{e_t^i}$ to enrich the entity representation. The concatenation result is denoted by $V_{e_t^i}$.

After getting $V_{e_t^i}$, we concatenate it with V_{m_t} and then pass the concatenation result to a multilayer perceptron (MLP). The MLP outputs a scalar to represent the local similarity between the mention m_t and the candidate entity e_t^i. The local similarity is calculated by the following equations:

$$\Psi(m_t, e_t^i) = MLP(V_{m_t} \oplus V_{e_t^i}) \tag{1}$$

Where $\oplus$ indicates vector concatenation. With the purpose of distinguishing the correct target entity and wrong candidate entities when training the local encoder model, we utilize a hinge loss that ranks ground truth higher than others. The rank loss function is defined as follows:

$$L_{local} = max(0, \gamma - \Psi(m_t, e_t^+) + \Psi(m_t, e_t^-)) \tag{2}$$

When optimizing the objective function, we minimize the rank loss according to [14, 37]. In this ranking model, a training instance is constructed by pairing a positive target entity e_t^+ with a negative entity e_t^-, where $\gamma > 0$ is a margin parameter. Our purpose is to make the score of the positive target entity e_t^+ be at least a margin γ higher than that of negative candidate entity e_t^-.

With the local encoder, we obtain the representation of mention context and candidate entities, which will be used as the input of the entity selector. In addition, the similarity scores calculated by MLP will be utilized for ranking mentions in the global encoder.

2.3 Global Encoder

In the global encoder module, we aim to enforce the topical coherence among the mentions and their target entities. So, we use an LSTM network which is capable of maintaining the long-term memory to encode the ranked mention sequence. What we need to emphasize is that our global encoder just encode the mentions that have been disambiguated by the entity selector which is denoted as V_{a_t}.

As mentioned above, the mentions should be sorted according to their contextual information and topical coherence. So, we firstly divide all mentions into several segments by the order they appear in the document based on the observation that the topical consistency attenuates along with the distance between the mentions. Then, we sort mentions in a segment from highest to lowest local similarity. As shown in Equation 1, the local similarity of m_i and its corresponding candidate entity e_i^t is defined as $\Psi(m_i, e_i^t)$. On this basis, we define $\Psi_{max}(m_i, e_i^a)$ as the the maximum local similarity between m_i and its candidate set $C_{m_i} = \{e_i^1, e_i^2, ..., e_i^n\}$. The $\Psi_{max}(m_i, e_i^a)$ is used as criterion when sorting mentions. For instance, if $\Psi_{max}(m_i, e_i^a) > \Psi_{max}(m_j, e_j^b)$, we place m_i before m_j. In this order, global encoder memorizes each selected entity and the encoding result will be served as input to the entity selector. Based on the topical coherence between the selected entities, entity selector will perform mention disambiguation from the global perspective.

Before using entity selector to choose target entities, we pretrain the global LSTM network. During the training process, we input not only positive samples but also negative ones to the LSTM. By doing this, we can enhance the robustness of the global encoder module. To pre-train this module, we adopt the following cross entropy loss function .

$$L_{global} = -\frac{1}{n}\sum_{x}\left[y \ln y^{'} + (1-y)\ln(1-y^{'})\right] \tag{3}$$

Where $y \in \{0, 1\}$ represents the real label of the candidate entity. If the candidate entity is correct, $y = 1$; otherwise $y = 0$. $y^{'} \in (0, 1)$ indicates the predicted result of our model. After pre-training the global encoder, we use the entity selector to choose the target entity for each mention and encode these selections.

2.4 Entity Selector

The entity selector module aims to select the target entity from the candidates based on the results of local and global encoder. In the process of sequence disambiguation, each selection will have an impact on subsequent decisions. Therefore, we convert the global entity disambiguation into a reinforcement learning problem and consider the entity selector as an agent. In our model, the agent is designed as a policy network which can learn a stochastic policy and prevents the agent from getting stuck at an intermediate state [39]. Under the guidance of policy, the agent decides which action (choosing one target entity from the candidates) should be taken at each state (current local and global encoding), and will receive a delay reward after all decisions are made. In the following, we will introduce the state, action and reward, and detail how to select target entity via a policy network.

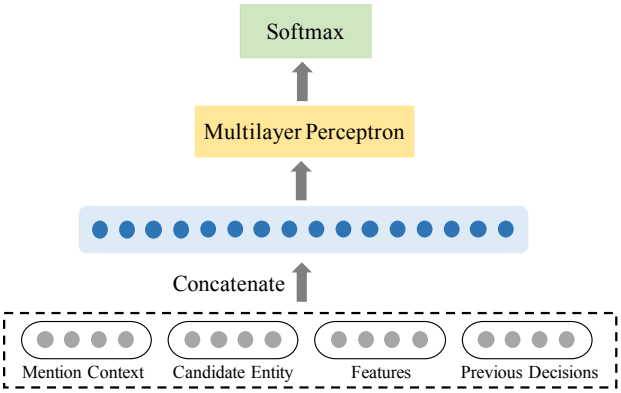

Figure 3: The architecture of policy network. It is a feedforward neural network and the input consists of four parts: mention context representation, candidate entity representation, feature representation, and encoding of the previous decisions.

State. The result of entity selection is based on the current state information. For time t, the state vector S_t is generated as follows:

$$S_t = V_{m_i}^t \oplus V_{e_i}^t \oplus V_{feature}^t \oplus V_{e^*}^{t-1} \tag{4}$$

Where $\oplus$ indicates vector concatenation. $V_{m_i}^t$ and $V_{e_i}^t$ respectively denote the vector of m_i and e_i at time t. For each mention, there are k candidate entities. In order to compare the semantic relevance between the mention and each candidate entity, we use multiple copies of the mention vector. Formally, we extend $V_{m_i}^t \in \mathbb{R}^{1\times n}$ to $V_{m_i}^{t\ '} \in \mathbb{R}^{k\times n}$ and then combine it with $V_{e_i}^t \in \mathbb{R}^{k\times n}$. Since $V_{m_i}^t$ and $V_{e_i}^t$ mainly represent semantic information, we add feature vector $V_{feature}^t$ to enrich lexical and statistical features. These features mainly include the popularity of the entity, the edit distance between the entity description and the mention context, the number of identical words in the entity description and the mention context, etc. In addition, the global feature $V_{e^*}^{t-1}$ is also added to S_t. As mentioned in global encoder module, $V_{e^*}^{t-1}$ is the output of the global LSTM network at time $t-1$, which encodes the mention context and the selected entity from time 0 to $t-1$. Thus, the state S_t consists of current information and previous decisions, containing the semantic features and statistical ones. Next, the concatenated vector will be fed into the policy network to generate action.

Action. According to the status at each time step, we take corresponding action. Specifically, we define the action at time step t is to

select the target entity e_t^* for m_t. The size of action space is the number of candidate entities for each mention, where $a_i \in \{0, 1, 2...k\}$ indicates the position of the selected entity in the candidate list. After performing all actions in the sequence we will get a delayed reward.

Reward. The agent takes the reward value as the feedback of its actions and learns the policy based on it. Since one selection has a long-term impact on subsequent decisions, we give a delay reward rather than an immediate one, reflecting whether the action improves the overall performance or not.

$$R(a_t) = p(a_t) \sum_{j=t}^{T} p(a_j) + (1 - p(a_t))(\sum_{j=t}^{T} p(a_j) + t - T) \quad (5)$$

where $p(a_t) \in \{0, 1\}$ indicates whether the current action is correct or not. If the action is correct, $p(a_t) = 1$; otherwise, $p(a_t) = 0$. Hence $\sum_{j=t}^{T} p(a_j)$ and $\sum_{j=t}^{T} p(a_j) + t - T$ respectively represent the number of correct actions and that of wrong ones from time t to the end of episode. Based on the above definition, our delayed reward can be used to guide the learning of the policy for entity linking.

Policy Network. After defining the state, action and reward, our main challenge is how to choose an action from the action space. To solve this problem, we sample the value of each action using a policy network $\pi_\Theta(a|s)$. The structure of the policy network is shown in Figure 3. The input of the network is the current state, including the mention context representation, candidate entity representation, feature representation, and encoding of the previous decisions. We concatenate these representations and fed them into a multilayer perceptron. For each hidden layer, we generate the output by:

$$h_i(S_t) = Relu(W_i * h_{i-1}(S_t) + b_i) \quad (6)$$

Where W_i and b_i are the parameters of the ith hidden layer, and we use *Relu* as the activation function. After getting the output of the last hidden layer, we feed it into a softmax layer which generates the probability distribution of actions. The probability distribution is generated as follows:

$$\pi(a|s) = Softmax(W * h_l(S) + b) \quad (7)$$

Where the W and b are the parameters of the softmax layer. For each mention in the sequence, we take one action to select the target entity from its candidate set. After performing all decisions in the episode, each action will get an expected reward and our goal is to maximize the expected total rewards. Formally, the objective function is defined as:

$$\begin{aligned} J(\Theta) &= \mathbb{E}_{(s_t, a_t) \sim P_\Theta(s_t, a_t)} R(s_1 a_1 ... s_L a_L) \\ &= \sum_t \sum_a \pi_\Theta(a|s) R(a_t) \end{aligned} \quad (8)$$

Where $P_\Theta(s_t, a_t)$ is the state transfer function, $\pi_\Theta(a|s)$ indicates the probability of taking action a under the state s, and $R(a_t)$ is the expected reward of action a at time step t. According to REINFORCE policy gradient algorithm[38], we update the policy gradient by the equation 9.

$$\Theta \leftarrow \Theta + \alpha \sum_t R(a_t) \nabla_\Theta \log \pi_\Theta(a|s) \quad (9)$$

Algorithm 1 The Policy Learning for Entity Selector

Require: Training data include multiple documents $D = \{D_1, D_2, ..., D_N\}$
Ensure: The target entity for mentions $\Gamma = \{T_1, T_2, ..., T_N\}$

```
Initialize the policy network parameter Θ, global LSTM network parameter Φ;
for D_k in D do
    Generate the candidate set for each mention
    Divide the mentions in D_k into multiple sequences S = {S_1, S_2, ..., S_N};
    for S_k in S do
        Rank the mentions M = {m_1, m_2, ..., m_n} in S_k based on the local similarity;
        for m_k in M do
            Sample the target entity e_k^* for m_k with Θ;
            Input the V_{m_k}^t and V_{e_k^*}^t to global LSTM network;
        end for
        // End of sampling, update parameters
        Compute delayed reward R(a_t) for each action;
        Update the parameter Θ of policy network:
            Θ ← Θ + α Σ_t R(a_t) ∇_Θ log π_Θ(a|s)
    end for
    Update the parameter Φ in the global LSTM network
end for
```

As the global encoder and the entity selector affect each other, we train them jointly after pre-training the two networks. The details of the joint learning are presented in Algorithm 1.

3 EXPERIMENT

In order to evaluate the effectiveness of our method, we train the RLEL model and validate it on a series of popular datasets that are also used by [14, 37]. To avoid overfitting with one dataset, we use both AIDA-Train and Wikipedia data in the training set. Furthermore, we compare the RLEL with some baseline methods, and our model achieves the state-of-the-art results. We implement our models in Tensorflow and run experiments on 4 Tesla V100 GPU.

3.1 Experiment Setup

Datasets. We conduct experiments on several different types of public datasets including news and encyclopedia corpus. The training set is AIDA-Train and Wikipedia datasets, where AIDA-Train contains 18448 mentions and Wikipedia contains 25995 mentions. In order to compare with the previous methods, we evaluate our model on AIDA-B and other datasets. These datasets are well-known and have been used for the evaluation of most existing entity linking systems. The statistics of the datasets are shown in Table 1.

- AIDA-CoNLL [20] is annotated on Reuters news articles. It contains training (AIDA-Train), validation (AIDA-A) and test (AIDA-B) sets.
- ACE2004 [34] is a subset of the ACE2004 Coreference documents.
- MSNBC [9] contains top two stories in the ten news categories(Politics, Business, Sports etc.)

Table 1: Statistics of document and mention numbers on experimental datasets.

Dataset	Doc Num	Mention Num	Mentions Per Doc
AIDA-Train	946	18448	19.5
AIDA-A	216	4791	22.1
AIDA-B	231	4485	19.4
ACE2004	36	251	7.1
MSNBC	20	656	32.8
AQUAINT	50	727	14.5
WNED-CWEB	320	11154	34.8
WNED-WIKI	320	6821	21.3
OURSELF-WIKI	460	25995	56.5

- AQUAINT [25] is a news corpus from the Xinhua News Service, the New York Times, and the Associated Press.
- WNED-CWEB [16] is randomly picked from the FACC1 annotated ClueWeb 2012 dataset.
- WNED-WIKI [16] is crawled from Wikipedia pages with its original hyperlink annotation.
- OURSELF-WIKI is crawled by ourselves from Wikipedia pages.

Training Details. During the training of our RLEL model, we select top k candidate entities for each mention to optimize the memory and run time. In the top k candidate list, we define the recall of correct target entity is R_t. According to our statistics, when k is set to 1, 5, 10, R_t is 0.853, 0.977, 0.993 respectively. Empirically, we choose top 5 candidate entities as the input of our RLEL model. For each candidate entity, in order to get the entity description information and reduce the impact of noise, we use TextRank algorithm [23] to select 15 keywords from its original description in wikipedia. Similarly, we choose 15 words around the mention as its context. In the global LSTM network, if the number of mentions does not reach the pre-defined sequence length, we adopt the mention padding strategy. In short, we use the last mention to pad the sequence until the number of mentions reaches the length.

Hyper-parameter setting. We set the dimensions of word embedding and entity embedding to 300, where the word embedding and entity embedding are released by [30] and [14] respectively. For parameters of the local LSTM network, the number of LSTM cell units is set to 512, the batch size is 64, and the rank margin γ is 0.1. Similarly, in global LSTM network, the number of LSTM cell units is 700 and the batch size is 16. In the above two LSTM networks, the learning rate is set to 1e-3, the probability of dropout is set to 0.8, and the Adam is utilized as optimizer. In the policy network, we set the number of MLP layers to 4 and extend the priori feature dimension to 50.

3.2 Comparing with Previous Work

Baselines. We compare RLEL with a series of EL systems which report state-of-the-art results on the test datasets. There are various methods including classification model [25], rank model [6, 34] and probability graph model [14, 16, 20, 21, 37]. Besides, Cheng *et al.*[5] formulate their global decision problem as an Integer Linear Program (ILP) which incorporates the entity-relation inference.

Table 2: In-KB accuracy result on AIDA-B dataset.

Methods	AIDA-B
Huang and Heck (2015)[21]	86.6%
Chisholm and Hachey (2015)[6]	88.7%
Guo and Barbosa (2016)[16]	89.0%
Globerson *et al.* (2016)[15]	91.0%
Yamada *et al.* (2016)[40]	91.5%
Ganea and Hofmann (2017)[14]	92.2%
Phong and Titov (2018)[37]	93.1%
our	**94.3%**

Globerson *et al.* [15] introduce a multi-focal attention model which allows each candidate to focus on limited mentions, Yamada *et al.*[40] propose a word and entity embedding model specifically designed for EL.

Evaluation Metric. We use the standard Accuracy, Precision, Recall and F1 at mention level (Micro) as the evaluation metrics:

$$Accuracy = \frac{|M \cap M^*|}{|M \cup M^*|} \tag{10}$$

$$Precision = \frac{|M \cap M^*|}{|M|} \tag{11}$$

$$Recall = \frac{|M \cap M^*|}{|M^*|} \tag{12}$$

$$F1 = \frac{2 * Precision * Recall}{Precision + Recall} \tag{13}$$

where M^* is the golden standard set of the linked name mentions, M is the set of linked name mentions outputted by an EL method.

Results. As same as previous work, we use in-KB accuracy and micro F1 to evaluate our method. We first test the model on the AIDA-B dataset. From Table 2, we can observe that our model achieves the best result. Previous best results on this dataset are generated by [14, 37] which both built CRF models. They calculate the pairwise scores between all candidate entities. Differently, our model only considers the consistency of the selected entities and ignores the relationship between incorrect candidates. The experimental results show that our model can reduce the impact of noise and improve the accuracy of disambiguation. Apart from experimenting on AIDA-B, we also conduct experiments on several different datasets to verify the generalization performance of our model.

From Table 3, we can see that RLEL has achieved relatively good performances on ACE2004, CWEB and WIKI. Previous models [5, 14, 37] achieve better performances on the news datasets such as MSNBC and AQUINT, but their results on encyclopedia datasets such as WIKI are relatively poor. To avoid overfitting with some datasets and improve the robustness of our model, we not only use AIDA-Train but also add Wikipedia data to the training set. In the end, our model achieve the best overall performance.

In most existing EL systems, entities with lower frequency are difficult to disambiguate. For further analysis, we focus on the disambiguation accuracy of the gold entities in AIDA-B dataset with low popularity. We divide the gold entities according to their

Table 3: Compare our model with other baseline methods on different types of datasets. The evaluation metric is micro F1.

Methods	MSNBC	AQUAINT	ACE2004	CWEB	WIKI	Avg

our	92.8%	87.5%	**91.2%**	**78.5%**	82.8%	**86.56%**

Table 4: The micro F1 of gold entities with different pageviews on part of AIDA-B dataset.

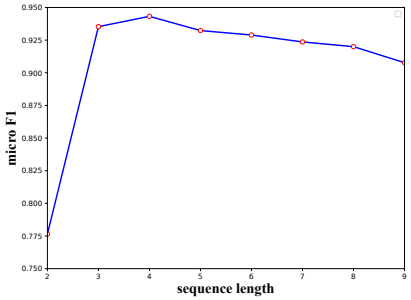
Pageview/million	Mention Num	Micro F1
< 0.01	307	91.93%
0.01-0.1	612	86.06%
0.1-1	968	88.97%
1-5	1006	96.03%
5-10	493	96.43%
> 10	825	99.39%

pageviews in wikipedia, and the statistical disambiguation results are shown in Table 4. Since some pageviews can not be obtained, we only count a part of gold entities. The result indicates that our model still works well for low-frequency entities. But for medium-frequency gold entities, our model doesn't work well enough. The most important reason is that other candidate entities corresponding to these medium-frequency gold entities have higher pageviews and local similarities, which makes the model difficult to distinguish.

3.3 Discussion on different RLEL variants

To demonstrate the effects of RLEL, we evaluate our model under different conditions. First, we evaluate the effect of sequence length on global decision making. Secondly, we test whether sorting the mentions have a positive effect on the results. Thirdly, we analyze the results of not adding globally encoding during entity selection. Finally, we compare our RL selection strategy with the greedy choice.

Sequence in different length. A document may contain multiple topics, so we do not add all mentions to a single sequence. In practice, we add some adjacent mentions to the sequence and use reinforcement learning to select entities from beginning to end. To analyze the impact of the number of mentions on joint disambiguation, we experiment with sequences on different lengths. The results on AIDA-B are shown in Figure 4. We can see that when the sequence is too short or too long, the disambiguation results are both very poor. When the sequence length is less than 3, delay reward can't work in reinforcement learning, and when the sequence length reaches 5 or more, noise data may be added. Finally, we choose the 4 adjacent mentions to form a sequence.



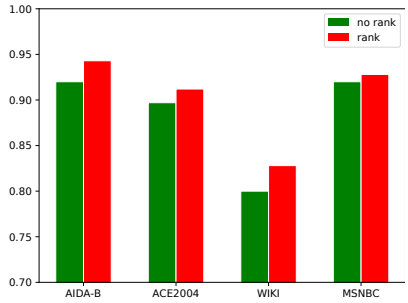


Figure 4: The performance of models with different sequence lengths on AIDA-B dataset.

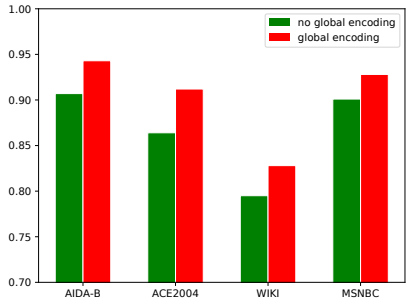
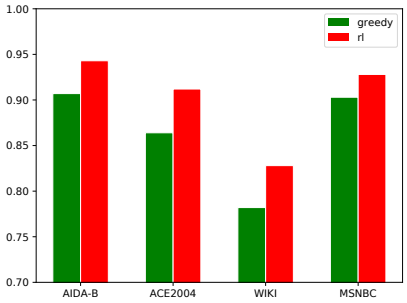


Influence of ranking mentions. In this section, we test whether ranking mentions is helpful for entity selections. We directly input the mentions into the global encoder by the order they appear in the text. We record the disambiguation results and compare them with the method which adopts ranking mentions. As shown in Figure 5a, the model with ranking mentions achieved better performances on most of datasets, indicating that it is effective to place the mention that with a higher local similarity in front of the sequence. It is worth noting that the effect of ranking mentions is not obvious on the MSNBC dataset. The reason is that most of mentions in MSNBC have similar local similarities, so the order of disambiguation has little effect on the final result.

Effect of global encoding. Different from previous global methods which use pairwise similarity between entities to capture their correlation, our model encodes the selected entity information in sequence. To evaluate whether the global encoding contributes to disambiguation, we compare the performance between the model with and without adding the global information. When the global encoding is not taken in to account, the current state only contains the local information, i.e., the mention context representation, candidate entity representation and feature representation. From the results in Figure 5b, we can see that the model with global encoding achieves an improvement of 4% accuracy over the model without global encoding.



Different entity selection strategies. To illustrate the effectiveness for adopting the reinforcement learning for entity selection, we compare two entity selection strategies like [12]. Specifically, we

a.The influence of ranking mentions for entity selection.

b. The effect of the global encoding for entity selection.

c. Comparison of reinforcement learning selection with greedy choice.

perform entity selection respectively with reinforcement learning and greedy choice. The greedy choice is to select the entity with the largest local similarity from candidate set. But the reinforcement learning selection is guided by delay reward, which has a global perspective. In the comparative experiment, we just replace the RL selection with a greedy choice, keeping the other conditions consistent. From the results in Figure 5c, we can draw a conclusion that our entity selector performs much better than greedy strategies.

3.4 Case Study

Table 5 shows two entity selection examples by our RLEL model. For multiple mentions appearing in the document, we first sort them according to their local similarities, and select the target entities in order by the reinforcement learning model. From the results of sorting and disambiguation, we can see that our model is able to utilize the topical consistency between mentions and make full use of the selected target entity information.

4 RELATED WORK

4.1 Entity Linking

Entity linking can be roughly divided into two major categories: local and global disambiguation. Early studies use local models to resolve mentions independently, they usually disambiguate mentions based on lexical matching between the mention's surrounding words and the entity profile in the reference KB. Various methods have been proposed to model mention's local context ranging from binary classification [25] to rank models [4, 11]. In these methods, a large number of hand-designed features are applied. For some marginal mentions which are difficult to extract features, researchers also exploit the data retrieved by search engines [7, 8] or Wikipedia sentences [36]. However, the feature engineering and search engine based methods are both time-consuming and laborious. Recently, with the popularity of deep learning models, representation learning is utilized to automatically extract semantic features [2, 17]. The entity representations learned by jointly modeling textual contexts and knowledge base are effective in combining multiple sources of information. To make full use of the information contained in representations, we also utilize the pre-trained entity embeddings in our model.

In recent years, with the assumption that the target entities of all mentions in a document shall be related, many novel global models for joint linking are proposed. Assuming the topical coherence among mentions, authors in [13, 33] construct factor graph models, which represent the mention and candidate entities as variable nodes, and exploit factor nodes to denote a series of features. Two recent studies [14, 37] use fully-connected pairwise Conditional Random Field(CRF) model and exploit loopy belief propagation to estimate the max-marginal probability. Moreover, PageRank or Random Walk [16, 19, 42] are utilized to select the target entity

for each mention. The above probabilistic models usually need to predefine a lot of features and are difficult to calculate the max-marginal probability as the number of nodes increases. In order to automatically learn features from the data, Cao *et al.* [1] applies Graph Convolutional Network to flexibly encode entity graphs. However, the graph-based methods are computationally expensive because there are lots of candidate entity nodes in the graph.

To reduce the calculation between candidate entity pairs, Globerson *et al.* [15] proposed a coherence model with an attention mechanism, in which each mention only focuses on a fixed number of mentions. Unfortunately, choosing the number of attention mentions is not easy in practice. Two recent studies [31, 32] finish linking all mentions by scanning the pairs of mentions at most once, they assume each mention only needs to be consistent with one another mention in the document. The limitation of their method is that the consistency information is too sparse, resulting in low confidence. Similar to us, Guo *et al.* [16] also sort mentions according to the difficulty of disambiguation, but they did not make full use of the information of previously referred entities for the subsequent entity disambiguation. Nguyen *et al.* [27] use the sequence model, but they simply encode the results of the greedy choice, and measure the similarities between the global encoding and the candidate entity representations. Their model does not consider the long-term impact of current decisions on subsequent choices, nor does they add the selected target entity information to the current state to help disambiguation.

4.2 Reinforcement Learning

In the last few years, reinforcement learning has emerged as a powerful tool for solving complex sequential decision-making problems. It is well known for its great success in the game field, such as Go [35] and Atari games [26]. Recently, reinforcement learning has also been successfully applied to many natural language processing tasks and achieved good performance [12, 22, 39]. Feng *et al.*[12] used reinforcement learning for relation classification task by filtering out the noisy data from the sentence bag and they achieved huge improvements compared with traditional classifiers. Zhang *et al.* [41] applied the reinforcement learning on sentence representation by automatically discovering task-relevant structures. To implement automatic taxonomy induction from a set of terms, Han *et al.* [18] designed an end-to-end reinforcement learning model to determine which term to select and where to place it on the taxonomy, and this model effectively reduced the error propagation between two phases. Inspired by the above works, we also use reinforcement learning in our framework.

5 CONCLUSIONS

In this paper we consider entity linking as a sequence decision problem and present a reinforcement learning based model. Our model learns the policy on selecting target entities in a sequential manner and makes decisions based on current state and previous ones. By utilizing the information of previously referred entities, we can take advantage of global consistency to disambiguate mentions. For each selection result in the current state, it also has a long-term impact on subsequent decisions, which allows learned policy strategy has a global view. In experiments, we evaluate our method on AIDA-B and other well-known datasets, the results show that our system outperforms state-of-the-art solutions. In the future, we would like to construct an end-to-end model which simultaneously optimize mention ranking and mention disambiguation.

Measurement and Early Detection of Third-Party Application Abuse on Twitter

Shehroze Farooqi
The University of Iowa

Zubair Shafiq
The University of Iowa

ABSTRACT

Third-party applications present a convenient way for attackers to orchestrate a large number of fake and compromised accounts on popular online social networks. Despite recent high-profile reports of third-party application abuse on popular online social networks, prior work lacks automated approaches for accurate and early detection of abusive applications. In this paper, we perform a longitudinal study of abusive third-party applications on Twitter that perform a variety of malicious and spam activities in violation of Twitter's Terms of Service (ToS). Our measurements spanning over a period of 16 months demonstrate an ongoing arms race between attackers continuously registering and abusing new applications and Twitter trying to detect them. We find that hundreds of thousands of abusive applications remain undetected by Twitter for several months while posting tens of millions of tweets. We propose a machine learning approach for accurate and early detection of abusive Twitter applications by analyzing their first few tweets. The evaluation shows that our machine learning approach can accurately detect abusive application with 92.7% precision and 87.0% recall by analyzing their first seven tweets. The deployment of our machine learning approach in the wild shows that attackers continue to abuse third-party applications despite Twitter's recent countermeasures targeting third-party applications.

CCS CONCEPTS

• **Security and privacy → Social network security and privacy**.

1 INTRODUCTION

Background. Popular social networking sites, including Twitter, allow developers to use third-party applications to enhance user experience. Millions of applications use Twitter's third-party developer platform to support news, gaming, entertainment, analytics, research, and publishing solutions [2]. Third-party Twitter applications (or simply Twitter applications) use OAuth [33] for getting permissions from users to read/write/message on their behalf [11, 15]. Twitter applications have perpetual access to user accounts unless users explicitly revoke their permissions. Naturally, an attacker can control a large number of accounts by tricking users into installing a malicious application [45] or compromising a popular legitimate application [36, 51].

Motivation. Third-party Twitter applications present a convenient way for attackers to orchestrate fake or compromised accounts through Twitter API [12]. Attackers can install third-party applications on fake accounts that they themselves create or buy in bulk from underground marketplaces [35, 58]. Attackers can also trick users (e.g., phishing [27], malicious browser extensions [41]) into installing their applications to compromise accounts. Attackers can even recruit real users on crowdturfing marketplaces to install their applications in exchange for monetary and non-monetary incentives (e.g., free followers) [36, 58, 60]. On several occasions during the last couple of years, Twitter has disclosed large-scale abuse by hundreds of thousands of third-party applications on their platform [7, 10, 45].

Limitations of Prior Art. Prior research has paid little attention to directly mitigate the role of third-party applications in propagating malware and spam on Twitter [34, 43, 52, 54, 55, 55, 57, 61]. While some prior research has reported the spread of malware and spam by third-party Twitter applications [34, 52, 55, 57], most efforts are focused on detecting the *sources* (fake and compromised accounts) and *targets* (retweets) of malicious activities on Twitter. We believe that directly targeting such abusive third-party Twitter applications is crucial for robust detection of increasingly sophisticated malicious activity on Twitter. Our belief is in line with Twitter's recently announced plans to target fake, coordinated, and automated account activities conducted by third-party applications on their platform [9, 10].

Measuring abusive Twitter Applications. In this work, we conduct a 16-month long longitudinal measurement study of abusive third-party applications that perform a variety of malicious and spam activities in violation of Twitter's Terms of Service (ToS) [20]. To collect a comprehensive ground truth of abusive Twitter applications, we retrospectively check whether tweets by third-party applications are removed by users or Twitter's abuse detection systems [5, 8, 58]. Prior work has also leveraged retrospective analysis of deleted/suspended tweets/accounts to study spam and malware campaigns on Twitter [56, 57]. We are able to identify 167,013 abusive third-party Twitter applications through retrospective analysis of tweets collected over a period of 16 months using Twitter's APIs [12, 17]. Our measurements reveal that there is an ongoing

arms race between attackers registering and abusing new applications and Twitter actively trying to detect and remove them. More specifically, we show that attackers are able to use a large pool of hundreds of thousands of abusive applications to post tens of millions of tweets. Abusive applications often evade detection for several months while posting millions of tweets for astroturfing [32, 52, 55], phone spam [39], and tricking users with deceiving claims to compromise accounts [4, 26, 57].

Early Detection of Abusive Twitter Applications. Accurate and early detection of abusive third-party applications can help in significantly mitigating malware and spam on Twitter. To this end, we propose a machine learning approach for the early detection of abusive third-party Twitter applications by analyzing their first few tweets. Specifically, we extract a variety of user-based (e.g., account age) and tweet-based features (e.g., retweets to tweets ratio) on the first-$k \in \{2, 3, ..., 25\}$ tweets to train a supervised machine learning classification model to distinguish between abusive and benign Twitter applications as early as possible. We implement and evaluate our machine learning approach before and after Twitter's recent countermeasures targeting third-party application abuse [9]. The evaluation shows that our machine learning approach is able to accurately detect abusive applications with 92.7% precision and 87.0% recall. We also show that our machine learning approach detects abusive applications months before Twitter does, during which time they are able to post tens of millions of tweets.

Key Contributions. We summarize our contributions as follows.

• *Longitudinal Measurement Study of Abusive Applications on Twitter.* We perform a longitudinal measurement study to establish a ground truth of abusive Twitter applications that captures diverse malicious and spamming behaviors. We showed that these abusive applications stay undetected for a long time posting tens of millions of tweets despite Twitter's ongoing efforts to detect them.

• *Machine Learning Approach for Early Detection.* We propose a machine learning approach to accurately and early detect these abusive applications by analyzing their first-$k \in \{2, 3, ..., 25\}$ tweets. We select $k = 7$ as a suitable trade-off between classification accuracy and early detection. Our machine learning model detects abusive applications with a precision of 92.7% and a recall of 87.0% using 10-fold cross validation as soon as they post their first seven tweets. We show that our model detects a large fraction of these abusive applications several months before Twitter detects them while they post tens of millions of tweets during this time period.

• *In The Wild Deployment.* The deployment of our machine learning model in the wild shows that attackers are still able to register and abuse third-party applications despite Twitter's new countermeasures [9]. We show that our machine learning model accurately detects these abusive third-party applications as soon as they post their first seven tweets while they evade detection by Twitter for a long time. Finally, we show that our machine learning model detects a large fraction of new abusive applications that are missed by Twitter's existing abuse detection systems.

We have disclosed our findings to Twitter's Site Integrity team, who is actively trying to mitigate abuse of third-party applications on their platform [9]. Our machine learning approach can complement Twitter's abuse detection systems for accurate and early detection of Twitter API abuse by third-party applications.

2 BACKGROUND

In this section, we first provide an overview of third-party application support on popular online social networks. We then discuss our threat model for third-party applications and the prevalence of their abuse on Twitter.

2.1 Third-Party Applications

Online social networks provide APIs to develop third-party applications such as games, entertainment, education, and utilities. To allow third-party application development, online social networks implement authorization frameworks such as OAuth [33]. For example, Twitter uses the OAuth 1.0a authorization framework [33], which enables third-party applications to gain access to Twitter's streaming and REST APIs as well as Twitter's Single Sign-On (SSO) service [12, 19]. When creating a new third-party application, developers have to specify a set of permissions required from users who would install the application on their accounts. OAuth supports both *read* and *write* permissions. The read permissions allow a third-party application to retrieve data (e.g., timeline tweets/posts, list of followers/friends) from a user's account. The write permissions allow a third-party application to perform write actions (e.g., posting tweets/posts, following users or liking pages) on a user's behalf. Popular online social networks such as Twitter and Facebook have millions of third-party applications that are regularly used by hundreds of millions of users [3, 23].

2.2 Threat Model

While third-party applications are widely used for benign purposes, unfortunately, they can also be exploited by attackers to compromise and orchestrate a large number of accounts for nefarious purposes. Prior work has reported several instances of widespread abuse of third-party applications for spreading spam and malware on online social networks [34, 52, 55, 57].

The typical modus operandi of attackers is as follows. Attackers register a new third-party application with the aim of installing it on as many fake/compromised accounts as possible. Attackers install the registered application on fake accounts that they themselves create or buy in bulk from underground marketplaces [35, 58]. Attackers may also compromise an account by tricking its user into installing the application. After installing the application on a sufficient number of accounts, attackers can use the access tokens [1] via the APIs to conduct malicious activities at scale.

The abuse of third-party applications has been shown time and again on popular online social networks [36, 50, 52, 55, 57]. For example, prior work reported the abuse of third-party applications to escalate the reputation of a target account by retweeting/liking/following from compromised/fake accounts on Twitter [52, 55] and Facebook [36]. Prior work has also reported the abuse of third-party applications to run spam or malware campaigns from compromised/fake accounts on Twitter [57] and Facebook [50].

In this paper, we specifically focus on investigating abuse by third-party applications on Twitter. It is noteworthy that Twitter

recently disclosed a large-scale abuse of third-party applications on their platform [10] in the aftermath of a congressional investigation into Russian interference in the 2016 U.S. election [7]. Specifically, Twitter announced that they removed hundreds of thousands of third-party applications that were abusing their API during 2017 through 2018 [10, 45]. Also noteworthy is Twitter's recently announced policy to vet new third-party applications at registration [9]. However, despite Twitter's existing detection systems and new countermeasures, we will show later that attackers continue to abuse third-party applications on Twitter to this day.

2.3 Abusive Twitter Applications

We refer to a third-party Twitter application as "abusive" if it violates Twitter's rules [20]. The violations of these rules mostly include malicious and spammy behaviors such as posting links to malicious content, aggressive following and un-following behavior, abusing reply or mention function, hijack trending topics or hashtags, duplicate updates, etc. Other violations of these rules, unrelated to malicious and spammy behaviors, include the unlawful use of Twitter platform such as illegitimate distribution of copyrighted or hacked material, graphical violence, and harassment.

It is challenging to manually establish the ground truth for third-party Twitter applications (e.g., manual detection of the violation of Twitter's rules) because of the scale and diversity of abusive behavior. To automatically get a comprehensive ground truth of abusive Twitter applications, we retrospectively check whether tweets by third-party applications are removed by users or Twitter's abuse detection systems due to the violation of their rules [20]. Prior work has exploited similar retrospective analysis of deleted tweets and suspended accounts to study spam and malware campaigns on Twitter by fake/compromised accounts [56, 57]. In particular, if all tweets by a Twitter application are removed, it is highly likely that the application is violating Twitter's rules and can be labeled as abusive. In addition to retrospective ground truth labeling of abusive Twitter applications, we further expand our ground truth out-of-band by including follower market applications that compromise accounts by incentivizing users to install the applications in exchange for "free followers" [13, 55]. We next explain our methodology to collect data of these abusive applications.

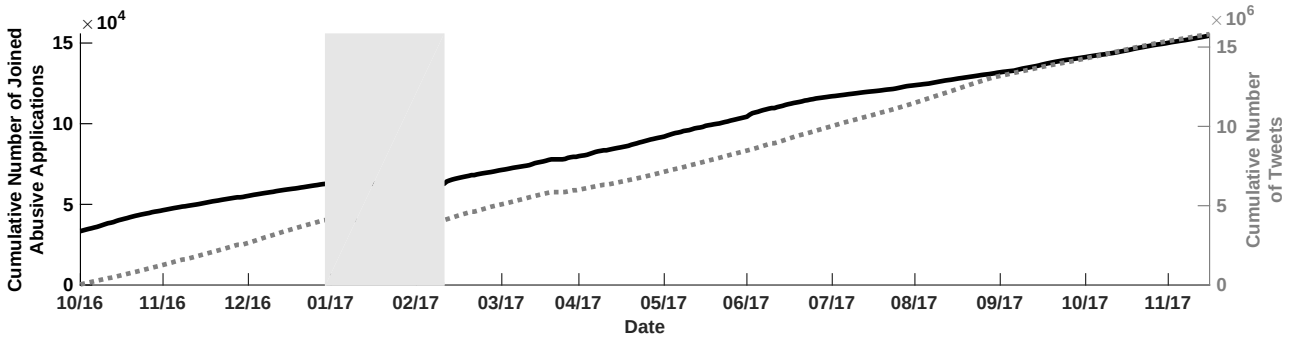
3 MEASURING ABUSIVE APPLICATIONS

In this section, we conduct a longitudinal measurement study of third-party Twitter applications to demonstrate that abusive applications are able to evade detection by Twitter's abuse detection systems for extended time periods while they post tens of millions of tweets during this time.

3.1 Data collection

We leverage Twitter's streaming API to gather tweets by different third-party Twitter applications and REST API to establish a ground truth of benign and abusive applications.

Streaming API. We rely on Twitter's streaming API to collect publicly available tweets. Twitter's streaming API offers a `sample` stream that returns 1% sample of all public tweets [48]. Each tweet contains the tweet's text and metadata, which includes timestamp, user's screen name, and the source field that contains the name of the application used to post the tweet. We collect 1.5 billion tweets by 112 million users from 456,987 applications from September 2016 to December 2017. We refer to this collection of tweets as the *Twitter sample dataset*.



Retrospective Analysis of Removed Tweets. We retrospectively query the current status of tweets of all third-party applications in the Twitter sample dataset to check whether they are removed using Twitter's REST API. We provide sufficient time to Twitter's abuse detection systems to remove tweets by abusive third-party applications. Specifically, we start querying Twitter's REST API to check the deletion status of tweets in August 2018, which is at least 8 months apart from the tweets in the Twitter sample dataset. Note that we cannot query the deletion status of tweets for all applications due to the rate limits imposed by Twitter's REST API [16]. Hence, for each application, we select a random sample of at most 100 tweets whose deletion status is queried using Twitter's REST API. Since 87% of applications have less than or equal to 100 tweets, we sample tweets for only 13% applications and consider all tweets of the remaining applications. In total, we query the deletion status of 12 million tweets posted by 456,987 applications of which 36% tweets are removed. 49% of applications have no removed tweets while 37% applications have all of their tweets removed. To minimize false positives in our labeling, we conservatively label the 37% applications with all of their tweets removed as abusive. We next explain our methodology to identify and crawl follower markets to expand our ground truth of abusive applications.

Follower Markets. We query Google and Twitter search to identify follower markets. First, we search Google using keywords such as "free followers" and "increase followers". We manually analyze search results to identify popular follower markets. Second, we search Twitter using hashtags such as "followers" and "increaseFollowers". We manually analyze URLs in tweets to find follower markets. Using this methodology, we are able to identify 50 follower markets that ask Twitter users to install third-party applications in exchange for "free followers". Our eyeball analysis shows that abusive applications used by follower markets change over time. Therefore, we periodically crawl follower markets to extract the names of their abusive applications. To automate this process, we use Selenium WebDriver [18] to open each follower market website every 15 minutes. Upon clicking the sign-in button to install the application, we are redirected to Twitter's application authorization page. We extract the name of the abusive application, without installing it, from the authorization page. We crawl these 50 follower markets from September 2016 to August 2017 and identify names of 14,150 distinct abusive applications. Out of these 14,150, we find 6,437 abusive applications in our Twitter sample dataset.

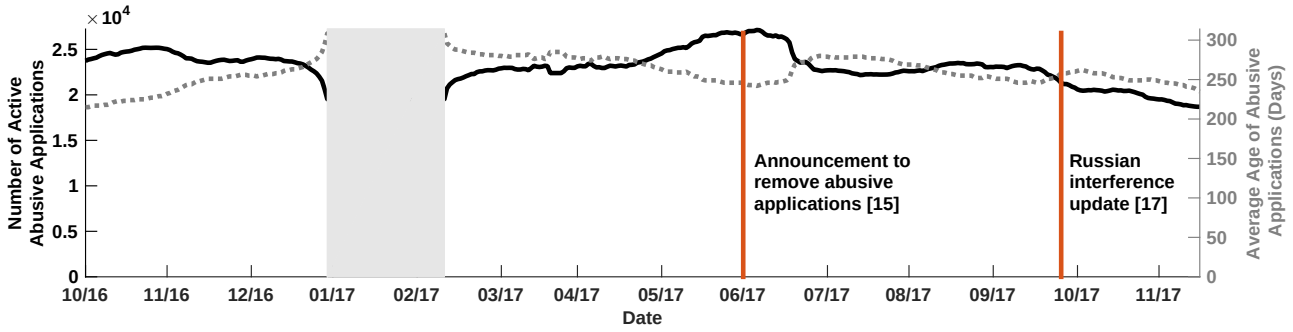


Table 1 summarizes the statistics of third-party Twitter applications in our Twitter sample dataset. In total, we are able to identify 168,227 distinct abusive applications through retrospective analysis of removed tweets and crawling follower markets.

3.2 Arms Race

We investigate the arms race between attackers continuously creating new abusive applications and Twitter trying to detect and remove them [10, 45]. Specifically, we study how quickly Twitter detects and removes abusive applications while they post tens of

(a) Cumulative number of daily joined abusive applications and their tweets count

(b) Count and average of daily active abusive applications

Figure 1: Illustration of the arms race between attackers and Twitter in registering and removing abusive Twitter applications. Attackers use a large pool of abusive applications to post tens of millions of tweets. While Twitter's existing countermeasures detect some abusive applications, attackers always have tens of thousands of active abusive applications that stay undetected for several months.

All Applications	Abusive (Retrospective)	Abusive (Follower markets)	Abusive (Combined)
456,987	167,013	6,437	168,227

Table 1: Summary of abusive applications identified from retrospective analysis of removed tweets and follower markets in our Twitter sample dataset.

millions of tweets observed in the Twitter sample dataset. Figure 1(a) plots the cumulative number of new abusive applications observed every day and the cumulative number of tweets posted by them [1]. We find that attackers use a large pool of applications to post abusive tweets. On average, attackers daily register 392 new abusive applications and post 41,705 tweets. In total, we observe more than 17 million tweets posted by 168,227 abusive applications. Since our Twitter sample dataset is limited to at most 1% sample of daily tweets, the actual number of tweets posted by abusive application is likely higher by roughly two orders of magnitude. Thus, we estimate the number of daily and total tweets posted by abusive applications to be in the order of millions and billions, respectively. Our estimates are close to the recent disclosure by Twitter that mentioned 2.2 billion tweets posted by abusive applications [10].

As Twitter detects and removes some of these abusive applications, we expect attackers to register new applications to make up for the removed applications. To evaluate Twitter's existing abuse detection systems, we plot the distribution of number of daily active abusive applications and their average age in Figure 1(b). Note that we estimate the *age* of an abusive application by calculating the difference between the first time and the last time the application appeared in Twitter sample dataset. We say that an application is removed by Twitter's abuse detection systems [5, 8, 56, 58], when it stops appearing in our dataset. Since there is no definitive way for us to know whether or not an application is removed by Twitter, we optimistically assume that these applications are removed by Twitter. We observe that attackers always have a substantial number of active abusive applications ranging between 18,687-27,132. These active applications stay undetected for a long time with an average age of more than six months.

While recently announced countermeasures by Twitter detect some abusive applications, we note that a vast majority of abusive applications still go undetected for a long time period. Specifically, Twitter announced plans to implement new machine learning based approaches to detect and remove abusive applications in June 2017 [5]. In Figure 1(b), we observe a sharp but small decline in the number of active abusive applications. It is interesting to note that attackers seem to adapt to these new countermeasure and the number of active applications stabilizes by August 2017. We observe another decline in the number of active applications after Twitter announced additional countermeasures against abusive third-party applications in September 2017 [7]. However, we note that a vast

[1]Our data collection stopped during the time period represented by the grey shaded region due to an error in the data collection script.

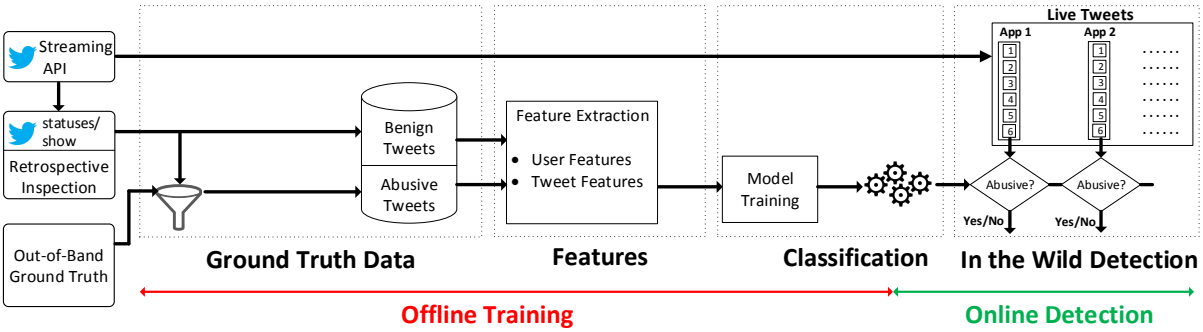

Figure 2: Our proposed approach for early detection of abusive third-party applications on Twitter. In the offline phase, we analyze the first-k tweets of each application to extract user-based and tweet-based features. We then train a supervised machine learning model to classify benign and abusive applications. In the online phase, we use the trained model to detect abusive applications by analyzing their first-k tweets from Twitter's streaming API.

majority of the abusive application still remain active despite Twitter's countermeasures.

It is noteworthy that the applications detected during these sharp declines in Figure 1(b) are relatively new because the average age of active applications increased after the decline. This shows that while Twitter detects some abusive applications, a large number of long-lived abusive applications remain undetected. Specifically, 5,404 abusive applications remain undetected during the 16 month period and are able to post 2.9 million tweets.

Takeaway: Our results indicates an ongoing arms race between attackers and Twitter on the registration and removal of abusive Twitter applications. Essentially, attackers are able to use a large pool of abusive applications to post tens of millions of tweets while being resilient to Twitter's countermeasures. While Twitter's existing countermeasures detect some abusive applications, a large number of abusive applications stay undetected for a long time. As we discuss next, we propose a machine learning approach for the early detection of abusive applications.

4 PROPOSED APPROACH

Since abusive third-party Twitter applications are able to evade detection for a long time, we are interested in detecting these abusive applications as early as possible before they are able to post many tweets. In this section, we present a machine learning approach for early detection of abusive third-party Twitter applications. Figure 2 provides an overview of our approach. In the offline phase, we train a supervised machine learning model that analyzes the first-k tweets of an application to detect abusive applications. More specifically, we extract a variety of user-based and tweet-based features to distinguish between benign and abusive applications. Using a labeled repository of tweets for benign and abusive applications, we then train a supervised machine learning classifier to detect abusive applications. In the online phase, we use the trained supervised machine learning model to detect abusive applications *in the wild* by analyzing their first-k tweets from Twitter's streaming API.

4.1 Ground Truth

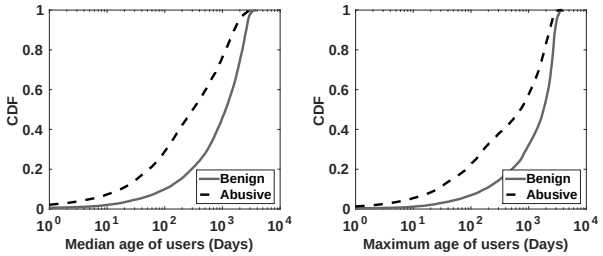
Next, we explain our method to establish the ground truth for benign and abusive applications in our Twitter sample dataset. Recall from Section 3.1 that we may strictly label an application as abusive if all of its tweets are removed or benign if none of the tweets are removed. However, this strict definition would result in mislabeling many abusive and benign applications. For instance, a user may remove tweets posted through a benign application due to spelling or grammatical mistakes [22]. Similarly, a user may remove tweets posted through an abusive application after recovering a compromised account [14, 57]. Moreover, Twitter's abuse detection systems may remove a subset of tweets by an abusive application, unrelated to detection of the abusive application [6]. Therefore, we need to relax our labeling criterion from all-or-nothing. To this end, we define two thresholds, α and β, to label an application as abusive or benign, respectively. We label an application as abusive if the percentage of removed tweets is more/less than α/β. On one extreme, we select the value of $\alpha = 90\%$ as 37% of applications have at least 90% of their tweets removed. On the other extreme, we select $\beta = 30\%$ as 58% of applications have less than 30% removed tweets. To reaffirm this selection of β, note that the percentage of removed tweets for several popular benign applications (e.g., Twitter for iPhone, Twitter for Android, Twitter Web Client) is less than 30%. To conclude, we are able to label 95% applications as benign or abusive using 90%-30% α and β selections. Note that we filter applications with only one user/tweet representing less than 2% tweets in our Twitter sample dataset. Overall, our ground truth contains 19,343 benign and 24,588 abusive applications in our Twitter sample dataset.

Next, we present case studies of a select spam and malicious campaigns. We manually analyze the content of a sample of labeled abusive applications to identify these campaigns.

Scam installs. We find several known malicious campaigns that deceive users into installing their abusive applications to compromise accounts and post spam tweets from these accounts. For example, we identify a malicious campaign that claims to inform users who visited their timeline [26, 47]. This is a deceiving claim to trick users into installing abusive applications since Twitter does not provide timeline visit information to third-party applications. As another example, attackers register applications with names that impersonate Twitter (e.g., `Twitter Age Confirmation` and `Twitter Age Verification`) to trick users into installing their abusive applications [4]. We find over 250 abusive applications that are part of such malicious campaigns.

Phone spam campaign. We find a malicious campaign promoting phone spam [39]. In this campaign, spammers mislead victims by making false promises and expect users to contact them on listed phone numbers in the posted tweets. We find 47 abusive applications that are part of this spam campaign.

Astroturfing campaigns. We find several astroturfing campaigns that exploit abusive applications to run their operations. Some examples of these campaigns provide fake followers [55] and retweets [52]. We identify thousands of abusive applications that participate in such astroturfing camapaigns.



4.2 Features

We extract a comprehensive set of features to capture distinguishing characteristics of benign and abusive applications. Our feature extraction has two key differences compared to prior work. First, while prior research computed per-tweet features to detect spam/malicious tweets or per-user features to detect fake/compromised user accounts, we compute features on a per-application basis to directly detect abusive applications. Second, unlike prior research, we compute features from the first-k tweets of each application for early detection of abusive applications.

We compute a variety of user-based and tweet-based features to detect abusive applications. For user-based features we focus on following characteristics of users: (1) **number of followers*, (2) **number of followings*, (3) average number of followers to followings ratio, (4) ratio of users with default images set as profile, (5) ratio of verified users, (6) **age of user accounts*, (7) **number of tweets*, and (8) average ratio of total tweets to age of user accounts . For tweet-based features we focus on following characteristics of tweets: (1) ***number of user mentions*, (2) ***number of hashtags*, (3) percentage of tweets with hashtags, (4) percentage of unique hashtags, (5) entropy of hashtags, (6) average of retweet-to-tweet ratio, (7) entropy of URLs, (8) percentage of URLs, and (9) percentage of unique URLs. For many of the user-based and tweet-based features, we compute various summary statistics for italicized features across all tweets of an application. Features with * represent mean, median, minimum, and maximum whereas features with ** represent mean, median, minimum, maximum, and standard deviation. In total, we extract 38 user-based and tweet-based features. We next analyze the effectiveness of a select subset of these features in distinguishing between abusive and benign applications.

Account Age. Figure 3(a) plots the distribution of the median age of user accounts of abusive and benign applications. We note that the user accounts of benign applications are significantly older than those of abusive applications. More specifically, 68% abusive applications have median user account age of two years or less. In contrast, 37% benign applications have median user account age of two years or less. We surmise that the median age of user accounts of abusive applications is low because attackers continuously create fresh user accounts which are, sooner or later, suspended due to violation of Twitter rules [56].

Figure 3(b) plots the distribution of maximum user account age for abusive and benign applications. We note that a large fraction of benign applications has at least one account that is very old. Specifically, more than 75% of benign applications have at least one user account aged two years or more. In contrast, more than 50% of

(a) Average (b) Maximum

Figure 3: We observe that the user accounts of benign applications are older than the user accounts of abusive applications.

abusive applications have no user account aged two years or more. While attackers can obfuscate maximum user account age feature by adding an aged user account, the median age of user accounts is more robust to obfuscation because it relies on the whole user account population of an application.

Retweet-to-tweet Ratio. Figure 4 plots the distribution of retweet-to-tweet ratio of abusive and benign applications. We note that a large fraction of abusive applications posts only retweets while this behavior is quite uncommon among benign applications. Specifically, 32% abusive applications have retweet-to-tweet ratio of 1 whereas only 5% benign application have retweet-to-tweet ratio of 1. Such abusive applications are likely being used to artificially boost reputation of tweets [52]. Attackers can try to post original tweets to obfuscate retweet-to-tweet ratio feature. To generate original tweets, attackers can use duplicate content but this will also be detected due to the violation of Twitter rules. Attackers can also recruit crowdturfing workers [44] to generate organic content to obfuscate ratio of retweet-to-tweet feature but it may prohibitively increase their cost for large-scale spam operation [30].

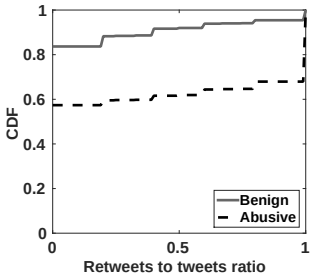


Figure 4: We observe that a large fraction of abusive applications only post retweets while this behavior is quite uncommon among benign applications.

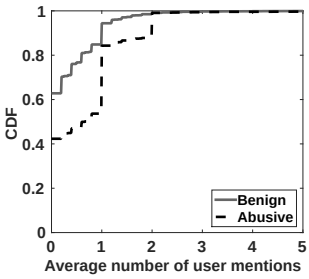

Figure 5: We observe that abusive applications mention more users in their tweets as compared to benign applications.

Number of User Mentions. Figure 5 plots the distribution of average number of user mentions in tweets posted by abusive and benign applications. It is interesting to note that abusive applications mention more users than benign applications. Specifically, 46% abusive applications have an average of one or more user mentions while only 5% benign applications have an average of one or more user mentions. Abusive applications mention more users in tweets to either lure other victims into installing their applications or increase the reach of their tweets. Attackers can try to reduce

or stop mentioning users altogether to manipulate their average number of mentions; however, it would negatively impact their ability to reach to other users.

4.3 Classification

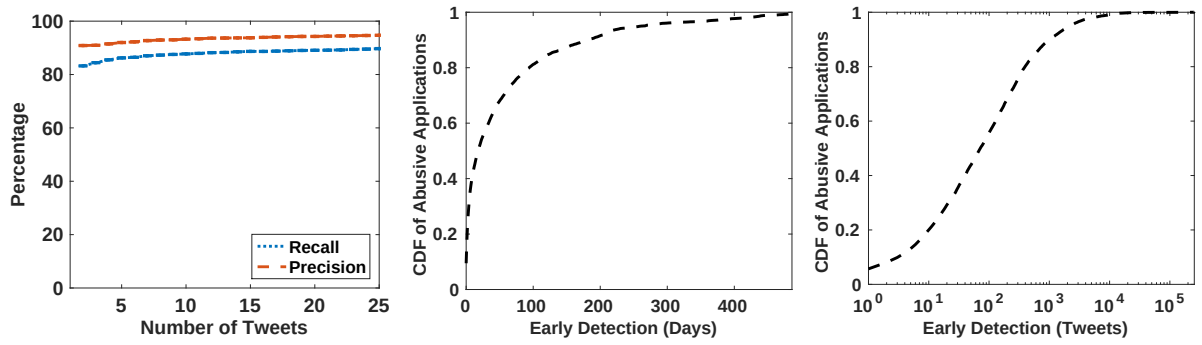
We leverage previously discussed user-based and tweet-based features to train a supervised machine learning model to classify an application as abusive or benign. For classification, we tried several classification algorithms using Python's scikit library and ended up selecting the Random Forest classifier because it outperformed other algorithms. For training the model, we use the ground truth of 19,343 benign and 24,588 abusive applications. We first use 10-fold cross-validation to evaluate the accuracy of our trained Random Forest classification model. We then use our trained Random Forest classification model to detect abusive applications in the wild on new data collected from Twitter's streaming API.

5 EVALUATION

In this section, we evaluate the effectiveness of our machine learning approach in detecting abusive applications as early as possible. First, we use cross-validation to study the classification accuracy for varying values of first-k tweets. We show that our machine learning approach is able to detect abusive applications with very high accuracy several weeks before they are detected by Twitter. Second, we employ our machine learning approach to detect abusive applications based on their first few tweets on a new Twitter dataset, which is collected after Twitter's recently announced countermeasures were implemented. We show that attackers still register new abusive applications that go undetected by Twitter while our machine learning approach detects them quite early.

5.1 Cross-Validation

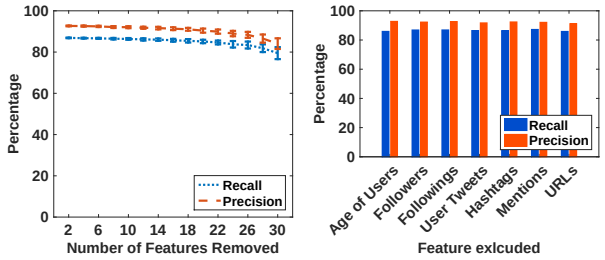
Early Detection. We train and test a Random Forest classifier on varying values of first-$k \in \{2, 3, ..., 25\}$ tweets using 10-fold cross-validation. For each value of k, we sample from the set of abusive and benign applications with at least k tweets. Since number of benign applications are slightly less than abusive applications, we randomly sample benign applications for each value of k to match the number of abusive applications to create a balanced dataset for cross-validation. We train and test our model using 100 random samples of benign applications for each value of k and report averages and standard deviations of precision and recall metrics. Figure 6 plots precision and recall as a function of k. We observe the best average precision and recall of 94.7% and 89.7% at $k = 25$, respectively. Recall that our objective is to accurately detect abusive applications as early as possible. We observe that precision and recall improve as k increase but they start to plateau beyond $k = 7$ in Figure 6(a). Specifically, precision increases from 90.9% for $k = 2$ to 92.7% for $k = 7$ and recall increases from 83.2% for $k = 2$ to 87.0% for $k = 7$. Therefore, we select $k = 7$ as a suitable tradeoff between early detection and classification accuracy.



We quantify the early detection of abusive applications correctly detected by our model for $k = 7$ in terms of days and tweets. Early detection in terms of days is defined as the difference between the estimated age of application (defined in Section 3.2) and the age of application when they are detected by our model. Early detection in terms of tweets is defined as the difference between the total number of tweets posted by the applications and the number of tweets posted by applications when they are detected by our model.

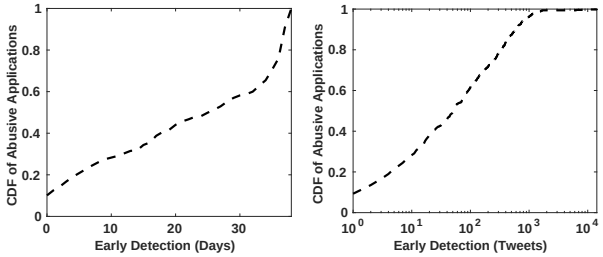
Figure 6(b) shows that our trained model is able to detect abusive applications weeks and sometimes months before Twitter does so. Specifically, 42% abusive applications are detected at least a month earlier by our model whereas 21% abusive applications are detected at least 3 months earlier by our model. It is noteworthy that our model has detected 60 abusive applications on the first day of their appearance that otherwise remain undetected throughout the data collection period of 16 months. Figure 6(c) shows that our trained model detects abusive applications before they continue posting hundreds of millions of tweets. Specifically, 45% abusive applications posted 100 or more tweets where 10% abusive applications posted 1000 or more tweets after detection by our model. In total, all abusive applications posted 9,146,439 tweets after detection by our model. Since our Twitter sample dataset is limited to at most 1% sample of daily tweets, the actual number of tweets posted by abusive applications is likely higher by roughly two orders of magnitude. Thus, we estimate that abusive applications posted tweets in the order of hundreds of millions after detection by our model.

We manually analyze a small sample of false positives i.e., benign applications incorrectly classified as abusive by our machine learning model during cross-validation. Our manual analysis uncovers that several applications labeled as benign in our ground truth are in fact abusive. This indicates that our precision is actually more than our estimate reported in Figure 6(a). We surmise that activities of many abusive applications remain undetected by Twitter's existing abuse detection systems during our data collection period; hence, these abusive applications are incorrectly labeled as benign in our ground truth. This also shows that our ground-truth is a conservative estimate of abusive applications. Despite being a conservative estimate, as discussed in Section 4.1, we argue that our ground truth captures a diverse set of abusive behaviors.



We also acknowledge that abusive applications that post less than 7 tweets will not be detected by our model. However, we argue that these low-activity applications do not pose a significant threat due to their low tweet volume. In other words, while posting fewer tweets allows abusive applications to go undetected, it also limits their ability to conduct abuse on a large scale. Moreover, if needed, we can detect these low-activity abusive applications using our machine learning model trained for smaller values of k with reasonably high precision and recall.

Feature Ablation. We perform an ablation experiment to understand the impact of removing features on the classification accuracy of our model in Figure 7. We randomly remove a varying number of features from 0 to 30 to train and test our model. We repeat this experiment 100 times for each number of removed features. Figure 7(a) shows that precision and recall decreases as we remove more features but this decrease is not substantial. Specifically, the average precision and recall decrease by only 8.6% and 7.4%, respectively, when the number of removed features increase from 2 to 30. We perform another ablation experiment to understand the contribution of individual feature sets of user-based and tweet-based features. Specifically, we remove one feature set at a time to train and test our model. Figure 7(b) shows that the classification accuracy does not



(a) Ten-fold cross validation (b) Early Detection at $k = 7$ (Days) (c) Early Detection at $k = 7$ (Tweets)

Figure 6: We achieve best precision and recall of 94.7% and 89.7%, respectively, at $k = 25$. We select $k = 7$ as a suitable trade-off between early detection and classification accuracy, where we detect 42% of abusive applications at least a month before Twitter during which time these abusive applications post millions of tweets.

(a) Removing features randomly (b) Excluding a feature set

Figure 7: Ablation experiment at $k = 7$ shows that our features are resilient to obfuscation attempts by attackers. More specifically, (a) shows that our feature set is resilient to obfuscation attempts against a combination of features and (b) shows that our classification results are not dependent on individual user-based and tweet-based features.

(a) Early Detection In the Wild (Days) (b) Early Detection In the Wild (Tweets)

Figure 8: The deployment of our machine learning approach in the wild shows that attackers continue to register new applications that go undetected for a long time despite Twitter's new countermeasures while our machine learning approach detects them several weeks before Twitter by analyzing their first seven tweets.

significantly degrade without any individual feature set. The lowest precision of 91.2% and recall of 85.9% is observed when we remove the *URLs* feature set which includes entropy of URLs, unique percentage of URLs, and ratio of URLs to tweets. We conclude that our trained machine learning model is resilient against attempts to obfuscate a specific feature set or a combination of features.

5.2 In the Wild Detection

Next, we show that attackers are able to register new applications and abuse them despite Twitter's most recent countermeasures against them. We also show that our machine learning approach can detect these new abusive applications that are missed by Twitter's countermeasures.

Overview of Twitter's new countermeasures. Recall from Section 3.2 that Twitter has several countermeasures in place to detect and remove abusive applications [5, 10]. However, these countermeasures have not sufficiently deterred attackers from abusing third-party applications. To mitigate the abuse of third-party applications, Twitter recently enforced several new countermeasures [9]. Specifically, Twitter introduced a new policy to review use cases and check policy compliance of new third-party Twitter applications at registration to mitigate abuse. Twitter also introduced new rate limits on the use of POST endpoints (e.g., tweet/retweet, like/follow). Finally, Twitter introduced new ways for users to detect and report abusive applications. Since these countermeasures were implemented after our data collection period that ended in December 2017, we are interested in studying whether they are effective in mitigating abuse of third-party applications. More specifically, we want to find out whether attackers can still register new applications and evade detection and whether our machine learning approach can accurately detect them as early as possible.

In the Wild Deployment. To study the effectiveness of Twitter's newly introduced countermeasures, we use Twitter's streaming API to collect a new tweet dataset during September-October 2018 which is after Twitter's new countermeasures went into effect. To focus on new high-activity applications, we filter the applications that also appeared in our older dataset and those with fewer than seven tweets. We use Twitter's REST API to retrospectively query the deletion status of tweets of 2,225 new applications. Using the approach outlined in Section 3, we find that Twitter removed 532 new applications. In other words, Twitter removed about a quarter (24%) of new applications, which were able to bypass vetting at registration and post hundreds of thousands of tweets before being eventually detected by Twitter.

Next, we use our machine learning model trained on Twitter sample dataset to classify the 2,225 new applications. Our model is able to detect 93% (495 out of 532) of the applications removed by Twitter. It is noteworthy that our model detects these abusive applications that evade detection for weeks while posting hundreds of thousands of tweets. Figure 8 shows that 40% of these abusive applications are detected by our model at least a month before Twitter's new countermeasures. Figure 6(c) shows that 62% of these abusive applications posted at least 100 tweets after detection by our model, which uses only the first-7 tweets. In total, these abusive applications posted 239,485 tweets after detection by our model and before being detected by Twitter's countermeasures. Note that we estimate that abusive applications posted tweets in the order of tens of millions after detection by our model since our tweet collection from Twitter's streaming API is an approximately 1% sample of all tweets. In addition to these 495 abusive applications, our model also classifies 390 new abusive applications that go undetected by Twitter. We manually inspect 10% of these applications sorted in the descending order of our model's detection probabilities. We find that 95% of all the inspected applications are clearly abusive. Among the abusive applications missed by Twitter, we find applications that are part of various spam campaigns such as astroturfing, and profile visit scam [26] (also discussed in Section 4.1).

Takeaway. The deployment of our machine learning approach in the wild shows that attackers continue to register new third-party application and post tens of millions of tweets despite Twitter's new countermeasures. We also show that our machine learning approach accurately and early detect these abusive applications that go undetected by Twitter. We believe that our proposed machine learning approach can complement Twitter's existing efforts for accurate and early detection of abusive third-party applications.

5.3 Limitations & Discussion

Next, we address some limitations of our machine learning approach, discuss its deployment to complement Twitter's existing abuse detection systems, as well as ideas for future extensions.

Evasion and Countermeasures. Like any machine learning based system, our approach is susceptible to evasion if attackers become aware of the details of our machine learning framework. Attackers can attempt to manipulate the features used by our machine learning model to evade detection. However, as demonstrated in Figure 7, our approach is resilient to obfuscation attempts against a particular feature or even different combinations of user-based and tweet-based features. Hence, attackers would need to manipulate multiple feature sets, some of which would likely be cost prohibitive for them. For example, our machine learning model captures the pattern that average account age for abusive applications is less as compared to benign applications. To obfuscate average account age, attackers would need to either discard newer fake/compromised accounts limiting the scale of their operations or purchase "aged" accounts that are reportedly much more expensive than newly created accounts [58]. Even if attackers are able to successfully manipulate multiple features and evade detection, we can periodically retrain our machine learning model using new ground truth to capture the evolving behavior of abusive applications. We can further design new features to better capture the changing behavior of abusive applications since our machine learning framework is readily amenable to the addition of new features as needed. Finally, after becoming aware of our early detection system, attackers can mimic the behavior of benign applications initially and delay abusive activities to evade early detection by our machine learning approach. To address this issue, our machine learning approach can be adapted to continuously monitor an application's tweets in a streaming fashion. Since our work focuses on the early detection of abusive applications, the implementation and evaluation of continuous application monitoring is outside the scope of this paper.

Low-volume Abusive Applications. Our machine learning approach will not be able to detect low-volume abusive applications that post only a few tweets because our machine learning model needs at least seven tweets for detection. First, we surmise that attacker could deliberately post very few tweets to evade detection by our machine learning approach. However, this would significantly reduce the scale of abusive activities, especially given Twitter's revamped application registration process that limits automation [9]. Second, it is also likely that Twitter's existing abuse detection systems [5, 8, 9] are able to detect many abusive applications before they post seven tweets needed by our machine learning approach. In other words, we only observe sophisticated abusive applications via Twitter's streaming API that bypass Twitter's abuse detection systems. Thus, we believe that our machine learning approach nicely complements Twitter's existing countermeasures by early detection of abusive applications that otherwise remain undetected by Twitter.

Handling False Positives While our machine learning approach detects abusive applications with a seemingly non-negligible false positive rate of approximately 6%, we argue that it is sufficiently low to be practical at Twitter's scale. Twitter can employ a review system that allows developers to submit an appeal to review incorrectly flagged applications. Note that Twitter already employs a review process to vet developers [9] which can be extended to review appeals for potentially mislabeled abusive applications. Recall that we observed 2,225 applications through Twitter's streaming API with sufficient activity over the duration of 39 days in September-October 2018. Thus, we argue that a false positive rate of 6% translates into a very manageable 5 false positives per day.

Third-Party Application Abuse on Other Online Social Networks. There have been several high-profile reports of third-party application abuse on popular online social networks including Twitter [10], Facebook [29, 36], and Google+ [46]. Our machine learning approach provides a footprint for other popular online social networks for accurate and early detection of third-party application abuse. Unfortunately, we are unable to investigate abuse of third-party applications on other online social networks due to lack of publicly available data. Nonetheless, online social networks operators can replicate our proposed machine learning framework shown in Figure 2. Most of our features (e.g., age of user accounts, number of followers, number of followings) can be directly translated to other online social networks such as Facebook, Instagram, and Snapchat. Moreover, online social network operators can further design new features based on their proprietary data to better capture behavior of abusive applications on their platform. Our

machine learning framework is readily amenable to addition of new features.

6 RELATED WORK

We divide prior work into three categories. First, we discuss prior work on the abuse of third-party applications on Twitter and Facebook. Second, we discuss prior work on detection of fake or compromised accounts on Twitter. Third, we discuss prior work on the measurement and detection of spam and malicious activities on Twitter.

Third-Party Application Abuse on Twitter. Prior work has reported on the exploitation of third-party Twitter applications for nefarious purposes [31, 34, 52, 55, 57]. Chu et al. [31] reported the abuse of third-party applications by bots on Twitter. Stringhini et al. [55] also reported the abuse of third-party applications by Twitter follower markets. Egele et al. [34] and Thomas et al. [57] each independently reported more than 9,000 abusive third-party applications being used to spread spam on Twitter. Prior research has also used third-party application information to aid detection of compromised accounts [34] and spam [52] on Twitter. Twitter tries to block applications used by attackers; who periodically register new applications to avoid the shutdown. While Twitter has recently removed more than 240,000 abusive applications [8], as we showed in this paper, the cat-and-mouse game between Twitter trying to detect abusive applications and attackers continuously creating new applications is still ongoing. To the best of our knowledge, we are the first to attempt to directly detect abusive third-party Twitter applications.

Third-Party Application Abuse on Facebook. Prior work has also reported on the exploitation of third-party Facebook applications for nefarious purposes [36, 50]. Most closely related to our work is that of Rahman et al. [50]. The authors proposed a machine learning approach to detect abusive third-party applications on Facebook. They found a collusion network of 5,307 abusive Facebook applications that promote each other. A key difference between our work and theirs is that we focus on *early* detection of abusive applications but their detection is post hoc. More recently, Farooqi et al. [36] reported that spammers exploit legitimate third-party Facebook applications to provide fake likes and comments. While they employed temporal clustering and IP rate limits to mitigate the abuse of legitimate third-party Facebook applications, we propose a supervised machine learning approach for early detection of abusive third-party Twitter applications.

Fake/Compromised Accounts. There is a large body of prior work on the detection of fake or compromised accounts in online social networks [21, 24, 25, 28, 34, 40, 42, 43, 49, 53, 54, 59, 61, 62]. First, researchers have leveraged account information such as demographics and number of followers/friends to detect fake or compromised accounts [21, 25, 43, 53, 54]. For example, Stringhini et al. [54] trained machine learning models using account features such as number of friends and messages to detect spamming accounts on Facebook and Twitter. Second, researchers have leveraged social connectivity information to detect fake or compromised accounts [28, 61, 62]. For example, Cai and Jermaine [28] used the latent community model to detect Sybil communities that are linked relatively loosely with the rest of the social graph. Third, researchers have leveraged activity patterns to detect fake or compromised accounts [24, 34, 40, 42, 59]. For example, Egele et al. [34] detected compromised accounts by identifying synchronized changes in account behavior within a short time period. It has been shown time and again that more sophisticated attackers can mimic account information, social connectivity, and activity patterns of real accounts to evade detection by such approaches. While our work is complementary to prior research on the detection of fake or compromised accounts, we believe that it may be more effective to directly target the mechanisms used by attackers to orchestrate fake or compromised accounts. Therefore, we focus on detecting abusive third-party Twitter applications that are used by attackers to control fake or compromised accounts.

Spam/Malware Activities. A large body of prior work has focused on the detection and characterization of spam activities on online social networks [37, 38, 49, 52, 55]. Grier et al. [38] characterized different types of spam activities such as phishing, malware, and scam on Twitter. Gao et al. [37] clustered user activity based on URL and textual similarity to detect and characterize spam campaigns on Facebook. Stringhini et al. [55] trained a machine learning model using activity based features such as the rate of change of followers/followings to detect Twitter follower market customers. Song et al. [52] trained a machine learning model using activity based features such as re-tweet time distribution to detect crowdturfing targets (e.g., tweets) on Twitter. Nilizadeh et al. [49] distinguished between benign and spam activities (e.g., tweets) based on their dissemination patterns in communities that share some topics of interest. While prior research has focused on the detection and characterization of malicious activities in online social networks, we aim to detect abusive applications as early as possible to minimize their malicious activities.

7 CONCLUSION

In this paper, we presented a machine learning based approach for accurate and early detection of abusive third-party applications on Twitter. First, we performed a longitudinal measurement study of abusive third-party Twitter applications over a period of 16 months. Our measurements demonstrated an ongoing arms race between attackers registering and abusing new applications and Twitter actively trying to detect and remove them. Second, since abusive applications go undetected for several months, we proposed a machine learning approach for accurate and early detection of abusive applications by analyzing their first few tweets. The evaluation showed that our machine learning approach can accurately detect abusive applications several months before Twitter's existing abuse detection systems, preventing these abusive applications from posting millions of spam and malicious tweets. Third, the deployment of our machine learning model in the wild showed that attackers continue to abuse third-party applications despite new countermeasures enforced by Twitter. Our machine learning approach can complement Twitter's existing abuse detection systems for accurate and early detection of abusive third-party applications.

ABSTRACT

Online services are playing critical roles in almost all aspects of users' life. Users usually have multiple online identities (IDs) in different online services. In order to fuse the separated user data in multiple services for better business intelligence, it is critical for service providers to link online IDs belonging to the same user. On the other hand, the popularity of mobile networks and GPS-equipped smart devices have provided a generic way to link IDs, *i.e.*, utilizing the *mobility traces* of IDs. However, linking IDs based on their mobility traces has been a challenging problem due to the highly heterogeneous, incomplete and noisy mobility data across services.

In this paper, we propose *DPLink*, an end-to-end deep learning based framework, to complete the user identity linkage task for heterogeneous mobility data collected from different services with different properties. *DPLink* is made up by a *feature extractor* including a location encoder and a trajectory encoder to extract representative features from trajectory and a *comparator* to compare and decide whether to link two trajectories as the same user. Particularly, we propose a pre-training strategy with a simple task to train the *DPLink* model to overcome the training difficulties introduced by the highly heterogeneous nature of different source mobility data. Besides, we introduce a multi-modal embedding network and a co-attention mechanism in *DPLink* to deal with the low-quality problem of mobility data. By conducting extensive experiments on two real-life ground-truth mobility datasets with eight baselines, we demonstrate that *DPLink* outperforms the state-of-the-art solutions by more than 15% in terms of hit-precision. Moreover, it is expandable to add external geographical context data and works stably with heterogeneous noisy mobility traces. Our code is publicly available[1].

1 INTRODUCTION

Smartphones and other mobile devices have made it easy for users to access various online services nearly everywhere and at any time. It is very common for a user to have multiple online identifiers (IDs) in different services such as online social networks (OSN), e-commerce services, online games, etc. Service providers have strong motivations to massively mine user data for monetization and optimizing user experience [16]. To capture a more comprehensive understanding of user behavior, it is increasingly intriguing to link user IDs across multiple services to fuse the separated data [37, 40].

To these ends, linking online IDs plays a critical role in the data fusion for better business intelligence. Early research has explored different ways to link user IDs by using service-specific data such as user profile attributes [9] and social graphs [15]. However, these approaches depend on whether these services have the same data type. For example, e-commerce services often do not have social graphs to match with an online social network. Moreover, users may fill in the fake information (*e.g.*, name, gender) in their profiles, which makes the linkage even harder.

In this paper, we explore a more generic approach to link user IDs by leveraging the spatial-temporal locality of user activities. The key intuition is that no matter what online services a user accesses, we can bind them to the user's *physical presence*, which is characterized by time and location. This becomes possible because most online services today have a mobile version with the location as parts of the service (*e.g.*, Uber, Yelp, Twitter). In addition, with some tolerance on granularity, even network accessing related information can be translated into location [14]. Our goal is to link multiple online IDs that belong to the same users across different services. Despite the inspiring prospects and results of user identity linkage, there are several key challenges that remain to be solved:

Heterogeneity nature of mobility data: Due to the different usage behavior of users and various collection mechanisms, the properties of mobility data (*e.g.*, sample rate, time periods) are drastically different across services. For example, the mobility traces

https://doi.org/10.1145/3308558.3313424

collected by an Internet Service Provider (ISP) are over 3 times denser than those collected by an online social network. Early works simply assume mobility traces of different services have similar sample rate [20] or time period [24], which are sensitive to the heterogeneous mobility data and do not perform well in practice. Due to this challenge, the general trajectory similarity [17, 21] algorithm designed for the trajectory from the same data source also fails to model the correlated relationship between the different data source and can not be effectively applied in the linkage problem.

Poor quality of mobility data: The data quality of collected mobility data is not always so good. *On the one hand*, the collected data only records the time and location information of mobility which is not enough to mine the hidden semantics of it. *On the other hand*, due to the limitation of devices and other artificial reasons [31, 36], the collected data usually contains noisy records to generate significant spatial and temporal mismatches between trajectories from different service. Because of the limitation of algorithms and the lack of proper data, existing approaches [24, 25] ignore the hidden semantics of mobility trajectory. Although, some works [32] propose prior knowledge-based solutions to address the mismatch problem. These solutions require proper manual parameter settings and are difficult to be applied in reality.

In this paper, we propose *DPLink*, an end-to-end deep learning based framework, to achieve linking IDs belonging to the same user for mobility data collected from different services with heterogeneous nature. *DPLink* is consist of two main components: *feature extractor module* and *comparator module*. The *feature extractor module* is designed to extract vector features from input raw trajectory and model relations between the trajectories from the different data source. The following *comparator module*, implemented as a multi-layer feed-forward network, is aimed to yield the final similarity score of the extracted representative trajectory feature vectors.

As the core component of *DPLink*, *feature extractor* contains two level encoders: *location encoder* and *trajectory encoder*. The *location encoder* is designed to integrate multi-dimensional input and extract the low-level feature of isolated locations. The multi-modal embedding based design in location encoder makes *DPLink* expandable to other available geographical features like PoI context. The following *trajectory encoder* is designed to capture the transitional relations of a single trajectory itself and model the correlation between two different trajectories. In the *trajectory encoder*, the transitional relations of single trajectory are captured by a *recurrent encoder*. Then a *selector* is introduced at the end of *trajectory encoder* to force the model to focus on the discriminative parts of trajectory and model the correlations between two different trajectories. With the help of this attention based selector, *DPLink* not only is able to observe the similar parts of two trajectories but also works robustly with noisy and missing trajectory.

Besides, we propose a pre-training mechanism to address the training challenges introduced by the heterogeneity nature of mobility data. Following our proposed training mechanism, our model is first trained to complete a warm-up task as linking trajectory from one mobility data but with different time periods. Due to the regularity of human mobility [10, 27] and the consistency and high quality of used mobility data, this single data based linkage task is much easier for *DPLink* to complete than the linkage task on cross-domain datasets with different quality. Intuitively, this single data based linkage task acts as a simple *auxiliary task* to help the model to first learn about the basic knowledge of the trajectory space. Then, the pretrained network with prior knowledge of the physical world and trajectory data is trained to complete the final *target task*: user identity linkage task on different data collected from different services.

Our contributions can be summarized as follows:

- We are the first to use deep learning techniques in the user identity linkage problem based on the heterogeneous mobility traces collected from different services with different quality. Our model does not assume any property of mobility data and works with heterogeneous mobility data across services.
- We utilize recurrent network with pooling unit as a trajectory encoder to extract transitional features from each single trajectory and introduce attention based selector to capture potential correlations between trajectories from two different data source. With fusing these two features together, our model obtains a comprehensive high-level understanding of trajectory.
- We propose a simple yet effective pre-training mechanism to adapt to the heterogeneity nature of different source mobility data. And the proposed training mechanism greatly improves the performance and robustness of our deep learning model on user identity linkage task on the different data source.
- We perform experiments on two real-life mobility datasets and compare the performance of our model with eight baselines. Extensive results demonstrate that *DPLink* outperforms the state-of-the-art solutions by more than 15%. Moreover, our model succeeds in utilizing additional geographical context data to further improve the performance and works robustly with noisy data.

The rest of this paper is organized as follows. We first formulate the problem in Section 2. Following the formulation, in Section 3, we describe the details of the whole framework of *DPLink*. In Section 4, we apply our model to two real-world mobility datasets and conduct extensive experiments. After systematically reviewing the related works in Section 5, we finally conclude our paper in Section 6.

2 PROBLEM FORMULATION

Let $\mathcal{A}$ represents the set of online account IDs, and S represents the set of different online platforms. Then, $\forall s \in S$, $\mathcal{A}^s$ denotes the set of online account IDs on platform s. Let a tuple $p = (l, t, e)$ represents a location record in location l with semantic label e at time t. Note that locations and times may be recorded at a different granularity and levels of precision in different source mobility data (*e.g.*, GPS coordinates or nearest base station in location record). Thus, without loss of generality, locations and times are divided into bins corresponding to geographical regions (*e.g.*, street block) and intervals of time (*e.g.*, one hour). In this paper, semantic label e is the distribution of point of interests (PoIs). But, we demonstrate that it is not limited to the PoI context, other information like textual context from user review can also be easily applied to our model without too much modification of network. We further define $\mathcal{T}$ as the set of all time bins, $\mathcal{L}$ as the set of all locations, and $\mathcal{E}$ as the set of PoIs.

Given any online ID $u \in \mathcal{A}$, we define its location records as, $\mathcal{R}(u) = \{p_1, p_2, ..., p_n\}$, where n denotes the number of location

Table 1: A list of commonly used notations.

Notat.	Description
$\mathcal{A}$	The set of all online IDs.
S	The set of types (platform) for online IDs.
$\mathcal{A}^s$	The set of online account IDs on platform s.
$\mathcal{T}$	The set of all time slots.
t	time stamp.
$\mathcal{L}$	The set of all regions.
l	location indicator.
$\mathcal{E}$	The set of PoIs.
e	semantic information.
$p = (l, t, e)$	A location record.
x	The embedded location record.
h	The hidden state of recurrent network.
u, v	online user ID.
$\mathcal{R}(u)$	location records sequence for online ID u.
$r(u)$	trajectory slice for online ID u.
$I(u, v)$	Binary variable indicating whether ID u and v belong to the same users.
N	The number of linking candidates for online ID u.

records. Taking the continuity of mobility data into consideration, we further partition the location records into meaningful trajectories $\mathcal{R}(u) = \{r_1(u), r_2(u), ...\}$ with maximum time window T_w (*e.g.*, 1 day). Given a pair of online IDs $u \in \mathcal{A}^1$ and $v \in \mathcal{A}^2$, let a binary variable $I(u, v)$ indicates whether these two IDs belong to the same user when the trajectories of them $r(u), r(v)$ are known,

$$I(u, v) = \begin{cases} 1, & u,v \text{ belong to the same user.} \\ 0, & u,v \text{ belong to different user.} \end{cases}$$

Further, given a target ID u, a list of candidates IDs $v_1, v_2, ..., v_N \subseteq \mathcal{A}^2$ and their trajectories $r(u)$ and $r(v_i)$ for $i = 1, 2, ..., N$, we aim to build a function, which is approximate to the identity function I enough, to find the best matching trajectory $r(v_i)$ and ID v_i.

Following the aforementioned definitions, many researchers [24, 25, 32] proposed insightful algorithms to work out this problem. However, because of the data quality problem and heterogeneity of mobility trajectory, these methods are still far from application in reality. Inspired by the powerful representation ability of deep learning models, we propose a deep learning based framework to address these challenges and aim to achieve better performance

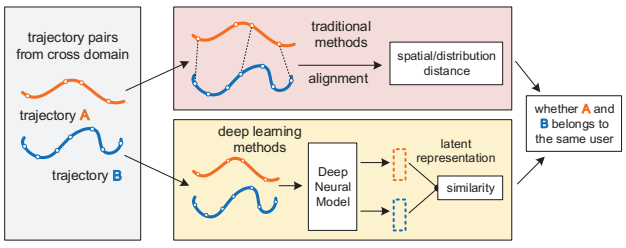

Figure 1: Different working mechanism of traditional methods and our proposed model.

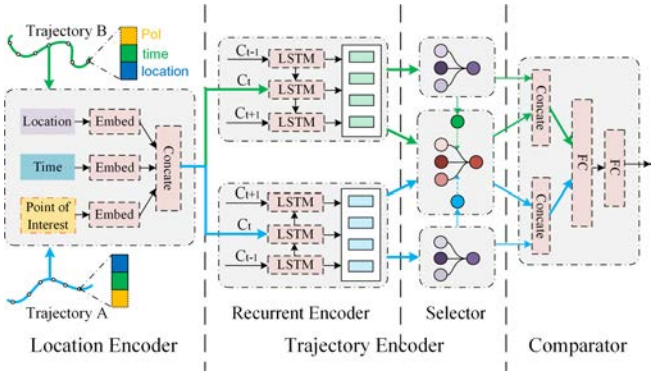

Figure 2: Main architecture of *DPLink* consisting of three major components: location encoder, trajectory encoder (including recurrent encoder and attention based selector), and comparator network.

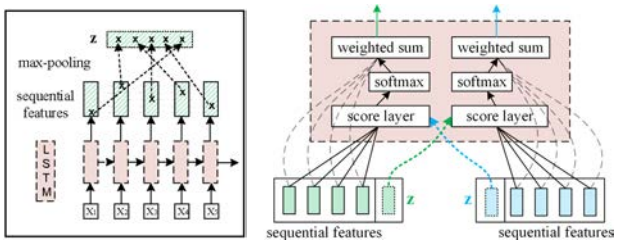

on real-life mobility dataset. The difference in workflows between existing works and our work is shown in Figure 1. In the traditional workflow of existing works, they usually first align the trajectory from the spatial or probabilistic view and then calculate the spatial or distribution distance to obtain a score. However, instead of aligning trajectory directly, we aim to utilize deep learning tool to first obtain the latent representation of mobility trajectory and then calculate the similarity between these two vectors as the similarity of trajectories. The details of our proposed model can be found in the next section.

3 MODEL AND METHOD

The structure of *DPLink* is presented in Figure 2. *DPLink* contains three major components: *location encoder*, *trajectory encoder*, and *comparator network*. The input trajectory pairs are first processed by *location encoder* and then fed into *trajectory encoder* to extract multi-level representative features. Particularly, *DPLink* uses a attention based *selector* at the end of *trajectory encoder* to focus on the similar parts of the trajectory pair and avoid the potentially harmful influence of missing and noisy data. Finally, the generated vector pair, which represents the original trajectory pair, are fed into the *comparator network* to calculate the similarity score of two input trajectories.

3.1 Location Encoder

Location encoder is a multi-modal embedding module, which is designed to reorganize and embed the spatial and temporal features of a trajectory point $p_i = (t_i, l_i)$ into a single vector x_i. Further, due to the flexibility of embedding network, we can also easily model external information e_i like geographical context information in the embedding network. In this way, our model is able to capture the hidden semantic behind the spatial-temporal point, which is difficult to utilize and model for existing methods. We design three sparse linear embedding layers to encode each type of input (*e.g.*, one-hot) into a dense vector representation. Then, we concatenate them together to obtain an ensemble vector x_i. To strengthen the modeling ability of the embedding module, we add *tanh* function

(a) Recurrent encoder. (b) Attention-based selector.

Figure 3: Details of trajectory encoder in *DPLink*.

as the final non-linear activation function. The formulation of the embedding module is as follows,

$$x_i = tanh(W_p p_i + b_p) = tanh([W_t t_i + b_t; W_l l_i + b_l; W_e e_i + b_e]),$$

where W and b denote the learnable parameters of embedding layers, $tanh$ denotes the non-linear activation function, $[;;]$ denotes the concatenate function.

As mentioned above, the location fed into our model is in the form of a one-hot vector. Compared with the original geographic coordinates, one-hot vector lose the information of spatial dependencies, which means that regions close to each other in the physical world can be far away in the one-hot space. However, the spatial dependency is important in measuring trajectory similarity. In order to enable *DPLink* to learn about the spatial adjacency of location, we introduce mobility prediction task to help our model learn the meaning of closeness of location. This task is to predict the next location of an object with knowing its trajectory history. Due to the regularity of mobility, the location points of the trajectory which neared in the time dimension is also neared in the spatial dimension. In other words, the location encoder is enforced by the mobility prediction task to embed the adjacent location in the physical world into the adjacent space in the latent high-dimensional space in a neural network.

It is noted that this multi-modal embedding module is shared by the network to simultaneously process two input trajectories. This sharing mechanism guarantees that two types trajectories from the same geographical space can be projected into another same latent space. Besides, the shared embedding module also greatly reduces the parameters of the whole network.

3.2 Trajectory Encoder

Following the *location encoder* is the *trajectory encoder*, which contains a *recurrent encoder* to extract the transitional level feature of single trajectory and a *selector* to extract correlated level features of trajectory pair.

3.2.1 Recurrent Encoder. Based on the embedded vector representation $\{x_1, x_2, ..., x_n\}$ of original trajectory $\{p_1, p_2, ..., p_n\}$, recurrent encoder is introduced to capture the sequential transitions and model the mobility pattern of a single trajectory. The output encoded trajectory feature is recorded as vector representations $\{h_1, h_2, ..., h_n\}$. As Figure 3(a) shows, the recurrent encoder is made up of a recurrent neural network with max/mean pooling operation. Recurrent neural network is a standard class of neural networks, which is designed with cycle and internal memory to model the sequential information. We use the widely used long short term memory (LSTM) [11] and its popular variation gated recurrent unit (GRU) [5] as the basic unit of our recurrent encoder.

To enhance the ability of sequential pattern modeling, we apply stacked techniques in the recurrent encoder. In practice, we stack several recurrent layers by feeding the output of the former recurrent layer into the next recurrent layer. To overcome the potential overfitting introduced by too many recurrent units, we apply dropout to the output of every recurrent layer.

Since the number of features extracted from the recurrent network is still identical to the length of trajectory, we introduce pooling operation (*e.g.*, max pooling and mean pooling) after recurrent network to obtain fix-length vector representation of trajectory. Actually, this operation is beyond only feature reshaping but also achieves a certain range of performance improvement in our experiment. This is because that pooling operation acts as a simple self-feature filter to select the important features. As Figure 3(a) shows, with the help of recurrent network with max pooling, we model the sequential relations $\{h_1, h_2, ..., h_n\}$ and finally obtain a single feature vector z for each trajectory. And we call this single feature vector z as the *primary representation vector* for trajectory.

3.2.2 Co-Attention based Selector. To handle the data quality problem and enable our model to focus on the critical parts of the trajectory pair for matching and linking, we propose to design a co-attention based selector network. We first briefly introduce the background knowledge of attention mechanism.

Given a query vector q and a series of candidate vectors $\{h_1, h_2, ..., h_n\}$, attention mechanism can be implemented with two steps: 1) to calculate the "correlation" between the query vector q and all these candidate vectors $\{h_1, h_2, ..., h_n\}$; 2) with these normalized "correlation" as weights $\{\alpha_1, \alpha_2, ..., \alpha_n\}$, to calculate the weighted sum y of candidate vectors as the comprehensive representation of them. This weighted sum y is regarded as the summary of the most related parts of candidates $\{h_1, h_2, ..., h_n\}$ for the query q. There are three widely used attention methods: *dot*, *general*, *mlp*. The main difference between these attention implementations is the calculation of "correlation". The formulation of typical attention methods are as follows,

$$y = \sum \alpha_i h_i, \quad \alpha_i = \sigma(f(q, h_i)),$$
$$f_{dot}(q, h_i) = h_i^T q,$$
$$f_{gen}(q, h_i) = h_i^T W q,$$
$$f_{mlp}(q, h_i) = v^T tanh(Wq + Uh_i),$$

where W, U, v are the learnable parameters, f represents the score function, σ is the soft-max function, h_i represents i_{th} candidate vector, q is the query vector and y is the final output.

Figure 3(b) presents the core idea of the co-attention based selector. In the common application of attention mechanism like neural machine translation, there is only one candidate sequence, where the query vector q of attention is naturally constructed from candidates $\{h_1, h_2, ..., h_n\}$, *e.g.*, $q = h_n$. Different from the former, we introduce co-attention mechanism to adapt general attention network for pair input to capture and model the correlation relationship. For the candidates $\{h_1^A, h_2^A, ..., h_n^A\}$ from trajectory A, we

use the *primary representation vector* z_B of trajectory B as the query vector $q_A = z_B$. Meanwhile, we use the *primary representation vector* z_A of trajectory A as the query vector $q_B = z_A$ for the candidates $\{h_1^B, h_2^B, ..., h_m^B\}$ from trajectory B. In this way, we directly connect two trajectories before the final comparator network and give them opportunities to find the related parts of each other. Further, this co-attention based selector will reduce the harmful effects from potential noisy records. After the processing of co-attention network, we obtain the final feature vector of trajectory: y_A for original trajectory A $\{p_1^A, p_2^A, ..., p_n^A\}$ and y_B for original trajectory B $\{p_1^B, p_2^B, ..., p_m^B\}$.

3.3 Comparator Network

The final component of our model is a comparator network, which is implemented as a multilayer feed-forward network. The final layer of the comparator network is a neural unit with *sigmoid* function acting as a logistic regression function to generate the final similarity score. The feature vectors (y_A, z_A) and (y_B, z_B) are independently fused together to obtain the final vector presentation of each trajectory. Then these two vector representations are fed into multi-layer feed-forward network to yield the similarity *score*. From the view of the problem, the comparator network gives two input trajectories a second chance to exchange information and validate each other. From the view of the network, the comparator network can be regarded as a simple but effective classifier for binary classification to judge whether two input vectors belong to the same class. Due to the *sigmoid* function, the output score is a normalized probability which can be optimized by binary cross entropy loss function.

3.4 Training strategy

Our model works in an end-to-end manner without requiring handcrafting features. Since we translate the user identity task into a binary classification problem, we choose binary cross entropy loss as the objective loss function.

$$Loss = -\sum_{i=1}^{n} y_i \log x_i + (1 - y_i) \log(1 - x_i),$$

In the training, the Adaptive Moment Estimation (Adam) algorithm is utilized to optimize the model. Several widely used tricks, such as dropout, L2 regularization, and learning rate schedule, are used to avoid the overfitting problem. The detailed settings for these parameters can refer to the next section.

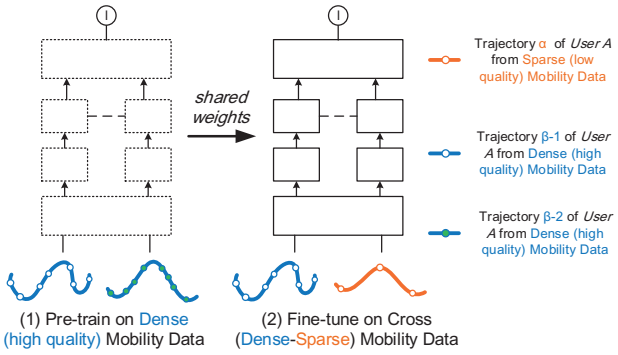

Figure 4: Two step training strategy for user identity linkage task.

However, due to the heterogeneous nature of mobility trajectories from the different service and platform, our model always fails to converge and stops with really poor performance when directly trained from scratch. The intuition that mobility trajectories from different platforms share identical underlying spatial-temporal pattern is the precondition for completing the user identity linkage task. Nevertheless, due to the heterogeneous nature of mobility trajectories from different data source, our model struggles to explore the huge spaces and learn the true knowledge of it. On the one hand, different platforms provide users with various services and users generate different mobility behaviors with various intentions. On the other hand, the sample rate and recording mechanism of collecting data in different platforms are also different. All of these lead to the heterogeneous nature of mobility trajectories, which make it difficult for our model to learn valuable knowledge. Consequently, our original model fails to link trajectories across different mobility data.

Here, we propose to pretrain the whole model with a simple task as warm-up to first obtain the basic knowledge of the physical world and trajectory pattern. Once our model achieves good performance on this simple task, we start to train it with the final user identity linkage task on different mobility data source. This warm-up task is to identify whether two mobility trajectories from the same platform in different periods (*e.g.*, different days) belong to the same user. This warm-up task is proposed based on the observation from the regularity of human mobility [10, 27], people usually go to the same places (*e.g.*, to and from where he needs to go like home and office) and generate similar even the same trajectories in different work days. Furthermore, the trajectory used in the warm-up task are both from the identical high-quality mobility dataset, which is denser and without too many missing records. Due to the regularity of mobility and the high-quality mobility dataset, the warm-up task becomes an easier and directional task to help the model to converge and learn the useful prior knowledge for the future difficult task.

The two-step training strategy is presented in Figure 4. Our training strategy can be regarded as a kind of network-based transfer learning method. The prior knowledge learned from the first linkage task on a single dataset is transferred to the final linkage task (*target task*) on different datasets by sharing partial network weights.

4 PERFORMANCE EVALUATION

In this section, we conduct extensive experiments on two real-world datasets to answer the following research questions:

- **RQ1:** How does *DPLink* perform in the user identity linkage problem on real-life datasets compared with existing algorithms?
- **RQ2:** How does the proposed training mechanism help to improve the performance of *DPLink* on the user identity linkage task?

Table 2: Statistics of the datasets.

Dataset	Users	Records	Locations	Rec./U.	Loc./U.	Duration
Twitter	1228	53337	8975	43	25	21 months
Foursquare	2970	44915	8975	15	12	48 months
ISP	2844	325215	12576	114	19	1 week
Weibo	1761	49651	12576	28	5	1 week

- **RQ3:** Can *DPLink* be applied in data with poor quality (*e.g.*, noisy records)? Is it possible to utilize more external geographical context data (*e.g.*, PoI information) to improve the performance?

In what follows, we first describe the experimental settings, and then answer the above three research questions one by one.

4.1 Experimental Settings

4.1.1 Datasets. We carry out experiments with two real-world cross-domain mobility datasets. The first dataset is the mobile network record dataset provided by one of the largest major Internet Service Provider (ISP) in China and the social network location service records obtained from Weibo[2]. The second dataset, provided by Zhang et al. [41], is the location check-in records from Foursquare[3] and Twitter[4] with the same users. Different generation and collection mechanism of these datasets ensure the representativeness of our experiments. Table 2 summarizes the basic statistical information of datasets. Below, we describe these datasets in detail.

ISP-Weibo. The ISP dataset contains 325215 mobility records that cover the metropolitan area of Shanghai from April 19 to April 26 in 2016. The location records are generated in the base station level when users access cellular network via mobile devices for communication and the Internet. Each trajectory is characterized by anonymized user ID. It contains a series of spatial-temporal points produced by the user, where each point includes a base station ID and a timestamp. We replace the base station ID with a certain longitude-latitude coordinate according to the base station information provided by ISP. The Weibo dataset is generated from ISP dataset. Our collaborators from ISP collected the Weibo sessions from the ISP datasets in the same time window with the permission of Weibo. In Weibo dataset, each mobile trace is characterized by a Weibo ID and contains a series of GPS coordinates that show up in HTTP sessions between the mobile application and the Weibo server. These GPS coordinates are produced when users access the location service in their mobile applications like check-in. Before we access the dataset, the collaborators have mapped the Weibo ID into the same anonymized user ID in the ISP dataset to protect the personal privacy.

Foursquare-Twitter. This dataset contains the trajectories data from Foursqaure, a popular location-based social network (LBSN), and Twitter, a micro-blogs social network around the world. As its primary function, Foursquare provides users various location-related services like location check-ins and posting online reviews. Twitter also provides users with basic location-based services like location check-ins. Provided by Zhang et al. [41], the data is crawled from the web pages of thousands of users who use both platforms with at least one location records during November 2012 in the east coast of U.S.. Based on the crawled raw data, the trajectory is also characterized as a user's account ID and a series of GPS coordinates with timestamp.

[4]https://www.twitter.com

Table 3: PoIs category distribution on ISP-Weibo dataset.

Related Function	PoI Categories
Residence	residence, life services.
Entertainment	food, hotel, gym, shopping, leisure.
Business	finance, office building, company, trading area.
Industry	factory, industrial estate, economic development zone.
Education	school, campus.
Scenery spot	scenery spot, tourism development.
Suburb	villages, towns.

Table 4: Typical parameter settings.

Item	Value	Features	input	output
batch size	32	location	10000	200
learning rate	1e-3	time	24	10
drop out	0.3	PoI	20	10
fine-tune lr	0.0005	hidden state	200	200

We crawled 0.75 million point of interests (PoI) of Shanghai from BaiduMap[5] as the additional geographical context of ISP-Weibo dataset. As Table 3 shows, the crawled PoI dataset contains 20 categories and can be classified into 7 region functions. For every base station in ISP dataset, we calculate the distribution of PoIs for it in the surrounding 1 kilometer area. This PoIs distribution serves as a soft function label for the region and describes the potential intention of the user's movement.

It's noted that all the user IDs in our datasets are anonymized to protect user's privacy. Meanwhile, we store the data in a secure local server and only core researchers can access the data with strict non-disclosure agreements.

4.1.2 Baselines. We compare the performance of our model with eight state-of-the-art baselines. Six of them are classic user identity linkage algorithms, another two are deep learning based trajectory representation models.

NFLX: With knowing some external information, Narayanan et al. [23] propose a statistical model based mobility trace similarity score to identify the users in Netflix dataset. NFLX cannot be directly applied into cross-domain linkage problem and we follow the method [24] to adapt it to our problem.

MSQ: Ma et al. [20] incorporate general knowledge in forms of global movement constraints and preferences to identify users from dataset. Specifically, they consider negative square difference between two mobility traces as their similarity score.

[5]https://map.baidu.com/

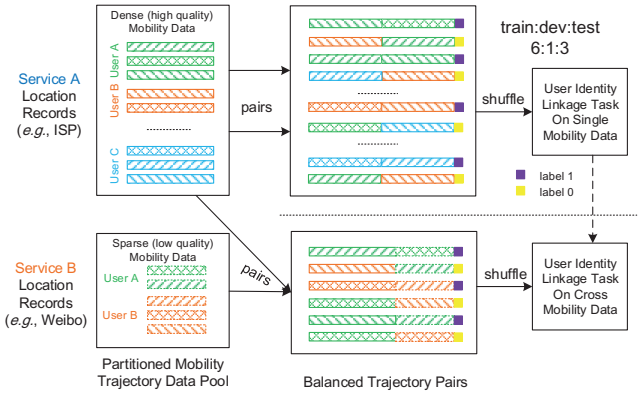

Figure 5: Build training/validation/testing dataset.

HIST: Naini et al. [22] focus on linking users by matching the location histograms of their mobility traces. Firstly, they compute a user's visiting frequency of each location and then define a similarity score of two histograms based on Kullback-Leibler divergence.

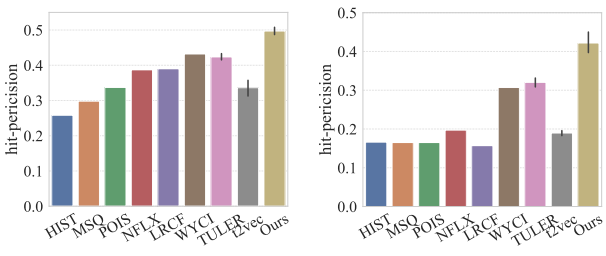
LRCF: Goga et al. [8] take the popularity of different locations into consideration. LRCF applies the term frequency-inverse document frequency(TF-IDF) [28] weighting scheme to location visiting histograms and measures mobility trace similarity using a cosine distance.

WYCI: Rossi et al. [25] propose a time based probabilistic user identifying algorithm. They use the frequency of user login in different locations to approximate the probability of visiting these locations. Then they determine if a mobility trace belongs to a user by computing the user's probability to produce the mobility trace.

POIS: POIS [24] algorithm uses the "encountering" events to measure the similarity of two different-domain mobility traces. It assigns every "encountering" event a weight based on statistical model and uses the weighted sum as the similarity measure.

As we are the first deep learning based model for user identity linkage task on different mobility datasets, we compare our model with two deep learning based models for trajectory representation.

TULER: Gao et al. [7] utilize the recurrent network to encode the trajectory into a single vector to identify users in single mobility data. TULER cannot be directly applied to our problem, thus we train two independent TULER models for each mobility data and check whether these two models can identify each input trajectory as the same user.



t2vec: Li et al. [17] propose to adapt seq2seq model with a spatial proximity aware loss function to infer and represent the underlying route information of a trajectory for efficient trajectory similarity computation. Following the philosophy of original paper, we adapt it to our problem by using sparse (low sampling) trajectory from one dataset as input and using dense (high sampling) trajectory with same user ID from another dataset as the underlying route to learn the representation of trajectory. Then, we use this representation to link different IDs.

4.1.3 Preprocessing. Figure 5 presents the details of how to build training/validation/testing dataset in our experiment. As Figure 5 shows, the first step is to divide the lengthy location records into continuous mobility trajectories. After this operation, we obtain two independent mobility trajectory pools, where each trajectory is labeled with its user ID, for two different mobility data. As mentioned in the training section, we first pretrain the model with user identity linkage task on single data as a warm-up and then fine-tune the model with user identity linkage task on cross-domain mobility data. Furthermore, we choose the high-quality mobility data with more frequent and longer records, which is called *dense* mobility trajectory data to complete the warm-up linkage task. Another mobility data source with fewer mobility records called *sparse* mobility data is only used in target user linkage task on cross-domain datasets. The mechanism of building data in two training stages are the same, while the main difference is to choose which data to use.

We first introduce the core step of building experiment data for user identity linkage task on single domain data as follows. We randomly choose two trajectories from the dense mobility data pool with identical owner labels to build positive trajectory pair. The basic intuition behind this operation is the regularity of human mobility [10, 27], which means that the mobility trajectory of one user keeps similar in the different periods with extremely high probability. To meet the sample balance requirement of binary classification problem in training stage, for every positive trajectory pair we randomly select two trajectories from dense mobility data pool with different user IDs to form a negative trajectory pair. In the training stage and validation stage, only this one negative sample is enough.

However, in reality, we usually have lots of online ID candidates for matching, and we need to compare them together to find the best matching. To simulate this practical case, in the testing stage, we choose N negative candidates for matching. Particularly, for each online ID, we choose those left online IDs whose trajectory have at least one intersection with it as candidates. Based on the statistics of our data, the average number of these candidates for each online ID is around 20. To meet the requirement of batch size for efficient computation, we select 32 as the default setting for N in the experiment. To build experimental data for user identity linkage task from different data sources (*target task*), we follow the similar steps mentioned before. Different from choosing two input trajectories from the same mobility dataset for warm-up linkage task, we choose one trajectory from dense mobility data and another trajectory from sparse mobility data for final user identity linkage task. In our experiment, the proportion of training, validation and testing data is 6:1:3. It's noted that we divide not only the trajectory but also the users by shuffling the trajectory data with user label. This operation makes sure the generalization of our experiment, where some users may only have few data in the training step and even they only appear in the testing step.

4.1.4 Metrics and Parameter Settings. Our model is implemented on Pytorch platform and the typical parameter settings of our model are presented in Table 4. In the experiments, we select GRU as the default recurrent unit and *dot* attention as the default attention mechanism for efficient computation. The results for LSTM and other basic components are similar. Following the aforementioned evaluation dataset, our model is trained and validated in a binary classification manner, and finally evaluated in the search and ranking manner.

(a) @ISP-Weibo dataset. (b) @Foursquare-Twitter dataset.

Figure 6: The performance of our model and baselines on two real-life datasets.

In the training step, we use the F1 score and AUC to measure the performance of our model, which are both widely used metrics in classification problems. The F1 score is defined as,

$$F1 = \frac{2 * Precision * Recall}{Precision + Recall}.$$

AUC, known as the area under the receiver operating characteristic (ROC) curve, is equal to the probability that a classifier will rank a randomly chosen positive instance higher than a randomly chosen negative one. With P positive instances and Q negative instances, AUC can be calculated by the following formulation,

$$AUC = \frac{\sum_{i \in +} rank_i - P(1+P)/2}{P \times Q}.$$

In the validation step, we also use the F1 score and AUC as the metrics to cooperate with the early stopping mechanism to find the best parameters and avoid overfitting.

In the testing step, we use hit-precision as the metric to evaluate the performance of algorithms in the user identity linkage task with more than one (*e.g.*, $N = 32$, as mentioned in the preprocessing section) candidate online IDs. After *DPLink* deciding the score for each candidate, we rank these candidates by score and calculate the hit-precision. Hit-precision of top-k candidates is defined as follows,

$$h(x) = \begin{cases} \frac{k-x}{k}, & \text{if } k > x >= 0 \\ 0, & \text{if } x >= k \end{cases}$$

We choose $k = 5$ as the default setting for hit-precision.

4.2 Overall performance on user identity linkage task. (RQ1)

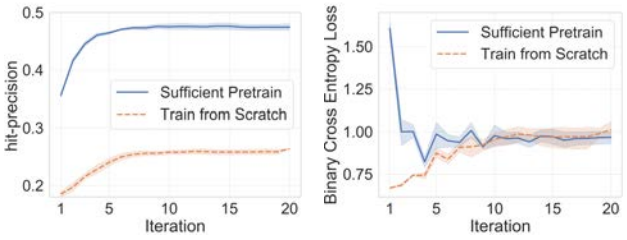
We evaluate our model with eight baselines on ISP-Weibo and Foursquare-Twitter datasets to present the performance on user identity linkage task. The results are presented in Figure 6.

We first analyze the results of ISP-Weibo dataset. Among six classic linkage baselines, WYCI algorithm with the tolerance of different sample rate performs best with 0.432 hit-precision. Besides, the performance of NFLX and LRCF with the tolerance of mismatch from the spatial or temporal view are also similar well. Particularly, the hit-precision of our model is 0.497, which is 15% higher than the best baseline WYCI.

Besides, we compare our model *DPLink* with other two state-of-the-art trajectory representation algorithms: TULER and t2vec. The results demonstrate that our model outperforms both of them more than 17%. TULER is designed for directly identifying the user from single mobility dataset. It fails to obtain better performance due to two potential reasons: 1) TULER cannot identify any new users because the user set is decided in the training step. However, in our experiments, the users in the testing step is not identical to the training step; 2) each TULER only focus on its single mobility dataset and ignores the potential correlation between two different mobility dataset. Based on seq2seq model, t2vec is proposed to infer and represent the underlying route information of a trajectory for efficient trajectory similarity computation. In practice, t2vec needs extremely high-quality dataset (*e.g.*, taxi trajectory dataset with less than 1 minute sampling period) to learn good enough representative function. It fails to handle with the poor quality (low sampling and missing records) and the heterogeneity nature of our cross-domain mobility dataset. *DPLink* is designed for the user identity linkage task and succeeds in dealing with these challenges with special network design and training strategy. On the one hand, the location encoder and trajectory encoder help *DPLink* extract representative features from a single trajectory. On the other hand, the attention based selector enables *DPLink* to capture the correlation between two trajectories with different properties from different mobility data. Finally, the MLP based comparator network acts as a powerful classifier to obtain the final result.

The similar results can also be found in the Foursquare-Twitter dataset. Because of the smaller volume and sparse nature of Foursquare-Twitter dataset, the performance of all the methods is lower. However, due to the powerful representation ability of neural network and transfer learning based training strategy, our model still achieves about 0.4 hit-precision. Compared with the-state-of-the-art methods, the performance gain of our model can be up to 25%. In a word, the evaluation results of two real-life datasets demonstrate the superiority of our model than other the-state-of-the-art methods.

4.3 The effects of the training strategy. (RQ2)



In this section, we conduct experiments to demonstrate the effect of pre-training strategy for *DPLink*. We take the results on ISP-Weibo dataset for example.

Table 5 shows the performance of our model with different training strategies on ISP-Weibo dataset. Obviously, the pretrain step is crucial for better performance. Furthermore, we choose to remove different components of *DPLink* from the sharing weights step to locate the most important component for the performance. As Table 5 shows, removing location embedding and selector weights from the sharing step leads to the worst performance, which denotes the crucial role of location encoder and attention-based selector in modeling. Besides, the effect of removing the recurrent encoder is smaller and the removing the comparator network weights even does not harm the performance at all. These little effects tell us that the transitional relations and classification knowledge are not hard to learn from beginning in this task.

We dive into the training process to understand the importance of pretrain step. As Figure 7(a) shows, after pretraining, the initial performance of our model before fine-tuning on target task can

Table 5: Performance of different training mechanisms on ISP-Weibo dataset. For example, "Full−Location Encoder" denotes that the embedding weights of location encoder is not shared in the pretrain step, which means the location encoder is trained from scratch in user identity linkage task.

Training Strategy	hit-precision (mean+std)	Δ
Train from Scratch	0.257 ± 0.025	-48.3%
Full Pretrain	0.497 ± 0.013	0
Full−Location Encoder	0.404 ± 0.018	-18.7%
Full−Recurrent Encoder	0.438 ± 0.005	-11.9%
Full−Selector	0.395 ± 0.014	-20.5%
Full−Comparator	0.499 ± 0.009	+0.4%

(a) The testing performance curves. (b) The testing loss curves.

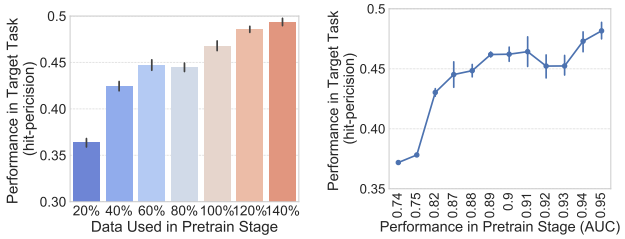


Figure 7: The comparison results between two types training mechanisms on ISP-Weibo dataset.

be higher than 0.35, which is better than the best performance of model trained from scratch. With fine-tuning on target task, the hit-precision of our model can be further improved to 0.49. Figure 7(b) presents the variation trend of testing loss of models with different training mechanism. Due to the heterogeneity of mobility data, the model trained from scratch becomes over-fitted at the very start. Meanwhile, the pretrained model really learns the knowledge about the task and performs better and better.

Figure 8 presents the effects of data volume and model performance of pretrain step on the performance of our model on target task. As Figure 8(a) shows, with more and more data utilized on single domain linkage task in the pretrain step, the final performance of our model on target task also becomes better and better. This observation tells us that enough unlabeled data on a single domain can help to improve the performance of model on target task and reduce the requirement of labeled cross-domain data. Figure 8(b) shows us that better pretrained model on single domain linkage task produces better fine-tune model on target task.

4.4 The expansion capability and stability of *DPLink* model. (RQ3)

In this section, we evaluate whether *DPLink* can utilize external information with the help of multi-modal embedding based location encoder to improve the performance on user identity linkage task and whether it works robustly with noisy records.

(a) The effect of data volume used in pretrain stage. (b) The effect of the performance in pretrain stage.

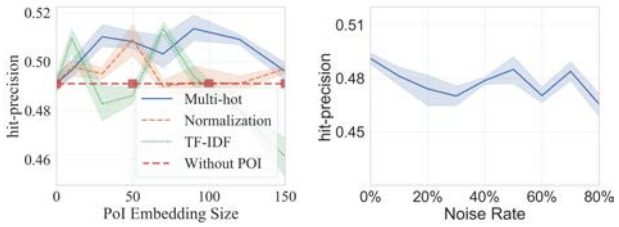

Figure 8: The effects of different pertrain parameters on ISP-Weibo dataset.

To evaluate the expansion capability of multi-modal embedding network, we build three kinds of PoI distribution features: 1) multi-hot distribution, which only describes whether specific type PoI exists in the region; 2) normalized probability distribution of different PoIs in the region; 3) tf-idf distribution, the enhanced version of normalized probability distribution. The evaluation results are presented in Figure 9(a). The results show that *DPLink* is able to apply external PoI information to further improve the performance from 0.49 to more than 0.51. Particularly, the multi-hot feature of PoI distribution performs much better and stable. However, *DPLink* is not limited to only use this kind of PoI distribution feature. Other external information like textual information can also be directly applied to our model after simple pre-processing like word2vec operation.

Figure 9(b) presents the performance variations of *DPLink* with noisy trajectory input. In Figure 9(b), noise rate in 20% means that 20% trajectories in the data are randomly selected to randomly replace one real data point in it with a noisy point. As Figure 9(b) shows, the performance of our model keeps stable with the increase of noise rate, which demonstrates the robustness of *DPLink* . Furthermore, we visualize the attention weights of three kinds of points in the trajectory to verify whether our co-attention based selector really plays an import role in filtering out the harmful effects of noisy records. Three types points are 1) intersection location between two trajectories; 2) noisy point inserted by the program; 3) other location points. In Figure 10, we analyze the average attention weights of three types points in 4 scenarios which include the dense/sparse (high/low quality) mobility data with positive/negative labels. As Figure 10 shows, the average attention weight for intersection point is the highest and the weight for the noisy point is the lowest, which distinctly demonstrates the selecting value of our co-attention based selector.

5 RELATED WORK

Applications of Identity Linkage: A number of applications can benefit from linking IDs across services. For example, Kumar et al. [16] investigated the user migration patterns across social media to provide guidance for online social network design. Zafarani et al. [40] and Yan et al. [37] leveraged linked IDs across social networks for better friend recommendations. Yang et al. [38] leveraged linked IDs across sites for better video recommendations.

(a) The effects of geographical context with different PoI embedding size.

(b) The effects of noisy records with different noise level.

Figure 9: The effects of data quality (geographical context and noisy records) on our model.

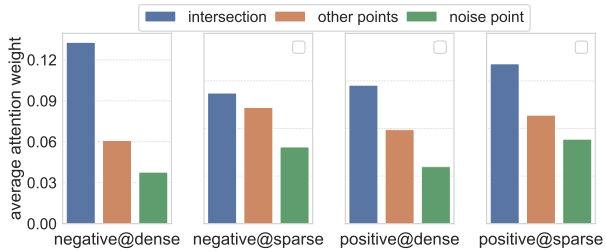

Figure 10: Average attention wights of three types points on testing dataset. For example, "negative@dense" means that the attention weights are from the dense(high quality) mobility trajectory with negative label.

All these works indicate the strong motivations for the service provider to link IDs belonging to the same user. Besides, some researchers [30, 35] tried to protect users from identification attack by matching mobility trajectory.

Identity Linkage using Trajectory Data: A few recent works examine the possibility of linking IDs based on location data [2–4, 13, 20, 22–26, 29, 33, 34]. Mudhakar et al. [29] and Ji et al. [12, 13] focused on linking IDs based on users' graph/network structures. They adapted their algorithms to location trajectories by constructing a "contact graph" to model users encountering with each other. However, these algorithms still require using social network graphs, which are not available in our scenario. In addition, some algorithms are designed to tolerate data noise such as temporal mismatching [23] and spatial mismatching [20]. Wang et al. [32] proposed algorithms with tolerating spatial or temporal mismatches (or both) and modeling user behavior for better linkage performance. Other algorithms implemented de-anonymization attacks based on *individual user's* mobility patterns [22, 25, 26]. Finally, researchers also developed identity linkage algorithms based on "encountering" events [2–4, 24]. By considering the location context (*e.g.*, user population density), it achieved a better performance [4, 24]. However, none of them is able to capture the trajectory dynamics and integrate semantic information simultaneously.

Representation Learning for Trajectories: Recently, deep learning has been used for spatial-temporal data mining [6, 18, 39, 42] such as next location prediction [6, 19] and trajectory embedding [7, 17, 39]. Yao et al. [39] used a recurrent network with manually features to cluster trajectory into several clusters. Gao et al. [7] proposed to identify users in one mobility dataset via a recurrent network encoder. However, the uniqueness of an individual in one dataset does not imply that this user can be easily recognized in another dataset. Besides, this method can not be applied to new users whose data has not been trained with the model. Based on one dense taxi trajectory dataset, Li et al. [17] used a seq2seq model to measure the similarity of sub-trajectories extracted from one dense trajectory, which requires high data quality and fails to model the relationship of trajectories from different datasets.

Due to the limitation of model design, all these existing methods are not suitable for user identity linkage problem for different mobility data. Compared with these methods, our model is not only designed to extract comprehensive trajectory features but also model the correlated relationship between trajectories. This interaction ability is based on the attention mechanism introduced by Bahdanau et al. [1] in neural machine translation task. Feng et al. [6] is the first work to introduce the attention model to predict human mobility. However, instead of achieving mobility prediction, our focus is to measure the trajectory similarity from the different data source to link online IDs.

6 CONCLUSION

In this paper, we investigated the task of user identity linkage by leveraging the power of deep learning. We proposed an end-to-end deep learning framework to link different accounts from heterogeneous mobility data. Proposed model employs location encoder and trajectory encoder to model the complicated single trajectory feature and apply co-attention based selector to focus on discriminative parts when matching two mobility trajectory. Extensive experiments on two real-life mobility datasets show that *DPLink* significantly outperforms eight baselines on the user identity linkage task. Compared with the existing solutions, the proposed model achieves general similarity measurement for heterogeneous mobility data. Besides, it is robust to the noise of trajectory and is easy to extend to external information like PoI distribution.

There are several future directions for our work. First, because of the limitation of the datasets, we only consider simple external geographical context data like PoIs category. In the future, we plan to expand the multi-modal embedding module to process the raw textual information in the check-in data. Second, although the pre-training mechanism works well, it is still not easy to directly train a good model for sparse mobility data. Thus, design more stable network structure and better training mechanism is also an important direction.

ABSTRACT

Network embedding aims at learning an effective vector transformation for entities in a network. We observe that there are two diverse branches of network embedding: for homogeneous graphs and for multi-relational graphs. This paper then proposes MARINE, a unified embedding framework for both homogeneous and multi-relational networks to preserve both the proximity and relation information. We also extend the framework to incorporate existing features of nodes in a graph, which can further be exploited for the ensemble of embedding. Our solution possesses complexity linear to the number of edges, which is suitable for large-scale network applications. Experiments conducted on several real-world network datasets, along with applications in link prediction and multi-label classification, exhibit the superiority of our proposed MARINE.

1 INTRODUCTION

The task of network embedding aims at learning a representation for each entity in a network. The idea is to *embed* some properties of a network into a vector space so that each entity is represented by a low-dimensional feature vector. Such form of representation is more ready for machines to perform further analysis, since most of the machine learning and data mining models accept unstructured feature vectors for training and prediction.

We observe that there are two branches of studies for network embedding. One is to propose an embedding method for *homogeneous graphs* (Figure 1 left) [1, 7, 8, 10, 12, 17, 29–31, 33, 36–38, 40–42, 45, 50–52], in which there is only one single type of nodes and links. The major goal of this branch of work is to preserve certain properties in the linking structure of a network. *Proximity* is the most emphasized property in the embedding of homogeneous graphs. Roughly speaking, proximity estimates the closeness between nodes, and thus a proper network embedding model shall assign similar embeddings to nodes close to each other in a graph. Preserving proximity will allow the model to accurately perform some relevant tasks such as community detection (e.g. closer nodes shall be grouped together) and link discovery (e.g. nodes with common neighbors should be linked). The other branch tries to obtain the embeddings of nodes in a *multi-relational graph*,

i.e., *knowledge graph* (Figure 1 right) [3–5, 9, 11, 13–15, 18–20, 25–28, 34, 35, 39, 44, 47–49]. A multi-relational network assumes there are different types of links (e.g. different relationships between users) in the graph, where key information depicting entities are encoded. Each directed edge can be represented by a triplet (i, k, j), where node i connects to node j via relation k. For example, a node X may connect to a node Y with relation *teacher_of*, but it can link to another node Z with relation *colleague_of*. The majority of the models for multi-relational graph embedding use an individual embedding transformation for each type of edge relation. Then based on certain algebraic operation (usually through addition or multiplication) to combine embeddings of nodes and relations, the multiple relationships in the embedding space can be recovered.

Even though a homogeneous network can be regarded as a special case of multi-relational network with single type of relation, our preliminary experiments have found that existing multi-relational graph embedding methods do not necessary perform well on homogeneous networks. It is probably because most of the existing studies do not emphasize on preserving the proximity information in the network.

Thus, in this paper we propose a multi-relational graph embedding model that preserves not only the relation information but also the proximity information, with the goal to create a unified model that is suitable for embedding both homogeneous and multi-relational networks. Although these two branches of studies respectively propose embedding methods in its own domain, to our knowledge, there has not yet been an effective unified model that works for both homogeneous and heterogeneous scenarios, which is the goal of this paper. Moreover, we also realize that directly applying the existing homogeneous proximity models shall not work for our situation since they do not consider the existence of a variety of relations. Here we propose a novel idea to regularize the importance of each embedding dimension based on the relation in generating the score function for each relation triplet. That is, we argue that some embedding dimensions are more important in predicting a type of relation while others are more important for other relations. For instance, to determine whether an edge belongs to 'classmate' relationship, a latent dimension that represents 'school attended' is probably more important than a latent dimension that represents 'favorite movies'. However, the later shall be more critical to determine the 'friendship' relationship between nodes than the former. To achieve such goal, we propose a tensor-factorization solution to regularize the importance of each embedding dimension based on the type of relations, trained based on the observed relations in the network data.

Besides a general framework to embed either type of the networks, we further intend to incorporate node attribute information into the embedding space. In practice one can usually observe attributes (e.g. demographics or metadata) of nodes in a network. Since such attributes provide semantic depiction about nodes, they shall be considered together in the embeddings of nodes. For instance, in a social network a user node can sometimes be associated with some demographic information such as age or gender. There is no reason to not incorporate such information in the node embedding. For example, we hope the embeddings of two female nodes are closer than the embeddings of two opposite-sex nodes, given the other conditions are similar. Mathematically, such non-graphical information attached to a node can be formulated as a real-valued attribute vector for each node (note that a categorical attribute can always be expanded into multiple binary ones). We notice that some network embedding studies [12, 17, 30, 40, 45, 50, 51] have considered node attributes in learning embeddings, but most of the existing approaches require at least a few labels to guide the learning. Furthermore, a very limited number of multi-relational network embedding methods [18, 19, 48] consider node attributes, as we have not yet seen any benchmark evaluation dataset that contains attributes for nodes in multi-relational networks.

In this paper, we propose the **M**ulti-relation, **A**ttribute, p**R**oximity **I**nformed **N**etwork **E**mbedding (MARINE)[1], a probabilistic network embedding model whose goal is to preserve *the proximity property, the edge relation and the node attributes information* in a low-dimensional embedding space. To achieve the goal, MARINE maximizes the likelihood of not only the existing graph structure but also the observed node attributes. To elaborate, we assign a function to score each (source_embedding, relation_embedding, target_embedding) tuple and try to maximize the difference of scores between the observed tuples and the unobserved ones. The scoring function leverages the modeling of tensor factorization and embedding translation. We show that the tensor factorization component can preserve the proximity information for each type of relation, which aligns well with the goal of most homogeneous network embedding methods. Inspired by the results of word embedding [23], we also consider the embedding translation, realizing the relation information with the relative positions among embeddings. In addition, we require the learned node embeddings to maximize the generation likelihood of node attributes, which assumes the embeddings of two nodes shall be closer if they have similar attributes. Finally, we discover an effective usage of our framework as an ensemble framework for multiple embeddings, and conduct preliminary experiments to verify its usage in this direction.

We evaluate the model based on three different applications with eight real-world datasets. The applications include link prediction, and multi-label classification. We demonstrate that the designed objective based on maximizing the above ideas allows the proposed MARINE to outperform state-of-the-art competitors in both homogeneous networks and multi-relational networks in terms of effectiveness and robustness. With the support of additional attributes, MARINE can further boost its performance. We also provide the visualization on various embedding results as another form of evaluation. Last but not least, we show MARINE of complexity linear in the number of nodes or edges, which enables the efficient implementation in large-scale network data.

We summarize the contributions of this paper, as listed below:

- We propose a unified unsupervised embedding method, MARINE, to enhance the existing solutions for multi-relational network embedding models by preserving the proximity and attributes information in addition to various types of relations.
- Our proximity model is specifically designed for multi-relational data, which allows the dynamic adjustment of importance weights for embedding dimensions given different relations.

[1]The code is available via https://github.com/ntumslab/MARINE

- MARINE enjoys the running time linear to the number of nodes and edges. Our framework also enables the embedding ensembles. We conduct thorough experiments to justify the above claims.
- We empirically conduct several experiments on real-world networks, to examine how MARINE performs in the applications of link prediction and multi-label classification. The results show the superiority capability of MARINE in learning better network representations.

The rest of the paper is organized as follows. Section 2 briefly summarizes related work. Section 3 introduces MARINE in detail. Section 4 reports the experimental results. Finally we discuss and conclude our work in Section 5.

2 RELATED WORK

We first discuss existing studies in homogeneous network embedding. Most of the past models focus on preserving the proximity property as it captures the neighborhood topology information of nodes. Some important network mining tasks, such as link prediction and community detection, can be addressed by discovering proximity relations among nodes. Specifically, between any node pair (i, j), the h-order proximity estimates either the number of h-hop shortest paths from i to j or the probability of a h-hop random walk from i to j. Relevant studies based on proximity assume higher similarity between the embedding vectors of two nodes with high proximity. Singular value decomposition or matrix factorization is commonly used to learn such embeddings [1, 8, 12, 29, 36, 38, 40, 42, 50, 51] These models rely on a matrix $\boldsymbol{A} \in \mathbb{R}^{N \times N}$ pre-computed based on certain proximity estimation. Then let $\boldsymbol{A}$ be approximated by a low-rank matrix multiplication. Some models [7, 17, 41] consider deep neural network structures like auto-encoders to exploit their non-linear mappings between graph topology and embedding vectors. Inspired by recent word embedding algorithms [23], another class of homogeneous graph embedding methods [10, 30, 31, 52] gathers random walk sequences as training set. The similarity of two nodes is expected to be high if their positions are close in most of the random walk sequences. There are some common concerns about the existing approaches. First, several models [8, 12, 40, 42, 50, 51] require to factorize a dense matrix, and thus cannot be scale to large graphs as the complexity reaches $O(N^2)$. Second, some approaches [1, 10, 12, 30, 31, 38, 40–42, 45] assumes symmetric relations, that is, $\boldsymbol{x}_i^\top \boldsymbol{x}_j = \boldsymbol{x}_j^\top \boldsymbol{x}_i$ for edge (i, j), and therefore cannot be used to handle directed graphs. Third, as having been pointed out in LINE [37], it is hard for random walk-based methods to explain explicitly what graph properties are preserved in the embedding space. Our model is developed to address the above issues.

On the other hand, multi-relational network embedding approaches often focus on learning a vector $\boldsymbol{r}_k$ that represents the embedding of edge relation k. Based on different assumptions, previous studies propose various scoring functions given a relation embedding $\boldsymbol{r}_k$ and the embeddings $\boldsymbol{x}_i, \boldsymbol{x}_j$ of two adjacent nodes. It is further assumed that an observed edge (i, k, j) with nodes (i, j) and relation k shall obtain a higher score value than an unobserved edge, and a multi-relational graph can be regarded as a set of multi-relational edges. There are two major classes of the

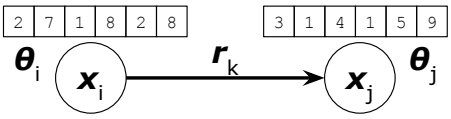

Figure 2: The notations in MARINE. There is an edge with relation k linking from node i to node j, whose attributes are θ_i and θ_j, respectively.

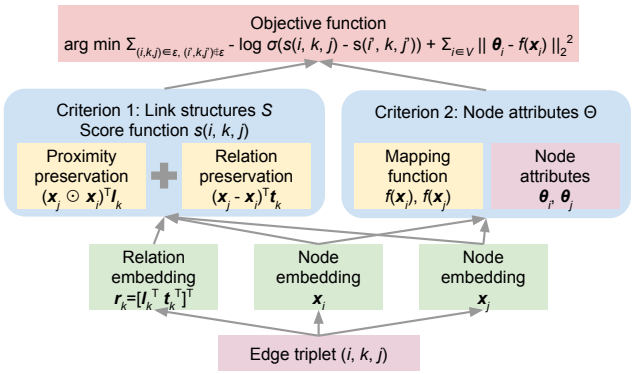

Figure 3: The overview of our proposed MARINE.

scoring functions. One is to build a bilinearity-like form $\boldsymbol{x}_i^\top \boldsymbol{R}_k \boldsymbol{x}_j$ or its non-linear extensions [3, 13, 27, 28, 34, 35, 39, 49] to learn the correlations between nodes (i, j) with respect to a relation k. By viewing an embedding vector as a point in multi-dimensional space, another set of scoring functions aim to constrain the positions of every embedding points [4, 5, 9, 11, 14, 15, 19, 20, 26, 44, 47, 48]. Given the transition scale $\boldsymbol{r}_k$ of a specific edge relation k, let it be fitted by the translation scale from point $\boldsymbol{x}_i$ to $\boldsymbol{x}_j$. In other words, they try to minimize distance $\|f(\boldsymbol{x}_i) + \boldsymbol{r}_k - g(\boldsymbol{x}_j)\|$, where certain mapping functions f and g are added to map the node embedding space to the edge embedding space. We refer readers to a survey paper [25] that introduces recent multi-relational network embedding methods in details. To the best of our knowledge, the existing multi-relational network embedding works has not yet considered the proximity information.

3 METHODOLOGY

3.1 Problem Definition

Since homogeneous graph is a special case of multi-relational graph and undirected graph is a special case of directed graph (i.e. undirected graph can be regarded as a bi-directional directed graph), here our task is formulated over the general directed multi-relational graph. We also assume the nodes are associated with some attributes. Out task can be formulated as:

Definition 3.1. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{R})$ denote a directed multi-relational graph, where $\mathcal{V}$ is a set of nodes, $\mathcal{R}$ is a set of edge relations, and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{R} \times \mathcal{V}$ is a set of edges. Each node $i \in \mathcal{V}$ is appended with attributes represented as a vector $\boldsymbol{\theta}_i \in \mathbb{R}^a$.

Then our goal can be defined as:

Definition 3.2. Given graph $\mathcal{G}$, we would like to learn an embedding vector $\boldsymbol{x}_i \in \mathbb{R}^d$ ($d \ll |\mathcal{V}|$) for each node $i \in \mathcal{V}$ in an *unsupervised* manner.

Furthermore, for each type of edge in a multi-relational graph, we will learn an embedding vector $\boldsymbol{r}_k$ for its relation k. Figure 2 describes the notations. We expect the embedding would capture not only the proximity information but also the the information from link relation as well as the node attributes. In the next sections, we begin to introduce how MARINE learns embeddings with desired properties.

3.2 Design Criteria

Since the learning of embedding is generally unsupervised, here we formulate the task as an optimization problem. As stated previously, we would like to preserve both the link structure and node attributes information. The link structure information can be further decomposed into two components: proximity and relation. We will then formulate the criteria in a probabilistic form:

Criterion 1. **Link Structures** $\mathcal{S}$ preservation: Given a relation $k \in \mathcal{R}$, let an observed edge $(i,k,j) \in \mathcal{E}$ and a non-existing edge $(i',k,j') \notin \mathcal{E}$. Our model would like to assign scores $s(i,k,j) > s(i',k,j')$. Such score reflects the query: *how likely there is a relation of type k from node i point to j*.

Criterion 2. **Node Attributes** Θ preservation: We assume for any two nodes (i,j), the distance between their embeddings $(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is positively correlated with the distance between their attributes $(\boldsymbol{\theta}_i, \boldsymbol{\theta}_j)$.

Given the two design criteria, our task becomes a maximum a posteriori (MAP) problem to find the optimal embedding $\boldsymbol{x}$ and $\boldsymbol{r}$, given $\mathcal{S}$ and Θ. Using Bayes' Rule:

$$\begin{aligned}\arg\max_{\boldsymbol{x},\boldsymbol{r}} & p(\boldsymbol{x},\boldsymbol{r} \mid \mathcal{S},\Theta) \\ &= \arg\max_{\boldsymbol{x},\boldsymbol{r}} \frac{p(\mathcal{S},\Theta \mid \boldsymbol{x},\boldsymbol{r})p(\boldsymbol{x},\boldsymbol{r})}{p(\mathcal{S},\Theta)} \\ &= \arg\max_{\boldsymbol{x},\boldsymbol{r}} \underbrace{p(\mathcal{S},\Theta \mid \boldsymbol{x},\boldsymbol{r})}_{\text{Likelihood}} \underbrace{p(\boldsymbol{x},\boldsymbol{r})}_{\text{Prior}}. \end{aligned} \tag{1}$$

The denominator $p(\mathcal{S},\Theta)$ can be eliminated due to no involvement in the maximization in $\boldsymbol{x},\boldsymbol{r}$. To simplify the analysis, here we assume no prior knowledge about the target embeddings, and hence the prior distribution $p(\boldsymbol{x},\boldsymbol{r})$ is assumed to be *uniform* and can be ignored in the optimization process. Nevertheless, generalization to non-uniform prior is possible with careful design on the form of distribution. To make the joint probability p tractable, we adopt an independence assumption $\mathcal{S} \perp \Theta$ between $\mathcal{S}$ and Θ. We also assume that the edge relation embedding $\boldsymbol{r}$ is independent of to the node attributes given the node embedding, i.e., $\boldsymbol{r} \perp \Theta \mid \boldsymbol{x}$. Therefore we can simplify (1) as:

$$\begin{aligned} p(\mathcal{S},\Theta|\boldsymbol{x},\boldsymbol{r}) &= p_{\mathcal{S}}(\mathcal{S}|\boldsymbol{x},\boldsymbol{r})p_{\Theta}(\Theta|\boldsymbol{x},\boldsymbol{r}) \\ &= \underbrace{p_{\mathcal{S}}(\mathcal{S}|\boldsymbol{x},\boldsymbol{r})}_{\text{Criterion 1}} \underbrace{p_{\Theta}(\Theta|\boldsymbol{x})}_{\text{Criterion 2}}. \end{aligned} \tag{2}$$

We will elaborate $p_{\mathcal{S}}$ and p_{Θ} in Section 3.3 and 3.5.

The overview of our proposed MARINE is presented in Figure 3. Given an edge triplet, MARINE learns their representations based on the observations on link structures $\mathcal{S}$ and node attributes Θ. We will elaborate the details of each component in the following subsections.

3.3 Preserving Link Structures $\mathcal{S}$

$p_{\mathcal{S}}$ in Criterion 1 depends on the link structure. To fulfill this criterion, we formulate the following likelihood function with respect to edges:

$$\begin{aligned} p_{\mathcal{S}}(\mathcal{S} \mid \boldsymbol{x},\boldsymbol{r}) &= \prod_{\substack{(i,k,j)\in\mathcal{E} \\ (i',k,j')\notin\mathcal{E}}} \Pr\left(s(i,k,j) > s(i',k,j') \mid \boldsymbol{x},\boldsymbol{r}\right) \\ &= \prod_{\substack{(i,k,j)\in\mathcal{E} \\ (i',k,j')\notin\mathcal{E}}} \sigma\left(s(i,k,j) - s(i',k,j')\right). \end{aligned} \tag{3}$$

Inspired by [32], (3) can be also approximated by differentiable sigmoid functions $\sigma(z) = \frac{1}{1+\exp(-z)}$. As we maximize the likelihood (3), the gap between $s(i,k,j)$ and $s(i',k,j')$ is enlarged consequently, which satisfies the requirement of Criteria 1. The scoring function s is defined based on the corresponding embeddings $\boldsymbol{x}_i, \boldsymbol{x}_j, \boldsymbol{x}_{i'}, \boldsymbol{x}_{j'}, \boldsymbol{r}_k$ (see (4)) to preserve the proximity and relation information, as will be elaborated next.

3.4 Score Function Design

Criterion 1 demands the designed score function s to generate higher scores for an observed edge $(i,k,j) \in \mathcal{E}$, and lower ones for the non-existing counterpart $(i',k,j') \notin \mathcal{E}$. To incorporate both proximity and relation information, we design the score function as follows:

$$s(i,k,j) = \underbrace{(\boldsymbol{x}_j \odot \boldsymbol{x}_i)^\top \boldsymbol{l}_k}_{\text{Proximity preservation}} + \underbrace{(\boldsymbol{x}_j - \boldsymbol{x}_i)^\top \boldsymbol{t}_k}_{\text{Relation preservation}}, \tag{4}$$

where $\odot$ denotes the Hadamard product. We express edge relation embedding $\boldsymbol{r}_k = \begin{bmatrix}\boldsymbol{l}_k^\top & \boldsymbol{t}_k^\top\end{bmatrix}^\top \in \mathbb{R}^{2d}$ as the concatenation of two embedding vectors $\boldsymbol{l}_k \in \mathbb{R}^d, \boldsymbol{t}_k \in \mathbb{R}^d$, to achieve two different preservation targets in (4). The first term of (4) is essentially a tensor factorization to preserve proximity information. The second term implies that translation direction between embeddings shall be closer for the same edge relation. We do not set a relevant weight between two terms of (4), since the weight is absorbed in $\boldsymbol{l}_k$ or $\boldsymbol{t}_k$. In the following paragraphs, we will discuss the insight of (4).

3.4.1 Proximity Preservation. Most previous studies on homogeneous network embedding adopt matrix factorization (see Section 2) to learn embedding. Under such framework, given the embeddings $\boldsymbol{x}_i, \boldsymbol{x}_j$ of node pair (i,j), the existing studies mostly exploit inner product $a_{ij} = \boldsymbol{x}_i^\top \boldsymbol{x}_j = \sum_{u=1}^d x_{iu}x_{ju}$ to fit the proximity-related value a_{ij}. Random walk-based solutions also exploit the inner product operation to learn the similarities among embeddings. Using $\boldsymbol{x}_i^\top \boldsymbol{x}_j$ presumes a strong assumption that each dimension in the embedding space is equally important. Here we argue that for different types of relations, the importance or weight of each dimension to evaluate the proximity quality shall be different. We take a multi-relation social network where nodes are people as the example. Suppose that a single embedding dimension implies "salary" of

a node. Let us compare two different relations: "colleagues" and "friends". This particular dimension shall play a more important role to determine the former relationship than it is to the later one. It is because two colleagues are more likely to earn salary in the similar range than two friends. To model the influence of each dimension of embedding given different relations, we expand two-way matrix factorization into the *three-way tensor factorization*. The axes in this tensor indicate subject node i, edge relation k and object node j. Each binary element is set to 1 for edge $(i,k,j) \in \mathcal{E}$, and 0 for $(i,k,j) \notin \mathcal{E}$ Similar to the assumption in matrix factorization, a low rank d is assumed for this tensor. The score of the embeddings of tuples $\boldsymbol{x}_i, \boldsymbol{x}_j, \boldsymbol{l}_k$ is evaluated by a tensor product:

$$\sum_{u=1}^{d} x_{iu} x_{ju} l_{ku} = (\boldsymbol{x}_i \odot \boldsymbol{x}_j)^\top \boldsymbol{l}_k. \tag{5}$$

Note that in our design, the importance of each embedding dimension is regularized by the learned relation embedding $\boldsymbol{l}_k$, meaning that different embedding dimensions can play different roles in determining whether a relation shall exist between two nodes. The next question we would like to answer is that *why such design can satisfy the proximity constraint*. Next we would like to establish the connections of our model to the first and second order proximity defined in homogeneous networks.

Below we first provide formal definitions to such proximity.

Definition 3.3. Given a pair of nodes (i,j), *the first-order proximity* for their embeddings $\boldsymbol{x}_i, \boldsymbol{x}_j$ means a high score between $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ in the embedding space, if there is an edge adjacent to i and j in the network.

Definition 3.4. Given a pair of nodes (i,j), *the second-order proximity* for their embeddings $\boldsymbol{x}_i, \boldsymbol{x}_j$ means a high score between $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ in the embedding space, if nodes (i,j) share the same neighbor set in the network.

Previous studies often adopt the inner product $\boldsymbol{x}_i^\top \boldsymbol{x}_j$ or the squared Euclidean distance $\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2^2$ as the score function to achieve proximity preservation. Our design criteria guarantees to *explicitly* preserve the first-order proximity in a homogeneous network. By Criterion 1, given fixed relation k, we have $s(i,k,j) > s(i',k,j')$ for observed edge $(i,k,j) \in \mathcal{E}$ and unobserved edge $(i',k,j') \notin \mathcal{E}$. Modeling Criterion 1 in MARINE likelihood (3) satisfies the first-order proximity. Here we would like to prove that applying (5) to a homogeneous network (or a multi-relation network with single type of relation) can *implicitly* keep the second-order proximity.

Lemma 3.5. *Considering (5), MARINE* ***implicitly*** *preserves the* ***second-order proximity*** *in a homogeneous network.*

Proof. Given a fixed relation k, let two nodes (i,j) have the same set of direct successors. That is, for any node v ($v \neq i, v \neq j$), we have either $(i,k,v) \in \mathcal{E}$, $(j,k,v) \in \mathcal{E}$ or $(i,k,v) \notin \mathcal{E}$, $(j,k,v) \notin \mathcal{E}$. With the progress of training, the objective function eventually will cause observed edges and non-existing edges to become separable in scores. Then there must exist a threshold ϵ such that

$$s(i,k,v) \geq \epsilon \text{ as } (i,k,v) \in \mathcal{E},$$
$$s(i',k,v') < \epsilon \text{ as } (i',k,v') \notin \mathcal{E}$$

, and eventually we can obtain $\epsilon = 0$. If we consider only the tensor factorization part $s(i,k,v) = (\boldsymbol{x}_i \odot \boldsymbol{x}_v)^\top \boldsymbol{l}_k = (\boldsymbol{l}_k \odot \boldsymbol{x}_v)^\top \boldsymbol{x}_i$, then for the above-mentioned node v, we have:

$$s(i,k,v) \cdot s(j,k,v) = (\boldsymbol{l}_k \odot \boldsymbol{x}_v)^\top \boldsymbol{x}_i \boldsymbol{x}_j^\top (\boldsymbol{l}_k \odot \boldsymbol{x}_v) \geq \epsilon^2 = 0,$$

where $\boldsymbol{l}_k \odot \boldsymbol{x}_v \in \mathbb{R}^d$. It implies that matrix $\boldsymbol{x}_i \boldsymbol{x}_j^\top$ is a positive semi-definite matrix that has the non-negative trace property:

$$\boldsymbol{x}_i^\top \boldsymbol{x}_j = \text{tr}(\boldsymbol{x}_i \boldsymbol{x}_j^\top) \geq 0.$$

In practice, with sufficient number of training epochs, our scores (4) can move farther from the zero threshold such that $s(i,k,v) \cdot s(j,k,v) \gg 0$. It could lead to a high inner product $\boldsymbol{x}_i^\top \boldsymbol{x}_j$. In other words, $(\boldsymbol{x}_i, \boldsymbol{x}_j)$ could be close to each other in the embedding space, if nodes (i,j) share direct successors. Similar proof can applied to direct predecessors $(v,k,i), (v,k,j)$. □

3.4.2 Relation Preservation. This part was inspired by a word embedding approach [23] illustrating the distribution of word embeddings in a two-dimensional space. It implicitly reveals the two clusters of words, even though no label is provided to guide the learning. Between two clusters, there exists an implicit relation controlling the translation direction from one point to its adjacent point in the other cluster. In contrast to implicit relation learning in [23], we choose to put an explicit embedding translation term in our score metric (4), thanks to the availability of the relation information in multi-relational networks. Specifically, we expect that given an edge (i,k,j), the vector direction from $\boldsymbol{x}_i$ to $\boldsymbol{x}_j$ shall be close to the relation embedding vector $\boldsymbol{t}_k$. The idea can be modeled by the inner product:

$$(\boldsymbol{x}_j - \boldsymbol{x}_i)^\top \boldsymbol{t}_k. \tag{6}$$

In real-world multi-relational networks, similar type of nodes might connect to similar types of others via similar relation (e.g. sales to customers). They are more likely to be clustered together, as shown in our visualization experiment.

As an additional bonus, the embedding translation term brings an asymmetric similarity metric, that is, $s(i,k,j) \neq s(j,k,i)$ by our definition (4). Notice that the tensor factorization term is symmetric since $(\boldsymbol{x}_i \odot \boldsymbol{x}_j)^\top \boldsymbol{l}_k = (\boldsymbol{x}_j \odot \boldsymbol{x}_i)^\top \boldsymbol{l}_k$. In a directed network, the direction of an edge determines an asymmetric relation between two nodes. Directed graphs are quite popular in real world. For instance, the 'following' information in an online social network is directional, meaning the opposite does not always hold. We observe that a few prior approaches [31, 38, 41] cannot leverage the edge direction information due to symmetric scoring functions. Using the asymmetric nature of the embedding translation term (6), we are allowed to model embeddings for directed graphs.

3.5 Node Attributes Θ

Based on Criteria 2, we need to design p_Θ such that node attributes $\boldsymbol{\theta} \in \mathbb{R}^a$ can affect the learning of embeddings $\boldsymbol{x} \in \mathbb{R}^d$. To satisfy the criterion, we define a bijective mapping function $\boldsymbol{\theta} = f(\boldsymbol{x})$ to bridge $\boldsymbol{\theta}$ and $\boldsymbol{x}$. Thus embedding $\boldsymbol{x}_i = f^{-1}(\boldsymbol{\theta}_i)$ could approach $\boldsymbol{x}_j = f^{-1}(\boldsymbol{\theta}_j)$ if the corresponding attribute vectors $\boldsymbol{\theta}_i \approx \boldsymbol{\theta}_j$. Here

we impose a multi-variate normal distribution for $\boldsymbol{\theta}$:

$$p_\Theta(\Theta \mid \boldsymbol{x}) = \prod_{i \in \mathcal{V}} \mathcal{N}(\boldsymbol{\theta}_i \mid f(\boldsymbol{x}_i), \frac{1}{2\alpha} I) = \prod_{i \in \mathcal{V}} \left(\frac{\pi}{\alpha}\right)^{-\frac{a}{2}} \exp\left(-\alpha \|\boldsymbol{\theta}_i - f(\boldsymbol{x}_i)\|_2^2\right). \quad (7)$$

where $\mathcal{N}(\boldsymbol{\theta} \mid \boldsymbol{\mu}, \Sigma)$ denotes a multi-variate normal distribution with mean vector $\boldsymbol{\mu}$ and covariance matrix Σ. Since the maximum probability density appears in the mean for normal distributions, (7) can model the approximate mapping $\boldsymbol{\theta} \approx f(\boldsymbol{x})$ with uncertainty as variance $\frac{1}{2\alpha}$. Any differentiable bijective functions f are allowed, though in our experiments a naive linear mapping $f(\boldsymbol{x}) = \boldsymbol{W}\boldsymbol{x} + \boldsymbol{b}$ works well, which alleviates the need to tune potential hyperparameters of complex functions f. In the following sections, we use notation $\boldsymbol{\phi} \in \{\boldsymbol{W}, \boldsymbol{b}\}$ as the parameters in function f.

3.6 Objective Function and Optimization

Combining (3) and (7), when minimizing the negative logarithm of (2), we finally aim at solving:

$$\arg\min_{\boldsymbol{x}, \boldsymbol{r}, \boldsymbol{\phi}} L = \sum_{\substack{(i,k,j) \in \mathcal{E} \\ (i',k,j') \notin \mathcal{E}}} -\log \sigma\left(s(i,k,j) - s(i',k,j')\right) + \alpha \sum_{i \in \mathcal{V}} \|\boldsymbol{\theta}_i - f(\boldsymbol{x}_i)\|_2^2. \quad (8)$$

We remove the constant terms in parameters $\boldsymbol{x}, \boldsymbol{r}, \boldsymbol{\phi}$. For large-scale graphs the complexity is a concern, as there may exist quadratic number of edge pairs $((i,k,j),(i',k,j'))$ in (8). Fortunately we can adopt the commonly used *negative sampling* technique to sample a small subset of negative edge pairs for training. Referring to the idea in [32], we sample $Q \in \mathbb{N}$ negative edges $(i',k,j') \notin \mathcal{E}$ for each positive edge $(i,k,j) \in \mathcal{E}$, given relation k fixed. Viewing an edge pair $((i,k,j),(i',k,j'))$ as a training instance, we can apply Stochastic Gradient Descent (SGD) to efficiently update $\boldsymbol{x}, \boldsymbol{r}, \boldsymbol{\phi}$ in differentiable (8). For our objective function $\tilde{L}$, with respect to one training instance $((i,k,j),(i',k,j'))$, SGD optimizes a parameter z using the repetition of following update rule:

$$z \leftarrow z - \eta \frac{\partial \tilde{L}}{\partial z}, \quad (9)$$

where η denotes the learning rate that can be automatically adjusted by certain optimizers like Adam [16]. Here we present the derivatives of objective function $\tilde{L}$ over $\boldsymbol{x}_i, \boldsymbol{x}_j, \boldsymbol{l}_k, \boldsymbol{t}_k, \boldsymbol{\phi}$ for SGD optimization.

$$\frac{\partial \tilde{L}}{\partial \boldsymbol{x}_i} = -\sigma\left(s(i',k,j') - s(i,k,j)\right)\left((\boldsymbol{x}_j \odot \boldsymbol{l}_k) - \boldsymbol{t}_k\right) - 2\alpha\left(\boldsymbol{\theta}_i - f(\boldsymbol{x}_i)\right)\frac{\partial f}{\partial \boldsymbol{x}_i} \quad (10)$$

$$\frac{\partial \tilde{L}}{\partial \boldsymbol{x}_j} = -\sigma\left(s(i',k,j') - s(i,k,j)\right)\left((\boldsymbol{x}_i \odot \boldsymbol{l}_k) + \boldsymbol{t}_k\right) - 2\alpha\left(\boldsymbol{\theta}_j - f(\boldsymbol{x}_j)\right)\frac{\partial f}{\partial \boldsymbol{x}_j} \quad (11)$$

$$\frac{\partial \tilde{L}}{\partial \boldsymbol{l}_k} = -\sigma\left(s(i',k,j') - s(i,k,j)\right)\left(\boldsymbol{x}_j \odot \boldsymbol{x}_i\right) \quad (12)$$

$$\frac{\partial \tilde{L}}{\partial \boldsymbol{t}_k} = -\sigma\left(s(i',k,j') - s(i,k,j)\right)\left(\boldsymbol{x}_j - \boldsymbol{x}_i\right) \quad (13)$$

$$\frac{\partial \tilde{L}}{\partial \boldsymbol{\phi}} = -2\alpha\left(\boldsymbol{\theta}_j - f(\boldsymbol{x}_j)\right)\frac{\partial f}{\partial \boldsymbol{\phi}} \quad (14)$$

3.7 Model Analyses

3.7.1 Complexity. The execution time of MARINE is determined by its SGD optimization as discussed previously. Given Q negative sample edges for each positive edge, we have $Q|\mathcal{E}|$ positive-negative edge pairs to optimize our parameters. Therefore the overall time complexity is $O(Q|\mathcal{E}|\omega)$ where ω is the number of epochs. Our experiments show $\omega = 500$ is sufficient for convergence. Since $Q \ll |\mathcal{E}|$ ($Q = 5$ in our experiments) and $\omega \ll |\mathcal{E}|$ in practice, MARINE enjoys time complexity that is linear to the number of positive edges $|\mathcal{E}|$, satisfying the scalability requirement. The training data contain $|\mathcal{E}|$ edges and $a|\mathcal{V}|$ attributes where each node has a attributes. As $a \ll |\mathcal{V}|$, MARINE possesses space complexity $O(|\mathcal{E}| + a|\mathcal{V}|)$ is efficient for practical applications.

3.7.2 Hyparameters. Observing the objective function in (8), there is only one hyperparameter α to be tuned by human, while all the other parameters can be learned during optimization. Note that a more complex mapping function f could lead to more hyperparameters. However our experiment results suggest that a linear mapping function without any hyperparameter can yield satisfiable results.

3.7.3 Embedding Ensemble. Even the external node attributes are not available, (7) can still be effective if we extract node attributes from the input graphs (e.g. degree information). Furthermore, the formula can be used as an embedding ensemble framework. That is, to treat the embedding outcomes of one model as the existing attributes Θ of the nodes. As will be described in the next section, positive experiment results support such idea.

4 EXPERIMENTS

4.1 Experimental Setup

Following a similar setup as most of network embedding studies, we conduct *Link Prediction* and *Multi-label Classification* tasks for evaluations. Three widely compared classic models (DeepWalk, LINE, TransE) and two of the start-of-the-art models (SDNE, ProjE) in network embedding are chosen to compare with MARINE. Note that DeepWalk, LINE and SDNE are models for homogeneous networks, while the other two are models for multi-relational networks. All the embedding dimensions are fixed to **128**; for the methods requiring negative sampling, we set the number of negative samples to **five** times of the positive samples (i.e, $Q = 5$) as mentioned in [10, 37]. Other hyperparameters are set to the default values suggested by the original papers.

- Competitors from homogeneous network embedding:
  - **DeepWalk** [31]: walk length $t = 80$; number of walks per source $\gamma = 10$; window size $w = 10$.

- **LINE** [37]: total number of samples $T = 10$ billion; 64-dimensional first-order proximity embeddings concatenated with 64-dimensional second-order proximity embeddings.
- **SDNE** [41]: first-order proximity weight $\alpha = 0.2$; reconstruction penalty $\beta = 10$; dimensionality of hidden layers $D = [1000]$.

- Competitors from multi-relational network embedding:
  - **TransE** [4]: margin in score function $\gamma = 1$; dissimilarity measurement $d = L_2$.
  - **ProjE** [34]: the original algorithm, denoted as 'ProjE-ori' in our tables, uses 25% of the total entities as negative samples suggested by the authors. However, to be fair in the comparison, we further compare with the performance of five negative samples per training instance (denoted as 'ProjE-Q5'). In addition, the *list-wise* version is selected since it reaches the best performance as reported in the paper.

While training our model, Adam optimizer [16] with suggested values (learning rate 0.001, parameters $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$) is adopted. In all experiments, MARINE is trained for at most 500 epoches. All embeddings are initialized from samples of a uniform distribution ranged in $[-0.05, 0.05]$. For all experiment tasks, MARINE learns the representation without using node attributes, except for the experiments in Section 4.4.

4.2 Unsupervised Link Prediction

We use the same evaluation protocol as proposed in [4]. For each pair of an edge relation k and an object node j, we rank all triplets $(i, k, j)\ \forall\ i$ in the descending order of scores, based on the scoring function $s(i, k, j)$ of each model. The same procedure is then repeated for $(i, k, j)\ \forall\ j$. The performance is evaluated with respect to the hit rate at 10 and Mean Reciprocal Rank (MRR). According to the objective functions in the referenced papers, we review the scoring functions of the baseline models in Table 1.

We use three datasets for link prediction evaluation:

- Datasets used in previous approaches for multi-relational networks:
  - **WordNet (WN18)** [24] is a lexical database for English. It groups English words into sets of synonyms called synsets, and records a number of relations among these synonym sets. The relationships include *hypernyms*, *hyponyms*, *meronym*, and other lexical relations. WN18 has 18 relations, 40,943 nodes, and 141,442 edges.
  - **Freebase (FB15K)** [2] is a large collaborative knowledge base of general facts. For instance, a triplet *(Curtis Armstrong, place_of_birth, Detroit)* indicates that a human entity '*Curtis Armstrong*' and a city entity '*Detroit*' have the relationship '*place_of_birth*'. FB15k has 14,951 nodes, 483,142 edges, and 1,345 relations.
- Datasets used in previous approaches for homogeneous networks:
  - **Protein-Protein Interactions (PPI)** [6] is the dataset used in [10], which is the subgraph of the PPI network for Homo Sapiens. The original network has 3,890 nodes (proteins), 76,584 edges (interactions), and 50 labels representing the biological states. For link prediction task, we randomly remove 10% of existing edges for testing data while ensuring the residual graph is connected.

The experimental results are listed in Table 2. The relatively weak performance of DeepWalk, LINE, and SDNE is expected, since the information of relations (and their direction in edges) is not utilized. The results show that MARINE significantly outperforms all other competitors when 5 negative links are sampled. It is competitive to the state-of-the-art ProjE-ori which samples 25 percentage of the negative samples. We further increase the negative sample size of MARINE to 100, denoted as MARINE-Q100, and found the performance can further be improved. We also realized that our model performs significantly better on homogeneous network PPI, which reflects that the current multi-relational solution might not be the best solution for homogeneous network embedding.

Note that ProjE's performance drops significantly while training with fewer number of negative samples. The requirement of massive negative samples in ProjE results in quadratic training complexity, which is less suitable for large-scale networks.

From Table 2, we can find that the proximity preservation part in MARINE dominantly contributes to the performance. As the relation preservation part used in MARINE, the performance of MARINE in WN18 and FB15K, where edge muti-relations are provided, is relatively better than that in PPI. Besides, the overall performance can be significantly enhanced with the exploitation of both terms together. The relation term mainly focuses on learning different relations, while the link prediction evaluates the model to distinguish different nodes.

4.3 Multi-label Classification

We follow the same evaluation protocol as in [10]: The embeddings generated unsupervisedly by each model are used as the input training features to train a multi-label classification, using one-vs-rest logistic regression with L2 regularization[2]. The training and testing data are split equally, and the procedure is repeated 10 times to get the average. Micro F1-score and Macro F1-score are used to evaluate the performance. The regularization strength parameter $C = 1.0$ is not tuned, leaved as default value.

Three datasets are used for multi-label classification evaluation. The first two networks are homogeneous and the last one contains multiple relations.

- Homogeneous graphs including labels:
  - **PPI** [6] has been introduced in previous subsection.
  - **Wikipedia** [22] is the first billion bytes of the English Wikipedia dump. The processed data [10] builds a co-occurrence network of words, and the labels represent the Part-of-Speech tags. The network has 4,777 nodes, 184,812 edges and 40 labels.
- Multi-relational networks including labels:
  - **Movies** [46] is a complex network containing 41,412 entities with 20 labels (e.g., films, actors, directors) and 134,938 directed edges from 34 social relations (e.g., 'lived-with' and 'married-to').

[2] scikit-learn package LogisticRegression's LibLinear solver is used.

Table 1: Score functions of our competitors. σ here denotes the softmax function.

Model	Score function	Ranking order
DeepWalk	$\boldsymbol{x}_i^\top \boldsymbol{x}_j$	descending
LINE	$\boldsymbol{x}_i^\top \boldsymbol{x}_j$	descending
SDNE	$\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2$	ascending
TransE	$\|\boldsymbol{x}_i + \boldsymbol{r}_k - \boldsymbol{x}_j\|_2$	ascending
ProjE	$\sigma(\boldsymbol{x}_i^\top \tanh(\boldsymbol{u} \odot \boldsymbol{x}_j + \boldsymbol{v} \odot \boldsymbol{r}_k + \boldsymbol{b}) + c)$	descending

Table 2: Link Prediction results. Models are evaluated by Hit Rate at top 10 (HR@10) and Mean Reciprocal Rank (MRR).

Dataset	PPI		WN18		FB15k	
	HR@10	MRR	HR@10	MRR	HR@10	MRR
DeepWalk	0.0131	0.0187	0.4165	0.1503	0.0369	0.0187

MARINE-Q5	**0.0954***	**0.0723***	**0.4033***	**0.1044***	**0.9511***	**0.7315***
ProjE-ori	0.1083	0.0849	0.4134	0.1338	0.9049	0.6243
MARINE-Q100	0.1064	0.0829	0.4117	0.1219	0.9587	0.7925
Ensemble(MARINE, LINE)	0.1085	0.0822	0.4132	0.1137	0.9502	0.6617

* outperforms the second-best model at 0.01 level paired t-test.

The results are listed in Table 3. Again, given micro F1-score and macro F1-score, it is observed that MARINE significantly outperforms the others. In particular for the movie datasets that contain multiple relations, even MARINE-Q5 can outperform ProjE-ori significantly. For homogeneous networks PPI and Wikipedia, we can see that the most contribution to MARINE performance lies in the proximity preservation part, which consists with the perspective of previous homogeneous network embedding papers. By contrast, in the multi-relational network Movies the relation preservation part devotes more to MARINE in classification problems. We notice that using the original negative sampling strategy, ProjE can slightly outperform our MARINE. However we emphasize that ProjE samples $O(|\mathcal{V}|^2)$ negative node pairs to achieve high performance, which is not scalable at all. Under the same condition of sampling only 5 negative edges per positive edge example, MARINE shall significantly perform better than ProjE.

4.4 Exploiting Node Attributes

In this section, we discuss whether considering the node attributes allows our model to further boost the performance. As the datasets we used previously do not contain attributes, here we exploit the HepTh co-author citation network consisting of 5,501 author and 17,286 paper entities to predict the future citation counts using the network embeddings. The attributes are the ages of papers in HepTh. Following the same setup as [43], we train the embeddings on citations before 1999 and predict the number of citations after 2000. Random Forest Regressor (number of estimators = 32) is used

Figure 4: Visualization of HepTh. The orange spots indicate papers, while the purple spots indicate authors.

to train on embeddings for prediction. Five-fold cross-validation experiment is conducted; MAE (Mean Absolute Error) is chosen as the evaluation metric. The baseline usage of attributes relies simply on concatenating the embeddings with the attributes for training. We can see from Table 4 that not all models can benefit from additional attributes, while our model yields significantly better results than simply concatenating attributes with embeddings.

We also want to evaluate the performance of embedding ensemble as described in Section 3.7.3. We try to combine our model with LINE by treating its embedding results as our features, since LINE performs well among classic baseline embedding models. The last row in Table 3 shows that based on the ensemble of MARINE and LINE, we can gain improvement on two of the three datasets. The only exception is for the Movies dataset, probably due to the large performance gap between these two models.

Table 4: MAE evaluation of predicting citation counts. The comparison of the usage of node attributes in each embedding model.

usage	w/o attributes	concatenate

ProjE-ori	5.9996	5.8402
MARINE-Q5	5.9525	5.8201
MARINE utilizes attributes as Θ		5.7042

4.5 Visualization

Here we want to show how the embedding results are visualized in the low-dimensional space. We apply visualization tool t-SNE [21] on the embeddings learned from, for the ease of presentation, HepTh dataset. All the models learn the embeddings without attributes. As Figure 4 suggests, the models that consider multi-relational networks are able to better distinguishing between different types of nodes. Both MARINE and ProjE can separate different types of nodes, and MARINE further groups the same type of nodes (purple spots) together. It shows that MARINE considers the relations of edges while preserving proximity simultaneously.

5 CONCLUSIONS

In this paper, we consider the two main branches of network embedding models: for homogeneous networks and for multi-relational networks, or knowledge graphs. Our conclusion is that although the existing multi-relational network embedding methods can be adopted to homogeneous networks, the performance can further be boosted while considering the relation-based proximity, as proposed in this paper. Our experimental results suggest that by considering graph proximity, relations, and attributes altogether, it is possible to yield a more robust network embedding model suitable for different types of networks. Finally, comparing with the state-of-the-art

solution ProjE that requires significant amount of negative links sampled, our model enjoys linear time and space complexity during computation.

ABSTRACT

The study of influence maximization in social networks has largely ignored disparate effects these algorithms might have on the individuals contained in the social network. Individuals may place a high value on receiving information, e.g. job openings or advertisements for loans. While well-connected individuals at the center of the network are likely to receive the information that is being distributed through the network, poorly connected individuals are systematically less likely to receive the information, producing a gap in access to the information between individuals. In this work, we study how best to spread information in a social network while minimizing this access gap.

We propose to use the maximin social welfare function as an objective function, where we maximize the minimum probability of receiving the information under an intervention. We prove that in this setting this welfare function constrains the access gap whereas maximizing the expected number of nodes reached does not. We also investigate the difficulties of using the maximin, and present hardness results and analysis for standard greedy strategies. Finally, we investigate practical ways of optimizing for the maximin, and give empirical evidence that a simple greedy-based strategy works well in practice.

1 INTRODUCTION

Information flow in networks has been a subject of extensive study. Among the many motivations for the study of how information propagates in a network has been advertising (how can we spread information most effectively on a budget) and clustering (how do groups form and organize in a network).

One of the most important questions in this area is how to maximize influence in a social network. Here the goal is to choose where to place initial sources of information so as to maximize the flow of information via word-of-mouth. First formalized by Kempe, Kleinberg, and Tardos [21], there has been a long series of work in the literature on influence maximization.

However, this work has not typically focused on the impact that the information has on the individuals in the network. For example, one important application of information flow in networks is for recruitment. Social networks like LinkedIn are increasingly used to provide access to jobs and information that can greatly impact an individual's career development. Often just as important as the individuals themselves are the connections *between* individuals – their social networks – in making hiring decisions. This is because information transmitted amongst social networks may accrue amongst the best-connected individuals in the network. As the adage goes, "it's not what you know, but who you know." With more and more of our social life mediated through online networks, the role that networks play in opening up opportunities is increasingly important. This includes not only recruitment, but also advertising and other kinds of marketing.

However, network structure can create haves and have-nots in the game of access. Insiders who are well-connected in the network have easier access to relevant information about opportunities for advancement that can in turn lead to even better connections. Outsiders who lack access to such information will find it much harder to improve their network status. This access gap may lead to a form of inequality that is different from the traditional forms of inequality based on class, race, gender, or other attributes, but nonetheless provides a significant challenge.

Thus, we are concerned with each individual's access to information and not just the number of people reached or the amount of information being distributed. How might we ensure that the access gap in information is reduced? Rather than asking how far we can spread information on a budget, we instead ask which people are getting the information we're spreading.

1.1 Our Work

How can we formulate a notion of equitable access to information in a network, and how might we intervene in a network (on a budget) to minimize the gap in access to information? In particular, we examine how best to add seeds (individuals who start with the information) to a network to minimize this gap in access.

We propose a new measure of access in a network. In contrast to previous work that maximizes the average probability that an individual receives the information (*max reach*), we instead propose to maximize the minimum probability. We formalize access as a *social welfare function* that assigns a real value to the set of utilities received by the individuals, in this case the probabilities of receiving the information. This allows us to evaluate the notions of access themselves: we consider a notion of access to be better if interventions that optimally maximize that notion do not widen the access gap. We show that every notion of access (amongst a wide class of such functions) does to some degree permit the access gap to increase in the worst case. On the other hand, if the access gap increases between two groups of individuals after an intervention, we show that our proposed notion of access at least prohibits situations where the access does not increase at all for the group which started off with less access to the intervention. Perhaps surprisingly, we show in Section 3 that a very large class of natural notions of access (including maximum reach) does not have this very basic prohibition. We desire this because without such a prohibition, in the worst case there's nothing stopping interventions from creating one permanently and significantly advantaged group with access to information and one group without any such access, which we regard as blatantly undesirable.

We show that maximizing the minimum probability is NP-hard, hard even to approximate well, and moreover that a number of standard greedy strategies have asymptotically worst-possible approximation ratios. Nonetheless, we show via experiments that a very simple greedy strategy performs well in practice: namely, choose the seeds to be the vertices currently estimated as having the smallest probabilities of receiving the information. We also demonstrate that by using this strategy, we decrease the correlation between vertices' probability of receiving the information and their location in the network, indicating that our measure of access is not merely a proxy for (static) network structure.

Limitations. We recognize that asking to maximize the minimum probability of access to information ignores the fact that not all individuals in a network might need a particular piece of information. For example, a hiring ad should be spread widely, but only to candidates who are eligible, are in the right geographic areas, and have desirable qualifications. More generally, interventions to improve access to information might themselves cause feedback loops (both virtuous and vicious): our work does not consider those dynamics. Nor does our work consider other notions of utility, like those that take into account the benefits of receiving the information more than once. We leave study of these issues for future work.

In summary, our main contributions are as follows.

- We propose a new measure of information access in a network. We demonstrate that this measure captures certain axiomatically desirable properties of any notion of equal access, and further that existing notions including the well-studied *maximum reach* concept do not.
- We investigate the problem of maximizing access theoretically, presenting hardness results as well as analysis of standard greedy strategies.
- We do a comprehensive empirical evaluation of heuristics for achieving a high level of access, demonstrating that a greedy-based strategy is quite effective at improving equality of access in a network for a given budget of interventions.

1.2 Related Work

Granovetter's seminal work on the strength of weak ties [16] first broached the idea that network position can confer advantages or disadvantages (including in hirings scenarios). Indeed, weak ties can influence success in hiring and careers [15]. In an algorithmic setting, boyd, Levy, and Marwick [4] illustrate how modern social networks like LinkedIn might be vehicles for a more direct propagation of advantage and disadvantage. In that light, our work, which focuses on how to mitigate such effects in the context of information access, falls into the paradigm explored by fairness-aware decision-making in which the goal is to design decision-making systems that ensure the end result is non-discriminatory to individuals or groups of individuals. Our work can be viewed as an attempt to quantify one aspect of *social capital*, a notion introduced by Coleman [7] to capture how social standing within a system could be interpreted as a resource that has utility for an agent. Recently, Benthall and Haynes [3] consider how to use a social network to define racial aspects of social standing, but don't consider interventions in the social network.

Rather than directly model an explicit fair goal for a decision in this setting, via assuming we have access to a sensitive feature like race on which we would focus our attention, we instead model the utility that each individual receives. This formalizes how best to optimize for access to information without necessarily requiring *equal* access. While most of the literature in algorithmic fairness uses equality-based definitions [9–11, 18, 27, 33, 36] (typically either group fairness or individual fairness), the welfare approach to fairness that we use is starting to become more popular. For example, Heidari et al. [19] propose a specific welfare function to use for classification and regression problems.

Our choice of welfare function is based on axiomatic considerations: by determining which functions satisfy specific mathematical criteria used to model gaps in access. The resulting function that seeks to maximize the minimum probability of receiving information bears some resemblance to the *difference principle* outlined by Rawls [30], in that it seeks to intervene so as to provide benefit to the "least-advantaged", here interpreted as those with the least probability of access.

Our work relies on a framework for information propagation that comes from the broad area of *influence maximization*. Influence maximization seeks ways to spread information in a network efficiently using a small collection of *seeds*. The typical measure of information spread used is the expected number of nodes that receive the information (the max reach measure). While influence maximization assigns the same utility to an individual as we do,

the welfare function in that setting is just the sum of the individual utilities. This *utilitarian* approach was initiated by Domingos and Richardson [31] and is formalized as a discrete optimization problem in Kempe, Kleinberg, and Tardos [21]. There is also work into making this process faster [5, 34] or suitable for more general situations, where factors like pricing must be taken into account [2].

A related body of algorithmic work [12, 25, 26] posits that one way to decrease polarization in social networks is to connect people with opposing views by exposing them to new information. Such work differs in focus and approach to modeling from this work because that work is concerned with poor connectivity between communities and we are concerned with individuals who are simply poorly connected.

2 DEFINITIONS

Let G be a graph with n nodes. To describe information flow in G we will use a standard probabilistic model for how information travels – the *independent cascade* (IC) model [21]. In this model, a node either possesses information or not. A set of *seed* nodes start out with the information, and information flow proceeds in rounds. Each newly informed node v informs its neighbors u in the next round i.i.d. with probability of transmission $\alpha_{u,v}$. Once a node is informed, it stays informed, and no longer passes on the message. In this work, we will use the IC model with a fixed probability α of transmission.

Welfare Functions. In the IC model with parameter α, we can associate with each vertex v the probability p_v that v is informed after all information has been passed. We now define a social welfare function $\mu : [0,1]^n \to \mathbb{R}$ to represent how effectively information is spread: it takes as input the probability of infection for each vertex, and outputs the overall welfare.

Definition 1. *The welfare of a set of vertices $V = \{v_1, \ldots, v_{|V|}\}$ in G with seed set S is $\mu_G(S, V) = \mu(p_{v_1}, \ldots, p_{v_{|V|}})$. If V is all n vertices, we abbreviate this as $\mu_G(S)$.*

When the graph is clear from context, we will omit the subscript G and write $\mu(S, V)$ and $\mu(S)$ respectively.

Seed sets represent an *intervention* in the information network. Thus, a primary goal in the study of information flow is to find a *budgeted intervention*: a set of seeds S_+ of size no more than k for a given graph G (possibly with initial seeds S) with maximum welfare

$$S^* = \arg\max_{\substack{S_+ \cup S: \\ |S| \le k}} \mu_G(S_+ \cup S).$$

In other words, S^* is the initial seeds S along with a set of k vertices which maximizes access for G. Later, we will also consider the set of seeds that maximize welfare for a particular set of vertices:

$$S_V = \arg\max_{\substack{S_+ \cup S: \\ |S| \le k}} \mu_G(S_+ \cup S, V).$$

Kempe, Kleinberg, and Tardos [21] and subsequent work use as their welfare function *reach*, the expected number of nodes reached. In our notation, and normalizing to make it conveniently $[0,1]$-valued, this becomes the following:

Definition 2 (Reach). $\mu_{reach}(S, V) = \frac{1}{|V|} \sum_{v \in V} p_v$.

We can easily generalize this to a wider class of notions of welfare. We consider generalized means:

Definition 3 (ϕ-mean). $\mu_\phi(S, V) = \left(\frac{1}{|V|} \sum_{v \in V} p_v^\phi \right)^{1/\phi}$.

Note in the limit, this becomes the geometric mean for $\phi = 0$, the minimum for $\phi = -\infty$, and the maximum for $\phi = +\infty$. In other words, $\mu_{-\infty}(S, V) = \min_{v \in V} p_v$.

We say that a function $\mu_G(S, V) = \mu(x_1, \ldots, x_m)$, each $x_i \in [0,1]$ representing the probability that a node i receives the information, is *monotonically increasing* if $\mu(x_1, \ldots, x_m) \ge \mu(x'_1, \ldots, x'_m)$ when $x_i \ge x'_i$ for all i. A function μ is *strictly monotonically increasing* if $\mu(x_1, \ldots, x_m) > \mu(x'_1, \ldots, x'_m)$ when $x_i \ge x'_i$ for all i and in addition there is some j such that $x_j > x'_j$. μ is *symmetric* if $\mu(x_1, \ldots, x_m) = \mu(x_{\sigma(1)}, \ldots, x_{\sigma(m)})$ for all permutations σ.

In this work, we restrict our attention to symmetric, monotonically increasing welfare functions so that no vertex is privileged above the others and, all else equal, increasing an individual's probability of receiving the information is never undesirable. The ϕ-means are such functions. Moreover, if a continuous welfare function satisfies four natural conditions (symmetry, strictly monotonically increasing, independence of unconcerned agents, and independence of common scale[1]) as a consequence of the Debreu-Gorman theorem [8, 14] the only such welfare functions up to ordering over preferences are the ϕ-means [19, 32], as long as all probabilities are non-zero. In other words, at least in the case of connected undirected graphs, ϕ-means are an extremely wide class of symmetric, monotonically increasing welfare functions, making them a natural class to examine.

3 GAPS IN ACCESS

Optimizing a welfare function is a way to improve access to information in the aggregate. But our concern in this work is whether individuals or subgroups are being left behind in the process. Is it possible that even though an aggregate measure of information access is increasing, the gap in information access between groups is getting larger? In this section, we will focus on evaluating welfare functions with respect to information access properties we would like to ensure.

We now define the *access gap*, which captures how much better some individuals are doing than others.

Definition 4. *The* access gap *of a (non-trivial) partition V, V' of the vertices of a graph G with seed set S under a welfare function μ is*

$$\mu(S, V) - \mu(S, V').$$

Note we only define the access gap over bipartitions, rather than arbitrary subsets. This is to prevent the following situation: Given a partition V_1, V_2, V_3 of G and initial seed set S, suppose $\mu(S, V_1) = \mu(S, V_2)$ are both very large, but $\mu(S, V_3)$ is much smaller. Consider S^*, the optimal seed set for this graph, and suppose now $\mu(S^*, V_1) > \mu(S^*, V_2) = \mu(S^*, V_3)$. We now have a gap between the access of V_1 and V_2, but this gap was a by-product of significantly increasing the

[1] Independence of common scale means that the ordering over alternatives should not change when multiplying each probability by a common positive factor, and independence of unconcerned agents means that the ordering should be independent of a probability that doesn't change, i.e. if $\mu(x, x_1, \ldots, x_m) \ge \mu(x, x'_1, \ldots, x'_m)$, then $\mu(y, x_1, \ldots, x_m) \ge \mu(y, x'_1, \ldots, x'_m)$ for all y.

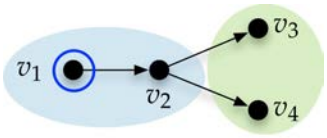

Figure 1: Example showing that the rich can get richer under the optimal intervention. If only one additional seed may be added, it is v_2 for any monotonic welfare measure. Under this intervention, the access gap between $\{v_1, v_2\}$ and $\{v_3, v_4\}$ (the two colored sets) widens.

access of V_3. Since this may well be desirable behavior, we preclude this situation by only considering gaps between bipartitions.

In particular, we want to know when the access gap increases. We call this the *rich getting richer* phenomenon.

Definition 5 (Rich get richer). *In a graph G with initial seeds S under a welfare function μ, we say that the* rich get richer *if there is a (non-trivial) partition V, V' where the optimal intervention S^* satisfies*

$$\mu(S^*, V') - \mu(S^*, V) > \mu(S, V') - \mu(S, V) > 0.$$

Unfortunately, stopping the rich from getting richer in arbitrary graphs may be too much to hope for. Even simple examples show that under many notions of welfare, including all ϕ-means, the rich get richer.

Proposition 3.1. *Suppose μ is symmetric, increasing, and satisfies the following condition: For any $x_1, \ldots, x_m$ in $[0, 1]$, there is some $1 \le \phi < \infty$ such that*

$$\min_i x_i \le \mu(x_1, \ldots, x_m) \le \left(\frac{1}{m}\sum_{i=1}^{m} x_i^{\phi}\right)^{1/\phi}.$$

Then under μ, when $0 < \alpha < \frac{1}{2\phi}$, there exists a graph and initial seed set where the rich get richer.

Note that the upper bound in this third condition is easy to satisfy; it suffices that $\mu(x_1, \ldots, x_m)$ is strictly less than $\max_i x_i$ when not all of the x_i are equal to each other. In addition the assumption that $\phi \ge 1$ is only assumed for the sake of convenience, since $\left(\frac{1}{m}\sum x_i^{\phi}\right)^{1/\phi}$ is monotonic in ϕ.

Proof. Consider the example graph G in Figure 1 and suppose $0 < \alpha < 1$. Let $V = \{v_3, v_4\}$ and $V' = \{v_1, v_2\}$. Note that $p_{v_1} = 1$, $p_{v_2} = \alpha$, and $p_{v_3} = p_{v_4} = \alpha^2$. Then $\mu(S, V) = \mu(p_{v_3}, p_{v_4}) = \mu(\alpha^2, \alpha^2) = \alpha^2$. Yet $\mu(S, V') = \mu(1, \alpha) \ge \alpha > \alpha^2$, so we have $\mu(S, V') > \mu(S, V)$.

What is the optimal seed to add? If we add v_2 to the seeds, then we have $p_{v_1} = p_{v_2} = 1$ and $p_{v_3} = p_{v_4} = \alpha$. Otherwise, if we add v_3 to the seeds, then $p_{v_1} = p_{v_3} = 1$, $p_{v_2} = \alpha$, and $p_{v_4} = \alpha^2$. Note $\mu(1, 1, \alpha, \alpha) \ge \mu(1, \alpha, 1, \alpha^2)$ by symmetry and monotonicity, so without loss of generality the optimal modification is to make v_2 a seed. Then it is easy to calculate $\mu(S^*, V') - \mu(S^*, V) = \mu(1, 1) - \mu(\alpha^2, \alpha^2) = 1 - \alpha^2$. Thus we have the rich getting richer if $1 - \alpha > \mu(1, \alpha) - \alpha^2$. But $\mu(1, \alpha) \le \left(\frac{1+\alpha^{\phi}}{2}\right)^{1/\phi}$, so it suffices to show that $\frac{1+\alpha^{\phi}}{2} < \left(1 - \alpha + \alpha^2\right)^{\phi}$. Then since $\phi \ge 1$ and $0 < \alpha < \frac{1}{2\phi}$,

$$\frac{1+\alpha^{\phi}}{2} \le \frac{1+\alpha}{2} < 1 - \phi\alpha + \phi\alpha^2 \le (1 - \alpha + \alpha^2)^{\phi}.$$

□

Proposition 3.1 holds for all ϕ-means for $\phi < \infty$. We will show in Section 3.1 that the rich get richer not only for the $+\infty$-mean but a whole other class of welfare functions as well (a consequence of Proposition 3.2). Given this, keeping the rich from getting richer appears to be too much to hope for.

3.1 k-imbalance

If we can't keep the rich from getting richer in the worst case, what can we prevent? A particularly concerning case of the rich getting richer is when the access of the worse-off group V doesn't improve at all. That is, a case where $\mu(S, V') > \mu(S, V)$ under the initial seeds S and the rich get richer, but for the set of seeds S^* that maximize welfare $\mu(S^*, V) \le \mu(S, V)$. This might not be so bad if the only way to improve the access of V is to increase the access of V to the point where it is even higher than that of V', so that V' becomes the worse-off group. On the other hand, this situation becomes particularly egregious when in addition $\mu(S_V, V) \le \mu(S, V')$, i.e. the optimal improvement for V still does not improve the access of V to the point where it is larger than the access that V' started out with prior to intervention (recall that S_V – defined in Section 2 – is the seed set that maximizes reach for V). If this can happen when adding k seeds, we will call μ *k-imbalanced*. That is, k-imbalance is a particularly egregious form of the rich getting richer. If μ is not k-imbalanced for any $k > 0$, we will call it *balanced*.

We believe that balance is a natural desideratum because it prevents interventions from never helping the worse-off group at all. Stronger versions of preventing disparity in access may still be preferred, like avoiding the rich from getting richer, so balance may only represent a necessary but not sufficient condition for preventing disparity. In this section, we show a wide class of μ are $\Omega(n)$-imbalanced, but that $\mu_{-\infty}$ is balanced.

Definition 6 (k-imbalance). *A welfare function μ is k-*imbalanced *if there exists a graph G with initial seed set S and partition of the vertices V and V' where the optimal intervention S^* and optimal intervention for S_V under the addition of no more than k seeds satisfies the following:*

(1) $\mu(S, V) < \mu(S_V, V)$ (There is a set of seeds to add that improves the access of V.)
(2) $\mu(S_V, V) \le \mu(S, V')$ (Not only does V' start off with more access than V, but V' starts off with more access than V can possibly achieve.)
(3) $\mu(S^*, V') > \mu(S, V')$ (The access of V' improves.)
(4) $\mu(S^*, V) \le \mu(S, V)$ (The access of V does not improve.)

In other words, a welfare function is imbalanced if

$$\mu(S^*, V) \le \mu(S, V) < \mu(S_V, V) \le \mu(S, V') < \mu(S^*, V').$$

Note that it is immediate that if μ is k-imbalanced for any $k > 0$, then the rich get richer under μ. As k increases, it should be the case that it becomes more difficult to find examples of imbalance, as it is harder to avoid improving the access of V'. Nonetheless, we can show that a wide class of welfare functions, including reach, is $\Omega(n)$-imbalanced:

Proposition 3.2. *Suppose μ is symmetric and strictly increasing. Then μ is $\Omega(n)$-imbalanced.*

Proof. It suffices to consider the simplest case: when there is no communication, i.e. G is the disjoint graph of n vertices. V and V' will each be exactly half of the vertices (for n even). The initial seed set S will be entirely contained in V' and will be size $n/4$. Now we will add an additional $n/4$ seeds. Note first that since μ is symmetric, each of the vertices (with the exception of the initial seeds) are identical. So S_V is any set of $n/4$ additional seeds in V: each additional seed must improve the welfare of V because μ is strictly increasing. But in this case, V and V' become identical, so we have $\mu(S, V) < \mu(S_V, V) \leq \mu(S, V')$. But by symmetry, the optimal seeds to add can be any $n/4$ vertices, in which case we can assume they are all in V'. Thus the welfare of V does not increase while the welfare of V' does. □

It turns out that balance is a useful definition, insomuch as it is actually possible to achieve.

Proposition 3.3. *$\mu_{-\infty}$ is balanced.*

Proof. Suppose $\mu_{-\infty}$ is imbalanced, witnessed by some partition V, V' of G and initial seed set S. Recall imbalance implies that $\mu_{-\infty}(S, V) < \mu_{-\infty}(S, V')$. Then by definition of $\mu_{-\infty}$, the vertex v with minimum probability is in V, i.e. $\mu_{-\infty}(S) = \mu_{-\infty}(S, V)$. Remember S^* maximizes the minimum probability, and $\mu_{-\infty}(S_V, V) > \mu_{-\infty}(S, V)$, so there is at least one graph that increases that minimum probability, which in turn means that S^* does as well. Thus $\mu_{-\infty}(S^*, V) > \mu_{-\infty}(S, V)$, a contradiction. □

On the other hand, $\mu_{-\infty}$ is a special case, and every other ϕ-mean is maximally imbalanced: there exists a graph, initial seed set, and partition of the vertices that verifies the other ϕ-means are imbalanced.

Proposition 3.4. *For $\phi > -\infty, \alpha < 1, \mu_\phi$ is $\Omega(n)$-imbalanced.*

Proof. If $\phi = +\infty$, so μ_ϕ is the maximum probability, then as soon as the graph has at least one seed, then $\mu_\phi(S) = 1$, and any added seeds after that don't change the value, so μ_ϕ is trivially $\Omega(n)$-imbalanced. Otherwise, if $\phi > 0$, μ_ϕ is strictly increasing, and from Proposition 3.2 we know it is $\Omega(n)$-imbalanced. And if $\phi \leq 0$, then μ_ϕ is strictly increasing once all probabilities are non-zero, at which point we use a similar tactic to when μ is strictly increasing, except we will need a connected graph. We will use the star graph, with one central vertex the seed, and all other vertices connected to that seed. In addition there will be some $n/2 - 1$ additional seeds, all in V', which consists of those seeds, the central seed, plus $n/2$ more vertices. V will be the other n vertices, so that G is $2n$ nodes. Our goal will be to add an additional $n/2$ seeds. Remember, since G is connected (all vertices have non-zero probability) μ_ϕ is strictly increasing. Then the optimal graph for V is to add all $n/2$ additional seeds to V, in which case we have $n/2$ vertices with probability 1 and $n/2$ vertices with probability α. But V' in G is exactly the same, so we have $\mu(S, V) < \mu(S_V, V) \leq \mu(S, V')$. However, all non-seeds are isomorphic, so we may assume all $n/2$ new seeds are added to V'. □

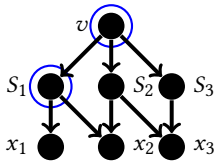

Figure 2: Corresponds with the set cover problem 'Is there $k = 1$ set among $S_1 = \{x_1, x_2\}$, $S_2 = \{x_2, x_3\}$, $S_3 = \{x_3\}$ that cover all elements?' Note that since the answer is no, then the minimum probability is no more than $p_{x_3} = 1 - (1 - \alpha^2)^2$.

We note that one could consider many variations of ϕ-means, including replacing mean with median, maximum with minimum, etc. These variations do not affect the results that we present here. We defer a detailed analysis of these variations to the full version of the paper.

4 MAXIMIN ACCESS

The previous section established $\mu_{-\infty}$ as a better access measure than others, at least when it comes to achieving balance. We now study the problem of maximizing $\mu_{-\infty}$, which we call the *maximin access* problem. We start by showing that this is NP-hard even to approximate well.

Theorem 4.1. *Suppose $\alpha < \frac{\sqrt{5}-1}{2}$. Then choosing k seeds to maximize min access is NP-hard. In this case, the maximin access cannot be approximated better than $O(\alpha)$ and if furthermore $\alpha = O(1/n)$ then the maximum cannot be attained efficiently without an additional $O(\ln n)$ factor seeds.*

Proof. We reduce from Set Cover, where an instance is defined by a collection of subsets $S_1, \ldots, S_m$ over a ground set $U = \{x_1, \ldots, x_n\}$ and an integer k, and the decision problem is whether or not there is a collection of k subsets whose union is U. Further, we can assume $k < n < m$. Given such an instance, we construct a directed graph (example showed in Figure 2). We start with the natural directed bipartite graph corresponding to a set cover instance, where there is a vertex i corresponding with each set S_i and a vertex j corresponding with each element x_j. There is a directed edge from i to j whenever x_j is contained in S_i. We then add a single extra vertex v and directed edges from v to each vertex i corresponding with one of the sets, and ask to maximize the minimum probability by adding $k + 1$ seeds.

Since v has in-degree zero, in order for the maximin access to be greater than zero, v must be chosen as a seed. In this case, since $k < m$, regardless of which seeds are chosen, there is some set S_i such that $p_i = \alpha$. Therefore the maximum min access is no more than α. Without loss of generality, no vertex corresponding to an element x_j need be chosen as a seed. Otherwise, the seed may be moved to any vertex corresponding with a set S_i such that $x_j \in S_i$. The maximin access cannot go down, because we still have $p_j \geq \alpha$.

If there is a set cover, then the maximum min access is at least α: choose the vertices corresponding to the cover for the seeds (plus v), in which case $p_v = 1$, $p_i \geq \alpha$ because they are either seeds or distance one from v, and $p_j \geq \alpha$, because they are distance one from a seed. If there is no set cover, then there is no way to choose the

seeds amongst the S_i such that all vertices are within distance one from a seed. Assume that every element x_j is contained in at most two subsets amongst the S_i (this is now the Vertex Cover problem, an NP-hard special case of Set Cover). So there must be some p_j such that $p_j \leq 1-(1-\alpha^2)^2$. Thus when $\alpha > 1-(1-\alpha^2)^2$, i.e. $\alpha < \frac{\sqrt{5}-1}{2}$, any algorithm that maximizes the min access chooses the set cover if there is one. So any algorithm that has an approximation ratio strictly better than $\frac{1-(1-\alpha^2)^2}{\alpha} = O(\alpha)$ must in fact be exact, and therefore also find the set cover.

Even in the general case of Set Cover, we can still distinguish between when there is and is not a set cover: The existence of a set cover still means the maximin probability is at least α, while the lack of a set cover implies there is at least one vertex with probability no more than $1-(1-\alpha^2)^m$, which is upper-bounded by α when $\alpha = 1/m$. Therefore, since set cover is $O(\ln n)$-inapproximable, we cannot approximate the best k seeds to add without an additional $O(\ln n)$-factor seeds. □

Moreover, if we can find the seeds that maximize the minimum probability, even approximately, we can boost this result to also compute the minimum probability itself approximately. This serves as additional evidence that this problem is hard, as there is no known method to even approximately compute the minimum probability.

Proposition 4.2. *If there is an $\alpha^{f(n)}$-approximation algorithm for maximin access, there is an $\alpha^{2f(n)+2}$-approximation for the minimum access of a vertex in a graph G given a seed s. That is, if the minimum access is p_{min} in G, then we can given an estimate $\hat{p}$ such that*

$$\alpha^{2f(n)+2} p_{min} \leq \hat{p} \leq (1/\alpha)^{2f(n)+2} p_{min}.$$

Proof. Given an instance (G, s, α), we construct a graph G' similar to the one in Figure 5. (We may assume that G is connected.) If the diameter of G is ℓ, add to G a simple undirected path of length ℓ starting from s, and call it G'. Call the end of this path v. In G, $p_{\min} \geq \alpha^\ell$, which means that if we compute the single optimal seed in G', it must be on the path from s to v.

Define x so that $\alpha^{\ell-x} = \alpha^x \cdot p_{\min}$, i.e. $x = \ell/2 - \frac{\log(1/p_{\min})}{2\log(1/\alpha)}$. Then the optimal placement for a seed is at distance k from s, where $\lfloor x \rfloor \leq k \leq \lceil x \rceil$, because for any k we have $p'_v = \alpha^{\ell-k}$ and $p'_{\min} = \alpha^k \cdot p_{\min}$, where p' denotes probabilities in G'.

Suppose that we have a $(1/\alpha)^{f(n)}$-approximation algorithm for maximin access, and it chooses some seed distance k' from s (we may assume that the seed is on the simple path, otherwise we may always choose $k' = 0$). Since it is a $(1/\alpha)^{f(n)}$-approximation on a simple path, k' must be within $f(n)$ of k. Now we can approximate $p_{\min}$ using k' as an estimate of k: We estimate it as $\hat{p} = \alpha^{\ell-2k'}$.

Then $\alpha^{\ell-2k'} \leq \alpha^{\ell-2(k+f(n)} \leq \alpha^{\ell-2(x+1+f(n))}$, and likewise $\alpha^{\ell-2k'} \geq \alpha^{\ell-2(x-1-f(n))}$, so this is within $\alpha^{2f(n)+2}$ of $p_{\min} = \alpha^{\ell-2x}$.

□

4.1 Maximin algorithms

The above results imply that it is hard to maximize $\mu_{-\infty}$ even approximately. Nonetheless, Theorem 4.1 still leaves open the possibility of an α^c-approximation (for fixed number of seeds and $c > 1$). In this section, we present the heuristics we will use, along with a few baselines. We will show in Section 4.2 that, unfortunately, these natural heuristics have a worst-possible approximation ratio (a ratio exponential in n). These results do not preclude good performance in practice, which we discuss in Section 5.

Making our task yet more challenging is that, unlike maximizing reach [21], maximin is not a submodular objective.[2] Nonetheless, it is natural to try a greedy approach, where in each iteration, we add to the seeds the vertex that maximizes the objective function. We refer to this heuristic as **Greedy** (Algorithm 1). To do this, we use the simple approach of estimating each probability p_v for every possible vertex to add to the seed set. (See below for details on how we estimate these probabilities.)

Algorithm 1 Greedy

Input: Graph G, initial seed set S, number of seeds to add k

for k iterations **do**
  for all $j \notin S$ **do**
    $prob \leftarrow \text{ProbEst}(G, S \cup \{j\})$ ▷ Algorithm 4
    $nextMin[j] \leftarrow \min_i prob[i]$ ▷ The minimum probability when the seeds are $S \cup \{j\}$
  $v \leftarrow \arg\min_j nextMin[j]$
  add v to S
return S

We contrast this approach to the faster approach, which we will call **Myopic** (Algorithm 2), whereby we instead in each round choose the vertex with the currently smallest probability as the new seed, without actually evaluating the new value of the objective function.

Algorithm 2 Myopic

Input: Graph G, initial seed set S, number of seeds to add k

$k' \leftarrow k$
if $|S| = 0$ **then**
  Initialize S as the vertex with the highest degree
  $k' \leftarrow k - 1$
for k' iterations **do**
  $prob \leftarrow \text{ProbEst}(G, S)$ ▷ Algorithm 4
  $v \leftarrow \arg\min_i prob[i]$ ▷ pick node with min probability
  add v to S
return S

We also consider a naïve variation (**Naïve Myopic**, Algorithm 3) which, instead of proceeding in rounds, given initial estimates for the probabilities, picks for the seeds the k vertices with the smallest probabilities.

So far, we have omitted how to estimate the probabilities for each vertex. Unfortunately, computing the probability p_v for each vertex exactly is #P-hard [29]. Even computing probabilities of receiving the information with a guaranteed approximation ratio is a long-standing open problem [20]. So in this paper, we use a Monte Carlo method, simulating the IC model a fixed number of times, and estimating the probabilities for each vertex as the

[2] This can be seen using the construction in the proof of Proposition 4.4, starting with one seed in the center of a simple path. Adding one additional seed then does nothing, but adding two seeds increases the minimum probability.

Algorithm 3 Naïve Myopic

Input: Graph G, initial seed set S, number of seeds to add k

$k' \leftarrow k$
if $|S| = 0$ **then**
  Initialize S as the vertex with the highest degree
  $k' \leftarrow k - 1$
$prob \leftarrow \text{ProbEst}(G, S)$ ▷ Algorithm 4
Add to S the k' vertices $i \notin S$ with smallest probability $prob[i]$
return S

percent of times the information reached that vertex under the simulations (Algorithm 4). Of course, this requires having at least one seed, which is not the case in the first round of Myopic and Naïve Myopic. So we always choose the first seed as vertex with the highest degree. This approach for dealing with the first round, as well as estimating the probabilities, provides a simple way to compare these heuristics. As such, for the experiments we also choose the first seed as the highest degree vertex for the Greedy heuristic as well, again to simplify comparison. We leave for future work other approaches for these issues.

Algorithm 4 ProbEst (Monte Carlo probability estimation)

Input: Graph G, seed set S
Parameters: α, Number of simulation rounds R

Initialize $hits[i] \leftarrow 0$ for each i a vertex of G
for R iterations **do** ▷ Simulate the IC model R times
  for all $i \in S$ **do**
    $hits[i]$++ ▷ $hits[i]$ is the number of times i has received the information
  $activeQueue \leftarrow S$ ▷ Keep track of which vertices are currently active
  while $activeQueue$ non-empty **do**
    Dequeue i from $activeQueue$
    for all neighbors j of i **do**
      $transmit \leftarrow$ True with probability α, else False
      if j has not been in $activeQueue$ and $transmit$ **then**
        $hits[j]$++
        Enqueue j to $activeQueue$
$prob[i] \leftarrow hits[i]/R$
return $prob$

An alternative approach that avoids estimating probabilities is to pick seeds that are far from each other, under the intuition that a node far away from the current seeds is likely to have a small p_i and therefore should be picked as the next seed. The resulting heuristic is to pick in each round the node that is furthest from the current set of seeds as the next seed; we call this heuristic **Gonzalez** because of its resemblance to the well-known algorithm for k-center clustering [13].

One could choose other proxies for the utility p_v such as nodes of low degree (or high degree), or nodes that do not contain seeds in a fixed radius ball around them. In our experiments with these heuristics, they were dominated in both quality and performance by the ones mentioned above, and we will not discuss them further.

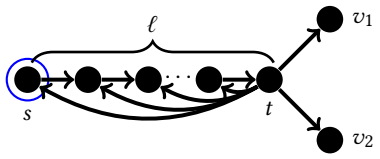

Figure 3: G

4.2 Approximation ratios of maximin algorithms

We now show that Myopic, Naïve Myopic, Greedy, and an exact version of Gonzalez all have approximation ratios that are exponential in n, even if we assume the probabilities required by Myopic, Naïve Myopic, and Greedy can be estimated exactly. This is to emphasize that their poor behavior in the worst case doesn't just stem from the difficulty of approximating the probabilities given a seed set, but the heuristics themselves.

4.2.1 Myopic and Naïve Myopic. Note that in the case $k = 1$, Myopic and Naïve Myopic are identical algorithms. Thus we can show that in this case, both algorithms behave poorly in the worst case, even in the non-trivial case when we start with at least one initial seed.

Proposition 4.3. *Given a graph and non-zero initial seed set, choosing as the seed with smallest p_v yields a solution with approximation ratio no better than $O(\alpha^n)$.*

Proof. Consider the graph G depicted in Figure 3. If we are allowed to add only a single additional seed besides the initial seed set $\{s\}$, then this algorithm will choose to add either v_1 or v_2, because in G they minimize $\min_v p_v$, where $p_{v_1} = p_{v_2} = \alpha^{\ell+1}$. But since we can only reach one of the two, we still have $\min_v p_v = \alpha^{\ell+1}$. But the optimal vertex to add to the seed set is t, where now $\min_v p_v \geq \alpha^2$. Then we get an approximation ratio no better than $O\left(\frac{\alpha^{\ell+1}}{\alpha^2}\right) = O(\alpha^n)$. □

4.2.2 Greedy. We now consider what happens if Greedy is used to choose the k seeds. One problem with Myopic was that, as demonstrated via Figure 3, choosing the vertex with the smallest probability ignores the actual objective function (which in that example is maximized by choosing vertex t). What happens when we attempt to maximize the actual objective function? Again, we assume that for any seed set we are given the exact probabilities instead of approximate probabilities, which we refer to as a *probability oracle*.

Proposition 4.4. *Greedy, even with a probability oracle, has an approximation ratio no better than $O(\alpha^{n/6})$.*

Proof. Consider the simple undirected path of length n, with no initial seeds, where we may add $k = 2$ seeds. The greedy algorithm, in the first iteration, must choose the central vertex (assume n is even). In the second iteration, no vertex can increase the minimum probability, so the minimum probability is $\alpha^{n/2}$. However, the optimal minimum probability is much larger: If the two seeds trisect the path so that they are $n/3$ apart, then no vertex is distance more than $n/3$ from a seed, in which case the minimum probability is at least $\alpha^{n/3}$. □

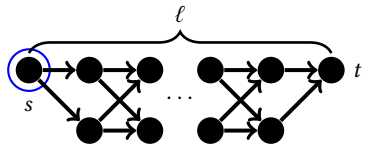

Figure 4: H_ℓ

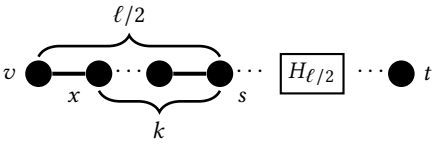

Figure 5: H, which consists of a simple path of length $\ell/2$, whose vertex s is the vertex s of in-degree 0 in $H_{\ell/2}$, depicted in Figure 4.

4.2.3 Minimax distance. Gonzalez is a heuristic to minimize the maximum distance of any vertex from a seed. One motivation behind this algorithm is that in Figure 3, adding an edge from s to t in G takes care of the issues found with Myopic by ensuring that all vertices have distance no more than two from the seed. In general, minimizing the maximum distance exactly is difficult, but even if we could do so, this approach still has a bad approximation ratio.

To show this, we construct a (sparse, max degree two) graph where nonetheless the vertex t furthest away from the seed still has a relatively high probability of receiving the information. This is the case for H_ℓ, shown in Figure 4, that's sufficiently sparse but p_t is large.

Lemma 4.5. *The probability of t being infected in H_ℓ, where each edge has weight $\alpha = 1/2$, is $p_t = \Theta(1/\ell)$.*

Proof. Denote by level k the vertices distance k from s, and by symmetry, the probability of being infected at that level p_k. We want to calculate p_ℓ. Note $p_0 = 1$ and $p_{k+1} = 1 - (1 - \alpha p_k)^2 = p_k - \frac{1}{4}p_k^2$, a variant of the logistic map.

Then $\frac{1}{p_{k+1}} = \frac{1}{\frac{1}{4}p_k(4-p_k)} = \frac{1}{p_k} + \frac{1}{4-p_k}$. Note $1/4 \le \frac{1}{4-p_k} \le 1/3$. Unwinding the recurrence, we get $\frac{1}{p_{k+1}} = \frac{1}{p_0} + \sum_{j=0}^{k} \frac{1}{4-p_j}$, and in particular we have $\frac{1}{p_0} + \frac{k+1}{4} \le \frac{1}{p_{k+1}} \le \frac{1}{p_0} + \frac{k+1}{3}$, i.e. $\frac{1}{p_k} = \Theta(k)$. □

Proposition 4.6. *The algorithm that minimizes the maximum distance from a seed has approximation ratio $O(\sqrt{n}/2^{n/6})$ when $\alpha = 1/2$.*

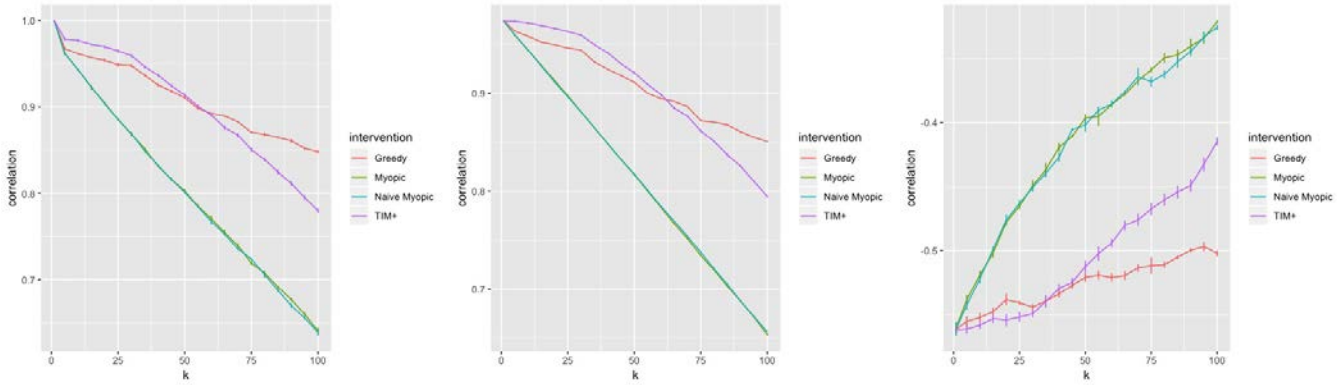
Proof. Suppose we can choose at most one seed in H, shown in Figure 5. Minimizing the max distance means the seed we use is s, and for sufficiently large ℓ the minimum probability is $p_v = \alpha^{\ell/2}$, at least for $\alpha = 1/2$ (using the previous lemma). However, the optimal seed to use is x, where x is a vertex $k \le \ell/2$ distance from s. Under this seed set, p_v remains the vertex with the minimum probability of getting infected so long as, for some constant c, $\alpha^{\ell/2-k} \le \frac{2c\alpha^k}{\ell}$ (again using the previous lemma). Solving for k to maximize the minimum probability, we get $k = \ell/4 - \frac{\log\left(\frac{\ell}{2c}\right)}{2\log\left(\frac{1}{\alpha}\right)}$. Then the approximation ratio is no better than $\frac{\alpha^{\ell/2+1}}{\alpha^{\ell/2-k+1}} = \alpha^k = \frac{\sqrt{\ell}\alpha^{\ell/4}}{\sqrt{2c}} = O(\sqrt{\ell}(1/2)^{\ell/4})$, and finally note H has $\frac{5}{2}\ell - 4$ edges, $\frac{3}{2}\ell + 1$ vertices, and the maximum in-degree (and out-degree) is two. □

Despite the hardness results of this section, we will show in the next section that these algorithms perform well in practice.

5 EXPERIMENTS

Our experimental evaluation will investigate the following question: does maximizing $\mu_{-\infty}$ create real changes in access? Is this different from the interventions achieved via maximum reach? And how effective are the proposed strategies for optimizing $\mu_{-\infty}$? Since our goal in this paper is to introduce and validate a method for reducing access gaps, we will not focus on achieving the fastest implementations (although we will compare the efficiency of different heuristics).

5.1 Experimental procedure



For our evaluation, we used social networks sourced from the SNAP [23] and ICON [6] repositories as described in Table 1.

$\mu_{-\infty}$ is a stringent objective function: it minimally requires having at least one seed in every connected component to achieve non-zero minimum probability, which may require a large number of added seeds if for example there are many disconnected nodes. Since the access gap is maximally large if there is at least one seed and a vertex with $p_v = 0$, we assume that the number of added seeds is large enough to cover all components of the graph. This allows us to add seeds to each component of the graph separately. As a simplifying assumption, in the experiments, we only consider the case (in directed graphs) when the components are strongly connected. In particular, rather than running the heuristics on all of the components, we just use the largest strongly connected component of the graph.

We also varied our intervention size between $k = 1$ and 100, independent of the size of the graph. This is a typical number of seeds used for interventions in the literature, and considering the application – recommending a job position – is a practical intervention size. We varied α – the probability of message transmission across an edge – in the range $\{0.1, 0.2, 0.3, 0.4, 0.5\}$[3]. Above this range information spreads so effectively that all algorithms are indistinguishable. Below this range the utilities p_v obtained are small enough that it is hard for Monte Carlo estimation to distinguish between them. We run 1000 simulations in order to estimate probabilities for any given seed set and repeat each heuristic 20 times, reporting the average result.

As a baseline, we used the algorithm TIM+ [35], which was designed to optimize maximum reach. While this procedure is not a true baseline (it does not directly optimize $\min p_i$), it provides insight into how existing methods for maximum reach might work in this newer setting. We also use as a baseline picking the k seeds uniformly at random (which we will refer to as Random).

[3]We report results for $\alpha \ge 0.3$ for brevity. Behavior below this range was similar.

(a) Initial probabilities (with one seed). (b) Degree of the vertex. (c) Distance from the center.

Figure 6: Correlations between the set of probabilities of access after intervention and three proxies for position in a network in the Arenas graph. Bars correspond to one standard deviation computed over 20 runs of each of the heuristics.

Table 1: Overview of the data sets we use.

Name	Nodes	Edges	Direction
EU [22]	803	24729	Directed
Arenas [1, 17]	1133	5451	Directed
Irvine [28]	1294	19026	Directed
Facebook [24]	4039	24729	Undirected
ca-GrQc [22]	4158	13428	Undirected
ca-HepTh [22]	8638	24827	Undirected

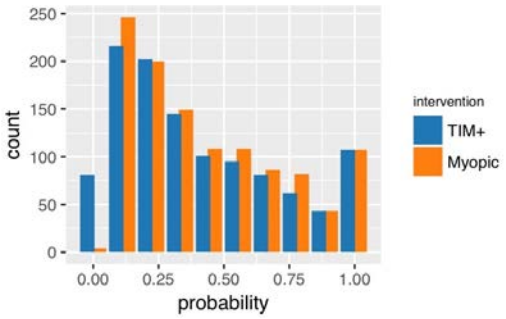
5.2 Maximin and network structure

In practice, what are the effects of using maximin over max reach as the objective? We give evidence that when maximizing reach instead of using maximin, interventions end up strongly reflecting the existing structure of the network. That is, vertices are more likely to become seeds if they are close to the center of the network, where probabilities of receiving the information are *already* high and do not need as many additional interventions.

We show this by measuring the correlation between the probability of receiving information before intervention versus after intervention. We use as a simple proxy for 'before intervention' the probabilities p_v when the vertex with the highest degree is the sole seed. Figure 6a shows the correlation between these two sets of probabilities in the Arenas graph, and indeed the correlation is significantly higher when using TIM+ than when using Myopic.

Assuming every vertex is equally deserving of information, we do not want 'well-positioned' vertices to have an advantage simply because they are well-positioned. Thus, we look at the correlation between the probability of information access after intervention and a few other proxies for position in a network. Figures 6b and 6c show the results for the degrees of the vertices as well as their distances from the center of the graph. Using TIM+, as the distance decreases towards the center or the degree of the node increases, the probabilities of information access increase, leading to a larger (negative) correlation. Again, this effect is lessened by using Myopic, whose resulting probabilities correlate less than TIM+ with both the degree of the vertex and the distance from the center. In other words, Myopic reduces the correlation between vertices' probability of receiving the information and how well connected the vertices are. Naïve Myopic yields very similar results to Myopic, as again seen in Figure 6.

In addition, Myopic changes the distribution of probabilities $\{p_{v_1}, \ldots, p_{v_{|V|}}\}$. Not only does it decrease the number of vertices with very low probability of receiving the information, but it also increases the number of vertices with larger probabilities over a broad range of probabilities, as seen in Figure 7.



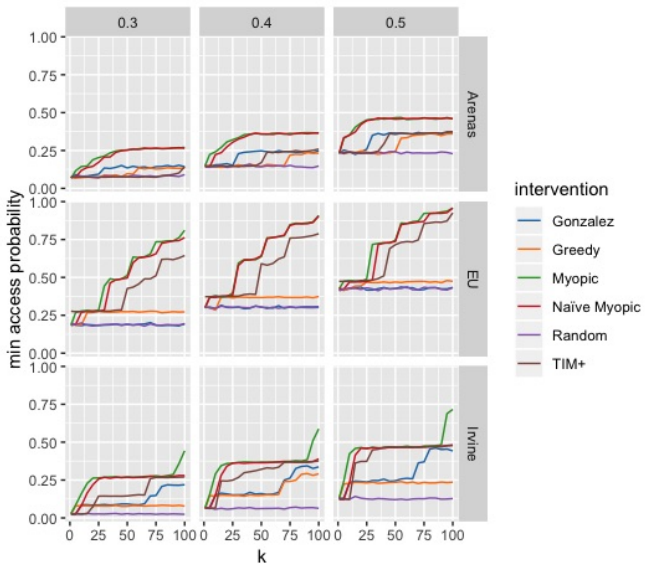


Figure 7: Distribution of probabilities over all vertices in the Arenas graph after adding 100 seeds with $\alpha = 0.1$.

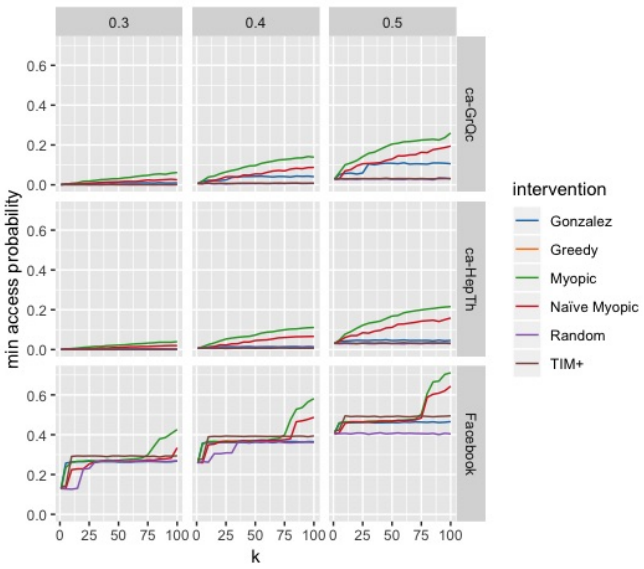

5.3 Heuristic performance

We now study the behavior of the heuristics described in the previous section. We would like to know how they compare in terms of effectiveness (maximizing $\mu_{-\infty}$) and speed.

We present effectiveness results in Figure 8. We omitted the heuristic Greedy when experimenting with larger data sets because it was prohibitively slow. Note that in both charts, the Myopic and Naïve Myopic heuristics consistently outperform the other methods for all ranges of α and intervention size k. The heuristics that do not use estimation are all consistently poor performers, and TIM+ performs well but is consistently dominated. For the smaller data sets, shown in Figure 8a, Greedy also does fairly well.

(a) Smaller data sets.

(b) Larger data sets.

Figure 8: Comparison of the six heuristics with respect to the minimum probability for values of $\alpha = \{0.3, 0.4, 0.5\}$.

Table 2: Speed of each of the heuristics on three data sets for 100 seeds. Times to completion are averaged over 20 runs.

Algorithm	Average time (s)		
	Arenas	EU	Irvine
Random	0.007	0.015	0.012
Gonzalez	0.021	0.031	0.033
Naïve Myopic	0.086	0.208	0.184
TIM+	0.876	1.826	1.046
Myopic	8.910	19.438	16.755
Greedy	507.35	759.296	1399.26

The running time of the heuristics is summarized in Table 2, which shows there is a natural tradeoff between running time and effectiveness. In particular, while the methods that make no use of estimation yield poorer quality results, they run extremely fast because they avoid the expensive step of estimating probabilities. Among the heuristics that estimate probabilities, Naïve Myopic is the fastest, with TIM+ also comparable, while the Myopic heuristic is an order of magnitude more expensive. Greedy is still another order of magnitude slower than Myopic, making it prohibitively expensive to compute in even relatively small graphs.

5.4 Performance on max reach

While the goal of the introduced heuristics is to maximize the minimum information access, it is also valuable to measure them by their average reach $\frac{1}{|V|}\sum_{v \in V} p_v$ to see if they are effective at spreading information to a large number of vertices. We compare the performance of Naïve Myopic and Myopic to TIM+ on this measure over three datasets (see Figure 9). The results show that while Naïve Myopic does not perform well to maximize reach, Myopic appears to outperform TIM+ even though TIM+ was designed for average reach and Myopic was not. This is likely because each seed added by Myopic is guaranteed to increase reach on the graphs, while algorithms that focus on maximizing reach may inadvertently provide access to nodes already reached. However, recall that Myopic is much slower than TIM+ (see Table 2) and so this potential improvement does not come without pitfalls. This tradeoff between average and minimum reach seems worthy of further study.

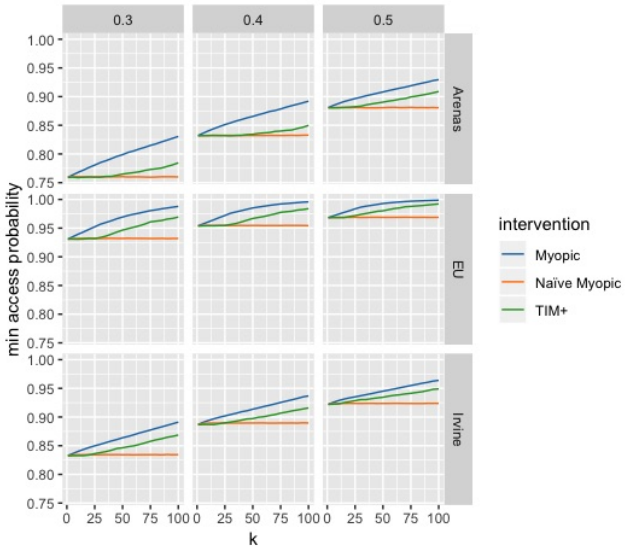

Figure 9: Comparison of three heuristics with respect to reach, the average probability after intervention, for $\alpha = \{0.3, 0.4, 0.5\}$.

ABSTRACT

Web systems that provide the same functionality usually share a certain amount of items. This makes it possible to combine data from different websites to improve recommendation quality, known as the *cross-domain recommendation* task. Despite many research efforts on this task, the main drawback is that they largely assume the data of different systems can be **fully shared**. Such an assumption is unrealistic — different systems are typically operated by different companies, and it may violate business privacy policy to directly share user behavior data since it is highly sensitive.

In this work, we consider a more practical scenario to perform cross-domain recommendation. To avoid the leak of user privacy during the data sharing process, we consider sharing only the information of the item side, rather than user behavior data. Specifically, we transfer the item embeddings across domains, making it easier for two companies to reach a consensus (e.g., legal policy) on data sharing since the data to be shared is user-irrelevant and has no explicit semantics. To distill useful signals from transferred item embeddings, we rely on the strong representation power of neural networks and develop a new method named as NATR (short for ***N**eural **A**ttentive **T**ransfer **R**ecommendation*). We perform extensive experiments on two real-world datasets, demonstrating that NATR achieves similar or even better performance than traditional cross-domain recommendation methods that directly share user-relevant data. Further insights are provided on the efficacy of NATR in using the transferred item embeddings to alleviate the data sparsity issue.

CCS CONCEPTS

• Information systems → Collaborative filtering; **Recommender systems**; **• Security and privacy → Privacy-preserving protocols**.

1 INTRODUCTION

In the current Web ecosystem, it is common that some websites have a certain degree of homogeneity in their functionality and provided information. For example, there are many overlapped hotels on Trip.com and Booking.com, overlapped movies on IMDb and Douban[1], and overlapped products on Amazon and eBay. From the perspective of building recommendation services, it means

[1]Douban.com is a Chinese website that allows registered users to rate movies, music, books, etc.

https://doi.org/10.1145/3308558.3313538

that the models for such two homogeneous domains are dealing with many items that are the same. This provides opportunities to improve the recommendation quality by enriching data. For example, if domain A does not have sufficient data on some items (*i.e.*, sparse or cold-start items) while the other domain B does have, e.g., a movie first released in US may have many ratings on IMDb but not on Douban, then the recommendation for these items on domain A can be potentially improved by integrating the data of domain B. The task of leveraging auxiliary data from other domains to improve recommendation quality of the target domain is known as the *cross-domain recommendation* [1, 10, 15, 32, 35, 43].

Existing works on cross-domain recommendation have primarily focused on directly aggregating data from multiple domains [1, 15, 32, 35, 43]. In other words, these methods assume that during model training of the target domain, user behavior data of other domains are directly accessible. For example, the representative Collective Matrix Factorization (CMF) [32] method extends Matrix Factorization (MF) by jointly learning user embeddings and item embeddings from the user-item interaction matrix of multiple domains. Despite effectiveness, the assumption that user behavior data can be fully shared across domains is questionable. Typically, different domains (websites) are operated by different companies, and thus it is difficult to let them share user behavior data due to the constraint of company policy.

In this work, we aim to provide a more realistic solution for cross-domain recommendation. To avoid any chance of leaking user privacy, we abandon the sharing of user-relevant data, neither behavior logs nor demographic attributes. However, this will pose challenges to transfer the collaborative filtering (CF) signal from one domain to another, since CF is typically modeled through mining user-item interaction data (e.g., user purchase and click logs). To address this technical challenge, we propose to share the item embeddings, which are learned by reconstructing user-item interaction matrix. The advantages are two-fold: 1) item embeddings can still encode certain CF signal by reflecting item similarities based on user behaviors (e.g., which items are frequently co-rated by users)[2], and 2) item embeddings are latent vectors that have no explicit semantics; as such, the risk of leaking user privacy can be kept to a minimum, which makes it easier for two companies to reach a legal policy for data sharing[3].

Our proposed solution, which has three steps, is illustrated in Figure 1. In the first step, an embedding-based recommender model, MF for example, is trained on the user-item interaction matrix of the auxiliary domain to obtain item embeddings. In the second step, item embeddings of the auxiliary domain are sent to the target domain; note that only the embeddings of overlapped items are necessary to be sent, which are subjected to the data-sharing policy between two companies. Finally, the target domain trains a recommender model with the consideration of the transferred item embeddings. The first two steps are straightforward to implement, and the main challenges lie in how to design a model to effectively incorporate transferred item embeddings in the last step. We summarize the key challenges as follows.

[2]A representative example of using the signal in item embeddings for recommendation is the item-based CF methods [13, 17].

[3]https://www.nytimes.com/interactive/2018/06/03/technology/facebook-device-partners-users-friends-data.html

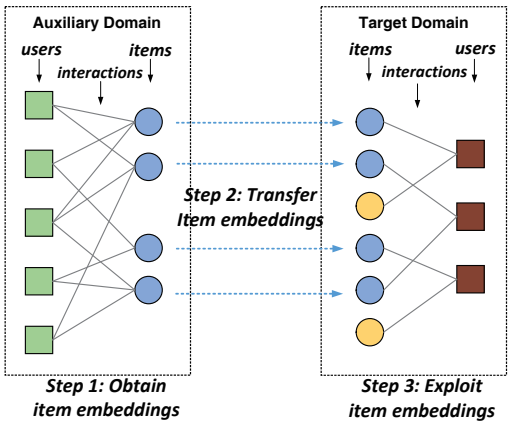

Figure 1: Illustration of our solution for cross-domain recommendation without sharing user-relevant data.

- **Unclear predictive signal of transferred item embeddings**. It is unclear whether and which transferred item embeddings contain useful signal in estimating a user's preference on an item in the target domain. Note that one motivation of conducting cross-domain recommendation is to alleviate the data sparsity problem in the target domain. However, the data sparsity problem may also exist in the auxiliary domain for some items, or the other way round the data in the target domain is already sufficient and does not require extra supplement. As such, it is challenging to distill useful signal from the transferred item embeddings and integrate them into the predictive model of the target domain.
- **Varying importance of transferred item embeddings**. As mentioned, the data of the auxiliary domain is not oracle — it is likely that user behaviors on some items are sparse and are insufficient to learn good embeddings for them. As such, it is a common case that the quality of item embeddings varies, where items of many users behaviors may have good quality and vice versa. Since it is already difficult to judge the quality of learned item embeddings for the auxiliary domain, it becomes even more challenging for the target domain to utilize such unknown- and varied- quality item embeddings well.
- **Embedding dimension discrepancy in latent space**. The data for training in the two domains may be of different scale and have different distribution. Therefore, the optimal embedding size for the two domains may be different. As such, existing cross-domain recommendation solutions that perform regularization on embedding matrices will fail [26]. Moreover, even though we restrict their embedding sizes to be the same, the semantics of their embedding dimensions are different and cannot be directly aligned.

To solve the above mentioned challenges, we design a novel model named **N**eural **A**ttentive-**T**ransfer **R**ecommendation (NATR). Briefly, our proposed method relies on the strong representation power of neural networks and discriminative power of attention

mechanisms to leverage the transferred item embeddings. Specifically, we design 1) a domain-level attention unit to dynamically adjust the importance of the predictive signal of the two domains; 2) an item-level attention unit to determine which embeddings of transferred items are more useful in constructing user representation for further prediction; and; 3) a domain adaption layer to bridge the discrepancy between the embedding space of the two domains. By tailoring our solution for addressing the highlighted challenges, our NATR method demonstrates its strong performance in cross-domain recommendation, and meanwhile preserves user privacy during data sharing.

To summarize, the main contributions of this work are as follows.

- We present a new paradigm for cross-domain recommendation without sharing user-relevant data, in which only item-side data can be shared across domains. To allow the transferring of CF signal, we propose to share the item embeddings which are learned from user-item interactions of the auxiliary domain.
- We propose a new solution NATR to resolve the key challenges in leveraging transferred item embeddings. The two-level attention design allows NATR to distill useful signal from transferred item embeddings, and appropriately combine them with the data of the target domain.
- We conduct extensive experiments on two real-world datasets to demonstrate our proposed method. More ablation studies verify the efficacy of our designed components, and the utility of transferred item embeddings in addressing the data sparsity issue.

The remainder of this paper is as follows. We first formulate the research problem in Section 2. We then elaborate our proposed method in Section 3. We conduct experiments in Section 4, before discussing related work in Section 5. Lastly, we conclude this paper in Section 6.

2 PROBLEM FORMULATION

We first introduce some notations used in the paper. We represent matrices, vectors, and scalars as bold capital letters (*e.g.,* $\mathbf{X}$), bold lower letters (*e.g.,* $\mathbf{x}$), and normal lowercase letters (*e.g.,* x), respectively. If not otherwise specified, all vectors are in a column form; $\mathbf{X}^T$ denotes the transpose of $\mathbf{X}$. We use symbols σ, *ReLU*, and $\odot$ to denote the *sigmoid* function, rectifier function, and element-wise production operation, respectively.

2.1 Cross-domain Recommendation

A typical problem setting of *cross-domain recommendation* is leveraging the data from an *auxiliary* domain to facilitate the recommendation quality in a *target* domain with overlapped items. In the *target domain*, where M and N denote the number of users and items, respectively, we have a user-item interaction matrix $\mathbf{Y}^t \in \mathbb{R}^{M \times N}$ with a binary value at each entry defined as,

$$y^t_{ui} = \begin{cases} 1, & \text{if } u \text{ has interacted with } i; \\ 0, & \text{otherwise.} \end{cases} \tag{1}$$

Similarly, in the *auxiliary domain*, we have another binary user-item interaction matrix $\mathbf{Y}^a \in \mathbb{R}^{K \times L}$, where K and L are the number of users and items. Note that a portion of L items also occurs in the target domain, which are named as *bridge items*. From the interaction matrices $\mathbf{Y}^t$ and $\mathbf{Y}^a$, the goal of cross-domain recommendation is to learn a predictive function to estimate the likelihood that a given user u will interact with item i in the target domain.

2.2 Cross-domain Recommendation Without Sharing User-relevant Data

Distinct from the typical problem settings of cross-domain recommendation, we abandon the direct sharing of user behavior data (the user-item interaction matrix $\mathbf{Y}^a$ in the auxiliary domain). This is because directly sharing user behavior data may violate the business privacy policy of different companies operating the auxiliary and target domains. Instead, we propose a solution that only transfers the embeddings of bridge items which are offline learned in the auxiliary domain, as illustrated in Figure 1. We define the transferred item embedding matrix $\mathbf{Q}^a = [\mathbf{q}^a_1, \cdots, \mathbf{q}^a_N] \in \mathbb{R}^{D' \times N}$ as,

$$\mathbf{q}^a_i = \begin{cases} \tilde{\mathbf{q}}^a_i, & \text{if item } i \text{ is a bridge item;} \\ \mathbf{0}, & \text{otherwise;} \end{cases} \tag{2}$$

where $\mathbf{0} \in \mathbb{R}^{D'}$ is an all-zero vector and $\tilde{\mathbf{q}}^a_i \in \mathbb{R}^{D'}$ is the offline learned embedding of item i in the auxiliary domain. It should be noted that we organize the transferred item embeddings in $\mathbf{Q}^a$ in the same order of item IDs in the target domain to enable looking up an item embedding with its ID. Here we assume the availability of $\tilde{\mathbf{q}}^a_i$, *i.e.,* the company operating the auxiliary domain has employed an embedding-based recommendation system [19]. Note that the assumption is practical since embedding-based recommendation solutions are widely applied in the industry [4, 5].

After introducing the transferred item embeddings $\mathbf{Q}^a$ from the auxiliary domain, we formulate the problem of cross-domain recommendation without sharing user-relevant data as follows,

Input: The user-item interaction data in the target domain $\mathbf{Y}^t$, and the transferred item embeddings $\mathbf{Q}^a$ from the auxiliary domain.

Output: A predictive model to estimate the likelihood that a user u will interact with an item i in the target domain. Specifically, taking u, i, and $\mathbf{y}^t_u$ which is the interaction history[4] of u in the target domain, as input, the model has to predict,

$$\hat{y}^t_{ui} = f(u, i, \mathbf{y}^t_u), \tag{3}$$

where $\hat{y}^t_{ui} \in [0, 1]$ denotes the probability of interaction between user u and item i.

After obtaining the predictive model, we can use it to score all items for a given user u, and select the top-ranked (*i.e.,* with higher interaction probability) items as the recommendation results for u. It should be noted that there indeed exist user and item attributes in both the auxiliary and target domains. However, to simplify the scenario of the cross-domain recommendation task, we only emphasize the user-item interactions, which is a common setting of existing works [26, 43].

3 PROPOSED METHOD

To solve the problem of cross-domain recommendation without sharing user-relevant data, we rely on the strong representation ability of neural networks and devise a new solution, named NATR,

[4]Note that $\mathbf{y}^t_u$ is the transpose of the u-th row of $\mathbf{Q}^t$.

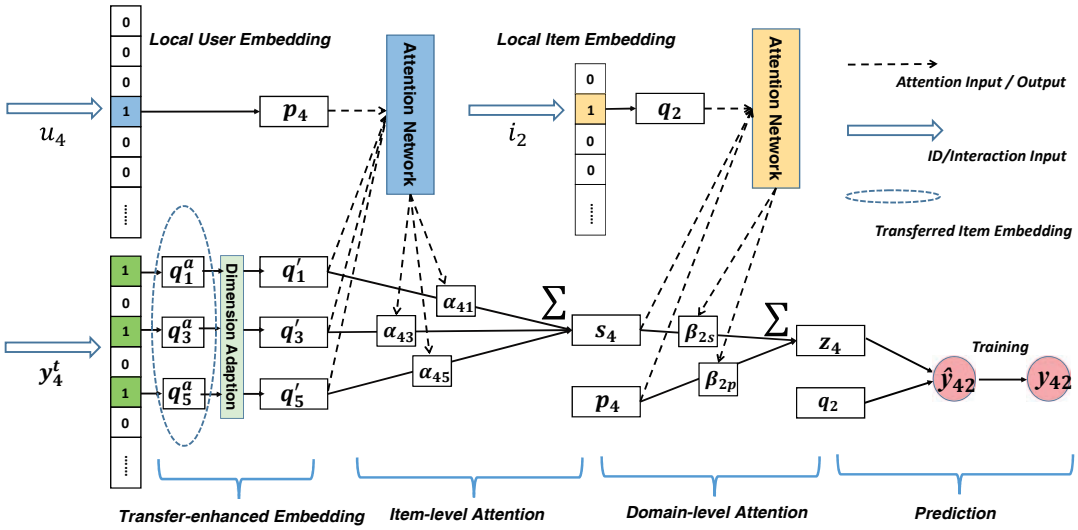

Figure 2: The architecture of our proposed Neural Attentive Transfer Recommendation model. (Here we take the prediction of user-item pair $(4, 2)$ as an example; user 4 has interacted with item 1, 3, and 5 in the target domain; then we utilize q_1^a, q_3^a, and q_5^a transferred from the auxiliary domain to assist predicting y_{42} in the target domain. Note that q^a is the only available auxiliary data in the target domain.)

exploiting the transferred item embeddings. Figure 2 illustrates the architecture of our proposed NATR model, which are made up of the following four layers.

- **Transfer-enhanced Embedding Layer**. We project sparse user and item representations into dense vectors. A dimension-adaption module is adopted to solve the dimension discrepancy problem of transferred item embeddings.
- **Item-level Attentive Layer**. To enrich user representations, we fuse the transferred embedding of items a user interacted with to an *additional user embedding* with an item-level attention unit to model the varying importance of items.
- **Domain-level Attentive Layer**. With a consideration of the diversity across domains, we make use of a domain-level attention unit to control the influence of predictive signals from two domains.
- **Prediction Layer**. Finally, we utilize an inner-product model as the predictive function since our work mainly focuses on devising a framework to exploit the transferred item embeddings.

In the following, we elaborate the details of the aforementioned four layers.

3.1 Transfer-enhanced Embedding Layer

Latent factor model (LFM) is one kind of general framework in collaborative recommender systems, which associates each user and item with real-valued vectors . Considering that LFMs have achieved success in a wide range of recommendation tasks [16, 17, 19, 24, 28], we project sparse user and item representations into real-valued vectors. Specifically, we first encode user ID (u) and item ID (i) into one-hot encodings as follows,

$$\mathbf{v}_u^U = \text{one-hot}(u), \mathbf{v}_i^I = \text{one-hot}(i), \tag{4}$$

where $\mathbf{v}_u^U$ ($\mathbf{v}_i^I$) $\in \mathbb{R}^N$ is a vector with all zero values except the u-th (i-th) entry with value 1. We then project the sparse one-hot encodings ($\mathbf{v}_u^U$ and $\mathbf{v}_i^I$) and multi-hot interaction history ($\mathbf{y}_u^t$) to *local embeddings* and *transferred embeddings*, respectively.

Local embeddings. To project the one-hot user (item) encoding, we employ an embedding layer, which is defined as a fully connected layer without bias term as follows,

$$\mathbf{p}_u = \mathbf{P}^T \mathbf{v}_u^U, \quad \mathbf{q}_i = \mathbf{Q}^T \mathbf{v}_i^I, \tag{5}$$

where $\mathbf{P} \in \mathbb{R}^{N \times D}$ and $\mathbf{Q} \in \mathbb{R}^{M \times D}$ are the parameters to be learned. The obtained embeddings $\mathbf{p}_u$ and $\mathbf{q}_i \in \mathbb{R}^D$ are named as *local embeddings* since they are learned merely with information from the target domain.

Transferred embeddings. In our problem, transferred embeddings of bridge items are the only auxiliary data accessible in the target domain. From the perspective of representative learning, there are two manners to leverage these item embeddings in collaborative filtering: user-based [24, 28] and item-based [13, 17]. Specifically, when predicting the probability that user u will choose item i in the target domain, user-based CF means directly combining embeddings of i of two domains to match $\mathbf{p}_u$ while item-based manner means matching $\mathbf{q}_i$ with transferred embedding of user's historically interacted items. There are two key aspects to make item-based manner a more convincing choice. First, when item i is not a bridge item, user-based CF solution cannot bring any help to prediction. Second, user-based CF can only distill implicit preferences while neglecting the explicit preferences of a user (*i.e.*, the historically

interacted items), while item-based CF can extract explicit preferences through leveraging transferred embeddings of bridge items and multi-hot encoding of historical interactions to enrich user representation.

Therefore, we look up the transferred embedding $\mathbf{q}_j^a$ from $\mathbf{Q}^a$ for each item j with $y_{uj}^t = 1$. Note that $\mathbf{q}_j^a$ will be an all-zero vector if item j is not a bridge item (see Equation 2 for details). As mentioned above, there may exist the challenge of *embedding dimension discrepancy* across two domains, *i.e.,* $D \neq D^{'}$, since the training data in two domains may be of different scale and have different distribution. To solve this problem, we employ a fully-connected layer to adapt the dimension of transferred embeddings, which is formulated as follows,

$$\mathbf{q}_j^{'} = \mathbf{W}_0^T \mathbf{q}_j^a + \mathbf{b}_0, \tag{6}$$

where $\mathbf{W}_0 \in \mathbb{R}^{D^{'} \times D}$ and $\mathbf{b}_0 \in \mathbb{R}^D$ are learnable parameters of mapping matrix and bias. Note that $\mathbf{W}_0$ and $\mathbf{b}_0$ are the only parameters here as the transferred embedding matrix $\mathbf{Q}^a$ is learned offline in the auxiliary domain.

With the above neural components, we project the sparse one-hot and multi-hot encodings into local user and item embeddings, $\mathbf{p}_u$ and $\mathbf{q}_i$, and transferred item embeddings, $\{\mathbf{q}_j^{'} | y_{uj}^t = 1\}$. We introduce our item-based CF solution of leveraging transferred item embeddings detailedly in the following parts.

3.2 Item-level Attentive Layer

The key objective of embedding-based recommendation model is to capture relation between of user and item in the latent space [41], therefore it is critical to explicitly build the relation between transferred item embeddings and local user embedding in our problem. As mentioned above, motivated by item-based CF [13, 17], which encodes the historical interaction behaviors of a user to enrich the user representation, we fuse the transferred item embeddings $\{\mathbf{q}_j^{'} | y_{uj}^t = 1\}$ into an *additional user embedding* $\mathbf{s}_u$. Besides historical interactions, $\mathbf{s}_u$ also contains CF signals transferred from the target domain, which can further enhance user representation. Our first inspiration to calculate $\mathbf{s}_u$ is average pooling, a widely used modeling component in neural networks, formulated as follows,

$$\mathbf{s}_u = \frac{\sum_{\{j | y_{uj}^t = 1\}} \mathbf{q}_j^{'}}{|\mathbf{y}_u^t|}, \tag{7}$$

where $|\mathbf{y}_u^t|$ is the l_1-norm of vector $\mathbf{y}_u^t$, which equals to the number of items user u has interacted with.

However, as mentioned above, there exists another key challenge of *varying importance of embeddings*. Considering that different interacted items have embeddings with varying quality and varying importance to represent the preference of a given user, such naive operation may not work well in real scenario. Therefore, we apply a non-uniform coefficient when fusing the transferred item embeddings:

$$\mathbf{s}_u = \frac{\sum_{\{j | y_{uj}^t = 1\}} \alpha_{uj} \mathbf{q}_j^{'}}{|\mathbf{y}_u^t|}. \tag{8}$$

To model the various item importance in a user-sensitive fashion, here we introduce attention mechanism, which has achieved great success in recommendation tasks [3, 13, 40] and natural language processing [20, 37]. Specifically, the item-level attention unit learns a specific weight α_{uj} for every transferred item embedding $\mathbf{q}_j^{'}$ according to the following formulation,

$$\begin{aligned} \alpha_{uj} &= \frac{e^{a_{uj}}}{\sum_{\{k | y_{uk}^t = 1\}} e^{a_{uk}}}, \\ a_{uj} &= \mathbf{w}_1^T ReLU(\mathbf{p}_u \odot \mathbf{q}_j^{'}) + b_1, \end{aligned} \tag{9}$$

where $\mathbf{w}_1 \in \mathbf{R}^D$ and b_1 denote the weight matrix and bias of a fully connected layer. The input of the item-level attention unit is the interaction between the user and target item, which makes the learned attention score sensitive to the given user.

3.3 Domain-level Attentive Layer

After obtaining the *local* and *additional* user embeddings, our task become learning a prediction function based on these three embeddings. Different from traditional recommendation models, here we have an extra user embedding. To exploit two user embeddings, we fuse them into an *unified embedding*. This is inspired by some cross-domain recommendation models [33, 43], which have demonstrated that fusing embedding vector learned from multi-modal data is a simple but yet effective way to combine signals. Another option is to separately estimate the interaction probability with the two embeddings and fuse the predictions (late fusion). Here we employ early fusion that merges embeddings, allowing us to explicitly capture the interaction between two embeddings.

The *unified embedding* via fusion can be denoted as,

$$\mathbf{z}_u = \beta_{si} \mathbf{s}_u + \beta_{pi} \mathbf{p}_u, \ s.t., \ \beta_s + \beta_p = 1, \tag{10}$$

where β_{si} and β_{pi} are learnable weights for $\mathbf{s}_u$ and $\mathbf{p}_u$, respectively. The aim of β_{si} and β_{pi} is to balance the information from auxiliary and target domain regarding the target item i. In other words, these two weights are item-sensitive. We devise such design to address the key challenge of *unclear predictive signal* which has been mentioned before. That is, in real scenario evaluating different items needs varying amount of auxiliary information. Although we can directly learn β_{si} and β_{pi} by optimizing a final objective function, we rely on the promising representation ability of attention network to model them. Formally, a domain-level attention module is designed as,

$$\begin{aligned} \beta_{si} &= \frac{e^{b_{si}}}{e^{b_{si}} + e^{b_{pi}}}, \ \beta_{pi} = \frac{e^{b_{pi}}}{e^{b_{si}} + e^{b_{pi}}}, \\ b_{si} &= \mathbf{w}_2 ReLU(\mathbf{s}_u \odot \mathbf{q}_i) + b_2, \\ b_{pi} &= \mathbf{w}_2 ReLU(\mathbf{p}_u \odot \mathbf{q}_i) + b_2, \end{aligned} \tag{11}$$

where $\mathbf{w}_2 \in \mathbb{R}^D$ and b_2 are the parameters of the attention network. Note that the input of the attention network is the interaction between user ($\mathbf{s}_u / \mathbf{p}_u$) and item embeddings, which enables the learned attention scores to be sensitive to item i.

3.4 Prediction Layer

After the operation in aforementioned layer, our problem further turns to predict user interaction with two embeddings: unified user embedding vector $\mathbf{z}_u$ and item embedding vector $\mathbf{q}_i$. Here we adopt a predictive function to estimate y_{ui}^t which is the interaction probability between a given pair of user and item (u, i). Since our work mainly focuses on a general framework for cross-domain

recommendation without sharing user-relevant data, we adopt a simple but widely-used inner product model, to estimate the value of y_{ui}^t, which is formulated as

$$\hat{y}_{ui}^t = \sigma(\mathbf{z}_u{}^T \mathbf{q}_i), \tag{12}$$

where σ is the *sigmoid* function. Note that this predictive function can be easily extended to more complicated ones, such as the multi-layer perceptron in [14].

To conclude, with three specially devised layers and a prediction layer, aforementioned three key challenges of our problem are addressed one by one.

3.5 Training

Objective Function. Following the probabilistic optimization framework [14, 28], we first define the likelihood function for an implicit interaction as follows,

$$P_r = \prod_{(u,i)\in\mathcal{Y}_+^t} \hat{y}_{ui}^t \prod_{(u,i)\in\mathcal{Y}_-^t} (1-\hat{y}_{ui}^t), \tag{13}$$

where $\mathcal{Y}_t^+$ denotes the set of observed interactions in interaction matrix of the target domain $\mathbf{Y}^t$ (entries with value of 1), and $\mathcal{Y}_-^t$ denotes negative instances sampled from the unobserved interactions in $\mathbf{Y}^t$ (entries with value of 0). We further take the negative logarithm of the joint probability, and obtain the loss function (*a.k.a, logloss* [29]), which is widely used to optimize recommendation systems with implicit feedbacks [14, 17, 24], to be minimized as follows,

$$\mathcal{L} = -(\sum_{(u,i)\in\mathcal{Y}_+^t} \log \hat{y}_{ui}^t + \sum_{(u,i)\in\mathcal{Y}_-^t} \log(1-\hat{y}_{ui}^t)). \tag{14}$$

To prevent over-fitting, we adopt l_2 regularization on the parameters in the proposed neural model and obtain the overall objective function,

$$\Gamma = \mathcal{L} + \lambda \sum_{\mathbf{\Theta}\in\{\mathbf{P},\mathbf{Q},\mathbf{W}_0,\mathbf{b}_0,\mathbf{w}_1,b_1,\mathbf{w}_2,b_2\}} \|\mathbf{\Theta}\|_F^2. \tag{15}$$

Mini-batch Training. We adopt stochastic gradient descent (SGD) [34], a widely generic solver for neural models, to optimize our proposed NATR model in the mini-batch mode. To construct a mini-batch, we first sample a batch of historical user-item interaction pairs (u, i). For each (u, i), we then adopt a negative sampling technique [24], which is widely used to handle implicit feedbacks in existing researches [14, 28, 43], to randomly select unobserved items $\{i_1^{'}, \cdots i_n^{'}\}$ for user u with a sampling ratio of n. After the sampling, we obtain n triplets $\{(u, i, i_1^{'}), \cdots, (u, i, i_n^{'})\}$ for each instance in the batch. With the constructed mini-batch, we take a gradient step to minimize the objective function.

4 EXPERIMENTS

In this section, we conduct extensive experiments on two real-world datasets to answer the following research questions:

- **RQ1:** How does our proposed NATR model perform compared with the state-of-the-art methods for cross-domain recommendation tasks?
- **RQ2:** Can the proposed NATR alleviate the data sparsity problem in the target domain?
- **RQ3:** What are the effects of the item-level and domain-level attention models in our proposed NATR?

In what follows, we first describe the experimental settings, and then answer the above three research questions.

Table 1: Statistics of our evaluation datasets.

Dataset	Item#	Auxiliary Domain		Target Domain	
		User#	Rec#	User#	Rec#
ML-NF	5,568	31,038	2,269,179	14,630	152,206
TC-IQI	4,851	35,398	314,621	19,999	78,429

4.1 Experimental Settings

4.1.1 Datasets. We experiment with two real-world datasets that both contain implicit interactions from two domains.

- **ML-NF Dataset.** MovieLens and Netflix are two popular platforms with movie recommendation services, in which there are a large portion of overlapped movies. Here we take MovieLens (ML) and Netflix (NF) as the *auxiliary* and *target* domains (*i.e.,* our target is to improve the recommendation performance in NF), respectively. We obtain user-movie interactions in ML and NF from two widely used public movie rating datasets[5][6]. Note that we identify movies with the same name in the two datasets as *bridge items*. Here we conduct whole-string matches to avoid wrong matches as possible. By filtering bridge items and their associated ratings[7], we reserve 5,568 movies, 14,630 ML users and 31,038 NF users in this dataset. Finally, we intentionally transform the rating data into binary (1/0 indicate whether a user has interacted with an item or not) to fit the problem setting of implicit feedback [16].
- **TC-IQI Dataset.** This dataset is collected by [43] to evaluate *cross-domain recommendation* performance of online video contents. In this dataset, there are historical interactions between users and videos from two mainstream video websites, iQiyi[8] (IQI) and Tencent Video[9] (TC) in China. To investigate the performance of facilitating recommendation performance in target domain via leveraging information from auxiliary domain, we regard *IQI* (*TC*) as the *target* (*auxiliary*) domain since interactions in IQI are sparser. Similarly, we filter *bridge items* via exact name matching across videos from these two domains, and only reserve bridge items and interactions associated with them. Note that videos in this dataset are professional production content (PGC) widely available on multiple websites.

After the above pre-processing steps, we obtain two final datasets for performance evaluation, the statistics of which are summarized in Table 1.

[5] https://grouplens.org/datasets/movielens/
[6] https://www.kaggle.com/laowingkin/netflix-movie-recommendation/data
[7] To better evaluate the performance, we follow the setting of previous works [27, 32] and only reserve the bridge items (*i.e.*, neglect items occurring only in one domain). However, our model is also suitable to perform recommendation for those items not overlapped, which has been introduced in detail in Section 3.1
[8] https://www.iqiyi.com
[9] https://v.qq.com

4.1.2 Evaluation Protocols. Following existing works [12, 31], we employ the widely used *leave-one-out* evaluation protocol in the evaluation stage. Similar with [14, 18], given a user in the target domain, we randomly sample 99 items that are not interacted with the user, each method ranks one test item among the 99 sampled items. We then adopt two metrics, *HR* and *NDCG*, which are widely used in the literature of recommendation [6, 14, 39], to report the ranking performance of each method:

- **HR@K:** *Hit Ratio* (HR) measures whether the test item is contained by the top-K item ranking list (1 for yes and 0 for no).
- **NDCG@K:** *Normalized Discounted Cumulative Gain* (NDCG) extends HR by assigning higher scores to the hits at higher positions in the ranking list.

It should be noted that we calculate HR@K and NDCG@K for each test user, and report the average ones over the whole user set.

4.2 Performance Comparison (RQ1)

4.2.1 Baselines. We compare the performance of our proposed NATR with five baselines, which can be divided into two groups: *single-domain* and *cross-domain*. Here *single-domain* methods refer to those which are merely trained with data from the target domain, while *cross-domain* methods jointly consider the data from both the target and auxiliary domains.

The compared *single-domain* methods are introduced as follows:

- **PMF [24].** *Probabilistic Matrix Factorization* (PMF) is a MF based model which exploits negative sampling to handle implicit interaction data. It adopts *logloss* as the loss function and samples several negative items with a ratio when a positive item is fed for training. We tune the learning rate and regularizer and report the best testing performance.
- **GMF.** *Generalized Matrix Factorization* (GMF) is one of the variants of NCF (Neural Collaborative Filtering) [14], which is the state-of-the-art solution for recommendation tasks with implicit feedbacks. This method assign various weights for different dimensions in the dot-product prediction function, which can be regarded as a generalization of vanilla MF. We optimize this model and tune its associated hyper-parameters similarly with the paper.
- **NATR-local.** As mentioned in Section 3.1, our NATR model utilize an item-based CF to leverage transferred item embeddings. Therefore, it is still questionable whether the item-based CF is the only component to improve performance while transferred item embeddings do not help? To demonstrate the effectiveness of transferred embeddings, we degenerate the NATR via adopting local item embeddings rather than transferred item embeddings in the item-level attention unit. Therefore, it is a kind of *single-domain* method. We name it NATR-local and tune it similarly with NATR to report the best performance.

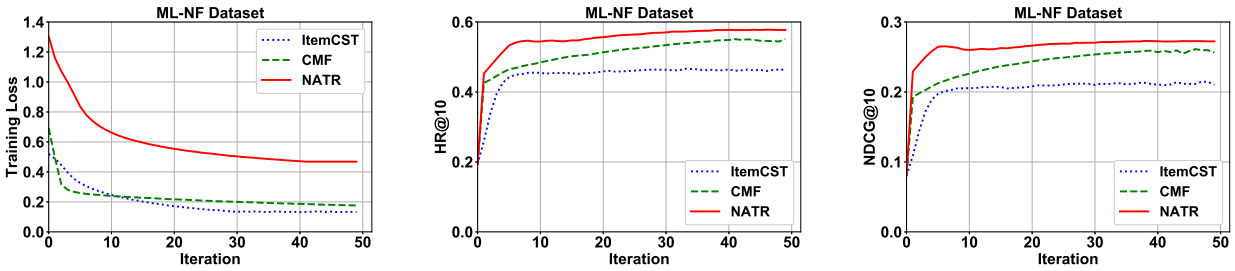
The compared *cross-domain* baselines are as follows.

- **CMF [32].** *Collective Matrix Factorization* (CMF) decomposes the data matrices of multiple interactions simultaneously while sharing embedding vectors of users or items. Here we factorize two interaction matrices from two domains, sharing embedding vectors of those *bridge items*. We carefully tune the weight of two domains, learning rate and regularizer to report the best performance. It is worth mentioning that a recent study on cross-domain recommendation [43] proposed a method named MPF, which adapted vanilla CMF to a special case where all users and items are all overlapped across domains. Apparently this special setting does not fit our problem where only item can be overlapped and regretfully MPF cannot be adapted to our task.
- **ItemCST [26].** *Coordinate System Transfer* (CST) also assumes that both users and items are overlapped and adds two regularization terms in objective functions. Specifically, the two terms set constraints to the embedding distance in two domains for those overlapped users or items. Thus, CST can be adapted to our problem by only reserving item-side regularization term in our task, and we name it as ItemCST. We tune the learning rate and coefficient of regularization term to report the best performance.

  To conclude, CMF is the state-of-art cross-domain recommendation method while facing with high risk of leaking user privacy since it assumes that all interaction data are fully shared. ItemCST is an adapted method from CST and as it only needs the transferred item embeddings to compute the regularization term of item, it preserves user-relevant data.

We implement the baseline methods and our NATR model in TensorFlow[10] It should be noted that we set the embedding size of all compared methods to be 64, which is a typical setting in literature [14, 17]. Our primary experiments also demonstrate that 64 is an embedding size with enough ability to represent the user and item.

4.2.2 Parameter Settings. To determine the optimal hyper-parameters of the method, we construct a validation set via randomly selecting an interacted item for each test user, which has not been selected as the test item. For our NATR, we initialize parameters with a widely used initialization method proposed in [11]. During the training phase, we intentionally set the negative sampling ratio as 4 to construct mini-batches with size of 256 as described in Section 3.5. To optimize the NATR model, we employ the Adagrad [7] optimizer and search its learning rate within {0.001, 0.002, 0.005, 0.01}. In addition, we tune the λ in Equation 15, which balances the loss and regularization terms, in {1e-2, 1e-3, 1e-4,1e-5,1e-6}. As mentioned before, ItemCST and our NATR only rely on the transferred item embeddings as auxiliary data, and in this paper, without loss of generality, we adopt PMF in the auxiliary domain and carefully tune its learning rate and regularizer to obtain item embeddings.



We first compare the top-K recommendation performance with baseline methods. We investigate the top-K performance with K setting to {1, 2, 5, 10}[11]. As described in the evaluation protocols, we test the performance of a ranking list with 100 items. As such, it is reasonable to choose relatively small K [14]. For every method,

[10] https://www.tensorflow.org

[11] Note that HR@K equals to NDCG@K when setting $K = 1$.

we carefully tune the hyper-parameters to report the best performance. In Table 2, we report the top-K recommendation performance for the two utilized real-world datasets. We compare our proposed NATR method with three single-domain baselines and two cross-domain ones. From these results, we have the following observations:

- **NATR significantly improves recommendation performance in the target domain.** 1) For those *single domain* methods that are trained with only interaction data from the target domain, the recommendation performance is relatively poor. PMF achieves the worst performance, which can be explained as the limited representation ability of MF model. 2) NATR-local, a degenerative model of the proposed NATR, outperforms PMF and GMF *w.r.t.* all metrics on the ML-NF dataset and most metrics on the TC-IQI dataset, which justifies the effectiveness of explicitly encoding users' historical interactions. 3) Compared with PMF, GMF, and NATR-local, the proposed NATR outperforms the best of them by 28.26% and 39.11% in HR@10 and NDCG@10 for ML-NF dataset and by 0.23% and 11.09% in HR@10 and NDCG@10 for TC-IQI dataset. It demonstrates that leveraging the item embeddings from the auxiliary domain enhances the recommendation quality in the target domain, which

(a) HR@10 (b) NDCG@10

Figure 5: Performance of all methods on items with different number of interaction records on ML-NF dataset.

further indicates that the proposed NATR is a promising solution for the cross-domain recommendation task.

- **NATR performs even better than those cross-domain methods with the risk of leaking user privacy.** We can observe that our proposed NATR model achieves the best performance compared to CMF and ItemCST regarding every evaluation metrics in the NF-ML dataset. For HR@10 and NDCG@10, NATR outperforms the best of them by 18.94% and 4.94%, respectively. We guess the reason of such results is that a joint training with data from two domains (CMF and ItemCST) might distract the loss during the optimization and converge at a status which balances the two domains rather than the optimal status of the target domain. We leave further investigations at the future work. To further study how these methods perform, we present the training loss and testing performance in each interaction in Figure 3 (for ML-NF dataset) and Figure 4 (for TC-IQI dataset). For every method in the two figures, we report the best parameter settings. For both datasets, all methods achieve stable performance after about 50 iterations. With fine hyper-parameter tuning to solve over-fitting, our proposed NATR can effectively outperform ItemCST and achieve similar or even better performance than CMF.
- **NATR effectively distills the CF signal encoded in transferred item embeddings.** NATR-local, a degenerative model of our proposed NATR, only utilizes interaction data from the target domain without exploiting transferred item embddings. Specifically, it replace the transferred item embedding in NATR to local item embeddings. On one hand, the experimental results in Table 2 show that NATR-local achieves better performance than GMF, a competitive method for single domain, demonstrating that taking the explicit preferences of users into consideration can improve recommendation performance. On the other hand, NATR outperforms NATR-local on two datasets which means the combining transferred embeddings are better than only a local CF solution on the target domain. This confirms the utility of transferred item embeddings in encoding CF signal from the auxiliary domain.

To summarize, these comparisons on two real-world datasets verify that our proposed NATR model can effectively leverage transferred item embeddings to improve the recommendation performance in the target domain.

4.3 Data Sparsity Problem (RQ2)

As mentioned in the introduction, one of the primary purposes for cross-domain recommendation is to alleviate item data sparsity problem (*i.e.*, items' records are too few) in the target domain. In particular, for those items with few interactions, of which the embeddings cannot be learned well in the target domain itself, transferred embeddings from the auxiliary domain play a bigger role. To study extensively how our proposed NATR model effectively helps to alleviate the item data sparsity issue, we compare the recommendation performance for items with different level of sparsity.

Specifically, we divide the items to several groups according to number of interaction records in the training set. Note that each group have similar number of items, which make the experimental results more reasonable. Then we apply the evaluation protocol, *leave-one-out*, which is the same with above experiments. For each item, its performance is defined as the average of HR@10 and NDCG@10 when it is in the test set. We compare the proposed NATR model with all five baseline methods in Figure 5. From the results, we can observe that when the interaction records of an item become sparser, the recommendation performance will go worse. For example, in the first group, of which each item has been interacted by only 1-10 users, the best performance of those single-domain methods is about only 0.220 for HR@10 and 0.098 for NDCG@10. Fortunately, with the help of the auxiliary domain, cross-domain methods can achieve better performance for those sparse items. Out of these methods, our proposed NATR model can achieve similar performance compared with CMF and better than ItemCST, which verifies that NATR can serve as a competitive cross-domain recommendation method without sharing user-relevant data.

In summary, our NATR model can improve recommendation performance effectively, no matter the historical records of items are sparse or dense. For items with sparser records, the improvement is more evident and meaningful.

4.4 Impact of Attention Mechanism (RQ3)

In NATR, we utilize the attention mechanism to solve two primary challenges. First, a domain-level attention unit is applied to distill useful signals from transferred item embeddings adn integrate them into the target domain. Second, an item-level attention unit is adopted to handle varying importance of transferred item embeddings. An intuitive question is whether the designed attention unit can really help in our model?

To answer it, we conduct experiments on two degenerative methods of NATR, in which two utilized attention network components are replaced by the simple operation of pooling (*i.e.*, average summation), respectively. We adopt the same evaluation methods with above experiments, and the performance comparison is shown in Table 3. We can observe that when removing item-level attention unit, the top-10 recommendation performance become poor, which

Table 3: Impact of Attention Mechanism.

Dataset	ML-NF	
Methods	**HR@10**	**NDCG@10**
NATR	0.5781	0.2726
Without Item-level Attention	0.5624	0.2655
Without Domain-level Attention	0.5669	0.2722

demonstrate the challenge of varying importance and our attention solution can address it. Besides, removing domain-level attention unit also make the recommendation performance worse. That is, the auxiliary domain cannot be considered as the same with the target domain simply. To conclude, the experimental results demonstrate the necessity of our two specially designed attention units.

In conclusion, extensive experiments on two real-world datasets verify the efficacy of our proposed model, and further studies demonstrate that our model can alleviate data sparsity problem. Moreover, the utility of our specially designed attention networks components is verified.

5 RELATED WORK

In this paper, we propose a solution for cross-domain recommendation without sharing user-relevant data based on neural networks. The closed related work can be divided into cross-domain recommendation and neural network based recommendation.

Cross-domain Recommendation To alleviate cold start and data sparsity issue, cross-domain recommendation is a typical solution which takes data from multiple domains into consideration. With the help of the auxiliary domain, cross-domain recommendation methods can achieve better performance (*i.e.* recommendation accuracy) than single-domain ones. Approaches of cross-domain recommendation can be broadly classified into two types: collaborative and content-based.

Collaborative cross-domain recommendation refers to those approaches utilizing interaction data (rating history, for example) from two domains. Ajit *et al.* [32] proposed a MF based model, CMF (Collective Matrix Factorization), which assumes a common global user factor matrix for all domains, and it factorizes matrices from multiple domains simultaneously. Li *et al.* [22] proposed a model named CBT (Code Book Transfer) which builds a matrix named codebook to represent cluster-level rating pattern and this codebook is shared by two domains. A recent study [43] considered a special task in which both users and items are overlapped, and they proposed a MF based model which assumes part of the user embeddings and whole item embeddings are shared across domains. With a similar setting, Man *et al.* [23] proposed a neural method which employs multi-layer perceptron to adapt user and item embeddings between two domains. Pan *et al.* [26] utilize auxiliary interaction data with a regularization term concerned with overlapped user and item in objective function in MF model. Another category of cross-domain recommendation models is content-based ones, which sharing attributes of user or items from auxiliary domain [1, 8, 45]. Agarwal *et al.* [1] proposed a MF based model in cross-domain recommendation when multi-modal user profiles are available. Elkahky *et al.* [8] transformed user profile and item attributes to dense vectors through deep neural network and matched them in latent space. Zhang *et al.* [45] utilize textual, structure and visual knowledge of items as auxiliary domain to aid building item embedding.

In this paper, we focus on collaborative cross-domain recommendation with auxiliary interaction data, a widely used setting in literature. Specifically, our problem is a typical system-level cross-domain recommendation task, where same items are shared across domains, according to the definition in two surveys [2, 21]. There is a common assumption in existing methods that the whole interaction data can be fully shared across domains, which has the risk of leaking user privacy since various domains may be operated by different companies. In this work, we advocate a more realistic settings that only item-side data can be shared.

Neural Network Based Recommendation. Salakhutdinov *et al.* [30] proposed RBM (Restricted Boltzmann Machines) to predict explicit ratings, which was the first work to apply neural networks to recommender systems. Recently, similar as the research field of CV and NLP, neural networks have achieved great success in recommender systems. Some works [14, 36, 42, 44, 46] relied on neural networks to learn to match function between users and items directly, which can be regarded as the extension of traditional collaborative filtering approaches. He *et al.* [14] proposed a general neural architecture for collaborative filtering, which learns the user-item interaction function via generalized matrix factorization and multi-layer perceptrons. Zhang *et al.* [46] mapped user and item to Hamming space and obtained matching score via neural networks. Tay *et al.* [36] proposed a relational-translation based match function to learn from interactions. Yang *et al.* [42] utilized neural networks to match user-item interaction and user-user relation simultaneously to perform a social recommendation task. Ying *et al.* [44] relied on graph conventional network for collaborative filtering to match huge mount of users and items in real recommender systems. Gao *et al.* [9] introduce multi-task learning to nueral networks to solve the task of recommendation with users' multiple types of behaviors. Besides, some works utilized neural networks to extract the auxiliary information and features in recommender systems, such as textual [25, 47], visual [3, 38], video [5], and hybrid [48].

In this paper, we propose a novel neural model to solve the challenges of extracting useful knowledge from item embedding of the auxiliary domain with the power of neural networks in representative learning.

6 CONCLUSION

In this work, we present a new cross-domain recommendation solution, which can avoid user privacy leakage by transferring only item embeddings from the auxiliary domain. To better exploit the transferred item embeddings, we propose a neural network method named NATR, combining item-level and domain-level attention mechanisms to address the challenges in cross-domain learning. We conduct extensive experiments on two real-world datasets, demonstrating that our NATR method can improve the recommendation performance of the target domain by 18.94%. To the best of our

knowledge, this is the first work that concerns user privacy in cross-domain recommendation, and presents a sound solution to exploit the predictive signal without sharing any user-relevant information.

There are three points about this work that we plan to address in future. First, although our method has taken the dimensionality discrepancy into consideration via a dimension-adaption fully-connected layer, we only empirically verify its effectiveness when two domains have the same embedding size. As such, we will study how different sizes of transferred embeddings would affect the recommendation performance. Second, we will study scalability of our method in industrial scenario where amount of users and items are very huge. Last, since this work only focuses on collaborative cross-domain recommendation, we will study the similar task in content-based scenario.

ABSTRACT

Good quality similarity metrics can significantly facilitate the performance of many large-scale, real-world applications. Existing studies have proposed various solutions to learn a Mahalanobis or bilinear metric in an online fashion by either restricting distances between similar (dissimilar) pairs to be smaller (larger) than a given lower (upper) bound or requiring similar instances to be separated from dissimilar instances with a given margin. However, these linear metrics learned by leveraging fixed bounds or margins may not perform well in real-world applications, especially when data distributions are complex. We aim to address the open challenge of "Online Adaptive Metric Learning" (OAML) for learning adaptive metric functions on-the-fly. Unlike traditional online metric learning methods, OAML is significantly more challenging since the learned metric could be non-linear and the model has to be self-adaptive as more instances are observed. In this paper, we present a new online metric learning framework that attempts to tackle the challenge by learning a ANN-based metric with adaptive model complexity from a stream of constraints. In particular, we propose a novel Adaptive-Bound Triplet Loss (ABTL) to effectively utilize the input constraints, and present a novel Adaptive Hedge Update (AHU) method for online updating the model parameters. We empirically validates the effectiveness and efficacy of our framework on various applications such as real-world image classification, facial verification, and image retrieval.

1 INTRODUCTION

Learning a good quality similarity metric for images is critical to many large-scale web applications such as image classification, face verification, and image retrieval. These applications are widely used for user identity verification in mobile apps and image recommendation in multi-media search engines. Therefore, having a scalable and high-performance technique for learning a good image similarity metric is becoming increasingly important. Various online metric learning (OML) solutions applying neural networks [4, 6, 12, 14, 19] have been proposed to learn a similarity metric from a stream of constraints. These constraints are typically collected and constructed from user clicks, indicating the similarity and dissimilarity relations among images. Two kinds of constraints, i.e., pairwise and triplet constraints, are widely-accepted in previous studies. A pairwise constraint consists of two similar or dissimilar images, while a triplet constraint is of the form (A, B, C), where image A is similar to image B, but is dissimilar to image C. Compared to offline metric learning approaches, OML algorithms do not require the entire training data to be made available prior to the learning task and hence are more suitable for web applications.

Despite the success of existing OML approaches in many applications, some intrinsic drawbacks have been recently observed. First, most of the existing OML algorithms [6, 12, 14, 19] are designed to learn a pre-selected linear metric (e.g., Mahalanobis distance) by solving a convex optimization problem. These simple metrics are unable to capture the non-linear semantic similarities among instances in complex application scenarios such as image retrieval with fine-grained sub-classes. Second, the performance of existing OML solutions depend heavily on the quality of input constraints, i.e., the true similarity or dissimilarity among example images (training data) provided by the user. These algorithms learn the metric model only from the "hard" constraints within the input and are biased towards them, thereby weakening the model robustness. Here, a constraint is "hard" if the dissimilar images in it is computed as similar by current metric and vice-versa. Moreover, filtering out "hard" constraints from a large volume of candidates is computationally expensive, and is impossible to perform in a real-time setting. In

addition, a real-world input stream usually contains limited number of "hard" constraints because we have little control on the source, i.e., the users. As a result, existing OML approaches may suffer from low constraint utilization in practical applications, leading to poor performance.

These intrinsic drawbacks result in the open challenge of "Online Adaptive Metric Learning" (OAML), i.e., how to learn a metric function with adaptive complexity as more constraints are observed in the stream, while maintaining high constraint utilization during the continuous learning process. This metric function should have a dynamic hypothesis space, ranging from simple linear functions to highly non-linear functions.

In this paper, we propose a novel framework that is able to learn a ANN-based metric from a stream of constraints with full constraint utilization, and more importantly, is able to dynamically adapt its model complexity when necessary. To achieve this, we first amend the common ANN architecture so that the output of every hidden layer is given as input to an independent metric embedding layer (MEL). Each MEL represents an embedding space where similar instances are closer to each other and dissimilar instances are further away from each other. A metric weight is then assigned to each MEL, measuring its importance in the entire metric model. We propose a novel Adaptive-Bound Triplet Loss (ABTL) to evaluate the similarity and dissimilarity errors introduced by the arriving constraint at each online round, and present a novel Adaptive Hedge Update (AHU) method to update the parameters of the metric model along with the metric weights based on these errors. Note that the proposed ABTL eliminates the unique dependency on "hard" constraints in existing methods, thereby improving both the constraint utilization and the quality of learned metrics. We refer to the proposed approach as Online metric learning with Adaptive Hedge Update (OAHU).

The contribution of this paper are as follows:

- We present a novel online metric learning framework - called OAHU - that addresses the challenges in "Online Adaptive Metric Learning" by learning a ANN-based metric with adaptive model complexity and achieving full constraint utilization.
- We theoretically show the regret bound of OAHU and demonstrate the optimal range for parameter selection.
- We empirically evaluate OAHU on real-world image classification, face verification, and image retrieval tasks, and compare its results with existing state-of-the-art online metric learning algorithms.

Rest of this paper is organized as follows. We first review related works in Section 2. Then, we formalize the online metric learning problem and discuss our proposed solution in Section 3. Next, we discuss the empirical evaluation of OAHU in Section 4, and finally conclude in Section 5.

2 RELATED WORK

Existing online metric learning solutions can be broadly classified into two categories: bilinear similarity-based or Mahalanobis distance-based methods.

The bilinear similarity-based methods learn a distance metric given by $d(\boldsymbol{x_1}, \boldsymbol{x_2}) = \boldsymbol{x_1}^T A \boldsymbol{x_2}$. A popular bilinear-based method is OASIS [6]. It is an online dual approach with a passive-aggressive algorithm which computes a similarity metric to solve the image retrieval task. Sparse Online Metric Learning (SOML) [5] is another technique which learns a metric by simplifying the full matrix A by a diagnoal matrix w, i.e., $A = diag(w)$, to handle very high-dimensional cases. To reduce the memory and computational cost, the Sparse Online Relative Similarity (SORS) [1] method adopts an off-diagonal l_1 norm of A as the sparse regularization to pursue a sparse model during the learning process. These three methods are based on triplet constraints where relative similarity/dissimilarity among images are specified.

On the other hand, Mahalanobis distance-based methods focus on learning a distance metric given by $d(\boldsymbol{x_1}, \boldsymbol{x_2}) = (\boldsymbol{x_1} - \boldsymbol{x_2})^T A (\boldsymbol{x_1} - \boldsymbol{x_2})$. Several algorithms have been proposed. Pseudo-metric Online Learning Algorithm (POLA) [22] introduces successive projection operations to learn the optimal metric. Whereas, LEGO [12] learns a Manalanobis metric based on LogDet regularization and gradient descent. RDML [14] uses a regularized online metric learning algorithm. Recently, Li et al. [19] introduced a closed-form solution called OPML, which adopts a one-pass triplet construction strategy to learn the optimal metric with a low computational cost. All these methods, except OPML, are based on pairwise constraints where the similarity or dissimilarity among pairs of images are specified.

In general, triplet constraints are more effective than pairwise constraints [6, 23, 25] because they allow simultaneous learning of similar and dissimilar relations. Therefore, similar to OASIS and OPML, we focus on triplets to learn a high-quality metric. However, in contrast to all the previous online metric learning algorithms, our approach does not depend on the Mahalanobis or bilinear distance since their linearity property [2] may limit expressiveness when exposed to complex data distributions in practical applications. Instead, we introduce a self-adaptive ANN-based metric that flexibly selects an appropriate metric function according to the scenario on which it is deployed.

3 OAHU

3.1 Problem Setting

Given a sequence of triplet constraints $S = \{(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-})\}_{t=1}^T$ that arrive sequentially, where $\{\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-}\} \in \mathcal{R}^d$, and $\boldsymbol{x_t}$ (anchor) is similar to $\boldsymbol{x_t^+}$ (positive) but is dissimilar to $\boldsymbol{x_t^-}$ (negative), the goal of online adaptive metric learning is to learn a model $\boldsymbol{F} : \mathcal{R}^d \mapsto \mathcal{R}^{d'}$ such that $||\boldsymbol{F}(\boldsymbol{x_t}) - \boldsymbol{F}(\boldsymbol{x_t^+})||_2 \ll ||\boldsymbol{F}(\boldsymbol{x_t}) - \boldsymbol{F}(\boldsymbol{x_t^-})||_2$.

The overall aim of the task is to learn a metric model with adaptive complexity while maintaining a high constraint utilization rate. Here, the complexity of $\boldsymbol{F}$ needs to be adaptive so that its hypothesis space is automatically enlarged or shrinked as necessary.

In practical applications, the input triplet stream can be generated as follows. First, some seed triplets can be constructed from user clicks. Then, more triplets are formed by taking transitive closures[1] over these seed triplets. The generated triplets are inserted into the stream in chronological order of creation. In this paper, we assume

[1] If $(\boldsymbol{x_1}, \boldsymbol{x_2})$ and $(\boldsymbol{x_1}, \boldsymbol{x_3})$ are two similar pairs, then $(\boldsymbol{x_2}, \boldsymbol{x_3})$ is a similar pair. If $(\boldsymbol{x_1}, \boldsymbol{x_2})$ and $(\boldsymbol{x_2}, \boldsymbol{x_3})$ are two similar pairs, then $(\boldsymbol{x_1}, \boldsymbol{x_3})$ is a similar pair. If $(\boldsymbol{x_1}, \boldsymbol{x_2})$ is a similar pair and $(\boldsymbol{x_1}, \boldsymbol{x_3})$ is a dissimilar pair, then $(\boldsymbol{x_2}, \boldsymbol{x_3})$ is a dissimilar pair. If $(\boldsymbol{x_1}, \boldsymbol{x_2})$ is a similar pair and $(\boldsymbol{x_2}, \boldsymbol{x_3})$ is a dissimilar pair, then $(\boldsymbol{x_1}, \boldsymbol{x_3})$ is a dissimilar pair.

$\boldsymbol{x}_t^*$: Any anchor, positive or negative instance in a triplet.	E_l: l^{th} metric model in OAHU.
$f^{(l)}(\boldsymbol{x}_t^*)$: Metric embedding of $\boldsymbol{x}_t^*$ generated by E_l.	$\mathcal{L}^{(l)}(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-)$: The local loss of $(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-)$ evaluated by E_l.
$\mathcal{L}_{overall}(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-)$: The total loss of $(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-)$ evaluated in OAHU.	$\alpha^{(l)}$: Weight of metric model E_l.
$D^{(l)}(\boldsymbol{x}_i, \boldsymbol{x}_j)$: Distance between $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ measured in E_l based on $f^{(l)}(\boldsymbol{x})$.	$d_{sim}^{(l)}(\boldsymbol{x}_i, \boldsymbol{x}_j)$ / $d_{dis}^{(l)}(\boldsymbol{x}_i, \boldsymbol{x}_j)$: Similarity/Dissimilarity threshold in E_l for a pair $(\boldsymbol{x}_i, \boldsymbol{x}_j)$.
$\mathcal{T}_{sim}^{(l)}$ / $\mathcal{T}_{dis}^{(l)}$: Upper bound of $d_{sim}^{(l)}(\boldsymbol{x}_i, \boldsymbol{x}_j)$ / Lower bound of $d_{dis}^{(l)}(\boldsymbol{x}_i, \boldsymbol{x}_j)$.	$\mathcal{L}_{attr}^{(l)}(\boldsymbol{x}_t, \boldsymbol{x}_t^+)$ / $\mathcal{L}_{rep}^{(l)}(\boldsymbol{x}_t, \boldsymbol{x}_t^-)$: Attractive/Repulsive loss of $(\boldsymbol{x}_t, \boldsymbol{x}_t^+)$ / $(\boldsymbol{x}_t, \boldsymbol{x}_t^-)$ evaluated in E_l.
L: Number of hidden layers in OAHU.	d: Dimensionality of input data.
S_{hidden}: Number of units in each hidden layer in OAHU.	S_{emb}: Dimensionality of learned metric embedding.
β: Discount factor for the update of $\alpha^{(l)}$.	s: Smooth factor for the update of $\alpha^{(l)}$.
η: Learning rate.	$W^{(l)}$ / $\Theta^{(l)}$: Parameter of l^{th} hidden layer/Parameter of l^{th} metric embedding layer.

Table 1: Commonly used symbols and terms

the existence of such triplet stream and focus on addressing the challenges of online metric learning in such scenarios.

3.2 Overview

To learn a metric model with adaptive complexity, we need to address the following question: *when* and *how* to change the "complexity" of metric model in an *online* setting? In this section, we will discuss the details of the proposed framework OAHU that addresses the question in a data-driven manner.

Figure 1 illustrates the structure of our OAHU framework. Inspired by recent works [11, 24], we use an over-complete network and automatically adapt its effective depth to learn a metric function with an appropriate complexity based on input constraints. Consider a neural network with L hidden layers: we connect an independent embedding layer to the network input layer and each of these hidden layers. Every embedding layer represents a space where similar instances are closer to each other and vice-versa. Therefore, unlike conventional online metric learning solutions that usually learns a linear model, OAHU is an ensemble of models with varying complexities that share low-level knowledge with each other. For convenience, let $E_l \in \{E_0, E_1, E_2, \ldots, E_L\}$ denote the l^{th} metric model in OAHU, i.e., the network branch starting from input layer to the l^{th} metric embedding layer, as illustrated in Figure 1. The simplest model in OAHU is E_0, which represents a linear transformation from the input feature space to the metric embedding space. A weight $\alpha^{(l)} \in [0, 1]$ is assigned to E_l, measuring its importance in OAHU.

For a triplet constraint $(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-)$ that arrives at time t, its metric embedding $f^{(l)}(\boldsymbol{x}_t^*)$ generated by E_l is

$$f^{(l)}(\boldsymbol{x}_t^*) = h^{(l)}\Theta^{(l)} \tag{1}$$

where $h^{(l)} = \sigma(W^{(l)}h^{(l-1)})$, with $l \geq 1, l \in \mathbb{N}$, and $h^{(0)} = \boldsymbol{x}_t^*$.

Here $\boldsymbol{x}_t^*$ denotes any anchor ($\boldsymbol{x}_t$), positive ($\boldsymbol{x}_t^+$) or negative ($\boldsymbol{x}_t^-$) instance based on the definition in Section 3.1, and $h^{(l)}$ represents the activation of l^{th} hidden layer. Note that we also explicitly limit the learned metric embedding $f^{(l)}(\boldsymbol{x}_t^*)$ to reside on a unit sphere, i.e., $||f^{(l)}(\boldsymbol{x}_t^*)||_2 = 1$, to reduce the potential model search space and accelerate the training of OAHU.

During the training phase, for every arriving triplet $(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-)$, OAHU first retrieves the metric embedding $f^{(l)}(\boldsymbol{x}_t^*)$ from l^{th} metric model according to Eq. 1, and then produces a local loss $\mathcal{L}^{(l)}$ for E_l by evaluating the similarity and dissimilarity errors based on $f^{(l)}(\boldsymbol{x}_t^*)$. Thus, the overall loss introduced by this triplet is given by

$$\mathcal{L}_{overall}(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-) = \sum_{l=0}^{L} \alpha^{(l)} \cdot \mathcal{L}^{(l)}(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-) \tag{2}$$

Since the new architecture of OAHU introduces two sets of new parameters, $\Theta^{(l)}$ (parameters of $f^{(l)}$) and $\alpha^{(l)}$, we need to learn $\Theta^{(l)}$, $\alpha^{(l)}$ and $W^{(l)}$ during the online learning phase. Therefore, the final optimization problem to solve in OAHU at time t is given by

$$\begin{aligned} &\underset{\Theta^{(l)}, W^{(l)}, \alpha^{(l)}}{\text{minimize}} && \mathcal{L}_{overall} \\ &\text{subject to} && ||f^{(l)}(\boldsymbol{x}_t^*)||_2 = 1, \forall l = 0, \ldots, L. \end{aligned} \tag{3}$$

To solve the above optimization problem, we propose a novel Adaptive-Bound Triplet Loss (ABTL) in Section 3.3 to estimate $\mathcal{L}^{(l)}$ and introduce a novel Adaptive Hedge Update (AHU) method in Section 3.4 for online updating $\Theta^{(l)}$, $W^{(l)}$ and $\alpha^{(l)}$.

3.3 Adaptive-Bound Triplet Loss

3.3.1 Limitations of Existing Pairwise/Triplet Loss. Existing online metric learning solutions typically optimize a pairwise or triplet loss in order to learn a similarity metric. A widely-accepted pairwise loss [22] and a common triplet loss [19] are shown in Equation 4 and 5 respectively.

$$L(x_t, x_t') = \max\{0, y_t(d^2(x_t, x_t') - b) + 1\} \tag{4}$$

$$L(x_t, x_t^+, x_t^-) = \max\{0, b + d(x_t, x_t^+) - d(x_t, x_t^-)\} \tag{5}$$

Here $y_t \in \{+1, -1\}$ denotes whether x_t is similar (+1) or dissimilar (−1) to x_t' and $b \in \mathcal{R}$ is a user-specified fixed margin. Compared to the triplet loss that simultaneously evaluates both similarity and dissimilarity relations, the pairwise loss can only focus on one of the relations at a time, which leads to a poor metric quality. On the other hand, without a proper margin, the loose restriction of triplet loss can result in many failure cases. Here, a failure case is a triplet that produces a zero loss value, where dissimilar instances are closer than similar instances. As the example shown in Figure 2, for an input triplet (x_t, x_t^+, x_t^-), although x_t^+ is closer to x_t^- and further from x_t, models optimizing triplet loss would incorrectly ignore this constraint due to its zero loss value. In addition, selecting an appropriate margin is highly data-dependent, and requires extensive domain knowledge. Furthermore, as the model improves performance over time, a larger margin is required to avoid failure cases.

Next, we describe an adaptive-bound triplet loss that attempts to solve these drawbacks.

3.3.2 Adaptive-Bound Triplet Loss (ABTL). We define that instances of the same classes are mutually attractive to each other, while instances of different classes are mutually repulsive to each other. Therefore, for any input triplet constraint $(\boldsymbol{x}_t, \boldsymbol{x}_t^+, \boldsymbol{x}_t^-)$, there is an attractive loss $\mathcal{L}_{attr} \in [0, 1]$ between $\boldsymbol{x}_t$ and $\boldsymbol{x}_t^+$, and a repulsive

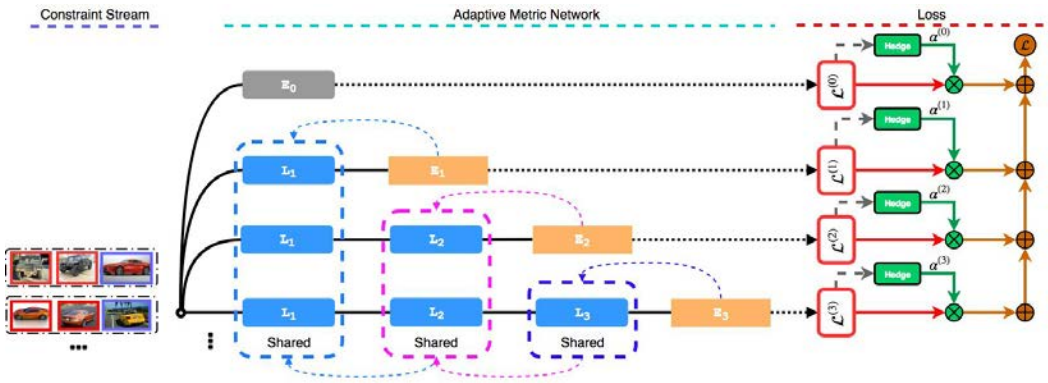

Figure 1: Overview of the OAHU. The chromatic dashed arrows represent update contributions and directions. Each $L_i \in \{L_1, L_2, \ldots\}$ represents a linear transformation layer followed by a ReLU activation. $\{E_0, E_1, \ldots\}$ are the embedding layers connected to corresponding input or hidden layers. Note that E_0 here represents a linear metric model, i.e., a linear transformation from the input feature space to the embedding space.

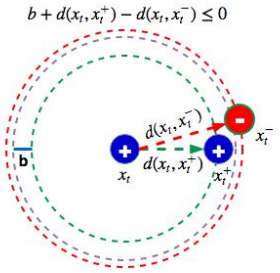

Figure 2: A failure case of triplet loss.

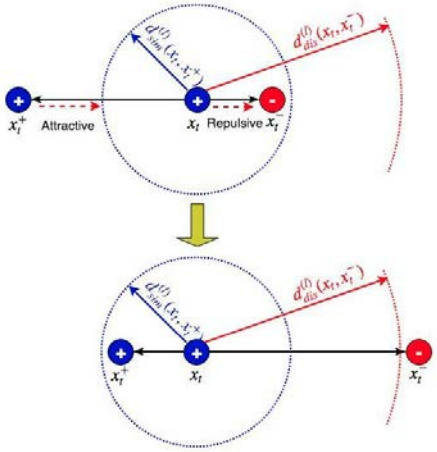

Figure 3: Schematic illustration of ABTL.

loss $\mathcal{L}_{rep} \in [0, 1]$ between $\boldsymbol{x_t}$ and $\boldsymbol{x_t^-}$. In the l^{th} metric model $E_l \in \{E_0, \ldots, E_L\}$, we focus on a distance measure $D^{(l)}(\boldsymbol{x_i}, \boldsymbol{x_j})$ defined as follows:

$$D^{(l)}(\boldsymbol{x_i}, \boldsymbol{x_j}) = ||f^{(l)}(\boldsymbol{x_i}) - f^{(l)}(\boldsymbol{x_j})||_2, \quad \forall l = 0, 1, 2, \ldots, L \tag{6}$$

where $f^{(l)}(\boldsymbol{x})$ denotes the embedding generated by E_l. Since $||f^{(l)}(\boldsymbol{x})||_2$ is restricted to be 1, we have $D^{(l)}(\boldsymbol{x_i}, \boldsymbol{x_j}) \in [0, 2]$. In each iteration, let $D^{(l)}_{orig}(\boldsymbol{x_1}, \boldsymbol{x_2})$ denote the distance between $\boldsymbol{x_1}$ and $\boldsymbol{x_2}$ before applying the update to $f^{(l)}$ (i.e., updating $\Theta^{(l)}$ and $\{W^{(j)}\}_{j=0}^{l}$) and $D^{(l)}_{update}(\boldsymbol{x_1}, \boldsymbol{x_2})$ denote the distance after applying the update.

Figure 3 illustrates the main idea of ABTL. The objective is to have the distance $D^{(l)}_{update}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ of two similar instances $\boldsymbol{x_t}$ and $\boldsymbol{x_t^+}$ to be less than or equal to a similarity threshold $d^{(l)}_{sim}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ so that the attractive loss $\mathcal{L}^{(l)}_{attr}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ drops to zero; on the other hand, for two dissimilar instances $\boldsymbol{x_t}$ and $\boldsymbol{x_t^-}$, we desire their distance $D^{(l)}_{update}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$ to be greater than or equal to a dissimilarity threshold $d^{(l)}_{dis}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$, thereby reducing the repulsive loss $\mathcal{L}^{(l)}_{rep}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$ to zero. Equation 7 presents these constraints mathematically.

$$\begin{cases} D^{(l)}_{update}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) \leq d^{(l)}_{sim}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) \\ D^{(l)}_{update}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) \geq d^{(l)}_{dis}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) \end{cases} \tag{7}$$

Unfortunately, directly finding an appropriate $d^{(l)}_{sim}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ or $d^{(l)}_{dis}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$ is difficult, since it varies with different input constraints. Therefore, we introduce a user-specified hyper-parameter $\tau > 0$ to explicitly restrict the range of both thresholds. Let $\mathcal{T}^{(l)}_{sim}$ denote the upper bound of $d^{(l)}_{sim}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$, and $\mathcal{T}^{(l)}_{dis}$ denote the lower bound of $d^{(l)}_{dis}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$,

$$\begin{cases} \mathcal{T}^{(l)}_{sim} = \tau \geq d^{(l)}_{sim}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) \\ \mathcal{T}^{(l)}_{dis} = 2 - \tau \leq d^{(l)}_{dis}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) \end{cases} \tag{8}$$

Without loss of generality, we propose

$$\begin{cases} d^{(l)}_{sim}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) = a_1 e^{D^{(l)}_{orig}(\boldsymbol{x_t}, \boldsymbol{x_t^+})} + b_1 \\ d^{(l)}_{dis}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) = -a_2 e^{-D^{(l)}_{orig}(\boldsymbol{x_t}, \boldsymbol{x_t^-})} + b_2 \end{cases} \tag{9}$$

where a_1, b_1, a_2 and b_2 are variables need to be determined. Note that $d^{(l)}_{sim}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ and $d^{(l)}_{dis}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$ are monotonically increasing

and decreasing, respectively. Therefore, $d_{sim}^{(l)}$ preserves the information of original relative similarity, i.e., $d_{sim}^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_2}) < d_{sim}^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_3})$ if $D_{orig}^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_2}) < D_{orig}^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_3})$. This property is critical to many real-world applications that require a fine-grained similarity comparison, such as image retrieval.

The values of a_1, b_1, a_2 and b_2 are then determined by the following boundary conditions:

$$\begin{cases} d_{sim}^{(l)}|_{D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+})=2} \leq \mathcal{T}_{sim}^{(l)} = \tau & d_{sim}^{(l)}|_{D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+})=0} = 0 \\ d_{dis}^{(l)}|_{D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})=0} \geq \mathcal{T}_{dis}^{(l)} = 2 - \tau & d_{dis}^{(l)}|_{D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})=2} = 2 \end{cases} \tag{10}$$

Thus we have

$$\begin{cases} d_{sim}^{(l)}\left(\boldsymbol{x_t}, \boldsymbol{x_t^+}\right) = \frac{\tau}{\mathrm{e}^2 - 1}\left(\mathrm{e}^{D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+})} - 1\right) \\ d_{dis}^{(l)}\left(\boldsymbol{x_t}, \boldsymbol{x_t^-}\right) = -\frac{2-(2-\tau)}{1-\mathrm{e}^{-2}}\left(\mathrm{e}^{-D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})} - 1\right) + (2 - \tau) \end{cases} \tag{11}$$

Provided with $d_{sim}^{(l)}$ and $d_{dis}^{(l)}$, the attractive loss $\mathcal{L}_{attr}$ and repulsive loss $\mathcal{L}_{rep}$ are determined by

$$\begin{cases} \mathcal{L}_{attr}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) = \max\left\{0, \frac{1}{2-c_1} D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) - \frac{c_1}{2-c_1}\right\} \\ \mathcal{L}_{rep}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) = \max\left\{0, \frac{-1}{c_2} D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) + 1\right\} \end{cases} \tag{12}$$

where $c_1 = d_{sim}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ and $c_2 = d_{dis}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$.

Therefore, the local loss $\mathcal{L}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-})$, which measures the similarity and dissimilarity errors of the input triplet $(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-})$ in E_l, is the average of $\mathcal{L}_{attr}^{(l)}$ and $\mathcal{L}_{rep}^{(l)}$:

$$\mathcal{L}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-}) = \frac{1}{2}\left(\mathcal{L}_{attr}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) + \mathcal{L}_{rep}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})\right) \tag{13}$$

Next, we answer an important question: What is the best value of τ? Here, we demonstrate that the optimal range of τ is $(0, \frac{2}{3})$. The best value of τ is thus empirically selected within this range via cross-validation.

Theorem 3.1. *With $\tau \in (0, \frac{2}{3})$, by optimizing the proposed adaptive-bound triplet loss, different classes are separated in the metric embedding space.*

Proof. Let $D(c_1, c_2)$ denotes the minimal distance between classes c_1 and c_2, i.e., the distance between two closest instances from c_1 and c_2 respectively. Consider an arbitrary quadrupole $(x_1, x_2, x_3, x_4) \in Q$ where $\{x_1, x_2\} \in c_1$, $\{x_3, x_4\} \in c_2$, and Q is the set of all possible quadrupoles generated from class c_1 and c_2. Suppose (x_2, x_3) is the closest dissimilar pair among all possible dissimilar pairs that can be extracted from (x_1, x_2, x_3, x_4) [2]. We first prove that the lower bound of $D(c_1, c_2)$ is given by $\min_{(x_1, x_2, x_3, x_4) \in Q} D^{(l)}(x_1, x_4) - D^{(l)}(x_1, x_2) - D^{(l)}(x_3, x_4)$. Due to the triangle inequality property of p-norm distance, we have

$$\begin{aligned} D^{(l)}(x_1, x_4) &\leq D^{(l)}(x_1, x_2) + D^{(l)}(x_2, x_4) \\ &\leq D^{(l)}(x_1, x_2) + D^{(l)}(x_2, x_3) + D^{(l)}(x_3, x_4) \end{aligned} \tag{14}$$

[2] it can always be achieved by re-arranging symbols of x_1,x_2,x_3 and x_4

Therefore,

$$\begin{aligned} D(c_1, c_2) &= \min_{(x_1, x_2, x_3, x_4) \in Q} D^{(l)}(x_2, x_3) \\ &\geq \min_{(x_1, x_2, x_3, x_4) \in Q} D^{(l)}(x_1, x_4) - D^{(l)}(x_1, x_2) - D^{(l)}(x_3, x_4) \end{aligned} \tag{15}$$

By optimizing the adaptive-bound triplet loss, the following constraints are satisfied

$$\begin{cases} D^{(l)}(x_1, x_2) \leq d_{sim}^{(l)}(x_1, x_2) \leq \mathcal{T}_{sim}^{(l)} \\ D^{(l)}(x_3, x_4) \leq d_{sim}^{(l)}(x_3, x_4) \leq \mathcal{T}_{sim}^{(l)} \\ D^{(l)}(x_1, x_4) \geq d_{dis}^{(l)}(x_1, x_4) \geq \mathcal{T}_{dis}^{(l)} \end{cases} \tag{16}$$

Thus

$$\begin{aligned} D(c_1, c_2) &\geq \min_{(x_1, x_2, x_3, x_4) \in Q} D^{(l)}(x_1, x_4) - D^{(l)}(x_1, x_2) - D^{(l)}(x_3, x_4) \\ &\geq \mathcal{T}_{dis}^{(l)} - 2\mathcal{T}_{sim}^{(l)} \\ &= 2 - \tau - 2\tau \\ &= 2 - 3\tau \end{aligned} \tag{17}$$

if $\tau \in (0, \frac{2}{3})$, we have $3\tau < 2$. Therefore,

$$D(c_1, c_2) \geq 2 - 3\tau > 0 \tag{18}$$

Equation 18 indicates that the minimal distance between class c_1 and c_2 is always positive so that these two classes are separated. □

3.3.3 Discussion. Compared to pairwise and triplet loss, the proposed ABTL has several advantages:

- Similar to triplet loss, ABTL simultaneously evaluates both similarity and dissimilarity errors to obtain a high-quality metric.
- The similarity threshold $d_{sim}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ is always less than or equal to $D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ and the dissimilarity threshold $d_{dis}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$ is always greater than or equal to $D_{orig}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$. Thus, every input constraint contributes to model update, which eliminates the failure cases of triplet loss and leads to a higher constraint utilization rate.
- The optimal range of τ is provided with a theoretical proof.

3.4 Adaptive Hedge Update (AHU)

With adaptive-bound triplet loss, the overall loss in OAHU becomes

$$\begin{aligned} \mathcal{L}_{overall}(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-}) &= \sum_{l=0}^{L} \alpha^{(l)} \cdot \mathcal{L}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-}) \\ &= \sum_{l=0}^{L} \frac{\alpha^{(l)}}{2}\left(\mathcal{L}_{attr}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) + \mathcal{L}_{rep}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})\right) \end{aligned} \tag{19}$$

We propose to learn $\alpha^{(l)}$ using the Hedge Algorithm [9]. Initially, all weights are uniformly distributed, i.e., $\alpha^{(l)} = \frac{1}{L+1}, l = 0, 1, 2, \ldots, L$. At every iteration, for each metric model E_l, OAHU transforms the input triplet constraint into E_l's metric embedding space, where the constraint similarity and dissimilarity errors are

evaluated. Thus $\alpha^{(l)}$ is updated based on the local loss suffered by E_l as:

$$\alpha_{t+1}^{(l)} \leftarrow \begin{cases} \alpha_t^{(l)} \beta^{\mathcal{L}^{(l)}} & \beta^{\min_l \mathcal{L}^{(l)}} \log \mathcal{L}^{(l)} > \beta - 1 \\ \alpha_t^{(l)} [1 - (1-\beta)\mathcal{L}^{(l)}] & otherwise \end{cases} \tag{20}$$

where $\beta \in (0,1)$ is the discount factor. We choose to update $\alpha^{(l)}$ based on Equation 20, to maximize the update of $\alpha^{(l)}$ at each step. In other words, if a metric model produces a low/high $\mathcal{L}^{(l)}$ at time t, its associated weight $\alpha^{(l)}$ will gain as much increment/decrement as possible. Therefore, in OAHU, metric models with good performance are highlighted while models with poor performance are eliminated. Moreover, following Sahoo et.al [21], to avoid the model bias issue [7, 10], i.e., OAHU may unfairly prefer shallow models due to their faster convergence rate and excessively reduces weights of deeper models, we introduce a smooth factor s used to set a minimal weight for each metric model. Thus, after updating weights according to Equation 20, the weights are set as: $\alpha_{t+1}^{(l)} = \max(\alpha_{t+1}^{(l)}, \frac{s}{L+1})$. Finally, at the end of every round, the weights α are normalized such that $\sum_{l=0}^{L} \alpha_{t+1}^{(l)} = 1$.

Learning the parameters $\Theta^{(l)}$ and $W^{(l)}$ is tricky but can be achieved via gradient descent. By applying Online Gradient Descent (OGD) algorithm, the update rules for $\Theta^{(l)}$ and $W^{(l)}$ are given by:

$$\begin{aligned} \Theta_{t+1}^{(l)} &\leftarrow \Theta_t^{(l)} - \eta \nabla_{\Theta_t^{(l)}} \mathcal{L}_{overall}(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-}) \\ &= \Theta_t^{(l)} - \eta \frac{\alpha^{(l)}}{2} \left(\nabla_{\Theta_t^{(l)}} \mathcal{L}_{attr}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) + \nabla_{\Theta_t^{(l)}} \mathcal{L}_{rep}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) \right) \end{aligned} \tag{21}$$

$$\begin{aligned} W_{t+1}^{(l)} &\leftarrow W_t^{(l)} - \eta \nabla_{W_t^{(l)}} \mathcal{L}_{overall}(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-}) \\ &= W_t^{(l)} - \eta \sum_{j=l}^{L} \frac{\alpha^{(j)}}{2} \left(\nabla_{W_t^{(l)}} \mathcal{L}_{attr}^{(j)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}) + \nabla_{W_t^{(l)}} \mathcal{L}_{rep}^{(j)}(\boldsymbol{x_t}, \boldsymbol{x_t^-}) \right) \end{aligned} \tag{22}$$

Updating $\Theta^{(l)}$ (Equation 21) is simple since $\Theta^{(l)}$ is specific to E_l, and is not shared across different metric models. In contrast, because deeper models share low-level knowledge with shallower models in OAHU, all models deeper than l layers contribute to the update of $W^{(l)}$, as expressed in Equation 22. Algorithm 1 outlines the training process of OAHU.

3.5 Regret Bound

Overall, hedge algorithm enjoys a regret bound of $R_T \leq \sqrt{TlnN}$ [9] where N is the number of experts and T is the number of trials. In our case, N is the number of metric models (i.e., $L+1$) and T is the number of input triplet constraints. The average worst-case convergence rate of OAHU is then given by $O(\sqrt{ln(N)/T})$. Therefore, OAHU is guaranteed to converge after learning from sufficiently many triplets.

3.6 Application of OAHU

In this part, we discuss the deployment of OAHU in different practical applications. Although OAHU can be applied in many applications, we mainly focus on the three most common tasks: classification, similarity comparison, and analogue retrieval. Note that the following discussion describes only one possible way of deployment for each task, and other deployment methods can exist.

Algorithm 1 OAHU: Online Metric Learning with Adaptive Hedge Update

Require: Discount Factor $\beta \in (0,1)$; Smooth Factor s; Control Parameter $\tau \in (0, \frac{2}{3})$; Learning rate η; A randomly initialized ANN with L hidden layers that is parameterized by $\Theta^{(l)}$,$W^{(l)}$ and $\alpha^{(l)}$.

Ensure: $\alpha^{(l)}$, $\Theta^{(l)}$ and $W^{(l)}$

1: Initialize $\alpha^{(l)} = \frac{1}{L+1}, \forall l = 0, 1, \ldots, L$
2: **for** $t = 1, 2, \ldots, T$ **do**
3: Receive a triplet constraint $(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-})$
4: Transform and retrieve the metric embedding $f^{(l)}(\boldsymbol{x_t})$, $f^{(l)}(\boldsymbol{x_t^+})$ and $f^{(l)}(\boldsymbol{x_t^-})$ from each model E_l.
5: Evaluate $\mathcal{L}_{attr}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+})$ and $\mathcal{L}_{rep}^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^-})$ (Eq. 12), $\forall l = 0, 1, \ldots, L$.
6: Compute $L^{(l)}(\boldsymbol{x_t}, \boldsymbol{x_t^+}, \boldsymbol{x_t^-}), \forall l = 0, 1, \ldots, L$ as per Eq. 13.
7: Update $\Theta_{t+1}^{(l)}, \forall l = 0, 1, 2, \ldots, L$ as per Eq. 21.
8: Update $W_{t+1}^{(l)}, \forall l = 0, 1, 2, \ldots, L$ as per Eq. 22.
9: Update $\alpha_{t+1}^{(l)}, \forall l = 0, 1, 2, \ldots, L$ as per Eq. 20.
10: $\alpha_{t+1}^{(l)} = \max(\alpha_{t+1}^{(l)}, \frac{s}{L+1}), \forall l = 0, 1, 2, \ldots, L$.
11: Normalize $\alpha_{t+1}^{(l)}$, i.e., $\alpha_{t+1}^{(l)} = \frac{\alpha_{t+1}^{(l)}}{\sum_{j=0}^{L} \alpha_{t+1}^{(j)}}, \forall l = 0, 1, 2, \ldots, L$.
12: **end for**

3.6.1 Classification. Given a training dataset $\mathcal{D} = \{(\boldsymbol{x_i}, y_i)\}_{i=1}^{n}$ where $\boldsymbol{x_i} \in \mathcal{R}^d$ is an training instance and $y_i \in \{1, 2, \ldots, c\}$ is its associated label, we determine the label $y \in \{1, 2, \ldots, c\}$ of a test instance $\boldsymbol{x} \in \mathcal{R}^d$ as follows:

- For every metric model E_l in OAHU, we find k nearest neighbors of $\boldsymbol{x}$ measured by Eq. 6, each of which is a candidate similar to $\boldsymbol{x}$. Hence, $k(L+1)$ candidates in total are found in OAHU. Let $\mathcal{N} = \{\{(\boldsymbol{x_j^{(l)}}, y_j^{(l)})\}_{j=1}^{k}\}_{l=0}^{L} = \{\mathcal{N}_l\}_{l=0}^{L}$ denotes these candidates where $\boldsymbol{x_j^{(l)}}$ is the j^{th} neighbor of $\boldsymbol{x}$ found in E_l and $y_j^{(l)}$ is its associated label. The similarity score between $\boldsymbol{x}$ and $\boldsymbol{x_j^{(l)}}$ is given by

$$S(\boldsymbol{x}, \boldsymbol{x_j^{(l)}}) = \mathrm{e}^{-\frac{D^{(l)}(\boldsymbol{x_j^{(l)}}, \boldsymbol{x}) - d_{min}}{d_{max} - d_{min}}} \cdot \alpha^{(l)} \tag{23}$$

  where $d_{min} = \min_{\mathcal{N}_l} D^{(l)}(\boldsymbol{x_j^{(l)}}, \boldsymbol{x})$ and $d_{max} = \max_{\mathcal{N}_l} D^{(l)}(\boldsymbol{x_j^{(l)}}, \boldsymbol{x})$.
- Then, the class association score of each class c_i is calculated by:

$$S(c_i) = \sum_{y_j^{(l)} = c_i} S(\boldsymbol{x}, \boldsymbol{x_j^{(l)}}) \tag{24}$$

- The final predicted label y of $\boldsymbol{x}$ in OAHU is determined as:

$$y = \arg\max_{c_i} S(c_i) \tag{25}$$

3.6.2 Similarity Comparison. The task of similarity comparison is to determine whether a given pair $(\boldsymbol{x_1}, \boldsymbol{x_2})$ is similar or not. To

do this, a user-specified threshold $\mathcal{T} \in (0, 1)$ is needed. The steps below are followed to perform the similarity comparison in OAHU.

- First, for every metric model E_l, we compute the distance $D^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_2})$ between $\boldsymbol{x_1}$ and $\boldsymbol{x_2}$. Since $D^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_2}) \in [0, 2]$, we divide $D^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_2})$ by 2 for normalization.
- The similarity probability of $(\boldsymbol{x_1}, \boldsymbol{x_2})$ is then determined by

$$P(\boldsymbol{x_1}, \boldsymbol{x_2}) = \sum_{l=0,\ldots,L} \alpha^{(l)} \cdot p_l \tag{26}$$

  where $p_l = 1$ if $D^{(l)}(\boldsymbol{x_1}, \boldsymbol{x_2})/2 < \mathcal{T}$; Otherwise, $p_l = 0$.
- $(\boldsymbol{x_1}, \boldsymbol{x_2})$ is similar if $P(\boldsymbol{x_1}, \boldsymbol{x_2}) \geq 0.5$ and is dissimilar if $P(\boldsymbol{x_1}, \boldsymbol{x_2}) < 0.5$.

3.6.3 Analogue Retrieval. Given a query item $\boldsymbol{x}$, the task of analogue retrieval is to find k items that are most similar to $\boldsymbol{x}$ in a database $\mathcal{D}$. Note that analogue retrieval is a simplified "classification" task where we only find similar items and ignore the labeling issue.

- We first retrieve the $k(L + 1)$ candidates that are similar to $\boldsymbol{x}$ following the same process in classification task. Let $\mathcal{N} = \{\{\boldsymbol{x_j^{(l)}}\}_{j=1}^{k}\}_{l=0}^{L} = \{\mathcal{N}_l\}_{l=0}^{L}$ denote these candidates. The similarity score between $\boldsymbol{x_j^{(l)}}$ and $\boldsymbol{x}$ is:

$$Sim(\boldsymbol{x_j^{(l)}}, \boldsymbol{x}) = \mathrm{e}^{-\frac{D^{(l)}(\boldsymbol{x_j^{(l)}}, \boldsymbol{x}) - d_{min}}{d_{max} - d_{min}}} \cdot \alpha^{(l)} \tag{27}$$

  where $d_{min} = \min_{\mathcal{N}_l} D^{(l)}(\boldsymbol{x_j^{(l)}}, \boldsymbol{x})$ and $d_{max} = \max_{\mathcal{N}_l} D^{(l)}(\boldsymbol{x_j^{(l)}}, \boldsymbol{x})$.
- Then we sort these items in descending order based on their similarity scores and keep only the top k distinct items as the final retrieval result.

3.7 Time and Space Complexity

Overall, the execution overhead of OAHU mainly arises from the training of the ANN-based metric model, especially from the gradient computation. Assume that the maximum time complexity for calculating the gradient of one layer is a constant C. The overall time complexity of OAHU is simply $O(nL^2C)$, where n is the number of input constraints and L is the number of hidden layers. Therefore, with pre-specified L and ANN architecture, OAHU is an efficient online metric learning algorithm that runs in linear time. Let d, S_{hidden} and S_{emb} denote the dimensionality of input data, number of units in each hidden layer and metric embedding size respectively. The space complexity of OAHU is given by $O\Big(d \cdot S_{emb} + L \cdot S_{hidden}(d + S_{emb}) + \frac{L(L-1)}{2} S_{hidden}^2\Big)$.

3.8 Extendability

As discussed in Section 3.6, OAHU is a fundamental module that can perform classification, similarity comparison, or analogue retrieval tasks independently. Therefore, it can be easily plugged into any existing deep models (e.g., a CNN or RNN) by replacing the classifier, i.e., fully-connected layers, with OAHU. The parameters of those feature-extraction layers (e.g., a convolutional layer) can be fine-tuned by optimizing $\mathcal{L}_{overall}$ directly. However, in this paper, to prove the validity of the proposed approach, we only focus on OAHU itself and leave the deep model extension for future work.

Task	Dataset	# features	# classes	# instances
Image Classification	FASHION-MNIST	784	10	70,000
	EMNIST	784	47	131,600
	CIFAR-10	1024	10	60,000
Face Verification	LFW	73	5749	13,233
Image Retrieval	CARS-196	4096	196	16,185
	CIFAR-100	4096	100	60,000

Table 2: Description of Datasets

4 EMPIRICAL EVALUATION

To verify the effectiveness of our method, we evaluate OAHU on three typical tasks, including (1) image classification (***classification***), (2) face verification (***similarity comparison***), and (3) image retrieval (***analogue retrieval***).

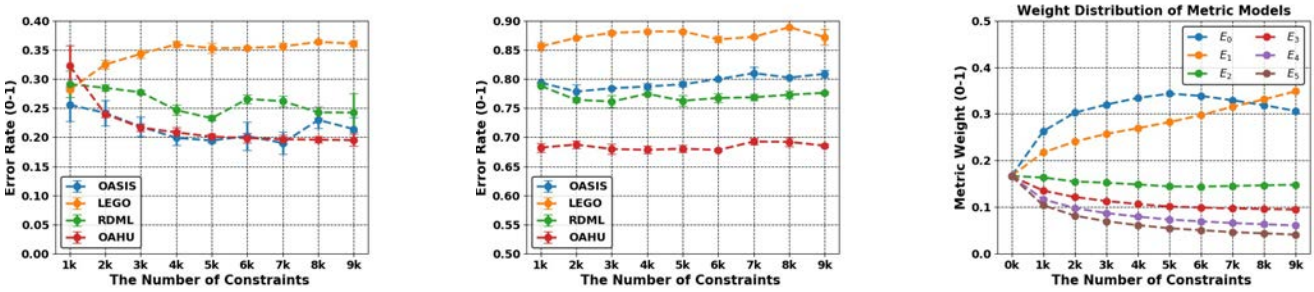
4.1 Baselines

To examine the quality of metrics learned in OAHU, we compare it with several state-of-the-art online metric learning algorithms. (1) LEGO [12] (pairwise constraint): an online metric learning algorithm that learns a Mahalanobis metric based on LogDet regularization and gradient descent. (2) RDML [14] (pairwise constraint): an online algorithm for regularized distance metric learning that learns a Mahalanobis metric with a regret bound. (3) OASIS [6] (triplet constraint): an online algorithm for scalable image similarity learning that learns a bilinear similarity measure over sparse representations. Finally, (4) OPML [19] (triplet constraint): a one-pass closed-form solution for online metric learning that learns a Mahalanobis metric with a low computational cost.

4.2 Implementation

We have implemented OAHU using Python 3.6.2 and Pytorch 0.4.0 library. All baseline methods were based on code released by corresponding authors, except LEGO and RDML. Due to the unavailability of a fully functional code of LEGO and RDML, we use our own implementation based on the authors' description [12, 14]. Hyper-parameter setting of these approaches, including OAHU, varies with different tasks, and will be discussed later for each specific task.

4.3 Image Classification



4.3.1 Dataset and Classifier. To demonstrate the validacy of OAHU on complex practical applications, we use three publicly available real-world benchmark image datasets, including **FASHION-MNIST**[3] [26], **EMNIST**[4] [8] and **CIFAR-10**[5] [16] for evaluation. To be consistent with other image datasets, we convert images of CIFAR-10 into grayscale through the OpenCV API [3], resulting in 1024 features. The *k-NN* classifier is employed here, since it is widely used for classification tasks with only one parameter, and is also consistent with the deployment of OAHU discussed in Section 3.6.1. Details of these datasets are listed in "Image Classification" part of Table 2.

4.3.2 Experiment Setup and Constraint Generation. To perform the experiment, we first randomly shuffle each dataset and then divide

it into development and test sets with the split ratio of 1 : 1. Hyper-parameters of these baseline approaches were set based on values reported by the authors and fine-tuned via 10-fold cross-validation on the development set. Because OPML applies a one-pass triplet construction process to generate the constraints, we simply provide the training data in the development set as the input for OPML. For other approaches including OAHU, we first randomly sample 5,000 seeds (i.e., pairwise or triplet constraints) from the training data and then construct 5,000 more constraints by taking transitive closure over these seeds. Note that the same number of constraints were adopted by the authors of LEGO [12] and OPML [19] when comparing their approaches with baselines. Thus our comparison is fair. In OAHU, we set $\beta = 0.99$, $L = 5$, $S_{hidden} = 100$, $s = 0.1$, $\eta = 0.3$ and $S_{emb} = 50$ as default. The value of τ was found by 10-fold cross-validation on the development set. To reduce any bias that may result from random partition, all the classification results are averaged over 10 individual runs with independent random shuffle processes.

4.3.3 Evaluation Metric. Similar to most of the baselines, e.g., LEGO [12] and OPML [19], we adopt the error rate and macro F_1 score[6] as the evaluation criterion. Moreover, the p-values of student's t-test were calculated to check statistical significance. In addition, the statistics of win/tie/loss are reported according to the obtained p-values. The constraint utilization $\mathcal{U}$, i.e., the fraction of input constraints that actually contribute to model update, is also reported for each method.

4.3.4 Analysis. Table 3 compares the classification performance of OAHU with baseline methods on benchmark datasets. We observe that LEGO and RDML perform poorly on complex image datasets, e.g., EMNIST (47 classes), since they learn a Mahalanobis metric from pairwise constraints, and are biased to either the similarity or dissimilarity relation when updating model parameters. OASIS performs better than OPML because the bilinear metric eliminates the positive and symmetric requirement of the covariance matrix, i.e., A in $d(\boldsymbol{x}_1, \boldsymbol{x}_2) = \boldsymbol{x}_1^T A \boldsymbol{x}_2$ which results in a larger hypothesis space [6]. However, OAHU outperforms all the baseline approaches by providing not only significantly lower error rate, but also higher F_1 score, indicating the best overall classification performance among all competing methods.

To illustrate the effect of different numbers of constraints on the learning of a metric, we vary the input constraint numbers[7] for all competing methods except OPML. Here we do not compare with OPML because it internally determines the number of triplets to use via a one-pass triplet construction process. Therefore, explicitly varying the input triplet number for OPML is impossible. Figure 4a and Figure 4b show the comparison of error rates on FASHION-MNIST and CIFAR-10 dataset respectively. The large variance of error rates observed in both OASIS and RDML (i.e., error bars in the figures) indicates the strong correlation of their classification performance with the quality of input constraints. All baseline approaches present an unstable, and sometimes, even worse performance with an increasing number of constraints. This is because these baselines are biased to those "hard" constraints

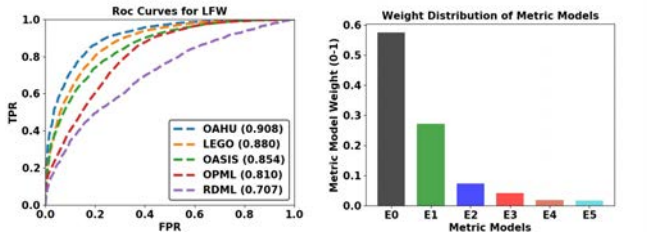
[6] http://scikit-learn.org/stable/modules/generated/sklearn.metrics.f1_score.html

[7] It is done by first generating 10,000 constraints as discussed in Section 4.3.2 and then uniformly sample the desired number of constraints from them.

leading to positive loss values and incorrectly ignore the emerging failure cases (see Figure 2). In contrast, OAHU provides the best and most stable classification performance with minimal variance, indicating its robustness to the quality of input constraints and better capability of capturing the semantic similarity and dissimilarity relations in data.

OAHU is better mainly because it not only learns from every input constraint by optimizing the adaptive-bound triplet loss (see constraint utilization $\mathcal{U}$ in Table 3), but also automatically adapts the model complexity to achieve better performance (see Figure 4c).

4.4 Face Verification



4.4.1 Dataset and Experiment Setup. For face verification, we evaluate our method on Labeled Faces in the Wild Database (LFW) [18]. This dataset has two views: View 1 is used for development purpose (contains a training and a test set), and View 2 is taken as a benchmark for comparison (i.e., a 10-fold cross validation set containing pairwise images). The goal of face verification in LFW is to determine whether a pair of face images belongs to the same person. Since OASIS, OPML, and OAHU are triplet-based methods, following the setting in OPML [19], we adopt the image unrestricted configuration to conduct experiments for a fair comparison. In the image unrestricted configuration, the label information (i.e. actual names) in training data can be used and as many pairs or triplets as one desires can be formulated. We use View 1 for hyper-parameter tuning and evaluate the performance of all competing algorithms on each fold (i.e., 300 intra-person and 300 inter-person pairs) in View 2. Note that the default parameter values in OAHU and baselines were set using the same values as discussed in Section 4.3.2. Attribute features of LFW are used in the experiment so that the result can be easily reproduced and the comparison is fair. Attribute features[8] (73 dimension) provided by Kumar et al. [17] are "high-level" features describing nameable attributes such as race, age etc., of a face image. Details of LFW are described in "Face Verification" part in Table 2.

4.4.2 Constraint Generation and Evaluation Metric. We follow the same process described in Section 4.3.2 to generate constraints for training purpose. However, we add an additional step here: if a generated constraint contains any pair of instances in the validation set (i.e., all pairs in View 1) or the test set (i.e., all folds in View 2), we simply discard it and re-sample a new constraint. This step is repeated until the new constraint does not contain any pair in both sets. In the experiment, 10,000 pair or triplet constraints in total are generated for training.

Note, due to the one-pass triplet generation strategy of OPML, we let itself determine the training triplets. For each test image pair, we first compute the distance between them measured by the learned metric, and then normalize the distance into $[0, 1]$. The widely accepted Receiver Operating Characteristic (ROC) curve and Area under Curve (AUC) are adopted as the evaluation metric.

4.4.3 Analysis. The ROC curves of all competing methods are given in Figure 5a with corresponding AUC values calculated. It can be observed that the proposed approach OAHU outperforms all baseline approaches by providing significantly higher AUC value.

[8]http://www.cs.columbia.edu/CAVE/databases/pubfig/download/lfw_attributes.txt

(a) (b)

Figure 5: (a) ROC Curves of OAHU and contrastive methods on LFW dataset. AUC value of each method is given in bracket. (b) Metric weight distribution of OAHU.

(a) Failure Cases **(b) Successful Cases**

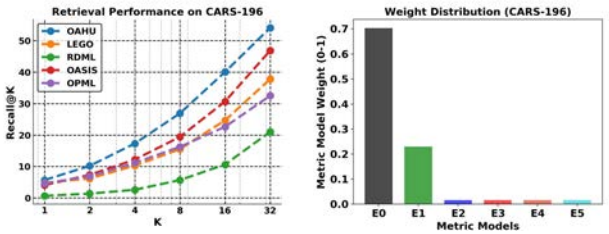


Figure 6: Face verification examples in the test set (View 2) ($\mathcal{T} = 0.55$). For images belonging to same person, $P(\boldsymbol{x}_1, \boldsymbol{x}_2)$ should be close to 1 and for images belonging to different people, $P(\boldsymbol{x}_1, \boldsymbol{x}_2)$ should drop to 0.

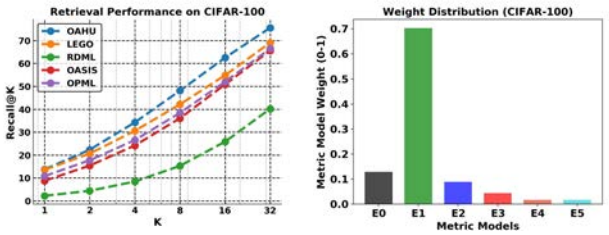
As demonstrated in Figure 5b, OAHU is better mainly because it automatically adapts the model complexity to incorporate non-linear models, which help to separate instances that are difficult to distinguish in simple linear models. Figure 6 presents some example comparisons in the test set for both successful and failure cases. Here, the comparison probability $P(\boldsymbol{x}_1, \boldsymbol{x}_2)$ computed based on Eq. 26 is expected to approach 1 if both images are from the same person and should be close to 0 if they belong to different people. Apparently, although OAHU performs much better than baselines, it may still fail in some cases where severe concept drift, e.g. aging and shave, are present.

4.5 Image Retrieval



4.5.1 Dataset and Experiment Setup. To demonstrate the performance of OAHU on image retrieval task, we show experiments on two benchmark datasets, which are CARS-196[9] [15] and CIFAR-100[10] [16]. The CARS-196 dataset is divided into 8,144 training images and 8,401 test images, where each class has been split roughly in a 50-50 ratio. Similarly, we randomly split CIFAR-100 into 30,000 training images and 30,000 test images by equally dividing images of each class. For each image in CARS-196 and CIFAR-100, its deep feature, i.e., the output of the last convolutional layer, is extracted from a VGG-19 model pretrained on the ImageNet [20] dataset. Details of these 2 datasets are listed in the "Image Retrieval" part of Table 2. We form the development set of each dataset by including

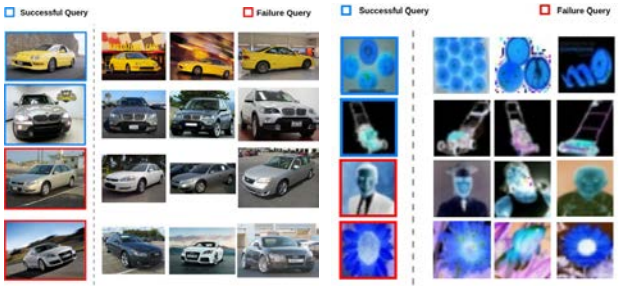
(a) (b)

Figure 7: (a) Recall@K score on the test split of CARS-196. (b) Metric weight distribution of OAHU on CARS-196.



(a) (b)

Figure 8: (a) Recall@K score on the test split of CIFAR-100. (b) Metric weight distribution of OAHU on CIFAR-100.

all its training images. For each dataset, hyper-parameters of baseline approaches were set based on values reported by the authors, and fine-tuned via 10-fold cross-validation on the development set. In OAHU, we set $\beta = 0.99$, $L = 5$, $S_{hidden} = 100$, $s = 0.1$, $\eta = 0.3$ and $S_{emb} = 50$ as default. The value of τ in OAHU was found via 10-fold cross-validation on the development set.

4.5.2 Constraint Generation and Evaluation Metric. With the training images in the development set, we generate the training constraints in the same way as Section 4.3.2. However, in this experiment, we sample 50,000 constraints (25,000 seeds) for each dataset due to the vast amount of classes included in them. The Recall@K metric [13] is applied for performance evaluation. Each test image (query) first retrieves K most similar images from the test set and receives a score of 1 if an image of the same class is retrieved among these K images and 0 otherwise. Recall@K averages this score over all the images.

4.5.3 Analysis. The Recall@K scores on the test set of CARS-196 and CIFAR-100 are shown in Figure 7a and Figure 8a, respectively. We observe that OAHU outperforms all baseline approaches by providing significantly higher Recall@K scores. In addition, the Recall@K score of OAHU grows more rapidly than that provided by most baselines. Figure 7b and Figure 8b illustrate the metric weight distribution of OAHU on CARS-196 and CIFAR-100 respectively. Compared to the baselines that are only linear models, OAHU takes full advantage of non-linear metrics to improve the model expressiveness. Figure 9 shows some examples of successful and failure queries on both datasets. Despite the huge change in the viewpoint,

(a) CARS-196 (b) CIFAR-100

Figure 9: Examples of successful and failure queries on the CARS-196 and CIFAR-100 datasets using our embedding. Images in the first column are query images and the rest are three most similar images. Best viewed on a monitor zoomed in.

configuration, and illumination, our method can successfully retrieve examples from the same class and most retrieval failures come from subtle visual difference among images of different classes.

4.6 Sensitivity of Parameters

The three main parameters in OAHU is the control parameter τ. We vary τ from 0.1 to 0.9 and S_{emb} from 10 to 100 to study their effect on the classification performance. We observe that both classification accuracy (1-error rate) and F_1 score significantly drop if τ is greater than 0.6 but remain unchanged with various τ values if $\tau \leq 0.6$. This observation verifies Theorem 3.1 which states that classes are separated if $\tau \in (0, \frac{2}{3})$. On the other hand, the classification accuracy of OAHU peaks at embedding size $S_{emb} = 50$ where all semantic information are maintained. If we further increase the embedding size, noisy information is going to be introduced which degrades the classification performance. Therefore, we suggest to choose $\tau = 0.1$ and $S_{emb} = 50$ as default.

5 LIMITATIONS AND CONCLUSIONS

In this paper, we propose a novel online metric learning framework, called OAHU, that learns a ANN-based metric with adaptive complexity and a full constraint utilization rate. Compared to the state-of-the-art baselines, OAHU not only obtains the best performance by automatically adapting its complexity to improve the model expressiveness, but also is more robust in terms of the quality of input constraints. Like existing state-of-the-art solutions, OAHU fails when facing severe concept drift data that invalidate the learned similarity metric. We leave the extension of OAHU to severe concept drift scenarios for future work.

ABSTRACT

Mental health illness such as depression is a significant risk factor for suicide ideation, behaviors, and attempts. A report by Substance Abuse and Mental Health Services Administration (SAMHSA) shows that 80% of the patients suffering from Borderline Personality Disorder (BPD) have suicidal behavior, 5-10% of whom commit suicide. While multiple initiatives have been developed and implemented for suicide prevention, a key challenge has been the social stigma associated with mental disorders, which deters patients from seeking help or sharing their experiences directly with others including clinicians. This is particularly true for teenagers and younger adults where suicide is the second highest cause of death in the US. Prior research involving surveys and questionnaires (e.g. PHQ-9) for suicide risk prediction failed to provide a quantitative assessment of risk that informed timely clinical decision-making for intervention. Our interdisciplinary study concerns the use of Reddit as an unobtrusive data source for gleaning information about suicidal tendencies and other related mental health conditions afflicting depressed users. We provide details of our learning framework that incorporates domain-specific knowledge to predict the severity of suicide risk for an individual. Our approach involves developing a suicide risk severity lexicon using medical knowledge bases and suicide ontology to detect cues relevant to suicidal thoughts and actions. We also use language modeling, medical entity recognition and normalization and negation detection to create a dataset of 2181 redditors that have discussed or implied suicidal ideation, behavior, or attempt. Given the importance of clinical knowledge, our gold standard dataset of 500 redditors (out of 2181) was developed by four practicing psychiatrists following the guidelines outlined in Columbia Suicide Severity Rating Scale (C-SSRS), with the pairwise annotator agreement of 0.79 and group-wise agreement of 0.73. Compared to the existing four-label classification scheme (no risk, low risk, moderate risk, and high risk), our proposed C-SSRS-based 5-label classification scheme distinguishes people who are supportive, from those who show different severity of suicidal tendency. Our 5-label classification scheme outperforms the state-of-the-art schemes by improving the graded recall by 4.2% and reducing the perceived risk measure by 12.5%. Convolutional neural network (CNN) provided the best performance in our scheme due to the discriminative features and use of domain-specific knowledge resources, in comparison to SVM-L that has been used in the state-of-the-art tools over similar dataset.

1 INTRODUCTION

According to recent data from the US Centers for Disease Control and Prevention (CDC), suicide is the second leading cause of death for people aged between 10-34 [45] and fourth leading cause for people aged 35-64, escalating the suicide rate in the US by 30% since

1999[1]. Suicide Prevention Resource Center in the US[2] reports that 45% of people who committed suicide had visited a primary care provider one to two months before their death. These visits were often scheduled for something other than complaints of depression or suicide, suicidal patients may be too embarrassed to bring up suicide. Clinicians often have no prior warning that the patient is currently suicidal or will be developing significant signs of suicidality. Hence, novel strategies are necessary to proactively detect, assess, and enable timely intervention to prevent suicide[3].

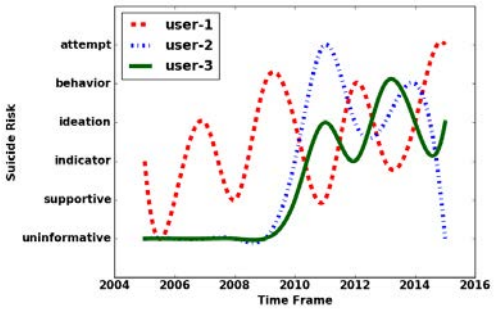

Figure 1: Changing Suicide Risk of 3 Redditors over a period of 11 years

Mental health conditions have been closely linked to suicide [17]. Depression, bipolar and other mood disorders are known to be the main risk factors for suicide, while substance abuse and addiction have been closely linked to suicidal thoughts[4]. SAMHSA[5] reports that people with BPD, Alcoholism, and Drug Addiction are more prone to having suicidal behaviors (e.g., holding gun to the head, driving sharp knife through nerves) and committing suicide. Apart from mental health conditions, there are various other factors exacerbating an individual's urge to commit suicide such as workplace/sexual harassment, religious scripts encouraging self-sacrifice, and heroic portrayal of death in movies. Moreover, popular celebrities who commit suicide can lead to "copycat" suicides or Werther effect [39]. It refers to the contagious influence that a popular figure's suicide can have on an individual, encouraging them to commit suicide. There are several resources for patients to seek help from such as CrisisTextLine, teen line, 7cups.com, imalive.org, and The Trevor Project for LGBTQ. Additional measures are necessary to improve timely intervention [5]. Unobtrusive collection and analysis of social media data can provide a means for gathering insights about an individual's emotions, and suicidal ideation and behavior [33]. A system capable of gleaning digital markers of suicide risk assessment from social media conversations of a patient (see Figure 1) can help a mental health professional (MHP) for making informed decisions as the patients may be reluctant to directly share all the relevant information due to the social stigma associated with mental illness and suicide[22].

There is a significant body of work addressing issues concerning suicide and mental health using social media content. TeenLine, Tumblr, Instagram, Twitter, and Reddit have been common sources of data for research in computational social science [7, 8, 56]. Among these, Reddit has emerged as the most promising one due to the anonymity it affords, its popularity as measured by its content size, and its variety as evident from the diverse subreddits being used for posting that reflects a user's state of mind and mental health disorder, e.g., r/Depression, r/SuicideWatch, r/BipolarSoS. Analysis of the content on Reddit can be leveraged to help an MHP develop an insight into the current situation of an individual, to improve the quality of the diagnosis and intervention strategies if necessary. Shing et al.[54] analyzed the postings of users in SuicideWatch and other related subreddits (e.g., r/bipolarreddit, r/EatingDisorder, r/getting_over_it, and r/socialanxiety) for assessment of suicide risk. The critical opportunity to improve upon these efforts is to utilize reliable domain-specific knowledge sources for understanding the content from a clinical perspective. Specifically, this strategy can augment raw Reddit content to normalize it into a standard medical context and improve the decision-making process of the MHP.

Prior research on suicide risk assessment employs four-label (no risk, low risk, moderate risk, and high risk) classification scheme for categorization of suicidal users [54]. In this research, we provide a C-SSRS-based five-label (supportive, indicator, ideation, behavior, and attempt) classification scheme guided by clinical psychiatrists, which allows the MHP to determine an actionable measure of an individual's suicidality and appropriate care [65]. We compared our 5-label scheme with two other variants: 4-label (indicator, ideation, behavior, and attempt) and (3+1)-label (supportive + indicator, ideation, behavior, and attempt) for monitoring progression and for alerting an MHP as necessary.

Apart from identifying the risk factors of suicide, we can develop approaches to generate answers to the questions from the content in C-SSRS[6], such as (1) Have you wished you were dead or wished you could go to sleep and not wake up? and (2) Have you actually had any thoughts of killing yourself? Our study aims to develop mapping and learning approaches for estimating the suicide risk severity level of an individual, based on his/her posted content [1].

Key Contributions: (1) We develop an annotated gold standard dataset of 500 Reddit users, out of 2181 potentially suicidal users, using their content from mental health-related subreddits. (2) Using domain-specific resources- SNOMED-CT, DataMed, Drug Abuse Ontology (which incorporates DSM-5 [60]) and ICD-10, we created *suicide risk severity lexicon*, curated by MHPs. This enabled us to create a competitive baseline for evaluating our approach. (3) Using four evaluation metrics (graded recall, confusion matrix, ordinal error, and perceived risk measure), we show that the C-SSRS based 5-label classification scheme improves upon the state-of-the-art scheme to characterize suicidality of a user. (4) Our evaluation shows that CNN emerges as a superior model for suicide risk prediction task outperforming the two competing baselines: rule-based and SVM-linear. Technological advancements over the last decade have transformed the health care system with a trend towards real-time monitoring, personal data analysis, and evidence-based diagnosis. Specifically, with the anticipated inclusion of individual's social data and the rapidly growing patient-generated health data [52], MHPs will be better informed about the patient's conditions including their suicidality to enable timely intervention.

2 RELATED WORK

In this section, we describe prior research related to our study.

2.1 Suicide and Social Media

Jashinsky et al. [28], and Christensen et al. [9] predicted the level of suicide risk for an individual over a period of time using Support Vector Machines (SVM) and the features of Term Frequency-Inverse Document Frequency (TF-IDF), word count, unique word count, average word count per tweet, and average character count per tweet. De Choudhury et al. [17] identified linguistic, lexical, and network features that describe a patient suffering from a mental health condition for predicting suicidal ideation. Analysis of content that contains self-reporting posts on Reddit can provide insights on mental health conditions of users. Utilizing propensity score matching, [17] measured the likelihood of a user sharing thoughts on suicide in the future. Another study from Sueki [58] investigated the linguistic variations among different authors on social media, and observed correlation between suicidal behavior and suicide-related tweets. Furthermore, Cavazos-Rehg et al. [8] performed a qualitative analysis of user's content on Tumblr to better understand discourse of self-harm, suicide, and depression. The study highlights Tumblr as a platform for development of suicide prevention efforts through early intervention. Further, people on social media with mental health conditions, often look for similar people [48].

2.2 Analysis of Suicidal Risk Severity

So far, prior research studied the identification of signals for predicting the suicide risk, mental health conditions leading to suicide [15, 16, 47], psychological state and well-being [50, 51]. Nock et al. [40] reported that ∼9% of people have thoughts of suicide, ∼3% map out their suicidal plans, ∼3% make a suicide attempt and ≤1% people constitute what are known as "suicidal completers". Much information extracted from the content of an individual provide explicit, implicit or ambivalent clues for suicide. These clues can help an MHP assess suicide severity, and better structure the treatment process [11].

Shing et al.[54] used 1.5M posts from 11K users on SuicideWatch subreddit. In the study, experts and crowd-source workers annotated the posts from 245 users using labels defined in [12]. The study evaluates the annotation quality of experts and non-experts and performs risk and suicide screening experiments using linguistic and psycho-linguistic features based on machine/deep learning classifiers. The study fails to bring together different mental health conditions that lead to suicide. Inclusion of supportive users on social media, who are not suicidal, as these constitute the negative samples. Further, the rubric for annotating the dataset was not authoritative, whereas, we utilize C-SSRS endorsed by NIH and SAMHSA.

2.3 Models for Suicide Prediction

In a recent study on predicting suicide attempt in adolescents, Bhat et al. employed deep neural networks for predicting the presence of suicide attempts using >500K anonymized Electronic Health Records (EHR) obtained from California Office of Statewide Health Planning and Development (OSHPD). Through a series of experiments, researchers achieved a true positive rate of 70% and a true negative rate of 98.2% [4]. Another study by Walsh et al. [61] on predicting suicidal attempts using temporal analysis, employs Random Forest (RF) over a cohort of 5167 patients. The study segregates the cohort of patients into 3250 cases and 1917 controls. They achieved an F1-score of 86% with a recall of 95% [61]. The study used binary classification scheme for Electronic Health Records (EHR) dataset, which is not suitable for identifying supportive and indicator users. A transfer learning from social media to EHR can improve its effectiveness [62]. Amini et al. utilized SVM, and decision trees besides RF and Neural Networks (NN), for assessing the risk of suicide in a dataset of individuals from Iran [2]. A recent study by Du et al. [19] used deep learning methods to detect psychiatric stressors leading to suicide. They built binary classifier for identifying suicidal tweets from non-suicidal tweets using Convolutional Neural Networks (CNN). Once suicidal tweets are detected,they performed Named Entity Recognition (NER) using Recurrent Neural Networks (RNN) for tagging psychiatric stressors in a tweet classified as suicidal.

3 BACKGROUND STUDY

We detail the medical knowledge bases underlying the suicide risk severity lexicon used in a baseline (see Section 5.2).

3.1 Domain-specific Knowledge Sources

Medical knowledge bases are resources manually curated by domain experts providing concepts and their relationships for processing the content. As our study aims to assess the severity of at-risk suicidal users, the domain knowledge that corresponds to different levels of suicidality of a patient is crucial. In this work, we employ ICD-10, SNOMED-CT, Suicide Ontology, and Drug Abuse Ontology (DAO) [7] for creating a suicide lexicon to be used in one of our baselines.

Concepts in **SNOMED-CT** are categorized into procedure, observable entity, situation, event, assessment scale, therapy, disorder, and finding and can be extracted using "parents", "children", and "sibling" relationships. For example, Suicide by Hanging [SNOMED ID: 287190007] is a child concept of Suicide [SNOMED ID: 44301001] and sibling concept of Assisted Suicide [SNOMED ID: 51709005], Drug Overdose - Suicide [SNOMED ID: 274228002], Suicide while incarcerated [SNOMED ID: 23546003], and Suicide by self-administered Drug [SNOMED ID: 891003]. **ICD-10** is a medical standard that provides information on patient's health state such as severity, complexity, comorbidities, and complications. Concepts in ICD-10 are categorized into signs, symptoms, abnormal findings, and diagnosis. For example, "suicide attempt" is categorized under a Personal history of self-harm [ICD-10 ID: Z91.5]. It is also categorized under Borderline Personality Disorder [ICD-10 ID: F60.3], Intentional self-harm [ICD-10 ID: X60-X84], and Severe depressive episode with psychotic symptoms [ICD-10 ID: F32.3]. "suicidal ideation" is categorized under Post-traumatic stress disorder[ICD-10 ID: F43.1]. **Suicide Ontology** is an ontology, called "suicideonto"[7] built through text mining and manual curation by domain experts. The ontology contains 290 concepts defining the context of suicide. **Drug Abuse Ontology (DAO)** is a domain-specific hierarchical framework developed by Cameron et al. [7] containing 315 entities (814

[7] https://bioportal.bioontology.org/ontologies/suicideo

instances) and 31 relations defining drug-abuse and mental-health concepts. The ontology has been utilized in analyzing web-forum content related to buprenorphine, cannabis, a synthetic cannabinoid, and opioid-related data [13, 14, 34]. In [21] it was expanded using DSM-5 categories covering mental health and applied for improving mental health classification on Reddit.

3.2 Existing Domain Specific Lexicons

Prior research [6, 38] highlighted the disparity between the informal language used by social media users and the concepts defined by domain experts in medical knowledge bases. Medical entity normalization fills such a gap by identifying phrases (n-grams, or topics) within the content and mapping them to concepts in medical knowledge bases [36]. We use (i) two lexicons, namely, TwADR-L and AskaPatient (see Table 1) to map the social media content to medical concepts [36], and (ii) anonymized and annotated suicide notes made available through Informatics for Integrating Biology and the Bedside (i2b2) challenge to identify content with negative emotions (see Table 2).

Table 1: Existing domain specific lexicons used in this study

Lexicon	#SNOMED Concepts	Max. #phrases per Concept	Sample SNOMED to informal terms mapping
TwADR-L	2172	36	**SNOMED Concept:** Acute depression **Phrases:** 'acute depression', 'just want to finally be happy', 'hated my life', 'depression'
AskaPatient	3051	56	**SNOMED Concept:** Anxiety **Phrases:** 'anxious', 'anxiety issues', 'anxiety', 'anzity'

TwADR-L [36] maps medical concepts in SIDER[8] to their corresponding informal terms used in Twitter. The lexicon has 2172 medical concepts, each of which has up to 36 informal Twitter terms. Each informal term is assigned a single medical concept. AskaPatient[9] [36] maps informal terms from AskaPatient web forum to medical concepts in SNOMED-CT and Australian Medical Terminology [35]. Since this lexicon was created from a web forum, it is more informative compared to TwADR-L. i2b2 Suicide Notes is a dataset generated as a part of the emotion recognition task in 2011 [63]. We have ~2K suicide notes annotated for different emotions, and of them with negative emotions were removed, resulting in 817 suicide notes (see Table 2 for examples).

Table 2: Suicide notes aggregated by emotion labels defined in i2b2.

Emotion Label	#Suicide Notes	Example
abuse	9	My son got married to a horrible woman who does not care curses swears and pushes me around.
anger	69	I have no idea why I could let one person hurt me I loved you for so long but I think I hate you now.
fear	25	In this case you would finally meet defeat so crushing will drain strip you off your courage and hope
guilt	208	God is just and it is true that I am a no good but God will see all that I had to pass through
hopelessness	455	Dear Jane Dont think to badly of me for taking this way out but I am frustrated by taking so much pain
sorrow	51	My heart has been hurt hard and grieving.

[8]http://sideeffects.embl.de
[9]https://www.askapatient.com/

3.3 Suicide Risk Severity Lexicon

Besides the existing lexicons (see Section 3.2), we have built a comprehensive lexicon containing terms related to each level of suicide risk severity (see Table 3). The lexicon was created using Suicideonto[10], DSM-5 [21], and concepts in i2b2 suicide notes. Besides these four severity levels, we consider a separate class of "supportive" users who are not suicidal, but use a similar language. The lexicon was created using the aforementioned medical knowledge bases and slang terms from DAO. The lexicon was validated by the domain experts, and used for annotation and for our baseline (see Section 5.2).

Table 3: Suicide Risk Severity lexicon

Suicide Class	# Terms in a class	Examples
Indicator	1535	Pessimistic character, Suicide of relative, Family history of suicide
Ideation	472	Suicidal thoughts, Feeling suicidal, Potential suicide care
Behavior	146	Planning on cutting nerve, Threatening suicide, Loaded Gun, Drug-abuse
Attempt	124	Previous known suicide attempt, Suicidal deliberate poisoning, Goodbye Attempted suicide by self-administered drug, Suicide while incarcerated.

3.4 Columbia Suicide Severity Rating Scale

Each C-SSRS severity class (ideation, behavior, or attempt) is composed of a set of questions that characterize the respective category. Responses to the questions across the C-SSRS classes eventually determine the risk of suicidality of an individual [44]. One of the challenges researchers face when it comes to dealing with social media content is the disparity in the level of emotions expressed. Since the C-SSRS was originally designed for use in clinical settings, adapting the same metric to a social media platform would require changes to address the varying nature of emotions expressed. For instance, while in a clinical setting, it is typically suicidal candidates that see a clinician; on social media, non-suicidal users may participate to offer support to others deemed suicidal. To address these factors, we have defined two additional classes to the existing C-SSRS scale with three classes. We have provided the description of the five classes in Section 4.4.1.

3.5 Suicide Seed Terms

Not all users in subreddit SuicideWatch (SW) are suicidal. We identify suicidal candidates in subreddit SW by looking into the nature of words used in users' posts.

We analyzed the content of SW subreddit against Zipf-Mandelbrot law to precisely identify terms that are 'prominent' in the online discussion of suicidal thoughts balancing frequency and relevance. In Figure 2, the cyan line follows Zipf-distribution while the green line follows the

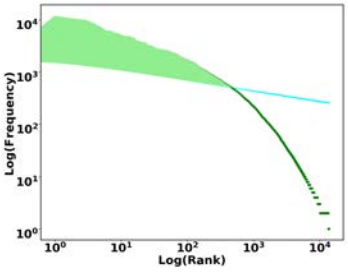

Figure 2: Zipf-Mandelbrot law over SW content for identifying prominent suicide seed terms. Highlighted is the selected region.

[10]https://bioportal.bioontology.org/ontologies/suicideo

Mandelbrot distribution. We are particularly interested in the region of the graph shaded in the top left corner off the cut-off mark between the two lines (light green).

Table 4: Suicide seed terms selected through Figure 2. W: Word, Ph:Phrase, SW: SuicideWatch.

W/Ph.	Freq. W/Ph in SW	W/Ph.	Freq. W/Ph in SW
Commit Suicide	539	Death	215
Hopelessness	130	Gun	577
Sadness	453	Isolation	104
Therapist	194	Trans[11]	96
Kill	577	Sleep	193

This region represents terms in the document that are frequently used by users while also having higher ranks (numerically small values). This effectively eliminates terms that are simply frequently used in the document, but have low ranks. Identified terms were validated by clinical psychiatrists and a curated list of 339 words with a cut-off frequency of 725. A sample list of 10 words is shown in Table 4.

Having identified the suicidally prominent terms, and in conjunction with negation detection technique, we filtered noisy users (users who don't 'positively' use one or more of these terms in their posts) and identified prominently suicidal users.

3.6 Embedding Models

Word embeddings are a set of techniques used to transform a word into a real-valued vector. This allows words with similar meanings to have similar representations and be clustered together in the vector space. Normally, we either generate domain-specific word embeddings local to our problem or employ general purpose word embeddings [32]. We utilize embeddings from ConceptNet[12] (vocabulary= 417193, dimension= 300), a multi-lingual knowledge graph created from expert sources, crowd-sourcing, DBpedia, vocabulary derived from Word2Vec[13] [49], and Glove[14] [43] [57].

4 DATASET CREATION AND ANALYSIS

In this section, we analyze the data, its features and our procedure to identify a small cohort of Redditors that resemble potential candidates for suicidal users (see Figure 3). Our dataset comprises 270,000 users with 8 Million posts from 15 mental health related subreddits; r/StopSelfHarm (SSH), r/selfharm (SLF), bipolar (r/bipolar (BPL), r/BipolarReddit (BPR), r/BipolarSOs, r/opiates (OPT), r/Anxiety (ANX), r/addiction (ADD), r/BPD, r/SuicideWatch (SW), r/schizophrenia (SCZ), r/autism (AUT), r/depression (DPR), r/cripplingalcoholism (CRP), and r/aspergers (ASP) [21]. We used 93K users who actively participated in the SuicideWatch subreddit providing 587466 posts. To further enrich our dataset, we gathered the posts of these users in the remaining 14 subreddits. The timeframe of our dataset is between 2005 and 2016.

4.1 Potential Suicidal Redditors

Subreddit "SuicideWatch" (SW) had nearly 93K redditors as of 2016. To create a representative sample dataset containing users at five-levels of suicide risk, we used seed terms generated using

[11]https://bit.ly/2NEK9bc
[12]http://conceptnet.io
[13]https://code.google.com/archive/p/word2vec/
[14]https://nlp.stanford.edu/projects/glove/

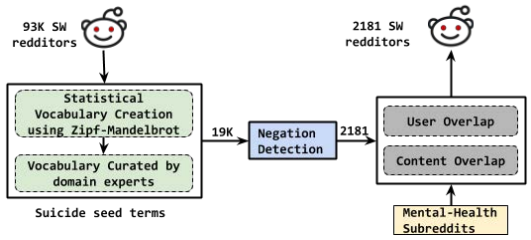

Figure 3: Procedure for generating the annotated dataset. Only 9 mental health subreddits were considered because of significant content overlap (see Figure 4)

Zipf-Mandelbrot (see Section 3.5). We obtained a working set of 19K redditors using such terms. Next, we employed negation detection procedure (see Section 4.2) to eliminate non-suicidal users. Finally, we obtained 2181 users who are potentially suicidal and had participated in other mental health subreddits. For referencing, we denote these users and their content in SW as U^{SW}.

4.2 Negation Detection

Negation detection is a crucial part as the presence of negated sentences can confound a classifier [23]. For example, *I am not going to end my life because I failed a stupid test* is not suicidal, whereas *My daily struggles with depression have driven me to alcohol* reflects user's mental health. The former sentence can give false positive, if we just extract 'going to end my life' as a precursor to a suicide attempt. We employ a negation detection tool and probabilistic context-free grammar that supports negation extraction and negation resolution to improve classifier performance [23].

4.3 User and Content Overlap

As individuals form communities based on shared topics of interest related to mental health conditions [59, 64] in different subreddits, we performed user and content overlap analysis between SW and other mental health subreddits to enrich the contents of users. This analysis provides deeper insight into how potentially suicidal users communicate on problems including causes, symptoms, and treatment solutions. Through user overlap we infer the population level similarity between a mental health subreddit and SW, whereas using content we quantify overlap in context for each user. We calculated the user overlap through the intersection of the users in U^{SW} and i^{th} mental health subreddit (U^{MH_i}). Content overlap was calculated using a cosine similarity measure through domain-specific lexicon, LDA2Vec [37] and ConceptNet.

We leverage the quantified similarity of suicide-related topics between content of the users in U^{SW} and other subreddits (U^{MH_i}), to append the content of users U^{SW}. This procedure will contribute to the holistic nature of the content and enable more discriminative features in the classifier. For example, a post in SW: *I dont think Ive thought about it every day of my entire life. I have for a good portion of it, however, my boyfriend may be able to determine whether I'm worth his time* seems to imply that the user is *non-suicidal*. However, after appending following post taken from "depression" subreddit: *Having a plan for my own suicide has been a long time relief for me as well. I more often than not wish I were dead*, we notice that the user has *suicidal ideations*. As the content in Reddit posts contain slang terms for medical entity, we employed a normalization procedure using standardized lexicons to provide a cleaner interpretation of a

patient's condition, meaningful to a mental health professional or clinician. To perform medical entity normalization, we utilize three lexicons (see Section 3.2), namely, i2b2, TwADR, and AskaPatient, which were created from Medical Records, Twitter, and Web Forum respectively. The normalization used string match.

Content overlap using TwADR-L and AskaPatient: We trained an LDA model with topic coherence over the normalized content to find coherent topics for SW subreddit. Subsequently, using the trained LDA model of SW content, we generated two sets of Topics at user level for U^{SW}, and U^{MH_i}. The topical similarity (TS) was calculated between topics of U^{SW}, and those U^{MH_i}. For the calculation of TS, the user should be present in U^{SW} and U^{MH_i} and should have an average similarity greater than 0.6 (defined empirically). We formalized TS as;

If $u \in U^{SW} \cap U^{MH_i}$, then

$$\left(\frac{1}{|U^{SW}|-1}\sum_{v \in U^{SW} \setminus \{u\}} \cos(\vec{u}^{MH_i}, \vec{v}^{SW})\right) > 0.6 \quad (1)$$

In the above equation, topic vector of users in U^{MH_i} is denoted as $\vec{u}^{MH_i}$ and that of U^{SW} as $\vec{v}^{SW}$.

The resultant column vector contains the similarity between MH_i and SW and has a dimension of **14x1**. Equation 1 used with for two lexicons: TwADR-L and AskaPatient for abstracting the concepts within the reddit posts. To create each column vector, we trained two topic models because TwADR-L lexicon has been created using Twitter and AskaPatient Lexicon using Forum content.

Content Overlap using i2b2: Table 2 shows 6 emotion labels in i2b2 suicide notes dataset. For quantifying the user's content with appropriate emotion label (Table 2), we generated embeddings of content in SW and other MH subreddits for each user using ConceptNet embedding model. We also generated the representations of the emotion labels of the suicide notes through concatenation and dimensionality reduction of the embedding vectors of their corresponding suicide notes [20]. Then, we performed the cosine similarity measure over: (i) embeddings of content from mental health subreddits for each user and the emotion labels, and (ii) embeddings of content from the SW subreddit for each user and the emotion labels. We formalize similarity between i2b2 label and user content embedding as follows:

$$UL(SW, L) = cos(\vec{u}, \vec{l}), u \in U^{SW}, l \in L \quad (2)$$

where UL(SW,L) stores the similarity values between the users in U^{SW} and the emotions labels in i2b2 (L), forming a matrix of dimension 2181 x 6. It is calculated using cosine similarity between the vector of a user ($u \in U^{SW}$) and an emotion label ($l \in L$). Each row of the matrix represents the similarity value for a user embedding generated from all their posts against embedding of each label in i2b2 generated from suicide notes. A similar matrix (using Equation 2) is created for users in other mental health subreddits ($u \in U^{SW} \cap U^{MH_i}$) and emotion labels L. We denote such a matrix as $UL(MH_i, L)$ of dimensions 2181 x 6. $UL(SW, L)$ and $UL(MH_i, L)$ are interpreted as matrices showing to what degree users' contents are close to six emotions. Thereafter, we generate a similarity score ($SS(MH_i, SW)$) as a product of $UL(SW, L)$ and transpose of $UL(MH_i, L)$. Formally we define it as:

$$\text{SS}(MH_i, SW) = \frac{\sum_{\vec{u} \in UL(SW,L)} \sum_{\vec{v} \in UL(MH_i,L)^T} \vec{u}.\vec{v}}{(|U^{SW}|-1)^2} \quad (3)$$

If the users are in U^{SW} and U^{MH_i}, their content will be appended to SW from MH_i only if the content overlap is greater than 0.6 in Equations 1 and 3. The procedure repeated over all MH subreddits and we obtain results shown in Figure 4.

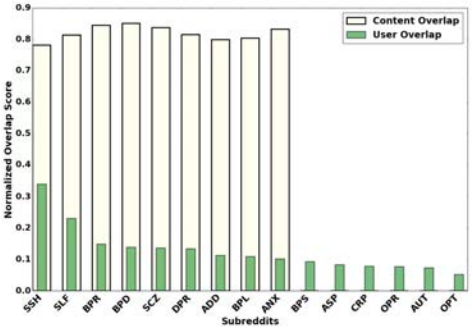

Figure 4: User Overlap and Content Overlap based quantification of influence of other mental health related subreddit to SW. Subreddits *SSH* and *SLF* have the highest content overlap with SW followed by *BPR* and *BPD*.

4.4 Gold Standard Dataset Creation

We describe different classes of suicidality, characterizing users who suffer from mental health conditions or involve themselves in a supportive role on social media. Further, we describe annotated dataset with examples and annotation evaluation using Krippendorff.

4.4.1 5-labels of Suicide Risk Severity: C-SSRS begins with ***Suicidal Ideation*** (*ID*), which is defined as thoughts of suicide including preoccupations with risk factors such as loss of job, loss of a strong relationship, chronic disease, mental illness, or substance abuse. This category can be seen to escalate to ***Suicidal Behavior*** (*BR*), operationalized as actions with higher risk. A user with suicidal behavior confesses active or historical self-harm, or active planning to commit suicide, or a history of being institutionalized for mental health. Actions include cutting or using blunt force violence (self-punching and head strikes), heavy substance abuse, planning for suicide attempt, or actions involving a means of death (holding guns or knives, standing on ledges, musing over pills or poison, or driving recklessly). The last category, an ***Actual Attempt*** (*AT*), is defined as any deliberate action that may result in intentional death, be it a completed attempt or not, including but not limited to attempts where a user called for help, changed their mind or wrote a public "good bye" note. When reviewing users' risk levels for social media adaptation, two additional categories were added to define user behaviors less severe than the above categories.

The first addition was a ***Suicide Indicator*** (*IN*) category which separated those using at-risk language from those actively experiencing general or acute symptoms. Oftentimes, users would engage in conversation in a supportive manner and share personal history while using at-risk words from the clinical lexicon. These users might express a history of divorce, chronic illness, death in the family, or suicide of a loved one, which are risk indicators on the C-SSRS, but would do so relating in empathy to users who expressed ideation or behavior, rather than expressing a personal desire for self-harm. In this case, it was deemed appropriate to flag such users as *IN* because while they expressed known risk factors that could be monitored they would also count as false positives if they were accepted as individuals experiencing active ideation or behavior.

The second additional category was named as ***Supportive*** (*SU*) and is defined as individuals engaging in discussion but with no language that expressed any history of being at-risk in the past

or the present. Some identified themselves as having background in mental health care, while others did not define their motive for interacting at all (as opposed to a family history). Since posting on Reddit is not itself a risk factor, so we give these users a category with even lower risk than those expressing support with a history of risk factors. Any use of language such as a history of depression, or "I've been there" would re-categorize a user as exhibiting suicidal indicator, ideation, or being at greater risk, depending on the language used. These new categories for an adapted C-SSRS should help account for those who communicate in suicide-related forums but were at a low or undefined risk.

4.4.2 Description of the Annotated Dataset: For the purpose of annotation, we randomly picked 500 users from a set of 2181 potential suicidal users. In the annotated data, each user on an average has 31.5 posts within the time frame of 2005 to 2016.

The annotated data comprises of 22% supportive users, 20% users with some suicidal indication but cannot be classified as suicidal, 34% users with suicidal ideation, 15% users with suicidal behaviors, and 9% users have made an attempt (success or fail) to commit suicide. Supportive users constitutes 1/5th of the total data size and prior studies have ignored them. Table 5 shows posts from redditors and their associated suicide risk

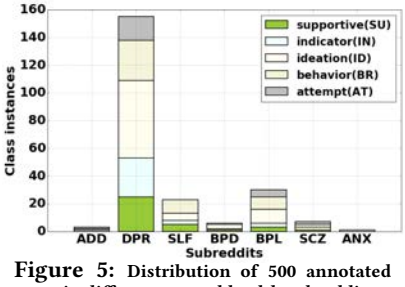

Figure 5: Distribution of 500 annotated users in different mental health subreddits

Table 5: Paraphrased posts from candidate suicidal redditors and associated suicide risk severity level

Always time for you to write your happy ending .... doesnt need to be spelled out with alcohol and Xanax.... keep an open mind	SU
Ive never really had a regular sleep schedule....no energy to hold a conversation....no focus on study....barely eat and sleep....fluffy puppy dog face	IN
Sometimes I literally cant bear to move....my depression....since I was 14....suffering rest of my life....only Death is reserved for me.	ID
Driving a sharp thing over my nerve. Extreme depression and loneliness.... worthless excuse for a life....used everything from wiring to knife blades	BR
I am going to off myself today...loaded gun to my head..determined....huge disappointment....screwed family life....breaks my heart everyday.	AT

severity level. To identify which mental health subreddits (except SW) contributed most to suicidality, we mapped potential suicidal Redditors to their subreddits (see Figure 5).

4.4.3 Evaluation of Annotation: Four practicing clinical psychiatrists were involved in the annotation process. Each expert received 500 users dataset comprising of 15755 posts. We perform two annotation analysis defined for ordinal labels: **(1)** A pair-wise annotator agreement using Krippendorff metric (α) to identify the annotator with highest agreement with others, **(2)** An incremental group wise annotator agreement to find the robustness of the earlier annotator [55]. For group wise agreement, we denote a set of annotators as G with cardinality ($|G|$) range from 2 to 4. α is calculated as $1 - (\frac{D_o(A_j,S)}{D_e})$, where $D_o(A_j, S)$ is observed disagreement and D_e is expected disagreement. The pairwise annotator agreement is a subset of groupwise and we formally define it as:

Table 6: (left). Pairwise annotator agreement, (right). Group wise annotator agreement. A,B,C,and D are annotators.

	B	C	D
A	0.79	0.73	0.68
B	-	0.68	0.61
C	-	-	0.65

	B	B&C	B&C&D
A	0.79	0.70	0.69

$$D_o(A_j, S) = \frac{1}{N.|S|} \sum_{i=1}^{N} \sum_{m \in S} |A_j^i - S_m^i|^2, S \subset G \setminus \{A_j\} \quad (4)$$

$$D_e = \frac{2}{N \cdot |G|(|G|-1)} \sum_{i=1}^{N} \sum_{m,q \in G, m \neq q} |G_m^i - G_q^i|^2 \quad (5)$$

where A_j is the annotator having highest agreement in pairwise α. S is the subset of a group of annotators G that excludes A_j. G_m^i and G_q^i represents the two annotators m and q within the group G^i. i is the index over all the users in the dataset. Results of pairwise and group wise annotators agreement is in Table 6. We observe a substantial agreement between the annotators[15].

5 EXPERIMENTAL DESIGN

5.1 Characteristic Features

Prior research has shown the importance of psycholinguistics, lexical, syntactic, and emotion features in enhancing the efficacy of the classifier [24, 46]. We further improve our feature set with information provided by Reddit. In training our models we used *AFINN*[16], which is a list of words scored for sentiment, emotions, mood, feeling, or attitude. Posts on Reddit may have nearly equal number of upvotes and downvotes making them controversial. We computed *controversiality score (CScore)* as the ratio of the maximum value of the difference, between *upvotes* and *downvotes*, and 1, over *totalvotes*.

$$\text{CSscore} = \max\left(1, \frac{\#upvotes - \#downvotes}{\#totalvotes}\right)$$

We factored in *Intra-Subreddit Similarity* with and without nouns and pronouns as a measure of content similarity of posts between a user and others in a subreddit. To determine the level of personal experience in the social media text, we utilize *First Person Pronouns Ratio* that measures the extent to which a Redditor talks about his/her own experience compared to other Redditors' experience [10]. We used *Language Assessment by Mechanical Turk (LabMT)*, a list of 10,222 words with happiness, rank, internet usage scores, employing strict match and soft match with Reddit posts [18]. On social media, readability is an important factor. We use *height of the dependency parse tree* to measure readability, with parse tree height being proportional to readability [25]. We employ *maximum length of verb phrase* [26] to capture suicidality of individuals. Similarly, *number of pronouns* was used to determine whether they are sharing a direct experience or second hand experience [42]. The value of this feature was high for users classified as supportive or indicator, as these users usually help others. Moreover, *number of sentences* and *number of definite articles* are also discriminative [27].

[16] http://neuro.imm.dtu.dk/wiki/AFINN

5.2 Baselines

In this study, we use two baselines; (1) 4-class scheme for predicting the suicide risk [54] (2) an empirical baseline based on the suicide risk severity lexicon. We provide details of our lexicon-based empirical baseline. Suicide lexicon developed as a part of the study for initial filtering of users and annotation process is a suitable resource for a baseline. This baseline is a rule-based model for classifying a user based on a strict and soft match criteria according to presence of a concept in the user's content and the suicide risk severity lexicon. For a competitive baseline, we compared this baseline with word-embedding and TF-IDF based approaches for suicide classification [29]. As we also experimented with word-embedding models trained over suicide and non-suicide related content, using compositions of word vectors [3, 32, 41], the baseline based on suicide risk severity lexicon outperformed these competitive approaches.

5.3 Convolutional Neural Network

We have implemented a convolutional neural network (CNN) as proposed in [30] for our contextual classification task [53].

The model takes embeddings of user posts as input and classifies into one of the suicide risk severity levels. We combine embeddings of posts for each user through concatenation, and pass into the model.

$$posts_u = post_{u,1} \bigoplus post_{u,2} \bigoplus ..post_{u,p}.. \bigoplus post_{u,P} \quad (6)$$

$$post_{u,p} = \vec{v}_{u,p,1} \bigoplus \vec{v}_{u,p,2} \bigoplus ..\vec{v}_{u,p,w}.. \bigoplus \vec{v}_{u,p,W} \quad (7)$$

Here $\bigoplus$ represents the concatenation operation of P posts of user u, where each post p of user u ($post_{u,p}$) is the concatenation of vectors of each word w ($\vec{v}_{u,p,w}$) where W is the total number of words in a post. Embeddings of the posts for each user ($posts_u$) have variable length. Hence, we use minimum length padding to make the dimensions of the representations uniform. The model has a convolution layer with filter window {3, 4, 5} and 100 filters for each. After getting the convoluted features, we apply max-pooling and concatenate the representative pooled features. We pass the pooled features through a dropout layer with dropout probability of 0.3, followed by an output softmax layer. The learning rate was set to 0.001 with adam optimizer [31]. While training the model, we have used mini batch of size 4 and trained for 50 epochs. CNN's performance is compared and evaluated in Section 6.

5.4 Evaluation Metrics

We alter the formulation of False Positive (FP) and False Negative (FN) to better evaluate the model performance. FP is defined as the ratio of the number of times the predicted suicide risk severity level (r') is greater than actual level (r^o) over the size of test data (N_T). FN is defined as the ratio of the number of times r' is less than r^o over N_T. Since the numerators of FP and FN involves comparison between r' and r^o suicide risk severity levels, we termed the metrics as graded precision, and recall as graded recall. Ordinal Error (OE) is defined as the ratio of the number of samples where difference between r^o and r' is greater than 1. In our study it represents the model's tendency to label a person as having no-severity or low degree of severity, when he/she is actually at risk.

We formally define FP, FN, and OE as:

$$FP = \frac{\sum_{i=1}^{N_T} I(r'_i > r^o_i)}{N_T},\ FN = \frac{\sum_{i=1}^{N_T} I(r^o_i > r'_i)}{N_T},\ OE = \frac{\sum_{i=1}^{N_T} I(\Delta(r^o_i, r'_i) > 1)}{N_T}$$

where $\Delta(r^o_i, r'_i)$ is the difference between r^o_i and r'_i. r'_i and r^o_i are the predicted and actual response for i^{th} test sample.

5.4.1 Perceived Risk Measure (PRM): It is defined to better characterize the difficulty in classifying a data item while developing a robust classifier in the face of *difficult to unambiguously* annotate datasets. It captures the intuition that if a data item is difficult for human annotators to classify unambiguously, it is unreasonable to expect a machine algorithm to do it well, or in other words, misclassifications will receive reduced penalty. On the other hand, if the human annotators are in strong agreement about a classification of a data item, then we would increase the penalty for any misclassification. This measure captures the biases in the data using disagreement among annotators. Based on this intuition, we define PRM as the ratio of disagreement between the predicted and actual outcomes summed over disagreements between the annotators multiplied by a reduction factor that reduces the penalty if the prediction matches any other annotator. We formally define it as;

$$PRM = \frac{1}{N_T} \sum_{i=1}^{N_T} \left(\frac{1 + \Delta(r'_i, r^o_i)}{1 + \sum_{m,q \in G^i, m \neq q} \Delta(G^i_m, G^i_q)} \cdot \frac{\sum_{m \in G^i} I(r'_i = G^i_m)}{|\mathbf{G^i}|} \right) \quad (8)$$

Where the denominator is the disagreement between G^i_m and G^i_q annotators summed over all annotators in a group $\mathbf{G^i}$ (notations are same as in equation 5). $\frac{\sum_{m \in G^i} I(r'_i = G^i_m)}{|\mathbf{G^i}|}$ is the risk reducing factor calculated as the ratio of agreement of prediction with any of the annotators over the total number of annotators. In cases where r' disagrees with all the annotators in $\mathbf{G}$, the risk reducing factor is set to 1.

6 RESULTS AND ANALYSIS

We evaluate the model performance over different levels of suicide severity. We categorize our experiments into three schemes: **Experiment 1** evaluates the performance of the models over 5 labels (supportive, indicator, ideation, behavior, and attempt); **Experiment 2** evaluates models' performances over 4 labels in which supportive (or negative) samples are removed, and **Experiment 3** comprises labels defined according to 4-label categorization (where supportive and indicator classes are merged into one class : no-risk). Further, for each experiment, the input data is of two forms: **(I1)** Only textual features (TF) represented as vectors of 300 dimensions generated using ConceptNet embeddings , **(I2)** having Characteristics features (CF) (see Section 5.1) and textual features (CF+TF). All experiments were performed with 5 fold hold-out cross-validation. It was defined empirically, observing results at various folds. We show that the proposed 5-label classification scheme has better recall, and the perceived risk measure of the 5-label classification scheme is low compared to other reduced classification schemes. All the experiments have been performed with 5-fold cross validation and results are reported on hold-out test set.

6.1 Experiment 1: 5-Label Classification

For evaluation, we consider five learning models (SVM with Radial Basis Function (SVM-RBF), SVM with Linear Kernel (SVM-L), Random Forest (RF), Feed-Forward Neural Network (FFNN), CNN) that have been used in similar studies (see Section 2.3) over two types of inputs: I1 and I2. For input I1, the baseline is a suicide-lexicon based

classifier which is content-based, and for input I2, the baseline is SVM-L which is the best performing model in Shing et al. [54].

Table 7: Experiment with 5-label Classification

Approach	Input	With Supportive Class			
		Graded Precision	Graded Recall	F-Score	OE
Baseline	text	0.56	0.36	0.44	0.38
SVM-RBF	I1	0.53	0.51	0.52	0.12
	I2	0.57	0.62	0.61	0.12
SVM-L	I1	0.60	0.45	0.52	0.12
	I2	0.77	0.40	0.53	0.09
RF	I1	0.68	0.49	0.57	0.19
	I2	0.62	0.45	0.52	0.11
FFNN	I1	0.45	0.59	0.51	0.15
	I2	0.52	0.63	0.57	0.12
CNN	I1	0.71	**0.60**	0.65	0.10
	I2	0.70	**0.59**	0.64	0.09

Input type I1: Table 7 reports that CNN outperforms the baseline with an improvement of 40% in precision, 5% in recall, and 25% in F-score. Based on small improvement in recall, it is inferred that CNN has a tendency to predict a low risk level (e.g; Supportive) for a user who has an observed high risk (e.g; Behavior). SVM-RBF and SVM-L show an improvement in precision compared to baseline; however, there is 12% and 27% reduction in recall respectively. Further, RF showed a 40% increase in precision at a cost of 16% reduction in recall. On the contrary, FFNN performed relatively well in comparison to baseline concerning recall. Hence, at a fine-grained level of comparison, CNN outperforms the baseline with a considerable improvement in precision and recall. To better characterize the comparison between the models, we analyze them using OE. Such a measure is coarse-grained and focuses more on FN as opposed to acceptable FP. Based on Table 7, we observed that CNN showed the least error based on OE calculation, reporting that 1% of the people have been predicted with a severity level of difference 2 or more compared to observed. Such a measure of evaluation is important because it ignores the biases in the gold standard data. As a result, CNN correctly predicted the severity of 90% of users.

Input Type I2: In comparison to the second baseline, CNN outperforms SVM-L with an improvement of 32% in recall with reduction of 10% in precision. We infer from Table 7 that SVM penalized false positives more than false negatives because of its linearity and i.i.d (independent, identically distributed)[17] assumptions. Whereas, CNN's convoluted representation ignores i.i.d assumptions, the non-linearity induced by ReLU tries to balance FP and FN. It can be seen from recall of SVM-RBF for I2 which is higher than SVM-L. However, SVM-RBF fails to balance FP and FN because of i.i.d considerations. Further, from column OE in Table 7, we infer that CNN predicted a suicidality level >1 compared to observed, for 9% of the users, whereas SVM-L did for 10% of the users.

6.2 Experiment 2: 4-label Classification

To evaluate the models over 4-label classification scheme, we use the same approach as applied in Experiment 1 for the purpose of consistency. In addition, in this experiment, the baseline model created over suicide lexicon disregards supportive labels.

[17] https://bit.ly/2Rw9i5Z

Table 8: Experiment with 4-label Classification

Approach	Input	Without Supportive Class			
		Graded Precision	Graded Recall	F-Score	OE
Baseline	text	0.43	0.57	0.49	0.20
SVM-RBF	I1	0.63	0.47	0.54	0.12
	I2	0.66	0.59	0.62	0.12
SVM-L	I1	0.62	0.53	0.57	0.12
	I2	0.68	0.57	0.61	0.09
RF	I1	0.67	0.41	0.51	0.22
	I2	0.64	0.47	0.54	0.18
FFNN	I1	0.63	0.58	0.60	0.15
	I2	0.67	0.62	0.64	0.12
CNN	I1	0.72	**0.59**	0.65	0.11
	I2	0.70	**0.57**	0.62	0.1

Observing Tables 7 and 8, there is a noticeable improvement in the precision of the models due to reduction in the degree of freedom of the outcome variable (removal of supportive class). Moreover, Tables 7 and 8 show the reduction in recall and an increase in OE. Hence, 5-label scheme supports lower OE for best performing model than does 4-label scheme.

Input Type I1 and Input Type I2: For the content-based input, all the models outperform the baseline in terms of precision, however, only CNN model outperforms baseline in terms of recall. Interestingly, there is a decrease in the recall of the models with non-linear kernel from 5-label to 4-label classification scheme; yet, there is a marginal increase in true positives of SVM-L. It can be inferred that SVM-L is vulnerable to predicting some of indicator users as supportive and ideation users as indicator in experiment 1. However, CNN was able to identify supportive users and most of the classification was centered around ideation and indicator levels; 4-label scheme does not bring in major change in OE for CNN.

6.3 Experiment 3: 3+1 Classification

In this classification scheme, we collapsed the supportive and indicator classes into a common class: "control group". It allows us to create the classification structure as defined in [12]. For this experiment, we considered two top performing models from previous experiments: SVM-L and CNN.

Table 9: Experiment with 3+1-label Classification

Approach	Input	Collapsed Supportive and Indicator Class			
		Graded Precision	Graded Recall	F-Score	OE
SVM-L	I1	0.81	0.54	0.65	0.12
	I2	0.74	0.54	0.63	**0.09**
CNN	I1	0.83	**0.57**	0.676	0.07
	I2	0.85	**0.57**	0.68	**0.06**

Input type I1 and I2: Using such a classification scheme (see Table 9), we observe a significant improvement in precision of SVM-linear and CNN in comparison to previous experiments. Apart from the decrease in the degree of freedom of outcome, the model tries to predict the supportive+indicator and ideation classes as opposed to "behavior" and "attempt". Since supportive+indicator and ideation classes are in majority, they boost the precision of the model. However, the model shows a reduction in recall in this scheme compared to 5-label or 4-label classification scheme. Table 10 shows reduction in OE for CNN from 0.1 to 0.07 for I1 and 0.09 to 0.06 for I2 compared to 5-label classification. It is because 3+1 classification

scheme forces the model to compromise with the popular classes and affect the selection of suitable class. Moreover, through our 5-label classification scheme, we achieved an improvement of 4.2% in graded recall over the (3+1) scheme (see Tables 7 and 9).

6.4 5-label Confusion Matrix Analysis

In this evaluation metric we categorize our suicidality labels into two groups; (1) No-Treatment Groups: Supportive and Indicator User, (2) Treatment Groups: Ideation, Behavior, Attempt.

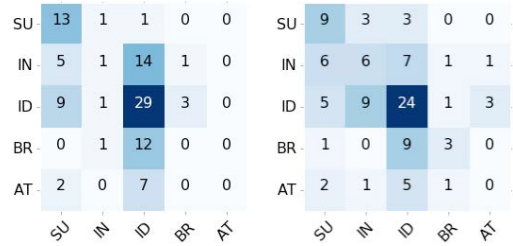

Figure 6: Confusion Matrix of 5-label scheme. (left) CNN, and (right) SVM-L. Y-Axis: True Level, X-Axis: Predicted Level

From Figure 6, out of 36 No-treatment users, CNN correctly classifies 20 users (56%) whereas SVM-L correctly classifies 22 users (61%). However, observing a larger 64 Treatment users, CNN correctly classifies 51 users (80%) whereas SVM-L correctly classifies 46 users (72%). Hence, CNN provides more suitable class for the users compared to SVM-L.

6.5 4-Label Confusion Matrix Analysis

Under the 4-label classification scheme, the No-treatment population involves users annotated as indicator whereas Treatment population contains users annotated as ideation, behavior and attempt. From Figure 7, we observe that CNN correctly classifies 59 out of 64 users (92%) annotated under Treatment whereas SVM-L classifies 53 out of 64 users (83%).

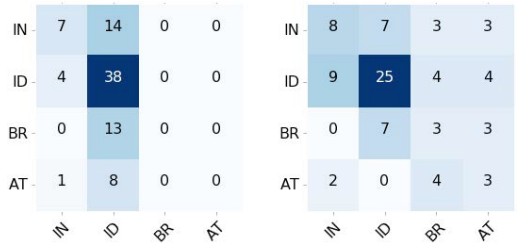

Figure 7: Confusion Matrix of 4-label scheme. (left) CNN, and (right) SVM-L

6.6 3+1 Label Confusion Matrix Analysis

There are 36 users under No-Treatment (supportive and indicator (SU+IN)) group and 64 users under Treatment group. Based on figure 8, we noticed that CNN correctly classifies 26 out of 36 (72%) No-Treatment users whereas SVM-L scored 16 out of 36 (44%). Further, CNN and SVM-L recognized 39 users (61%) and 46 users (72%) in the Treatment group. The decrease in CNN from 80% (5-label) to 61% is attributed to the increase in attempt, behavior, and ideation users classified as No-Treatment.

However, there was no change for SVM-L. But, on comparing 5-label and 3+1 label classification schemes, we observed that collapsing of the supportive and indicator classes can lead to increase in the false positive as SVM-L predicts them as behavior and attempt. There is a reduction in the true positive score for predictive

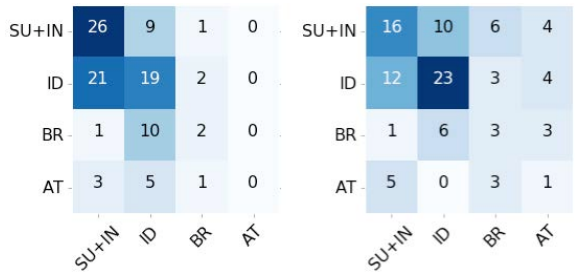

Figure 8: Confusion Matrix of (3+1)-label scheme. (left) CNN, and (right) SVM-L

and actual ideation classes, and users marked as "attempt" have been classified as "supportive and indicator (SU+IN)". As a result, the false negatives of the models have increased. Although this analysis proves the efficacy of 5-label classification over 3+1, CNN being a conservative model, there is a possibility of annotator bias in the data. So below, we perform PRM analysis of SVM-L and CNN over 2 classification schemes: 5-label and 3+1 label.

6.7 Perceived Risk Measure Analysis

Table 10: PRM based comparison of classification schemes

Scheme	Models	PRM
5-Label	CNN	0.14
	SVM-L	0.61
(3+1) Label	CNN	0.16
	SVM-L	0.54

On analyzing models behavior using PRM (Equation 8), Table 10 shows that there is a 12.5% difference between 5-label and 3+1 label classification schemes. Results can be interpreted as: For CNN under 5-label, there is 14% chance that model will provide an outcome that disagrees with every annotator, whereas, for (3+1)-label, it is 16%. Further, we observe that SVM-L has a high risk score compared to CNN in both classification schemes.

7 CONCLUSION

In this study, we presented an approach to predict severity of suicide risk of an individual using Reddit posts, which will allow medical health professionals to make more informed and timely decisions on diagnosis and treatment. A gold standard dataset of 500 suicidal redditors with varying severity of suicidal risk was developed using suicide risk severity lexicon. We then devised a 5-label classification scheme to differentiate non-suicidal users from suicidal ones, as well as suicidal users at different severity levels of suicide risk (e.g., ideation, behavior, attempt). Our 5-label classification scheme outperformed the two baselines. We specifically noted that CNN provided best performance among others including SVM and Random Forest. We make both the gold standard dataset and the suicide risk severity lexicon publicly available to the research community for further suicide-related research.

ABSTRACT

Most popular web browsers include "reader modes" that improve the user experience by removing un-useful page elements. Reader modes reformat the page to hide elements that are not related to the page's main content. Such page elements include site navigation, advertising related videos and images, and most JavaScript. The intended end result is that users can enjoy the content they are interested in, without distraction.

In this work, we consider whether the "reader mode" can be widened to also provide performance and privacy improvements. Instead of its use as a post-render feature to clean up the clutter on a page we propose `SpeedReader` as an alternative multistep pipeline that is part of the rendering pipeline. Once the tool decides during the initial phase of a page load that a page is suitable for reader mode use, it directly applies document tree translation *before the page is rendered*. Based on our measurements, we believe that `SpeedReader` can be continuously enabled in order to drastically improve end-user experience, especially on slow mobile connections. Combined with our approach to predicting which pages should be rendered in reader mode with 91% accuracy, `SpeedReader` achieves average speedups and bandwidth reductions of up to 27× and 84×, respectively. We further find that our novel "reader mode" approach brings with it significant privacy improvements to users. Our approach effectively removes all commonly recognized trackers, issues 115 fewer requests to third parties, and interacts with 64 fewer trackers on average, on transformed pages.

CCS CONCEPTS

• **Human-centered computing** → **Web-based interaction**; • **Information systems** → **Browsers**; **Clustering and classification**; *Content analysis and feature selection*; • **Security and privacy** → *Privacy protections.*

1 INTRODUCTION

"Web bloat" is a colloquial term that describes the trend in websites to accumulate size and visual complexity over time. The phenomena has been measured in many dimensions, including total page size [7], page load time [5, 44, 45], memory needed [30], number of network requests [16, 28], amount of scripts executed [26, 34, 37, 39] and third parties contacted [25, 26, 28]. This work suggests that growth in page size and complexity is outpacing improvements in device hardware. All of this has a predictably negative impact on user experience.

Web users and browser vendors have reacted to this "bloat" in a variety of ways, all partially helpful, but with significant downsides. Ad and tracking blockers are a popular and useful tool for reducing the size complexity of sites. Prior work has shown that these tools can be effective in reducing privacy leaks [31], network use, and extend device memory life. Such tools, which use filter lists, are inherently limited in the scope of improvements they can achieve. While these filter lists are large [42], they are small as a proportion of all URLs on the web. Similarly, while these lists are updated often, they are updated slowly compared to URL updates on the web.

Similarly, "reader mode" tools, provided in many popular browsers and browser extensions, are an effort to reduce the growing visual complexity of websites. Such tools attempt to extract the subset of page content useful to users, and remove advertising, animations, boilerplate code, and other non-core content. Current "reader modes" do not provide the user with resource savings since the referenced resources have already been fetched and rendered. The growth and popularity of such tools suggest they are useful to browser users, looking to address the problem of page clutter and visual "bloat".

In this work, we propose a novel strategy called **`SpeedReader`** for dealing with resource and bloat on websites. Our technique provides a user experience similar to existing "reader mode" tools, but with network, performance, and privacy improvements that exceed existing ad and tracking blocking tools, on a significant portion of websites. Significantly, `SpeedReader` differs from existing deployed reader mode tools by operating *before page rendering*,

which allows it to determine which resources are needed for the page's core content before fetching.

How we achieve speedups. SpeedReader achieves its performance improvements through a two-step pipeline:

(1) SpeedReader uses a classifier to determine whether there is a readable subset of the initial, fetched page HTML. This classifier is trained on a labeled corpus of 2,833 websites (see Section 3), and determines whether a page can be display in reader mode with 91% accuracy.
(2) If the classifier has determined that the page is readable, SpeedReader extracts the readable subset of document *before rendering*, using a variety of heuristics developed in prior research [24] and browser vendors [9, 23], and passes the simplified, reader mode document to the browser's render layer. This tree translation step is described in Section 4.

Deployment. Combined with a highly accurate classifier of "readable" pages, the drastic improvements in performance, reduction in bandwidth use and elimination of trackers in reader mode make the approach practical for continuous use. We therefore propose SpeedReader as a sticky feature that a user can toggle to be always on. This approximates the experience of using an e-book reader, but with strengths of content availability on the web. It is also a suitable strategy for content prerendering or prefetching that could be implemented by web browser vendors, automatically delivering graceful performance degradation in poor connectivity areas or on underpowered mobile devices until the rest of the page content can be fetched for a complete render.

Contributions.

- **Novel approach to Reader Mode** - combining machine-learning driven approach to checking whether content can be transformed to text-focused representation for end-user consumption.
- **Applicability** - we demonstrate that 22.0% of web pages are convertible to reader mode style in a dataset of pages reported popular by Alexa. We further demonstrate that 46.27% of pages shared on social networks are *readable*.
- **Privacy** - we demonstrate that using reader mode in the proposed design provides superior privacy protection, effectively removing all trackers from the tested pages, and dramatically reducing communication with third-parties.
- **Ad Blocking** - we show that our unique reader mode approach blocks ads *at least as well* as existing ad blocking tools, blocking 100% of resources labeled as advertising related by EasyList in a crawl of 91,439 pages, without the need to use hand curated, hard-coded filter lists.
- **Speed** - we find that the lightweight nature of reader mode content results in huge performance gains, with up to 27× page load time speedup on average, together with up to 84× bandwidth and 2.4× memory reduction on average.

Paper organization. The rest of this paper is structured as follows. Section 2 provides background information to place SpeedReader in context. Section 3 describes the design, evaluation and accuracy of the classifying step in the SpeedReader pipeline, and Section 4 gives the design and evaluation of the reader mode extraction step in the SpeedReader pipeline. Section 3.3 measures how many websites user encounters that are amenable to SpeedReader, under several browser use scenarios. Section 5 provides some discussion for how our findings can inform future readability, privacy and performance work, Section 6 places this work in the context of prior research, and Section 7 concludes.

2 BACKGROUND

2.1 Terminology

This subsection presents several terms that are not standardized. We present them up front, to ease the understanding of the rest of the work.

Reader mode. We use the term "reader mode" to describe any tool that attempts to extract a useful subset of a website for a simplified presentation. These tools can be either included in the web browser by the browser vendor, added by users through browser extensions, or provided by third parties as a web service. Our use of the term "reader mode" is generic to the concept, and should not be confused with any specific tool.

Classification and transduction. Reader mode tools generally include both a technique for determining whether a page is readable, which we refer to as "classification", and a strategy for converting the initial HTML tree into a simplified reader mode tree, which we refer to as "tree transduction". Though most reader mode tools include both steps within a single tool or library, they are conceptually distinct.

Readable. We use the term "readable" to describe whether a web page contains a subset of content that would be useful to display in a reader mode presentation. Reader mode presentation works best on pages that are text and image focused, and that are mostly static (i.e. few interactive page elements). Examples of such readable pages include articles, blog posts, and news sites. Reader mode presentation does not work well on websites that are highly interactive, or when a page's structure is significant to the page's content. Examples of such non-readable pages include web applications (e.g. Google Mail, Google Maps) or pages that are indexes of other content.

2.2 Existing Reader Modes

Several popular web browsers include reader modes designed to simplify a page's presentation, so that browser users can read the page's contents without distraction of visual clutter such as advertisements, page animations, and unnecessary page boilerplate (e.g. footers, page navigation, comments).

In this section, we give a brief description of several existing reader mode tools, how they're deployed by their authors, and how they are used in the evaluations given in the rest of this paper.

Readability.js. Readability.js [9] is an open source reader mode library, implemented in JavaScript. It is maintained by Mozilla, and is used for the reader mode function in Firefox. The code is closely related to "Readability" [2], an open sourced library developed by Arc90 and used for their now-defunct readability.com web service. Classification works by looking for the element on the page with the highest density of text and link nodes. If the number and density of text and link nodes in that element exceed a given threshold, the library treats the page as readable. Tree transduction works

by normalizing the contents of the text-and-link dense element (to remove styling and other mark up), looking for near-by images for inclusion, and using text patterns in the document that identify the page's author, source and publication date.

Significant to SpeedReader, Readability.js does not consider any display or presentation information when performing either the classification or tree transduction steps. This means that the page does not need to be loaded and rendered to generate a reader mode presentation (though in practice Firefox does not use this library in this way).

Safari Reader View. Safari Reader View is a JavaScript library that implements the reader mode presentation in Safari. Like Readability.js, it is also a fork from Arc90's "Readability", though Apple has changed how the library works in significant ways. In addition to looking for elements with high text and anchor density, Safari Reader View also uses presentation-level heuristics, including where elements appear on the page and what elements are hidden from display by default. Relevant to SpeedReader, this means that Safari Reader View must load a page and at least some of its resources (e.g. images, CSS, JavaScript) to perform either the classification or tree transduction level decisions. Because significant portions of Safari Reader View require a document be fetched and rendered before being evaluated, we do not consider it further in this work (for reasons that are detailed in Sections 3 and 4).

BoilerPipe. BoilerPipe is an academic research project from Kohlschütter *et al.* [24], and is implemented in Java. BoilerPipe has not been deployed directly by any browser vendor. BoilerPipe does not provide functionality for (readability) classification, and assumes that any HTML document contains a readable subset. For tree transduction, BoilerPipe considers number of words and link density features. Like Readability.js, it does not require a browser to load and render a page in order to do reader mode extraction. Their analysis reveals a strong correlation between short text and boilerplate, as well as long text and actual content text (of the textual content) on the Web. Using features with low calculation cost such as number of words enables BoilerPipe to lower the overhead while maintaining high accuracy.

DOM Distiller. DOM Distiller is a JavaScript and C++ library maintained by Google, and used to implement reader mode in recent versions of Chrome. The project is based on BoilerPipe, though has been significantly changed by Google. The classification step in DOM Distiller uses a classifier based approach, and considers features such as whether the page's URL contains certain keywords (e.g. "forum", ".php", "index"), if the page's markup contains Facebook open graph, Google AMP, identifiers, or the number of "/" characters used in the URL's path, in addition to the text-and-link density measures used by Readability.js. At a high level, the tree transduction step also looks at text-and-link dense element in the page, as well as special-cased embedded elements, such as YouTube or Vimeo videos.

DOM Distiller considers some render-level information in both the classification and tree transduction steps. For example, any elements that are hidden from display are not included in the text-and-link density measurements. These render-level checks are a small part of DOM Distiller's strategy. We modified DOM Distiller to remove these display level checks, so that DOM Distiller could be applied to prerendered HTML documents. We note that the evaluation of DOM Distiller in this work uses this modified version of DOM Distiller, and not the version that Google ships with Chrome. We expect this modification to have minimal effects on the discussed measurements, but draw the reader's attention to this change for completeness.

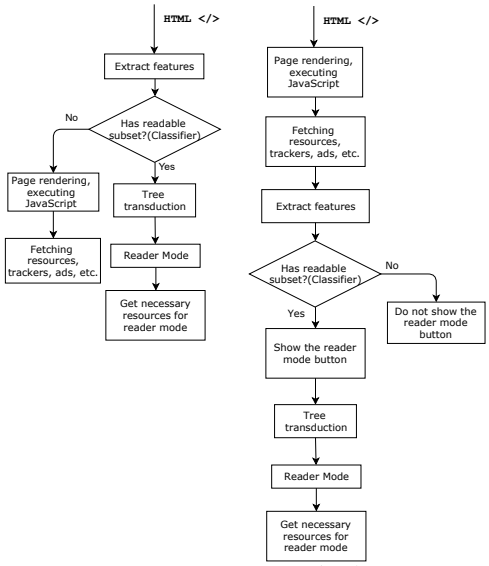

Figure 1: Comparison of SpeedReader (left) with other existing reader modes (right)

2.3 Comparison to SpeedReader

The reader mode functionality shipped with all current major browsers is applied after the document is fully fetched and rendered.[1] This greatly restricts the possible performance, network and privacy improvements existing reader modes can achieve. In fact, in some reader mode implementations we measured, using reader modes *increased* the amount of network used, as some resources were fetched twice, i.e. once for the initial page loading, and then again when presenting images in the reader mode display.

Most significantly, SpeedReader differs from existing reader mode techniques in that it is implemented strictly before the display, rendering, and resource-fetching steps in the browser. SpeedReader can therefore be thought of as a function that sits between the browser's network layer (i.e. takes as input the initial HTML document), and returns either the received HTML (when there is no readable subset), or a greatly simplified HTML document, representing the reader mode presentation (when there is a readable subset). Figure 1 provides a high level comparison of how SpeedReader functions, compared to existing reader modes.

The fact that SpeedReader only considers features available in the initial HTML and URL enables SpeedReader to achieve performance orders of magnitude above existing approaches. Figure 2

[1]While Readability.js does not require that the page be rendered before making reader mode evaluations, in practice Firefox does not expose reader mode functionality to users until after the page is fetched and loaded.

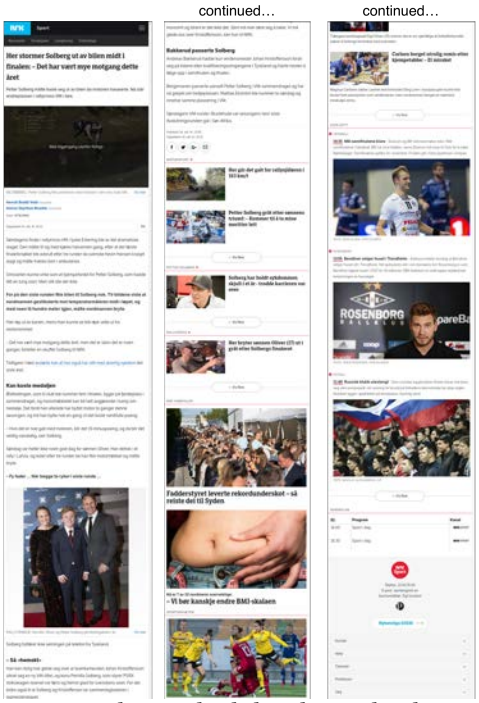

Figure 2: An example page loaded with Google Chrome browser with no modifications

provides a strawman example of a news page as delivered to a standard client: including portal branding and content, but also a range of links to different articles, images and trackers, for a total of 2.7MB of data transferred and 53 scripts executed. Figure 3 demonstrates the functionality of SpeedReader when applying existing reader mode transducers to just the initial HTML document. Therefore, for documents SpeedReader determines are readable, the sources of SpeedReader improvements include:

- Never fetching or executing script or CSS.
- Fetching far fewer images or videos (since images and videos not core to the page's presentation are never retrieved).
- Performing network requests to far fewer third parties (zero, in the common case).
- Saving processing power from not rendering animations, videos or complex layout operations, since reader mode presentations of page content are generally simple.

The above are just some of the ways that SpeedReader is able to achieve considerable performance improvements. The following sections describe how SpeedReader's classification and tree transduction steps were designed and evaluated, and what percentage of websites are amenable to SpeedReader's approach.

3 PAGE CLASSIFICATION

SpeedReader uses a two stage pipeline for generating reader mode versions of websites. This section presents the design and evaluation of the first half of the pipeline, the classification step.

Figure 3: The example page transformed with each of the evaluated SpeedReader transducers

3.1 Classifier Design

The classification step of SpeedReader uses a random forest classifier, trained on a hand-labeled data set of 2,833 websites. Our classifier takes as input a string, depicting an HTML document, and returns a boolean label of whether there is a readable subset of the document. We note that the input to the classifier is the initial HTML returned by the server, and not the final state of the website after JavaScript execution.

Our classifier is designed to execute quickly, since document rendering is delayed during classification. The classifier is trained using 50 estimators, it expands the nodes until all leaves are pure or contain less than 2 samples, and considers 21 features, each selected to be extractable quickly. Selected features include the number of text nodes, number of words, the presence of Facebook open graph or Google AMP markup, and counts for a variety of other tags.

Our classifier considers the following features. We have made the source code for our classifier available publicly as well.[2]

- Counts of the following tags: `<p>`, `<ul>`, `<ol>`, `<dl>`, `<div>`, `<pre>`, `<table>`, `<select>`, `<article>`, `<section>`, `<blockquote>`, `<a>`, `<img>`, `<script>`
- Count of block elements that contain at least 400 words.
- # of words in block elements that match above condition.
- Number of path segments in the URL.
- Boolean determination if the page has any of the following metatags: `amphtml`, `fb_pages`, `og_article`.
- Boolean determination if the page has plaintext match for any of `schema.org` markup for `Article`, `NewsArticle` or `APIReference`.

3.2 Classifier Accuracy

The goal of the classifier in SpeedReader is to predict whether the end result of a page's fetching and execution will result in a readable page, based on the initial HTML of the page. This section describes the data set we used to both train the SpeedReader classifier, and

[2] https://github.com/brave/speedreader-paper-materials.git

Table 1: Description of data set used for evaluating and training "readability" classifiers.

Data set	Number of pages	% Readable
Article pages	956	91.8%
Landing pages	932	1.5%
Random pages	945	22.0%
Total	**2,833**	**38.8%**

Table 2: Accuracy measurements for three classifiers attempting to replicate the manual labels described in Table 1.

Classifier	Precision	Recall
ReadabilityJS	68%	85%
DOM Distiller	90%	75%
SpeedReader Classifier	**91%**	**87%**

to evaluate its accuracy against existing popular, deployed reader mode tools.

Data Set. To assess the accuracy of our classifier, we first gathered 2,833 websites, summarized in Table 1. Our data set is made up of three smaller sets of crawled data, each containing 1,000 URLs, each meant to focus on a different kind of page, with a different expected distribution of readability. 1,000 pages were URLs selected from the RSS feeds of popular news sites (e.g. The New York Times, ArsTechnica), which we expected to be frequently readable. The second 1,000 pages were the landing pages from the Alexa 1K, which we expected to rarely be readable. The final 1,000 pages were selected randomly from non-landing pages linked from the landing pages of the Alexa 5K, which we expected to be occasionally readable. We built a crawler that, given a URL, recorded both the initial HTML response, and a screenshot of the final rendered page (i.e. after all resources had been fetched and rendered, and after JavaScript had executed). We applied our crawler to each of the 3,000 selected URLs. 167 pages did not respond to our crawler, accounting for the difference between the 3,000 selected URLs and the 2,833 pages in our data set.

Finally, we manually considered each of the final page screenshots, and gave each a boolean label of whether there was a subset of page content that was readable. We considered a page readable if it met the following criteria:

(1) The primary utility of the page was its text and image content (i.e. not interactive functionality).
(2) The page contained a subset of content that was useful, without being sensitive to its placement on the page.
(3) The usefulness of the page's content was not dependent on its specific presentation or layout on the website.

This meant that single page applications, index pages, and pages with complex layout were generally labeled as not-readable, while pages with generally static content, and lots of text and content-depicting media, were generally labeled readable. We also share our labeled data,[3] and a guide to the meaning behind the labels,[4] to make our results transparent and reproducible.

Evaluation. We evaluated our classifier on our hand labeled corpus of 2,833 websites, performing a standard ten-fold cross-validation.

[3]https://github.com/brave/speedreader-paper-materials/blob/master/labels.csv
[4]https://github.com/brave/speedreader-paper-materials/blob/master/labels-legend.txt

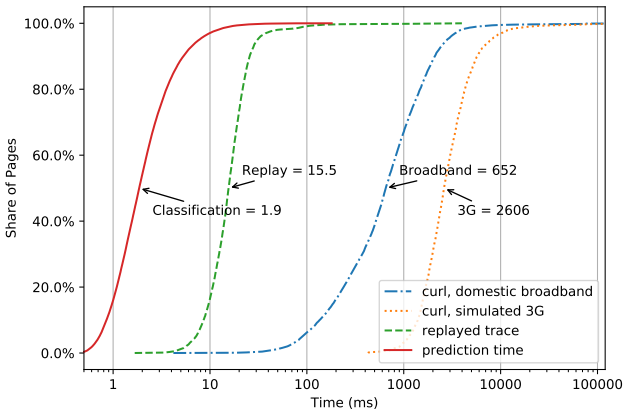

Figure 4: Time to fetch initial HTML document.

For comparison sake, we also evaluated the accuracy of the classification functionality in Readability.js and our modified version of DOM Distiller when applied to the same data set, to judge their ability to predict the final readability state of each document, given its initial HTML. We note that Readability.js is designed to be used this way, but that this prediction point is slightly different than how DOM Distiller is deployed in Chrome. In Chrome, DOM Distiller labels a page as readable based on its final rendered state. This evaluation of DOM Distiller's classification capabilities should therefore not be seen as an evaluation of DOM Distiller's overall quality, but only its ability to achieve the kinds of optimizations sought by `SpeedReader`. Table 2 presents the results of this measurement. As the table shows, `SpeedReader` strictly outperforms the classification capabilities of both DOM Distiller and Readability.js. DOM Distiller has a higher false positive rate than our classifier, while Readability.js has a higher false negative rate.

3.3 Classifier Usability

Problem Statement. Our classifier operates on complete HTML documents, before they are rendered. As a result, the browser is not able to render the document until the entire initial HTML document is fetched. This is different from how current browsers operate, where websites are progressively rendered as each segment of the HTML document is received and parsed. This entails a trade off between rendering delay (since rendering is delayed until the initial HTML document) and network and device resource use (since, when a page is classified as readable, far fewer resources will be fetched and processed).

In this sub-section, we evaluate the rendering delay caused by our classifier, under several representative network conditions. The rendering delay is equal to the time to fetch the entire initial HTML document. We find that the rendering delay imposed is small, especially compared to the dramatic performance improvements delivered when a page is readable (discussed in more detail in Section 4).

Classification Time. We evaluated the rendering delay imposed by our classifier by measuring the time taken to fetch the initial HTML for a page, under different network conditions, and compared it against the time taken for document classification.

Table 3: Measurements of how applicable our readability strategy is under common browser use scenarios.

Measurement	# measured	# readable	% readable
Popular pages	42,986	9,653	22.5%
Unpopular pages	40,908	8,794	21.5%
Total: Random crawl	**83,894**	**18,457**	**22.0%**
Reddit linked	3,035	1,260	41.51%
Twitter linked	494	276	31.2%
RSS linked	506	331	65%
Total: OSN	**4,035**	**1,867**	**46.27%**

First, we determined how long our classifier took to determine if a parsed HTML document was readable. We did so by parsing each HTML string with *myhtml*, a fast, open source, C++ HTML parser [4]. We then measured the execution time taken to extract the relevant features from the document, and to return the predicted label. Our classifier took 2.8 ms on average and 1.9 ms in the median case. Next, we measured the fixed, simulation cost time of serving each web page from a locally hosted web server, which allowed us to account for the fixed overhead in establishing the network connection, and similar unrelated browser book keeping operations. This time was 22.3 ms on average, and 15.5 ms median.

Finally, we selected two network environments to represent different network conditions and device capabilities web users are likely to encounter: a fast, domestic broadband link, with 50 Mbps uplink/downlink bandwidth and 2 ms latency as indicated by a popular network speed testing utility,[5] and a simulated 3G network, created using the operating system's *Network Link Conditioner*.[6] We use a default 3G preset with 780 kbps downlink, 330 kbps uplink, 100 ms packet delay in either direction and no additional packet loss. Downloading the documents on such connection took 1,372 ms / 652 ms (average/median) and 4,023 ms / 2,516 ms for the two cases respectively. Figure 4 summarizes the results of those measurements. Overall, the approximately 2.8 ms taken for an average document classification is a tiny cost compared to just the initial HTML download on reasonably fast connections. It could potentially be further optimized by classifying earlier, i.e. when only a chunk of the initial document is available. Initial tests show promising results, however this adds significant complexity to patching the rendering pipeline and we leave it for future work.

3.4 Applicability to the Web

While subsequent sections will demonstrate the significant performance and privacy improvements provided by SpeedReader, these improvements are only available on a certain type of web document, those that have readable subsets. The performance improvements possible through SpeedReader are therefore bounded by the amount of websites users visit that are readable.

In this subsection, we determine how much of the web is amenable to SpeedReader, by applying our classifier to a sampling of websites, representing different common browsing scenarios. Doing so allows us to estimate the benefits SpeedReader can deliver as well as its relevance to the web. As presented in Table 3, we find that a significant number of visited URLs are readable, suggesting that SpeedReader can deliver significant privacy and performance improvements to users. This subsection continues by describing how we selected URLs in each browsing scenario.

Websites by popularity. We first estimated how many pages hosted on popular and unpopular domains are readable. To do so, we first created two sets of domains, a popular set, consisting of the most popular 5,000 domains, as determined by Alexa, and an unpopular set, comprising a random sample of pages ranked 5,001–100,000. For each domain, we conducted a breadth three, depth three crawl. We first visited the landing page for the domain, and recorded all URLs linked to pages with the same TLD+1 domain. Then we selected up to three URLs from this set, and repeated the above process another time, giving a maximum of 13 URLs per domain, and a total data set of 91,439 pages. The crawl was conducted from AWS IP addresses on 17-20 October 2018.

Social network shared content. We next estimated how much content linked to from online social networks is readable, to simulate a user that spends most of their browsing time on popular online social networks, and generally only browses away to view shared content. We gathered URLs shared from Reddit and Twitter. We gathered links shared on Reddit by using RedditList [32] to obtain top 125 subreddits ranked based on their number of subscribers. We then visited the 25 posts of each popular subreddit and extracted any shared URLs. For Twitter, we extracted shared links from the top 10 worldwide Twitter trends by crawling and extracting shared links from their Tweets.

RSS / feed readers. Finally, we estimated how much content shared from RSS feeds is readable, to simulate a user who finds content mainly through an RSS (or similar) aggregation service. We built a list of RSS-shared content by crawling the Alexa 1K, identifying websites that included RSS feeds, and fetching the five most recent pages of content in each RSS feed.

3.5 Conclusion

In this section we have described how SpeedReader determines whether a page should be rendered in reader mode, based on its initial HTML. We find that SpeedReader outperforms the classification capabilities of existing, deployed reader mode tools. We also find that the overhead imposed by our classification strategy is small and acceptable in most cases, and dwarfed by the performance improvements delivered by SpeedReader, for cases when a page is judged readable.

4 PAGE TREE TRANSDUCTION

This section describes how SpeedReader generates a reader mode presentation of a page, for pages that have been classified as readable. Our evaluation includes three possible reader mode renderings, each presenting a different trade off between amount of media included, performance and privacy improvements.

Generating a reader mode presentation of an HTML document can be thought of as translating one tree structure to another: taking the document represented by the page's initial HTML and generating the document containing a simplified reader mode version. This process of tree mapping is generally known as tree transduction.

[5] speedtest.net - web service that provides analysis of Internet access performance metrics, such as connection data rate and latency

[6] Network Link Conditioner is a tool released by Apple with hardware IO Tools for XCode developer tools to simulate different connection bandwidth, latency and packet loss rates

Table 4: Description of data set used for evaluating the performance implications of different content extraction strategies.

Measurement	Value
Measurement date	17-20 October 2018
# crawled domains	10,000
# crawled pages	91,439
# domains with readable pages	4,931
# readable pages	19,765
% readable pages	**21.62%**

We evaluate Tree transduction by comparing the performance and privacy improvements of the three techniques (Readability.js, DOM Distiller and BoilerPipe) described in detail in Section 2.2.

4.1 Limitations and Bounds

We note that we did not attempt any evaluation of how users perceive or enjoy the reader mode versions of pages rendered by each considered technique. We made this decision for several reasons.

First, two of the techniques (Readability.js and DOM Distiller) are developed and deployed by large browser vendors, with millions or billions of users. We assume that these large companies have conducted their own usability evaluation of their reader mode techniques, and found them satisfactory to users.

Second, the third considered tree transduction technique, Kohlschütter et al's BoilerPipe [24], is an academic work that includes its own evaluation, showing that the technique can successfully extract useful contents from HTML documents. We assume that the authors' evaluation is comprehensive and sufficient, and that their technique can successfully render pages in reader mode presentations. Finally, we are planning to deploy a tree transducer different from existing techniques and a more thorough subjective evaluation of its presentation is left for future study.

4.2 Evaluation Methodology

We compared the performance and privacy improvements achieved through `SpeedReader`'s novel application of three tree transduction techniques: Readability.js, DOM Distiller and BoilerPipe. We conducted this evaluation in three stages.

First, we fetched the HTML of each URL in the random crawl data set outlined in Table 3, again from an AWS IP. The HTML considered here is only the initial HTML response, not the state of the document after script execution. We evaluated whether each of the 91,439 fetched pages that were classified as readable, by applying the `SpeedReader` classifier to each page. We then reduced the data set to the 19,765 pages (21.62%) were readable.

Second, we revisited each URL classified as readable to collect a complete version of the page. To minimize variations in page performance and content during the testing, we collected the "replay archive" for each page using the "Web Page Replay" (WPR) [22] performance tool. WPR is used in Chrome's testing framework for benchmarking purposes and works as a proxy that records network requests or responds to them instead of letting them through to the source depending on whether it works in "record" or "replay" mode.

Finally, we applied each of the three tree transduction techniques to the remaining 19,765 HTML documents, and compared the network, resource use, and privacy characteristics of each transformed page, against the full version of each page. We evaluate performance and privacy characteristics of each page by visiting the URL as replayed from its archive. These findings are described in detail in the next subsections.

Table 5: Performance comparisons of three popular readability tree transducer strategies, as applied to the data set described in Table 4. Values are given as Average, Median. Gain multiplier (×) is calculated for each page load and Average and Median values are reported.

Transducer	Resources (#)		Data (KB)		Memory (MB)		Load Time (ms)	
-	A	M	A	M	A	M	A	M
Default	144	91	2,283	1,461	197	174	1,813	1,069
ReadabilityJS	5	2	186	61	85	79	583	68
Dom Distiller	5	2	186	61	84	79	550	63
BoilerPipe	2	2	101	61	81	77	545	44
Gain (×)								
ReadabilityJS	51	28	84	24	2.4	2.1	20	11
Dom Distiller	52	32	84	24	2.4	2.1	21	12
BoilerPipe	77	48	84	24	2.4	2.1	27	15

We note that using a replay proxy with a snapshot of content often underestimates the costs of a page load. Despite taking care to mitigate the effects of non-determinism by injecting a small script that overrides date functions to use a fixed date and random number generator functions to use a fixed seed and produce a predictable sequence of numbers, it cannot account for all sources of non-determinism. For all requests that the proxy cannot match, it responds with a `Not Found` response. We notice that it results in a small number of requests being missed, primarily those responsible for dynamic ad loading or tracking. It also occasionally interferes with site publisher's custom resource fetching retry logic, where the same request is retried a number of times unsuccessfully, before the entire page load times out and the measurement is omitted.

4.3 Results: Performance

We measured four performance metrics: number of resources requested, amount of data fetched, memory used and page load time. These results are summarized in Table 5 and Figure 5.

We ran all measurements on AWS `m5.large` EC2 instances. For performance measurements, one test was executed at a time, per instance. For each evaluation, we fetched the page from a previously collected record-replay archive, with performance tracing enabled. Once the page was loaded and the performance metrics are recorded, we closed the browser and proxy, and started the next test. No further steps were taken to minimize the likelihood of test VM performance being impacted by interfering workloads on the underlying hardware. For all tests, we used an unmodified Google Chrome browser, version 70.0.3538.67, rendered in Xvfb.[7] Although profiling has overheads of its own [33], in particular for memory use and load times, we used a consistent measurement strategy across all tests, and therefore expect the impact to also be consistent and minor compared to relative performance gains.

We measured a page's load time as the difference between `navigationStart` and `loadEventEnd` events [46] in the main frame (i.e. the time until all sub-resources have been downloaded

[7]While Chrome "headless" mode is available, it effectively employs a different page rendering pipeline with different load time characteristics and memory footprint.

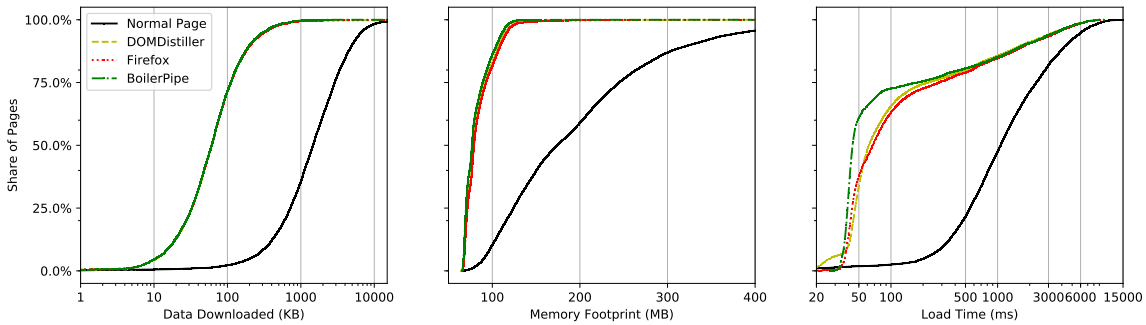

Figure 5: Performance characteristics of the different tree transducer strategies applied, showing the distribution of the key performance metrics.

and the page is fully rendered). Since page content is replayed from a local proxy, network bandwidth and latency variation impact is minimized and the reported load time is a very optimistic figure, especially for bigger pages with more sub-resources as illustrated in Figure 4. Although network cost is still non-zero, the number primarily reflects the time taken to process and render the entire page.

We also recorded the number of resources fetched and the amount of data downloaded during each test. Note that the amount of data downloaded for all of the tree transduction strategies reflects the size of the initial HTML rather than that of the transformed document, as the transformation happens on the client and does not result in additional network traffic. All measured transducers discard the majority of page content (both in page content like text and markup, but also referenced content like images, video files, and JavaScript). Figures 2 and 3 provide an example of how tree transduction techniques simplify page content.

For memory consumption, we measure the overall memory used by the browser and its subprocesses. Google Chrome uses a multi-process model, where each tab and frame may run in a separate process and content of each page also affects what runs in the main browser process. We note that our testing scenario does not consider the case of multiple pages open simultaneously in the same browsing session, as some of the resources are reused. The reported number is therefore that of the entire browser rather than the specific page alone, with some fixed browser runtime overheads.

Memory snapshots are collected with an explicit trigger after the page load is complete with `disabled-by-default-memory-infra` tracing category enabled. Despite including a level of fixed browser memory costs, we still see average memory reduction of up to 2.4× in average or median cases. Overall, depending on the chosen transducer, we show:

- average speedups ranging from 20× to 27×
- average bandwidth savings on the order of 84×
- number of requests is reduced 51× to 77×
- average memory reduction of 2.4×

4.4 Results: Privacy

`SpeedReader` achieves substantial privacy improvements, because it applies the tree transduction step *before* rendering the document, and thus before any requests to third parties have been initiated. The privacy improvements gained by `SpeedReader` are threefold: a reduction in third party requests, a reduction in script execution (an often necessary, though not sufficient, part of fingerprinting online), and a complete elimination of ad and tracking related requests (as labeled by EasyList and EasyPrivacy). This last measure is particularly important, since *92.8%* of the 19,765 readable pages in our data set loaded resources labeled as advertising or tracking related by EasyList and EasyPrivacy [10, 11].

Table 6: Comparisons of the privacy implications of three popular readability tree transducer strategies, as applied to the data set described in Table 4. Values are given as Average and Median values.

Transducer	# third-party		# scripts		Ads & Trackers	
	Avg	Med	Avg	Med	Avg	Med
Default	117	63	83	51	63	24
ReadabilityJS	3	1	0	0	0	0
Dom Distiller	3	1	0	0	0	0
BoilerPipe	1	1	0	0	0	0

This subsection proceeds by both describing how we measured the privacy improvements provided by `SpeedReader`, and the results of that measurement. These findings are presented in Table 6.

We measured the privacy gains provided by `SpeedReader` by first generating reader mode versions of each of the 19,765 readable URLs in our dataset, and counting the number of third parties, script resources, and ad and tracking resources in each generated reader mode page. We determined the number of ad and tracking resources by applying EasyList and EasyPrivacy with an open-source ad-block Node library [21] to each resource URL included in the page. We then compared these measurements to the number of third-parties, script units, and ad and tracking resource requests made in the typical, non-reader mode rendering of each URL.

We found that all three of the evaluated tree transduction techniques dramatically reduced the number of third parties communicated with, and removed all script execution and ad and tracking resource requests from the page. Put differently, `SpeedReader` is able to achieve privacy improvements at least as good, and almost certainly exceeding existing ad and tracking blockers, on readable pages. This claim is based on the observation that ad and tracking blockers do not achieve the same significant reduction in third party communication and script execution as `SpeedReader` achieves.

5 DISCUSSION AND FUTURE WORK

5.1 Reader Mode as a Content Blocker

Most existing reader mode tools function to improve the presentation of page content for readers, by removing distracting content and reformatting text for the browser user's benefit. While the popularity of existing reader modes suggest that this is a beneficial use case, the findings in this work suggest an additional use case for reader modes, blocking advertising and tracking related content.

As discussed in Section 4.4, SpeedReader prevents all ad and tracking related content from being fetched and rendered, as identified by EasyList and EasyPrivacy (Table 6). SpeedReader also loads between 51 and 77 times fewer resources than typical page rendering and reader modes (Table 5), a non-trivial number of which are likely also ad and tracking related. SpeedReader differs fundamentally from existing content blocking strategies. Existing popular tools, like uBlock Origin[20] and AdBlock Plus[15], aim to identify *malicious* or undesirable content, and prevent it from being loaded or displayed; all unlabeled content is treated as desirable and loaded as normal. SpeedReader, and (at last conceptually) reader modes in general, take the opposite approach. Reader modes try to identify *desirable* content, and treat all other page content as undesirable, or, at least, unneeded.

Our results suggest that the reader mode technique can achieve ad and tracking blocking quality *at least* as well as existing content blocking tools, but with dramatic performance improvements. We expect that SpeedReader actually outperforms content blocking tools (as content blockers suffer from false-negative problems, for a variety of reasons), but lack a ground truth basis to evaluate this claim further. We suggest evaluating the content blocking capabilities of reader mode-like tools as a compelling area for future work.

5.2 Comparison to Alternatives

SpeedReader exists among other systems that aim to improve the user experience of viewing content on the web. While a full evaluation of these systems is beyond the scope of this work (mainly because the compared systems have different goals and place different restrictions on users), we note them here for completeness.

AMP. Accelerated Mobile Pages (AMP)[17] is a system developed by Google that improves website performance, in a number of ways. Website authors opt-in to the AMP system by limiting their content to a subset of HTML, JavaScript and CSS functionality, which allows for optimized loading and execution. AMP pages are also served from Google's servers, which provide network level improvements. AMP differs from SpeedReader and other reader mode systems in that users only achieve performance improvements when site authors design their pages for AMP; AMP offers no improvement on existing, traditional websites.

Server-Assisted Rendering. Other browser vendors attempt to improve the user experience by moving page, loading, rendering execution from the client to a server. The client then fetches a rendered version of the page from the server (generally either rendered HTML or as a bitmap). The most popular such system is likely Amazon Silk[1]. While there are significant performance upsides with this thin-client technique, they come with significant downsides too. First, user privacy is harmed, since the rendering-server must manage and observe all client secrets when interacting with the destination server on the client's behalf. Additionally, while the server may be able to improve the loading and rendering of the page, its limited in the kinds of performance improvements it can achieve. Server assisted rendering does not provide any of the presentation simplification or content blocking benefits provided by SpeedReader.

5.3 SpeedReader Deployment Strategies

Always On. SpeedReader as described in this work is designed to be "always on", attempting to provide a readable presentation of every page fetched. Although Safari Reader View also supports an "always on" functionality, it lacks performance and privacy enhancement provided by SpeedReader (Section 2). While this decision maximizes the amount of privacy and performance improvements provided, it entails an overhead while loading each page (Figure 4), which may not be worthwhile in some browsing patterns such as interacting with application-like sites. Additionally, there may be times when users want to maintain a page's interactive functionality (e.g. JavaScript), even when SpeedReader has determined that the page is readable. Ensuring the user's ability to disable SpeedReader would be important in such cases. The system described in this work does not preclude such an option, but only imagines changing the default page loading behavior.[8]

Tree Transduction Improvements. The three evaluated techniques in Section 4, which are adapted from existing tools and research, can provide a reader mode presentation with different performance and privacy improvements. Users of SpeedReader could select which tree transduction technique best suited their needs. However, we expect that ML and similar techniques could be applied to the tree transduction problem, to provide a reader mode presentation that exceeds existing techniques. An improved tree transduction algorithm would achieve equal or greater performance and privacy improvements, while doing a better job of maintaining the meaning and information of the extracted content. We are currently exploring several options in this area, but have found the problem large enough to constitute its own unique work.

6 RELATED WORK

Content Extraction. The problem of removing boilerplate and extracting relevant content from a webpage has been extensively studied. Previous approaches primarily focused on the code structure, visual representation and the link between the two. Lin *et al.* [29] proposed a method to detect content blocks using <TABLE> tags and calculate their entropy to distinguish the informative blocks from the redundant ones. Laber *et al.* [27] proposed a heuristic method for extracting textual sections and title from news articles using <a>, <p> and <title> tags. Other studies have tried to detect *useful* segments in a web page using structural and positional information. Gupta *et al.* [18] introduced a DOM-based method to modify and remove irrelevant DOM nodes to extract the main content. Their

[8] Current browsers and reader modes load all pages in the standard manner, and allow the users to enable a reader mode presentation, while SpeedReader would load pages in the optimized reader mode presentation by default, when possible, and allow users to enable the standard loading behavior.

approach utilized filters to remove DOM nodes with advertisements, and link and text ratio thresholds to remove unwanted table cells. While the proposed rule-based method was simple, it had a poor performance in link rich pages where the main content contained many links. Weninger *et al.* [47] introduced a fast algorithm which calculated the HTML tag ratio of each line to cluster and extract text content. Their algorithm did not perform well on home pages as well as it suffered from high recall and low precision. Cai *et al.* [8] introduced a tag-free vision-based page segmentation algorithm to segment a webpage and extract its web content structure using the link between the visual layout and the content. Fan *et al.* [13] introduced Article Clipper, a web content extractor that leveraged visual cues in addition to HTML tags to extract non-textual and textual content and detect multi-page articles. Their approach underperformed in extracting captions which were links as well as images and captions that were outside of main content.

Heuristic methods are limited by their lack of adaptability. Some have proposed learning based methods to overcome this rigidness. Pasternack and Roth [35] described a semi-supervised algorithm, Maximum Subsequence Segmentation, which tokenized HTML into list of tags, words and symbols, and attempted to classify each block as either "in article" or "out of article" text. Kohlschütter *et al.* [24] developed BoilerPipe to classify text elements using both structural and text features, such as average word length and average sentence length. Sun *et al.* [40] proposed Content Extraction via Text Density (CETD) to extract the text content from pages using a variety of text density measurements. Their method relied on the observation that the amount of text in content sections is large, and the text in boilerplate sections contains more noise and links. Sluban and Grčar [38] introduced an unsupervised and language-independent method for extracting content from streams of HTML pages, by detecting commonalities in page structure. While their method outperformed other open-source content extractor algorithms, it suffered from high memory consumption and poor performance in diverse and small HTML data set.

Wu *et al.* [48] proposed a machine learning model using DOM tree node features such as position, area, font, text and tag properties to select and group content related nodes and their children. In their recent paper, Vogels *et al.* [43] presented an algorithm combining a hidden markov model and a convolutional neural networks (CNNs). Their model first preprocessed an HTML page into a Collapsed DOM (CDOM) tree where each single child parent node was merged with its child. CDOM was then segmented into blocks of main content and boilerplate using sequence labeling of DOM leaves. The features were then used to train two CNNs, obtain potentials and finally find the optimal labeling. Their approach outperformed previous studies on the CleanEval benchmark [3].

Web Complexity. While content extraction has attracted much attention in the scientific literature, fewer studies are conducted to understand website complexity and its impact on page load time and user experience. Gibson *et al.* [14] analyzed webpage template evolution using site-level template detection algorithms and found that templates, with little raw content value, represented 40-50% of the data on the Web and the rate continued to grow at a rate about 6% per year. Butkiewicz *et al.* [7] showed that modern websites, regardless of their popularity, were complex and such complexity could affect user experience. Moreover, their analysis demonstrated that the number of loaded objects and servers could indicate page load time, and both numbers were significant in News websites.

Performance and User Experience. While complexity of webpages can affect page load time, their visual complexity can impact user experience. Harper *et al.*showed that visual complexity in webpages, defined as diversity, density, and positioning of the elements, could increase cognitive load [19] and even have detrimental cognitive and emotional impact on users [41]. In many websites, online advertisements are the only source of income. Nonetheless, online ads, especially intrusive ads, have usability consequences [6]. As Pujol *et al.* [36] observed, 22% of the most active users of a major European ISP use Adblock Plus. As a result, providing the main content in a clutter free page, such as Reader Mode, not only decreases the complexity of a page, but also preserves privacy by limiting the number of requests for third-party services and trackers [12, 25] as well as improves user experience.

7 CONCLUSION

The modern web's progress has led us to the point far beyond Hypertext Markup for document discovery, to having full-fledged, media-rich experiences and dynamic applications. With this growth in capability, there has been a growth in page "bloat", making pages expensive to load, and bringing with it ubiquitous advertising and tracking. In this work, we propose `SpeedReader` as an approach broadening the applicability of "reader mode" browser features to deliver huge improvements to the end-user browsing experience.

Unique among reader mode tools, `SpeedReader` determines if a page is readable based only on the page's initial HTML, before the HTML is parsed and rendered, and before sub-resources are fetched. Our classifier can classify within 2 ms and with 91% accuracy, which makes it practical as an always-on part of the rendering pipeline to transform all suitable pages at load time. We find that `SpeedReader` is widely applicable, and can deliver performance and privacy improvements to 22% of pages on popular and unpopular websites, and a larger proportion of pages linked to from online social networks like Reddit (42%) and Twitter (31%). Since `SpeedReader` makes its modifications before sub-resources are fetched, it uses 84× less network than traditional page rendering (and current reader mode techniques). This results in page load time improvements, important in a range of scenarios from poor connectivity or low-end devices, to expensive data connectivity or simply wanting a clean and simple interaction with primarily textual content. `SpeedReader` also delivers page loading speedups of 20× - 27× and average memory reduction of 2.4×, while maintaining a pleasant, reader mode style user experience. Finally, when `SpeedReader` was applied to 19,765 readable webpages, it prevented 100% of advertising and tracking related resources from being fetched (as labeled by EasyList and EasyPrivacy).

ABSTRACT

One of the important yet insufficiently studied subjects in fair allocation is the externality effect among agents. For a resource allocation problem, externalities imply that the share allocated to an agent may affect the utilities of other agents.

In this paper, we conduct a study of fair allocation of indivisible goods when the externalities are not negligible. Inspired by the models in the context of network diffusion, we present a simple and natural model, namely *network externalities*, to capture the externalities. To evaluate fairness in the network externalities model, we generalize the idea behind the notion of maximin-share (MMS) to achieve a new criterion, namely, *extended-maximin-share* (EMMS). Next, we consider two problems concerning our model.

First, we discuss the computational aspects of finding the value of EMMS for every agent. For this, we introduce a generalized form of partitioning problem that includes many famous partitioning problems such as maximin, minimax, and leximin. We further show that a 1/2-approximation algorithm exists for this partitioning problem.

Next, we investigate on finding approximately optimal EMMS allocations, i.e., allocations that guarantee each agent a utility of at least a fraction of his extended-maximin-share. We show that under a natural assumption that the agents are α-self-reliant, an $\alpha/2$-EMMS allocation always exists. The combination of this with the former result yields a polynomial-time $\alpha/4$-EMMS allocation algorithm.

1 INTRODUCTION

Consider a scenario where there is a collection of m indivisible goods that are to be divided amongst n agents. For a properly chosen notion of fairness, we desire our division to be fair. Motivating examples are dividing the inherited wealth among heirs, dividing assets of a bankrupt company among creditors, divorce settlements, task assignments, etc.

Fair division has been a central problem in Economic Theory. This subject was first introduced in 1948 by Steinhaus [28] in the Polish school of mathematics. The primary model used the metaphor of cake to represent a single divisible resource that must be divided among a set of agents. *Proportionality* is one of the most well-studied notions defined to evaluate the fairness of a cake division protocol. An allocation of a cake to n agents is proportional if every agent feels that his allocated share is worth at least $1/n$ of the entire cake. Despite many positive results regarding proportionality in cake-cutting, moving beyond the metaphor of cake, the problem becomes more subtle. For example, when the resource is a set of indivisible goods, a proportional allocation is not guaranteed to exist for all instances[1].

For allocation of indivisible goods, Budish [10] introduced a new fairness criterion, namely *maximin-share*, that attracted a lot of attention in recent years [3, 6, 7, 14, 22, 27, 29]. This notion is a relaxation of proportionality for the case of indivisible items. Assume that we ask agent i to distribute the items into n bundles, and take the bundle with the minimum value. In such a situation, agent i distributes the items in a way that maximizes the value of the minimum bundle. The maximin-share value of agent i is equal to the value of the minimum bundle in the best possible distribution. Formally, the maximin-share of agent i, denoted by MMS_i, for a set $\mathcal{M}$ of items and n agents is defined as

$$\max_{P=\langle P_1,P_2,\ldots,P_n\rangle\in\Pi} \min_j V_i(P_j),$$

where Π is the set of all partitions of $\mathcal{M}$ into n bundles, and $V_i(P_j)$ is the value of bundle P_j to agent i. In a nice paper, Procaccia and Wang [27] show that in some instances, no allocation can guarantee maximin-share to all the agents, but an allocation guaranteeing each agent 2/3 of his maximin-share always exists. This factor has been recently improved to 3/4 by Ghodsi et al. [14].

Our goal in this paper is to generalize maximin-share to the environment with externalities. Roughly speaking, externalities are the influences (costs or benefits) incurred by other parties. The consequences of various economic activities on third parties are studied by both economists and computer scientists. For resource allocation

[1] For example, consider the case that there are two agents and the resource is a single indivisible item.

problems, externalities imply that the bundle allocated to an agent may affect the utility of the other agents. These externalities can be either positive or negative. In this work, we assume that the externalities are **non-negative**, which is a common assumption in the literature [9, 17, 24].

There are many reasons to consider externalities in an allocation problem. The goods to be divided might exhibit network effects. For example, the value of an XBox to an agent increases as more of his friends also own an XBox, since they can play online. Many merit goods generate positive consumption externalities. In healthcare, individuals who are vaccinated entail positive externalities to other agents around them, since they decrease the risk of contraction. Furthermore, allocating a good to an agent might exert externalities on his friends since they can borrow it.

We wish to take one step toward understanding the impact of externalities in the fair allocation of indivisible items. The messages of our paper can be summarized as follows. **First**, considering the externalities is important: the value of EMMS (the generalization we define to adapt MMS to the environment with externalities) and MMS might have a large gap. In fact, we show that even a small amount of influence can result in an unbounded gap between these two notions. Thus, when the externalities are not negligible, methods that guarantee MMS to all the agents might no longer be applicable. **Second**, with respect to our model and fairness notion, we can approximately maintain fairness in the environment with externalities. In the next section, we give a more detailed description of our results and techniques.

1.1 Our Contribution

We start by proposing a general model to capture the externalities in a fair allocation problem under the additive assumption. Although we present some of our results with respect to this general model, our focus is on a more restricted model, namely *network externalities*, where the influences imposed by the agents can be represented by a weighted directed graph. This model is inspired by the well-studied linear-threshold model in the context of network diffusion.

We suggest the *extended-maximin-share* notion (EMMS) to adapt maximin-share to the environment with externalities. Similar to maximin-share, our extension is motivated by the maximin strategy in a cut-and-choose game. We discuss two aspects of our notion.

First, we discuss the hardness of computing the value of EMMS_i, where EMMS_i is the extended-maximin-share of agent i. We introduce a generalized form of the partition problem that includes many famous partition problems such as maximin, minimax, and leximin partitioning problems. This generalized problem is NP-hard due to a trivial reduction from the classic partition problem. In Section 3, we propose a 1/2-approximation algorithm for computing EMMS_i (Theorem 3.2). In fact, we show that the LPT method, which is a famous greedy algorithm in the context of job scheduling, guarantees 1/2-approximation for the general partition problem. We also reveal several structural properties of such partitions.

Second, we consider the approximate α-EMMS allocations, that is, allocations that guarantee every agent a utility of at least a fraction α of his extended-maximin-share. We define the property of β-self-reliance and show that when the agents are β-self-reliant, there exists an allocation that guarantees every agent i a utility of at least $\beta/2$-EMMS_i (Theorem 4.2). This is our most technically involved result. The basic idea behind our method is as follows: every agent has an expectation value which estimates the utility that he must gain through the algorithm. Initially, the expectation value of agent i is at least $\mathsf{EMMS}_i/2$. In every step of the algorithm, we choose an agent and allocate him a bundle with a value at least as his expectation value. Based on this allocation, we decrease the expectation value of the remaining agents. The process of updating the expectation values is a fairly complex process which we describe in Section 4.2. The analysis of the algorithm is technically involved and heavily exploits the structural properties of the general partitioning problem. Finally, the combination of our existential proof with the 1/2-approximation algorithm for computing EMMS yields a polynomial time $\beta/4$-EMMS allocation algorithm.

1.2 Related Work

Maximin-share has received a lot of attention over the past few years [1–5, 8, 13–15, 18, 22, 27, 29]. The counter-example suggested by Procaccia and Wang [27] refutes the existence of any allocation with the maximin-share guarantee. In addition, Procaccia and Wang propose the first approximation algorithm that guarantees each agent 2/3 of his maximin-share. Recently, Ghodsi et al. [14] improve the approximation ratio to 3/4. For the special case of 3 agents, Procaccia and Wang [27] prove that guaranteeing 3/4 of every agent's maximin-share is always possible. Kurokawa et al. [22] show that when the valuations are drawn at random, an allocation with maximin-share guarantee exists with a high probability, and it can be found in polynomial time.

Other studies generalize maximin-share for different settings. For example, Farhadi et al. [13] generalize maximin-share to the case of asymmetric agents with different entitlements. They introduce the *weighted-maximin-share* (WMMS) criterion and propose an allocation algorithm with a 1/2-WMMS guarantee. Suksompong [29] considers the case that the items must be allocated to groups of agents. Gourvès and Monnot [15] extend maximin-share to the case that the goods collectively received by the agents satisfy a matroidal constraint and propose an allocation with a 1/2 maximin-share guarantee. Ghodsi et al. [14] and Barman et al. [7] consider maximin share guarantee for general valuation functions such as submodular, XOS, and subadditive set functions.

In recent years, considering externalities for different economic activities has received an increasing attention in computer science [4, 8, 9, 17, 19, 20, 23–25]. For example, Haghpanah et al. [17] study auction design in the presence of externalities. Pataki et al. [26] study the influences of the externalities on the Pareto optimal allocation of indivisible goods. Velez studies the fair allocation of indivisible goods and money with externalities [30]. In a more related work, Brânzei et al. [9] consider externalities in the cake cutting problem. They introduce a model for cake cutting with externalities and generalize classic fairness criteria to the case with externalities. Following this work, Li et al. [24] study truthful and fair methods for allocating a divisible resource with externalities.

2 MODEL

Throughout the paper, we assume $\mathcal{M}$ is a set of m indivisible items that must be fairly allocated to a set $\mathcal{N} = [n]$ of agents, where $[n]$

	b_1	b_2	b_3
1	1,5,2	4,6,1	7,1,0
2	3,8,5	1,8,7	4,6,9
3	1,5,3	6,5,7	5,4,1

Table 1: An instance in the general externalities model

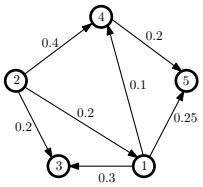
denotes the set $\{1, 2, \ldots, n\}$. We introduce our model in Section 2 and our fairness criteria in Section 2.2.

2.1 Modeling the Externalities

We start by proposing a general model to represent the externalities. In the **general externalities** model, we suppose that for every item b, $V_{j,i}(b)$ reflects the utility that agent i receives by allocating b to agent j. In this model, there is no restriction on the value of $V_{j,i}(.)$. Total utility of agent i for an allocation is defined to be the sum of utilities he receives by every item, i.e.,

$$U_i = \sum_{b \in \mathcal{M}} V_{j_b,i}(b)$$

where j_b is the index of the agent whose b is allocated. For example, consider the instance with 3 items and 3 agents demonstrated in Figure 1. In this figure, for each agent i and item b_j, three values are given, where the k'th value shows the utility gained by agent i, if we allocate b_j to agent k. For this instance, if we allocate each item b_i to agent i, then we have:



$$U_1 = 1 + 6 + 0 = 7,$$
$$U_2 = 3 + 8 + 9 = 20,$$
$$U_3 = 1 + 5 + 1 = 7.$$

The main focus of the paper is on a more restricted model where the externalities are due to the relationships between agents. For example, friends may share their items with a probability which is a function of their relationship. In this model, each agent i has a valuation function V_i, where for each bundle S, $V_i(S)$ represents the happiness of agent i, if we allocate S to him. We assume that $V_i(.)$ is additive, i.e., for every bundle S,

$$V_i(S) = \sum_{b_j \in S} V_i(b_j).$$

In addition, we consider a directed weighted graph G where for every pair of vertices i and j, the weight of edge $(\overrightarrow{j,i})$, denoted by $w_{j,i}$, represents the influence ratio of agent j on agent i. We refer such a graph as *influence graph*. If we allocate item b to agent j, the utility gained by agent i from this allocation would be $V_i(\{b\}) \cdot w_{j,i}$. For convenience, we define $w_{i,i} = 1$ for every agent i and $w_{j,i} = 0$, for every agent j which is not connected via a directed edge to i.

For instance, consider the example illustrated in Figure 1. For the allocation that allocates every item b_i to agent i ($1 \le i \le 5$), the total utility of the agents would be

	b_1	b_2	b_3	b_4	b_5
1	5	5	2	8	4
2	9	2	5	2	1
3	2	5	3	5	6
4	8	2	4	9	8
5	8	0	2	7	4

Figure 1: An instance in the network externalities model

$$U_1 = 5 + 5 \cdot 0.2 = 6,$$
$$U_2 = 2,$$
$$U_3 = 3 + 5 \cdot 0.2 + 2 \cdot 0.3 = 4.6,$$
$$U_4 = 9 + 8 \cdot 0.1 + 2 \cdot 0.4 = 10.6,$$
$$U_5 = 4 + 8 \cdot 0.25 + 7 \cdot 0.2 = 7.4.$$

We call such a model the **network externalities** model.

Definition 2.1. For the network externalities model, we say agent i is β-self-reliant, if

$$\frac{1}{\sum_{1 \le j \le n} w_{j,i}} \ge \beta.$$

For example in Figure 1, agent 4 is 2/3-self-reliant and agent 2 is 1-self-reliant. In real-world situations, we expect β to be a value close to 1. In other words, we expect an agent to be far more satisfied, when we allocate an item to him rather than allocating it to the other parties. However, being β-self-reliant for $\beta \simeq 1$ doesn't mean that we can ignore the externalities. We discuss more on this in Section 4.

Definition 2.2. For every agent i, we define the *influence vector* of agent i, denoted by $x_i = [x_{i,1}, x_{i,2}, \ldots, x_{i,n}]$ as the vector representing the influences of the agents on agent i in the influence graph, in a non-decreasing order.

As mentioned, we suppose that for every agent i, we have $w_{i,i} = 1$. As an example, for the graph in Figure 1, we have

$$x_1 = [0, 0, 0, 0.2, 1],$$
$$x_2 = [0, 0, 0, 0, 1],$$
$$x_3 = [0, 0, 0.2, 0.3, 1],$$
$$x_4 = [0, 0, 0.1, 0.4, 1],$$
$$x_5 = [0, 0, 0.2, 0.25, 1].$$

We emphasize that throughout the paper, our assumption is that the externalities and the valuations are all non-negative.

2.2 Extended Maximin Share

In this paper, we introduce the extended maximin-share (EMMS) criterion. As mentioned, the maximin-share (MMS) notion was introduced by Budish [10] as a fairness criterion in the division of indivisible items. In Section 1, we gave a formal definition of this notion. The intriguing fact about MMS solution is that it can be motivated by the "cut and choose" game. In this game, an agent divides the items into n bundles and lets other agents choose their bundle first. In the worst-case scenario, the least valued bundle remains, and hence the maximin strategy is to divide the items in a way that the minimum bundle is as attractive as possible.

To extend maximin-share to the case of the agents with externalities, again we consider the worst-case scenario in a "cut and choose" game which incorporates externalities. Suppose that an agent divides the items into n bundles, and other agents somehow distribute these bundles (one bundle to each agent). The maximin strategy of this agent is to divide the items in a way that maximizes his utility in the worst possible scenario (a scenario that minimizes his utility). We define the *extended-maximin-share* of agent i as his maximin value in a "cut and choose" game with externalities.

Formally, let $P = \langle P_1, P_2, \ldots, P_n \rangle$ be a partition of $\mathcal{M}$ into n bundles with the following properties:

- For every i, we have $P_i \neq \emptyset$.
- For every i, j where $i \neq j$, we have $P_i \cap P_j = \emptyset$.
- $\cup_i P_i = \mathcal{M}$.

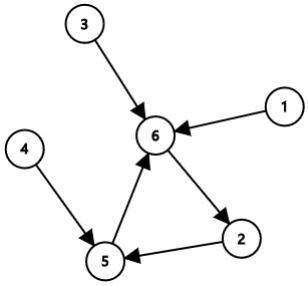
Furthermore, let $\mathcal{A} : P \rightarrow [n]$ be an allocation function that allocates every set P_i to agent $\mathcal{A}(P_i)$ (one set to each agent). For brevity, when P is clear from the context, we use $\mathcal{A}_i$ instead of $\mathcal{A}(P_i)$ to refer to the agent whom P_i is allocated to. Since exactly one bundle must be allocated to each agent, $\mathcal{A}$ is a bijection. The utility of agent i for an allocation $\mathcal{A}$ is:

$$U_i(\mathcal{A}) = \sum_j V_{\mathcal{A}_j, i}(P_j).$$

For example, consider the instance shown in Figure 2 and let

$$\mathcal{P} = \langle \mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3 \rangle = \langle \{b_1, b_3\}, \{b_2, b_5\}, \{b_4\} \rangle$$

be a partition of the items into three bundles. One possible allocation is to allocate every bundle $\mathcal{P}_i$ to agent i. For this allocation (namely, $\mathcal{A}_\mathcal{P}$), we have



$$\begin{aligned} U_1(\mathcal{A}_\mathcal{P}) &= (5+2) + (6+4) \cdot 0.8 = 15, \\ U_2(\mathcal{A}_\mathcal{P}) &= (9+5) \cdot 0.65 + (2+1) = 12.1, \\ U_3(\mathcal{A}_\mathcal{P}) &= (2+3) \cdot 0.6 + (0+6) \cdot 0.2 + 5 = 9.2. \end{aligned}$$

The worst allocation of P for agent i, denoted by $\mathcal{W}_i(P)$, is the allocation of P that minimizes the utility of agent i:

$$\mathcal{W}_i(P) = \arg \min_{\mathcal{A} \in \Omega_P} U_i(\mathcal{A}),$$

where Ω_P is the set of all $n!$ different allocations of P. For example, a worst allocation of $\mathcal{P}$ for agent 1 is to allocate $\mathcal{P}_3$ to agent 1, $\mathcal{P}_2$ to agent 3, and $\mathcal{P}_1$ to agent 2. The utility of agent 1 for this allocation is $3 + 7 \cdot 0.8 = 8.6$. Similarly, the best allocation of P is defined as:

$$\mathcal{B}_i(P) = \arg \max_{\mathcal{A} \in \Omega_P} U_i(\mathcal{A}).$$

	b_1	b_2	b_3	b_4	b_5
1	5	6	2	3	4
2	9	2	5	2	1
3	2	0	3	5	6

Figure 2: Another instance in the network externalities model

Again, the best allocation of $\mathcal{P}$ for agent 1 is to allocate $\mathcal{P}_2$ to agent 1, $\mathcal{P}_1$ to agent 2, and $\mathcal{P}_3$ to agent 3 which results in the utility of $10 + 7 \cdot 0.8 = 15.6$ for agent 1.

Finally, the extended-maximin-share of agent i, denoted by EMMS_i, is defined as:

$$\mathsf{EMMS}_i = \max_{P \in \Pi} U_i(\mathcal{W}_i(P)),$$

where Π is the set of all partitions of $\mathcal{M}$ into n non-empty subsets. We also define the *optimal partition* of $\mathcal{M}$ for agent i, denoted by O_i, as the partition that determines the value of EMMS_i,

$$O_i = \arg \max_{P \in \Pi} U_i(\mathcal{W}_i(P)).$$

Throughout the paper, when speaking of the network externalities model, we assume that the bundles in $O_i = \langle O_{i,1}, O_{i,2}, \ldots, O_{i,n} \rangle$ are sorted by their non-increasing values for agent i, i.e., for all j, $V_i(O_{i,j}) \geq V_i(O_{i,j+1})$. Thus, we have [2]

$$\mathsf{EMMS}_i = \sum_{1 \leq j \leq n} V_i(O_{i,j}) \cdot x_{i,j}.$$

It can be observed that for agent 1 in Figure 2, we have

$$O_1 = \langle \{b_1, b_3\}, \{b_4, b_5\}, \{b_2\} \rangle$$

and

$$\begin{aligned} \mathsf{EMMS}_1 &= U_1(\mathcal{W}_i(O_i)) \\ &= 7 \cdot 0.8 + 6 = 11.6. \end{aligned}$$

When the agent is clear from the context, for any partition P we use P_j to refer to the j'th valuable bundle of P for that agent.

Finally, an α-EMMS fair allocation problem with the externalities is defined as follows: is there an allocation such that every agent i receives a utility of at least $\alpha \cdot \mathsf{EMMS}_i$?

2.3 Average allocations

We also introduce another fairness notion for the extension of proportionality to the environments with externalities, namely *average-share*.

[2] If it is not clear why this equation holds, see Section 3.

Definition 2.3 (average-share). The average value of item b for agent i, denoted by $\overline{V}_i(\{b\})$, is defined as $\sum_j V_{j,i}(\{b\})/n$. The average-share of agent i is $\overline{V}_i(\mathcal{M}) = \sum_{b\in\mathcal{M}} \overline{V}_i(\{b\})$. Furthermore, an allocation is said to be average, if the total utility of every agent from this allocation would be at least as his average-share.

For the case of network externalities model, we have

$$\overline{V}_i(\mathcal{M}) = V_i(\mathcal{M})/n \cdot \sum_j w_{j,i}. \tag{1}$$

For the agents in Figure 2, we have

$$\overline{V}_1(\mathcal{M}) = (1.8/3) \cdot 20 = 12$$
$$\overline{V}_2(\mathcal{M}) = (1.65/3) \cdot 19 = 10.45$$
$$\overline{V}_3(\mathcal{M}) = (1.8/3) \cdot 16 = 9.6.$$

Average-share plays an important role in analyzing our algorithm for finding the (approximately) optimal partitions in Section 3. As we show in Section 2.4, this notion is stronger than extended maximin-share. However, no approximation of this notion can be satisfied even for very simple scenarios.

2.4 Basic Observations

In Section 2, we introduced two notions: average-share, and extended-maximin-share. For a better understanding of these notions, here we briefly compare them in the **general externalities** model. First, in Lemma 2.4, we prove that average share is stronger than extended maximin-share.

Lemma 2.4. *Average-share implies extended-maximin-share.*

Proof. Let $\mathbb{A} = \{A^1, A^2, \ldots, A^n\}$, where A^k is an allocation of O_i that allocates $O_{i,j}$ to agent

$$j' = ((j + k - 1) \bmod n) + 1.$$

Since in $\mathbb{A}$ each item is allocated to each agent once, $\sum_j U_i(A^j) = \sum_j V_{j,i}(\mathcal{M})$. Thus, the worst allocation in set $\mathbb{A}$ has a utility of at most $\sum_j V_{j,i}(\mathcal{M})/n = \overline{V}_i(\mathcal{M})$ for agent i. As a result, $\mathsf{EMMS}_i = U_i(\mathcal{W}_i(O_i)) \le \overline{V}_i(\mathcal{M})$. □

By a similar argument as in the proof of Lemma 2.4 we can show that for an arbitrary partition P,

$$\overline{V}_i(\mathcal{M}) \le U_i(\mathcal{B}_i(P)).$$

Therefore, for any partition P we have

$$\mathsf{EMMS}_i \le U_i(\mathcal{B}_i(P)).$$

In Lemma 2.5, we show that for $n = 2$, a *cut and choose* method guarantees EMMS_i to both the agents.

Lemma 2.5. *For two agents, the following two step algorithm yields a* 1-EMMS *allocation:*(*i*)*: Ask the first agent to partition the items into his optimal partition* O_1*, and* (*ii*)*: Ask the second agent to allocate* O_1 *(one bundle to each agent).*

Proof. We know $U_2(\mathcal{B}_2(O_1)) \ge \mathsf{EMMS}_2$. Furthermore, since $\mathcal{W}_1(O_1)$ determines the value of EMMS_1, we have:

$$U_1(\mathcal{B}_2(O_1)) \ge \mathsf{EMMS}_1.$$

□

Note that there are instances with two agents such that no approximation of average-share can be guaranteed. For example, when there is only one item with value 1 to both the agents, and no externalities. We later establish another difference between these two notions by providing allocations that approximately guarantee extended maximin-share.

3 COMPUTING EMMS

In this section, we study the problem of computing EMMS_i and O_i. A closer look at the model reveals that the challenges to calculate EMMS are twofold. One is to find the worst allocation of a given partition, and the other is to find a partition that maximizes the utility of the worst allocation. In Lemma 3.1 and Observation 1, we explore the hardness of these problems in the **general externalities** model. We then focus on the network externalities model and give a constant factor approximation algorithm for computing EMMS_i.

Lemma 3.1. *Given a partition* $P = \langle P_1, P_2, \ldots, P_n\rangle$ *of the items in* $\mathcal{M}$*, the worst allocation of* P *for agent* i *can be found in polynomial time.*

Proof. (sketch) Consider a complete bipartite graph $G(X, Y)$ where X represents the bundles of P, and Y represents the agents and there is an edge with weight $V_{j,i}(P_k)$ between every pair $x_k \in X$ and $y_j \in Y$. Finding $\mathcal{W}_i(P)$ is equivalent to finding the min-weight perfect matching in G. Classic network flow algorithms solve this problem in polynomial time [11]. □

Observation 1. *Since finding the maximin partition of a set of items is NP-hard [31], finding the optimal partition of m items and n agents with externalities is also NP-hard.*

Woeginger [31] also show that finding the maximin partition of a set of items without externalities admits a PTAS. However, their method does not directly extend to the case with externalities. To the best of our knowledge, finding an approximately optimal partition for an agent with externalities has not been studied before.

In the case of *network externalities*, our model is easier to deal with. Since the utility of each agent is a convex combination of his valuation, finding the worst allocation $\mathcal{W}_i(P)$ is trivial: consider an n-step allocation algorithm whose every step allocates the most valuable remaining bundle to a remaining agent with the least effect on agent i. Hence,

$$U_i(\mathcal{W}_i(P)) = \sum_j x_{i,j} \cdot V_i(P_j). \tag{2}$$

Recall that x_i (the influence vector of agent i) is non-decreasing, and the bundles in P are sorted in non-increasing order of their values for agent i. This property of the network externalities model allows us to approximate the value of EMMS_i with a constant ratio, using a simple greedy approach. On top of that, it is possible to infer relations between EMMS and some classic partitioning schemes.

Apart from the allocation of bundles, partitioning the items is another challenge to overcome. By definition, an optimal partition is a partition that maximizes Equation (2). Finding an optimal partition for a given vector x_i is in fact, a generalized form of partitioning problems that includes both maximin and minimax partitions. What happens if we partition the items by one of the famous partitioning

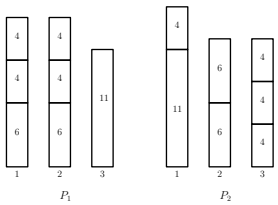


Figure 3: For $x_i = [1, 1, 0]$, minimax (P_1) is optimal, and for $x_i = [1, 0, 0]$, maximin (P_2) is optimal.

schemes such as minimax or maximin? A maximin partition is a partition that maximizes the value of the minimum bundle. It is easy to see that a maximin partition is optimal when $x_i = [1, 0, \ldots, 0]$. Likewise, minimax partition is a partition that minimizes the value of the maximum bundle, and it is the optimal partition when $x_i = [1, 1, \ldots, 1, 0]$. Another example is the leximin partition. A leximin partition first maximizes the minimum bundle, and subject to this constraint, maximizes the second least valued bundle, and so on. Real-world applications of leximin allocations are recently studied by Kurokawa, Procaccia and Shah [21]. For a small enough ϵ, the optimal partition for vector $x_i = [1, \epsilon, \epsilon^2, ..., \epsilon^{n-1}]$ is a leximin partition. See Figure 3 for an illustrative example.

Since none of these partitioning schemes are always optimal, approximating either of them is not desirable. However, the well-known greedy algorithm LPT [3] provides a partition

$$L_i = \langle L_{i,1}, L_{i,2}, \ldots, L_{i,n} \rangle$$

for agent i, such that $U_i(\mathcal{W}_i(L_i))$ is a constant approximation of EMMS_i. LPT is a simple greedy algorithm in the context of job scheduling. This algorithm starts with n empty bundles and iteratively puts the most valuable remaining item into the bundle with the minimum total value. It has been previously established that the partition provided by LPT is a constant approximation for both maximin and minimax partitions [12, 16].

Theorem 3.2. *For the network externalities model, we have*

$$U_i(\mathcal{W}_i(L_i)) \geq \mathsf{EMMS}_i/2. \tag{3}$$

To prove Theorem 3.2, we label some of the items as *huge*. Let $\Delta = V_i(\mathcal{M})/n$, and define Huge items as those items whose values are at least Δ[4]. Denote the set of huge items for agent i by $\mathcal{H}_i$.

Lemma 3.3. *For an instance with no huge item, we have $V_i(L_{i,n}) \geq \Delta/2$.*

Proof. Consider $L_{i,1}$ (the most valuable bundle of L_i for agent i). Trivially, we have $V_i(L_{i,1}) \geq \Delta$, and since there is no huge item, $L_{i,1}$ contains at least two items. On the other hand, according to method of LPT, the items within a bundle arrive in non-increasing order. Therefore, the last item added to $L_{i,1}$ has a value of at most $V_i(L_{i,1})/2$ and the total value of $L_{i,1}$ just before the last item arrives must have been at least $V_i(L_{i,1})/2$. Furthermore, whenever an item is added to a bundle, that bundle has the minimum value among all the bundles. Therefore, $V_i(L_{i,n}) \geq V_i(L_{i,1})/2 \geq \Delta/2$. □

[3]Longest processing time

[4]Notice that Δ and the average share are not necessarily equal.

Since $L_{i,n}$ is the least valued bundle of L_i for agent i,

$$\begin{aligned} U_i(\mathcal{W}_i(L_i)) &\geq \sum_i x_i V_i(L_{i,n}) \\ &\geq \sum_i x_i V_i(L_{i,1})/2 \geq \mathsf{EMMS}_i/2 \end{aligned}$$

Hence, when there is no huge item, regarding Lemma 3.3, Inequality (3) holds. Thus, to prove Theorem 3.2, it only suffices to consider the instances with huge items. Note that, when there are huge items in $\mathcal{M}$, $V_i(L_{i,n}) \geq \Delta/2$ does not necessarily hold. To deal with such situations, we consider some properties for O_i.

Definition 3.4. A partition P is *regular* for agent i, if no item b in some bundle P_j exists, such that $V_i(P_j) > V_i(\{b\}) > V_i(P_n)$ (recall that $V_i(P_n) = \min_j V_i(P_j)$).

Lemma 3.5. *For any partition P, there exists a regular partition P', such that $U_i(\mathcal{W}_i(P)) \leq U_i(\mathcal{W}_i(P'))$.*

Proof. If P is not regular, there exists an item b in some bundle P_j, such that

$$V_i(P_j) > V_i(\{b\}) > V_i(P_n).$$

We modify P as follows: we remove P_j and P_n from P and add two new bundles $A = \{b\}$ and $B = P_j \cup P_n \setminus \{b\}$ to P. Let l and l' be the indices of the newly added bundles in P (note that the bundles are rearranged by their non-increasing values for agent i), such that $j \leq l \leq l' \leq n$ (see Figure 4). We have:

$$V_i(P_j) > \max(V_i(A), V_i(B)) \geq \min(V_i(A), V_i(B)) > V_i(P_n).$$

By this modification, $U_i(\mathcal{W}_i(P))$ increases by a value of at least

$$\begin{aligned} &x_{i,l} \cdot (\max(V_i(A), V_i(B)) - V_i(P_j)) \\ &+ x_{i,l'} \cdot (\min(V_i(A), V_i(B)) - V_i(P_n)), \end{aligned}$$

which is non-negative since

$$V_i(P_j) + V_i(P_n) = \max(V_i(A), V_i(B)) + \min(V_i(A), V_i(B)),$$

and $x_{i,l} \leq x_{i,l'}$. Let

$$\mathcal{L}(P) = \{P_j \mid V_i(P_j) = V_i(P_n)\}.$$

After each modification, either $V_i(P_n)$ increases, or $|\mathcal{L}(P)|$ decreases. Therefore, sequence $(V_i(P_n), V_i(P_{n-1}), \ldots, V_i(P_1))$ increases lexicographically by each move, and hence we eventually end up with a regular partition P' after a finite number of modifications. □

Based on Lemma 3.5, in the rest of this paper we assume that the optimal partitions are regular. Furthermore, in Lemma 3.6 we show that L_i is also regular.

Lemma 3.6. *L_i is regular.*

Proof. For the sake of contradiction, let b be an item in bundle $L_{i,j}$ such that $V_i(L_{i,j}) > V_i(\{b\}) > V_i(L_{i,n})$. Since $V_i(L_{i,j}) > V_i(\{b\})$, $L_{i,j}$ contains at least one other item, say b'. Furthermore, since $V_i(\{b\}) > V_i(L_{i,n})$, after adding b to $L_{i,j}$ no other item can be added to $L_{i,j}$ (recall that in each step of LPT, we add an item to the least valued bundle). This means that b' is added to $L_{i,j}$ before b, which implies $V_i(b') \geq V_i(b)$. But this is a contradiction, because in the step that we add b to $L_{i,j}$, we have $V_i(L_{i,j}) \geq V_i(b') > V_i(L_{i,n})$, which means $L_{i,j}$ is not the minimum bundle in that step. □

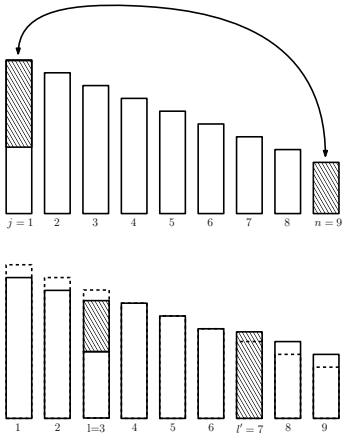

Figure 4: Switching the subsets

In a regular partition P for agent i, any bundle P_j containing a huge item $b \in \mathcal{H}_i$ has no other item. Otherwise, since

$$V_i(P_j) > V_i(\{b\}) \geq \Delta,$$

and $\Delta > V_i(P_n)$, partition P is not regular. This fact about regular partitions (including L_i and O_i) allows us to deal with huge items. We are now ready to prove Theorem 3.2.

Proof of Theorem 3.2. We use induction on the number of agents. For $n = 1$, the statement is trivial. For $n > 1$, we consider two cases. First, if $\mathcal{M}$ contains no huge items, by Lemma 3.3, we have $V_i(L_{i,n}) \geq \Delta/2$. Thus,

$$\begin{aligned} U_i(\mathcal{W}_i(\mathrm{tt}_i)) &= \sum_j V_i(L_{i,j}) \cdot x_{i,j} \\ &\geq \sum_j (\Delta/2) \cdot x_{i,j} \\ &= 1/2 \sum_j \Delta \cdot x_{i,j} \\ &= V_i(\mathcal{M})/2 \sum_j x_{i,j}/n \qquad (\Delta = V_i(\mathcal{M})/n) \\ &= \overline{V}_i(\mathcal{M})/2. \qquad \text{(Equation (1))} \end{aligned}$$

By Lemma 2.4, we have $\overline{V}_i(\mathcal{M}) \geq \mathsf{EMMS}_i$ which implies

$$U_i(\mathcal{W}_i(\mathrm{tt}_i)) \geq \mathsf{EMMS}_i/2.$$

Therefore, it only remains to consider the case that $\mathcal{M}$ contains at least one huge item. Let $B_{\mathcal{H}_i}(O_i)$ and $B_{\mathcal{H}_i}(L_i)$ be the set of the bundles containing huge items in O_i and L_i, respectively. We know that $B_{\mathcal{H}_i}(O_i) = B_{\mathcal{H}_i}(L_i)$, as the bundles in $B_{\mathcal{H}_i}(O_i)$ and $B_{\mathcal{H}_i}(L_i)$ do not contain anything but huge items, and each huge item is the only item within its bundle (recall that both O_i and L_i are regular). In addition, $B_{\mathcal{H}_i}(L_i)$ are the $|\mathcal{H}_i|$ most valuable bundles in L_i. Otherwise, a very similar argument as in the proof of Lemma 3.3 yields $V_i(L_{i,n}) \geq \Delta/2$.

Let $\mathcal{W}'_i(O_i)$ be the worst possible allocation of O_i with the constraint that allocates $|\mathcal{H}_i|$ huge items to the $|\mathcal{H}_i|$ agents with the least influence on agent i. By definition, $U_i(\mathcal{W}'_i(O_i)) \geq U_i(\mathcal{W}_i(O_i))$. Moreover, in both $\mathcal{W}'_i(O_i)$ and $\mathcal{W}_i(L_i)$, huge items are allocated

Figure 5: The gap between MMS_i and EMMS_i may be large, even with very small externalities

to the same set of agents, say $\mathcal{N}_{\mathcal{H}_i}$. Now, consider the sub-instance with items $\mathcal{M} \setminus B_{\mathcal{H}_i}(O_i)$ and agents $\mathcal{N} \setminus \mathcal{N}_{\mathcal{H}_i}$. Note that since $V_i(L_{i,n}) < \Delta/2$, the set $\mathcal{M} \setminus B_{\mathcal{H}_i}(O_i)$ (and hence, $\mathcal{N} \setminus \mathcal{N}_{\mathcal{H}_i}$) is non-empty.

By the induction hypothesis, for this sub-instance, Inequality (3) holds. Now, adding huge items and their corresponding agents back, increases the utility of agent i by the same amount for both of the allocations. Thus,

$$U_i(\mathcal{W}_i(L_i)) \geq 1/2 \cdot U_i(\mathcal{W}'_i(O_i)) \geq 1/2 \cdot U_i(\mathcal{W}_i(O_i)).$$

□

4 α-EMMS ALLOCATION PROBLEM

In this section, we focus on the allocations that guarantee every agent i an approximation of EMMS_i. We start this section by comparing EMMS_i to MMS_i.

Let M_i be the maximin partition of $\mathcal{M}$ for agent i. The maximin-share of agent i is equal to the value of the least valued bundle in M_i. Moreover, by definition, we have :

$$\mathsf{EMMS}_i = U_i(\mathcal{W}_i(O_i)) \geq U_i(\mathcal{W}_i(M_i)).$$

This, together with the fact that $U_i(\mathcal{W}_i(M_i)) \geq \mathsf{MMS}_i$ (recall that we have $w_{i,i} = 1$) implies that $\mathsf{EMMS}_i \geq \mathsf{MMS}_i$ always holds. Now, in Lemma 4.1 we show that the gap between EMMS_i and MMS_i could be unbounded even for the instances with 3 agents.

Lemma 4.1. *For any $c \geq 1$, there is an instance with 2 agents, where $\mathsf{EMMS}_1 > c \cdot \mathsf{MMS}_1$.*

Proof. Simply consider the influence graph depicted in Figure 5 and two items b_1 and b_2 such that $V_1(\{b_1\}) = 1$ and $V_1(\{b_2\}) = c/\epsilon$, where ϵ is a small constant less than $1/2$. For this instance, $\mathsf{EMMS}_1 = 1 + c$, and $\mathsf{MMS}_1 = 1$ which means

$$\mathsf{MMS}_1/\mathsf{EMMS}_1 < 1/(1+c).$$

□

The proof of Lemma 4.1 highlights that even for very few externalities, the gap between EMMS and MMS might be large. Thus, the external effects are not negligible even if the impacts of the parties on each other are small.

Our main result is stated in Theorem 4.2. We show that for the network externalities model when all the agents are α-self-reliant, an $\alpha/2$-EMMS allocation always exists. This completely separates extended maximin-share from average-share, since no approximation of the average-share can be guaranteed even for 1-self reliant agents.

Theorem 4.2. *Let $\mathbb{C}$ be an instance such that all the agents are α-self reliant. Then, $\mathbb{C}$ admits an $\alpha/2$-EMMS allocation.*

In the rest of this section, we prove Theorem 4.2 by proposing an $\alpha/2$-EMMS allocation algorithm for the network externalities model with α-self-reliant agents. For brevity, we name our algorithm *Bundle Claiming* (BC) algorithm. It is worth to mention that despite some similarities, this method is fundamentally different from the previous allocation methods for guaranteeing MMS. The main difference is that, here, for each agent, we must keep track of the items allocated to the other parties and based on that, update the utility that each agent must receive to be satisfied. This makes the analysis much more complex.

4.1 Bundle Claiming Algorithm (BC)

In this section, we present the ideas and a general description of Bundle Claiming. First, let us review the definition of EMMS_i. With abuse of notations, we suppose that v_i is a vector representing the values of the bundles in the optimal partition of agent i, i.e., $v_{i,j} = V_i(O_{i,j})$. Recall that the bundles in O_i are sorted by their non-increasing values for agent i. Hence, for all $j < n$, we have $v_{i,j} \geq v_{i,j+1}$. We have $\mathsf{EMMS}_i = \sum_j x_{i,j} v_{i,j}$.

Let $X_i = \sum_j x_{i,j}$. Observation 2 provides an upper bound on the value of $\sum_{j \geq k} x_{i,j} v_{i,j}$.

Observation 2. *For every k, we have $\sum_{j \geq k} x_{i,j} v_{i,j} \leq v_{i,k} \cdot X_i$.*

For example, in an instance with $n = 6$, for $k = 4$, Observation 2 implies:

$$v_{i,4} \cdot X_i \geq v_{i,4} x_{i,4} + v_{i,5} x_{i,5} + v_{i,6} x_{i,6}.$$

Observation 2 is a direct result of the following two facts: first, for all $j > k$, we have $v_{i,k} \geq v_{i,j}$ and second, $\sum_{j>k} x_{i,j} \leq X_i$.

Definition 4.3. For every agent i, we define ℓ_i to be the expectation level of agent i. Agent i with expectation level ℓ_i, has an expectation value of $v_{i,\ell_i}/2$.

In the beginning of the algorithm, the expectation level of all the agents are set to 1. Our algorithm consists of n steps. In each step, we find a bundle B with the minimum number of items that meets the expectation of at least one agent. Bundle B meets the expectation of agent i, if $V_i(B) \geq v_{i,\ell_i}/2$. We allocate B to one of the agents whose expectation is met (we say this agent is satisfied). Next, we update the expectation levels of the remaining agents. The updating process is a fairly complex process which we precisely describe in Section 4.2. Roughly speaking, we update the expectation levels in a way that the following property holds during the algorithm:

> **External-satisfaction property:** Let $\mathcal{S}$ be the set of currently satisfied agents. For every remaining agent i with expectation level ℓ_i, there is a partition of the agents in $\mathcal{S}$ into ℓ_i subsets, namely $N_{i,1}, N_{i,2}, \ldots, N_{i,\ell_i-1}, N_{i,F}$, such that for all $1 \leq j < \ell_i$, the total set of items allocated to the agents in $N_{i,j}$ is worth at least $v_{i,j}/2$ and at most $v_{i,j}$ to agent i, and the total set of items allocated to the agents in $N_{i,F}$ is worth less than $v_{i,\ell_i}/2$ to agent i.

Note that in the updating process, ℓ_i may increase by more than one unit. However, for every remaining agent i, $\ell_i \leq n$ must hold. As we show in Section 4.2, during our algorithm, $\ell_i \leq n$ always holds for every agent i. We use this property to show that if the external-satisfaction property holds for agent i, total amount of externalities incurred by the satisfied agents is at least $\sum_{k<\ell_i} v_{i,k} x_{i,k}/2$. The fact that EMMS_i is calculated with respect to the worst allocation of O_i is the key to prove this inequality.

Consider one step of the algorithm and suppose that a set B of items is allocated to agent i. Since B met the expectation of agent i, $V_i(B) \geq v_{i,\ell_i}/2$. Furthermore, the utility that agent i gained through the externalities of the satisfied agents is at least $\sum_{k<\ell_i} v_{i,k} x_{i,k}/2$. Assuming that agent i is α-self-reliant, his utility is at least

$$\begin{aligned}
&\sum_{k<\ell_i} v_{i,k} x_{i,k}/2 + v_{i,\ell_i}/2 \\
&\geq \sum_{k<\ell_i} v_{i,k} x_{i,k}/2 + \Big(\sum_{k\geq\ell_i} v_{i,k} x_{i,k}/X_i\Big)/2 && \text{(Observation 2)} \\
&\geq (1/2X_i) \sum_k v_{i,k} x_{i,k} && (X_i \geq 1) \\
&\geq \alpha/2 \sum_k v_{i,k} x_{i,k} \\
&= \alpha/2 \mathsf{EMMS}_i. && (4)
\end{aligned}$$

Inequality (4) ensures that the items allocated to agent i satisfy him. Furthermore, we use the external-satisfaction property to prove that the algorithm satisfies all the agents. To show this, it only suffices to prove that in each step of the algorithm there are enough items to meet the expectation of the remaining agents. Consider agent i which has not satisfied yet. The value of the items allocated to the satisfied agents not in $N_{i,F}$ is at most $\sum_{j<\ell_i} v_{i,j}$. Hence, the total value of the remaining items plus the items allocated to the agents in $N_{i,F}$ is at least $\sum_{j\geq\ell_i} v_{i,j}$. Moreover, the value of the items allocated to the agents in $N_{i,F}$ is less than $v_{i,\ell_i}/2$. Thus, the value of the remaining items is at least $v_{i,\ell_i}/2$ which is enough to meet the expectation of agent i. As said before, our algorithm maintains the property that $\ell_i \leq n$ for every remaining agent i.

The details of the bundle claiming algorithm is demonstrated in Algorithm 1. In the next section, we show how to maintain the external-satisfaction property in the algorithm.

Note that, there are only two parts of the BC algorithm whose implementations in polynomial time are not trivial. One is finding a minimum-sized set B meeting the expectation of at least one agent, and the other is the operations we perform in order to maintain the external-satisfaction property. In Observation 3, we show that the first part can be implemented in polynomial time.

Observation 3. *The minimum-sized set that meets the expectation of at least one remaining agent can be found in polynomial time.*

Proof. For every remaining agent i, we find a bundle Γ_i with the minimum size which meets the expectation of agent i as follows: sort the remaining items in their non-increasing values for agent i, and add the items to Γ_i one by one until the bundle meets the expectation of agent i. Finally, it only suffices to select the smallest bundle among these bundles. □

Furthermore, as we show in the next section, the operations we perform to preserve the external-satisfaction property can also be implemented in polynomial time.

ALGORITHM 1: Bundle Claiming algorithm

forall $a_j \in \mathcal{N}$ **do**
  $\ell_j \leftarrow 1$ ▷ Initializing the expectation levels
end
while $\mathcal{N} \neq \emptyset$ **do**
  forall $a_j \in \mathcal{N}$ **do**
    $\Gamma_j \leftarrow$ Minimum sized subset of $\mathcal{M}$, s.t.
    $V_j(\Gamma_j) \geq 1/2 \cdot v_{j,\ell_j}$;
  end
  $i \leftarrow \arg\min_i |\Gamma_i|$;
  Allocate Γ_i to agent i ;
  $\mathcal{N} \leftarrow \mathcal{N} \setminus i$, $\mathcal{M} \leftarrow \mathcal{M} \setminus \Gamma_i$;
  forall $j \in \mathcal{N}$ **do**
    $N_{j,F} \leftarrow N_{j,F} \cup \{i\}$. ;
    while $V_j(N_{j,F}) \geq 1/2 \cdot v_{j,l_j}$ **do**
      $Update(M_j)$ ▷ (see Section 4.2)
    end
  end
end

Finally, using L_i [5] instead of O_i in BC results in an $\alpha/4$-EMMS allocation algorithm.

Corollary 4.4. *Let $\mathbb{C}$ be an instance where for every agent i, $w_{i,i} \geq \alpha$. Then, an $\alpha/4$-EMMS allocation for $\mathbb{C}$ can be found in polynomial time.*

4.2 The External-satisfaction Property

Throughout this section, we suppose that $\mathcal{S}$ is the set of satisfied agents. Furthermore, for each agent i in $\mathcal{S}$, we denote the bundle allocated to him by B_i. We start by giving a detailed explanation of the updating process. As mentioned in the previous section, the external-satisfaction condition must hold during the entire algorithm. To maintain this property in the updating process, for every agent i, we define a mapping M_i that represents the partitioning of $\mathcal{S}$ for agent i (recall the definition of external-satisfaction).

Definition 4.5. For every agent i, we define

$$M_i : \mathcal{S} \rightarrow \{O_{i,1}, O_{i,2}, \ldots, O_{i,n}\} \cup \{F_i\}$$

as a mapping that corresponds each satisfied agent to a bundle in the optimal partition of O_i or to F_i. Furthermore, we define $N_{i,j}$ as the set of agents that are mapped to $O_{i,j}$ in M_i and $N_{i,F}$ as the set of agents mapped to F_i. During the algorithm, we say mapping M_i is valid, if the following conditions hold:

(1) $\forall j < \ell_i \quad \sum_{k \in N_{i,j}} V_i(B_k) \geq v_{i,j}/2$

(2) $\forall j < \ell_i \quad \sum_{k \in N_{i,j}} V_i(B_k) \leq v_{i,j}$

(3) $\sum_{k \in N_{i,F}} V_i(B_k) < v_{i,\ell_i}/2$

During the entire algorithm, mapping M_i must remain valid for every unsatisfied agent i. In the beginning, $\mathcal{S} = \emptyset$ and for every agent i, $\ell_i = 1$ and hence, M_i is valid. In each step of the algorithm, we satisfy an agent i by a bundle B_i. Next, for every unsatisfied agent j, we map agent i to F_j in M_j, i.e., we set $M_j(i) = F_j$. In fact, $N_{j,F}$ corresponds to the satisfied agents that are not mapped to any bundle of O_j in M_j. We use these agents to update ℓ_j. Throughout the algorithm, whenever the total value of the items allocated to the agents in $N_{j,F}$ reaches $v_{j,\ell_j}/2$, M_j becomes invalid and hence, we need to update ℓ_j and M_j to reinstate the validity of M_j. To do so, we pick a subset δ of the agents in $N_{j,F}$ with the minimum size to map them to O_{j,ℓ_j}. Regarding the validity conditions of M_j, total value of the items allocated to the agents in δ must be at least $v_{j,\ell_j}/2$ and at most v_{j,ℓ_j} (we call such subset a *compatible set*). If a compatible set δ exists, we map the agents in δ to O_{j,ℓ_j} in M_j and increase ℓ_j by one. However, there may be some cases that no subset of $N_{j,F}$ is compatible. For such cases, we use the argument in Lemma 4.6.

Lemma 4.6. *Suppose that total value of the items allocated to the agents in $N_{j,F}$ is at least $v_{j,\ell_j}/2$, but $N_{j,F}$ admits no compatible subset. Then, it is possible to modify M_j such that conditions (i) and (ii) remain valid for M_j and $N_{j,F}$ contains at least one compatible subset.*

Using Lemma 4.6 we can modify M_j and then update the mapping. Note that, after increasing ℓ_j, condition (iii) may still be violated. In that case, as long as condition (iii) is violated, we continue updating. Each time we update M_j, value of ℓ_j is increased by one. Since at least one agent is mapped to $O_{j,\ell}$ for each $\ell < \ell_j$, ℓ_j never exceeds n. In the appendix (Algorithm 2), you can find a pseudo-code for this process .

In the last part of this section, we prove Lemma 4.7 which shows that the value of the externalities imposed to agent i by the satisfied agents is lower-bounded by $\sum_{j<\ell_i} x_{i,j} v_{i,j}/2$. As said before, the fact that EMMS_i is defined with regard to the worst allocation of O_i plays a key role in proving Lemma 4.7.

Lemma 4.7. *Consider one step of the algorithm, and let agent i be an arbitrary remaining agent with $\ell_i > 1$. Then, we have*

$$\sum_{j \in \mathcal{S}} w_{j,i} \cdot V_i(B_j) \geq \sum_{j<\ell_i} x_{i,j} \cdot v_{i,j}/2. \tag{5}$$

Proof. We want to show that in every step of the algorithm, for each remaining agent i, Inequality (5) holds. To prove this, we apply a sequence of exchanges between the bundles allocated to the agents in $\bigcup_{j<\ell_i} N_{i,j}$ and show that in every exchange, value of the expression on the left-hand side of Inequality (5) does not increase [6]. Next, we show that after these exchanges, Inequality (5) holds, which means that the Inequality was held for the original allocation.

Let agent j be the agent in $N_{i,1}$ with the least influence on agent i (i.e., minimizes $w_{j,i}$). First, we allocate the bundles that belong to the other agents in $N_{i,1}$ to agent j and remove all the agents but agent j from $N_{i,1}$. Since agent j has the minimum weight (influence) among the agent in $N_{i,1}$, this operation does not increase the left-hand side of Inequality (5).

In addition, let agent j' be the agent with $w_{j',i} = x_{i,1}$. Since agent j' has the minimum weight among all the agents, we have $w_{j',i} \leq w_{j,i}$. Now, let B_j and $B_{j'}$ be the current bundles of agents j

[5] Partitioning provided by LPT algorithm

[6] Note that these exchanges are only to prove this lemma, and not in the algorithm.

and j' (if j' is not satisfied yet, $B_{j'} = \emptyset$). If $V_i(B_{j'}) < V_i(B_j)$, we swap the bundles of j and j'. This operation also does not increase the left-hand side of Inequality (5) since we have $w_{j',i} \leq w_{j,i}$. Finally, we exchange the set that agents j and j' belong to: we remove agent j from $N_{i,1}$, and add agent j' to $N_{i,1}$. In addition, if agent j' previously belonged to $N_{i,r}$ for some r, we add agent j to $N_{i,r}$. This exchange has no effect on the value of $\sum_{j \in S} w_{j,i} \cdot V_i(B_j)$. Furthermore, one can easily observe that after the exchange, condition (ii) holds.

We repeat the same procedure for $N_{i,2}, N_{i,3}, \ldots, N_{i,\ell_i - 1}$. After this sequence of exchanges, each $N_{i,j}$ contains one agent j', where $w_{j',i} = x_{i,j}$. Furthermore, after the exchanges, the second condition for the validity of M_i holds and hence, the value of the items of agent j' for agent i is at least $v_{i,j}/2$. Therefore, total amount of externalities of the satisfied agents is at least $\sum_{j < \ell_i} x_{i,j} v_{i,j}/2$. □

Proof of Lemma 4.6. Let δ be a subset of $N_{j,F}$ with the minimum size that satisfies condition (i). Such a set trivially exists. Since no subset of $N_{j,F}$ is compatible, we have $\sum_{k \in \delta} V_j(B_k) > v_{j,\ell_j}$. By minimality of δ, no proper subset of δ satisfies condition (i). It is easy to observe that this can only happen when δ contains only one agent, say k, with $V_i(B_k) > v_{j,\ell_j}$. We also show in Lemma 4.8 that $|B_k| = 1$; but for now suppose that $|B_k| = 1$ and b is the only item in B_k.

Since O_j is regular[7], there is an index $\ell < \ell_j$, such that bundle $O_{j,\ell} = \{b\}$. We modify M_j as follows: we map agent k to $O_{j,\ell}$ and map the former agents of $N_{j,\ell}$ to F_j. Clearly, conditions (i) and (ii) preserve for M_j after this process. Again, if no subset of $N_{j,F}$ is compatible, we repeat this modification. Each time we modify M_j, the number of indices ℓ for which $O_{j,\ell}$ is mapped to an agent j with $O_{j,\ell} = B_j$ increases by one. Therefore, the process terminates after a finite number of modifications. □

Algorithm 2 illustrates an overview of the update procedure, which completes the BC algorithm.

ALGORITHM 2: Update M_j

```
Resolve = 0
while Resolve == 0 do
    δ ← Minimum sized subset of N_{j,F}, s.t.
      Σ_{k∈δ} V_j(B_k) ≥ 1/2 · v_{j,ℓ_j}
    if Σ_{k∈δ} V_j(B_k) ≤ v_{j,ℓ_j} then
        N_{j,ℓ_j} = δ
        N_{j,F} = N_{j,f} \ δ
        ℓ_j ← ℓ_j + 1
        Resolve+ = 1                          ▷ Resolved
    else
        Let ℓ be an index s.t. O_{j,ℓ} = B_k, where δ = {k}.
        Swap δ (which is a subset of N_{j,F}) with N_{j,ℓ}.   ▷ One
          step closer to resolve
    end
end
```

Lemma 4.8. *Suppose that the total value of the items allocated to the agents in $N_{j,F}$ is at least $v_{j,\ell_j}/2$, but $N_{j,F}$ admits no compatible subset, and let δ be the minimal subset of $N_{j,F}$ that satisfies condition (i). Then, δ contains only one agent, say agent k and $|B_k| = 1$.*

Proof. As mentioned in Lemma 4.6, it is easy to observe that $|\delta| = 1$. Here, we argue that if agent k is the only agent in δ, then $|B_k| = 1$. As a contradiction, let z_1 be the first step of the algorithm that $\delta = \{k\}$, but $|B_k| > 1$. In addition, let z_2 be the step that B_k is allocated to agent k and let ℓ'_j be the expectation level of agent j in step z_2. Trivially, we have $z_2 \leq z_1$. □

Claim 1. *Either $v_{j,n} \geq v_{j,\ell'_j}/2$ or we have $|O_{j,\ell}| = 1$ for all $\ell \leq \ell'_j$.*

Proof of Claim 1. If for some $\ell \leq \ell'_j$, $O_{j,\ell}$ contains more than one item, $O_{j,\ell}$ has a proper subset s such that $V_j(s) \leq v_{j,\ell}/2$. By the same reasoning as Claim 3.5, moving s to bundle $O_{j,n}$ yields a new partition which is at least as good as O_j (See Figure 4). Hence, we can assume w.l.o.g. that $v_{j,n} \geq v_{j,\ell'_j}/2$ holds. □

Regarding Claim 1, we consider two cases.

First, assume that $|O_{j,\ell}| = 1$ for all $\ell \leq \ell'_j$. For this case, at least one of the items in $\bigcup_{\ell \leq \ell'_j} O_{j,\ell}$ is not allocated to any agent before step z_2, and this item singly meets the expectation of agent j. This contradicts the fact that at step z_2, B_k was the minimal set (Note that we supposed $|B_k| > 1$).

Second, assume that $v_{j,\ell_j} \geq v_{j,\ell'_j}/2$. In step z_2, the expectation value of agent j equals $v_{j,\ell'}/2$. Furthermore, $V_j(B_k) > v_{j,\ell_j}$ which means $V_j(B_k) > v_{j,\ell'_j}/2$. On the other hand, $V_j(B_k) < v_{j,\ell'_j}$, otherwise a proper subset of B_k would meet the expectation of agent j in step z_2. Therefore, in step z_2, $\delta = \{k\}$ is the only compatible set for updating M_j and hence, agent k is mapped to O_{j,ℓ'_j}. This also implies that $z_2 \neq z_1$, since we supposed that no compatible subset exists in step z_1.

Furthermore, notice that since $|B_k| > 1$, no item could singly meet the expectation of any agent, including agent j in step z_2. This means that every remaining item in step z_2 has the value less than $v_{j,\ell_j}/2$. On the other hand, in all the modifications before step z_1, the bundle allocated to the agent in δ consists of only one item (z_1 is te first step that the size of the bundle allocated to the agent in δ is more than 1). This means that after step z_2, no modification affects the agents that are mapped to bundles $O_{j,\ell}$ for $\ell \leq \ell'_j$. But this contradicts the fact that agent k is mapped to F_j in step z_1, because agent k is mapped to O_{j,ℓ'_j} and no modification changes $M_j(k)$.

5 CONCLUSION

An exciting open direction is to find approximation allocation algorithms for the general externalities model, with no restriction on the value of $V_{j,i}(\{b_k\})$. Many issues complicate the study of the general model. For example, the approximation algorithm presented for computing the value of EMMS_i is no longer applicable to this model. A good starting point is to study the general model for the cases with a few number of agents, e.g., 3 or 4 agents.

For the network externalities model, one can think of improving the approximation ratio of the allocation. In particular, it would be

[7] Recall the regularity from Definition 3.4

interesting to propose an allocation algorithm with approximation factor independent of the self-reliance of the agents.

Another interesting open direction that might be of independent interest is to find a maximum value β, such that there exists a partition P of the items in which $\mathcal{W}_i(P)$ is a β-approximation of $\mathcal{W}_i(O_i)$ for every agents i. Note that if such a partition exists, any allocation of it to the agents is a β-EMMS allocation.

Finally, it is very impressive to present a *PTAS* for finding the optimal partition for an agent in the network externalities model.

ABSTRACT

To make images on Twitter and other social media platforms accessible to screen reader users, image descriptions (alternative text) need to be added that describe the information contained within the image. The lack of alternative text has been an enduring accessibility problem since the “alt” attribute was added in HTML 2.0 over 20 years ago, and the rise of user-generated content has only increased the number of images shared. As of 2016, Twitter provides users the ability to turn on a feature that allows descriptions to be added to images in their tweets, presumably in an effort to combat this accessibility problem. What has remained unknown is whether simply enabling users to provide alternative text has an impact on experienced accessibility. In this paper, we present a study of 1.09 million tweets with images, finding that only 0.1% of those tweets included descriptions. In a separate analysis of the timelines of 94 blind Twitter users, we found that these image tweets included descriptions more often. Even users with the feature turned on only write descriptions for about half of the images they tweet. To better understand why users provide alternative text descriptions (or not), we interviewed 20 Twitter users who have written image descriptions. Users did not remember to add alternative text, did not have time to add it, or did not know what to include when writing the descriptions. Our findings indicate that simply making it possible to provide image descriptions is not enough, and reveal future directions for automated tools that may support users in writing high-quality descriptions.

1 INTRODUCTION

Twitter and other social media platforms have become increasingly visual [24] over the past decade as media such as photos, videos, and GIFs have become more prevalent as content. As visual media makes up a larger portion of total content on a social media platform, such as Twitter, such platforms risk becoming less accessible to people with vision impairments who use screen reading software to access the site [24].

An estimated 39 million people around the world are blind, and many access online sites through screen reader software. They are typical users of social networks [6, 34], but they are not always afforded access to content on social networks like Twitter [24], which are increasingly part of public discourse. Twitter is a platform for members of the media to disseminate and discuss information, as well as users to interact with celebrities in a different format than more traditional media [35]. Many research efforts have examined participation on Twitter in the context of politics around the globe [3], especially during elections [28]. It is important that all visual content on Twitter, including those relating to these topics, be accessible to people with vision impairments so they may have equal participation in public life on the Internet.

Social media platforms have taken different approaches to make visual content more accessible to blind users, although all approaches provide textual descriptions (alternative text) to user-posted images. For instance, Facebook and Instagram both automatically tag each image uploaded to the site using image detection and recognition algorithms [18, 36]. Users can edit and override this text after the image has been posted. Twitter, on the other hand, allows users to add their own descriptions when the image is posted, provided the user has previously enabled that feature.

The automatic alternative text provided by Facebook is always available, but is not yet trustworthy to blind users compared to high-quality alternative text written by humans [36]. However, few users have enabled Twitter’s image description feature for their account, and those that have do not always remember to write alternative

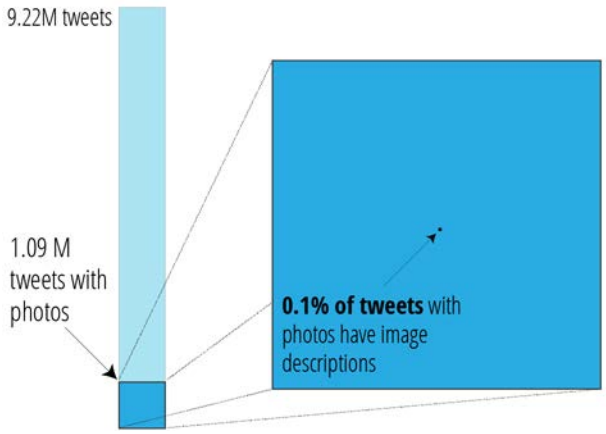

Figure 1: We sampled 9.22 million tweets, collecting 1.09 million with images. Only 0.1% of these tweets contained alternative text for people with vision impairments created using the opt-in image description feature on Twitter.

text. We were interested in further understanding why Twitter users chose to enable and use this feature to better understand what motivates them to provide image descriptions. This understanding will help us improve similar features on social networking sites and increase the number of users providing high-quality alternative text for their social media content.

To understand the current state of alternative text provided on Twitter, we collected a sample of 1.09 million photo tweets and found that only 0.1% contained alternative text. By looking at a sample of posts with alternative text written in English, we found that 83.4% of human-written descriptions were of high quality. We then interviewed 20 Twitter users who had written image descriptions to understand their motivations for writing them.

Our findings suggest that very few users enabled the ability to post alternative text, indicating that Twitter could increase accessibility by turning the feature on by default. Those who do use the feature often do so infrequently, but generally provide alternative text of high-quality (excluding automatic posts from bots). Users who do use the feature could still benefit from training or tools that would help them write better image descriptions. We suggest that researchers or Twitter community members who wish to improve accessibility for the site develop these tools and measure their impact on the accessibility of social media content.

2 RELATED WORK

Our investigation of the accessibility of Twitter is related to prior research on both manual and automatic methods to generate image descriptions, and the usage of alternative text on the web.

2.1 What are Image Descriptions?

Image descriptions, often referred to as alternative text or "alt text", are captions for images online or in other software. Alternative text is most commonly encountered on webpages, as it was added to the HTML 2.0 specification in 1995 [4]. However, at the time it was intended for users who used non-graphical browsers or preferred not to render images when accessing the web. Visually impaired users are not mentioned as an intended audience until the HTML 4.0 specification in late 1997 [9]. Accessibility of images for screen-reader users is one of the most commonly cited reasons to add alternative text to images today, but it is also recommended in case the image does not load for sighted users. Image descriptions are also expected to be added to software in other domains, including mobile phone applications on the iOS [2] and Android [14] platforms. Commercial software can also add alternative text to images in documents, such as Microsoft Word and Adobe Acrobat [1, 22].

Alternative text is not solely meant for human consumption, as various search engines consume it and use it to rank pages [19]. In fact, image descriptions have been used for a number of different applications including "semantic visual search, visual intelligence in chatting robots, photo and video sharing in social media, and aid for visually impaired people to perceive surrounding visual content" [17]. Image labels, captions, and descriptions provide a solid foundation for many of these kinds of applications.

In this paper we focus on alternative text image descriptions for people with vision impairments. Thus, our evaluation revolves around the descriptive quality of captions for a human, as in [25].

2.2 Methods to Generate Alternative Text

Currently, alternative text is primarily created by the developers of the website or authors of the website content. This text is manually written, and authors are recommended to follow the Web Content Accessibility Guidelines [10]. However, as many images on the web are not labelled correctly or at all [5, 16], researchers have sought to automatically generate image descriptions. Both for online accessibility and in situ photos, subsets of individual objects in photos can be labelled using object recognition algorithms [36]. More complex images can be described by scene description models, although this is usually less robust than human labelling. A commercial example of this is Microsoft Seeing AI [21]. However, researchers should remain skeptical of automatically-generated descriptions until they are of consistently high-quality, as prior work has also illuminated that there is a threshold for when image descriptions and captions can do more harm than good [25].

Because many images are complex and difficult to describe, especially for photos with a specific intent, the best alternative text is typically provided by human labelling. As relying on the original content authors to provide accessible images has not proven fruitful, researchers have proposed multiple ways to share alternative text for images between users [12] and collaboratively make websites more accessible without permission from the owner [26]. Guinness *et al.* proposed the Caption Crawler to automatically retrieve alternative text attached to the same image elsewhere on the web through reverse image searches, which achieves a similar goal without active crowdsourcing [15].

2.3 Alternative Text on the Web

The majority of image content on the web does not contain image descriptions. Bigham *et al.* found that less than 40% of significant images on the top 500 high-traffic websites contained alternative text [5]. This motivated the authors to create a tool to generate

alternative text automatically from surrounding web context and optical character recognition. They found that on top-ranked sites by traffic, they automatically generated captions for around 50% of not-described images. In a historical analysis of websites from 1997-2002, Hackett *et al.* found that websites were getting increasing complex and less accessible [16]. Notably, in both this study and Bigham *et al.*, government websites tended to be more accessible than other groups. A more recent (2017) survey of top websites by Guinness *et al.* found 20-35% of images lacking alt text in various categories [15]. Over the last ten years, the number of accessible images on the web has not noticeably changed.

With the rise of social media platforms, a significant amount of image content on the web are now generated by end-users, not website authors. This has lead to a large amount of content being inaccessible, as users did not have the option to add descriptions to their posts. Morris *et al.* found that over 25% of English tweets in June 2015 contained an image, and Twitter did not allow alternative text to be added at the time [24]. The post text itself was not a substitute for alt text, as the authors found that only 11.2% of tweets would serve as good descriptions for their accompanying images. In 2016, Twitter added an opt-in feature for users to write image descriptions for their images, which we examine in detail.

3 THE STATE OF TWITTER ACCESSIBILITY

We sought to quantify the usage of the image description feature across Twitter to understand how the introduction of image descriptions have made Twitter more accessible. We describe the image description feature, in general, followed by overall creation of alternative text by individual, popular, and public accounts.

3.1 Adding Image Descriptions

In 2016, Twitter added a feature to allow users to add image descriptions in their tweets that contain images [27]. By default this feature is disabled. The feature must be enabled by going to *Settings and privacy -> Accessibility* and clicking *Compose image descriptions* [30]. A note below the checkbox says *"Adds the ability to describe images for the visually impaired."* and a link provides more information in Twitter's documentation. Once the feature is enabled, a visual cue appears when a user uploads an image on the website or mobile application (Figure 2). The tweet author may add a description of up to 420 characters to each image (a tweet may contain up to four). Descriptions may not be added to videos or animated GIFs, the other common media formats on the site, and descriptions may not be added or edited after the tweet is posted. Image descriptions can be added to tweets posted through the API using the "ext_alt_text" tag [31], so third party tools may enable image descriptions for their users as well.

3.2 Snapshot of Image Description Usage

We first aimed to measure the amount of image descriptions on Twitter. Using Twitter's public API [32] we collected a sample of public tweets across 5 days in June 2018 for an average duration of 12 hours per day. This resulted in a collection of over 9 million tweets from all languages, including both original tweets and retweets (which may be duplicated). Approximately 1.09 million, or 11.84%, of those were tweets with at least one image. Only 1,144, or 0.1%, of those tweets (with images) contained image descriptions for at least one image.

3.2.1 Original Photo Tweets. Upon further examination of the tweets with images, we noted that 271,330, or about 25%, were original tweets. The other 75% were retweets. Only 177, or 0.07%, of original photo tweets contained image descriptions. When we examined the image descriptions in our sample we noticed that some images had URLs as alternative text (often the source of the image), which we filtered out as they are not descriptive. After removing URLs, there were 166 tweets remaining; 0.06% of the original 271,330 photo tweets.

3.2.2 Retweets. If a tweet contains an image description, retweets of it will still contain the description, but new descriptions cannot be added by other users. Retweeted tweets accounted for 75% of the image tweets in our sample, although many of these were duplicated. We had a total of 820,469 retweets, but only 426,084 were unique (51.2%). For unique retweets, 0.11% contained descriptions, which after removing URLs left only 0.05% or 207 tweets.

3.2.3 Photos vs Tweets. Twitter allows a user to attach up to four images to a single tweet, each with its own description. When examining each photo from original tweets we observed that 336,584 photos were shared, and similar to the other categories only 0.05% contained image descriptions (only 0.03% after filtering out URLs).

The details of our sample and breakdown of our analysis is shown in Table 1. Overall, this suggests that less that 0.05% of the image content on Twitter is accessible to screen reader users.

3.3 Accessibility of Popular Accounts

We wondered if, despite the fact that tweets from randomly-sampled users were mostly inaccessible, perhaps more popular accounts would enable and use the feature regularly. These accounts, run by celebrities or organizations, were more likely to have professionals writing their content. Additionally, if popular accounts were accessible, they would have a greater impact on the overall accessibility of Twitter, as they would appear in more user's timelines.

We collected the image tweets from the top 50 most popular Twitter accounts [33] by number of followers. The tweets collected included every image tweet available between the time the feature was launched and October 2018. We found that only 3 of the 50

Figure 2: The user interface for adding image descriptions on Twitter. The left image shows the "Compose Tweet" window with the "Add Description" pop up circled in blue. The right side is the subsequent window showing the added image with a field at the bottom to add a description.

Table 1: Number of tweets and retweets containing photos and alt-text.

	Day 1	Day 2	Day 3	Day 4	Day 5	Total
Tweets and Photo Tweets						
Total Tweets	1,860,947	1,757,012	1,366,244	2,243,235	1,997,713	9,225,151
Photo Tweets	225,679	189,445	145,778	269,098	261,789	1,091,799
Photo Tweets with alt text	195	199	205	297	248	1,144
Original Photo Tweets						
Original Tweets with photos	57,530	46,793	37,949	65,546	63,512	271,330
Original Photo Tweets with Alt	40	34	24	53	26	177
Photo Retweets						
Photo Retweets	168,149	142,652	107,839	203,552	198,277	820,469
Photo Retweets with alt	155	165	181	244	222	967
Original Photos and Retweeted Photos						
Total Original Photos	71,065	56,736	46,626	81,262	80,895	336,584
Total Retweeted Photos	287,909	241,828	183,244	355,346	349,894	1,418,221

accounts had ever used the feature: the official Twitter account, Bill Gates, and BBC Breaking News. Assuming they enabled the feature just before their first tweet with an image description, these three accounts collectively added descriptions to 14 (8.8%) of 159 image tweets. This assumption does not make much sense for the Twitter account, of course, as it introduced the feature [27]. Only 5 of Twitter's 44 image tweets since the introduction of the feature have included image descriptions. The other 47 popular accounts that never added descriptions for accessibility to their images included prominent news organizations (New York Times, CNN, ESPN), politicians (Barack Obama, Donald Trump, Narendra Modi), and celebrities (Katy Perry, Justin Bieber, Taylor Swift).

Based on prior work that found government websites more accessible [5, 16], we wanted to see if this trend carried across to government accounts on Twitter. Using a list (created by C-SPAN) of 577 accounts associated with members of the current U.S. Congress [8], we performed the same analysis as above. In all tweets since the introduction of the feature, 42 accounts had used the feature at least once, with an average of 3.8% of their image tweets containing a description.

4 ACCESSIBILITY FOR BLIND USERS

Understanding the state of accessible images on Twitter as a whole is valuable to inform how easy it is for a screen reader user to interact with any piece of content on the platform. However, this is not how most users experience Twitter content. They follow a set of users and only see the content authored, retweeted, or liked by the users they follow.

We analyzed the timelines of 94 self-reported blind users to determine if the experience of using Twitter is more accessible for people with vision impairments. To find blind users (who likely use screen readers to access Twitter), we collected a random sample of the accounts that follow the Twitter account of the National Federation of the Blind (@NFB_Voice), a large US-based organization led by blind people. From this sample, we selected an initial 100 users who self-identified as blind or visually impaired in their Twitter profile description. There is no definitive indication that these users also use a screen reader, but we assume that many do.

We wanted to understand if the timelines of these users had the same level of accessibility as Twitter as a whole, or if the accounts they follow posted accessible content more frequently. For each user, we collected all of the accounts they follow, known as "friends" on Twitter[1]. For 6 users, we were unable to retrieve this data, as the accounts they follow were private. For each friend of the 94 remaining accounts, we collected 200 of their most recent tweets (and retweets), or as many as were available. Using these tweets sorted chronologically, we recreated each user's Home timeline for one day in October 2018.

Table 2: Summary of the tweets in one day of recreated Home timeline for 94 blind Twitter users.

	Min	Max	Average	Median
Total friends	6	5,001	720.7	371
Total tweets in timeline	2	29,231	3,379.7	1,554.5
Percent photos in timeline	0.0%	39.7%	18.4%	18.3%
Percent alt Text in photos	0.0%	41.4%	4.6%	2.0%

This is not a perfect recreation of a user's Home timeline, as Twitter does not show every tweet chronologically [29]. Additionally, we could not gather tweets from accounts with higher privacy settings (protected accounts), and some posted tweets may have been deleted by the time we collected them. However, we believe this to be a good approximation of the content these Twitter users would have been exposed to if they logged into Twitter that day.

Overall, we found that the recreated timelines for these users included 18.4% of tweets with photos on average, and 4.6% of photo tweets contained image descriptions. Table 2 contains information about the range of content we observed in these users' timelines, and a visual depiction is shown in Figure 3. In general, these timelines were an order of magnitude more accessible than Twitter as a whole, indicating that these users may be involved in communities with more awareness of the image description feature. An alternative explanation is that these users chose not follow some accounts that post inaccessible images. Regardless of the explanation, while

[1]This does not indicate a mutual relationship, as it does on many other social networks.

these timelines are more accessible than our random sample of Twitter as a whole, they were still largely inaccessible.

5 QUALITY OF IMAGE DESCRIPTIONS

After investigating the prevalence of image descriptions on Twitter and finding low usage of the feature, we were curious about the quality of descriptions that do exist. Do authors write image descriptions in a way that is useful for people with vision impairments? Are the descriptions relevant to the photos?

To answer these questions, we developed a four-point rating scale from "Irrelevant" to "Great description" to assess the quality of image descriptions on Twitter posts (Figure 4). We filtered our sample of original photo tweets with descriptions to those in the English language (based on the "lang" attribute in the Tweet metadata), as we could not effectively assess non-English descriptions. This left 93 tweets from 71 users. To get a larger sample of tweets, we downloaded all tweets from these users with alt text.

5.1 Evaluating Image Descriptions

Prior work by Salisbury *et al.* [25] constructed conversations between crowd workers who were not allowed to view the image in a tweet, and crowd workers who were allowed to and expected to describe the image. From this, they built a set of structured questions to help guide composition of alternative text. We merged these questions and guidance from the Web Content Accessibility Guidelines [10] to develop a rating scale for image descriptions on Twitter. We used a rubric to rate the quality of image descriptions, and examples are shown in Table 4.

5.2 Findings

Two of the researchers used the rubric to redundantly code the quality of 500 photo tweets. We estimated the inter-rater reliability for this set by calculating a weighted Cohen's Kappa of 0.83 for these 500 ratings, which can be seen as strong agreement [20]. One of the researchers then rated an additional 500 photo tweets, resulting in a total of 1000 rated tweets.

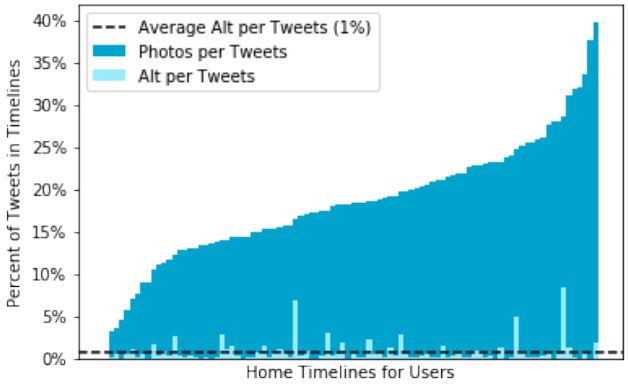

Figure 3: Each timeline analyzed, with the y-axis being percentage of total tweets. Dark blue: photos as a percent of tweets; lighter bars: alt text as a percent of tweets.

Using this set of 1000 rated tweets, we found that 62.6% of alt text rated as irrelevant or somewhat relevant. Only 15.8% rated as "great", with most elements of the image described. More details are available in Table 3.

5.3 Frequency of Use

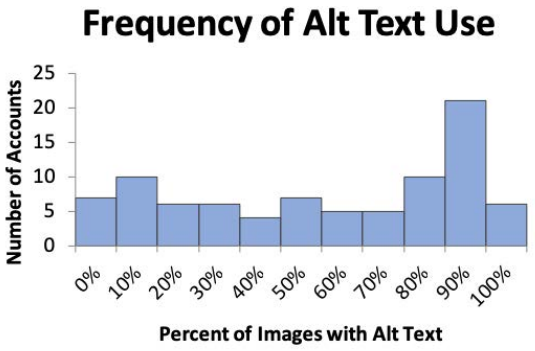
Some accounts included in our sample used alternative text often, while others only had included a description in a small fraction of the images they tweeted. We looked at all of the images each account had posted since they first used the image description feature. On average, accounts included image descriptions for 60.5% (median = 66.67%) of images tweeted. Many of the accounts who included image descriptions 90-100% of the time were automatically posting content as bots, however. After manually removing 19 of these accounts (Section 5.4, we found that humans tended to write image descriptions for 49.8% of their photos (median = 50%).

5.4 Quality of Bots vs. People

From this analysis, we noticed that many of the tweets with image descriptions were coming from the same accounts, and these accounts were either explicitly bots or exhibited bot-like behavior. The accounts we knew were explicitly bots indicated they were automated in their name or profile description. Some bots generated specific kinds of memes, such as taking images from museum

Table 3: Percentage of image descriptions rated using our rubric for different samples.

Rating	Sample 1	Sample 2 (no bots)	Combined
Irrelevant	32.6%	1.1%	16.9%
Somewhat relevant	30.0%	15.9%	23.0%
Good	21.6%	34.1%	27.9%
Great	15.8%	48.9%	32.4%
Sample Size	1000	1000	2000



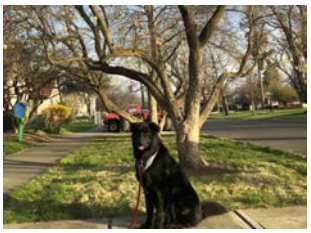


Figure 4: Histogram showing the frequency of image descriptions posted for the accounts in our sample. There is a spike in the 90-100% range that is comprised mostly of bots.

Table 4: Alt-Text Rating Examples. *Links and Usernames are removed from post text for anonymity.

Rating	Image	Post Text & Image Description	Rating and Reason
Irrelevant to image		**Post:** New Music Video - Beach House (@[username]) "Black Car": [link][link] **Alt:** Beach House	We rated the alt-text for this image as **irrelevant** because it does not describe anything in the actual image shown.
Somewhat relevant to image		**Post:** Trailering training class in Henderson yesterday. **Alt:** Trailering training class in Henderson yesterday.	We rated the alt-text for this image as **somewhat relevant** because it relates to the purpose of the image but just repeats the post text without describing more of the image.
Good: some aspects of image described		**Post:** Collecting all the shirts #DNNSummit **Alt:** Three t-shirts from DNN summit.	We rated the alt-text for this image as **good** because it describes most of the things in the image. It could also describe the color and/or what is on each shirt.
Great: almost everything is described		**Post:** "Taking a moment to appreciate beauty. #DogsOfTwitter @[username] #beauty #spring" **Alt:** Styx the dog sits in front of a tree with plastic Easter eggs dangling from the branches. It's very pretty.	We rated the alt-text for this image as **great** because it describes almost everything in the image. This particular description also points out information that might not be immediately apparent visually, either.

archives and superimposing fictional characters on them. Others posted automated information about location-based information such as earthquakes or air-quality, and included maps with their posts. Other accounts did not explicitly state they were bots but exhibited bot-like behavior such as blogs that re-posted articles from their website to drive traffic there from Twitter.

These bots exhibited different levels of accessibility. Some included information that described the entirety of a generated image. Others, such as blog-associated accounts, included human-written alt text for the images in their articles. Overall, however, we saw a general trend of descriptions associated with bot posts receiving a score of "Irrelevant" or "Somewhat relevant".

As we were interested in human-written alternative text, in addition to overall accessibility on Twitter, we sampled an additional random 1000 tweets from our users that excluded the 19 accounts that were explicit or suspected bots. One member of the research team rated this additional sample, finding that just under half of the sample rated as "Great" (48.9%) and 34.1% as "Good". The complete numbers of these samples are available in Table 3.

The difference between these two samples is stark, and indicates that the majority of poor image descriptions may be generated from automated sources. The human tweet authors in our sample described images at a moderately useful level ("good") or higher. Bots are currently important and lively sources of content in the Twitter ecosystem, and their content should be just as accessible to people with vision impairments. These results for human authors are promising, and show that many users write good image descriptions, if they enable and use the feature.

6 DESCRIPTION AUTHOR INTERVIEWS

We interviewed people who had used the image descriptions feature to add alternative text to images in their tweets. Prior work has demonstrated a clear accessibility need on social media platforms from the perspective of people with disabilities [6, 24, 34]. Twitter users that create content must be able to make their images accessible, as the responsibility of making Twitter and other social media platforms accessible should not fall solely on people with disabilities. We were interested in users' motivations for using the feature, their process for composing image descriptions for tweets, and why they may not always add descriptions to their tweets.

6.1 Participants

We interviewed 20 Twitter users who had written at least one tweet including an image and description. Participants were recruited via direct messages or emails to users identified in our sample from Section 5: Quality Ratings. We also recruited participants via an advertisement on Twitter posted by one of the authors. The mean age for participants was 41.6 years (std. dev.= 11.7) with a

Table 5: Participant Demographics.

PID	Age	Gender	Years On Twitter	Occupation
P1	32	male	10	Make and sell jewelry
P2	32	male	10	Client services

P19	48	male	9	Musician, Developer
P20	32	female	9	Marketing

range of time using Twitter from 4 to 12 years (very early adopters). None of the participants reported any visual impairments or use of screen reader technologies. Thus, participants in our study do not represent visually impaired users on Twitter, but rather represent the creators of content that visually impaired users might consume.

6.2 Interview Format

We conducted interviews in person, over the phone, and through Twitter direct messages. The interview consisted of four topics: activation and use of the image description feature, interactions with blind or screen-reader users regarding alt text, process of writing and examples of their alt text, and suggested changes for the image description feature on Twitter. Demographic information is listed in Table 5. The interview sections are described below.

Feature Use. We asked participants three questions regarding their use of the image descriptions feature: (1) why they activated the feature, (2) how they decide when to add descriptions, and (3) and how often they believe they add descriptions to the images they tweet. Our aim was to understand what motivated these users to activate the feature, how actively they provide image descriptions, and for what purpose.

Interactions with Followers. We asked participants about their interactions with followers who were blind or used screen readers. Specifically, we asked about any direct interactions participants had and how many of their followers they believed benefited from image descriptions.

Examples of Image Descriptions. We discussed participants' process for composing image descriptions for their tweets. We first asked participants to describe the elements they included in their descriptions and what they think about when composing them. Next, we chose specific examples from participants' tweets to discuss; one where they wrote alt text and one where they did not. We discussed how they wrote the specific image description for the example and reasons they may not have added descriptions for other images.

Changes to Image Description Feature. Finally, we asked participants to think of one thing they would change about the Twitter image descriptions feature.

Data and Analysis. Each interview was transcribed and analyzed using a theoretical approach to thematic analysis [7] based on the sections of the interview described above. We coded each transcripts based on the topics of the interview. The first and second authors redundantly coded the first five interviews, then discussed and refined the code book before independently coding the remaining 15 transcripts.

6.3 Findings

6.3.1 *Feature Discovery, Motivation, and Use.*

Discovery. Participants discovered the image description feature through a variety of ways. The most mentioned (6) was by the suggestion of someone they were following or a tweet they saw mentioning the capability to add descriptions to images on Twitter.

> *"Because [a specific user I follow] suggested it, I suspect. I can't say for certain. I would never have looked into the accessibility settings if someone hadn't said that this feature was hiding there." – P3*

Some participants (2) discovered the image descriptions feature through announcements, presumably made by Twitter, when the feature was released. Three participants anticipated the release of the image description feature before it was announced. P1 had even requested that Twitter add the capability, almost two years in advance of its release.

> *"I'd been waiting for it to be an option for a while - me and friends had contacted Twitter about it but nothing happened for a while. So as soon as it became available I switched it on...Quite a few of us have disabilities so we try to push for accessibility features like captioning/transcripts or image description." – P1*

Three other participants mentioned they activated the feature because someone else had used alternative text to describe images or they were involved in accessibility related work or communities.

> *"I learned about it through [work] colleagues and wanted folks using screen readers to be able to access media, too." –P15*

Motivation. In terms of why they chose to use the feature, some participants cited that adding alternative text to images was a low effort activity, but would have a high impact on the people it was intended for.

> *"I knew I wanted to use it because it's such a simple small thing that is no effort for me, but may mean a lot to the reader." – P4*

Four participants cited personal or professional connections to someone with a disability as motivation for their use of alternative text. P18 described their professional connections:

"I ran [several] - all accessibility-related accounts. It would have been disingenuous to have the disability community as our majority base of followers and not include alt-text, so we did as soon as it was available. Same for my personal account since I am in that field and was perhaps more aware of it than others might be." – P18

Two ther participants, like P4 and P7, were influenced more personally by their relationship with blind users:

"Maybe subconsciously because a close friend of mine is visually impaired and I used to describe some pictures I find on twitter to him over lunch table conversations but now since we don't meet a lot, this is one way I can keep my friend engaged with my conversations." – P7

Overall, participants demonstrated that, while perhaps not personally connected, providing image descriptions was a matter of "inclusion" that makes things better for everyone.

Habits of Use. With regard to participants' intended use of the feature it became clear that most (12/20) participants explicitly intended to add image descriptions to every image they posted. When we asked how often participants actually used alt text, we found that people experienced varying levels of success:

"Ok I'm not as good at doing alt-text [as] I thought. In my last 10 images, 5 had alt text." – P8

For others, adding the descriptions was a matter of convenience, citing that the applications they used either allowed it or made it straightforward to add the descriptions. Two participants described that when they had time, they would add image descriptions:

"Maybe its really the time which is the factor, when I feel like I am in a rush, I kind of miss adding it to alt-text and instead just describe it in the tweet text."–P7

Two other participants described being reminded by the interface (see figure 2) to add a description.

"The add a description prompt under the photo [which appears once users have activated the ability to write alt text in their accessibility settings] reminds me. I think I do it for every photo I add."–P11

We had two participants, P2 and P19, who created bots that generated original tweets with images that included descriptions. Both bots generated meme-like images by imposing content from online image archives with other images. The alt-text in both cases was just the description of the image that was in the library or museum archive. For these bots, including alternative text as part of the tweet metadata was supported by the Twitter API, thus making the inclusion of a description for every image very convenient.

One participant highlighted that they try to add image descriptions whenever the image is their own photo, whether it is a photo they took or a graphic they created. One participant, P20, mentioned that she switched to using the Twitter web interface or mobile app specifically because another third party tool she was using did not support adding image descriptions. This was similar to P6's professional commitment:

"If I include an image, I add alt text. If I don't feel like bothering, I don't include a picture. Professional pride" – P6

6.3.2 Follower Knowledge and Interaction. Half of participants (10/20) had no knowledge of any of their followers being blind or using screen readers. A majority of participants (11/20) had never been contacted by a blind person regarding their use of alt text.

"I have put stuff in my alt text to try to solicit a response and never gotten one, so I am not sure any of my twitter followers use screen readers." –P15

The other half of participants (10/20) were aware of at least one blind individual among their followers. A few (8) estimated specific numbers between 1 and 40, or "a small percentage". Participants had limited Interactions with their networks regarding alt-text; however, one participant mentioned having discussions where alternative text was mentioned.

6.3.3 Authoring Image Descriptions.

Description Process. We asked participants to share their process for writing image descriptions, both in general and in relation to a specific example of one of their own tweets. Some participants had specific strategies for describing an image. Depending on the intent of the post (mentioned explicitly by 6 participants), a majority of participants (11/20) described writing a general description of the image. One participant imagines trying to explain an image to a friend on the phone.

One participant mentioned describing the colors that appeared in the image. Others described determining the importance of objects, background, and other content in the image that the reader may not be able to ascertain from the main text of the tweet. Participants mentioned transcribing the text included in images or describing the objects, actions, and facial expressions in the image. Based on the content in the image, three participants tried to highlight the focus of the image.

For bot creators and specific content-focused accounts, participants mentioned that they used the image descriptions to convey the purpose of the tweet. For instance, to describe the important visual elements in the image to represent a joke or meme, or to convey why the image makes the joke funny in the context of the post (examples in Figure 5). We encountered two notable examples of content creators that had difficulty writing descriptions, a photographer and a bot creator with accounts that posts memes. P10 grappled with trying to describe the important photographic elements of her images:

"When it's a photograph being shown as a piece of art, that's where it gets difficult - especially since many of my photographs are quite abstract and tend to defy description! I try to touch on the straightforward visual facts of it (what is it a photograph of) but also get across the sense & feel of it where I can. The latter is in some ways more important with my photography. Things like colour tones (is it cool or warm, soft colours or vivid colours), are there any textures, what does it resemble." –P10

P2, who creates Twitter bot accounts, described nuances of conveying jokes presented through memes:

"[The first bot] deviates from my personal answers since its alt-text is the punchline and doesn't describe the visual content of the meme. That can be hard. For [these tweets] the verbosity is the joke, so I used [the alt-text] to convey that verbosity. For

(a)

(b)

Figure 5: The alternative text for (a) was: "Cartoon man in glasses holding book looking at a butterfly labeled 'microbes', asking "Is this ponies" For (b) it was: "Monochrome photograph of a number of dandelion seeds tangled together - much of the focus is soft, the the seed heads and fluff are clearly visible in places. There are hints of blue colour tone in the background."

> *[A different bot account] the joke is both that the character looks intelligent and is making a foolish mistake...the alt text template there mentions the book, the glasses, and then names the two disparate concepts [in the image]." –P2*

All of these examples illustrate a very nuanced process. The approaches vary from person to person and with the intent of the post and image.

Non-Use. Participants cited time constraints as the most common reason they might have missed adding alternative text, either because it was too time consuming, they were in a hurry and forgot (8), or they had to write multiple tweets in succession and missed adding alt-text in the process (5).

Other reasons were that participants simply forgot what the feature was for or that the feature was there. We encountered four participants who mentioned that they relied on the Twitter interface to remind them to add the description.

> *"Actually, looking at twitter on web, the cue for alt-text is "description" which sounds pretty optional at a glance. there's a chance i read "description" and forgot it was for the visually impaired in my rush to tweet and accumulate all the engagement. – P8*

Some participants stated that adding image descriptions from a mobile device was still not possible. However, it is currently possible to add descriptions from the Twitter mobile application. This suggests that either participants did not notice the feature or have not used the application since the capability was added.

6.3.4 Changes. The most common suggestion, mentioned by eight participants, to improve the image description feature on Twitter was to make the descriptions visible to sighted users, especially for their own tweets. P4 states:

> *"[I want] to be able to add the alt text after the tweet is posted. I don't need to edit tweets as a whole, but I would really want to be able to go through all my pics and add alt text. And I wish hovering over images would show what alt text I wrote, like they used to with other images online. Maybe more people would notice/become aware then?"–P4*

The only current process for viewing these descriptions requires the user to view the source code for the web page. This suggestion is also in line with the desired ability to edit the tweet content (and image description) after it has been posted, which is typically not supported on the platform.

The second most common suggestion (by 5 participants) was to make the image description feature "active" by default instead of as a setting that you have to turn on.

> *"I would make it automatically enabled for people so that users don't have to wade through the settings to turn it on. They could be helping so many more people if only they used this feature up front."–P20*

Other suggested changes included improving the interface reminder, addressing bugs, and providing automated support to generate image descriptions. Participant 1 also mentioned the need to increase and "normalize" the use of the feature in a similar manner to captioning. In addition to support from Twitter, one participant (P11) wanted access to individuals with vision impairments to provide guidance on writing good image descriptions. Finally, three participants mentioned increasing the character limit (currently 420 characters) for the alternative text to allow more thorough descriptions, especially for screenshots or pictures of text.

7 DISCUSSION

Our analysis of image description on Twitter revealed that very few people (including popular and government accounts) use the feature, with less than 0.1% of original image tweets having any descriptions at all. The image tweets exposed to blind users contain descriptions slightly more often (4.6%), but still are very inaccessible. The Twitter users that do use the feature author descriptions for about half of the images they tweet, and the descriptions they write tend to be "good" or "great" 83% of the time (bots excluded). Our analysis of interviews with image description writers examined the reasons for use (and non-use) of the feature, and lead us to two paths for improvements: those that Twitter (or similar social platforms) could currently undertake, and those that require further research and additional tools.

7.1 Improvements for the Image Description Feature

Interview participants identified many issues with the image description feature that, if fixed, would lead to higher or better usage. Participants requested that alternative text be visible to them and editable after posting. Interview participants had trouble recalling which images they added descriptions to, and what they wrote. The most common reason they did not add a description was that they forgot when posting quickly, and being able to add image descriptions after the fact would be valuable. Taken further, if users could add image descriptions to retweeted images, volunteers or friends of screen reader users could then make this content accessible.

Another common request was for Twitter to just turn on the ability to author image descriptions for everyone, rather than requiring users to find and enable this capability.

> *"Top wish: it should be turned on by default. It's almost like they're trying to hide it." –P6*

Most participants turned on the feature as soon as they found out about it, and try to include image descriptions for every tweet with images that they post. We agree that the image description feature is hard to find and understand, and Twitter should enable it for everyone to increase accessibility on its site.

However, just enabling the feature for everyone is likely not enough. It is currently designed for people who are familiar with image descriptions for people with vision impairments, and instantly enabling it for everyone could lead to misuse. It may be abused to make tweets appear higher in Twitter or external searches or include spam URLs. We have already observed users including subtle messaging in Twitter image descriptions for followers who know to look for it. Even without intentional abuse, new users who do not understand the purpose of the feature or how to write alt text may not produce high quality image descriptions. Twitter should provide clear on-boarding instructions for users when they first use the feature, explaining its purpose and why users should provide image descriptions for their images. In order to reduce confusion when posting a new image tweet, on image upload Twitter should provide instructions on how to write alt text or a template of structured questions, which prior work has found results in higher quality alt text in other media (*e.g.,* STEM textbook diagrams) [23].

7.2 Additional Tooling and Training for Users

We see two major opportunities for researchers to make social media platforms more accessible through additional tools.

Some content on Twitter is ripe for auto-generation of image descriptions. Automatic captions for generic images has been exemplified by ALT text bot [11], which provides automated alt text in response to tweets containing images. However, researchers could go further in areas where the content format is more constrained. Some photos are just photos of tweets, and could be accessible if linked to the original tweet. Screenshots or photos of text are popular (9.7% of the no-bot sample in Section 5), and robust optical character recognition could make these accessible.

Researchers should also develop tools to help users write better image descriptions. Many users do not know what elements to include in an image, and would benefit from specific instructions, such as the structured questions developed in Salisbury *et al* [25]. Automated tooling could rate how descriptive alt-text is, provide specific instructions based on recognized objects in an image, or even pre-fill the image description with an auto-generated scene description [25, 37]. This may help prompt the user to change or refine the image description before publishing.

7.3 Supporting Authorship through Automated Feedback

To provide a starting point for the goal of creating tools for image description authors, we used the sample rated in Section 5 to create an automatic rater for image descriptions. We merged ratings of "Irrelevant" and "Somewhat relevant" alt text as "low-quality" and ratings of "Good" or "Great" as "high-quality". An Extra Trees classifier [13] was trained on features extracted from a subset of the sample (1,320 tweets). The specific features used were: counts the of parts of speech in the alt text and post text, shared words between the alt text and post text, as well as the length of the alt text. This classifier achieved an overall accuracy on the remaining 680 tweets of 85.3% (AUC = 0.84, precision = 0.83, recall = 0.94), demonstrating it is able to distinguish between much of the alt text quality. The five most important features for this classifier were: number of prepositions in alt text, number of words shared between post text and alt text, length of alt text, number of present verbs in alt text, and number of plural nouns in alt text.

At a very simple level, a classifier like this demonstrates that automatic feedback could be given to users, when they compose their descriptions, on whether it appears to be low or high quality. Specific feedback could focus on how similar the alt text is to the post text, objects in the image that are not mentioned, or a lack of actions (verbs) and objects (nouns) in the written description.

7.4 Limitations

The primary limitation of this work is that we have not comprehensively studied the accessibility of Twitter as a whole, only photo tweets. Other forms of media, such as animated GIFs, videos, polls, and URL previews exist. URL previews in particular can contain alternative text that is pulled from the linked page, but this was not the subject of our analysis.

Our rating scale was developed from prior research on the experience of blind users interacting with alt text, but it was still designed and executed by sighted researchers rating image tweets, Therefore, it does not fully reflect what screen reader users seek when browsing images on Twitter.

8 CONCLUSIONS

Our findings show that image descriptions are very rarely provided on Twitter. This is in large part due to very few users having the feature turned on, but even the users who enabled the ability to provide alternative text descriptions did not always write them. Twitter would likely dramatically improve its overall accessibility if it encouraged all users to provide descriptions and enabled them to do so across all types of media. Access to social media is increasingly important for participation in many aspects of society, including social connection, entertainment, civic participation, and news consumption. By improving descriptions of visual content on social media networks, many users with vision impairments [34] will again have equal access to these vital platforms. As P15 states:

> *"Only built-in accessibility from the start provides more equitable access. Only doing it because/when someone asks for it or because we know a specific individual needs it, puts the burden on the person with the need, and that's not how accessibility should work. And in terms of accessibility online, alt text for static imagery is a low hanging fruit, easy and inexpensive to implement. Failure to do it is just inconsiderate laziness."–P15*

ABSTRACT

Cryptocurrencies are a novel and disruptive technology that has prompted a new approach to how currencies work in the modern economy. As such, online discussions related to cryptocurrencies often go beyond posts about the technology and underlying architecture of the various coins, to subjective speculations of price fluctuations and predictions. Furthermore, online discussions, potentially driven by foreign adversaries, criminals or hackers, can have a significant impact on our economy and national security if spread at scale.

This paper is the first to qualitatively measure and contrast discussion growth about three popular cryptocurrencies with key distinctions in motivation, usage, and implementation – Bitcoin, Ethereum, and Monero on Reddit. More specifically, we measure how discussions relevant to these coins spread in online social environments – how deep and how wide they go, how long they last, how many people they reach, etc. More importantly, we compare user behavior patterns between the focused community of the official coin subreddits and the general community across Reddit as a whole. Our Reddit sample covers three years of data between 2015 and 2018 and includes a time period of a record high Bitcoin price rise.[1]

Our results demonstrate that while the largest discussions on Reddit are focused on Bitcoin, posts about Monero (a cryptocurrency often used by criminals for illegal transactions on the Dark Web[2]) start discussions that are typically longer and wider. Bitcoin posts trigger subsequent discussion more immediately but Monero posts are more likely to trigger a longer lasting discussion. We find that moderately subjective posts across all three coins trigger larger, longer, and more viral discussion cascades within both focused and general communities on Reddit. Our analysis aims to bring the awareness to online discussion spread relevant to cryptocurrencies in addition to informing models for forecasting cryptocurrency price that rely on discussions in social media.

1 INTRODUCTION

Cryptocurrencies are an emerging and disruptive technology. The coins themselves, the underlying software, and the surrounding environment of social and trading behavior are highly volatile and evolve quickly. Cryptocurrencies are disproportionately used by criminals and hackers, and their use has political and economic implications. The way information about these novel distributive technologies spreads across online social platforms shapes online and offline discussions, and could potentially influence peoples' beliefs and decision making. Thus, it is crucial to understand, explain, and anticipate the social behavior and communication patterns in the social environments surrounding cryptocurrencies to understand this phenomena and devise appropriate responses [22, 30, 35].

A preliminary analysis of potential cryptocurrencies of interest identified Bitcoin (BTC), Ethereum (ETH), and Monero (XMR) as the top three cryptocurrencies in terms of both developer interest on GitHub and Bitbucket and community interest on social media platforms – Twitter, Reddit and Facebook as illustrated in Figure 1. For that analysis, we collected data from CoinGecko for 1,742 cryptocurrencies.[3] and compared coins in terms of developer interest features (a measure of activity in public repos on GitHub and Bitbucket) and community interest features (a measure of discussions and popularity on social media platforms) released by CoinGecko. *Bitcoin* is a market-leading cryptocurrency, which laid the foundation for blockchain's transparent digital ledger system (blockchain). *Ethereum* is a cryptocurrency as well as a blockchain development platform, where developers may build their own automated smart contracts. *Monero* is a cryptocurrency similar to Bitcoin but with added security and anonymity features which enable more privacy in transactions. Monero is often used by criminals for illegal transactions on the Dark Web[2].

[3]https://www.coingecko.com/en/coins/all

Figure 1: Cryptocurrencies plotted by developer and community interest according to CoinGecko.

To motivate our analysis we present discussion growth on Reddit between January 2015 and January 2018, covering a period that includes the record high Bitcoin price rise at the end of 2017, in the official r/bitcoin subreddit aligned with related real-world events in Figure 2. We observe a significant increase in Reddit discussion volume during the period of the record Bitcoin price increase. During that time, online discussions could be influenced by adversaries [24] who could potentially manipulate people's opinions [3, 10] regarding buying or selling Bitcoin. The same is true for other cryptocurrencies, for example, we discover high correlations measured as Normalized Mutual Information (NMI) between Reddit discussion volume and coin price for Bitcoin (NMI = 0.64), Ethereum (NMI = 0.89) and Monero (NMI = 0.82).

Our main contribution is a measurement-driven analysis of cryptocurrency discussion spread for three popular coins within two Reddit sub-populations: the *Official Subreddit* communities and a broader *Crypto-Ecosystem* comprised of multiple crypto-related communities. We measure the *speed* of cryptocurrency discussion spread to understand how quickly discussions begin (initial delay or responsiveness), how they grow over time, and how quickly they end (discussion lifetime). We evaluate the *scale* of cryptocurrency discussion spread by measuring discussion volume, audience size, and structural properties of discussion threads *e.g.,* the max-breadth, max-depth, and structural virality [16].

2 RELATED WORK

Information cascades in online social networks (OSNs) are a phenomena in which the idea becomes widely adopted due to influence of social network neighbors and has been widely studied [4, 5, 17, 18, 27, 28, 33]. Researchers presented analyses on how different types of information spread in different social environments e.g., how images spread on Flickr [6, 7], pins (images) on Pinterest [19, 20], videos on YouTube [36], reviews on Yelp [21], URLs on Yahoo [17], posts on Weibo [34], hashtags and URLs on Twitter [26, 31], posts and memes on Facebook [1, 9, 11] etc. Another line of work focused on predicting cascade properties e.g., size, depth [2, 8, 23, 25]

Unlike prior work that focused on how a specific piece of content e.g., an image, URL etc. spreads in a single social environment and what factors drive such information spread, we focus on analyzing threaded discussion cascades relevant to the cryptocurrency domain on Reddit. Our analysis is motivated by the phenomena where online discussion spread could potentially influence (and be influenced) by real-world external events e.g., market crashes and coin prices. The most similar work to ours is [12]. The authors focused on the most popular subreddits and performed the analysis of conversation patterns on Reddit by only considering one measurement of speed (responsiveness), and two scale measurements (volume and virality). We go beyond that: we empirically evaluate and contrast speed and scale of discussion spread related to cryptocurrencies using multiple measurements within the *Official Subreddit* communities and discussions within a broader *Crypto-Ecosystem.*

3 REDDIT DATA

In this study we chose to focus on analyzing discussion spread on Reddit for several reasons. Reddit is a highly popular social news aggregator[4] that allows communities of users to share and discuss information, opinions, and entertainment media. There are 330 million users active in 140 thousand communities on Reddit who post 2.8. million comments daily, and perform 11 million posts and 11 billion page views monthly[5]. Moreover, reconstructing cascades for Twitter and Facebook requires either access to the full data (not just a sample [13]), the collection of all followers to be able to reconstruct the cascades, or the application of other methods for correcting information cascades for missing data [32]. Unlike these social networks, Reddit post and comment data is public[6] and contains full discussion cascades.

Cryptocurrency Official Subreddits. The *Official Subreddit* dataset comprises all discussions posted to r/bitcoin,r/ethereum, and r/monero subreddits over a period of three years from 2015 through 2017. These three subreddits are the official communities for each of our cryptocurrencies of interest and had substantial traffic of, on average, 3.6K, 500, and 380 comments posted each day, for Bitcoin, Ethereum and Monero, respectively. As these communities are explicitly tied to each of the cryptocurrencies, we label each discussion with the subreddit's respective coin. This resulted in a total of 212,302 Bitcoin, 41,792 Ethereum, and 15,035 Monero discussions.

Cryptocurrency Ecosystems. To collect relevant discussions across the Reddit community in general for the *Crypto-Ecosystem* data, we collected the full comment threads for posts that were (a) submitted from January 2015 through August 2017 and (b) contained either keywords related to Bitcoin ('#btc', '#BTC', '#bitcoin', '@bitcoin', 'bitcoin'), Ethereum ('#eth', '#ETH', '#ethereum', '@ethereum', 'ethereum'), or Monero ('#xmr', '#XMR', '#monero', '@monero', 'monero') in the title or text (if the post includes text). This resulted in 38,118 posts and comments for Bitcoin, 8,989 for Ethereum, and 4,381 for Monero that were submitted from January 2015 through August 2017. These discussions are not partitioned by subreddit and, intuitively, discussions can be started by posts that include keywords for multiple coins. To avoid bias from one coin affecting analysis of another, we restrict the dataset to include only those discussions where the initial post included keywords for a single coin.

[4]The 18th most popular site globally and 5th most popular within the U.S. according to Alexa.com: https://www.alexa.com/topsites
[5]https://expandedramblings.com/index.php/reddit-stats/
[6]An archive of Reddit posts and comments is publicly available at https://files.pushshift.io/reddit/ and covers the time period of 2005 through 2018 as of February 2019.

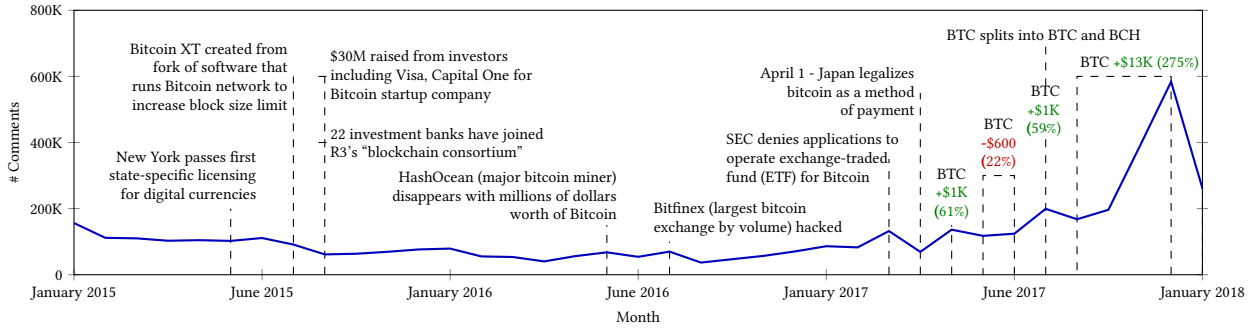

Figure 2: Motivation: discussion growth on Reddit for the r/bitcoin official subreddit related to real-world events and a record high Bitcoin price rise at the end of 2017.

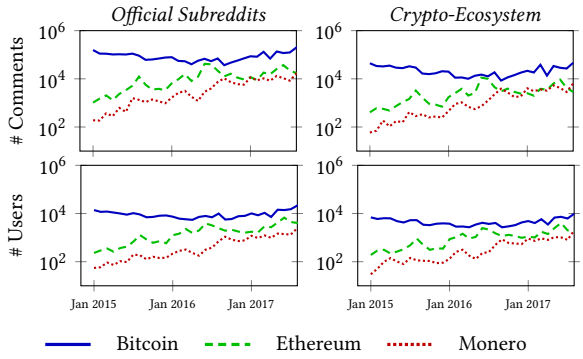

Figure 3: Discussion activity over time as the number of comments (above) and users (below) for each cryptocurrency of interest. Y-axes are presented on a log scale.

This resulted in 35,282 discussions for Bitcoin, 6,949 for Ethereum, and 3,324 for Monero. This restriction did not significantly reduce the sample size overall or for any one coin.

Figure 3 illustrates the volumes of comments posted (above) and users active (below) in cryptocurrency-related discussions each month within two datasets described above. To replicate our results, one could collect comments from the Reddit archive publicly available at https://files.pushshift.io/reddit/ and extract all comments posted to the official subreddits or with related keywords present in the body of the comment, as described above. Interestingly, we see that the volumes of active users and comments posted to the official subreddits, where we did not restrict posts to only those that included the set of keywords, follow very similar trends to the corresponding sets of discussions within the Crypto-Ecosystem dataset.

4 METHODOLOGY

On Reddit, users may contribute to discussions in several ways:

- starting a discussion by authoring a post which must be submitted to a specific community (subreddit),
- posting a comment in reply to a post,
- posting a comment in reply to another comment,
- voting (positively or negatively) on posts or comments.

These discussions can be viewed as tree structures or information cascades (aka comment trees on Reddit) [4, 12, 18] wherein the root node represents the initial post, and other nodes in the tree represent comments to the initial post. We define a discussion cascade as an undirected tree $T = (V, E)$, where V represent all messages (the original post and the follow-up comments in the discussion thread), and E represent the set of edges that connect messages linked by in-reply (or commenting) actions. Figure 4 presents the discussion cascade for an example post and ten comments. We focus on measuring discussion growth using comment trees within focused communities of the official subreddits and across multiple communities in the wider cryptocurrency ecosystems and characterize the speed, scale, and a high-level content analysis of cryptocurrency related discussions on Reddit for three coins of interest – Bitcoin, Ethereum, and Monero. Before studying discussion spread, similar to [5, 27], we discuss the affect of the topological structure of the network, and characterize the population of contributors as outlined below.

First, we examine the *population of contributors* who participated in these discussions in terms of how active they are, *e.g., are we analyzing the behavior of a large population with varied frequencies*

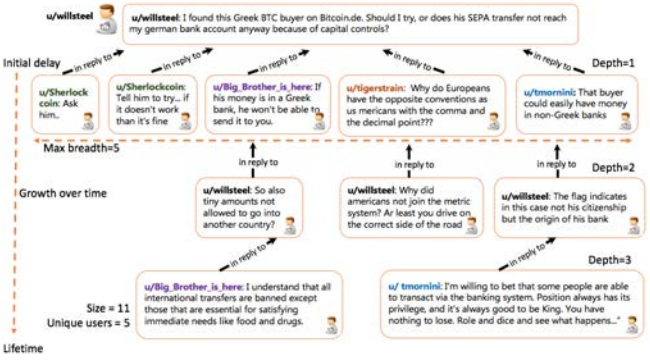

Figure 4: Discussion cascade (aka comment tree on Reddit) illustrated for a post with 10 comments. Discussion speed measurements – initial delay, growth over time, lifetime and discussion scale measurements – volume, audience and structural properties of information cascades are shown.

of activity or a primarily homogenous, densely connected network of highly active users? For that, we look at the mean averages and respective 95% confidence intervals for the volumes of discussions related to each coin that users initiate, *i.e.,* by submitting the initial post, or participating in the discussion through posts and comments.

Next, we examine *topology of user networks* (the forest of cascade trees) constructed created from the reply-links in the discussion threads as shown in Figure 4. We define a reply-link as follows: reply-link <*A*,*B*> exists if user *A* posted a comment in reply to a comment or initial post authored by user *B*. The goal is to determine how closely connected communities contributing to cryptocurrency discussions are, *e.g., are users discussing cryptocurrencies back and forth with the same set of users or engage new users?* The clustering coefficients of the resulting user networks measure the extent to which nodes cluster together in communities within each network.

Finally, we consider the *prevalence of posts that do not trigger any additional commentary* for each coin. We call these posts *ineffective posts*. Conversely, we define *effective posts* as posts that prompt at least one subsequent comment. We compare the relative rate of ineffective posts for each cryptocurrency of interest across both datasets. We examine whether there are consistent patterns in effectiveness of posts related to a given coin or patterns being pairs or sets of coins across datasets. To mitigate bias on measurements of growth and speed analyses from these ineffective posts, we remove them from subsequent analyses in all but one case: when we consider the size of discussions.

4.1 Measuring Speed of Discussion Spread

There are several ways to characterize the speed of discussion growth. In this work we choose to focus on the speed of the three main temporal phases of discussions to characterize discussions related to each coin based on:

(1) how quickly they begin,
(2) the speed with which they grow over time,
(3) how quickly they end.

Initial Delays (aka Responsiveness). The first speed-characteristic we consider the delay between when the initial post is submitted and when the first comment in the discussion is posted in response. This relies on a minimal discussion threshold of two contributions (*i.e.,* one post and one comment). We call this the *initial delay* of the discussion which we operationalize as a measure of the discussion's initial growth rate. As such, we only include discussions that grew beyond the initial post. To compare the average behavior in terms of initial growth, we compare the mean and median values for each coin of interest and determine whether there are statistically significant differences with Mann Whitney U (MWU) tests [29]. Finally, we plot the complementary cumulative distribution functions (CCDFs) for each coin. Complementary cumulative distribution functions plot the percentages of cascades with delays at least as long as a given delay. Through this analysis we characterize how quickly a post triggers a discussion thread.

Growth over time. Next, we consider *the time to reach each depth* in the discussion thread. That is, the delay between submission of the initial, root post and the first comment posted within each depth in the discussion tree. For this measure, we plot the mean average delay to reach each depth with associated 95% confidence intervals for each of the coins. As the mean tends to be influenced by extreme outliers, we also examine the median delay to reach each depth and determine whether there are more robust trends or whether trends remain consistent across both mean and median delays by depth. Similarly, we also compare the mean and median *size by depth*. That is, how quickly (as determined by the depth within the discussion) do the discussions grow at each stage. Through this analysis we identify whether discussions grow consistently or sporadically.

Lifetimes. Thirdly, we consider the *lifetime* which we define as the length of time a discussion is active, *i.e.,* the delay between the submission of the root post and the last comment in the discussion, to characterize how quickly discussions end. Similarly to the analysis we perform related to the initial delays, we compare and contrast the mean and median values and plot the CCDFs for each coin across datasets. Again, we test for significant differences in discussion lifetimes between coins with MWU tests as our approach to partition discussion cascades by coin results in independent sets of discussions.

4.2 Measuring Scale of Discussion Spread

Next, we measure the scale of cryptocurrency discussion growth. We focus on summarizing discussions in terms of the discussion volume, audience size, and structural properties e.g., max breath, max depth and structural virality.

Volume. The first measure of discussion scale we consider is the final size of the discussion, *i.e.,* the final volume of nodes within the discussion tree. Therefore, we define the size as the number of comments plus the initial post that prompted the discussion. As such, *ineffective posts* noted previously are discussions of size 1. We present CCDFs for discussion sizes for each coin and contrast behavior across two datasets. We also present and compare the mean, median, and maximum discussion sizes. MWU tests once again allow us to determine significant differences between coins. Intuitively, we would expect discussions posted to larger subreddits to have a higher maximum size and larger range, in general, for discussions sizes. This is because with larger subreddit sizes (and, thus, more contributors), there are more potential users who may be inclined to contribute to each discussion. However, while in the larger subreddits, there are more potential participants that could drive a discussion to a much larger size, there is also a higher influx of content to the larger subreddits where newer content quickly pushes old discussions down and out of view. This flow of new content may motivate users to join a more recently started or active conversation before they even see the older conversations.

Audience size. We can also consider size in terms of the audience or contributors to the discussion rather than the contributions (posts and comments). We define the population as the number of contributors (users) who participated in a discussion thread by submitting the initial post or a subsequent comment within the thread. We can then summarize the overall population sizes and compare the mean and median values across coins and datasets. Once again, because of the independence of the samples for each coin, we can identify whether significant differences in population sizes exist with MWU tests comparing each of the coins to another.

We also compare the maximum values to consider the upper range of populations who discuss each coin. This analysis provides an overview of the static property, population overall. We also consider the populations within the discussions' cascades and at varying phases of the discussion. To do so, we present the mean and median numbers of users who contribute within a given depth and focus on the initial depths within the discussion: *is there a consistent population contributing regularly or a large population whose contributions are concentrated within a single depth?*

Structural properties. Finally, we consider scale-based characteristics in terms of the structure of the discussion cascades. Here, we compare several static properties of discussion structure:

(1) the *structural virality* or Weiner Index (WI) of the cascade, a measurement of how closely nodes are connected within the discussion [16];
(2) the *max-depth*, *i.e.,* the length of the longest path from the root (initial post in the discussion) to a leaf node in the cascade;
(3) the *max-breadth*, *i.e.,* the largest number of comments within a single depth of the discussion tree.

Again, we compare the CCDF plots across coins and analyze first order statistics for each of the structural properties, with significant differences identified with MWU tests. Max-Depth and Max-Breadth provide insight into the primary dimensions of the cascade individually to identify whether discussions are typically wide or long. Structural virality, on the other hand, provides a more easily interpretable measure of the structure as a whole. Weiner index become minimum when all comments are directly added to the root, and maximum when the tree becomes a chain. In other words, *do discussions follow a "viral" structure of multiple branches off of branches within the discussion or a structure that is more reminiscent of a "broadcast" that is wide but not very deep?* To capture a dynamic measure of the structure as the discussion grew rather than the static properties represented with Max-Depth, Max-Breadth, and structural virality, we also plot the mean average and median breadth by depth. Here, we see how the breadth or width of the discussion cascade grows and shrinks over the initial depths. *Are these patterns of growth monotonic (*i.e., *consistently increasing or consistently decreasing), or do they oscillate between growing and shrinking at increasing depths?*

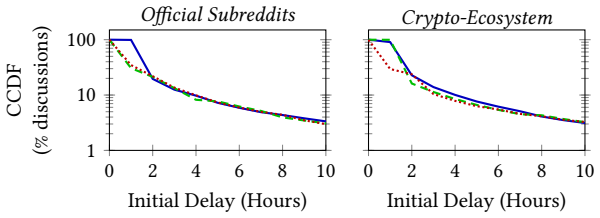
4.3 Content Subjectivity and Discussion Spread

We focus on the subjectivity of the initial posts and their effect on the discussion spread. To get post subjectivity we rely on TextBlob toolkit[7]. The subjectivity score is a float between 0 and 1, where 0 is very objective and 1 is very subjective. First, we compare the subjectivity of successful versus unsuccessful discussions at a very high level dichotomy: *did the initial post trigger subsequent discussion or did the discussion consist solely of the initial post?* We plot the kernel density estimations (KDE) of what we call *effective posts* that initiated discussions of at least one additional comment and *ineffective posts* that failed to initiate a discussion for each of the coins. We can then compare these KDE plots to identify changes in distributions of subjectivity – *do ineffective and effective posts have significantly different distributions of subjectivity?* Then, to gather a more nuanced view of how the initial post in discussions influence discussion growth, we compare correlations measured using normalized mutual information for each of the static discussion properties (virality, max-depth, max-breadth, size, and population) with the subjectivity of the initial (or "root") post in the discussion.

[7] https://textblob.readthedocs.io/en/dev/

Table 1: Average number of cascades a user initiated, *i.e.,* as the author of the initial post, or participated in as the author of an initial post or subsequent comment.

	Official Subreddits		*Crypto-Ecosystem*	
Coin	Initiated	Participated	Initiated	Participated
Bitcoin	3.79 ± 1.20	11.27 ± 1.19	1.90 ± 0.19	6.74 ± 0.54
Ethereum	3.23 ± 0.96	7.56 ± 1.13	1.80 ± 0.09	4.24 ± 0.42
Monero	2.90 ± 0.75	8.50 ± 1.22	1.84 ± 0.17	5.75 ± 0.76



5 RESULTS

Before we measure the speed and scale of information spread in cryptocurrency discussion growth, we first examine several influential characteristics of each dataset and the potential impacts on our analysis. Here, we examine the population of contributors who participated in these discussions, the user-networks for each dataset, and the prevalence of ineffective posts – posts that did not spread.

First, we look at the mean averages and respective 95% confidence intervals for the volumes of discussions related to each coin that users initiate, *i.e.,* by submitting the initial post, or participate in (through posts and/or comments), shown in Table 1. We find that *users are more active within a single subreddit dedicated to* i.e., *the Official Subreddits domain than within discussions focused on the same coin that are started in multiple related subreddits.* Thus, there should be less bias from a single user or group of users on the results of discussion growth in the Crypto-Ecosystem dataset. Intuitively, this composition of contributing users makes sense as users typically browse, subscribe, or otherwise follow specific subreddits based on the topics they cover than individual posts that discuss a topic of interest. Further, a recent study found that users tend to focus their interactions in a small number of subreddits [14].

Next, we consider the networks created with the reply-links to examine how closely connected these communities are. *Are users discussing back and forth with the same set of users or are most interactions with new users?* We find that users interact with, on average, 13 users in the r/Bitcoin subreddit, 8 users in the r/Ethereum and r/Monero subreddits within the Official Subreddits domain. Within the Crypto-Ecosystem domain, users who participate in Bitcoin-related discussions interact with approximately 9 users and we see a similar drop as we do in the Official Subreddits to around 5 and 7 for Ethereum and Monero, respectively. The clustering coefficients are also fairly low for both the Official Subreddits – 0.13 and Crypto-Ecosystem – 0.12 datasets. As shown in Table 1, users, on average, participate in a fairly low number of discussions (between 8 and 11 for Official Subreddits and between 4 and 7 for Crypto-Ecosystem) overall. Users are not densely connected through frequency in discussions or replies to specific users.

Next, we look at the prevalence of posts that do *not* trigger any additional commentary for each coin across datasets. We call these

	Official Subreddits			Crypto-Ecosystem		
coin	mean	median	max	mean	median	max
Bitcoin	4.61	11.17	6.31	5.26	15.25	6.00
Ethereum	7.60	27.60	6.28	8.12	36.37	5.00
Monero	2.85	20.98	4.38	2.56	23.36	3.00

Figure 5: CCDFs for the initial delays of discussions (above) and the mean delay in hours, the median delay in minutes, and the max delay in months (below).

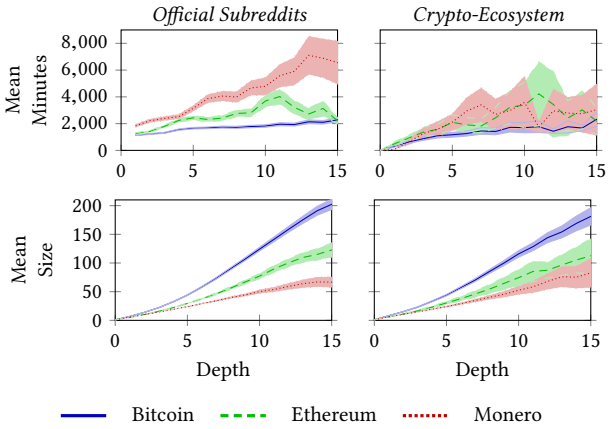


Figure 6: Discussion growth over time measured as the mean average minutes to reach a given depth (above) and the mean size of the discussion when it reaches a given depth (below). 95% confidence intervals are represented with shaded bands.

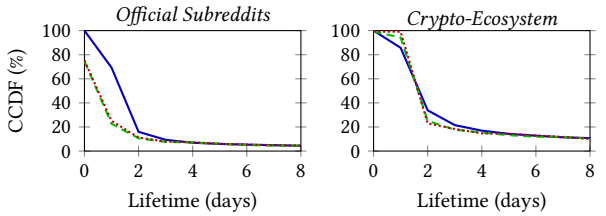
ineffective posts. We remove these posts from subsequent analyses in all but one case: when we consider the size of discussions. We find an interesting trend across both datasets where Bitcoin and Ethereum have similar rates of ineffective posts (31% and 33%, respectively, for the Official Subreddits and 8% and 9% for the Crypto-Ecosystem) and Monero has much lower rates (13% and 2%). The relative presence of ineffective posts related to the more popular Bitcoin and Ethereum coins are twice to five times as high as found in Monero discussions.

5.1 Speed of Discussion Spread

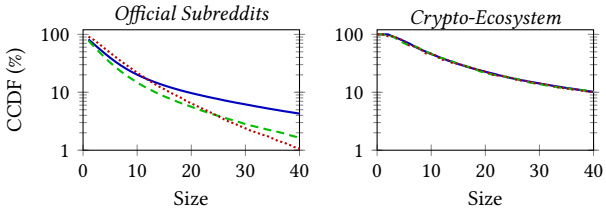
Here we examine the speed of discussion growth across the three coins of interest and two datasets. We aim to answer three main research questions: *how quickly do discussions begin, grow over time and end*. By answering these three questions we provide a well-rounded overview of both dynamic and static properties of the speed of discussion growth. As we noted previously, we removed what we call *ineffective posts*, posts that failed to trigger a discussion, from the following analysis.



5.1.1 Initial Delays. First, we examine how quickly discussions begin in Figure 5. As a result of the size of the r/bitcoin community and the number of new posts that are submitted to the subreddit, the outliers (e.g. extremely long reaction times from posts that either slowly made their way from the "new queue" to the main subreddit page or were possibly found through the search functionality long after the initial submission) may highly influence mean average delays. On the other hand, the median delay is less influenced by outliers. Bitcoin discussions in the official subreddit have the shortest initial delay of approximately 11 minutes. That is, the median delay between a post submitted to r/bitcoin and that post's first comment is around 11 minutes. In comparison it takes at least 20 minutes for a typical post to Monero to attract its first comment and over 27 minutes for Ethereum. We see that the same ordering is found in the Crypto-Ecosystem. Although there are larger initial delays, we still find that Bitcoin discussions begin the fastest, followed by Monero. Ethereum discussions are the slowest to start. But does this trend follow when we consider growth beyond the first comment?

5.1.2 Growth over Time. Now, we expand beyond the initial delay to the average time it takes for discussions to grow, in general. We examine the speed of discussion growth through the average time to reach each depth, the average size of cascade as each depth is reached and the population size within discussions as they grow.

First, we plot the mean minutes elapsed before discussions reached a given depth in Figure 6 (above) with 95% confidence intervals represented with shaded bands. Although the scale decreases greatly when medians are used instead of mean averages, we find that the trends between the three coins remain consistent. Bitcoin discussions grow the fastest followed by Ethereum then Monero. Although we see some overlap in the 95% confidence intervals when we plot the mean minutes to reach each depth for the Crypto-Ecosystem, the ordering remains consistent.



If we consider the size of discussions by the time each depth in the tree is reached, as illustrated in Figure 6 (below), we see that Bitcoin discussions are the largest at each depth and more efficiently increase the number of comments at each depth than Ethereum and Monero across both the datasets. Although the order is flipped (BTC > ETH > XMR), this finding is consistent with the pattern found in average time to reach depth in that Bitcoin shows the fastest growth to largest sizes. This pattern is consistent not only across both datasets but in both median and mean discussion size at each stage of evolution, as determined by the depth in the discussion tree.

5.1.3 Discussion Lifetimes. Finally, we look at how long discussions are active. The median and maximum periods of activity in discussions, *i.e.*, lifetimes, are presented in the Figure 7. We find that Monero discussions have the largest median lifetimes but not the largest maximum lifetimes. Discussions with the largest possible lifetimes are related to the Ethereum cryptocurrency. Interestingly, Bitcoin discussions have the lowest median lifetimes of all three

	Official Subreddits			*Crypto-Ecosystem*		
coin	mean	median	max	mean	median	max
Bitcoin	107.27	6.69	6.43	161.62	13.19	6.00
Ethereum	140.88	11.85	11.12	182.50	17.99	10.00
Monero	182.74	19.18	6.43	178.27	24.11	6.00

Figure 7: CCDFs for the lifetime of discussions (above), the mean, median (in hours), the max lifetimes in months (below).

	Official Subreddits			*Crypto-Ecosystem*		
coin	mean	median	max	mean	median	max
Bitcoin	18.02	6	7,867	20.63	8	2,843
Ethereum	12.74	5	3,816	15.66	7	2,111
Monero	26.98	16	942	17.55	11	692

Figure 8: CCDFs for discussion sizes (above) with the y-axis on a log scale, and the mean, median, and max sizes (below).

coins. In Figure 7, we illustrate the CCDF plots for discussion lifetimes focused on a window of up to eight days which captures 90-95% of all discussions. We see that there is a clear distinction between the complementary cumulative distribution functions for Bitcoin and the other two coins in the Official Subreddits dataset.

Bitcoin has the largest subreddit in terms of content submitted and users who subscribe or contribute, and, as shown in Figure 3 a larger and consistent stream of discussions and comments in both the Official Subreddits and Crypto-Ecosystem datasets. With the consistent flow of new content, users may be more inclined to contribute to a newer discussion than join and continue an older discussion that may no longer be visible because of its score or rank pushing it below a threshold of highly visible ranks. As rank bias influences which content gets voted on and seen by new users, this will also influence which discussions users decide to engage with.

As we noted previously, Monero is the least popular or well-known of the three coins. This is reflected in the smallest subreddit (both in terms of subscribers, contributors, and content) and the smallest sample of posts within the Crypto-Ecosystem. The lower amount and relative frequency, as opposed to the more popular Bitcoin and Ethereum cryptocurrencies, of new content submitted about Monero that would disrupt an existing discussion has probably influenced the larger median lifetimes. With a smaller core community, users who comment in the Monero subreddit may also be more committed to continuing conversations with other contributors, as opposed to users who are tangentially interested in who may visit the larger bitcoin subreddit and make one-off comments on posts they browse. Similarly, the posts related to Monero in the Crypto-Ecosystem dataset may be submitted to smaller subreddits or appeal to a smaller population.

5.2 Scale of Discussion Spread

In this section we present the results on the scale of cryptocurrency discussions, in particular, *how large* discussions grow and the structure of discussions overall and as they develop. In this section, we include the discussions comprised of the *ineffective posts* that we removed from the previous analysis on speed.

Table 2: Discussion audience size measured as median and max volumes of users who participated in each thread.

	Official Subreddits			*Crypto-Ecosystem*		
coin	mean	median	max	mean	median	max
BTC	7.30	3	3,037	11.00	5	685
ETH	5.05	2	707	7.63	4	707
XMR	7.09	5	177	8.63	6	370

5.2.1 Discussion Size. To measure discussion scale we consider the final size of the discussion, *i.e.,* the final volume of nodes within the discussion tree, and plot the CCDFs for discussion sizes for each coin in Figure 8. Across both datasets, the window of sizes up to 40 captures 90 to 99% of all cascades. We see that sizes are more heavily concentrated in lower range of sizes for the Official Subreddits dataset. The CCDF for the r/Bitcoin subreddit rises above the others, indicating more discussions of a larger final size in r/Bitcoin than in r/Ethereum and r/Monero.

When we compare the mean, median, and maximum discussion sizes in the table (below) in Figure 8, we see that the range of r/Bitcoin is much more extended. In contrast, the median size of a Bitcoin cascade is smaller than that of a Monero cascade. Further, Mann Whitney U comparisons of the distributions of each coin's discussion sizes find that, on average, Ethereum discussions are smaller than Bitcoin and Monero discussions ($p < 0.01$), and Bitcoin discussions are smaller than Monero discussions ($p < 0.01$). Although some Bitcoin discussions are much larger than Monero discussions, most are not. Again, this may be due to the size of the community. In the larger subreddits, there are more potential participants that could drive a discussion to a much larger size but there is also a higher influx of content to the larger subreddits where newer content quickly pushes old discussions down and out of view.

5.2.2 Discussion Audience. We can also consider size in terms of the audience or contributors to the discussion rather than the contributions (posts and comments). The overall population sizes are

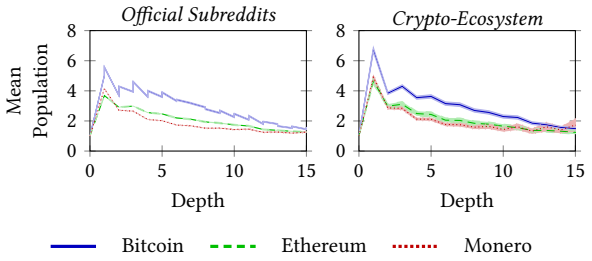


Figure 9: Discussion audience within depth measured as the mean population size at each depth with the 95% confidence interval represented with shaded bands (above), and the median contributor count at each depth (below).

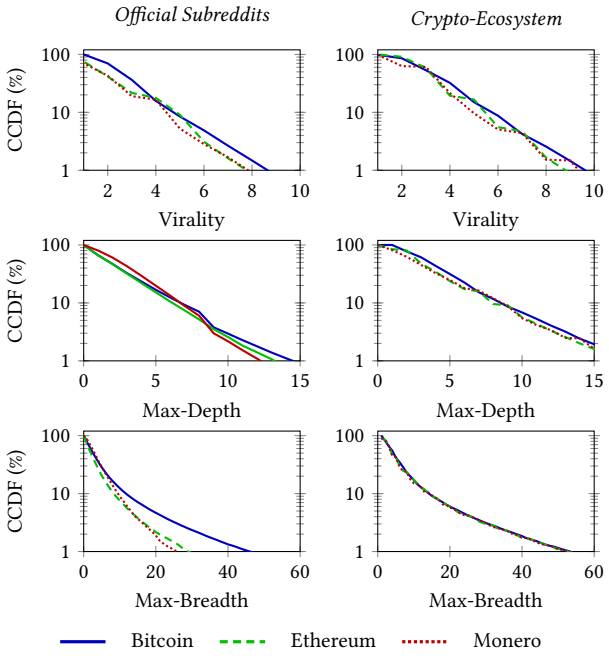

summarized in Table 2. Again, we present the median and maximum overall population (or audience) sizes for discussions related to each coin. The typical discussion is held between 2 and 6 users.

Among the official subreddits, the population sizes are quite similar but in the Crypto-Ecosystem when we consider only those discussions that explicitly reference the coin in the initial post, we see that Bitcoin and Ethereum have a median of five and four users participating, respectively, while Monero has a median of seven users. On the other hand, Monero has the lowest maximum population size while Bitcoin has the largest. The ordering (ETH < BTC < XMR) in terms of typical numbers of participants is also found when we compare the distributions of population sizes with Mann Whitney U tests ($p < 0.01$). As with size of contributions, Monero typically has larger populations in discussions but not the largest possible.

In Figure 9, we observe that the mean population size at each depth differs significantly between coins within the first 15 depths. Across both datasets, Bitcoin discussions have more users participating at each depth. In the Official Subreddits, discussions in r/Ethereum have more users at depths greater than two. That is, discussions in r/Monero on average have slightly more users who respond directly to the initial post than those in r/Ethereum, however this trend is flipped for comments in response to other comments. In the Crypto-Ecosystem dataset, we see an overlap between Ethereum and Monero discussions. When we consider the median population within each depth, we see more similar behavior among the three coins, with spikes above average at several depths for the Bitcoin discussions.

5.2.3 Discussion Structure. Finally, we look at how the scale of the discussion and evolution of the discussion in terms of the structure of the discussion tree. We compare static properties of discussions overall with CCDF plots of virality, max-depth, and max-breadth in Figure 10. As we see in the center row, few discussions have any one given chain grow beyond 5 comments. Less than 1% of discussions have a chain that is at least 15 comments long in the official subreddits, approximately 1-2% has such a chain in the Crypto-Ecosystem dataset.

We highlight the median values for each of the structural properties in Figure 10. We see that discussions tend to have fewer depths with a moderate (at most 3 to 6) number of comments at the most populated depth. Mann Whitney U comparisons of the distributions

	Official Subreddits			*Crypto-Ecosystem*		
	BTC	ETH	XMR	BTC	ETH	XMR
Virality	1.6	1.5	2.3	2.3	2.2	2.8
Max-Depth	1	1	3	3	3	4
Max-Breadth	3	3	6	4	3	4

Figure 10: CCDFs for structural measurements of discussion cascades with a log-scale used for each y-axis (above) and the median values of each property (below).

find that across both datasets, Ethereum has the shortest, narrowest, and least viral of all the coins ($p < 0.01$). That is, these discussions appear more like a broadcast of information than a viral cascade – the initial post is typically followed by a single layer of comments who respond directly to that initial post. Monero discussions have the most "viral" of all discussions, on average, with larger maximum depths and breadths, on average (MWU $p < 0.01$).

When we consider the average comment count (breadth) at each depth however, we see that Bitcoin discussions exhibit larger breadths at each of the initial depths. Figure 11 highlights the mean (above) and median (below) breadths found at each of the initial 15 depths. This illustrates the key differences between coins when we consider discussions as they grow versus the overall discussion after completion. While the maximum breadth of cascades is typically larger in Monero discussions, we see more consistently large breadths in Bitcoin. As we saw in the CCDF plots in Figure 10, Ethereum and Monero discussions exhibit similar patterns of behavior.

5.3 Post Subjectivity and Discussion Spread

In this section, we go beyond the static and dynamic measures of growth and discussion behavior to focus on the *contextual* features of the initial posts that either triggers or fails to trigger a discussion

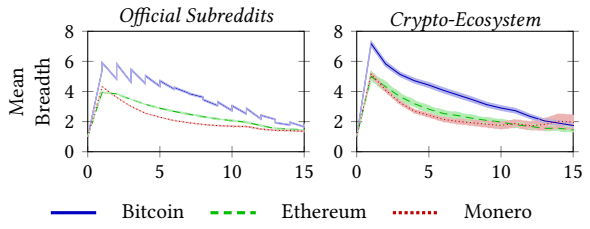

Figure 11: The mean breadth by depth with the 95% confidence interval represented with shaded bands (above), and the median breadth by depth (below).

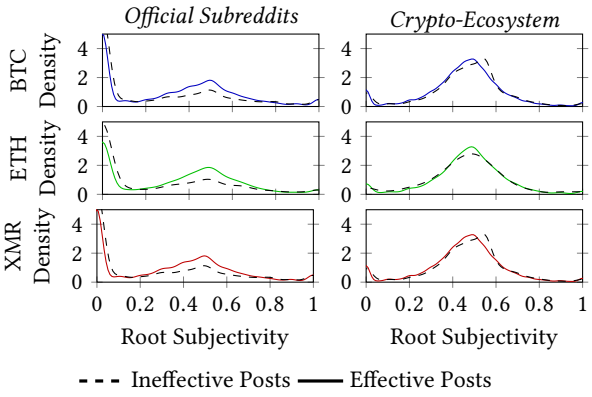

Figure 12: Kernel density estimation plots for *effective posts* that trigger a discussion that includes at least one comment and *ineffective posts* that fail to trigger any subsequent discussion.

to answer the question: *how does the subjectivity of the initial post influence discussion growth?*

First, we compare the subjectivity of effective vs. ineffective discussions at a very high level dichotomy: *did the initial post trigger subsequent discussion or did the discussion consist solely of the initial posts?* We plot the kernel density estimations (KDE) of what we call *effective posts* that initiated discussions of at least one additional comment and *ineffective posts* that failed to initiate a discussion for each of the coins in Figure 12. We see that KDE plots are centered approximately around 0.5, indicating moderate subjectivity, but that ineffective posts tend to skew left, peaking closer to 0.55, for Bitcoin and Monero. Interestingly, ineffective posts about Ethereum appear to remain centered around 0.5 but more evenly across the entire range from 0 to 1, indicating the inclusion of more strongly objective or subjective initial posts.

To gather a more nuanced view of how the initial post in discussions influence the growth, scale, and speed of discussions, we compare normalized mutual information for each of the static discussion properties in Table 3. We also calculated the correlation (Pearson R) of these discussion properties and the subjectivity of the initial post but found significant but low (R<0.05, $p < 0.05$) correlations. Paired with the high normalized mutual information results, we conclude these properties are related but the relationship is not linear. We see that the speed of discussion evolution

Table 3: Normalized Mutual Information between cascade measurements and subjectivity of the root node.

	Official Subreddits			*Crypto-Ecosystem*		
	BTC	ETH	XMR	BTC	ETH	XMR
Virality	0.29	0.36	0.52	0.61	0.68	0.76
Size	0.15	0.21	0.30	0.40	0.49	0.52
# Contributors	0.13	0.18	0.26	0.36	0.43	0.46
Max-Depth	0.10	0.15	0.22	0.29	0.37	0.39
Max-Breadth	0.12	0.17	0.24	0.32	0.40	0.42
Lifetime	0.56	0.68	0.76	0.88	0.92	0.91
Initial Delay	0.37	0.57	0.66	0.75	0.89	0.88

(lifetime and the initial delays) has the greatest mutual information with initial post subjectivity values.

Next, we examined the bivariate kernel density estimations for each of the static discussion cascade measurements and the subjectivity of the initial post (*i.e.,* the "root" of the discussion). We find that the plots within the *Crypto-Ecosystem* dataset illustrate very similar results to the overall distributions of subjectivities shown in Figure 12 at right. Variations in the plots appear to be largely indicative or representative of the differences in the static measurements, highlighted in the previous analyses.

6 SUMMARY

We presented measurement-driven analysis of cryptocurrency discussion spread for three coins of interest on Reddit, and contracted discussion tree patterns in the official coin subreddit and a broader Crypto-Ecosystem on Reddit. Our analysis and novel findings will not only bring the awareness to online discussion spread relevant to cryptocurrencies but will also inform models for forecasting cryptocurrency price that rely on conversations in social media.

We highlight our key findings on *the speed of discussion spread*:

- *Initial Delay* Bitcoin discussions in the official subreddit have the shortest initial delay of approximately 11 minutes. It takes at least 20 minutes for a post to Monero to attract its first comment and over 27 minutes for Ethereum. In the Crypto-Ecosystem delays are larger but coins follow the same trends.
- *Growth Over time* Bitcoin discussions grow the fastest followed by Ethereum then Monero. Bitcoin discussions are the largest at each depth and more efficiently increase the number of comments at each depth than Ethereum and Monero in the official subreddits and Crypto-Ecosystem. Bitcoin shows the fastest growth to largest sizes.
- *Lifetime* Monero discussions have the largest median lifetimes but not the largest maximum lifetimes. Discussions with the largest possible lifetimes are related to the Ethereum cryptocurrency. Interestingly, Bitcoin discussions have the lowest median lifetimes of all three coins.

We highlight our key findings on *the scale of discussion spread*:

- *Volume* On average, Ethereum discussions are smaller than Bitcoin and Monero discussions and Bitcoin discussions are smaller than Monero discussions.
- *Audience Size* The typical discussion is held between 2 and 6 users. In the Crypto-Ecosystem, Bitcoin and Ethereum have

a median of five and four users participating, respectively, while Monero has a median of seven users. ETH < BTC < XMR in terms of typical numbers of participants.

- *Structural properties* Ethereum has the shortest, narrowest, and least viral of all the coins. Monero discussions have the most "viral" of all discussions, on average, with larger maximum depths and breadths. Bitcoin discussions exhibit larger breadths at each of the initial depths.

Future work will extend our preliminary exploration results and further investigate the effect of the original post content on how cryptocurrency discussions spread. More specifically, we will look into content polarity e.g., positive, negative and neutral, novelty, uncertainty and readability. In addition, we will measure user reactions e.g., answer, elaboration, acknowledgement etc. [15] in the discussion cascades influence how discussions spread. Finally, measuring cryptocurrency-related discussion spread before and after the external events of interest e.g., coin price rise, market crash; across a variety of coin types (e.g., popular, stable, scam, etc.); and contrasting signals across multiple social media platforms e.g., Twitter vs. Reddit is of interest.

Goal-setting And Achievement In Activity Tracking Apps: A Case Study Of MyFitnessPal

ABSTRACT

Activity tracking apps often make use of goals as one of their core motivational tools. There are two critical components to this tool: *setting* a goal, and subsequently *achieving* that goal. Despite its crucial role in how a number of prominent self-tracking apps function, there has been relatively little investigation of the goal-setting and achievement aspects of self-tracking apps.

Here we explore this issue, investigating a particular goal setting and achievement process that is extensive, recorded, and crucial for both the app and its users' success: weight loss goals in MyFitnessPal. We present a large-scale study of 1.4 million users and weight loss goals, allowing for an unprecedented detailed view of how people set and achieve their goals. We find that, even for difficult long-term goals, behavior within the first 7 days predicts those who ultimately achieve their goals, that is, those who lose at least as much weight as they set out to, and those who do not. For instance, high amounts of early weight loss, which some researchers have classified as unsustainable, leads to higher goal achievement rates. We also show that early food intake, self-monitoring motivation, and attitude towards the goal are important factors. We then show that we can use our findings to predict goal achievement with an accuracy of 79% ROC AUC just 7 days after a goal is set. Finally, we discuss how our findings could inform steps to improve goal achievement in self-tracking apps.

1 INTRODUCTION

The purpose of an activity tracking app is to help users better understand their behavior. Health-focused apps and fitness devices are the most prevalent, often tracking activities like exercise, eating, and heart rate. Beyond physical health, other types of behaviors are becoming increasingly popular to track as well; for instance, iPhones now come pre-installed with an app that tracks screen time spent in other apps.

In many cases, users wish not only to observe their behavior, but also to improve it [20, 43]. Activity tracking apps often aim to help their users do this, and the guidance they provide can take many forms, ranging from general advice and tips from experts, peer pressure from social networking features, reminders or notifications that ask the user to take a specific timely action, and enforcement of explicitly articulated goals [44]. We think of all these mechanisms as methods to promote behavioral change [4]. They play an important role in people's well-being, akin to the many methods for behavior change in the offline world that one is familiar with, which might include requests or demands from loved ones, medical professionals, bosses, or in the most extreme cases, governmental intervention via fines and criminal punishment.

A nearly universal feature in activity tracking apps, goals are one of the most popular and effective methods for behavioral change [31, 45]. They take many forms. For instance, Apple Watch has three "rings" for the user to fill in, each representing a different daily behavioral goal: one for standing 12 times, one for total calories burned (set by the user), and one for 30 minutes of exercise. Other apps have focused on moderating digital behaviors by setting goals for the amount of time spent on social networking sites [2]. Perhaps the most well-known goal is walking 10,000 steps per day assigned by many fitness-focused activity trackers [7].

Goals in activity tracking apps involve both the setting of a goal (the selection of a desired outcome) and also the achievement of that goal (the process of working towards the selected outcome). Setting a good goal is critically important for users' success: too hard, and the user will become frustrated and give up. Too easy, and they won't achieve as much health benefit as they could have [46]. There has been interesting recent work on goals in activity tracking apps [5, 13, 25, 29, 36, 40, 48], but it remains a topic where there is still much to be understood – particularly on the issue of setting a good goal, since it can be difficult to find records of the process by which goals are both set and subsequently achieved, along with the behaviors that led to those goals being achieved. This has led to the problem that, despite the importance of goal-setting and achievement in activity tracking apps, users often receive limited guidance on selecting a goal that they will actually meet. While most activity trackers use general guidelines from relevant domain expertise combined with demographic information [10] to help users make a choice, after the initial goal is set they often provide limited on-going advice as to whether that goal choice is turning out to have been a good one. Some work has gone further and used current trajectory towards a goal to intervene. For instance, they can notify a user if they are not on track to meet their goal by a certain time frame if they keep that trajectory, or are consistently not meeting daily goals [1, 12, 22, 34, 38]. However, these methods do not consider a holistic view of the many important behaviors that lead to a goal being met, and make simplistic assumptions about linear progressions.

Present Work: Weight Loss Goals in MyFitnessPal. In this paper we consider the goal-setting aspects of activity tracking apps by focusing on a setting where detailed information on both how goals are selected and many related behaviors while attempting to achieve those goals can be studied. Our setting is the process of selecting and working towards weight loss goals in MyFitnessPal. This process has a clearly defined structure: first, upon creating a MyFitnessPal account, all users select weight loss goals, and do so without any guidance from the app. Users optionally provide a free-text reason for their selection of that goal. Users then may then use the app to log their food intake and weight to help them track their progress towards that goal. Meeting their weight loss goal is important for their health: achieving a self-determined weight goal has been linked to long-term weight loss, while the failure to reach a self-determined weight may discourage someone's belief in their ability to control their weight, resulting in abandonment of weight loss behaviors and weight re-gain [14, 27].

MyFitnessPal weight loss goals thus have the key ingredients we need: they take place in a goal-setting and achievement process carried out by users of a activity tracking app who are working towards meeting that goal, users use the app to help guide their lower-level behaviors that will help them to meet that goal, and given the nature of activity tracking, all of this is logged, making the analysis possible. It also serves as an instance of a broader type of goal-setting, familiar from the off-line world as well as the on-line world, in which people aim to lose weight by setting a weight loss goal.

Both the process of goal-setting and the process of losing weight has been studied extensively in medical literature [14]. By contrast, because of our interest in the issue of goal-setting and achievement in activity tracking apps, we study the process from the perspective of early detection of goals that will never be met: we ask which goals users set, how users behave shortly after they set them, and how those behaviors lead to those goals being achieved. Because we are interested in exploring how activity tracking apps may be able to help users select better goals, we focus specifically on behavior that takes place during the first 7 days after a goal is set, and examine whether we might be able to detect early-on that a long-term weight loss goal will never be met. Such early-detection would enable an intervention warning a user that they are working towards a goal they are unlikely to meet, which means we may be able to encourage them to re-think a more realistic goal and prevent them from spending too much time working towards and becoming invested in that goal, only to ultimately become discouraged and re-gain weight because they did not meet it. This could potentially be considered a "just-in-time intervention" [33].

Present work: Main Results. We analyze 2.8 million weight loss goals with 44.6 million weights logged over a period of three years. We begin by validating our dataset through a comparison of the goals the people set in MyFitnessPal to prior studies from before the age of activity trackers, finding that women set more ambitious goals than men and younger adults set more ambitious goals than older adults (Section 4). We also use the unprecedented size of our dataset to show that some findings in prior work are likely due to selection effects. We then analyze goal completion rates and duration, finding that men and older adults are more likely to meet their goals (even when accounting for goal difficulty), but that overall completion rates are low (Section 5).

We then turn to the problem of early detection of goals that will never be met (Section 6). We investigate user's behavior over the first seven days after they set their goal. We find that, contrary to what some prior clinical studies might suggest, there's no such thing as "too much" early weight loss when it comes to meeting your goal (Section 6.1), and that people who log their weight more frequently within the first week are more likely to meet their goals (Section 6.2). We show that more calories reported per day during the first 7 days leads to a lower likelihood of meeting goals, but only for users who are committed loggers; surprisingly, for many users, logging more calories actually indicates a higher propensity to meet a weight loss goal (Section 6.3). We then turn to the motivations behind the goals that people set, introducing a novel application of topic modeling algorithms to identify four primary motivators and show how achievement rates vary with these motivators (Section 6.4).

Finally, we show that whether a user will achieve their target weight can be predicted just based on the initial behavior during the first few days after the target is set. We build a machine learning model to predict target achievement with promising accuracy. We conclude with a discussion of how these results can be translated into actionable suggestions for activity tracking apps as well as traditional offline weight loss programs.

2 RELATED WORK

Goal-setting Theory and Weight Loss. There is a vast body of work discussing the mechanics and psychological aspects of goals, as well as how goals can be used for health-related behaviors. Locke and Latham's seminal work summarizes empirical research on goal-setting theory [27]. Other researchers have focused on how those findings apply specifically to health goals [19, 46].

As with goal-setting theory, there is also a vast body of work discussing the mechanics of weight loss and weight loss goals. As weight loss goals tend to focus on longer term weight loss (as discussed later, we find most people want to lose significant percent of their body weight), literature relating to longer-term weight loss and maintenance, such as Elfhag and Rossner conceptual review of the subject, is most relevant to our work [14]. Other work has focused on characterizing weight loss goals, both in terms of what goals people set and which goals are associated with the best outcomes [16, 24, 26, 27, 49].

Our work first verifies that findings from these smaller-scale offline studies generally apply to our activity tracking dataset in terms of which goals people choose to set and their likelihood of meeting them, while also using the unprecedented scale of our dataset to present new insights. We then extend existing work by specifically investigating early behaviors that predict whether or not a user will meet their weight loss goal in an activity tracking app.

Implementing Goals in Activity Trackers. Activity trackers provide users with an environment to both set goals and track their progress towards their goals. In the best case, they might also be described as systems to help people implement their goals [18]. Some work has looked at different higher-level strategies for

implementing goals in self-trackers, typically through qualitative small-scale studies [8, 11, 32]. Other work has investigated the role that goals play in changing behavior in self-trackers [9, 15, 15, 35]. Rather than exploring the best way to implement goals in activity trackers, our work is a case study of one of the world's most popular implementations: MyFitnessPal.

Adaptive Goals. While goals in self-trackers frequently take into account one's current size and weight, personalized or adaptive goals that take behavior in to account are used sparsely in practice [37]. Some researchers have sought to assign adaptive fitness goals based on a particular user's historical data, in order to improve a goal that is too difficult or too easy. These typically employ simple algorithms that raise goals that the user is easily achieving, and lower goals that the user is struggling to achieve [1, 12, 22, 34, 38]. MyBehavior, in a study of 17 users, suggested exercise or actions to take, but not goals [42]. Hermanny *et al.* explored using heart rate variability to set goals [21]. These adaptive goals can be considered part of a new class of "just-in-time interventions" [33].

Critically, existing work has focused on measuring progress directly related to the goal (e.g. steps for step count goals, calories for calorie goals). Our work builds on a large dataset covering many behaviors related to achieving the goal and findings from work in goal-setting theory to understand whether a goal will be met by taking a holistic view of a user's behavior. We are aware of one other paper which aimed to predict whether a weight loss goal will be met; however their model relied upon users having already been working towards their goal for at least two months and to have logged a large number of weights, meaning it was only applicable to less than 1% of the total number of users in their dataset [47].

3 DATASET DESCRIPTION

This section describes the mechanics of the activity tracking app MyFitnessPal, the dataset used in this paper.

The Mechanics of MyFitnessPal. MyFitnessPal enables its users to track many health-related behaviors. Users can log their food intake, their exercise, and their weight. Users can also set health and behavioral goals. There are three main goals in the app: total weight loss, weekly weight loss, and calories per day. In this paper, we focus on the total weight loss goal: the weight that the user would like to achieve. All users enter a total weight loss goal upon creating a MyFitnessPal account. The app does not provide any guidance when a user is selecting their total weight loss goal. Users also decide upon a weekly weight loss goal between 0 and 2 lbs per week, in increments of half a pound. The default value for this field is 1 lb per week. Using this weekly weight loss goal and demographic information entered by the user (such as current weight and height), the app then automatically assigns the user a calories per day limit. Each food that a user logs is counted against this limit, while exercise is counted as burning off some of those calories.

To log a food item, users type the name of what they ate into the app's search bar, which will then return a list of matches from which the user can choose. Many of these items are branded and will contain full nutritional content supplied by their manufacturer (e.g. a McDonald's Big Mac or Trader Joes Granola). Other generic items, such as eggs or chicken breasts, will also contain nutritional content. If the user does not find a suitable match in the app's database, they can optionally log their item manually and choose which, if any, nutrient content to provide. There are two methods for logging a weight. First, a user can manually enter their current weight into the app whenever they would like. Second, users can connect MyFitnessPal an many internet-connected "smart" scale, which automatically transfer weights they record to the app.

Progress towards the calories per day limit is prominently displayed on the main page of the app. Users can easily view their weight loss progress by clicking on a large icon in the bar at the bottom of the screen.

Table 1: Descriptive statistics from our dataset of MyFitnessPal users.

Characteristics	Value
# of users studied	1,413,431
Observation period	August 2014 - April 2017
Weights logged	44,568,749
Weight goals set	2,803,073
Food items logged	8,785,560,832
Free-text goal justifications	56,014
Mean age	38.69
% users female	71.9
% users underweight	0.34
% users normal weight	29.39
% users overweight	36.28
% users obese	33.99

The Dataset. We use a dataset of 1.4 million MyFitnessPal users over three years, from August 2014 through April 2017. Users set 2.8 million goals, log 44.6 million weights, and eat 8.8 billion food items. Table 1 provides descriptive statistics for our dataset.

In this paper, we focus on weight loss goals and ask the question of which users will ultimately achieve their goal. A user's goal is considered achieved if, at some point in the future after setting the goal, the user logs a weight that is at least as low as that goal. As we are interested in users who showed at least some amount of interest in using the app to track their weight loss progress, we filter to users with at least 7 days between the first and last logged weight of their goal. To remove any minors, extreme outliers, or users who entered likely fake information, we also filter out users who entered a weight over 1000 pounds, an age less than 18 or over 80, and who's weight change goal was more than a 100% difference from of their current weight. This removed 3,681 users users.

4 WHAT WEIGHT GOALS DO PEOPLE CHOOSE?

Performance towards a weight loss goal is, of course, significantly dependant upon the goal's difficulty. This section focuses on goal selection. We aim to validate our dataset by comparing the weight loss goals that users set in MyFitnessPal to the weight loss goals that people set before the age of self-trackers. In particular, we study which goals users choose for themselves; stratifying by demographic information. As mentioned earlier, MyFitnessPal provides no guidance when users are selecting weight targets, which enables

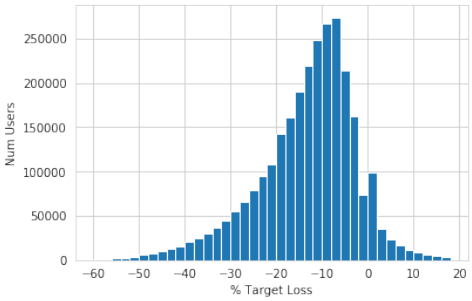

Figure 1: Histogram of weight loss goals as a percent of initial weight. We see a somewhat skewed distribution (skewdness of -0.46), with a peak around 10% weight loss.

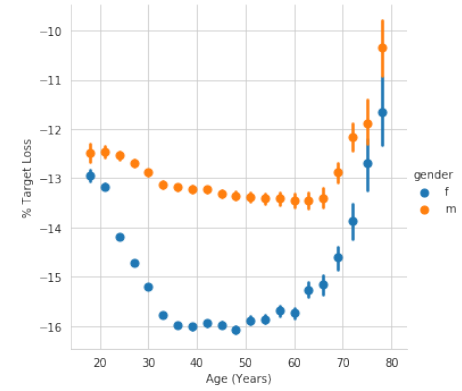
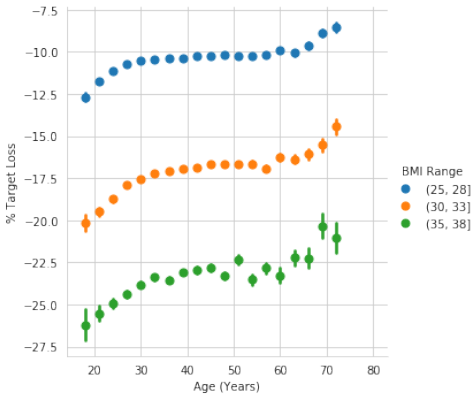
an unbiased analysis. While we do note that there is likely a selection bias in terms of who chooses to use MyFitnessPal, towards people who are interested in loosing weight, this bias towards users interested in self-improvement is likely present in many activity tracking apps.

4.1 Aiming Low: Initial Target Selection



We begin by plotting a histogram of weight loss goals, in terms of percent of current weight, in Figure 1. We find a somewhat skewed (skewedness = -0.46) distribution with a peak around 10% weight loss. We also see that a non-trivial portion of users are actually aiming to gain weight. We remove these users for our later analysis, as this is outside the scope of this paper.

4.2 Declining Ambition: User Age



In this section, we ask how ambition changes with age. To answer this question, we begin by plotting the amount of weight users aim to lose (as a percent of current weight) by age. We find a U-shaped curve, shown in Figure 2a. For instance, for women between the ages of 18 to 35, users aim to lose an increasingly large percent of their weight, moving from 13.2% to 15.7% loss (Mann-Whitney U $p < 0.001$). The number then stays relatively constant around 15.7% up until the age of 60. However, after age 60, users aim to lose an increasingly smaller amount of weight, with users at age 75 returning approximately to the same goal as those at age 18 (Mann-Whitney U $p < 0.001$).

To validate our results, we can compare them to a 1989 large-scale telephone-based survey of weight loss goals [49]. To our knowledge, this is the most recent such survey, though notably, it occurred long before the existence of activity tracking apps. The survey reports results from 21,109 American households, asking if they were currently aiming to lose weight. If the survey participant said yes, then the study included that goal in their results. This means that both this survey and our behavioral tracking dataset focus on users aiming to lose weight, thus removing the potential for selection bias on that co-variate. The survey reports results separately for men and women.

Similarly to our results, the survey found a U-shaped curve, but with larger magnitudes. For women between ages 18-29, the survey reports a mean of 17.3 percent loss, compared to our 14.3. Between

(a)

(b)

Figure 2: Weight loss goal as percent of current weight, by age. (A): Without stratification by BMI. We find a U-shaped curve in agreement with existing literature. The U is significantly deeper for women than for men. (B): With this stratification (results shown only for women), we now see that younger adults set the most ambitious goals, but get less ambitious up until the age of 30, from which point goals stay relatively consistent. Then, around 60, older adults set increasingly less ambitious goals. Error bars in all plots correspond to bootstrapped 95% confidence intervals (here, they are mostly too small to be visible).

ages 40-49, the survey reports a mean of 18.1, compared to our 16.0. And between ages 70-79, the survey reports a mean of 14.9, compared to our 13.4. The similar shape of their curve to ours helped to validate our results, while at the same time showing that at all ages, users in MyFitnessPal are slightly less ambitious than those in the 1989 survey.

Having validated our dataset, we now ask, how can we explain this U-shaped curve present in both our work and existing work? The U-shape seems to go against what we might expect, given the fact that younger people tend to be less conservative and take more risks than older people [16]. We note that neither we nor the work we validate our results against have thus far accounted for the fact that age is strongly correlated with whether someone is at a healthy

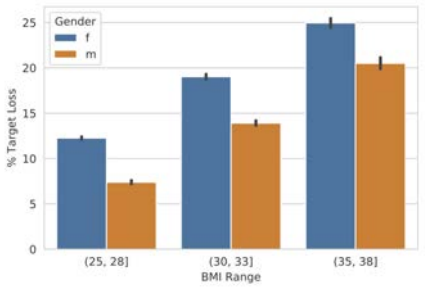


Figure 3: Women set more ambitious goals than men; when controlling for BMI, women aim to lose approximately 5% more weight.

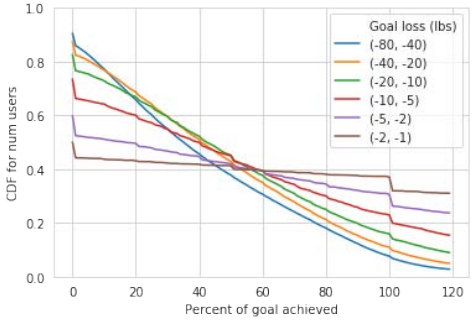

Figure 4: CDF of goal achievement, stratified by goal difficulty. X-axis indicates percent of goal achieved while y-axis indicates the portion of users who have achieved at least that amount of their goal. We find that across the board, goals are unlikely to be achieved. Only 30% of the easiest goals are ever reached, while less than 5% of the most difficult goals are ever reached.

weight, with younger adults more likely to be at a healthy weight. We hypothesize that the U-shaped curve may be due to the fact that younger users will be healthier on average than older users, and thus simply need to lose less to reach a healthy weight. To test this, we take advantage of the unprecedented size of our dataset and stratify our earlier plot by BMI (Body Mass Index, a number based on height and weight used to determine if someone is classified as having a normal weight, overweight, or obese). We do so in Figure 2b. We now find that, when accounting for how healthy a user's existing weight is, we see that younger users actually set significantly more ambitious weight loss goals than older users.

4.3 Gender Matters: User Gender

We now turn to gender differences. Given our findings from the previous section, In Figure 3 we again stratify by BMI to control for selection bias, as men tend to have a higher BMI than women. We find that women set more ambitious goals than men and that, regardless of BMI, this effect size is about a difference of 5% (Mann-Whitney U $p =< 0.0001$). This is somewhat in agreement with the 1989 survey mentioned above, but with a larger magnitude (they saw a difference of at most 4.1%).

5 DO PEOPLE REACH THEIR GOALS?

Next, we explore goal achievement rates along with the amount of time taken for goal achievement. We find that overall, 18.2% of weight loss goals are met. This is remarkably close to an earlier finding from 2005 that approximately 20% of people overweight individuals are successful at long-term weight loss [50].

5.1 How many people reach their goals?

Clearly, goal difficulty should impact goal achievement. We hypothesize that more difficult goals are less likely to be achieved. Therefore, we start by breaking down target achievement as a function of goal size. Figure 4 shows a cumulative distribution function (CDF) with a different line for target size buckets. The x-axis indicates percentage of target reached ($x = 100$ indicates that a target has been achieved). We find that target achievement is relatively low, and decreases as targets become more ambitious. People with the easiest goals (between 1 and 2 percent of their initial weight) are most likely to achieve their targets, with nearly 30% of these users reaching at least 100% of their initial weight loss goal. Of users with the most difficult goals (between 40 and 60 percent of their initial weight), only 10% are likely to achieve their target.

The x-axis of the above plot begins at zero, indicating that a user's weight has not changed. We note that the plotted y-value of our CDF does not begin at 1.0 for any of the goals; this is because a large portion of users end up gaining weight, putting their goal achievement progress to the left of our x-axis starting point. Interestingly, despite that fact that users who set easier goals are more likely to achieve them, we also find that users who set easier goals are more likely to go in the opposite direction and gain weight. For instance we see that only 40% of users with the easiest goals lose weight, while 90% of users with the hardest goals end up losing weight. This finding highlights the importance of not setting a goal that is "too easy" for a user.

We also notice a blip at 100 percent achievement, indicating that while many users either change their target or stop using the app once they've reached their goal, others continue to lose weight even after achieving their target.

We also find that men are more likely to meet their weight loss goals, even when accounting for the fact that men set easier goals: for instance, men who aim to lose 5-10% of their weight succeed 28% of the time, while women who aim to lose 5-10% of their weight succeed 20% of the time.

5.2 How long does it take to reach your target?

Having established how many people reach their targets, we now ask how long it takes them to do so. In Figure 5, we show a CCDF of time taken to achieve a goal as function of goal difficulty. We find that more difficult goals take longer to achieve. For the easiest goals, half of all users who meet their goal do so within 100 days. For the most difficult goals, this number is closer to 300 days.

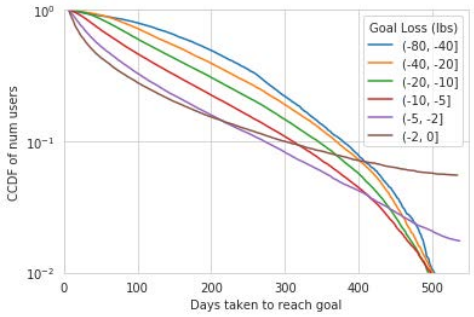

Figure 5: CCDF of days taken to achieve a goal, stratified by goal difficulty. More difficult goals take more time to achieve.

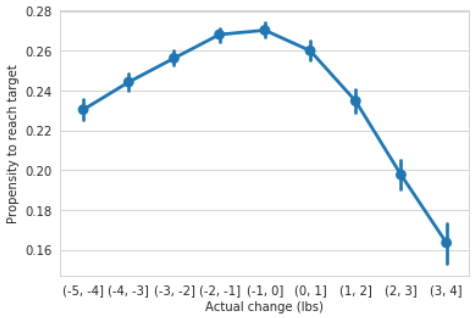
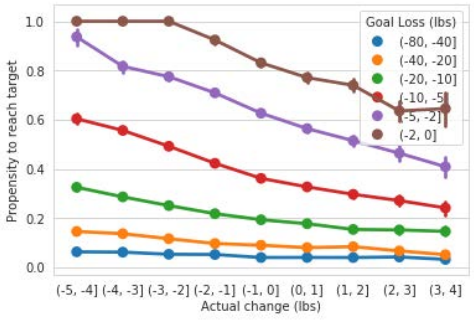
6 EARLY WARNING SIGNS

Having seen that few users ever meet their goals, we now ask what are the early behavioral factors that indicate a user will or won't meet their goal? We ground our analysis in the existing body of literature on short and long term weight loss. We work to both answer open questions in the literature and to determine how existing findings apply specifically to early detection in weight loss target achievement.



We focus specifically on the first seven days after the first weight of a goal has been logged. We find that even for difficult, long-term goals such as losing twenty pounds, behavioral differences observed during just the first seven days are indicative of large changes – up to double – the propensity to reach that goal.

6.1 Initial Weight Loss Patterns



Too much too fast?. Initial weight loss has been identified as a predictor for later weight loss, and also for weight loss maintenance [14]. Some studies have found that the greater the initial weight loss, the better the subsequent outcome [3]. However, other work has found that greater initial weight loss actually predicts future weight gain, explained by the fact that overly quick weight loss is considered unsustainable and clinically unhealthy [30].

Goal-setting theory suggests that early progress towards a goal could serve to provide future motivation, while slow initial progress may cause frustration and ultimately lead to an abandonment of the goal [28]. This taken together with the clinical findings discussed above, make it uncertain as to whether there may be such a thing as "too much" initial progress towards a weight loss goal.

To answer this question, first plot propensity to meet weight loss goal by weight change over the first seven days. Figure 6a shows that we find a U-shaped curve suggested by prior weight loss maintenance literature. On the right, we see that as people gain more weight during the first week, that are less likely to meet their weight loss goals. On the left we see that, as people lose more weight, they are also less likely to meet their goals. We note that the downward trend seems to start around -2 lbs per week, which is exactly what prior literature would suggested: 2 lbs per week of weight loss is often considered the maximum healthy amount [23].

(a)

(b)

Figure 6: Propensity to meet weight loss goal by weight loss over the first week. (A): Without stratification by goal difficulty, we find a U-shaped curve in agreement with existing literature suggesting that "too much" early weight loss is unsustainable and leads to worse longer-term outcomes. (B): With stratification by goal difficulty, we now see that people who lose more weight in the first week are far more likely to reach their goals. Contrary to what medical literature might suggest, there is no such thing as "too much" unsustainable early weight loss which ultimately leads to worse results.

However, we hypothesize that there may be a different reason for this U-shape curve than the idea that "too much" early weight loss is unsustainable and leads to weight gains, as suggested by prior literature. We hypothesize that this U-shaped curve may be due to the fact that people who lose less weight during the first week have also set easier goals on average. To test this, we can stratify our earlier chart by goal difficulty. We show this result in Figure 6b. We now find that there is in fact no amount of initial weight loss which reduces a user's propensity to meet their weight loss goal. Further, see a large difference in propensity to meet goals based on initial weight loss: for instance, a user who loses between 4-5 pounds over the first two weeks of their 20-40 pound loss goal is twice as likely meet that goal as one who loses between 1 and 2 pounds (Mann-Whitney U $p < 0.001$). This finding suggests that follow-up studies to highly cited clinical weight loss papers may be warranted, to determine whether the idea of "too much early weight loss" is due to confounding by motivational reasons rather than physical limitations around unsustainable weight loss

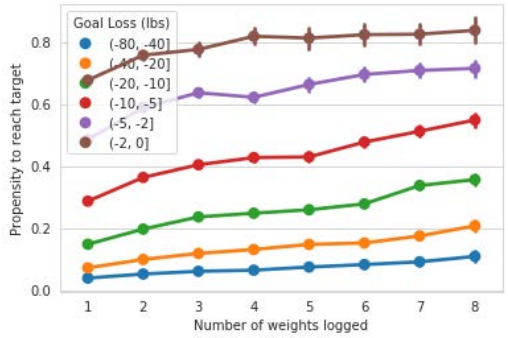


Figure 7: Propensity to achieve goal by number of days logged a weight over the first seven days, stratified by goal difficulty. We see that across all difficulty of goals, people who log weights more frequently over the first week are more likely to achieve their goal.

6.2 Self-monitoring

Self-monitoring means observing oneself and one's behaviour. Indeed, this is the core purpose of an activity tracker. Most activity tracking apps today rely on their users manually choosing log many important behaviors. While step count is typically logged automatically, workouts, food intake, and weights often involve some amount of manual input.

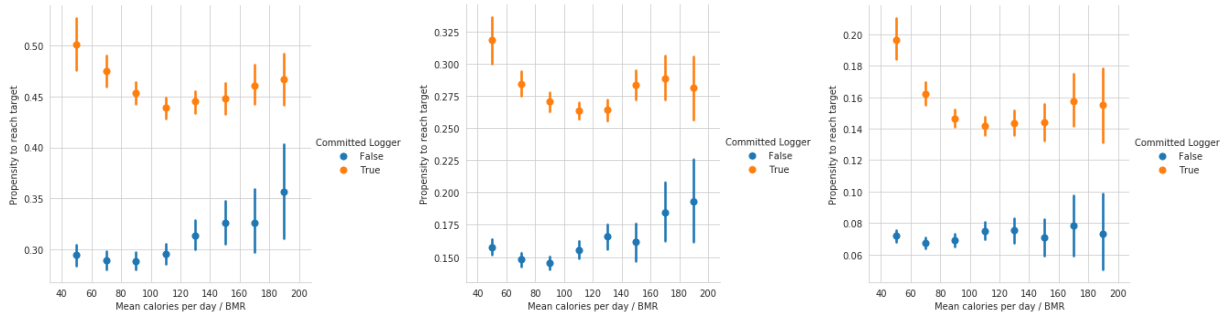
Regular self-monitoring of weight has been linked to long-term weight loss maintenance, which suggests that it may also be important for meeting weight loss goals [6]. In Figure 7, we plot the number of days that a user logged their weight over the first 7 days of a goal. We see that, for all difficulty of weight goals, people who log more regularly over the first seven days are significantly more likely to ultimately meet their goal. For a goal between 40-80 lbs, users who log a weight all 7 days of their first week are more than twice as likely to ultimately meet their goal than those who log only once, moving from 10% to 20% likelihood (Mann-Whitney U $p < 0.001$). Similarly, for a goal between 10 and 20 lbs, we see a change between logging one weight and seven weights from 15% up to 35% (Mann-Whitney U $p < 0.001$).

6.3 Dietary Intake

One of the core features of MyFitnessPal is the ability to log food intake. Obviously, food intake is strongly associated with weight loss. Longer-term weight loss and maintenance has been linked to eating smaller portions and higher quality nutrients [14].

In MyFitnessPal, users log individual food items, where each item has an associated calorie amount (typically populated by MyFitnessPal's food database). We hypothesize that users might fall into two categories: uncommitted loggers, who likely aren't particularly motivated to log their food and don't log everything they eat, and committed loggers, who are motivated to log what they eat. We assign users to groups based on total days logged over the first 7 days: users who logged at least one food item all 7 days are considered a committed logger, and users who did not are considered an uncommitted logger. How likely are these groups to meet their weight loss goals?

Table 2: The four topics discovered from NMF topic model trained on weight loss goal reasons supplied by users when setting their goal. Each topic lists the top ten words associated with it.



1. Kids role model	2. Lifestyle	3. Health	4. Clothes
good	live	shape	fit
example	life	health	clothes
set	long	weight	old
family	longer	family	able
children	enjoy	need	jeans
kids	happy	tired	wear
daughter	family	time	energy
energy	able	lose	cute
role	kids	kids	size
model	time	energy	comfortable

Figure 8 shows propensity to meet a weight loss goal by mean calories per day over the first 7 days, normalized by each user's Basal Metabolic Rate (BMR, the amount of calories an individual consumes per day at rest), for both committed and uncommitted food loggers. To avoid confounding by goal difficulty, each chart contains only a specific range of goal weight losses. We find that, regardless of amount calories logged, committed food loggers are far more likely to meet their weight loss goals. We also see that, as committed loggers log more calories, they are less likely to meet their goals, which is what we would expect given that eating more calories results in worse weight loss. However, this effect only lasts up until around 110% BMR calories logged, after which more calories logged actually seems to correspond with a higher propensity to meet the goal (though we note that confidence intervals all overlap). This is likely explained by the fact that some of these users are not actually eating more, but rather are extreme loggers who log all food that they eat.

For uncommitted loggers, we see a very slight curve for which more eating indicates a lower propensity to meet a goal, followed by a higher propensity. The difference between the top of the curve and the bottom of the curve is extremely small, which is likely because for these uncommitted loggers, more food loggers mostly is indicative of an increasingly higher commitment to logging, rather than more eating. Overall, we find that logging more calories leads to the expected reduction in propensity to meet a weight loss goal, but only for committed food loggers.

6.4 Motivation

When a user sets their target, MyFitnessPal optionally allowed users to fill in a free text form which asked why they were selecting their goal. We call this a "weight loss reason". Attitude has been found to be important in weight loss maintenance [14], which suggests it may also be important in meeting weight loss goals. We hypothesize that the weight loss reason provided by a user may provide a glimpse into their mindset and attitude towards setting and meeting their goal. In this section, we examine these weight loss reasons to determine whether they are indicative of propensity to meet a weight loss goal.

(a) 5-10 lb goal loss. (b) 10-20 lb goal loss. (c) 20-40 lb goal loss.

Figure 8: Committed food loggers during the first 7 days of a goal are much more likely to meet their weight loss goals than less committed loggers. Further, committed loggers who log more calories are less likely to meet their goal, while uncommitted loggers who log more calories are more likely to meet their goal.

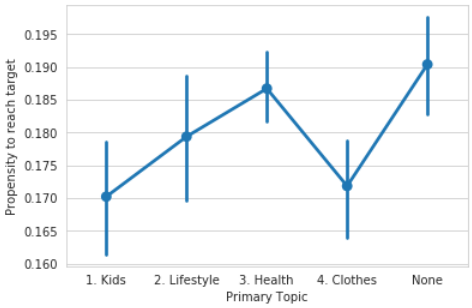


Figure 9: Propensity to achieve goal by motivation. Motivations derived from learning a topic model over free-text goal reasons provided by users and then assigning each goal a primary topic.

After filtering to users who choose to use this field, we end up with 56,014 goals associated with a reason. We first provide a few sample reasons to give a sense of the type of reasons provided by MyFitnessPal users (note that for anonymization, we slightly change the exact text while retaining the meaning). Many are somewhat generic, with users writing that they are setting their goal "To feel better, and have more energy!" and "I would like to get in shape and get back to the weight where I felt comfortable with my body." However, some reasons were quite specific to the user's personal situation, such as "My dad's adopted and doesn't know his family history, but he had a heart attack at age 34 and a RI before age 46. I already have heart issues (which admittedly are well controlled with meds, but still....."

The choice to fill in this field seems likely to be related to propensity to self monitor and commitment to the app which, as discussed earlier, are linked to a higher propensity to achieve one's goal. Surprisingly, we find that users who fill in a weight loss reason are less likely to meet their goals (20.5% vs 17.6%) (Mann-Whitney U $p < 0.001$). However, this difference can likely be explained by the fact that people who supply a weight loss reason aim to lose nearly 50% more weight (33.8 lbs vs 24.6 lbs, Mann-Whitney U $p < 0.001$) and, as we showed earlier, more difficult goals are less likely to be met.

We now ask: what is different about the reasons given by people who meet their goals versus the people who don't? We first find that people who meet their goals use 1.4 fewer words (Mann Whitney U $p < 0.0001$) than those who do meet their goals, at 19.2 words compared to 20.6 words. This is surprising, as one might expect that a longer reason indicates more commitment to the app or more thought-out reasons for losing weight. But how do these reasons differ in terms of the content's subject matter?

Topic Models. Studies have found that people who are motivated to lose weight by a desire for greater self-confidence or superficial considerations such as appearance (e.g. a "healthy narcissism") are more successful at maintaining weight loss than those who are primarily motivated by medical concerns or from pressure by those around them [14]. To determine if we see a similar effect in propensity to meet weight loss goals, we would like to map each weight loss reason to an easily interpretable category. To do this, we propose a novel application of topic modeling algorithms.

Topic models are an unsupervised learning approach to automatically infer interesting patterns in large text corpora [39]. We use this exploratory approach with the goal of understanding what topics are commonly discussed in goal reasons provided by users, with the aim of understanding how they differ in goals which are or are not achieved. Topic modeling has previously been used to extract health-related topics from Twitter [17, 39].

We build our topic model using non-negative matrix factorization (NMF) on extracted term frequency-inverse document frequency (tf-idf) features from our corpus, which helps to select the most useful terms. We use the "English" stopwords list from scikit-learn [41] along with a few words we added manually: want, look, feel, better, healthy, healthier. We use these as stopwords because they were present in far too many articles, to the point that they dominated every topic generated, and in this situation a typical approach to improve topic models is to remove such words. We experiment with selecting a number of topics between k=3 and 20, ultimately selecting k=4 after finding them the most clearly interpretable and differentiated.

Table 2 presents the top 10 terms from each of the four discovered topics, along with our manually assigned topic labels. We assign each goal reason a "primary topic" by selecting the topic with the highest associated score from our NMF model, with a minimum required score of 0.01 (22.4% of goals did not meet this threshold for any of the four topics). We find the topics to be:

(1) **Role model for kids:** users with a reason in this topic discussed how they wished to set a better example for their children. Primary topic for 12.4% of users.
(2) **Lifestyle:** users wanted to live longer, happier lives so that they'd have more time to spend with their family. Primary topic for 12.8% of users.
(3) **Health:** users were concerned about their health and wanted to get in better shape. Primary topic for 36.9% of users.
(4) **Clothes:** reasons in this topic discussed wanting to fit into older clothes that they used to be able to fit in to, or being able purchase and fit into new clothes that they found attractive. Primary topic for 15.4% of users.

Now that we have learned topics for our goal reasons, we can examine which reasons reflect a higher propensity to meet one's goal. To do this. In Figure 9, we plot propensity to meet goals by primary topic. We first note that, unlike in prior sections of this paper, we are unable to stratify by goal difficulty due to the smaller size of this dataset. This means that some results may be explained by the fact that, for instance, people who's primary motivation is fitting in to clothes set slightly easier goals (2 lbs) than those who primary motivation is health. That said, we do find that people primarily motivated by health are more likely to meet their goals than people primarily motivated by clothing, which seemingly goes against what the prior work cited above would suggest.

7 PREDICTING GOAL ACHIEVEMENT

Next, we build on insights from previous sections to predict the likelihood that a user will ever achieve their goal after observing their behavior over the first 7 days.

7.1 Features Used For Learning

To illustrate the predictive power of the different feature sets reported earlier in this paper, we define a series of models, each with a different feature set corresponding to one of the goal-related behaviors. We focus on six types of features:

(1) **Weight loss goal:** In Section 4, we saw propensity to meet a weight loss goal varied significantly with the difficulty of the goal, with easier goals more likely to be met.
(2) **Demographics:** we found that propensity to meet a goal also varied with the user's age and gender, with men and younger adults more likely to meet their goals.
(3) **Initial weight loss:** In Section 5.1, we saw that people who lost more weight over the first 7 days were more likely to meet their goal.
(4) **Self-monitoring:** In Section 5.2, we saw that users who log their weights more frequently over the first 7 days are more likely to meet their goals.
(5) **Calories logged and frequency of logging:** In Section 5.3, we saw that logging more calories indicates a lower likelihood of meeting a goal, but only for committed loggers.
(6) **Motivation:** In Section 5.4, we analyzed free-text motivation provided by users. We use word-level TF-IDF results (for the top 5000 words) as features in this model. This is the same methodology used to train our topic models discussed in Section 5.4.

7.2 Experimental Setup

We aim to predict the likelihood that a user will ever achieve their weight loss goal, after observing their behavior only in the first 7 days. As in Section 6, we filter to users for who there is at least 7 days between the start of their goal and the last weight logged of their goal (though we do not require a minimum number of weight logged during this period). We also remove all users who have already met their goal within the first several days, as it would not be a fair task to predict goal achievement after a user has already achieved their goal. We note that, as shown in Figure 6, most users take far longer than 7 days to meet their goals. We also remove users who didn't last at least 7 days to avoid users who download the app as a curiosity and use it very briefly without ever truly attempting to meet their goal. Further, we filter to users who use the features of the app that we discuss in this paper at least once: specifically, users must log at least one food item, and also must fill in the free-text motivation field when setting their goal. After applying these filters, we arrive at a dataset containing 33,642 goals. (This large reduction from our overall dataset is primarily due to the fact that most users chose not to provide a free-text weight loss reason, as the app provided no motivation for them to do so. Without that restriction, we would have over 900,000 goals in our prediction dataset, and we find that ROC AUC would be only slightly reduced).

We experiment with several classification models, including Linear Regression, Gradient Boosted Trees, Support Vector Machines, and Random Forests. We find that Random Forest models are the most effective for our task, and so we report results from only from those models. Because of the unbalanced dataset (only 18.6% of users achieve their goal) and the trade-off between true and false positive rate associated with prediction, we choose to compare models using the area under the receiver operating characteristic (ROC) curve (AUC) which is equal to the probability that a classifier will rank a randomly chosen positive instance higher than a randomly chosen negative one. Thus, a random baseline will score 50% on ROC AUC. We use a 10-fold cross-validation for estimation. We standardize all features to have zero mean and unit variance.

7.3 Results

Figure 10 shows the prediction accuracy of our models. With a model trained on all available features, we achieve a an accuracy of 79% ROC AUC.

We find the most predictive features to be the initial goal and the user's motivation. Strikingly, motivation is significantly more predictive than eating patterns. We note that our motivation model was trained with a simple TF-IDF analysis of the words a user writes in their short free-text goal justification. Future work should explore more sophisticated models and more deeply analyze how free-text motivation for a goal can predict goal achievement rates. Surprisingly, we see that initial weight loss on its own was not

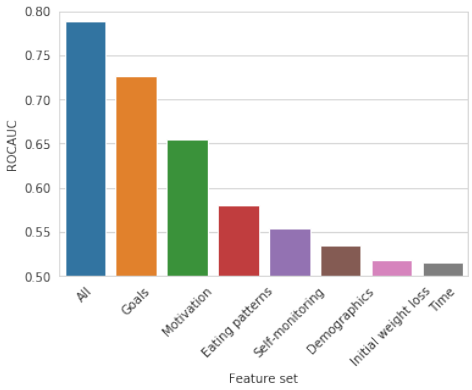

Figure 10: ROC AUC for predicting whether a user will achieve their weight loss goal from observing their behavior over the first seven days after setting it. We report accuracy for each feature set individually and all features together. We reach 79% ROC AUC in a combined model with all features.

a strong predictor of propensity to meet a goal, which is likely explained by the fact that initial loss is somewhat meaningless without knowing the goal that the loss is working towards.

8 DISCUSSION

Goals are a critical component of activity tracking apps. However, long-term goals such as weight loss are rarely met. This paper moves towards addressing this challenge by analyzing user behavior related to both setting and achieving their goals. In particular, we focus on how behavior during the first week after setting a goal predicts whether or not that goal will be achieved. We do so because early detection and notification of goals that are too hard may enable a new class of interventions where users can be encouraged make their goals easier before becoming frustrated and leaving the app. We identify a set of factors which predict goal achievement related to demographics, initial weight loss, self-monitoring, dietary intake, and motivation, summarized in Section 1.

Limitations. There are several important limitations to our work, primarily related to generalizability and causality. First, we note that a weight loss goal is a long-term health goal, which we saw typically takes weeks, months, or even years to achieve. It is an open question as to whether the characteristics of users who achieve short-term goals, such as "walk 10 minutes today", might differ.

We also note that our results are correlational in nature. Ideally, the factors we analyze would represent causal effects to help us understand how to improve weight loss goal achievement. While in our analysis we both build off of prior causal findings and make efforts to reduce potential confounders, the factors that lead to weight loss are enormously complex and causal analysis is often extremely difficult or impossible. However, this is not a necessary requirement for such factors to be useful in machine learning models that predict whether or not a goal is likely to be met. We show that even simple models can predict goal achievement after observing just one week of behavior with reasonably high accuracy.

Implications And Future Work. In addition to uncovering important factors in how people set and achieve their weight loss goals in an activity tracking app, our work also suggests several practical implications. Our work shows that it is possible to predict whether a user will achieve their weight loss goals after observing just their first week of behavior while attempting to meet that goal. This opens the door for activity tracking apps to build a new type of intervention which notifies a user that they seem unlikely to meet their long term goal. Such an intervention might enable users to decide that they should set an easier goal, before they become frustrated and drop out of the app.

Future work should consider several important directions to determine both how to create such an intervention and to determine the effectiveness of such an intervention. First, work should investigate what a activity tracking app do when it recognizes that a goal will never be met, and how users respond to potential interventions. For instance, it is possible than if the user is told too forcefully that they will never meet their goal, perhaps they'll just immediately give up without aiming for an easier goal. On the other hand, if a user is simply assigned an easier goal, it is possible that they will internally still be interested in meeting their first goal, and thus do not truly have an easier one.

9 CONCLUSION

We present a quantitative analysis of the weight loss goals that people set in MyFitnessPal, and the early behaviors that lead to the achievement of those goals. We find that women set more ambitious goals than men, and that younger users set more ambitious goals than older users. We find that most of these goals are never achieved, but that easier goals are far more likely to be achieved than harder ones. We then show that propensity to meet a goal varies significantly by behavior observed during the first week after setting the goal, despite the fact that goals often take months or even years to achieve. We find that, contrary to what findings from medical studies on weight-loss maintenance might suggest, there is no amount of early weight loss which is "too much"; rather more early progress towards a goal predicts a higher propensity to achieve that goal. We also find that people who log more calories are less likely to meet their goal, but only when we account for commitment to logging. We introduce a novel application of topic modeling to show the four primary motivations that users have for selecting their goals. Finally, we show that the results presented in our paper are sufficiently strong to predict, after observing seven days of behavior, whether a user will ultimately meet their goal, with an accuracy of up to 79% ROC AUC. Our findings suggest that activity tracking apps may be able to help their users avoid the pitfalls of failing to meet their goals by asking them them select a more realistic goal after observing their holistic behavior and motivations early-on.

ABSTRACT

With the overwhelming popularity of Knowledge Graphs (KGs), researchers have poured attention to link prediction to complete KGs for a long time. However, they mainly focus on promoting the performance on binary relational data, where facts are usually represented as triples in the form of (*head entity*, *relation*, *tail entity*). In practice, n-ary relational facts are also ubiquitous. When encountering such facts, existing studies usually decompose them into triples by introducing a multitude of auxiliary virtual entities and additional triples. These conversions result in the complexity of carrying out link prediction concerning more than two arities. It has even proven that they may cause loss of structural information. To overcome these problems, in this paper, without decomposition, we represent each n-ary relational fact as a set of its role-value pairs. We further propose a method to conduct Link Prediction on N-ary relational data, thus called NaLP, which explicitly models the relatedness of all the role-value pairs in the same n-ary relational fact. Experimental results validate the effectiveness and merits of the proposed NaLP method.

1 INTRODUCTION

Since Google announced Knowledge Graph (KG) in 2012[1], KG has been increasingly popular in these years. And link prediction on KG has caught much attention for a long time, to complete KG and further promote KG based applications. Usually, a KG is represented as a set of binary relational triples in the form of (*head entity*, *relation*, *tail entity*), where n-ary relational facts are decomposed into multiple triples via introducing virtual entities, such as the Compound Value Type (CVT) entities in Freebase [1]. Actually, n-ary relational facts are not in the minority, as an example, in Freebase, more than $\frac{1}{3}$ of its entities are involved in n-ary relational facts [31]. Based on these public KGs of binary form, researchers have developed numerous methods for link prediction [21, 29], which includes the tasks of head entity prediction, relation prediction and tail entity prediction. The popular tensor/matrix based methods [4, 17, 20, 23, 27, 28] and translation based ones [2, 11–13, 15, 16, 30, 32] have been developed and improved for so long. They view triples in a KG as entries in a tensor/matrix, or relational translations between head entities and tail entities. Relatively newly developed neural network based methods [3, 5, 7, 19, 25, 26] use neural network to learn the information propagation of the entities across the edges (relations) of a KG and integrate existing effective methods, or use neural network to model triples directly. Regardless of these various methods, link prediction is essentially reduced to scoring triples by designing different score functions and casted into a ranking/classification task, with valid triples preceding invalid ones in terms of their scores or having different labels from invalid ones.

However, manipulating n-ary relational facts into triples has some deficiencies. Firstly, it makes link prediction involving more than two arities need to consider many triples. Since existing link prediction methods on triples, like the above methods, usually model triples one by one individually and correspondingly conduct link prediction on only a single triple each time, it is intricate to

[1] https://googleblog.blogspot.com/2012/05/introducing-knowledge-graph-things-not.html

carry out link prediction involving more than one triple. Secondly, there is a loss of structural information in some of the conversions from n-ary relational facts to triples [31], which may lead to inaccurate link prediction. Thirdly, the added virtual entities along with the corresponding triples bring in more parameters to be learned.

With these considerations in mind, in this paper, each n-ary relational fact is represented as a set of its role-value pairs instead of being converted into multiple triples. Hence, no additional entities and data are introduced, and all the structural information is retained. Then, we propose a method to handle link prediction on n-ary relational data. Specifically, in this paper, link prediction on n-ary relational data is to predict the missing value or role of a relational fact.

Recently, there are also a few studies for link prediction on n-ary relational data directly. In m-TransH [31], a relation (binary or n-ary relation) is defined by the mappings from a sequence of roles corresponding to this type of relation, to their values. Each specific mapping is an instance of this relation. Then, a translation based method is proposed to model these instances. However, m-TransH does not take the relatedness of the components in the same n-ary relational fact into consideration. RAE [34] further improves m-TransH by complementally modeling the relatedness of values, i.e., the likelihood that two values co-participate in a common instance. Although RAE achieves favorable performance, it does not consider the roles explicitly when evaluating the above likelihood. Actually, under different sequences of roles (corresponding to different relations), the relatedness of two values is greatly different. For example, under the role sequence (*person*, *award*, *point in time*, *together with*) (in this paper, the examples including the role names are all derived from the raw data in Wikidata[2]), *Marie Curie* and *Henri Becquerel* are more related than under the role sequence (*person*, *spouse*, *start time*, *end time*, *place of marriage*), since they won *Nobel Prize in Physics* in *1903* together. To address these problems, our method explicitly models the relatedness of the role-value pairs involved in the same n-ary relational fact. The above example also elucidates its necessity.

In general, the main contributions of this paper can be summarized as follows:

- We advocate a representation form for n-ary relational facts, which represents each n-ary relational fact as a set of its role-value pairs.
- We propose a link prediction method NaLP on n-ary relational data, which captures the relatedness of the role-value pairs in the same n-ary relational fact explicitly.
- Experimental results and further analyses testify the effectiveness and superiority of the proposed NaLP method.

In addition, as publicly available n-ary relational datasets are limited, we build a practical one WikiPeople based on the raw data in Wikidata, which is available on github[3] for further research.

2 RELATED WORKS

According to the fact type that link prediction focuses on, link prediction and its methods can be divided into two categories, i.e., link prediction on binary relational data and link prediction on n-ary relational data.

2.1 Link Prediction on Binary Relational Data

The rapid development of KG has triggered the spring up of a great many methods, including tensor/matrix based methods, translation based methods, and neural network based ones, for link prediction on binary relational data.

Among tensor/matrix based methods [4, 17, 20, 23, 27, 28], the well-known one, RESCAL [23], views a KG as a three-way tensor, where each way corresponds to head entities, relations and tail entities, respectively. And the entry corresponds to the score indicating the validity of the triple formed by the values of the thee ways. If a triple (h, r, t) is observed in the KG, the entry is set to 1, otherwise, set to 0. Through minimizing the reconstruction error of the tensor, the embeddings of entities and relations are learned. Then, the reconstructed tensor from the learned embeddings is used to conduct link prediction, with triples corresponding to entries of high score as valid ones. Similarly, a matrix factorization based method, ComplEx [28], constructs a matrix for each relation, which is decomposed and optimized via minimizing the reconstruction error like RESCAL to learn the embeddings. Differently, complex values are used to define the embeddings, so as to deal with antisymmetric relations effectively.

Translation based methods are derived from the simple but effective method TransE [2]. Its popular translation assumption advocates that valid triples can be viewed as relational translation operations from head entities to tail entities. Based on this assumption, different types of translations and accordingly different score functions measuring the similarity between the relational translation results of head entities and the target tail entities are defined [2, 11–13, 15, 16, 30, 32]. The embeddings of entities and relations are then learned via minimizing score function based loss, which encourages valid triples to have much larger scores than invalid ones. Among these methods, the seminal one, TransE, performs translation operations in a shared space of entities and relations. Further, TransH [30] thinks translation operations should be conducted in relation-specific hyperplanes. Thus, it relates each relation with a hyperplane. Then, entities are projected into the hyperplanes of relations before translations.

Inspired by the excellent performance of neural network in various applications, it has been introduced into link prediction on binary relational data and achieved extremely promising results [3, 5, 7, 19, 25, 26]. Among them, the R-GCN method [25] introduces relational graph convolutional networks as its encoder to get the embeddings of entities, and uses the existing method [33] as its decoder to compute the scores of triples with the embeddings of entities from the encoder and the embeddings of relations randomly initialized. Differently, ConvE [3] models entity prediction directly, which reshapes and concatenates the embeddings of the known entity and relation to apply two-dimensional convolution on the concatenated matrix. Then, after a fully connected projection, it generates the prediction entity. By comparing it with the target entity, ConvE minimizes a binary cross-entropy loss. SENN [7] integrates the prediction tasks of head entities, relations and tail entities in a unified neural network framework based on

[2]https://www.wikidata.org/wiki/Wikidata:Main_Page
[3]https://github.com/gsp2014/WikiPeople

shared embeddings. Fully connected layers are applied to model the prediction processes. ConvKB [19] represents each triple as a three-column matrix, where each column vector corresponds to an element of the triple. This matrix is fed into a convolution layer to generate different feature maps, which are then concatenated into a single feature vector representing the triple. After passing it to a fully connected layer, ConvKB obtains a score indicating the validity of the triple.

2.2 Link Prediction on N-ary Relational Data

As n-ary relational facts are complicated and usually difficult to deal with, most of existing studies convert them into multiple triples, with the introduction of virtual entities and additional triples [1], and research works for link prediction on n-ary relational data directly are relatively much scarcer and newer.

Based on the link prediction method TransH [30] on binary relational data, m-TransH [31] is proposed to generalize it to n-ary relational data. The m-TransH method presents a mathematical definition of relations (including binary and n-ary relations) as the mappings from sequences of roles to their values. Each mapping is an instance of the corresponding relation. Then, the score function of an instance is defined by the weighted sum of the projection results from its values to its relation hyperplane, where the weights are the real numbers projected from its roles. RAE [34] further considers the relatedness of values, i.e., the likelihood that two values co-participate in a common instance, and adds this relatedness loss with a weighted hyper-parameter to the embedding loss of m-TransH. Although with the additional modeling of the relatedness of values, RAE outperforms m-TransH, it does not look into the roles when computing the relatedness. Since roles are also a fundamental part of instances, taking them into consideration may make a difference as illustrated afore.

3 THE NALP METHOD

In this paper, link prediction on n-ary relational data is transformed into estimating whether a relational fact is valid and then casted into a classification task.

In this section, we first demonstrate our representation form of n-ary relational facts, then outline the framework of the proposed NaLP method and elaborate its two key components, respectively. Subsequently, some characteristics of NaLP are discussed. And the details of model training are introduced in the following part.

3.1 The Representation of N-ary Relational Facts

In this paper, we represent each n-ary relational fact as a set of its role-value pairs. As an example, the representation of the fact that *Marie Curie* received *Willard Gibbs Award*, is as follows:

$$\{person : Marie\ Curie, award : Willard\ Gibbs\ Award\}.$$

It is an n-ary relational fact of arity 2, i.e., a binary relational fact, as it has two role-value pairs.

And the facts where some roles have more than one value are represented similarly. For example, the representation of the fact that *Marie Curie* received *Nobel Prize in Physics* in *1903* together with *Henri Becquerel* and *Pierre Curie*, is as follows:

$$\{person : Marie\ Curie, award : Nobel\ Prize\ in\ Physics, point\ in\ time : 1903, together\ with : Henri\ Becquerel, together\ with : Pierre\ Curie\}.$$

It is an n-ary relational fact of arity 5, with 5 role-value pairs.

Formally, given an n-ary relational fact with n roles, and each role r_i having m_i values ($i = 1, 2, \ldots, n$), the representation of this n-ary relational fact is the following set of role-value pairs:

$$\{r_1 : v_1, \ldots, r_1 : v_{m_1}, r_2 : v_{m_1+1}, \ldots, r_2 : v_{m_1+m_2}, \ldots, r_n : v_{m_1+m_2+\cdots+m_{n-1}+1}, \ldots, r_n : v_{m_1+m_2+\cdots+m_n}\}.$$

It is an n-ary relational fact of arity $(m_1 + m_2 + \cdots + m_n)$.

3.2 The Framework of NaLP

Then, we propose a link prediction method NaLP on n-ary relational data. It is designed based on two considerations. On one hand, a role and its value are tightly linked to each other, thus should be bound together. On the other hand, as mentioned in the beginning of Section 3, we aim to judge the validity of a relational fact, i.e., a set of role-value pairs. That is, for a set of role-value pairs, we need to determine whether it is able to form a valid relational fact. Intuitively, all the role-value pairs of a valid relational fact are closely related. And if all the role-value pairs from a set are closely related, then, we assume that this set of role-value pairs has high probability to constitute a valid relational fact. With these considerations in mind, the framework of NaLP is designed as illustrated in Figure 1, which consists of two key components, role-value pair embedding and relatedness evaluation. For clarity, in the figure, we only exemplify one n-ary relational fact in the following form:

$$Rel = \{r_1 : v_1, r_2 : v_2, \ldots, r_m : v_m\},$$

where m is the arity of the relational fact *Rel*. The role set of *Rel* is denoted as $R_{Rel} = \{r_1, r_2, \ldots, r_m\}$ and r_i may be the same to r_j ($i, j = 1, 2, \ldots, m, i \neq j$), as demonstrated in Section 3.1; the value set of *Rel* is denoted as $V_{Rel} = \{v_1, v_2, \ldots, v_m\}$. In what follows, as an example, we illustrate the learning details of this n-ary relational fact.

For the given relational fact *Rel*, the embeddings of its roles in R_{Rel} and values in V_{Rel} are looked up from the embedding matrices $\mathbf{M_R} \in \mathbb{R}^{|R|\times k}$ of roles and $\mathbf{M_V} \in \mathbb{R}^{|V|\times k}$ of values, respectively, where R is the set of all the roles on dataset; V is the set of all the values; k is the latent dimension of the vector space. Following the convention, in what follows, the embeddings are denoted with the same letters but in boldface. As depicted in Figure 1, after passing these embeddings to the role-value pair embedding component, we get the embedding matrix of the m role-value pairs, i.e., *Rel* (see Section 3.3). This resulting embedding matrix is fed into the relatedness evaluation component to compute the pair-wise relatedness of all the role-value pairs, then estimate their overall relatedness, which is used to obtain the evaluation score (see Section 3.4). Particularly, this framework equips NaLP with the ability to be permutation-invariant to the input order of the role-value pairs and deal with relational facts of different arities (see Section 3.5). Subsequently, the evaluation score is used to generate loss (see Section 3.6).

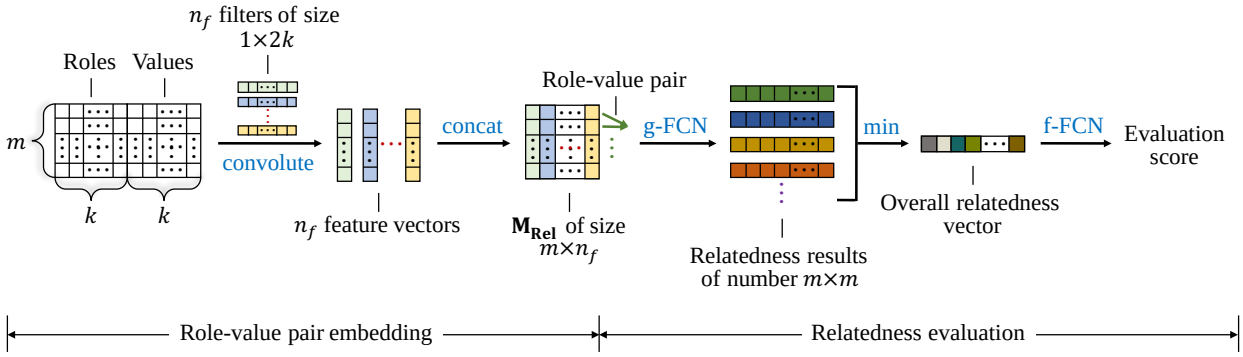

Figure 1: The framework of the proposed NaLP method.

3.3 Role-Value Pair Embedding

The role-value pair embedding component aims to obtain the embeddings of the input role-value pairs. This process contains two sub-processes, i.e., convolution and concatenation, corresponding to "convolute" and "concat" in Figure 1, respectively.

3.3.1 "convolute". As presented in Figure 1, before convolution, the embeddings of the roles r_i and the corresponding values v_i ($i = 1, 2, \ldots, m$) in the relational fact *Rel* are concatenated, and form a matrix of dimension $m \times 2k$, where each role-value pair makes up a row.

Then, this concatenated matrix is passed to the convolution with filter set Ω of n_f filters. To capture the features of the role-value pairs, the dimensions of the filters are all set to $1 \times 2k$. After convolution, we get n_f results of dimension m. And Rectified Liner Units (ReLU) [18] is applied to these results to get n_f feature vectors.

3.3.2 "concat". We concatenate the n_f feature vectors to form a matrix of dimension $m \times n_f$. Then, this matrix can be treated as the embeddings of the m role-value pairs, and each row corresponds to the embedding of one role-value pair. Specifically, each entry of a row encodes the feature of this dimension.

Formally, the embedding matrix $\mathbf{M_{Rel}} \in \mathbb{R}^{m\times n_f}$ of the role-value pairs, i.e., the relational fact *Rel* is defined as:

$$\mathbf{M_{Rel}} = \text{concat}\left(\Upsilon(\text{concat}(\mathbf{R_{Rel}}, \mathbf{V_{Rel}}) * \Omega)\right), \tag{1}$$

where Υ is the ReLU function [18], i.e., $\Upsilon(x) = \max(0, x)$; $*$ denotes the convolution operator; $\text{concat}(\mathbf{R_{Rel}}, \mathbf{V_{Rel}})$ is the aforementioned embedding concatenation process of the role-value pairs before convolution.

3.4 Relatedness Evaluation

This component computes the pair-wise relatedness of all the input role-value pairs, estimates their overall relatedness and obtains the evaluation score, corresponding to "g-FCN", "min" and "f-FCN" in Figure 1, respectively. Before introducing these sub-processes, let's see the principle behind this component.

3.4.1 The Principle. The principle of its design goes deep into determining whether a set of role-value pairs is able to form a valid relational fact. As demonstrated in Section 3.2, this is reduced to computing the overall relatedness of all the role-value pairs in the set. However, the overall relatedness of a set with more than two objects is intricate to measure. When the number of objects is large, corresponding to relational fact of high arity, the evaluation is further complicated. Whereas, computing the relatedness between two objects is relatively much simpler. Thus, how to determine the tricky overall relatedness via the simple relatedness between the role-value pairs?

Straightforwardly, if all the role-value pairs form a closely related set, i.e., a valid relational fact, then every two pairs from the set are greatly related. Thus, for any two pairs, the values of their relatedness feature vector, measuring the relatedness in many different views, are all expected to be sufficiently large. That is, for each feature dimension, the minimum over this dimension of every two pairs is not allowed to be too small. Hence, based on this observation, we apply element-wise minimizing over the pair-wise relatedness of all the role-value pairs to approximately evaluate their overall relatedness. Accordingly, the relatedness evaluation component is designed to contain the computation of the relatedness between the role-value pairs and the overall relatedness of all the role-value pairs, before estimating the final evaluation score.

3.4.2 "g-FCN". The relatedness between the role-value pairs is captured via a Fully Connected Network (FCN) with ReLU as its activation function. In particular, the widely used FCN is also adopted to infer the ways in which two objects are related and achieves marvelous performance in computer vision [8, 24]. In this paper, it turns out that a one-layer FCN already works very well. Thus, only a fully connected layer is adopted in this sub-process.

Concretely, the embeddings of any two role-value pairs are concatenated to form a vector of dimension $2n_f$, and then fed into the fully connected layer with n_{gFCN} nodes. The resulting vector of dimension n_{gFCN} is the relatedness feature vector with entries greater than or equal to 0, each dimension of which indicates the relatedness of the input two role-value pairs in some respect.

3.4.3 "min". As discussed in Section 3.4.1, the overall relatedness of all the role-value pairs is simply approximated by element-wise

minimizing over their pair-wise relatedness. Thus, the overall relatedness $\mathcal{R}_{\mathbf{Rel}}$ of Rel is defined as:

$$\begin{aligned}\mathcal{R}_{\mathbf{Rel}} &= \min_{i,j=1}^{m}\Big(\text{g-FCN}\left(\text{concat}([\mathbf{M}_{\mathbf{Rel}}]_i, [\mathbf{M}_{\mathbf{Rel}}]_j)\right)\Big) \\ &= \min_{i,j=1}^{m}\Upsilon\big(\text{concat}([\mathbf{M}_{\mathbf{Rel}}]_i, [\mathbf{M}_{\mathbf{Rel}}]_j)\mathbf{W}_{\mathbf{gFCN}} + \mathbf{b}_{\mathbf{gFCN}}\big),\end{aligned} \tag{2}$$

where $\min(\cdot)$ is the element-wise minimizing function; $[\mathbf{x}]_i$ is the i-th entry of $\mathbf{x}$; $\mathbf{W}_{\mathbf{gFCN}}$ of dimension $2n_f \times n_{\text{gFCN}}$ and $\mathbf{b}_{\mathbf{gFCN}}$ of dimension n_{gFCN} are the weight matrix and bias vector of g-FCN, respectively. The resulting $\mathcal{R}_{\mathbf{Rel}}$ is a vector of dimension n_{gFCN}, with each entry implying the degree of the overall relatedness in terms of certain feature corresponding to that dimension.

3.4.4 "f-FCN". Then, $\mathcal{R}_{\mathbf{Rel}}$ is used to generate the evaluation score. A one-layer FCN is also found to be sufficient and applied in this sub-process. In this way, the evaluation score $s(Rel)$ of Rel is defined as:

$$\begin{aligned}s(Rel) &= \text{f-FCN}(\mathcal{R}_{\mathbf{Rel}}) \\ &= \mathcal{R}_{\mathbf{Rel}}\mathbf{W}_{\mathbf{fFCN}} + b_{\text{fFCN}},\end{aligned} \tag{3}$$

where $\mathbf{W}_{\mathbf{fFCN}}$ of dimension $n_{\text{gFCN}} \times 1$ and b_{fFCN} are the weight matrix and bias variable of f-FCN, respectively.

3.5 Look into NaLP

Note that, in m-TransH [31] and RAE [34], all relations along with their role sequences are predefined, and the inputs of the models are the instances of these relations, i.e., the sequences of ordered values. Since the i-th value of an input instance corresponds to the i-th role of its relation, the order of the input values are usually not allowed to be changed randomly. Whereas, each input of the proposed NaLP method is a set of role-value pairs, corresponding to a relational fact. Thus, the order of the objects in each input matters in m-TransH and RAE, while it has no impact on NaLP. Actually, NaLP is permutation-invariant to the input order of the role-value pairs and is able to cope with relational facts of different arities. Let's look into these two characteristics.

3.5.1 A Simple Explanation of Permutation Invariance. Suppose that the role-value pairs of Rel are input into NaLP in the original order with the indexes from 1 to m, and a permutation ρ to the indexes results in a new order with the indexes from $\rho(1)$ to $\rho(m)$.

On these grounds, we simply explain the permutation invariance as follows:

- In the process of role-value pair embedding, the embedding matrix $\mathbf{M}_{\rho(\mathbf{Rel})}$ of the permutated role-value pairs $\rho(Rel)$ is the permutation of the original $\mathbf{M}_{\mathbf{Rel}}$, with the $\rho(i)$-th row of $\mathbf{M}_{\mathbf{Rel}}$ placed in the i-th row of $\mathbf{M}_{\rho(\mathbf{Rel})}$, i.e.,

$$[\mathbf{M}_{\rho(\mathbf{Rel})}]_i = [\mathbf{M}_{\mathbf{Rel}}]_{\rho(i)}. \tag{4}$$

- In the process of relatedness evaluation, the overall relatedness $\mathcal{R}_{\rho(\mathbf{Rel})}$ of $\rho(Rel)$ is as follows:

$$\begin{aligned}&\mathcal{R}_{\rho(\mathbf{Rel})} \\ &= \min_{i,j=1}^{m}\Big(\text{g-FCN}\left(\text{concat}([\mathbf{M}_{\rho(\mathbf{Rel})}]_i, [\mathbf{M}_{\rho(\mathbf{Rel})}]_j)\right)\Big) \\ &= \min_{i,j=1}^{m}\Upsilon\left(\text{concat}([\mathbf{M}_{\rho(\mathbf{Rel})}]_i, [\mathbf{M}_{\rho(\mathbf{Rel})}]_j)\mathbf{W}_{\mathbf{gFCN}} + \mathbf{b}_{\mathbf{gFCN}}\right) \\ &= \min_{i,j=1}^{m}\Upsilon\left(\text{concat}([\mathbf{M}_{\mathbf{Rel}}]_{\rho(i)}, [\mathbf{M}_{\mathbf{Rel}}]_{\rho(j)})\mathbf{W}_{\mathbf{gFCN}} + \mathbf{b}_{\mathbf{gFCN}}\right).\end{aligned} \tag{5}$$

That is, we obtain $m \times m$ relatedness results, the same to those in the original version, but with the order of the results changed. Since $\min(\cdot)$ is permutation-equivariant, we have:

$$\mathcal{R}_{\rho(\mathbf{Rel})} = \mathcal{R}_{\mathbf{Rel}}. \tag{6}$$

- Then, the evaluation score $s(\rho(Rel))$ of $\rho(Rel)$ is as follows:

$$\begin{aligned}s(\rho(Rel)) &= \text{f-FCN}(\mathcal{R}_{\rho(\mathbf{Rel})}) \\ &= \mathcal{R}_{\rho(\mathbf{Rel})}\mathbf{W}_{\mathbf{fFCN}} + b_{\text{fFCN}} \\ &= \mathcal{R}_{\mathbf{Rel}}\mathbf{W}_{\mathbf{fFCN}} + b_{\text{fFCN}} \\ &= s(Rel).\end{aligned} \tag{7}$$

- Therefore, NaLP is permutation-invariant to the input order of the role-value pairs.

3.5.2 Handling Relational Facts of Different Arities. Suppose that two batches of relational facts of arities m and m', respectively, are input into NaLP subsequently. In the process of role-value pair embedding, they result in the embedding matrices of the role-value pairs with m and m' rows, respectively. In the process of relatedness evaluation, correspondingly, we obtain $m \times m$ and $m' \times m'$ relatedness results. As $\min(\cdot)$ in Equation (2) returns one vector among all these results of number $m \times m$ or $m' \times m'$, the number of results makes no difference. Thus, NaLP is able to deal with relational facts of different arities.

3.6 Model Training

In the following, we present the loss function and the training process of the proposed NaLP method in detail.

3.6.1 The Loss Function. As above described, we obtain the evaluation score $s(Rel)$ of Rel. Following ComplEx [28], the loss of Rel is defined as:

$$\mathcal{L}(Rel) = \log\left(1 + e^{-I_{Rel}s(Rel)}\right), \tag{8}$$

where $I_{Rel} = 1$, if Rel is a valid relational fact, and $I_{Rel} = -1$, otherwise.

It is straightforward to optimize NaLP with the standard back-propagation. The popular stochastic optimization method Adam [14] with hyper-parameter learning rate λ is used as the optimizer in this paper.

3.6.2 The Training Process. Algorithm 1 presents the training process of the NaLP method.

Before training, the training set is reorganized into several training groups, each of which keeps the relational facts of the same arity (Line 1). In order to guarantee that NaLP masters basic relational facts of low arities before learning relational facts of high arities, we sort the above resulting groups by their arities in ascending order (Line 2). Similar operations are applied to train model on the path queries of length 1 and then all the path queries [9]. Subsequently, the embedding matrices $\mathbf{M}_{\mathbf{R}}$ and $\mathbf{M}_{\mathbf{V}}$ are randomly initialized from uniform distribution, respectively, with $-\frac{1}{\sqrt{k}}$ as minimum and $\frac{1}{\sqrt{k}}$ as maximum; truncated normal distribution with 0.0 as mean and 0.1 as standard deviation is adopted as initializer to initialize all the filters in Ω [19]; $\mathbf{W}_{\mathbf{gFCN}}$ and $\mathbf{W}_{\mathbf{fFCN}}$ are randomly initialized via xavier initializer [6], respectively; $\mathbf{b}_{\mathbf{gFCN}}$ and b_{fFCN} are randomly initialized with zeros (Line 3).

Algorithm 1 The training process of the NaLP method.

Input: Training set T, role set R, value set V, max number of epochs *nepoch*, embedding dimension k, batch size β, number of filters n_f in Ω, the hyper-parameter n_{gFCN} of $\mathbf{W}_{\mathbf{gFCN}}$.
Output: $\mathbf{W}_{\mathbf{R}}$ and $\mathbf{W}_{\mathbf{V}}$, as well as the parameters of NaLP.

1: $T \leftarrow$ group T by the arities of the facts;
2: $T \leftarrow$ sort the groups in T by their arities in ascending order;
3: **Initialize** $\mathbf{M}_{\mathbf{R}}, \mathbf{M}_{\mathbf{V}} \leftarrow \text{uniform}(-\frac{1}{\sqrt{k}}, \frac{1}{\sqrt{k}})$;
$\Omega \leftarrow \text{truncated_normal}(0.0, 0.1)$;
$\mathbf{W}_{\mathbf{gFCN}}, \mathbf{W}_{\mathbf{fFCN}} \leftarrow \text{xavier_initializer}()$;
$\mathbf{b}_{\mathbf{gFCN}}, b_{\text{fFCN}} \leftarrow \text{zeros_initializer}()$;
4: **repeat**
5: **for** each group $T' \in T$ **do**
6: **for** $j = 1$ to $\left\lceil \frac{|T'|}{\beta} \right\rceil$ **do**
7: $S^+ \leftarrow \text{sample}(T', \beta)$; //sample β training facts from T'
8: $S^- \leftarrow \text{neg_sample}(S^+, \beta)$; //obtain β negative samples
9: $S \leftarrow S^+ \cup S^-$;
10: $loss \leftarrow 0$;
11: **for** $\forall Rel \in S$ **do**
12: $\mathbf{R}_{\mathbf{Rel}} \leftarrow \text{look-up}(\mathbf{M}_{\mathbf{R}}, R_{Rel})$; //look up R_{Rel}
13: $\mathbf{V}_{\mathbf{Rel}} \leftarrow \text{look-up}(\mathbf{M}_{\mathbf{V}}, V_{Rel})$; //look up V_{Rel}
14: $\mathbf{M}_{\mathbf{Rel}} \leftarrow$ get the embedding matrix of the role-value pairs following Equation (1);
15: $\mathcal{R}_{\mathbf{Rel}} \leftarrow$ compute the overll relatedness of *Rel* following Equation (2);
16: $s(Rel) \leftarrow$ generate the evaluation score following Equation (3);
17: $\mathcal{L}(Rel) \leftarrow$ compute the loss of *Rel* following Equation (8);
18: $loss \leftarrow loss + \mathcal{L}(Rel)$;
19: **end for**
20: Update the embeddings of the roles and values in S (i.e., the related rows of $\mathbf{M}_{\mathbf{R}}$ and $\mathbf{M}_{\mathbf{V}}$), the filters in Ω, $\mathbf{W}_{\mathbf{gFCN}}$, $\mathbf{W}_{\mathbf{fFCN}}$, $\mathbf{b}_{\mathbf{gFCN}}$, as well as b_{fFCN} via $\nabla loss$;
21: **end for**
22: **end for**
23: **until** the evaluation result on the validation set drops continuously or this process has been iterated for *nepoch* times

During training, Lines 5-22 are repeated until the evaluation result on the validation set drops continuously or reaching the max number of epochs *nepoch*. In this paper, *nepoch* is set to 5000. In each epoch, $\left\lceil \frac{|T'|}{\beta} \right\rceil$ batches of training facts are sampled from each training group T', where $\lceil \cdot \rceil$ is the ceiling function. For each selected training fact, similar to the negative sampling method adopted in TransE [2], we randomly replace one of its values with a random value that the corresponding role holds, or one of its roles is replaced with a relatively lower probability, to obtain a negative sample not contained in the dataset (Line 8). Thereafter, the selected training facts and their negative samples are used to train the model. For each such relational fact *Rel*, the embeddings of its roles and values are looked up from $\mathbf{M}_{\mathbf{R}}$ and $\mathbf{M}_{\mathbf{V}}$, respectively (Lines 12 and 13). Then, they are fed into the role-value pair embedding component to obtain the embedding matrix of the role-value pairs (Line 14). After passing this embedding matrix to the relatedness evaluation component, we obtain the overall relatedness $\mathcal{R}_{\mathbf{Rel}}$ and the evaluation score $s(Rel)$ of *Rel* (Lines 15 and 16). Subsequently, based on $s(Rel)$, loss is computed and added to the loss of the current batch (Lines 17 and 18). Finally, parameter update is performed in batch mode (Line 20).

Specifically, batch normalization [10] is applied after convolution in the role-value pair embedding component to stabilize and accelerate the training process.

4 EXPERIMENTS

In this section, we evaluate the proposed NaLP method through link prediction. Then, overall relatedness analysis is conducted to have a better understanding of NaLP. And some important hyper-parameters are analyzed their impacts on the robustness of NaLP. Before elaborating these experiments, we will first introduce the datasets and metrics, as well as the baselines and experimental settings.

4.1 Datasets and Metrics

4.1.1 Datasets. We conduct our experiments on two datasets. The first one is the public n-ary relational dataset JF17K, which is derived from the popular KG Freebase [1]. All the facts in it are in good quality with the role sequences equal to the predefined standard ones and the corresponding values existing and known. This is usually not the case. And we build a relatively more practical dataset WikiPeople, which is also our second experimental dataset. It is constructed as follows:

- We download the Wikidata dump[4] and extract the facts concerning entities of type *human*.
- Then, these facts are further denoised. For example, facts containing element related to image are filtered out, and facts containing element in {*unknown value*, *no values*} are removed.
- Subsequently, we select the subsets of elements which have at least 30 mentions. The facts related to these elements are kept. Further, each fact is parsed into a set of its role-value pairs.
- The remaining facts are randomly split into training set, validation set and test set by a proportion of 80%:10%:10%.

Actually, WikiPeople is relatively more flexible, where data incompleteness, insert and update are universal. As an example, the role sequence of some n-ary relational facts like "*Marie Curie* received *Nobel Prize in Chemistry* in *1911*" is [*person*, *award*, *point in time*]. Then, the following similar facts in Wikidata[5] correspond to the three cases of data incompleteness, insert and update, respectively:

- *Marie Curie* received *Willard Gibbs Award*.
- *Marie Curie* received *Matteucci Medal* in *1904* with *Pierre Curie*.
  Marie Curie received *Nobel Prize in Physics* in *1903* together with *Henri Becquerel* and *Pierre Curie*.
- *Marie Curie* received *Davy Medal* with *Pierre Curie*.

[4] https://archive.org/details/wikibase-wikidatawiki-20171120
[5] https://www.wikidata.org/wiki/Q7186

In the first example, the value of the role *point in time* is unknown. In the second examples, one or two new roles *together with* are in need. In the third one, the value of the role *point in time* is unknown and a new role *together with* appears. Fortunately, our representation form of relational facts, which represents each relational fact as a set of its role-value pairs, is able to cope with all these cases, as exemplified in Section 3.1.

In real scenario, since there is possible missing in the process of knowledge extraction, and knowledge also grows and updates rapidly with many new contents flowing in, in the dataset derived from one snapshot, the above phenomena of data incompleteness, insert and update are inevitable. Thus, the developed WikiPeople dataset is practical. Note that, in this paper, no special handling is done to values from continuous domain (e.g., point in time, date of birth, date of death, etc.), and they are tackled like other values from discrete domain.

The detailed statistics of the two experimental datasets are displayed in Table 1, where $\#Relation$, $\#Train$, $\#Valid$ and $\#Test$ are the sizes of the relation set, the training set, the validation set and the test set, respectively. Here, $\#Relation$ is counted according to RAE [34] to have a better understanding of the two datasets.

4.1.2 Metrics. We adopt the standard Mean Reciprocal Rank (MRR) and Hits@N as metrics for comparison. These metrics are computed in the similar way of binary dataset [2]. For each test fact, one of its values/roles is removed and replaced by all the values/roles in V/R. These corrupted facts are fed into NaLP to obtain the evaluation scores. Then, these corrupted facts are sorted according to their evaluation scores in descending order. The rank of the test fact is finally stored. This whole procedure is repeated for all the other values/roles of the test fact. Thus, MRR is the average of these reciprocal ranks and Hits@N is the proportion of ranks which are less than or equal to N. In this paper, $N \in \{1, 3, 10\}$, i.e., the results in terms of Hits@1, Hits@3 and Hits@10 are reported. The traditional mean rank (the average of these ranks) is not adopted as a metric, since it is sensitive to outliers [22]. For these chosen metrics, the higher the value of MRR/Hits@N, the better the performance of the prediction.

In the test process, except the test fact, other corrupted facts that may also be valid, i.e., exist in the training/validation/test set, are discarded before sorting the facts.

4.2 Baselines and Experimental Settings

4.2.1 Baselines. Prior works for link prediction on n-ary relational data directly are scarce, and the state-of-the-art works are m-TransH [31] and its enhanced version RAE [34]. Since RAE performs better than its simplified version m-TransH, we only compare the proposed NaLP method with RAE.

4.2.2 Experimental Settings. For the proposed NaLP method, the reported results are given for the best set of hyper-parameters after grid search on the following values, by reference to ConvKB [19]: The embedding dimension $k \in \{50, 100\}$, the batch size $\beta \in \{128, 256\}$, the learning rate $\lambda \in \{5e^{-6}, 1e^{-5}, 5e^{-5}, 1e^{-4}, 5e^{-4}, 1e^{-3}\}$, the number of filters n_f of the convolution in {50, 100, 200, 400, 500}, the hyper-parameter n_{gFCN} of $\mathbf{W}_{\mathbf{gFCN}}$ in {50, 100, 200, 400, 500, 800, 1000, 1200}. The finally adopted optimal settings are: $k = 100$, $\beta = 128$, $\lambda = 5e^{-5}$, $n_f = 200$, $n_{\text{gFCN}} = 1000$ for JF17K, and $k = 100$, $\beta = 128$, $\lambda = 5e^{-5}$, $n_f = 200$, $n_{\text{gFCN}} = 1200$ for WikiPeople.

For the RAE method, as it does not report the ranges of hyper-parameters, we use the following ranges, by reference to its best settings on JF17K: The embedding dimension $k \in \{50, 100\}$, the margin ϵ of the first update step in $\{0.1, 0.5, 1.0, 2.0\}$, its weight hyper-parameter w of the regularization term and its threshold hyper-parameter δ in $\{1e^{-3}, 0.01, 0.1\}$, the batch sizes of the three update steps $\beta_1, \beta_2 = \beta_3 \in \{128, 256, 512, 1000\}$ (note that the second and third update steps share the same batch size), their learning rates $\lambda_1, \lambda_2, \lambda_3 \in \{5e^{-5}, 5e^{-4}, 5e^{-3}, 1e^{-3}, 1.5e^{-3}\}$. The finally adopted optimal settings are: $k = 100$, $w = 0.1$, $\delta = 1e^{-3}$, $\epsilon = 0.5$, $\beta_1 = 512$, $\beta_2 = \beta_3 = 128$, $\lambda_1 = 5e^{-3}$, $\lambda_2 = 1.5e^{-3}$, $\lambda_3 = 5e^{-4}$ for WikiPeople.

Note that, on WikiPeople, the best set of hyper-parameters are determined according to the evaluation results on the validation set in terms of MRR. And, on JF17K, since it lacks a validation set, we tune the hyper-parameters on the test set.

Particularly, we reproduce the experimental results reported in RAE on JF17K and compute more detailed results in terms of the above fine-grained metrics. Note that, before running NaLP on JF17K and RAE on WikiPeople, we need to transform the representation form of facts. It is effortless to transform each value sequence in JF17K to a set of role-value pairs, by adding the corresponding roles. To conduct the inverse transformation on WikiPeople, relations along with their role sequences are defined in advance, then only the value sequence of each fact is stored. Specifically, a new relation is defined when the aforementioned case of data incompleteness/insert/update appears.

4.3 Link Prediction

Link prediction on n-ary relational data has two tasks, i.e., value prediction and role prediction.

4.3.1 Value Prediction. In order to illustrate the performance of the proposed NaLP method on value prediction, we report the experimental results compared with RAE in terms of all the fine-grained metrics in Table 2.

From the results, it is clear that on both datasets, NaLP consistently outperforms RAE in terms of all the four metrics, which indicates the effectiveness and superiority of NaLP. Specifically, on the dataset in good quality, i.e., JF17K, NaLP improves the performance by 0.056 on MRR, 7.1% on Hits@1 and 5.7% on Hits@3. It testifies the strength of NaLP considering the relatedness of role-value pairs rather than only the relatedness of values in RAE. On the relatively more practical dataset, i.e., WikiPeople, the superiority of NaLP is significant. NaLP has considerable increase on all the four metrics, especially 0.166 on MRR, 17.0% on Hits@1 and 18.2% on Hits@3. It is not surprising, since NaLP is capable of better coping with diverse data than RAE. Data incompleteness/insert/update, which is ubiquitous on WikiPeople, is handled elegantly in NaLP, while new relation is defined in RAE, which may lead to data sparsity, when the instances of the new relation are in small number. Hence, it results in the relatively much worse performance of RAE on WikiPeople. Moreover, the overall better results of NaLP regarding more fine-grained metrics, i.e., MRR, Hits@1 and Hits@3,

WikiPeople	0.728	0.763	0.735	0.578	0.670	0.595	0.856	0.835	0.852	0.941	0.922	0.938

elucidate that NaLP is more effective in picking exactly valid values out.

To further elaborately evaluate the performance of NaLP on value prediction, we group the test set into binary and n-ary categories according to the arities of the facts. The detailed results on these two categories are presented in Table 3.

It can be seen from Table 3 that on the two datasets, NaLP demonstrates its advantage on both binary and n-ary categories. In more detail, on JF17K, the performance gap between NaLP and RAE is pronounced, especially in terms of MRR, Hits@1 and Hits@3. On WikiPeople, RAE is more significantly left behind by a large margin. These verify that NaLP is able to well deal with value prediction on both binary and n-ary categories. Notably, on JF17K, both RAE and NaLP perform much more poorly on binary category than on n-ary category. To analyze the reason behind, we dig into the dataset. It can be observed from Table 1 that JF17K has less n-ary relations. Although, the ratios between the sizes of n-ary and binary categories on the relation set ($136/186 = 0.731$) and the training set ($32,169/44,210 = 0.728$) are similar and less than 1, JF17K has much more test facts on n-ary category and the above ratio is greater than 1 ($14,151/10,417 = 1.358$). Since the test facts are used to tune the hyper-parameters (due to the lack of validation set), the relatively more facts on n-ary category in the test set encourage the models to do prediction on n-ary category much better. Thus, it is reasonable that both RAE and NaLP obtain worse performance on binary category than on n-ary category in JF17K.

4.3.2 Role Prediction. As there is no other method that conducts role prediction on n-ary relational data, and even RAE is deliberately designed only for value prediction, we conduct role prediction experiment only on the proposed NaLP method. Table 4 demonstrates the detailed experimental results in terms of all the four metrics on binary category, n-ary category and the whole dataset. The experimental results also illustrate the power of NaLP. NaLP achieves excellent results on all the metrics. We attribute this to the reasonable modeling of role-value pairs. Thus, it not only enhances the performance of value prediction, but also benefits role prediction.

4.4 Overall Relatedness Analysis

In the proposed NaLP method, the overall relatedness vector of a set of role-value pairs, i.e., a relational fact, is the crucial intermediate result. We conduct further analyses to dig deep into what it has learned.

According to Section 3.2, a valid relational fact is expected to have an overall relatedness vector of large value, while an invalid relational fact is on the contrary. And how to evaluate the degree

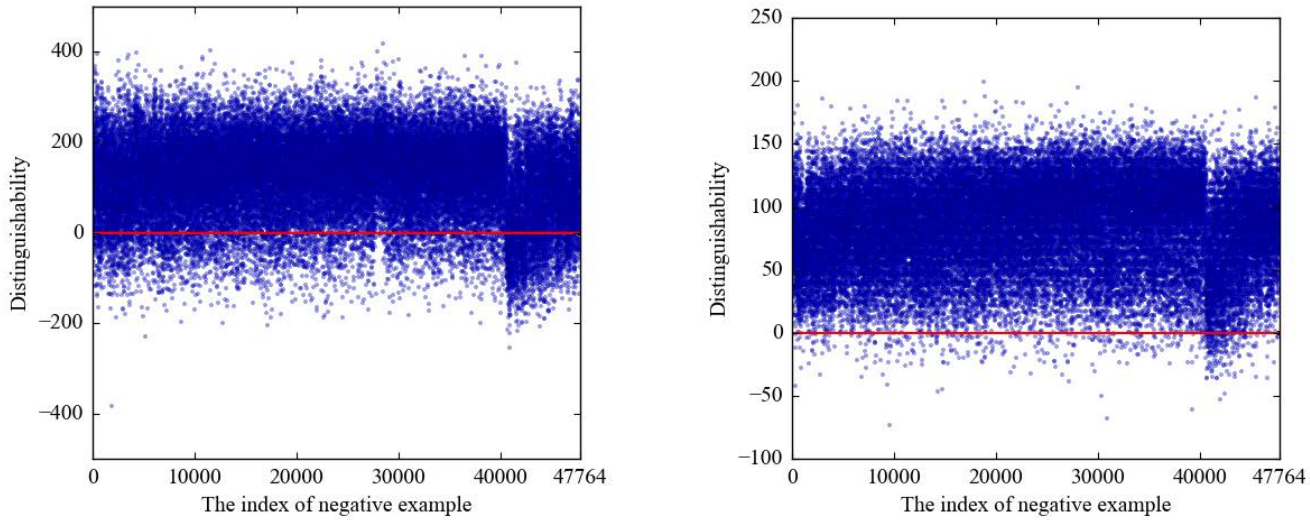

Figure 2: The visualization of the distinguishability results of Case-1 concerning the binary relational fact Fact-1: {*son* : *Michael Douglas*, *father* : *Kirk Douglas*} (left) and Case-2 concerning the n-ary relational fact Fact-2: {*person* : *Marie Curie*, *award* : *Nobel Prize in Physics*, *point in time* : *1903*, *together with* : *Henri Becquerel*, *together with* : *Pierre Curie*} (right).

of largeness? Actually, the relative magnitude between a valid relational fact and its negative samples is relatively more meaningful. Specifically, it is expected that a valid relational fact has larger values in a majority of dimensions of the overall relatedness vector compared to its negative samples, and thus the valid relational fact is distinguishable from its negative samples. Therefore, we propose the following metric to measure this type of distinguishability:

$$d(Rel^+, Rel^-) = \text{sum}\left(\text{sgn}(\mathcal{R}_{\text{Rel}^+} - \mathcal{R}_{\text{Rel}^-})\right) - \text{sum}\left(\text{sgn}(\mathcal{R}_{\text{Rel}^-} - \mathcal{R}_{\text{Rel}^+})\right), \tag{9}$$

where Rel^+ is a valid relational fact, and Rel^- is one of its negative samples; $\mathcal{R}_{\text{Rel}^+}$ and $\mathcal{R}_{\text{Rel}^-}$ are the overall relatedness vectors of Rel^+ and Rel^-, respectively; $\text{sgn}(x)$ is the function that returns 1, if $x > 0$, otherwise, returns 0; $\text{sum}(\cdot)$ is the element-wise sum function. In Equation (9), the left part of the minus sign counts the number of dimensions that $\mathcal{R}_{\text{Rel}^+}$ is larger than $\mathcal{R}_{\text{Rel}^-}$, and the right part is defined similarly. Hence, $d(Rel^+, Rel^-)$ measures the relative amount that $\mathcal{R}_{\text{Rel}^+}$ has more dimensions of larger values than $\mathcal{R}_{\text{Rel}^-}$.

Based on this proposed metric, we select two typical cases from the validation set, one binary case and one n-ary case, which are predicted correctly by NaLP, to carry out overall relatedness analysis. Note that, we only sample cases regarding value prediction, since role prediction is much simpler due to the much smaller role set. The sampled cases are as follows:

- Case-1: Predict *Michael Douglas*, given the role *son* and the remaining role-value pair of the binary relational fact {*son* : *Michael Douglas*, *father* : *Kirk Douglas*}, denoted as Fact-1.
- Case-2: Predict *Nobel Prize in Physics*, given the role *award* and the remaining role-value pairs of the n-ary relational fact {*person* : *Marie Curie*, *award* : *Nobel Prize in Physics*, *point in time* : *1903*, *together with* : *Henri Becquerel*, *together with* : *Pierre Curie*}, denoted as Fact-2.

Similar to the evaluation procedure, we replace *Michael Douglas* in Fact-1 and *Nobel Prize in Physics* in Fact-2 with all the values in V, then these corrupted facts are fed into NaLP to obtain the overall relatedness vectors. Subsequently, the distinguishability metric is computed following Equation (9). Figure 2 depicts these distinguishability results.

As exhibited in Figure 2, most distinguishability results lie in the area above 0. It visually corroborates that the overall relatedness vector of a fact really captures many discriminant features to further estimate the validity of the fact. Therefore, our conjecture on relatedness (see Section 3.2) makes sense to a certain degree. Due to the diversity of relational facts, the dimension of the overall relatedness vector is encouraged to be large. In this way, there is sufficient dimensions to encode various features. This is consistent with the large optimal value of n_{gFCN} (see Section 4.2.2). Specifically, in the left part of Figure 2, corresponding to the binary Case-1, the distinguishability metric of the negative sample indexed as 1844, corresponding to *Kirk Douglas* is extremely small. As the two role-value pairs *son* : *Kirk Douglas* and *father* : *Kirk Douglas* share the same part *Kirk Douglas*, there is no doubt that their relatedness is large, and the negative sample formed by this two role-vale pairs is easy to be judged as valid. NaLP is unable to filter out such situation. Actually, one value usually cannot correspond to two or more roles of the same fact. Thus, some rules may helpful to deal with the above deficiency. We leave it for future work. From the right part of Figure 2, corresponding to the n-ary Case-2, we have the following two observations:

- The negative samples indexed as 9556, 30913 and 39270, corresponding to *Marie Curie*, *Henri Becquerel* and *1903*, obtain the smallest, the second smallest and the third smallest

distinguishability results, respectively. These three values participate in some other roles of Fact-2, which is similar to the situation of *Kirk Douglas* in Case-1.

- Besides the negative samples corresponding to values of type *human*, some negative samples corresponding to values of type *time*, *club* or *institution* also achieve relatively smaller distinguishability results. It is acceptable, since NaLP does not take value type into consideration.

4.5 Hyper-parameter Analysis

To investigate the robustness of the proposed NaLP method, we further analyze the impacts of its important hyper-parameters, i.e., the number of filters n_f in the role-value pair embedding component and the hyper-parameter n_{gFCN} of $\mathbf{W}_{\mathbf{gFCN}}$ in the relatedness evaluation component. Without loss of generality, these experiments are all conducted on WikiPeople concerning value prediction.

4.5.1 The Impact of the Number of Filters n_f. To make the comparison fair, we keep all the hyper-parameters except n_f to be the optimal settings, and only vary the value of n_f in {50, 100, 200, 400, 500}, as mentioned in Section 4.2.2. To be clear, the evaluation results on the validation set with regard to only MRR are illustrated in the left part of Figure 3.

From the left part of Figure 3, it can be observed that the value of n_f affects the results indistinctively when the value lies in {100, 200, 400, 500}. Thus, NaLP is insensitive to the value of n_f, when the value is not too small, and is robust. The best performance with respect to MRR is obtained when n_f is set to 200.

4.5.2 The Impact of the Hyper-parameter n_{gFCN} of $\mathbf{W}_{\mathbf{gFCN}}$. Similarly, we vary the value of n_{gFCN} in {50, 100, 200, 400, 500, 800, 1000, 1200} and adopt all the other optimal hyper-parameter settings. We also demonstrate the evaluation results on the validation set in terms of only MRR in the right part of Figure 3.

In the right part of Figure 3, it turns out that different values of n_{gFCN}, no less than 400, demonstrate insignificant difference on performance and NaLP is thus robust. Among all these setting, $n_{\text{gFCN}} = 1200$ results in slightly better performance.

5 CONCLUSIONS AND FUTURE WORK

In this paper, we represented each n-ary relational fact as a set of its role-value pairs and proposed a method to cope with Link Prediction on N-ary relational data, called NaLP. The design of the framework equips NaLP with the feature of permutation invariance to the input order of the role-value pairs, and the ability to well handle relational facts of different arities. By evaluating the pair-wise relatedness of all the role-value pairs in the same relational fact, NaLP is able to estimate their overall relatedness approximately. The resulting overall relatedness vectors further enable NaLP to pick up many determinant features to decide the validity of the input relational facts. Furthermore, since publicly available n-ary relational datasets are limited, we developed a practical one, WikiPeople, and it was published for further research. Experimental results on the public dataset and the newly developed WikiPeople manifest the merits and superiority of the proposed NaLP method. On value prediction, compared to the state-of-the-art method, NaLP improves all the metrics significantly, especially on WikiPeople. Specifically, NaLP improves the performance even by 7.1% in terms of Hits@1 on the public dataset, and has more than 17.0% increase in terms of Hits@1 and Hits@3 on WikiPeople.

For future work, on one hand, we will explore more expressive neural network models to capture more favorable features for validity evaluation. On the other hand, in this paper, we use only relational facts to conduct link prediction, and in the future we will introduce additional information, such as rules and value types, to further improve the developed model.

ABSTRACT

User's digital identity information has privacy and security requirements. Privacy requirements include *confidentiality* of the identity information itself, *anonymity* of those who verify and consume a user's identity information and *unlinkability* of online transactions which involve a user's identity. Security requirements include *correctness*, *ownership assurance* and *prevention of counterfeits* of a user's identity information. Such privacy and security requirements, although conflicting, are critical for identity management systems enabling the exchange of users' identity information between different parties during the execution of online transactions. Addressing all such requirements, without a centralized party managing the identity exchange transactions, raises several challenges. This paper presents a decentralized protocol for privacy preserving exchange of users' identity information addressing such challenges. The proposed protocol leverages advances in blockchain and zero knowledge proof technologies, as the main building blocks. We provide prototype implementations of the main building blocks of the protocol and assess its performance and security.

1 INTRODUCTION

Access to services offered by online service providers (SPs) is controlled by identity verification processes. Such a process requires users to verify different types of identity information, depending on the sensitivity of the service. Some services require to verify individual pieces of identity information, such as email address, phone number and Social Security Number (SSN), and some other services require to verify composite identity information such as driver's license and passport. Certain other services require to perform rigorous due diligence processes to satisfy certain compliance requirements such as Know Your Customer (KYC) compliance in banking/financial services [5]. Similar example scenarios which involve lengthy identity verification processes include, but not limited to, joining a new employer, applying for temporary visa in a foreign country, etc.

The amount of resources and effort that users and SPs have to devote to these identity verification processes vary depending on the type of identity information being verified. For examples, verifying an email address only requires the SP to send an email to the given email address, asking the user to click a link in it, verifying an SSN may require the SP to consume a paid service offered by the SSN authority, and verifying KYC compliance requires the SP to perform background checks on the user to verify the user's status of credit score, Anti-Money Laundering (AML), Counter Terrorist Financing (CTF), Politically Exposed Person (PEP) [5], etc. Once an SP has verified the identity of a user, the package of information associated with such *verified identity* becomes an asset of the SP, which we refer to as *identity asset* (the National Strategy for Trusted Identities in Cyberspace (NSTIC) labels such verified identity information as belonging to LOA (Level Of Assurance) 2+ category [20]). On the other hand, since an identity asset contains personal information about a user, the user also becomes an owner of the identity asset, leading to having two legitimate owners per *identity asset*.

Currently, when a user needs to consume similar services from different SPs, the user is treated as an "alien" by each SP and is required to go through a similar identity verification performed by each SP. These repeated processes not only are costly, but also are inherently error-prone, causing inconvenience to both parties. These issues magnify especially in scenarios involving lengthy identity verification such as consuming financial services from multiple banks, joining multiple employers, applying for temporary visa in multiple countries, etc. If there were a standard protocol through which different SPs could share the same *identity assets* of a user, that would result in substantial cost savings and notable convenience to both parties [5]. The SP who originally performed the identity verification for the user, and hence is one of the owners of the identity asset, can be incentivized for sharing the identity

asset, in exchange of a monetary compensation by the subsequent SP(s) that the user interacts with.

Let us consider the following **use case**: *The user Ursula first consumes financial services from bank A where bank A performs identity verification and due diligence steps for KYC compliance on Ursula. Later Ursula needs to consume financial services from bank B as well. Bank B wants to know if Ursula has already performed KYC compliance verification and if so, both Ursula and bank B would like to re-use the corresponding identity asset.* However, in this use case, Ursula would not like to reveal to bank B which bank(s) she has interacted before, and would not like to reveal to bank A, which other bank(s) she is planning to be a customer of. Bank A and bank B themselves would also not like to reveal their identity to each other during potential identity asset exchange, due to competition in business. On the other hand, Ursula would not like the transactions she carries out with different banks based on the same identity asset to be linkable. Prominent privacy protection regulations, such as General Data Protection Regulation (GDPR) [27], also treats a user's transactional patterns as personal data and prohibits tracking such personal data. Therefore, *anonymity of the parties who exchange the identity asset* and *unlinkability of the transactions* are key privacy requirements to be addressed when designing a protocol to facilitate identity asset exchange during online transactions, in addition to protecting *confidentiality* of identity assets from external parties.

The existing identity management protocols, which facilitate sharing users' identity information, do not address all the key privacy requirements. For examples, OpenIDConnect [22], an industry standard widely used by SPs to obtain a user's identity information from an identity provider (IDP), does not preserve anonymity and unlinkability. Two nation-scale brokered identification systems built by the USA and UK governments, namely, Federal Cloud Credential Exchange (FCCX) [21] and GOV.UK Verify [15], respectively, focus on the aforementioned use case and the first privacy requirement, i.e. protecting from each other the anonymity of the parties who exchange users' identity information, in order to preserve users' privacy. Those systems, however, use a government managed broker to mediate the identity exchange transactions, in which case, the identity of the two exchanging parties is revealed to the broker, although the two parties stay anonymous to each other. Brandao et. al [7] have raised certain other privacy concerns on the introduction of such a centralized broker.

One of our goals is to avoid introducing such a centralized broker. Therefore, the proposed protocol is executed in a decentralized identity management ecosystem backed by a permissioned blockchain network (see Section 2.1). Distributed trust implemented on the basis of the consensus protocol through which blockchain peers validate protocol executions eliminates the requirement of a centralized broker. Participants of the decentralized identity management ecosystem invoke the identity exchange transactions with pseudonyms, in order to preserve anonymity and unlinkability. However, when anonymity and unlinkability are enforced in confidential identity asset exchanges, without a mediating centralized party, it is challenging to achieve the required security properties, such as *correctness*, *ownership assurance* and *counterfeits elimination* of the identity assets, and optionally, *financial fairness* of the identity asset exchange transactions, because the participants, appearing with a new pseudonym in each round of the protocol execution, can violate such security properties, as discussed in Section 3. This problem can be related to the challenge of preventing double spending in bitcoin [19] and ZeroCash [4], without a centralized financial institute managing the payment transactions. However, unlike in bitcoin and ZeroCash, whose goal is to prevent double spending of cryptocurrency, which has a single owner at a time, our goal is to enable multiple exchanges of the same identity asset which has two owners, which poses a different set of challenges. We have designed the dedicated phases of the protocol to address such challenges leveraging the power of ZK-SNARKS (see Section 2.2).

Our main contribution is PrivIdEx - a protocol realizing privacy preserving and secure exchanges of identity assets in a decentralized identity management ecosystem, including its: i) design, ii) implementation and iii) analysis and evaluation.

2 PRELIMINARIES

2.1 Permissioned Blockchain

We identify two main parties in a BC [25] network as follows: i) *peers* - they maintain the transaction ledger (i.e. BC) and host the smart contract(s); ii) *participants* - they perform transactions. The consensus algorithm defines rules to be followed by peers when ordering and validating the transactions to be added to the ledger. A *smart contract* defines the business logic for transaction execution and validation, which is invoked by participants and run independently by each peer for executing the transactions.

There are two types of BCs: i) Permissionless BCs - where any one can join the network and write to/read from the BC. Participants' identity is hidden by the random pseudonyms they choose, which results in lack of accountability. Cheating by the peers is avoided and the correctness of the ledger is preserved by employing an expensive consensus algorithm and the assumption that the majority of the computation power of the network is with honest parties. ii) Permissioned BCs - where a trusted certification authority (CA) issues signed X.509 certificates to actors (i.e. peers and participants), which include the public key of a RSA key pair and other identity attributes that determine their permissions (i.e. read/write access to BC). This preserves accountability and enables employing a less costly consensus algorithm. Permissioned BCs are categorized as public and private based on whether read access is controlled or not, respectively. We assume a decentralized identity management ecosystem backed by a permissioned BC when designing the proposed protocol, in particular, Hyperledger Fabric [12], a private permissioned BC.

2.2 ZK-SNARKs

ZK-SANRKs is an efficient construction to prove in zero-knowledge, a satisfying assignment to the class of problems called Quadratic Span Program (QSP) [14]. QSP is an NP-complete problem. According to the principles in complexity theory, for any NP problem L and an NP-complete problem M, there is a reduction function f, which is computable in polynomial time, s.t. $L(x) = M(f(x))$. Accordingly, ZK-SANRKs can be used to prove in zero-knowledge, a satisfying assignment to any NP problem following these high level steps: i) formulate the decision problem D as an NP statement, which is expressed in the following form: Given a set of public inputs X, I know a set of secret inputs W, s.t. condition D holds on X and W

(i.e. the satisfying assignment is constituted by X and W); ii) write an algorithmic program P to solve D; iii) convert P to an arithmetic circuit C; iv) convert C to a QAP (Quadratic Arithmetic Program - a variant of QSP); v) prove/verify satisfiability for the QAP in zero knowledge.

The ZK-SNARKs construction is expressed in following three algorithms: ***i) Generator (G)***: takes as inputs: C and secret parameters λ, and outputs a proving key (pk) and a verification key (vk). This is a one time setup step run by a trusted party, after which λ should be destroyed in order to preserve the soundness of the proofs. (pk, vk) := G(C, λ). ***ii) Prover (P)***: takes as inputs: C, pk and the satisfying assignment - which may have both private inputs w and public inputs x, and outputs the proof Φ. Φ := P (C, pk, w, x). ***iii) Verifier (V)***: takes as inputs: vk, Φ and public inputs x provided by the prover, and outputs the decision d as true, iff (w, x) is a satisfying assignment to P, and false, otherwise. d := V(vk, Φ, x).

In ZK-SNARK (*Zero-Knowledge Succinct Non-interactive Argument of Knowledge*), the *Zero-Knowledge* property enables participants to keep transaction information confidential, and still prove to peers that transactions are valid according to the smart contract. *Succinctness* makes the size of such proofs small (≈2KB) and verification time in the orders of milliseconds, irrespective of the complexity of the business logic defined in the smart contract. The *Non-interactive* property enables multiple peers to verify the proofs independently without interacting with the prover. There are other zero-knowledge proof constructions developed to achieve similar goals without a trusted setup, such as ZK-STARK [3] and Bullet Proof [8]. We use ZK-SNARK since it is more efficient and practical compared to the other constructions.

3 SYSTEM MODEL AND THREATS

3.1 System model

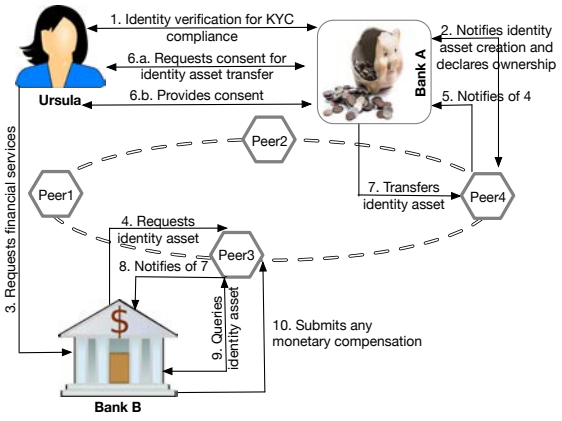

Figure 1: Plain protocol model for decentralized identity asset exchange, with no privacy features. This is the version 0 (V0) in the incremental development of a privacy preserving identity exchange protocol.

The following steps describe the basic flow of identity asset exchange for the use case mentioned in Section 1, which is illustrated in Figure 1: 1) When Ursula consumes financial services for the first time from bank A, identity verification and due diligence are performed by bank A to verify KYC compliance of Ursula, and the resulting identity asset is stored at bank A. Note that the details of how the identity verification is performed is out of scope of the identity exchange protocol. 2) Bank A notifies the identity ecosystem about the identity asset creation and claims its ownership. 3) At a later point in time, Ursula requests financial services from bank B and they discover by some means (either by querying the BC or using Ursula's private records, which we will discuss in Section 4) if the required identity asset is already created for Ursula. 4) If this is the case, Bank B requests from the identity ecosystem the relevant identity asset of Ursula. 5) Bank A receives the request submitted by bank B, via the transaction notification system of the BC. 6.a) If bank A decides to share the identity asset, bank A requests the consent from Ursula to transfer the identity asset to bank B. 6.b) Ursula provides her consent. 7) Bank A transfers the identity asset, along with Ursula's consent, via the identity ecosystem. 8) Bank B receives the notification about the valid identity asset transfer. 9) Bank B queries the identity asset from the ledger. 10) Optionally, if the transferred identity asset is correct, bank B submits a monetary compensation (if it is required, by the policies of the identity ecosystem) to bank A. This could be a bitcoin payment sent to bank A, if the underlying BC supports bitcoin transactions, which bank A can redeem later.

We make the following **three basic assumptions** in the context of decentralized identity asset exchange: 1) There is a criteria to define and verify uniqueness of an identity asset so that if multiple copies of a particular type of identity asset are created by multiple parties using identity information of a given user, they all become digitally identical (e.g. defining a standard format for an identity asset used for a particular identity verification scenario and considering the cryptographic hash (CRH) of the identity asset to be the criteria for verifying uniqueness). 2) If a particular type of identity asset is created for a given user in the identity ecosystem, all the SPs requiring a similar identity asset from the user should re-use it, without re-creating it. 3) The trusted CA, which issues the identity certificates to the actors of the BC network, does not collude with any actor in the BC.

Note that the plain protocol model for identity asset exchange shown in Figure 1 does not include any privacy features, i.e. all the participants appear in their real identities and identity assets are transferred in plain text. Although such a model is not used in a real world deployment, we use it as the baseline (version 0 - V0) protocol to identify what properties should be achieved in order to guarantee that an identity asset exchange protocol is secure, and to analyze the challenges in achieving the same security properties when privacy features are added to the protocol incrementally.

3.2 Threat model for protocol security

In what follows, we first identify the different ways in which an adversary can compromise the security of the plain protocol model. **1) Compromising *correctness***: A malicious identity asset provider (e.g. bank A) transfers an identity asset in step 6, which is different than the one it notified the creation of, in step 2. **2) Compromising *ownership assurance***: A malicious collusion of two of the three parties engaged in an identity asset exchange can compromise the

ownership assurance of one of the two legitimate owners as follows: i) a different user can collude with bank A to impersonate Ursula at bank B; ii) bank A and bank B can collude to transfer the identity asset without Ursula's consent; iii) after bank B obtains the identity asset from bank A, Ursula and bank B can collude to act as the original owners and transfer the identity asset to a different bank. Attacks i) and ii) are possible by sending a fake consent in step 6.b and attack iii) is motivated by any benefits obtained from the identity asset exchange, such as monetary compensation paid by the identity asset consumer to the identity asset provider. **3) Creating *counterfeits*** of an identity asset: Due to the same motivation for attack 2.iii, bank B may execute step 2 using the identity asset received from bank A, hence creating a counterfeit. **4) Compromising *financial fairness***: After receiving the identity asset, bank B can skip step 10.

Accordingly, *correctness*, *ownership assurance*, *counterfeits elimination* and *financial fairness* are key requirements to be addressed, in order to guarantee the security of an identity asset exchange protocol. In what follows, we describe the simple mechanisms that should be incorporated into protocol V0, in order to address those requirements. **1) *Correctness*** : The smart contract that defines the protocol requires from bank A to submit the cryptographic hash (CRH) of the identity asset in step 2. In step 7, bank A submits a pointer (e.g. transaction ID) to step 2 associated with the identity asset being transferred. Then the peers running the smart contract validate correctness by computing the CRH of the transferred identity asset and comparing it with the CRH submitted in step 2 associated with the same identity asset. **2) *Ownership assurance***: The protocol requires: i) from bank A to submit the CRH of the public keys of the two owners in step 2; ii) from Ursula and bank A to sign, using their private keys, the messages sent in step 6.b (consent by the user) and step 7 (identity asset transfer), respectively. Then the peers verify the signatures and confirm that the original owners of the identity asset indeed performed the transfer. Note that an adversary can replay the message sent in step 7. Therefore, the protocol should also require bank B to send a random nonce in the identity asset request message (step 4), which Ursula and bank A should include in the messages they sign in steps 6.b and 7. **3) *Counterfeits elimination***: To ensure that duplicates of an identity asset do not exist, the peers maintain a hash table storing the information submitted in step 2 of the protocol, indexed by the CRH of the identity asset. Each time step 2 is executed for a newly created identity asset, the peers check if the newly submitted CRH already exists in the hash table, in which case the peers reject it as an attempt to create a counterfeit of an identity asset. **4)*Financial fairness*** : It is unlikely that bank B skips step 10 in protocol V0 where it appears with its real identity, as it would damage its reputation. Even if bank B does so, it is easy to take actions against bank B for the dishonest behavior.

3.3 Threat model for users' privacy

In what follows we discuss an adversary's goals in compromising users' privacy (i.e. learning and tracking information that users do not intentionally share) in protocol V0. **1) Compromising *confidentiality* of users' identity information**: The adversary learns the users' identity information from the identity assets transferred in plain text via the BC in executions of step 7. **2) Compromising users' *transactional privacy***: i) the adversary learns the identity of the parties a user interacts with, because in protocol V0, all participants interact with the identity ecosystem using their real identities; ii) the adversary tracks a user's transaction patterns by linking the transactions that the user carries out with different SPs.

The following modifications to protocol V0 address those privacy concerns. **1) *Confidentiality***: Bank A encrypts the identity asset in step 7, using a key known to bank B. **2) *Anonymity*** of the parties whom a user interacts with: All the participants use a pseudonymous certificate issued by the CA, when interacting with the identity ecosystem. **3) *Unlinkability*** of the user's transactions: i) the participants use different pseudonymous certificates in executing step 2 and each round of identity asset transfer (i.e. steps 4 - 10); ii) bank A does not expose the CRH of the identity asset in plain text in step 2; instead it submits a commitment to the CRH of the identity asset. Otherwise, the identity asset consumers (e.g. bank B), can decrypt the identity asset received in step 9, compute its CRH and track the corresponding identity asset creation transaction (e.g. execution of step 2), in order to infer information such as when is the first time the user has consumed a similar service, etc. Note that in the proposed modifications 2 and 3 above, the participants obtain pseudonymous identity certificates from the CA, which do not include any identifiable attributes, but the public key of a new RSA key pair.

3.4 Challenges in preserving users' privacy and ensuring security of the protocol

In what follows we discuss how the aforementioned mechanisms for ensuring security and privacy properties conflict, which raise challenges in developing a privacy preserving and secure identity asset exchange protocol. We discuss such challenges w.r.t. three versions of the incrementally developed protocol, each of which is a result of incorporating privacy features one by one, into V0.

V1-*Confidentiality*: When the identity asset is encrypted, peers cannot verify its *correctness* simply by computing its CRH as in V0. The mechanisms for preserving *ownership assurance*, *counterfeit elimination* and *financial fairness* used in V0 are not affected though.

V2-*Confidentiality and Anonymity*: When the participants execute the protocol with pseudonyms, the *correctness* enforcement mechanism is not affected compared to V1. However, the mechanism to preserve *ownership assurance* in V0/V1 is affected, because there is the threat of a malicious identity consumer (e.g. bank B) sending a 'contract' which they want the identity asset provider and/or the user to sign, instead of a truly random nonce in step 4. Therefore, parties can not give away a signature on a challenge nonce, as a proof of ownership of the private key. There is no effect on the *counterfeit elimination* mechanism used in V0/V1, except that the owners of the identity asset should use the key pair related to their pseudonymous identity in steps 2, 6.b and 7. The *financial fairness* enforcement mechanism used in V0/V1 is affected, because pseudonymous bank B can intentionally skip step 10. Involving the CA to de-anonymize such identity consumers adds lot of overhead. Instead, this should be addressed by the protocol itself.

V3-*Confidentiality, Anonymity and Unlinkability*: It is more challenging to ensure *correctness* when unlinkability is enforced,

because now even the CRH of the identity asset is not exposed in step 2. It is also more challenging to preserve *ownership assurance* than in V2, because now the two owners of the identity asset use different pseudonyms in step 2 and in each round of steps 4-10, in contrast to using a single pseudonym across all transactions as in V2. The hash table based *counterfeit elimination* mechanism is no longer sufficient now, because the hash of the identity asset is not exposed in step 2 and any two parties appearing with new pseudonyms can execute step 2, submitting a commitment to a CRH of any identity asset. Preserving *financial fairness* also needs improved mechanisms because we need to make sure that the underlying monetary payment system also preserves unlinkability; otherwise, parties can be de-anonymized via linkability in the payment system.

Table 1 summarizes how introducing the properties for preserving users' privacy into protocol V0, in an incremental manner, affects the mechanisms for achieving the identified security properties. A checkmark in a given cell indicates that the combination of privacy properties in the given column pose challenges to the mechanism used in the previous version of the protocol, for ensuring the security property in the given row.

Table 1: Effect of introducing the properties for preserving users' privacy, in an incremental manner, on the properties for ensuring security of the protocol.

Properties to ensure the protocol is secure:	Properties to ensure users' privacy:		
	confidentiality	confidentiality + anonymity	confidentiality + anonymity + unlinkability
counterfeit elimination	-	-	✓
correctness	✓	-	✓
ownership assurance	-	✓	✓
financial fairness	-	✓	✓

4 PROTOCOL DESIGN

In what follows, we present the design of the proposed protocol, named PrivIdEx, addressing the aforementioned challenges. As shown in Figure 2, PrivIdEx involves four parties: Identity Asset Provider (IAP), User, Identity Asset Consumer (IAC), and Blockchain (BC). PrivIdEx consists of four phases, each of which serves one or more specific purposes and groups together a set of relevant steps from the identity asset exchange flow shown in Figure 1. Phase 0 is executed only once and phases 1-3 are executed each time an identity asset is exchanged. Note that T represents the transactions posted to the BC by participants, by invoking different functions in the smart contract, W represents the validation steps executed by peers on the transactions and M represents the messages exchanged between two parties offline (i.e. without involvement of the BC). The purpose(s) of each phase is (are) described as follows, with examples from protocol V0.

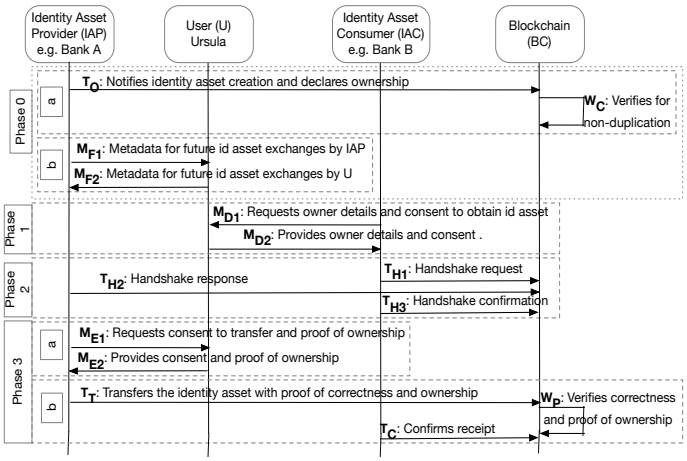

Figure 2: Overview of PrivIdEx design.

Phase 0 consists of two sub phases. Phase 0.a, executed between the IAP and the BC, serves for ownership declaration (T_O) by IAPs for newly created identity assets and verification by peers that such identity assets are not counterfeits. E.g. in protocol V0, the IAP sends the CRH of the public keys of the two owners and the CRH of the identity asset in T_O, which the peers verify in W_C using the hash table of ownership declarations maintained in the BC (see Section 3.2). Phase 0.b, executed between the IAP and the user, allows them to exchange meta data to be used in future identity asset exchange(s).

Phase 1 is executed between the IAC and the user. In M_{D1}, the IAC requests certain details of the IAP that has created the required identity asset (if any), and the user's consent for requesting such identity asset from the corresponding IAP. The meta data saved by the user in phase 0.b is used to construct the user's response (M_{D2}).

Phase 2 consists of a three-way handshake between the IAC and the IAP over the decentralized identity ecosystem. The IAC initiates the handshake by submitting to the BC a message (T_{H1}) addressed to the IAP who owns the identity asset. T_{H1} includes the user's consent received in M_{D2} and is signed by the IAC. All the participants receive a notification about T_{H1} via the BC. The corresponding IAP verifies the user's consent and submits a response handshake message (T_{H2}). The IAC acknowledges T_{H2} by sending a confirmation (T_{H3}). The handshake phase allows the IAP and the IAC to negotiate certain information pertaining to the identity asset exchange, e.g. in protocol V0, the IAC sends the random nonce to be signed by the two owners during the transfer phase, for the proof of ownership. The peers validate a handshake by verifying if T_{H2} and T_{H3} are associated with a corresponding T_{H1} and T_{H2}, respectively.

Phase 3 is where the actual identity transfer happens. In phase 3.a, executed between the IAP and the user, the IAP requests the user, via M_{E1}, to provide consent for transferring the identity asset and the proof of user's ownership of the identity asset. The user responds accordingly via M_{E2}. In phase 3.b, the IAP transfers the identity asset along with M_{E2} and the proof of its ownership of the identity asset, via T_T. The peers verify in W_P, that T_T is associated

with a valid handshake, and verify correctness and proofs of ownership. After receiving the notification about T_T from the BC, the IAC checks the transferred identity asset and posts a confirmation to the BC about the successful receipt of the identity asset in T_C.

In what follows, we present how those different phases are utilized and enhanced to address the challenges for achieving the security properties of the three versions of the incremental design of PrivIdEx (see Section 3.4).

4.1 V1- Confidentiality Preserving Protocol

When confidentiality is enforced, the IAP and the IAC agree on a key K for encrypting the identity asset (A), by integrating the Diffie-Hellman key exchange protocol into the three-way handshake in phase 2. In T_T, the IAP submits the encrypted identity asset: $C = Enc_K(A)$. Due to encryption of the identity asset, *correctness* is the only security property that is more challenging to achieve in V1, compared to V0 (see Section 3.4). To prove correctness, the IAP submits in T_T, the transaction id of T_O associated with A and a zero-knowledge (ZK) proof (Φ_1), proving the knowledge of a satisfying assignment to the NP statement - **NS1**: *Given a cipher text C', a hash value a', I know the following secrets: an identity asset A' and a key K' s.t $a' = CRH(A')$ and $C' = Enc_{K'}(A')$*. The IAP proves the satisfying assignment to NS1 with $A' = A$ and $K' = K$ as secret inputs, $C' = C$, and a' = the CRH of A submitted in the corresponding T_O, as the public inputs. If Φ_1 is verified successfully, the peers accept that T_T encrypts the same identity asset whose ownership was declared in the corresponding T_O.

4.2 V2 - Confidentiality and Anonymity Preserving Protocol

When anonymity is enforced: i) the IAP includes the two owners' pseudonyms in T_O instead of their real identities; ii) the IAP and the user records each other's pseudonym in phase 0.b; iii) the user sends to the IAC, via M_{D2}, the pseudonym of the IAP who created the identity asset; iv) the transactions posted to the BC are signed using the pseudonyms; v) when transaction notifications are received from the BC, each participant checks if the transaction messages are addressed to their pseudonym and responds accordingly. Due to the threats by the pseudonymous participants, *ownership assurance* and *financial fairness* are more challenging to achieve in V2 (see Section 3.4).

To prove ownership in V2, the user and the IAP create ZK proofs (Φ_{2U} and Φ_{2P} respectively) on the NP statement **NS2**: *Given a public key PK, a message M, I know a secret signature S, s.t. RSA_Sig_Verify(M, S, PK) = True*, where S = RSA_Sig(M, private key of PK). RSA_Sig outputs a signature, given a RSA private key, and a message M; RSA_Sig_Verify outputs True iff S is the correct signature for M, using the private key associated with PK. The user and the IAP prove satisfying assignments to NS2 with PK = the public key of the pseudonym included in the T_O associated with the identity asset being transferred, M = the random nonce sent by the IAC via T_{H1}, as public inputs, and S = the signature created on such nonce with the private key associated with the pseudonym, as the secret input. Proving the knowledge of S on the nonce sent by the IAC, without revealing S, avoids the risk of giving a signature on a potential 'contract' (see Section 3.4).

Φ_{2U} and Φ_{2P} are integrated in to the protocol design as follows. The IAP sends to the user, via M_{E1}, the nonce it received from the IAC in T_{H1}. The user sends Φ_{2U} via M_{E2}. Then the IAP creates Φ_1 (see Section 4.1) and Φ_{2P}, and sends T_T to the BC along with the transaction id of T_O associated with A, Φ_1, Φ_{2U} and Φ_{2P}. The peers validate T_T, by verifying correctness and ownership assurance via the ZK-proofs provided in T_T.

To ensure *financial fairness* in V2, the handshake phase is used as follows. The IAP informs the IAC about the required monetary compensation for transferring the identity asset via T_{H2},. If the IAC agrees to pay, it includes in T_{H3} a reference to a bitcoin payment made with a locking condition such as: *'the IAP can can unlock the payment only by using either of these: i) a T_C submitted by the IAC, indicating a successful receipt of the identity asset; ii) a successful W_P by the peers, if a T_C is not submitted after time 't' since the time of T_T'*. Such a locked payment [2, 24] made during the handshake phase prevents a pseudonymous IAC from skipping the required payment. The IAP can redeem the payment only if it transfers the correct identity asset, ensuring financial fairness to both parties.

4.3 V3 - Confidentiality, Anonymity and Unlinkability Preserving Protocol

As per Section 3.4, it is more challenging to achieve all four security properties in V3, compared to V2. In what follows we describe how each phase of the protocol is enhanced to address those challenges. Prior to phase 0.a, the user creates a commitment to the public key of her real identity (U_{pk}): $C_U = commit(U_{PK}, r_u)$ and sends C_U to the IAP. The IAP creates a commitment to the public key of its real identity (P_{pk}): $C_P = commit(P_{PK}, r_p)$ and a commitment to a - the CRH of the newly created identity asset: $C_a = commit(a, r_a)$. The IAP sends T_O to the BC, including the ownership declaration $O = C_U|C_P|C_a$, where | denotes concatenation, signed by a new pseudonym key.

The basic idea of *counterfeit elimination* in V3 is as follows. Let $B = \{a_1, a_2, ..., a_n\}$ be the set of CRH values of the identity assets associated with all the previous valid executions of T_O. This set is represented by a unique polynomial P of degree n, that has a_1, a_2,..., a_n as its roots. The polynomial P is represented as $P(x) = \prod_{i=1}^{n}(x - a_i)$. Let P_i be the i^{th} coefficient of P, for $i = 0, 1, ..., n$. P is initialized as $P(x) = 1$, and its degree increases with each new valid T_O. Hence, at any given time, if a number n of valid identity assets have been created in the identity ecosystem, then there is a number $n + 1$ of P_is. If the evaluation of $P(x)$ with $x = a$ results in zero (i.e. $P(a) = \sum_{i=0}^{n} P_i.a^i = 0$), it implies that the identity asset, whose CRH value is a, is a duplicate of an existing one. In order to preserve unlinkability, peers should only learn if $P(a) = 0$ or not, and nothing else. Therefore, the set of P_is are secretly encoded before being stored in the BC and $P(a)$ is computed in the encoded domain before being revealed to peers.

To prove that the created identity asset is not a counterfeit, the IAP submits T_O to the BC, including O and the following four items:
(I1) The result of computing $P(a)$ in the encoded domain, which is denoted by l, i.e. $l = En(P(a))$.
(I2) A ZK-proof Φ_3, proving that l is correctly computed and that the same a is used to compute both C_a (in O) and l.

(I3) The secretly encoded set of coefficients P'_i of the updated polynomial P', which has a as one of its roots (i.e. $P'(x) = P(x).(x - a)$, and therefore, P'_0 = -$a.P_0$, $P'_i = P_{i-1}$ - $a.P_i$, for $i = 1, ..., n$, and $P'_{n+1} = 1$).

(I4) A ZK-proof Φ_4, proving that I3 is correctly computed, using the same a used in C_a.

Details of the mechanism for counterfeit elimination are as follows. Let E be an additive threshold homomorphic encryption scheme, whose public key is known to everyone, but the secret key is distributed among the peers s.t. a group of at least $t + 1$ of them are required to perform decryption. E is instantiated with the Elgamal encryption scheme over a group G of order q. The public key $h = g^s$, where g a generator in G and s is the private key, which is distributed among the threshold peers. E is initialized with a distributed key generation protocol [13]. The encryption of an element $g' \in G$ is defined as: $E(g') = (g^k, h^k g')$, where $k \in Z_q$ is randomly chosen. An encoding scheme En to encode elements in Z_q is defined based on E as follows. $En(z) = (g^k, h^k g^z)$, where $z \in Z_q$. In fact, $En(z) = E(g^z)$. $En(\cdot)$ is an additively homomorphic encoding of z which allows us to carry out computation on polynomials whose coefficients are presented in encoded form. Moreover, while the value z cannot be recovered in general from $En(z)$, for our purposes we only need to be able to decide for a given $En(z)$ whether z is zero or not. In addition, the secrecy of z is guaranteed by the underlying Elgamal encryption scheme $E(\cdot)$.

Let the set of encoded P_is stored in the BC be $S_n = \{En(P_i) = E(g^{P_i}),$ for $i = 0, 1, ..., n\}$. Details of how the IAP computes I1-I4 are as follows.

(I1) Compute $l = En(P(a))$, given the set S_n:

- Compute a fresh encoding of zero as: $e_0 = En(0) = (g^k, h^k)$ for random $k \in Z_q$, in order to randomize the encoding of l.
- Then l is computed as follows:

$$l = (\prod_{i=0}^{n} (En(P_i)^{a^i})).e_0 \quad (1)$$

(I2) Create Φ_3 on the NP statement - **NS3**: *Given a commitment C_{IA}, an encoding L, and a set S of encoded coefficients of a polynomial P, I know secrets: r, a′, and k′ s.t. $C_{IA} = commit(a', r)$, $L = En(P(a') + 0) = En(P(a')).e_0$ and $e_0 = (g^{k'}, h^{k'})$.*

The IAP proves a satisfying assignment to NS3 with $C_{IA} = C_a$ in O, $L = l$ in (I1), and $S = S_n$ stored in the BC at the time of submitting T_O, as public inputs; and $r = r_a$ and $a' = a$ used in C_a and $k' = k$ used in e_0, as secret inputs.

(I3) Let the set of P'_is in the encoded domain be $S_{n+1} = \{En(P'_i)$ for $i = 0, 1, ..., n + 1\}$. S_{n+1} is computed as follows.

- Compute a fresh encoding of zero as: $e_0 = En(0) = (g^{k_0}, h^{k_0})$ for random $k_0 \in Z_q$, and $En(P'_0) = En((-a).P_0 + 0) = En(P_0)^{-a}.e_0$.
- For $i = \{1, .., n\}$, choose $k_i \in Z_q$ randomly and compute: $e_0^i = En(0)$, and $En(P'_i) = En(P_{i-1} + (-a).P_i + 0) = En(P_{i-1}).En(P_i)^{-a}.e_0^i$.
- Choose $k_1 \in Z_q$ randomly and compute $En(P_{n+1}) = En(1)$.

(I4) Create Φ_4 on the NP statement - **NS4**: *Given a commitment C_{IA}, a set S of encoded coefficients of a polynomial P^n and a set S' of the updated polynomial P^{n+1}, I know secrets: r, a′, k'_0, k'_1 and k'_i for $i = 1, ..., n$ s.t.:*

- *$C_{IA} = commit(a', r)$,*
- *$En(P_0^{n+1}) = En(-a'.P_0^n + 0) = En(P_0^n)^{-a'}.e_0$ and $e_0 = (g^{k'_0}, h^{k'_0})$,*
- *for $i = 1, .., n$, $En(P_i^{n+1}) = En(P_{i-1}^n).En(P_i^n)^{-a'}.e_0^i$ and $e_0^i = (g^{k'_i}, h^{k'_i})$,*
- *$En(P_{n+1}^{n+1}) = (g^{k'_1}, h^{k'_1}.g^1)$.*

The IAP proves a satisfying assignment to NS4 with $C_{IA} = C_a$, $S' = S_{n+1}$ computed in I3 above, $S = S_n$ stored in the BC, as public inputs, and with $a' = a$, $r = r_a$ used in C_a, $k'_0 = k_0$ used in $En(P'_0)$, $k'_1 = k_1$ used in $En(P'_{n+1})$ and $k'_i = k_i$ used in $En(P'_i)$ for $i = 1, .., n$, of I3, as secret inputs.

Once the IAP submits T_0 along with O and I1-I4, the validation W_C (see Figure 2) by peers is executed as follows. If the ZK-proof Φ_3 is successfully verified, each peer i executes the following steps to randomize l: choose $r_i \in Z_q$ randomly, compute $l_i = l^{r_i}$ and broadcast l_i to all the other peers together with a ZK-proof Ω_1^i, proving that the peer knows the value r_i. Then each peer computes l' as the sum of the cipher texts received from all the peers, i.e. $l' = \prod_{i=1}^{m} (l^{r_i}) = E(g^{P(a)(\sum_{i=1}^{m}(r_i))})$, where m is the number of peers. Then peers collectively decode l'. Note that we choose to randomize l and then decode l', instead of just decoding l, due to a potential collusion attack by an IAP and a peer to check if a given value matches the CRH of an already created identity asset. We refer the reader to the technical report [16] for the details of such attack and the definition of the NP statement associated with Ω_1.

If l' does not decode to an encoding of zero (i.e. l' does not decrypt to 1), peers verify the ZK-proof Φ_4. If Φ_4 is successfully verified, peers accept T_O as a valid ownership declaration, which is not associated with a counterfeit, and S_{n+1} as the encoded set of coefficients of the updated polynomial to be stored in the BC. Accordingly, protocol version V3 of PrivIdEx preserves counterfeit elimination, without revealing the CRH values of the identity assets associated with transactions T_O, thereby preserving unlinkability across T_O and T_T associated with the same identity asset. To enable proof of ownership and correctness, while preserving unlinkability, after successful verification of T_O, the peers add the CRH of the ownership declaration O, i.e. f = CRH(O), as a leaf in the Merkle hash tree (MHT) data structure stored in the BC. This marks the end of phase 0.a for protocol V3.

The basic idea of proving ownership during identity asset transfer (phase 3.b) is to prove that the user and the IAP know a *path P* in the MHT from a leaf f, which contains the CRH of a valid ownership declaration O, to the root RT and that the user and the IAP own the private keys associated with the public keys committed in C_U and C_P of such O, respectively. To prove correctness, the IAP proves a similar statement, that is, the IAP knows a path P from f, which contains O with a commitment C_a to a CRH value that matches the CRH value of the identity asset being transferred, to RT. Note that both the owners of the identity asset should prove in zero-knowledge, the knowledge of the same path P in the MHT.

During the identity asset transfer phase, when the IAP requests the user's proof of ownership to the identity asset via M_{E1}, the user creates a ZK-proof Φ_5 proving her ownership and sends it to the IAP via M_{E2}. The IAP then creates a ZK-proof Φ_6 proving its ownership and correctness and transfers the encrypted identity asset along with Φ_5 and Φ_6 via T_T. The NP statements associated with Φ_5 and Φ_6, of which the basic idea has been outlined above, are included in the technical report associated with the paper [16]. Peers verify

Φ_5 and Φ_6 in W_P and confirm that T_T preserves correctness and ownership assurance.

In order to ensure financial fairness while preserving unlinkability, protocol V3 should integrate an anonymous and an unlinkable payment system such as Zerocash [4], which also enables making locked payments described under protocol V2.

5 IMPLEMENTATION AND EXPERIMENTS

In what follows, we present the details of the implementation and experiments on the main building blocks of PrivIdEx. Our goals are two folds: i) understanding the challenges and feasibility of the implementation of some of the most complex building blocks, e.g. ZK-proofs for the NP statements used in PrivIdEx; ii) evaluating circuit size, execution times and storage requirements of ZK-proofs for the NP statements. Experiments were run in a desktop machine running Ubuntu 18.04.1 LTS with 16GB memory and Intel i7-4790 CPU @ 3.6GHz.

We used the ZK-SNARK construction (see Section 2.2) to prove/verify satisfying assignments to the NP statements listed in Section 4. ZK-proofs for the NP statements were created using ZK-SNARKs, following the five steps process listed in Section 2.2. First, the cryptographic primitives in the NP statements were instantiated with specific algorithms. Then the circuits for the NP statements were designed and implemented using the Jsnark [17] framework. The Jsnark framework allows one to write circuits in a format compatible with the ZK-SNARK compilers and provides building blocks called 'gadgets' for designing circuits. In order to compile the circuit into a QAP and to prove/verify in zero-knowledge the satisfiability of the assignment given by the prover, Jsnark interfaces with Libsnark [23] - the widely used library implementing the ZK-SNARK construction. The challenges in this process include, but not limited to: i) gadgets for certain cryptographic primitives, such as Elgamal encryption used in NS4, are not yet available in Jsnark; ii) as different existing Jsnark gadgets accept inputs in different formats, we had to standardize the input formats of these gadgets before wiring them together to form the required circuit.

In circuit 1 (see Figure 3) built for the NP statement NS1 used in V1 of PrivIdEx, the cryptographic hash (CRH) algorithm is instantiated with the widely used SHA-256 and the symmetric encryption algorithm is instantiated with SPECK128 [10], due to its light weight properties. The SPECK128 gadget is wrapped with the gadget implementing symmetric encryption in CBC mode. We evaluated the circuit size (see Table 2), running time (see Figure 4), and storage requirements (see Figure 5) associated with the three algorithms of ZK-SNARKs for circuit 1, by varying the size of the identity asset (A'). Increase in the size of A' increases the size of the proving key and the circuit (i.e., number of constraints in the circuit), which in turn affects the running times of the key generator, which takes the circuit as inputs, and the prover, which takes both the circuit and the proving key as inputs. However, the increase in running time of the prover is much less than that of the key generator, which is good because the prover is run each time an identity asset is exchanged, whereas the key generator is run only at system setup. Proof size, verification key size, and verifier running time are constant irrespective of the size of the secret input A'. Note that for the scope of this paper, we assume a fixed size for the identity assets (those with shorter sizes can use padding) exchanged in a given deployment of PrivIdEx, because it is an overhead to deploy multiple circuits for different sizes. We discuss the mechanisms to allow identity assets of different sizes in the technical report [16].

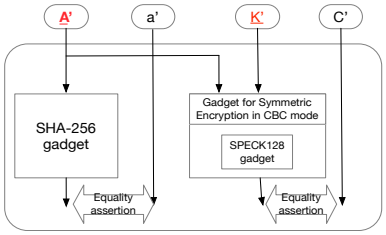

Figure 3: Circuit 1 built for NS1: *Given a cipher text C', a CRH value a', I know the following secrets: an identity asset A' and a key K' s.t $a' = CRH(A')$ and $C' = Enc_{K'}(A')$.*

Size of (A')	64 bytes	128 bytes	256 bytes	512 bytes	1024 bytes
Number of constraints	74,429	126,505	230,675	451,210	855,569

Table 2: Circuit size vs the size of the identity asset (A'), for Circuit 1.

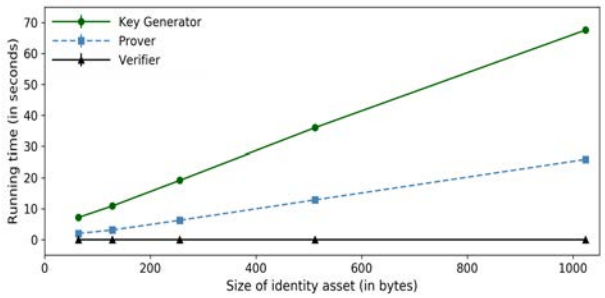

Figure 4: Running time vs the size of the identity asset (A'), for Circuit 1.

In circuit 2 (see Figure 6) built for the NP Statement NS2 used in V2 of PrivIdEx, the signature S is the only secret input, which is created by the provers (i.e. the IAP and the user) locally (i.e. outside of the circuit). Although PK theoretically consists of both RSA modulus and public exponent, only the RSA modulus is given as input PK, and the public exponent is set to a hard coded constant, according to the implementation details of the RSA algorithm [6]. In order to decide the size of the nonce M with optimal trade-off between security and performance of ZK-SNARKs for circuit 2, we evaluated the performance by varying the size of M. However, as shown in Table 3, there was a negligible impact on the performance when the size of the public input M was doubled. Therefore, we decided to use 128 bits as the size of the nonce.

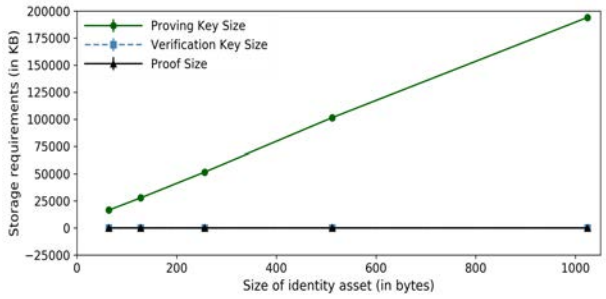

Figure 5: Storage size vs the size of the identity asset (A'), for Circuit 1.

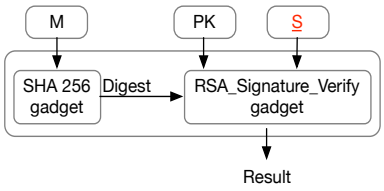

Figure 6: Circuit 2 for NS2: *Given a public key* PK*, a message* M*, I know a secret signature* S*, s.t RSA_Sig_Verify*(M, S, PK) = *True*, where S = RSA_Sig(M, private key of PK).

	64 bits	128 bits
Circuit size (number of constraints)	119,146	119,344
Key gen running time	12.8659(s)	12.8729(s)
Proving key size	32,903(KB)	32,938(KB)
Verification key size	3.2856(KB)	3.597(KB)
Prover running time	3.38(s)	3.3827(s)
Proof size	0.28(KB)	0.28(KB)
Verifier running time	0.0045(s)	0.0045(s)

Table 3: Performance numbers vs the size of the nonce (M), for Circuit 2.

A summary of the insights derived from the above experiments are as follows: 1) Increase in the size of *secret* inputs increases circuit size and prover key size, thereby increasing the running times of the key generator (which is run only once for the entire system lifetime) and the prover (which is run only once at ownership declaration and at each round of exchange of an identity asset). 2) Increase in the size of public inputs has negligible impact on the performance of ZK-SNARKS associated with a given circuit. 3) Proof size, verification key size, and verifier running time are negligibly affected (if at all) by the circuit complexity (e.g. circuit 1 and circuit 2 use different gadgets with varying complexity), size of secret inputs (e.g. experiments on circuit 1,) and size of public inputs (e.g. experiments on circuit 2). This makes using ZK-proofs based on ZK-SNARKs very suitable for use in PrivIdEx to ensure privacy and security properties of identity asset exchange in a decentralized identity ecosystem backed by a BC network, where multiple peers may run the verification algorithms associated with W_C and W_P (see Figure 2). We refer the reader to the technical report [16] for the details of the remaining circuits.

6 SECURITY AND PRIVACY PROOFS

In what follows, we prove that PrivIdEx (V3 - which addresses all three privacy requirements - see Section 4.3) protects against the threats mentioned in the threat models for user privacy (see Section 3.3) and protocol security (see Section 3.2).

The following lemma establishes that an adversary (referred to as Adv1), whose goal is to compromise the user's privacy (see Section 3.3), does not learn any information on the identity asset and the identity of the parties the user interacts with. Based on the information that Adv1 learn from the protocol transcripts of PrivIdEx, Adv1 cannot link different transactions of the same user.

Lemma 6.1. *PrivIdEx (V3) preserves confidentiality of the user's identity asset and anonymity and unlinkability of the user's transactions against Adv1.*

Proof (informal): Based on the security of the Diffie-Hellman key exchange used to establish a key between the IAP and the IAC, during the handshake in phase 2 of the protocol, Adv1 cannot learn the key used to encrypt the identity asset in T_T of phase 3.b (see Figure 2). Hence, *confidentiality* of the identity asset of the user is preserved against Adv1.

Due to the computationally hiding property of the underlying commitment scheme, the actual identities of the IAP and the user are not revealed to Adv1 via commitments: C_P and C_U included in the ownership declaration O of T_O in phase 0.b. Therefore, Adv1 does not learn the identity of the IAP who creates an identity asset for a user as well as the identity of the user for whom the identity asset is created, during phase 0.b. All the transactions posted to the BC include senders' and intended recipients' pseudonyms. A pseudonym P of a participant, i.e. P = CRH(public key in the pseudonymous certificate) is indistinguishable from a random string. Therefore, Adv1, which does not collude with the CA, does not learn the identity of the parties interacting via the BC. Due to the zero-knowledge property of ZK-SANRKs, the identity of which the ownership is proved in Φ_5 and Φ_6 is not revealed to Adv1 in T_T. Anonymity of the underlying payment scheme, which is used to pay any required monetary compensation, ensures that Adv1 does not learn the identity of the IAP or the IAC via the associated payment transactions. Therefore, throughout the protocol execution, *anonymity* of the participants is preserved from Adv1.

The different pieces of information involved in the protocol execution that Adv1 can use to link different transactions of the same user, are as follows: i) identity (i.e. pseudonyms) of the parties; ii) the CRH of the identity asset; iii) cipher text encrypting the identity asset; iv) any payment transactions created to pay monetary compensations for the identity assets. Since new pseudonyms are used by the participants for the execution of each round of the identity asset exchange, Adv1 cannot link such transactions via pseudonyms. Due to the computationally hiding property of the commitment scheme, the CRH of the identity asset is not revealed to Adv1 via commitment: C_h in O of T_O. Due to the encoding scheme En not allowing one to decode the encoded values in l and S_{n+1}, the CRH of the identity asset is not revealed to Adv1 via any of I1-I4 submitted to the BC via T_O. Due to zero-knowledge property of

ZK-SANRKs, the CRH of the identity asset, which is used to prove correctness in Φ_6, is not revealed to Adv1 in T_T. Hence Adv1 cannot link transactions via the CRH of the identity asset. Due to semantic security of the underlying symmetric encryption scheme, Adv1 cannot link the exchange transactions encrypting the same identity asset. Unlinkability of the underlying payment scheme ensures that Adv1 cannot link the identity asset exchange transactions via the associated payment transactions. Therefore, Adv1 does not learn any information helping to link transactions of the same user, hence, unlinkability is preserved against Adv1. ■ We refer the reader to the technical report [16] for the formal proofs of Lemma 6.1.

The following lemma establishes that an adversary (referred to as Adv2), whose goal is to compromise security of the identity asset exchange protocol (see Section 3.2), cannot create a counterfeit of an existing identity asset, transfer a fake identity asset that has not been legitimately created in the identity ecosystem, and claim false ownership to an identity asset.

Lemma 6.2. *PrivIdEx (V3) preserves correctness, ownership assurance and counterfeit elimination against Adv2.*

Proof (informal): Due to the additive homomorphic property of the encoding scheme based on the Elgamal encryption scheme, and the soundness property of ZK-SNARKs (which is based on the knowledge of coefficient assumption) used to create the ZK-proof Φ_3, Adv2 cannot submit an ownership declaration in T_O for an identity asset which is a counterfeit, without failing the validation W_C run by the peers in phase 0.b. Again, due to the soundness of ZK-SNARKs, used to create Φ_5 and Φ_6, we have that: i) an IAP controlled by Adv2 cannot transfer a fake identity asset because the IAP cannot provide commitments to a valid Merkle hash tree path of an ownership declaration O, which contains a commitment to a CRH value that matches the CRH of the identity asset being transferred, in the satisfying assignment to Φ6; ii) a user and an IAP controlled by Adv2 cannot claim false ownership because they cannot provide commitments to a valid Merkle hash tree path of an O, which contains commitments to the CRH of public keys for which they own the private keys, in the satisfying assignments to Φ_5 and Φ6. ■ We refer the reader to the technical report [16] for the formal proofs of Lemma 6.2.

Theorem 6.3. *PrivIdEx preserves the identified privacy properties against Adv1 and the security properties against Adv2.*

Theorem 6.3 follows from lemma 6.1 and Lemma 6.2.

7 RELATED WORK

Identity management research has a rich history. Here we focus on the proposals focusing on exchanging users' identity information between SPs. Next we discuss approaches for privacy enhancing techniques for BC applications and show that such approaches alone cannot address the problem that we focus on. OpenID Exchange (OIX) [11] and OpenID Connect [22] are industry standards which address some form of identity exchange. Such protocols, however, have one central IDP from whom other SPs obtain identity information of a user, and do not address a user's transactional privacy requirements. Identity Mixer [9] is an anonymous credential system which enables users to authenticate to SPs in an unconditionally unlinkable manner, while selectively disclosing users' identity information. Identity Mixer also involves a central IDP from which the user obtains identity tokens; the IDP is known to the SPs while the SPs are not known to the IDP. The USA and UK governments have developed nation-scale identity management systems which enable government identity consumers to obtain users' identity information from third party identity providers, where consumers and providers are anonymous to each other, in order to preserve users' privacy. However, such systems introduce a government managed broker to mediate the identity exchange transactions, which learns the identity of the two exchanging parties, and hence, can track the users' transactions. More recently, decentralized identity management systems have been proposed that leverage BC technology to avoid centralized parties managing users' identity [26]. However, such systems do not address all the privacy requirements that we consider.

Zerocash [4] enables a sender to transfer bitcoins to a recipient in an anonymous and unlinkable manner. PrivIdEx differs from Zerocash in multile respects, including: i) Zerocash prevents double spending of bitcoins whereas PrivIdEx enables transferring the same identity asset as many times as needed by the legitimate owners to different consumers; ii) there is only one anonymous owner for bitcoins at a given time, whereas there are two owners for an identity asset. Hawk [18] is a framework for privacy preserving smart contracts. Hawk alone does not address all the privacy and security requirements of a given use case, such as the one we focus on, which involves multiple phases and repeating interactions among the participants, based on the same identity asset. Zero Knowledge Asset Transfer (ZKAT) [1] by Heperledger Fabric is based on the unspent transaction output (UTXO) model of bitcoin. Hence, it supports exchange of monetary transactions which cannot be double spent, which is different from our use case. Therefore, ZKAT alone is not sufficient to enable privacy preserving and secure identity asset exchange.

8 CONCLUSION

We proposed PrivIdEx - a privacy preserving and secure protocol for identity asset exchange over a decentralized identity ecosystem backed by a permissioned BC network. PrivIdEx enables different SPs that a user interacts with to re-use the identity assets created for the user, eliminating the cost of repeated identity verification and due diligence processes, without having to worry about privacy and security concerns in doing so. Analysis of the threat model, protocol design and implementation and experiments are presented in an *incremental* approach to help readers understand the specific challenges posed when achieving each of the identified privacy properties and the mechanisms developed to address them, which also helps in selectively enabling those properties as required by a given identity ecosystem.

One potential future extension of PrivIdEx is to integrate it with the Identity Mixer based CA in Hyperledger Fabric [1] BC netowork to achieve unlinkability against collusions between the CA and an actor in the BC, so that we can eliminate the third assumption mentioned in Section 3.1. Other relevant future work is to generalize PrivIdEx to facilitate privacy preserving and secure exchange of any confidential digital asset with multiple owners, such as song lyrics,

music, write-ups, e-books, etc., which has not yet been addressed by the existing digital asset exchanging platforms.

ABSTRACT

Data-driven websites are mostly accessed through search interfaces. Such sites follow a common publishing pattern that, surprisingly, has not been fully exploited for unsupervised data extraction yet: the result of a search is presented as a paginated list of result records. Each result record contains the main attributes about one single object, and links to a page dedicated to the details of that object.

We present RED, an automatic approach and a prototype system for extracting data records from sites following this publishing pattern. RED leverages the inherent redundancy between result records and corresponding detail pages to design an effective, yet fully-unsupervised and domain-independent method. It is able to extract from result pages all the attributes of the objects that appear both in the result records and in the corresponding detail pages.

With respect to previous unsupervised methods, our method does not require any a priori domain-dependent knowledge (e.g, an ontology), can achieve a significantly higher accuracy while automatically selecting only object attributes, a task which is out of the scope of traditional fully unsupervised approaches. With respect to previous supervised or semi-supervised methods, RED can reach similar accuracy in many domains (e.g., job postings) without requiring supervision for each domain, let alone each website.

1 INTRODUCTION AND OVERVIEW

Data-driven websites across many application domains (e.g., real estate agencies, e-commerce) follow a common publishing pattern to provide access to the underlying data: A search interface to query specific types of objects (e.g., products, properties) yields the relevant objects as a list of result records, often paginated into *result pages*. Every result record contains key attributes about one single object, so that the user can get a first impression of the result before deciding to dig further into detailed information. Each result record includes a link to a *detail page*, containing more attributes [24].

To the best of our knowledge, no existing data extraction system has targeted the inherent data intra-site redundancy underlying this popular publishing pattern. Rather, most existing unsupervised approaches [2, 8, 9, 29, 30, 34, 35] can be applied either over a collection of result pages, or over a collection of detail pages. Other approaches rely on the same publishing pattern, but focus only on segmenting the result pages [28], or rely on the much weaker signals arising from the aligning of the labels of the fields on the search form directly against the labels of the data on the detail pages [37]; finally, there are several approaches that focus on the problem of finding redundancy [3, 38] among several sites, but the problem quickly trespasses on that of integrating data coming from autonomous sources [3, 5, 6, 23, 38], a problem that is well known not to have a simple solution [14].

This paper proposes RED, the first data extraction method that leverages this intra-site redundancy to extract data records from result pages. Given a set of result pages and the corresponding set of detail pages from a website, RED infers a collection of *extraction rules* (or simply *rules*). Each one is capable of extracting the values for a certain attribute, e.g., the price of a product, from all the records of a result page. These rules can be applied to every result page of the same website to extract all the relevant data.

We show that exploiting this publishing pattern on a site provides a *low-hanging fruit* opportunity for significantly improving the precision of fully unsupervised data extraction. Existing unsupervised approaches struggle to distinguish relevant data (i.e., object attributes) from noise. Moreover, they are based on a fragile trade-off between the expressiveness of formalism used for describing the extraction rules and the efficiency of the learning task. Conversely, intra-site redundancy distinguishes relevant data that appears both on result records and on detail pages from noise that only appears on either without any supervision, and allows to filter

out noisy candidate extraction rules even when using an expressive formalism to specify them.

Key idea: Exploit the inherent intra-site redundancy between result records and their corresponding detail pages to fully automatically distinguish between slots in the template structure that correspond to actual object attributes.

Figure 1 shows a (simplified) instance of a real estate website that serves as running example. It consists of a result page containing six records along with their corresponding detail pages. The result records and detail pages publish attributes such as Price, Location, number of Beds, and Type of properties. Colored annotations highlight overlapping values for attributes appearing within the records in the result page and the corresponding detail pages. For this example, RED is capable of generating rules extracting the correct values of all attributes for all result records. Figure 2a shows the values extracted by the extraction rules when applied to the example result page in input.

RED generates these rules in three, sequential steps: **(1)** During the *extraction rules generation* step, RED generates two sets of rules, namely the sets of *result rules* and *detail rules*: Figure 2b and Figure 2c show the values extracted by some of the generated rules (shown in Figure 5a and Figure 5b) on the result page and on the detail pages, respectively, for our running example (where r_i (d_i) is the i-th result (detail) rule generated). RED's extraction rules generation algorithm (Section 3) selects the rules from a fragment of XPath [13] expressions that, as empirically verified over many real websites, includes correct extraction rules.

The main challenge in this step is generating a *complete* set of rules efficiently: at least one correct detail rule and one correct result rule is needed for every attribute. It turns out that the completeness of the rules generation algorithm can be achieved only at expense of using a rather expressive family of extraction rules, which means generating many candidate rules, most of which are actually selecting noise.

(2) In the second step, *redundancy seeking*, RED aims to identify pairs of result/detail rules that are considered *redundant*, as they extract the same values for every object. In this quest for redundancy, RED is faced with various challenges. First, in addition to *neat* redundancy between correct rules, there is inevitably a lot of *noisy* redundancy: Some values may occur multiple times across the records (typical if the search is narrow, e.g., only properties in London, or because attributes have a narrow domain, e.g., Beds). Moreover, some values may be repeated several times within the same record or detail page (the third detail page contains a second occurrence of '`Studio`', dotted-blue underlined in Figure 1).

To complicate matters, certain attributes may be optional i.e., not report a value for some result record, such as the Price attribute which is missing for the third and sixth properties of our running example. Both rules r_0 and d_0 select Price values: d_0 is applied to each of the detail pages separately, and can therefore extract the price value if occurring on the page, or it can just report that the value is missing (indicated by *nil*). Conversely, r_0 is applied once on the whole result page (and not on the individual records): it can only extract the price values found on the page, irrespective of which record they belong to. Therefore, taken alone, r_0 is not able to distinguish which records contain a value, and which do not (in our example the third and last record). That leaves r_0 and d_0 mis-"aligned" and without further consideration they would not be considered redundant. This problem has been already tackled by known complex and error prone segmentation techniques for splitting a result page into records [19, 28, 29]. Rather, RED devises an innovative soft-segmentation technique (Section 4.1) which, again, leverages the underlying intra-site redundancy: In particular, RED exploits the presence of navigational links (named *detail links*) that point from each result record to the corresponding detail page. In Figure 1, for each record, one occurrence of the detail link is highlighted (by the departing orange solid arrow). All these detail link occurrences are captured by an extraction rule l, named *link rule*, whose generation is facilitated by the knowledge of urls of the detail pages given in input to RED.

(3) In its final step, named *noise removal*, RED addresses the issue of finding and discarding pairs of rules that exhibit some limited redundancy, but not sufficient to likely be correct extraction rules. RED addresses this challenge by implementing a noise cleaning process (Section 5) that aims at separating the redundancy resulting from the result/detail publishing pattern, from that arising by accident.

Finally, RED outputs all the result extraction rules left after the previous steps along with the special link rule, as shown in Figure 2a for the running example. It is worth noting that, while in this paper we are focusing on data extraction from result page records, RED is perfectly capable of inferring valid extraction rules also for attributes published on the detail pages. Aside of space reasons, we focus on result rules as executing only such rules at a large scale is much cheaper: Once the rules have been generated, no more detail pages have to be crawled, and that is a significant saving, as there are many more detail pages than result pages.

The paper is organized around the main contributions of RED:

- The first formal description of the typical result/detail publishing pattern and the definition of the *Finding Result Attributes Problem* (Section 2);
- A highly accurate, domain independent, and fully unsupervised data extraction method that leverages the redundancy implied by the publishing pattern on real-life websites. It is presented in three steps: a rules generation algorithm to efficiently generate complete sets of extraction rules (Section 3); a technique to measure the redundancy of rules (Section 4), even in the presence of optional attributes (Section 4.1); and finally, a technique to separate and validate regular, attribute redundancy from noisy, accidental redundancy (Section 5);
- A proof-of-concept showing the feasibility of the approach, and the experimental evaluation (Section 6) showing that RED can attain highly accurate results scoring at rule level an F-measure $F_r > 91\%$, and even better results at value level with $F_v > 96\%$. We demonstrate its advantages against state-of-the-art large scale data extraction systems.

The following related problems have been already tackled in literature and are beyond the scope of the present paper: finding deep Web sources [36, 39, 40, 43]; filling the search fields with meaningful values to collect result pages [1, 4, 17, 25, 31–33, 42]; crawling paginated search result pages [21].

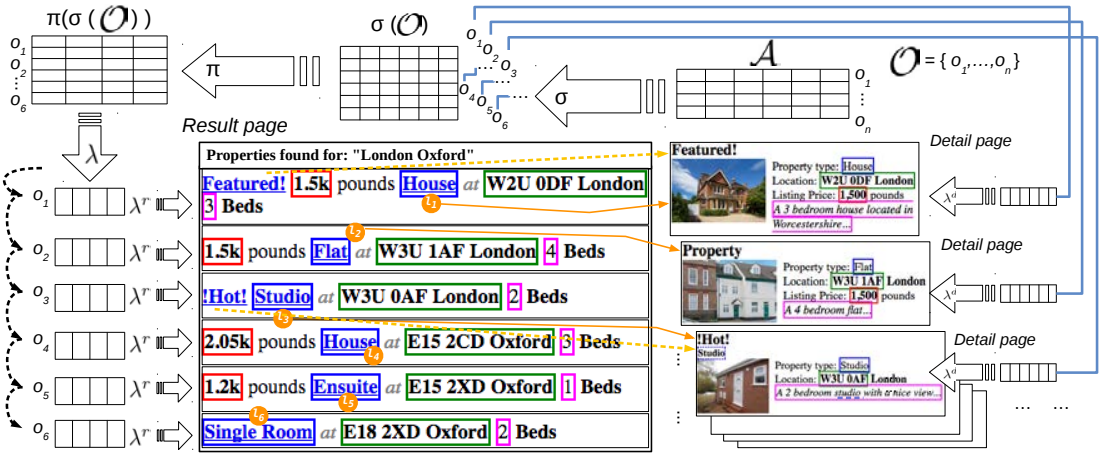

Figure 1: The result/detail publishing pattern.

r_0^b (Price)	r_2 (Type)	r_6 (Location)	r_9 (Beds)	l (Link)
1.5k	House	W2U 0DF London	3	l_1

d_7: ⟨*nil*, London, London, *nil*, Oxford, Oxford⟩

(c) Values extracted by detail rules.

Figure 2: Running example.

2 PROBLEM DESCRIPTION

The result/detail publishing pattern depicted in Figure 1 assumes that a website publishes data coming from an underlying abstract relation with attributes $\mathcal{A}$ containing all the available information about a set of objects O. In our example, the abstract relation contains one tuple for every published property, each with attributes such as the property's Price, Address, number of Beds, and Type.

Result pages and detail pages are generated by various *scripts* that retrieve data from the abstract relation, embed them into an HTML template, and publish them as web pages. This process performs a sequence of transformations: An initial selection (σ, to recycle a symbol from relational algebra) produces the set of objects to publish in each result page as encoded into HTML source code by the *result page script* λ. Every result page contains a set of *result records*, each produced by applying the *result record script* λ^r to one published object. The corresponding detail page is the result of applying the *detail script* λ^d on the very same object, and is linked from the corresponding result record.

According to the model depicted in Figure 1, even if the detail and result record scripts work on the same set of objects, they may end up publishing different sets of attributes. The detail pages include all the attributes of the abstract relation, whereas the result pages publish only a subset of these attributes selected by a projection operation π.

We now introduce the problem of recovering the values of the attributes published on the result pages. An extraction rule either locates one or several string values from a single page, or it produces a distinct special value *nil* to denote the absence of a value. For our purposes, extraction rules are specified by using XPath expressions [13] belonging to a simple but carefully designed fragment (as detailed in Section 3).

We distinguish two types of extraction rules, named *detail* and *result* rules after the type of pages they are meant to work on.

We call *detail rule* any extraction rule that when applied on a detail page, produces at most one value or *nil*. We use d to denote a detail extraction rule, and we use $d(p)$ to denote the value it extracts from detail page p. Precisely, $d(p)$ is either the XPath *string-value* obtained by applying the rule d on detail page p, or it is *nil* if the XPath expression returns an empty *node-set* [13].

A detail rule for an attribute A is said to be *correct* if it extracts its values from every detail page in the input and extracts *nil* for those pages that do not contain a value for A. We call *noisy* (or *incorrect*) a rule that is not correct: noisy rules mix values of several attributes or they extract part of the underlying HTML template. We distinguish the special case of a *partially-correct* rule for an attribute A, i.e., a rule extracting only correct values of attribute A except for some pages, on which it wrongly extracts *nil*. The value extracted by a detail rule is naturally associated with the object corresponding to the detail page it is applied to.

Similarly, we call *result rule* any extraction rule meant to work on result pages and we denote it by r. A result rule applied on a result page p produces zero, one, or several values denoted $r(p)$. Precisely, r returns the *string-value* for each node in the *node-set* returned by evaluating its XPath expression on the result page p [13].

Result rules, differently from detail rules, cannot produce *nil* values at all, even in the case that they return an empty node-set. Indeed, without knowing the exact boundaries of every result record, the values extracted by a result rule cannot be trivially associated to the record/object they belong to on the result page (Section 4.1 describes a solution to this problem).

Therefore, the notion of *correctness* of a result rule for an attribute A differs from the notion of correctness of a detail rule, even if they are associated with the same attribute: a result rule is correct if it produces exactly the ordered set of non-*nil* values of attribute A as they occur in the source of that page. By *partially-correct* result rule for an attribute A we mean a result rule extracting a strict subset of the correct values of A.

The problem that we aim to solve can be formulated as follows:

Problem (Finding Result Attributes). *Given a set of result pages P_r and the set of corresponding detail pages P_d over the same objects, find the correct values (including nil values) for every attribute A of the abstract relation published in the result pages.*

RED tries to solve this problem by producing a result rule r_A per every attribute A in the result pages, together with an additional result rule, named *link rule* and denoted by l, extracting exactly one occurrence of the link leading to the corresponding detail page per result record: an output result rule r_A associated with an optional attribute A is suitably annotated either r_A^a or r_A^b to specify how the values extracted by r_A should be padded with missing *nil* values, i.e., respectively *after* or *before* occurrences of the detail links.

3 EXTRACTION RULES GENERATION

We introduce an extraction rules generation algorithm working on both result and detail pages. It is a single-parameter algorithm designed to output rules from an XPath fragment whose expressiveness can be easily and effectively tuned by setting the parameter. Its goals are two-fold: on one hand, it aims at being complete, i.e., it has to generate at least a correct rule for every attribute; on the other hand, it should not generate too many noisy rules, because their presence makes the *Finding Result Attributes* problem harder.

The rules generation algorithm includes two main steps: *template analysis*, and *extraction rules enumeration*.

3.1 Template Analysis

The template analysis aims at identifying those nodes in the DOM tree [26] of the input pages that are *template* nodes (e.g., the `<li>` node, and the textual label: '`Price:`' in Figure 3a).[1]

RED's template analysis algorithm is inspired by ExAlg [2], suitably adapted to the result/detail publishing pattern. Our analysis just aims at deciding, for every node in the pages, whether it should be considered as part of the template or not; conversely, ExAlg also solves the complex problem of finding a *full* description of the HTML template.

The analysis on a set of input pages P builds on the notion of *occurrence-vector*, i.e., a vector f of $|P|$ integers indexed by the pages in P, so that $f(p)$ reports how many occurrences of *equivalent* nodes are present in the DOM tree of page p. Two nodes are said to be equivalent if and only if two conditions hold: (i) they are either text nodes with the same value, or they both are element nodes associated with the same element name and attribute names, (ii) their respective parent nodes are equivalent (or they both are the root nodes). Equivalent nodes with the same occurrence-vector are then grouped into the same *equivalence class*.

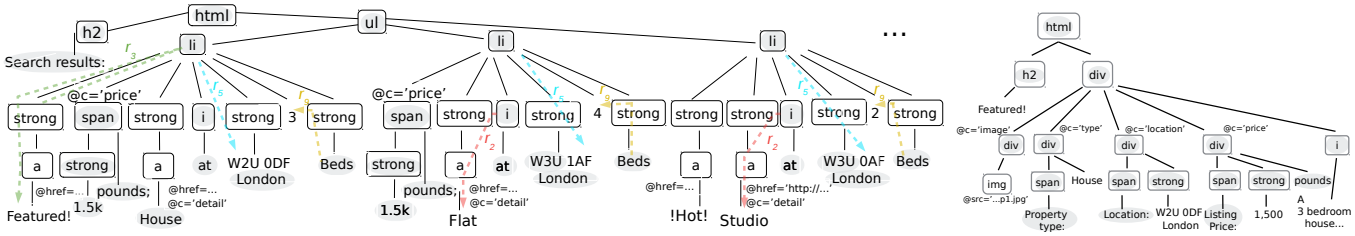
As observed in [2], by considering a sufficiently large number of pages, the nodes that occur in large and frequently occurring classes are the scaffold of the underlying template. An inherent and significant limitation of this kind of statistical analysis is that the inferred equivalence classes become easily noisy as their support (total number of occurrences) or size (total number of nodes) decreases. Indeed, ExAlg's template inference process described is extremely brittle to the presence of noisy equivalence classes and cannot deal with singleton collections of input pages.

As in the original proposal, we use thresholds on the minimum size and on the minimum support to prevent the algorithm from generating too many noisy classes.[2] However, it is worth noticing that in our setting the template analysis is just an optimization aiming at reducing the number of generated extraction rules and that we have empirically observed that a single result page, usually containing up to tens of records, is already enough for the specific goals of our analysis.

The classes whose occurrence-vector exactly reports the number of objects published per page are called the *root* equivalence classes: their nodes occur exactly once in every detail page and as many times as the number of result records in every result page (an information available as part of RED's input). We classify as template nodes those occurring in the root equivalence classes or in any other equivalence class that appears less frequently than the root equivalent class in every page.[3]

Example 3.1. The root equivalence classes for the running example are ϵ_0^r and ϵ_0^d reported in Figure 4; the resulting template nodes are depicted with gray background in Figure 3. Notice that all their nodes are template nodes. $\epsilon_2^d, \epsilon_3^d, \epsilon_4^d, \epsilon_5^d$ are discarded because their support is too small and indeed they are noisy classes listing values that occur more than once by chance. ϵ_3^r is discarded because it occurs more frequently than the root equivalence class ϵ_0^r. Also nodes in ϵ_1^r, ϵ_2^r are correctly classified as template nodes. Notice that nodes in ϵ_4^r and ϵ_5^r are erroneously classified as template nodes.

The wrong classification of a value as template node will not prevent the generation of correct rules for the corresponding attribute as long as other occurrences of the values of that attribute are correctly classified as target values.



3.2 Extraction Rules Enumeration

The rules generation algorithm builds on the output of the template analysis to enumerate result (respectively, detail) extraction rules associated with tree-paths starting from a uniquely identifiable template node within the result records (resp., detail page), named *pivot*, and reaching a non-template *target value* node.

[1] Text nodes are split in several contiguous siblings nodes by tokenizing at word level.

[2] We consider only equivalence classes whose support is at least 20% of the input objects, but never fewer than 2, and only classes including at least 3 nodes.

[3] These classes are those associated with the *main* data structure of the two types of pages, i.e., the list of records of the result pages and the flat record of the detail pages, or those optional attributes nested within them.

(b) Detail candidate rules.

Figure 5: Running example: extraction rules.

We use as candidate pivot every template node that is either a text, or an element with 'id' or 'class' attribute; every non-template text node is considered as a candidate target value. We then enumerate all the possible tree-paths leading from any pivot node to any target node by hopping over the tree along with a set of predefined XPath step expressions. Namely, we consider expressions capable of moving to the parent element node, to one of the children (either text or element), to the next/previous sibling element.

A couple of additional constraints on the tree-paths are enforced in order to reduce the number of enumerated tree-paths and discard those associated with incorrect rules. First, the path length is bounded by a threshold δ. Second, the analysis considers only a small subset of the input pages which is assumed unbiased.[4]

Each tree-path is translated into an executable extraction rule by appending several XPath step sub-expressions, eventually.

The first XPath step has to match the pivot, and takes one of the following forms depending on its node type: //e[contains(.,"v")] for a textual pivot v having e as parent node; //e[@id="v"] (resp., //e[@class="v"]), for an element pivot e having an id (resp., class) attribute valued v; just //e for any other element pivot.

Then it follows a sequence of XPath step expressions each after one of the hops composing the tree-path from the pivot to the target value: parent, child, following-sibling (abbreviated fs in Figure 5a), and preceding-sibling (ps); each step (except those on the parent axis) is also followed by an XPath positional predicate, e.g., '[4]', and by a node-test: The last step uses text() to target textual values, where all the other steps use '*' to select element nodes.

Example 3.2. Consider rule r_6 shown in Figure 5a: it is based on the 3 steps tree-path 'at ⇝ i ⇝ strong ⇝ W2U 0DF London' from the pivot node 'at' to the Location value. The XPath expression is obtained by combining: the expression selecting the pivot node (//i[contains(.,'at')]); the expression fs::*[1] to move to the next sibling element; and the final expression text()[1] to reach the target text value. A few tree-paths generating the result rules are shown directly in Figure 3 by means of colored dashed lines annotated with the rule and connecting the pivot to the target value across all the nodes in the path.

RED groups the generated rules by extracted values. Within a group producing the same values, only the rule associated with the shortest tree-path is retained, ties are broken by selecting the rule generated earlier. In the running example, r_7 is removed as it extracts the same values as r_5. The rationale to prefer shorter paths is that template nodes far away from the target values are

[4]We use at most 3 detail pages and 1 result page.

progressively less likely to generate rules that work reliably across all records and pages. More sophisticated criteria, such as those considering the robustness of the extraction rule [11, 22] could be adopted, but this is beyond the scope of the present paper.

4 REDUNDANCY SEEKING

RED analyzes the redundancy between all pairs of generated result and detail rules for identifying the likely correct rules. From an abstract point of view, a pair of result/detail rules can be considered *redundant* when the two rules end up extracting values associated with the same attribute of the abstract relation for every object.

Concretely, given one of such pairs composed of one result rule and one detail rule, a pairwise comparison of the extracted values is not trivial as they might extract a different number of values due to the presence of optional attributes. It is necessary to find out the correct alignment of the rules, i.e., where *nil* should be inserted to indicate a missing value within the list of values extracted by the result rule. We introduce a novel *soft segmentation* technique to find the alignment between result rules and detail rules, thus avoiding the tricky problem of finding the exact boundaries of every result record [20, 28]; then, we describe a score function for measuring the redundancy of a pair composed by one aligned result rule and one detail rule.

4.1 Soft Segmentation

The presence of optional attributes in the result pages can lead to the generation of rules that extract fewer values than the number of records. Soft segmentation is RED's technique for finding the correct alignment of the extracted values (w.r.t. the result records).

A prerequisite of the soft segmentation technique is the availability of exactly one detail link per each result record, i.e., that pointing to the corresponding detail page. RED leverages the knowledge of the detail pages, whose urls are assumed given as part of the input, to locate the detail link occurrences within the result records. As all occurrences must be associated with same "slot" of the underlying template, we have to disambiguate all the cases in which several copies of a detail link occur within the same result record, or optional detail links are present (e.g., for example in the first and third featured result records in Figure 1).

We apply the rules generation algorithm described in Section 3 by taking any of the link occurrences as target and generate a set of *link rules*. Only the rules extracting same number of links as the number of result records are considered, and in presence of several candidates, only the rule generated earliest is saved as link rule.

The soft segmentation technique finds out the correct alignment of the values extracted by a result rule w.r.t. detail the link occurrences during a traversal of the DOM tree. If a result rule is correct and extracts exactly the same number of values as the number of result records, the extracted values perfectly interleave with the detail link occurrences, i.e., either the values always occur before the links or they always occur after them. Conversely, in presence of result rules extracting fewer values, a correct alignment is needed.

Example 4.1. The link rule l of our running example is shown in Figure 5a. Let l_i denote the detail link node to the i-th detail page. Consider the correct rule r_9 extracting 6 values, in Figure 2b. It turns out that during an in-order traversal of the DOM tree in Figure 3a, detail links and extracted values interleave perfectly and occur as follows: $\langle l_1, 3, l_2, 4, l_3, 2, l_4, 3, l_5, 1, l_6, 2\rangle$. Instead, detail links and values extracted by r_8 do not: $\langle l_1$, W2U 0DF…, l_2, W3U 1AF…, $\underline{l_3}$, $\underline{l_4}$, E15 2CD…, l_5, E15 2XD…, $l_6\rangle$.

For dealing with these cases, *nil* values should be injected to reestablish the pattern that either every link precedes a value or vice-versa. At most two interleaving sequences of the values, called *alignments*, of a result rule, are possible: Given the result rule r, we use r^a (resp., r^b) to denote the alignment of the rule in which all nodes extracted by r are considered occuring *after* (resp., *before*) the corresponding detail link in every result record.

Example 4.2. Let s_8^a and s_b^b denote two sequences of exactly 12 elements (6 values plus 6 detail links) corresponding the alignment of rule r_8 w.r.t. detail links extracted by l in Figure 5a. Either every value occurs before a link:
$s_8^b = \langle \underline{nil}, l_1$, W2U…, l_2, W3U…, l_3, $\underline{nil}$, l_4, E15 …, l_5, E15…, $l_6\rangle$; or after a link:
$s_8^a = \langle l_1$, W2U…, l_2, W3U…, l_3, $\underline{nil}$, l_4, E15…, l_5, E15…, l_6, $\underline{nil}\rangle$.
We annotate r_8 to specify the relative position of the extracted values w.r.t. detail links so that the *nil* values can be properly inserted. Let p_r denote the result page of the running example:
$r_8^b(p_r) = \langle nil$, W2U 0DF…, W3U 1AF…, nil, E15 2CD…, E15 2XD…$\rangle$
$r_8^a(p_r) = \langle$W2U 0DF…, W3U 1AF…, nil, E15 2CD…, E15 2XD…, $nil\rangle$.

RED tries to enforce an admissible alignment to every produced result rule. Those rules that cannot be aligned are discarded.

Example 4.3. Consider the sequence of values extracted by r_1 and detail links in our running example:
$\langle$1.5k, l_1, Flat, l_2, Studio, l_3, House, l_4, Ensuite, l_5, l_6, at$\rangle$.
The presence of two consecutive links (l_5 and l_6) prevent values and links from interleaving perfectly. Thereby r_1 is removed.

Table 1 shows the alignments for all the result rules in Figure 5a w.r.t. link rule l for our running example.

Table 1: Aligned result rules after soft segmentation.

r_0^b:	$\langle$1.5k, 1.5k, nil, 2.05k, 1.2k, $nil\rangle$
r_2:	$\langle$House, Flat, Studio, House, Ensuite, Single Room$\rangle$
r_3^b:	$\langle$Featured!, 1.5k, nil, 2.05k, 1.2k, $nil\rangle$
r_5^a:	$\langle$at, W3U 1AF…, W3U 0AF…, E15 2CD…, E15 2XD…, $nil\rangle$
r_5^b:	$\langle nil$, at, W3U 1AF…, W3U 0AF…, E15 2CD…, E15 2XD…$\rangle$
r_6:	$\langle$W2U 0DF…,W3U 1AF…,W3U 0AF…,E15 2CD…,E15 2XD…,E18 2XD…$\rangle$
r_8^b:	$\langle nil$, W2U 0DF…, W3U 1AF…, nil, E15 2CD…, E15 2XD…$\rangle$
r_8^a:	$\langle$W2U 0DF…, W3U 1AF…, nil, E15 2CD…, E15 2XD…, $nil\rangle$
r_9:	$\langle$3, 4, 2, 3, 1, 2$\rangle$

The soft segmentation algorithm takes as input a result rule r, the link rule l and a set of result pages. It visits every page by ordering links and values into a sequence of occurrences and checks whether it is possible to inject *nil* values into the sequence to make values (including *nil*) and links to interleave perfectly. If so, it outputs at most two admissible alignments of the result rules, namely r^a and r^b (we simply write r where the alignments coincide).

4.2 Redundancy Score

Given a pair (r^*, d) composed of one aligned result rule (with $* \in \{a, b\}$) and one detail rule, and a set of objects O, the redundancy score of the pair is defined as the average pairwise score between their values:

$$\text{red}(r^*, d) = \sum_{o \in O} \frac{\text{score}(r^*(o), d(o))}{|O|}$$

where $d(o)$ and $r^*(o)$ denote the string extracted for object o by d and r^*, respectively. We then define the following *redundancy score* as a distance function over pairs of values:

$$\text{score}(v_1, v_2) = \begin{cases} 0 & \text{, if } v_1 \text{ substring of } v_2 \text{ or vice versa} \\ JS'(v_1, v_2) & \text{, otherwise} \end{cases}$$

where $JS'(v_1, v_2)$ is a *Jensen-Shannon* string distance modified for handling *nil*. If both v_1 and v_2 are *nil*, it returns 0. If either is *nil*, but not the other, it returns 1. In all other cases, it's a standard string distance. We noticed that the change of formats for the values of an attribute within the same site are very rare in real sites as they also tend to confuse the end user, i.e., the Price attribute is displayed as `1.5k` on a the result record whereas it is presented as `1,500` on the corresponding detail page of the running example in Figure 1. Hence, we observed only negligibly different results by adopting any other popular string distance function [7]. In practice, dealing with the substring cases is more important than the choice of the string distance function.

Example 4.4. Table 2 reports all the pairs scoring less than 0.4 ordered by their redundancy score for our running example. Each pair is composed of an aligned result rule from Table 1, and a detail rule from Figure 5b. The column "*Attributes*" reports whether the rules of the pair are correct, noisy, partially correct, or mis-aligned.

Table 2: Pairs of rules scoring less than 0.4.

pair π	red(π)	*Attributes*
(r_2, d_1)	0	Type correct
(r_6, d_4)	0	Location correct
(r_2, d_6)	0	Type vs Description
(r_8^b, d_7)	0	mis-alig. Location vs partial City
(r_8^a, d_5)	0	partial Location vs partial Location
(r_9, d_6)	0	Beds vs Description
(r_5^a, d_4)	0.333	noisy Location vs Location
(r_0^b, d_0)	0.397	Price correct

5 NOISE REMOVAL

RED uses the redundancy score to filter pairs of rules that are somewhat, but not sufficiently, redundant. Given a redundancy score threshold ρ, we consider as *not redundant* all the pairs of rules having a redundancy score greater than ρ. Unfortunately, many of the remaining pairs can still contain noisy rules: On one hand, there could be an incorrect alignment of the values, due to the presence of too many similar values in result records, e.g., (r_8^b, d_7) in Table 2; on the other hand, even noisy rules happen to be incidentally similar sometimes, e.g., (r_8^a, d_5) and (r_5^a, d_4). This is especially true when the range of the possible values of the compared attributes is rather limited; for example (the number of) Rooms, Beds, and Baths in the real estate domain are all small positive integers. Generally speaking, the correct result rules cannot be trivially separated from the incorrect ones with any fixed value of the threshold.

RED processes the redundant pairs by ascending redundancy score to remove the noisy pairs. First, the *result rule validation* analyzes whether a result rule has been correctly aligned and therefore properly fits in the HTML template of the result pages. Then, the *noise redundancy removal* leverages the redundancy scores to select for each attribute only the best pairs of rules, i.e., those having the lowest redundancy score.

5.1 Result Rules Validation

The result rules validation technique is based on the availability of some correctly aligned result rules as output of the previous processing steps. Beside the link rule, which is assumed to be correct, several other result rules might have only one alignment after the soft segmentation process, for example r_0^b and r_2 in Figure 1. RED leverages these already aligned and therefore inherently validated rules to validate other result rules.

A result rule r is validated against an already correctly-aligned rule g that is assumed correct. We can thereby infer two possible traversal sequences of their nodes corresponding to two positional alignments, and namely: s^b – extracted nodes of r are before those of g; and s^a – extracted nodes of r are after those of g. Then, as described in Section 4.1, we get the real traversal sequence s by traversing the DOM tree. If s does not matches any of s^b and s^a, r is not a valid result rule. We thereby remove r and all the redundant pairs containing r.

Example 5.1. For validating r_8^b based on r_9, RED considers two possible alignments of the values extracted by r_8^b w.r.t. r_9:
⟨3, 4, W2U 0DF..., 2, W3U 1AF..., 3, 1, E15 2CD..., 2, E15 2XD...⟩
⟨3, W2U 0DF..., 4, W3U 1AF..., 2, 3, E15 2CD..., 1, E15 2XD..., 2⟩ .
Neither of these matches the actual sequence in which these values occur on the page: ⟨W2U 0DF..., 3, W3U 1AF..., 4, 2, E15 2CD..., 3, E15 2XD..., 1, 2⟩.
Therefore, r_8^a fails to validate w.r.t. r_9 and is dropped.

5.2 Removing Redundant Noise

Once all the result rules have been validated, the surviving pairs include correct pairs together with partially correct and noisy redundant pairs that are incidentally similar.

The key assumption to remove the noisy pairs in the first category is that correct pairs have a better redundancy score than pairs containing noisy rules. The assumption is exploited in the first step of the algorithm removeRedNoise shown in Listing 1 (lines 2-9) and dealing with already validated result rules.

The second step of the algorithm (lines 10-17) prefers pairs of rules extracting fewer *nil* values: at this stage, all the noisy pairs have already been removed so that we can directly remove the result rules extracting a larger number of *nil*s. Notice that with the exception of the initial ordering (line 11 vs line 3), the two steps are performed by two almost identical loops (lines 2-9 vs lines 10-17). However, they cannot be merged because the latter loop expects as

Listing 1: removeRedNoise

```
Input: A set of redundant pairs Π = {(r, d) : red(r, d) < ϵ}.
Output: A set of correct rule pairs.
1  begin
2      Π′ ← ∅ ;
3      order pairs in Π by increasing redundancy score;
       /* Remove pairs with overlapping result DOM nodes */
4      foreach (r, d) ∈ Π do
5          remove (r, d) from Π ;
6          foreach (r′, d′) ∈ Π do
7              if DOMoverlap(r, r′) then
8                  remove (r′, d′) from Π ;
9          add (r, d) to Π′ ;                    /* saves only the best pair. */
       /* Prefer pairs whose detail rule extracts less nils.  */
10     Π″ ← ∅ ;
11     order Π' by decreasing n. of nil in the detail rules;
12     foreach (r, d) ∈ Π′ do
13         remove (r, d) from Π′ ;
14         foreach (r′, d′) ∈ Π′ do
15             if DOMoverlap(r, r′) then
16                 remove (r′, d′) from Π′ ;
17         add (r, d) to Π″ ;
18     return Π″;
```

input a list of pairs from which the noisy rules have been already removed, as produced by the first loop.

After the two processing steps, the surving pairs are the output result rules that RED classifies as correct.

Example 5.2. Consider again two pairs involving d_4 in Example 4.4, i.e., (r_6, d_4) and (r_5, d_4). The first step of removeRedNoise (lines 2-9) removes the latter pair, i.e., the pair with the worst redundancy score, since r_5 and r_6 extract overlapping nodes and only one of them is assumed to be correct.

Both pairs (r_6, d_4) and (r_8^a, d_5) are 0-scored and r_6 and r_8^a are two overlapping result rules: at most one of them can be correct. Both pairs reach the second loop (lines 10-17). The (r_8^a, d_5) pair is then removed because it contains the largest number of *nil* elements.

Table 3: Pair of rules after RED's noise removal step.

pair π	red(π)	note
(r_2, d_1)	0	Type
(r_6, d_4)	0	Location
(r_2, d_6)	0	Type vs Description
(r_9, d_6)	0	Beds
(r_0^b, d_0)	0.36	Price

Example 5.3. Table 3 reports (ordered by the redundancy score) the pairs after all the steps of the noise removal process. The pairs (r_2, d_1) and (r_2, d_6) are both 0-scored and the correct rule r_2 for Type is included in the output for its redundancy with the Description, an attribute on the detail pages that often "includes" the Type as a substring. So RED output on the running example is the set of aligned result rules r_0^b, r_2, r_6 and r_9 together with the link rule l.

6 EVALUATION

We inspect RED's characteristics and performance through a series of experiments on real-world websites. We first evaluate RED on a dataset derived from the one used in DIADEM [18], a state-of-the-art ontology-based data extraction system. We then apply RED to another dataset comprised of websites from a variety of application domains, a challenging setting for ontology-based data extraction systems that require some supervision on the level of the application domain. We show that, in contrast, RED can attain consistently high precision and recall over many domains.

As for the comparison with other fully unsupervised approaches beside DIADEM, we also considered DEPTA [41], another unsupervised system that, to the best of our knowledge, deals with the most similar setting to ours: unsupervised extraction from result pages, even a single result page.

6.1 Evaluation method

Datasets: We evaluate RED on two datasets, named DIA_DS and RED_DS, including 130 websites in total. DIA_DS consists of 100, still reachable websites from the original DIADEM's dataset, half in the REAL_ESTATE, half in the USED_CARS domain. We use DIADEM to generate wrappers on these sites and collect the detail pages for the dataset, as needed by RED.

RED_DS consists of 30 sites from 10 domains, obtained by randomly picking 3 sites from the *Alexa Top* 100 *Global Sites*. We exclude sites where the detail pages are not hosted on the site itself but rather refer to other sites (typically metasearch portals), as these cases do not fit RED's assumption that detail pages share a common template. Each test-case is related to a single website and it consists of one result page and the corresponding set of detail pages. All the records listed in the result pages are obtained by following the default sorting criteria from the website. Both datasets can be found on https://github.com/redwww/experiments.

Optional Attributes: To validate the need for dealing with optional attributes in result pages, we observed that in our datasets there is a considerable number of sites that contain optional attributes. In detail, 17% of sites in DIA_DS (i.e., 20 sites) and 36% of those in RED_DS (i.e., 13 sites) contain optional attributes. This well illustrates the importance of approaches, such as the soft segmentation technique, dealing with optional attributes in result pages.

Metrics: For each attribute of the result pages in our datasets, we manually crafted the correct XPath expression to extract correct data as golden standard, based on which we computed the number of true positives (tp), false negatives (fn), false positives (fp), precision $P = tp/(tp + fp)$, recall $R = tp/(tp + fn)$, and the F_1−measure, as $F = (2 \cdot P \cdot R)/(P + R)$.

These metrics have been computed both at (macro or) rule level and at (micro) level of extracted values. At rule-level, we consider a rule correct only if it extracts a set of values perfectly matching with that extracted by the golden rule, without any missing value: any rule extracting just a few noisy values or missing a single value, is considered the same as if it were completely wrong. We also calculate all the metrics at value-level by comparing the number of correct/noisy extracted values. In Table 4 and in Table 5 we report the main results for the two considered datasets: P, R, F stand for the precision, recall and F-measure, reported both at rule-level (e.g., F_r) and at value-level (e.g., F_v).

Table 4: RED vs DIADEM Performance.

System		DIADEM	RED	RED
Target Attributes		Ontology	Ontology	All
REAL_ESTATE	P_r	**0.94**	0.91	0.92
	R_r	**0.90**	**0.90**	0.91
	F_r	**0.92**	0.91	0.91
	P_v	**0.98**	**0.98**	0.98
	R_v	0.92	**0.94**	0.93
	F_v	0.95	**0.96**	0.96
USED_CARS	P_r	**0.97**	0.96	0.97
	R_r	**0.96**	**0.96**	0.96
	F_r	**0.96**	**0.96**	0.97
	P_v	**0.97**	0.96	0.97
	R_v	0.94	**0.98**	0.97
	F_v	0.95	**0.97**	0.97

6.2 Comparison with DIADEM

For a fair comparson between RED and DIADEM, we limit the target attributes to those in the ontology used by DIADEM, but also report RED's performance on all available attributes.

Table 4 presents $P/R/F$ results of RED and DIADEM systems over the dataset DIA_DS, both at the rule-level and at the value-level. Generally, RED and DIADEM perform roughly at the same high precision, recall, and F-measure. Considering that RED uses no domain ontology or other prior knowledge about the domain, that is quite remarkable. Moreover, RED can extract *all* the redundant attributes published in the result pages (as shown in the ALL column), not just the ones covered by the DIADEM ontology, achieving similar results. Overall, RED identifies 33% more attributes (about 800 attribute extraction rules) than DIADEM (about 600). The same close performance can be observed at site-level: RED extracts *all* attributes correctly in 73% of the websites, compared to 76% for DIADEM.

6.2.1 Failures & Limitations. The most frequent errors for RED and DIADEM systems can be grouped in two main categories.

Noise: DIADEM leverages its ontology to automatically annotate target pages. Wrong extracted values from DIADEM system are mainly due to misleading annotations. In our experiments, there are 5 sites where it suffers of this problem, e.g., top-lettings.co.uk. DIADEM extracts the template nodes `Available:` always occurring before the attribute AvailableDate and it wrongly takes it as a value of the attribute PropertyStatus. In contrast, RED's most common type of noise are partially correct rules, that extract only a fraction of the correct values.

Missing rules: Where DIADEM mostly misses attributes due to a lack of overlap with the background ontology, RED mostly misses attributes where the sites do not conform to its assumptions and specifically that result attributes also occur on the detail page and that attributes have a large enough domain to show some variability between result records. On site davidtompkins.co.uk the Description values in the result pages do not occur in detail pages. On cotswoldlettings.co.uk the Status of the properties is an optional attribute that can only take the value `SOLD` when present. RED wrongly considers all these values as part of the template.

6.3 Multi-domain evaluation

We further evaluate RED on RED_DS, a dataset covering 10 domains (Coffee, Concerts, Florist, Jewerlry, Job Search, Threatres, Books, Camera, Lighting, Sigars) with 3 randomly selected sites for each application domain. For space reasons, in Table 5 we just report the results for one example domain Cigars,[5] the quality metrics averaged over all the sites computed both at rule and value level, and other aggregated results; namely: total number of records (n) contained in the result page, total number of correct (tp), missing (fn) and incorrect (fp) values/rules produced.

Overall, RED attained a high performance at both rule-level (0.93 of F-measure) and value-level (0.96 of F-measure). At the value-level the precision is remarkable high (0.99).

Among 8 noisy rules in the output produced by RED, only 3 of them are entirely incorrect while all the other noisy rules are partially correct rules. On ncfjobs site, RED seems to perform badly as there are 4 noisy rules, out of which 3 are partially correct rules for Description, and 1 for JobTitle. All these noisy rules survived the noise-removal step because RED rules generation algorithm was not complete, i.e., it could not find correct rules for these attributes.

6.3.1 Comparison with other unsupervised approaches. For comparison with state-of-the-art unsupervised data extraction systems, we ran DEPTA [41] on the dataset RED_DS. This system is also capable of extracting records from result pages and does not require multiple sample pages. Although the algorithm was proposed in 2006, we compared with a runnable version re-implemented in 2012.[6] Since it blindly outputs multiple tables without telling the user which one contains the target data, we manually picked a single table containing the published records and evaluated precision, recall and F-measure at the *column*-level, to get scores comparable with RED's rule-level scores. This yields a negligible advantage for DEPTA as it is usually fairly easy to pick out the dominant table.

We evaluate DEPTA's record identification step over 14 out of 30 sites considered on which the prototype was able to produce a correctly-aligned table. Among these 14 sites, DEPTA achieves a respectable precision of 0.70 and recall of 0.93.

6.4 Robustness to parameter setting

RED depends on two key parameters: δ is the max allowed pivot-to-value distance used during the generation of the rules; ρ is the minimum threshold on the score to consider a pair of result/detail rules as not redundant during the search for correct pairs of rules.

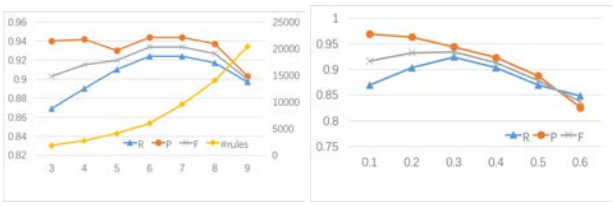

Figure 6a plots the performance of RED on the RED_DS dataset over several δ values (with fixed $\rho = 0.3$). While the precision is only slightly affected, the recall is significantly related to the maximum pivot-to-value distance. The larger the number of generated rules, the higher is the probability of generating correct rules. Unfortunately, it turns out that by generating too many rules, RED may end up introducing so many noisy rules that the probability of a noisy rule to be erroneously considered correct is increased, causing a loss in precision. In our experiments, $\delta = 6$ proved to be the sweet spot.

The other key parameter is the maximum redundancy score, ρ. A pair of result/detail rules is considered not redundant if its redundancy score is above ρ. It significantly affects the noise removal step whose task becomes harder and harder as noisy pairs are injected in the RED's processing pipeline. As shown in Figure 6b (with fixed

Table 5: Results of RED on RED_DS.

Domain	*Site*	n	tp_r	fn_r	fp_r	P_r	R_r	F_r	tp_v	fn_v	fp_v	P_v	R_v	F_v
Cigars	famous-smoke	60	8	1	1	0.88	0.88	0.88	439	15	20	0.95	0.97	0.96
	cigars-of-cuba	9	9	0	1	0.90	1	0.95	71	0	6	0.92	1	0.96
	vipcigars	18	3	0	0	1	1	1	54	0	0	1	1	1
10 domains	*30 sites*	*724*	*145*	*11*	*8*	*0.94*	*0.92*	*0.93*	*3365*	*248*	*28*	*0.99*	*0.93*	*0.96*

(a) Max pivot-value distance δ **(b) Max redundancy score ρ**

Figure 6: Performance by varying the two key parameters.

$\delta = 6$) the precision starts with maximum values, and then it gradually decreases as ρ becomes larger and larger. The noise removal process can still manage to remove most of the noises when ρ is at 0.4 but for larger values of the parameter there is a loss of precision, as the greater number of noisy pairs makes that process less effective. Conversely, too small values for ρ, meaning a too strict criteria for considering a pair of rules as redundant, makes RED wrongly remove some correct but not perfectly redundant pairs, as is evidenced by the recall loss of the plot in Figure 6b at $\rho < 0.3$.

For RED experimental evaluation, we measured RED performance by using the best empirically known values for the two parameters δ and ρ, i.e., $\rho = 0.3$ and $\delta = 6$.

Efficiency: By considering the number of input pages as a constant, RED efficiency can be conveniently analyzed in term of the initial number of rules generated. On RED_DS dataset, it generates an average number of 1259.17 result rules and 4912.10 detail rules, which reduce to 205.50 and 289.03 distinct vectors, respectively, after duplicates removal step; only 88.87 candidate pairs have a redundancy score smaller than ρ. RED achieves an average running time of 72.6 secs on a 64-bit Ubuntu system with an 8-core Intel *i*7 CPU at 3.40GHz, processing most sites in less than 30 seconds. RED running time is spent mostly on executing the generated extraction rules, a step that could be easily parallelised.

7 RELATED WORK

Web data extraction approaches and tools has been proposed both from research community and from industry [15, 16]. Due to the space limitation, we compare RED with the most related work and systems such as DEPTA [41], and DIADEM [18], which tackle with a similar problem as ours.

DEPTA executes two steps on a single result page, (*i*) identifying data records, and (*ii*) aligning values belonging to the same attribute. The first step, which is an enhancement of the MDR algorithm [29], works on a tag tree based on the visual containment relations of different HTML elements. It exploits the similarity of tag strings of nodes (and their descendant nodes) to find the data records. A further partial tree alignment method based on tree-edit distance is applied for the second step. DEPTA has two major drawbacks: First, it is highly sensitive even to small exceptions in the structure of the template (e.g., the record of some featured products may be presented differently from others) and optional nodes (e.g., the discount) in the repeated patterns. Second, due to the lack of any cues for identifying target values, it cannot easily separate target values from template nodes and other noises in the input pages.

One of the state-of-the-art system for domain-specific data extraction from result pages is DIADEM. We limit our discussion to its component most related to RED, i.e., that extracting data from result pages. DIADEM adopts automatic annotators to improve the data identification process, and requires the writing of a domain-dependent ontology which has to be designed and maintained by an expert. We exploit the intra-site highly precise redundancy to make RED more accurately target the relevant data without using any domain dependent feature.

Unsupervised approaches like RoadRunner [8], ExAlg [2], FiVaTech [27], TRINITY [35], and ViDE [30] all are based on the observation that pages providing homogeneous data are generated by using regular HTML templates, so they end up being mostly similar. It turns out that by analyzing the differences among a bunch of pages sharing a common template, it is then possible to reverse-engineer a model of that template, for example by means of regular expressions [2, 9]. However, in practice all these systems are not used for large scale extraction tasks because their performances are highly dependent on how well the input pages satisfy the underlying assumptions, to the point that the output quality level is unpredictable at scale [10]. In contrast, RED does not infer a precise description of the template, and it does not rely on it to find the data as all these latter systems, including ExAlg, do.

The work in [11, 12, 22] addresses the problem of XPath rules generation problem, but starts from a different input, i.e., a set of example nodes most of which are likely correct target nodes. These are usually provided by automatic annotators which are not available for every domain.

The approaches in [5, 23] and in [3] exploit content and/or schema redundancy and focus on template-based sites as RED does. However, they solve a completely different set of problems by adopting techniques based on the availability of data about the same objects across *several* autonomous sites. In other words, they focus on *inter*-site redundancy rather than on *intra*-site redundancy. It is therefore crucially important to align the different formats (e.g., Height expressed in inches on a site vs the same attribute expressed in centimeters on another site), a problem that we show is negligible intra-site. Also, since both approaches work directly on detail pages, they do not address record segmentation problems at all.

In [28] it is tackled the problem of segmenting result pages into records by exploiting links to detail pages exactly as RED. However, differently from RED, the authors do not consider at all the problem of extracting data from the result records once segmented; rather they describe two different approaches for tackling the segmentation problem: one formulates the task as a constraint satisfaction problem (CSP) and the other uses a probabilistic inference setting.

ABSTRACT

Fraud transactions are one of the major threats faced by online e-commerce platforms. Recently, deep learning based classifiers have been deployed to detect fraud transactions. Inspired by findings on adversarial examples, this paper is the first to analyze the vulnerability of deep fraud detector to slight perturbations on input transactions, which is very challenging since the sparsity and discretization of transaction data result in a non-convex discrete optimization. Inspired by the iterative Fast Gradient Sign Method (FGSM) for the L_∞ attack, we first propose the *Iterative Fast Coordinate Method (IFCM)* for discrete L_1 and L_2 attacks which is efficient to generate large amounts of instances with satisfactory effectiveness. We then provide two novel attack algorithms to solve the discrete optimization. The first one is the *Augmented Iterative Search (AIS)* algorithm, which repeatedly searches for effective "simple" perturbation. The second one is called the *Rounded Relaxation with Reparameterization (R3)*, which rounds the solution obtained by solving a relaxed and unconstrained optimization problem with reparameterization tricks. Finally, we conduct extensive experimental evaluation on the deployed fraud detector in TaoBao, one of the largest e-commerce platforms in the world, with millions of real-world transactions. Results show that (i) The deployed detector is highly vulnerable to attacks as the average precision is decreased from nearly 90% to as low as 20% with little perturbations; (ii) Our proposed attacks significantly outperform the adaptions of the state-of-the-art attacks. (iii) The model trained with an adversarial training process is significantly robust against attacks and performs well on the unperturbed data.

1 INTRODUCTION

With the rapid growth of information technologies, e-commerce has become prevalent nowadays. Large e-commerce platforms serve billions of users and connect them to factories, stores and third-party merchants with numerous products available. The big success of e-commerce also motivates the emergence of fraud transactions to illegally promote items and stores. In order to increase sales, fraudulent sellers turn to third-party malicious service platforms where they can hire human labors to create fake purchases and visits [26, 29, 33], and thus provide a fake impression that the target item is popular. This results in much higher rankings of the items from fraudulent sellers, and causes huge losses to the platforms as it hurts the user experience. Online fraud activities have caused a loss in billions of dollars[1], and it is reported that just in China, the online fraudulent industries involve over 1.6 million human labors and create billions of dollars of illegal incomes[2].

Fraud detection is critical to the development of e-commerce platforms. Recently, with billions of transaction data available, deep learning based models are proposed and deployed to detect fraud transactions on a real-time basis [6, 32, 34]. Inspired by recent findings in the domain of computer vision that deep learning based image classifiers could be fooled by imperceptible noises during test phases [27], we are interested in analyzing the vulnerability of deep fraud detector to slight perturbations on input data. This study has a high practical value for e-commerce platforms as the existence of such adversarial perturbations could indicate the risk of deploying deep fraud detectors. As shown in our motivating example, fraudulent sellers and malicious service providers are able to exploit such risks to bypass the detector with little costs.

In this paper, we aim to investigate the vulnerability of a deployed deep fraud detector being fooled by slight and feasible perturbations. However, the e-commerce domain is different from the computer vision area, since the transaction data are mostly discrete and sparse.

[1] https://www.signifyd.com/blog/2017/10/26/ecommerce-fraud-eight-industries/
[2] http://cn.chinadaily.com.cn/2015-11/05/content_22379527.htm

Few works considering discrete adversarial perturbations either propose a straightforward extension of the existing Fast Gradient Method [9], or take into account only the L_∞ attack [2], while they cannot handle more complex L_1 and L_2 attacks, which are of higher practical interests in our problem.

This paper makes the following contributions.

- First, inspired by the Fast Gradient Sign Method (FGSM), to handle the L_1 and L_2 norm bound constraints, we propose the Iterative Fast Coordinate Method (IFCM) which repeatedly conducts a one-unit descent on a single coordinate. IFCM can efficiently generate a large amount of adversarial perturbations with satisfactory effectiveness and is used in our proposed adversarial training process.
- Second, to address the discrete optimization for adversarial perturbations, we provide two novel attacks. The first attack is called the *Augmented Iterative Search (AIS)*. In each iteration, AIS proceeds to search for "simple" perturbations with one-unit descents on at most two coordinates. AIS also augments the searching process by restricting the space of two-coordinate perturbations based on the *Value of Perturbation (VoP)*. The second attack is called the *Rounded Relaxation with Reparameterization (R3)*, which is an optimization-based attack. R3 first relaxes the discrete optimization with reparameterization trick and rounds the continuous solution to obtain a discrete perturbation.
- Third, we conduct extensive experimental evaluations on the deployed fraud detector from TaoBao, one of the largest e-commerce platforms in the world, with millions of real-world transactions. The experimental results show that (i) The deployed fraud detector is threatened by the crafted adversarial perturbations. Our AIS and R3 attacks successfully decrease the detector's average precision from nearly 90% to as low as 20% with little perturbations. (ii) Our proposed AIS and R3 attacks significantly outperform adaptations of several state-of-the-art attacks, including the C&W attack [4], the Logit-Space attack [2], and the EAD attack [5]. (iii) We propose an adversarial training process with adversarial examples generated by the IFCM. Results show that the robustness of the detection model is significantly improved as we achieve an average precision above 85.9% under all tested attacks. Meanwhile, the average precision on the unperturbed data remains nearly 90%.

2 RELATED WORK

In this section, we review the related works in crafting adversarial examples to attack DNN models and various defense techniques.

2.1 Attacks on DNNs

FGSM [8] and its variant R+FGSM [28] are single step attacks, which perturb the input towards the gradient direction of the loss function. The extensions of FGSM iteratively perform single step attacks with smaller step size, such as BIM [13] and PGD [15]. Other iterative attacks include DeepFool [17], which approximates the decision boundary near the target instance with the linear hyperplane, and UAP [16] to produce a single perturbation which is capable of attacking multiple images. FGSM and R+FGSM are further extended to perturb towards the direction which maximizes the confidence score on the least likely labels for the target image [8, 28].

Besides gradient directional methods, Papernot et al. [21] propose the JSMA attack which uses the Jacobian matrix to get the salient map and modifies the features with high significance to confuse the classifier. C&W attack [3] relaxes the hard constraint on the distortion, and adds a penalty on the L_p norm ($p \in \{0, 2, \infty\}$) of perturbation. EAD [5] improves the transferability of adversarial examples through elastic-net regularization. Several works study the adversarial examples to evade DNN models in real-world applications, including the face recognition system [25], objection detection [11], and malware detection [9].

Most of the works focus on image recognition tasks and consider only continuous perturbations. While Grosse et al. consider the binary input [9] and adapt the fast gradient algorithms to solve their problem in a similar way as our IFCM$_1$, they only consider the L_1 attack. Buckman et al. propose the Gumbel-softmax trick to approximate the one-hot encoding of the discrete feature. However, their attack is suitable for L_∞ distortion bound and fails to consider the constraints that correlate the input features such as L_1 and L_2 norm constraints in our problem.

Our R3 attack is inspired by the optimization-based L_2 attacks [4, 5, 27]. These attacks all handle the L_2 norm constraint by imposing a penalty in the objective function and conducting a binary search to find a suitable constant coefficient of penalty term. This is a reasonable way to find the minimal distortion to successfully craft an adversarial example. However, in our problem, we are asked to find the most effective adversarial instance given the allowed distortion. While one could conduct a binary search to find the suitable constant coefficient that the distortion constraint is satisfied, the neural networks are non-convex in general and thus the binary search could be unstable to always generate a distortion satisfying the given constraint [27]. Our R3 attack utilizes the reparameterization trick to transform the constrained optimization to an equivalent unconstrained problem for which the solution always satisfies the distortion bound.

2.2 Defenses

There are several defense measures to improve the robustness of deep learning based classifiers, such as the defensive distillation [20, 22], which adopts the distillation technique [10] to retrain the same network with the confidence score outputted by the original model as the soft label, feature squeezing [30], detection approaches for adversarial instances [4], and adversarial training [8], a general process based on robust optimization that augments the training data with adversarial examples [8, 15, 35]. Some recent works propose to regularize or mask the gradient of the loss function with respect to inputs [24]. Almost all defenses are shown to be effective only for some attacks [31].

Recently, Athalye et al. pointed out that the defenses based on obfuscated gradients are threatened by their characteristic behaviors which can be exploited to design attacks circumventing them [1]. It is believed that adversarial training does not cause obfuscated gradient [1]. Thus, in this paper, we use adversarial training to achieve robust fraud detection and our experimental evaluation verifies the effectiveness of the strengthened detector.

3 DEEP FRAUD DETECTION AND ATTACKS

In this section, we first briefly introduce the deep learning model for fraud detection which is used by one of the largest e-commerce platforms in the world. We then present concrete examples to show the possible attacks by malicious sellers and service providers.

3.1 Deep Fraud Detection

Figure 1 shows the architecture of deep neural networks in deployed fraud detection system of TaoBao. The goal of the detector is to predict whether an online transaction is fraudulent. Each input transaction is represented as a feature vector $\mathbf{x}$ which concatenates two classes of features. The first is non-manipulable features, such as scores obtained with label propagation on the user-item transaction graph, to measure the offline maliciousness based on past records. Other non-manipulable features are prices[3]. In this paper, we focus on manipulatable features whose adjustment could have a significant effect on the detector's prediction. Without causing any confusion, we denote a transaction by a vector of only perturbable features. In the context of the investigated fraud detection, the perturbable features are those characterizing the user's preference, called *preference features*, defined as follows.

Let C be the set of all item categories, and $n = |C|$. A preference feature vector is represented by $\mathbf{x} \in \mathbb{N}^n$ with x_i denoting the number of records that the user interacts with items in the i-th category of C in a past period, normally 30 days. Such records include adding an item to the shopping cart, adding an item to "favorite", and so on. $\mathbf{x}$ represents the user's global interest in online shopping. Fraudulent buyers tend to show different preference patterns compared with benign users. Each transaction instance $\mathbf{x}$ is associated with a label $y \in \{0, 1\}$, such that $y = 1$ if the transaction is fraudulent and $y = 0$ otherwise.

All features are first normalized to be within $[0, 1]^n$ with a "smooth" normalization function to tackle the extreme values. Here, the feature value $\mathbf{x}$ is normalized to be $\frac{\log(\mathbf{x}+1)}{\log M}$ (element-wise) where M is the largest number of interactions observed in training data. The normalized preference features are passed to a cross layer [14] at first to exploit the interactions between different categories. The output of the cross layer is concatenated with non-manipulable features. The aggregated feature vector goes to a multi-layer feed-forward neural network, where each hidden-layer consists of rectified linear units as hidden neurons [18]:

$$relu(x) = \max(0, x).$$

The output of the last hidden-layer $\mathbf{z} \in \mathbb{R}^2$, called the *logit*, is then passed to a softmax layer to produce the confidence score on the transaction $\mathbf{x}$ being fraudulent

$$f^{\mathbf{w}}(\mathbf{x}) = \frac{e^{z_1}}{e^{z_0} + e^{z_1}},$$

where $\mathbf{w}$ denotes the parameters of the model, including the weights and biases on hidden neurons. The model is trained over a large-scale data set $\mathcal{D} = \{\mathbf{x}^i, y^i\}_{i=1}^N$ by minimizing the regularized total loss function $L^{\mathbf{w}}(\mathbf{x}, y)$ over $\mathcal{D}$

$$\min_{\mathbf{w}} \mathop{\mathbb{E}}_{(\mathbf{x},y)\sim\mathcal{D}} [L^{\mathbf{w}}(\mathbf{x}, y)] + \lambda \|\mathbf{w}\|^2, \tag{1}$$

where λ is the regularization coefficient. The commonly used loss function in classification tasks is the cross-entropy loss

$$L^{\mathbf{w}}(\mathbf{x}, y) = -\mathbb{1}_{\{y=1\}} \log f^{\mathbf{w}}(\mathbf{x}) - \mathbb{1}_{\{y=0\}} \log (1 - f^{\mathbf{w}}(\mathbf{x})),$$

and the stochastic gradient descent is widely applied to optimize the parameter $\mathbf{w}$ [7, 23].

3.2 Attacks to Fraud Detector

With billions of customers served on e-commerce platforms, the profit from fraud transactions could be huge for malicious sellers as they significantly promote the rankings of target items. Driven by the huge profit, a lot of malicious service platforms provide sophisticated tactics to bypass the strict detection and conduct fraud transactions. One common tactic is to mimic benign users' behavior such as using automatic visit script to visit different items before purchasing the target item, and hiring human labors to chat with the merchants before making a transaction. Figure 2 shows an example of automatic script to bypass the fraud detection, which is a piece of Java code as part of a mobile malicious service App which creates random perturbation to a target transaction such as dragging and browsing to behave like humans, intentionally visiting items from some categories, etc. According to domain experts, malicious platforms can create around 200,000 visits in per day and promote over 1000 items from malicious sellers. Since we verify that the vulnerability to slight perturbations exists for a fraud detector, the malicious platforms could exploit those threats to adapt the fraud transaction data in order to bypass the detection.

[3]Prices are hard to perturb in practice and the empirical study shows that slight perturbations on prices cause negligible changes.

Formally, let δ be the vector of perturbation on fraud instance $\mathbf{x}$ where δ_i is the amount of changes on x_i, and δ is discrete, i.e., $\delta \in \mathbb{Z}^n$. Assume $\delta \geq \mathbf{0}$ since it is more practical for realistic adversaries to add additional records of interactions via measures such as aforementioned automatic scripts[4]. In the domain of computer vision, the adversarial perturbations need to satisfy constraints that the perturbations are small enough, so that the ground truths of the adversarial instances remain the same as the original ones [8]. We also impose similar restrictions on δ, in order to capture the *feasibility* of perturbations in the sense that adversaries can conduct the perturbation with little effort. Such restrictions are expressed by the L_p norm bound on perturbations, and the common choices of p are $\{0, 1, 2, \infty\}$. Thus, the set of feasible δ bounded by L_p norm is defined as follows:

$$\Delta_q^p := \{\delta \mid \delta \in \mathbb{Z}^n, \|\delta\|_p \leq q, \delta \geq \mathbf{0}\}, \tag{2}$$

where q is the maximal distortion in L_p norm, and

$$\|\delta\|_0 = \sum_{i=1}^{n} \mathbb{1}_{\{\delta_i > 0\}}, \qquad \|\delta\|_1 = \sum_{i=1}^{n} |\delta_i|,$$

$$\|\delta\|_2 = \sqrt{\sum_{i=1}^{n} \delta_i^2}, \qquad \|\delta\|_\infty = \max_i |\delta_i|.$$

We focus on attacks bounded by L_1 and L_2 norms, which are suitable to describe realistic perturbations on the discrete and sparse preference features. L_0 attack is not practical as it allows the adversary to add infinitely many records on one category. L_∞ attack is not reasonable as the preference features are sparse in the sense that interactions on only few categories are recorded. Thus, even an adversarial perturbation with L_∞ norm of 1 violates the sparse nature of preference features.

For a suitable distortion metric L_p, our objective is defined as follows. For a deep fraud detector with model parameter $\mathbf{w}$, given a fraud transaction instance $\mathbf{x}$ in testing or deploying phase, we aim to find the adversarial example, an instance $\mathbf{x}^{adv}$ crafted with a feasible perturbation $\delta \in \Delta_q^p$, i.e., $\mathbf{x}^{adv} = \mathbf{x} + \delta$, to maximally decrease the fraudulent score on $\mathbf{x}^{adv}$. This can be done by solving the following optimization problem:

$$\min_{\delta \in \Delta_q^p} \quad f^{\mathbf{w}}(\mathbf{x} + \delta) \tag{3}$$

In the following sections, we present our three novel L_1 and L_2 attack algorithms. We first provide an *Iterative Fast Coordinate Method (IFCM)* which is efficient enough to generate a large number of adversarial examples with satisfactory attacking effectiveness. Therefore, IFCM is used in the defense measure of adversarial training. To evaluate the robustness of the detector more accurately, we provide two stronger attacks. One is the search-based attack called *Augmented Iterative Search (AIS)*, and the second one is optimization-based attack called *Rounded Relaxation with Reparameterization (R3)*. Though AIS and R3 cannot generate millions of adversarial examples for adversarial training, their scalability is sufficient to evaluate the robustness of the model, and both algorithms outperform the adaption of the state-of-the-art methods significantly in attacking effectiveness. Empirical evaluation shows that with adversarial training on samples generated by IFCM, the model is significantly more robust against stronger attacks such as AIS and R3.

[4]Note that, our attacks can be easily adapted to allow negative perturbations.

4 FAST ATTACK: IFCM

In this section, we propose a fast attack algorithm called *Iterative Fast Coordinate Method* (IFCM), which is inspired by the iterative gradient sign method [13]. Given the sparsity and discretilization of input data, IFCM conducts multiple gradient descents, each with step size 1 along a single coordinate. The descending coordinate is selected in different ways when generating L_1 and L_2 attacks respectively. In IFCM for L_1 attack (IFCM_1), the coordinate with the smallest partial derivative is chosen. While in IFCM for L_2 attack (IFCM_2), the selection of descending coordinate considers not only the value of partial derivative along that coordinate, but also the increment of L_2 norm caused by one unit descent along the coordinate. Thus, following the greedy algorithm for the knapsack problem, IFCM_2 selects the coordinate with the highest *Value of Perturbation* (VoP) which is defined later. The two variants of IFCM are illustrated as follows.

4.1 IFCM_1

Algorithm 1: Iterative Fast Coordinate Method for L_1 attack (IFCM_1)

input : Fraud instance $\mathbf{x}$, q, detection model parameter $\mathbf{w}$
output: Adversarial example $\mathbf{x}^{adv}$ with L_1 norm bounded distortion

1 $\mathbf{x}^{adv} \leftarrow \mathbf{x}$,$\delta \leftarrow \mathbf{0}_n$;
2 **while** $\sum_{i=1}^{n} \delta_i < q$ **do**
3 Compute the gradient $\nabla_{\mathbf{x}} f^{\mathbf{w}}(\mathbf{x}^{adv})$ with back-propagation;
4 $i_{min} = \arg\min_i \frac{\partial f^{\mathbf{w}}(\mathbf{x}^{adv})}{\partial x_i}$;
5 **if** $\frac{\partial f^{\mathbf{w}}(\mathbf{x}^{adv})}{\partial x_{i_{min}}} > 0$ **then**
6 **return** $\mathbf{x}^{adv}$;
7 $x_{i_{min}}^{adv} \leftarrow x_{i_{min}}^{adv} + 1$,$\delta_{i_{min}} \leftarrow \delta_{i_{min}} + 1$;
8 **return** $\mathbf{x}^{adv}$.

As illustrated by Algorithm 1, at each iteration, IFCM_1 computes the gradient $\nabla_{\mathbf{x}} f^{\mathbf{w}}(\mathbf{x}^{adv})$ of the fraudulent score with the current adversarial example (Line 3), and selects the coordinate i_{min} with the minimal partial derivative (Line 4). If the partial derivative of $f^{\mathbf{w}}(\mathbf{x}^{adv})$ with $x_{i_{min}}$ is negative, a step of coordinate descent along the coordinate i_{min} is conducted with step size 1. Otherwise, when the gradient $\nabla_{\mathbf{x}} f^{\mathbf{w}}(\mathbf{x}^{adv})$ is positive along every coordinate, or the maximal distortion q is reached, the algorithm terminates.

4.2 IFCM_2

The main difference between IFCM_2 and IFCM_1 lies in the choice of descending coordinate. IFCM_1 selects the coordinate by comparing the partial derivative, while the coordinate chosen in IFCM_2 is decided by *Value of Perturbation* (VoP). VoP is inspired by the greedy algorithm for knapsack problem. For each coordinate i, a unit descent on such coordinate decreases the fraudulent score $f^{\mathbf{x}^{adv}}$ by

Algorithm 2: Iterative Fast Coordinate Method for L_2 attack ($IFCM_2$)

input : Fraud instance $\mathbf{x}, q$, detection model parameter $\mathbf{w}$
output : Adversarial example $\mathbf{x}^{adv}$ with L_1 norm bounded distortion

1 $\mathbf{x}^{adv} \leftarrow \mathbf{x}, \delta \leftarrow \mathbf{0}_n$;
2 **while** $\sqrt{\sum_{i=1}^{n} \delta_i^2} < q$ **do**
3 Compute the gradient $\nabla_{\mathbf{x}} f^{\mathbf{w}}(\mathbf{x}^{adv})$ with back-propagation;
4 Compute VoP_i for $i \in [n]$;
5 $i_{max} = \arg\max_i VoP_i$;
6 **if** $VoP_{i_{max}} \leq 0$ **then**
7 **return** $\mathbf{x}^{adv}$;
8 $x_{i_{max}}^{adv} \leftarrow x_{i_{max}}^{adv} + 1, \delta_{i_{max}} \leftarrow \delta_{i_{max}} + 1$;
9 **return** $\mathbf{x}^{adv}$.

an estimated amount of $-\frac{\partial f^{\mathbf{w}}(\mathbf{x}^{adv})}{\partial x_i}$ (the *value*), and increases the L_2 norm of current perturbation δ by $\sqrt{\|\delta\|_2^2 + 2\delta_i + 1} - \|\delta\|_2$ (the *weight*). VoP_i is defined as the estimated decrease on the fraudulent score per unit increase of L_2 norm via increasing δ_i

$$VoP_i = \begin{cases} \frac{-\frac{\partial f^{\mathbf{w}}(\mathbf{x}^{adv})}{\partial x_i}}{\sqrt{\|\delta\|_2^2 + 2\delta_i + 1} - \|\delta\|_2} & \text{if } \sqrt{\|\delta\|_2^2 + 2\delta_i + 1} \leq q \\ -\infty & \text{otherwise.} \end{cases}$$

5 SEARCH-BASED ATTACK: AIS

In order to further evaluate the vulnerability of deep fraud detector to adversarial perturbation, we propose an attack method called *Augmented Iterative Search* (AIS) which shows superior performance in fooling the detector and outperforms all benchmarks significantly in our experimental evaluation. Since the size of perturbation space is a combinatorial number, for example, $|\Delta_q^1| = C_{n+q-1}^q$, the exhaustive search is intractable. Thus, AIS repeatedly searches for a "simple" perturbation which brings the largest decrease on the objective value of optimization (3) and accumulates those "simple" perturbations to form the final solution. The simplest perturbation perturbs only one coordinate with a single unit, which is the one with L_1 norm of 1, termed "single-unit" perturbation. AIS goes further by taking into account the perturbations which perturb two entries with non-zero changes, one with 1 and one with -1[5], termed "tuple-unit" perturbations. However, the number of feasible tuple-unit perturbations is of quadratic order $O(n^2)$ with n, which makes it impractical to exhaustively search all of them. Thus, AIS augments the search process of the tuple-unit perturbations by restricting the space of such perturbations, as we explain later.

5.1 AIS_1

Similarly as IFCM, we implement two variants of AIS, AIS_1 and AIS_2, for L_1 and L_2 attacks respectively. AIS_1 is illustrated in Algorithm 3. δ^t denotes the accumulative perturbations until iteration t and $\delta^0 = \mathbf{0}$. At each iteration t, the set of all single-unit perturbations is denoted by $\Delta_t^- \cup \Delta_t^+$ where Δ_t^- contains the single-unit perturbations which have value -1 on the only non-zero entry and the adoption of $\delta^- \in \Delta_t^-$ decreases the L_1 norm of accumulative perturbation δ^{t-1} by 1. Similarly, $\delta^+ \in \Delta_t^+$ has value 1 on the only non-zero entry.

$$\Delta_t^- = \{\delta \in \mathbb{Z}^n \mid \|\delta\|_1 = 1, \|\delta^{t-1} + \delta\|_1 = \|\delta^{t-1}\|_1 - 1, \delta^{t-1} + \delta \geq \mathbf{0}\}$$
$$\Delta_t^+ = \{\delta \in \mathbb{Z}^n \mid \|\delta\|_1 = 1, \|\delta^{t-1} + \delta\|_1 = \|\delta^{t-1}\|_1 + 1\}. \quad (4)$$

The set of all tuple-unit perturbations is denoted by $\Delta_t^{\pm}$

$$\Delta_t^{\pm} = \{\delta^+ + \delta^- \mid \delta^+ \in \Delta_t^+, \delta^- \in \Delta_t^-\}$$

However, the size of $\Delta_t^{\pm}$ is $mn - m$ where m is the number of non-zero entries in δ^{t-1}, and in the worst case, $\|\Delta_t^{\pm}\|$ can be quadratic with n. To augment the search of tuple-unit perturbation, AIS_1 replaces $\Delta_t^{\pm}$ with its restricted subset $\tilde{\Delta}_{t,k}^{\pm}$ with much smaller size. In order to do so, we first define the value of a "simple" perturbation δ with respect to current solution $\mathbf{x}^{adv}$ as the marginal decrease on the objective value of (3) due to the adoption of δ

$$V(\mathbf{x}^{adv}, \delta) = f^{\mathbf{w}}(\mathbf{x}^{adv}) - f^{\mathbf{w}}(\mathbf{x}^{adv} + \delta)$$

The restricted set $\tilde{\Delta}_{t,k}^{\pm}$ is defined as follows

$$\tilde{\Delta}_{t,k}^{\pm} = \{\delta^+ + \delta^- \mid \delta^+ \in \tilde{\Delta}_{t,k}^+, \delta^- \in \tilde{\Delta}_{t,k}^-\} \quad (5)$$

where $\tilde{\Delta}_{t,k}^+ \subset \Delta_t^+$ and $\tilde{\Delta}_{t,k}^- \subset \Delta_t^-$ contain the top k single-unit perturbations among Δ_t^+ and Δ_t^- respectively ordered by values in the descending order. The intuition behind $\tilde{\Delta}_{t,k}^{\pm}$ is that a tuple-unit perturbation is more likely to have higher marginal decrease on $f^{\mathbf{w}}(\mathbf{x}^{adv})$ if it consists of the single-unit perturbations with high values. The size of $\tilde{\Delta}_{t,k}^{\pm}$ is of order $O(k^2)$, and the choice of k balances the scalability and solution quality.

The search operation in AIS_1 is as follows. Given the L_1 norm bound of distortion, a reasonable policy is to process the spaces of perturbations Δ_t^-, Δ_t^+ and $\tilde{\Delta}_{t,k}^{\pm}$ separately with different priorities. Δ_t^- is assigned the highest priority as the perturbation within it can decrease the L_1 norm of the accumulative perturbation. Thus, if there exists one single-unit perturbation $\delta^- \in \Delta_t^-$ with positive value, it is returned and added to δ^{t-1}, the accumulative perturbation so far (Lines 4–6). If Δ_t^- contains no single-unit perturbation with positive value, $\tilde{\Delta}_{t,k}^{\pm}$ is processed. Similarly, the tuple-unit perturbation $\delta^{\pm}$ with positive value is returned and δ^t is updated (Lines 8–10). Finally, if both Δ_t^- and $\tilde{\Delta}_{t,k}^{\pm}$ cannot decrease the objective $f^{\mathbf{w}}(\mathbf{w}(\mathbf{x}^{adv}))$, AIS_1 searches for δ^+ with positive value from Δ_t^+, which increases the L_1 norm of accumulative perturbation by 1 (Lines 14–16).

5.2 AIS_2

The key difference between AIS_2 and AIS_1 is that, in AIS_1, a single-unit perturbation would always change the L_1 norm of the accumulative perturbation by 1, and the L_1 norm of the accumulative perturbation is unchanged when a tuple-unit perturbation is applied. However, this is not always the case when producing L_2 attacks. Therefore, the value of a "simple" perturbation needs to take into account not only the decrease of fraudulent score $f^{\mathbf{w}}(\mathbf{x}^{adv})$, but also the change of the L_2 norm of accumulative perturbation. Given

[5]Notice that the value of -1 does not necessarily violate the non-negative requirement on δ, which is the accumulative perturbation.

Algorithm 3: Augmented Iterative Search (AIS) for L_1 attack

input : Fraud instance $\mathbf{x}$, q, maximum iteration K,detection model parameter $\mathbf{w}$, k

output : Adversarial example $\mathbf{x}^{adv}$ with L_1 norm bounded distortion

$\mathbf{x}^{adv} \leftarrow \mathbf{x}$,$\delta^0 \leftarrow \mathbf{0}_n$;
for $t \leftarrow 1$ **to** K **do**
  Compute Δ_t^-, Δ_t^+ and $\tilde{\Delta}_{t,k}^{\pm}$ with (4) and (5);
  Solve $\min_{\delta \in \Delta_t^-} V(\mathbf{x}^{adv}, \delta)$ and get δ^-;
  if $V(\mathbf{x}^{adv}, \delta^-) > 0$ **then**
    $\delta^t \leftarrow \delta^{t-1} + \delta^-$, $\mathbf{x}^{adv} \leftarrow \mathbf{x}^{adv} + \delta^-$;
  else
    Solve $\min_{\delta \in \tilde{\Delta}_t^{\pm}} V(\mathbf{x}^{adv}, \delta)$ and get $\delta^{\pm}$;
    if $V(\mathbf{x}^{adv}, \delta^{\pm}) > 0$ **then**
      $\delta^t \leftarrow \delta^{t-1} + \delta^{\pm}$, $\mathbf{x}^{adv} \leftarrow \mathbf{x}^{adv} + \delta^{\pm}$;
    else
      if $\|\mathbf{x}^{adv} - \mathbf{x}\|_1 = q$ **then**
        return $\mathbf{x}^{adv}$
      Solve $\min_{\delta \in \Delta_t^+} V(\mathbf{x}^{adv}, \delta)$ and get δ^+;
      if $V(\mathbf{x}^{adv}, \delta) > 0$ **then**
        $\delta^t \leftarrow \delta^{t-1} + \delta^+$, $\mathbf{x}^{adv} \leftarrow \mathbf{x}^{adv} + \delta^+$;
      else
        return $\mathbf{x}^{adv}$;
return $\mathbf{x}^{adv}$

the current solution $\mathbf{x}^{adv}$ of optimization (3) and a feasible "simple" perturbation δ, we define the *Value of Perturbation (VoP)* as follows:

$$VoP(\mathbf{x}^{adv}, \delta) = \begin{cases} \frac{\Delta f^{\mathbf{w}}(\mathbf{x}^{adv}, \delta)}{d_2(\mathbf{x}^{adv}, \delta) + \epsilon} & \text{if } \|\mathbf{x}^{adv} + \delta\|_2 \geq \|\mathbf{x}^{adv}\|_2 \\ -d_2(\mathbf{x}^{adv}, \delta) \cdot \Delta f^{\mathbf{w}}(\mathbf{x}^{adv}, \delta) & \text{o.w.} \end{cases}$$

where ϵ is a small constant to avoid being divided by 0,

$$d_2(\mathbf{x}^{adv}, \delta) = \|\mathbf{x}^{adv} + \delta\|_2 - \|\mathbf{x}^{adv}\|_2,$$

and

$$\Delta f^{\mathbf{w}}(\mathbf{x}^{adv}, \delta) = f^{\mathbf{w}}(\mathbf{x}^{adv}) - f^{\mathbf{w}}(\mathbf{x}^{adv} + \delta),$$

Similar with AIS_1, we start from the definition of the single-unit perturbations, which form Δ_t^- and Δ_t^+. Δ_t^- is the same as defined in (4) while Δ_t^+ is a bit different, considering the L_2 norm constraint.

$$\Delta_t^+ = \{\delta \in \mathbb{Z}^n \mid \|\delta\|_1 = 1, \|\delta^{t-1} + \delta\|_1 = \|\delta^{t-1}\|_1 + 1, \|\delta^{t-1} + \delta\|_2 \leq q\}.$$

The restricted set $\tilde{\Delta}_{t,k}^{\pm}$ follows the definition in (5) where $\tilde{\Delta}_{t,k}^+ \subset \Delta_t^+$ and $\tilde{\Delta}_{t,k}^- \subset \Delta_t^-$ contain the k single-unit perturbations with top-k *VoP*s among Δ_t^+ and Δ_t^- respectively. AIS_2 searches the"simple" perturbation in a way that, the perturbations which can decrease the L_2 norm of accumulative perturbation are evaluated first. For this aim, we divide $\tilde{\Delta}_{t,k}^{\pm}$ into two sets, $\tilde{\Delta}_{t,k}^{\pm,m}$ which consists of perturbations whose adoption can decrease the L_2 norm of accumulative perturbation, and $\tilde{\Delta}_{t,k}^{\pm,p}$, the complementary set of $\tilde{\Delta}_{t,k}^{\pm,m}$.

$$\tilde{\Delta}_{t,k}^{\pm,m} = \{\delta \in \tilde{\Delta}_{t,k}^{\pm} \mid \|\delta^{t-1} + \delta\|_2 < \|\delta^{t-1}\|_2\} \quad \tilde{\Delta}_{t,k}^{\pm,p} = \tilde{\Delta}_{t,k}^{\pm} \setminus \tilde{\Delta}_{t,k}^{\pm,m}.$$

Algorithm 4 illustrates the details of AIS_2. First, AIS_2 processes

Algorithm 4: Augmented Iterative Search (AIS) for L_2 attack

input : Fraud instance $\mathbf{x}$, q, maximum iteration K,detection model parameter $\mathbf{w}$, k

output : Adversarial example $\mathbf{x}^{adv}$ with L_2 norm bounded distortion

1 $\mathbf{x}^{adv} \leftarrow \mathbf{x}$,$\delta^0 \leftarrow \mathbf{0}_n$;
2 **for** $t \leftarrow 1$ **to** K **do**
3 Compute Δ_t^-, Δ_t^+ and $\tilde{\Delta}_{t,k}^{\pm}$;
4 Solve $\min_{\delta \in \Delta_t^- \cup \tilde{\Delta}_{t,k}^{\pm,m}} VoP(\mathbf{x}^{adv}, \delta)$ and get δ^-;
5 **if** $VoP(\mathbf{x}^{adv}, \delta^-) > 0$ **then**
6 $\delta^t \leftarrow \delta^{t-1} + \delta^-$, $\mathbf{x}^{adv} \leftarrow \mathbf{x}^{adv} + \delta^-$;
7 **else**
8 Solve $\min_{\delta \in \Delta_t^+ \cup \tilde{\Delta}_{t,k}^{\pm,p}} VoP(\mathbf{x}^{adv}, \delta)$ and get δ^+;
9 **if** $VoP(\mathbf{x}^{adv}, \delta^+) > 0$ **then**
10 $\delta^t \leftarrow \delta^{t-1} + \delta^+$, $\mathbf{x}^{adv} \leftarrow \mathbf{x}^{adv} + \delta^+$;
11 **else**
12 **return** $\mathbf{x}^{adv}$
13 **return** $\mathbf{x}^{adv}$

$\Delta_t^- \cup \tilde{\Delta}_{t,k}^{\pm,m}$, with perturbations decreasing the L_2 norm of the accumulative perturbation. If there exists one "simple" perturbation $\delta^- \in \Delta_t^- \cup \tilde{\Delta}_{t,k}^{\pm,m}$ with positive *VoP*, it is returned and added to δ^{t-1}, the accumulative perturbation so far (Lines 4–6). Otherwise, $\Delta_t^+ \cup \tilde{\Delta}_{t,k}^{\pm,p}$ is proceeded (Lines 8–10). The algorithm terminates if no "simple" perturbation within $\Delta_t^- \cup \Delta_t^+ \cup \tilde{\Delta}_{t,k}^{\pm}$ has positive *VoP* (Line 12) or the maximum iteration K is reached.

6 OPTIMIZATION-BASED ATTACK: R3

In this section, we propose a novel attack framework called *Rounded Relaxation with Reparameterization (R3)*. R3 solves the following relaxed optimization problem of (3) and rounds the continuous solution to get the discrete perturbation.

$$\begin{aligned} \min_{\delta \in \mathbb{R}_{+,0}^n} \quad & f^{\mathbf{w}}(\mathbf{x} + \delta) \\ \text{s.t.} \quad & \|\delta\|_p \leq q. \end{aligned} \tag{6}$$

The main problem here is that the constrained non-convex optimization is hard to solve. Though one can apply the projected gradient descent to ensure the solution is always feasible, unlike the box-constraint in the common L_∞ attacks, the projection operation is challenging under the complex L_1 and L_2 norm constraints. Thus, we propose the reparameterization tricks to transform the constrained optimization (6) to the equivalent unconstrained optimization by exploiting the property of L_1 and L_2 norms.

For the L_1 attack, we notice that the unit L_1 norm ball $\mathcal{B}_1 = \{\delta \in \mathbb{R}_{+,0}^n \mid \|\delta\|_1 = 1\}$ is the set of all n-dimensional probability distribution vectors. Thus, we can resolve the unit L_1 norm constraint in (6) with Softmax reparameterization as follows. Let $\mathbf{z} \in \mathbb{R}^n$ be

the variable to reparameterize δ.

$$\delta_i = \frac{e^{z_i}}{\sum_{j=1}^{n} e^{z_j}} \quad \forall i \in [n]$$

To generalize it to the L_1 norm within $[0, q]$, we define $\mathbf{r} \in \mathbf{R}^n$ and reparameterize δ as follows

$$\delta_i = q \cdot \frac{(tanh(r_i) + 1) \cdot e^{z_i}}{2 \sum_{j=1}^{n} e^{z_j}} \quad \forall i \in [n] \tag{7}$$

One can easily verify that δ satisfies the L_1 norm constraint and every feasible δ can be reparameterized with suitable $\mathbf{r}$ and $\mathbf{z}$.

The L_2 norm constraint of δ can also be resolved with similar reparameterization trick using $\mathbf{r}$ and $\mathbf{z}$.

$$\delta_i = q \cdot \frac{(tanh(r_i) + 1) \cdot e^{z_i}}{2\sqrt{\sum_{j=1}^{n} e^{2z_j}}} \quad \forall i \in [n] \tag{8}$$

With reparameterization, we solve the following unconstrained optimization which is equivalent to (6).

$$\min_{\mathbf{r}, \mathbf{z} \in \mathbb{R}^n} \quad f^{\mathbf{w}}(\mathbf{x} + \delta) \tag{9}$$

where δ is in the forms of (7) and (8) for L_1 and L_2 attacks respectively.

We use the Adam optimizer to conduct gradient descent to solve (9). After the continuous solution δ is obtained, we round it into a discrete solution satisfying the L_p norm bound of q. The rounding process works as follows. We pick a threshold value η from $[0, 1]$. Let $\tilde{\delta}$ be the solution of (9). For each entry $\tilde{\delta}_i$, if the residual value $\tilde{\delta}_i - \lfloor \tilde{\delta}_i \rfloor$ is larger than η, we set δ_i be $\lfloor \tilde{\delta}_i \rfloor + 1$ and otherwise, δ_i is assigned with $\lfloor \tilde{\delta}_i \rfloor$. The binary search is conducted on possible threshold values and output the final solution δ such that no feasible δ with $\|\delta\|_p \leq q$ can be obtained with higher threshold value. As there are at most n different residual values, the binary search can be done within $\log(n)$ rounds.

7 ADVERSARIAL TRAINING FOR IMPROVING ROBUSTNESS

In order to improve the robustness of the deep fraud detector, we incorporate adversarial examples into the training process (Algorithm 5), and solve the following robust optimization

$$\min_{\mathbf{w}} \mathop{\mathbb{E}}_{(\mathbf{x}, y) \sim \mathcal{D}} [\max_{\delta \in \Delta_{q_1}^1 \cup \Delta_{q_2}^2} L^{\mathbf{w}}(\mathbf{x} + \delta, y)] \tag{10}$$

where we omit the regularization term. Adversarial training (Algorithm 5) is a common practice to solve (10). The idea is to incorporate the adversarial examples into the training process and to approximate the optimization of the inner problem in (10). Noticing that both L_1 and L_2 attacks are considered in this paper, at each iteration, for each fraud instance in minibatch $\mathcal{B}$ of training data, we uniformly pick p from $\{1, 2\}$ and generate one adversarial example with IFCM$_p$. All the generated adversarial examples are grouped into $\mathcal{B}^{adv}$, which is concatenated with $\mathcal{B}$ to form the new minibatch training data $\mathcal{B}'$. A training step is then conducted on $\mathcal{B}'$ with the following loss function

$$\begin{aligned} \tilde{L}^{\mathbf{w}}(\mathbf{x}, y) =& \mathbb{1}_{\{y=0\}} L^{\mathbf{w}}(\mathbf{x}, y) + (1 - \gamma) \mathbb{1}_{\{y=1\}} L^{\mathbf{w}}(\mathbf{x}, y) \\ &+ \gamma \mathbb{1}_{\{y=1\}} L^{\mathbf{w}}(\mathbf{x}^{adv}, y) \end{aligned} \tag{11}$$

where γ is the parameter balancing the loss of the original data and adversarial examples.

Algorithm 5: Adversarial training with IFCM

```
Randomly initialize the network for fraud detection;
repeat
    Read minibatch B ⊂ D from training set D;
    For each fraud instance in B, randomly selects p ∈ {1, 2}
      and create an adversarial example with IFCM_p, grouped
      into B^adv;
    Concatenate B^adv with B as B';
    Conduct one training step over B' with loss L̃ in (11);
until training converged;
```

8 EXPERIMENTAL EVALUATION

In this section, we present extensive experimental evaluation to illustrate the performance of our methods.

8.1 Experimental Settings

8.1.1 Dataset and Data Analysis. Our dataset is provided by TaoBao, one of the largest e-commerce platforms in the world. The dataset contains all transaction data in a period of 30 days. Each transaction is encoded as a feature vector to represent its statistics and characteristics, including various prices, the number of historical purchases on an item, the offline metrics on fraudulent suspicious of the buyer and item, and the statistics on a user's preference, depicted by the records of interactions on all categories in the past one month. We randomly sample 1.5 million fraud transactions and 1.5 million benign instances from the data in the first 25 days to form a balanced training set. We uniformly pick 300 thousand transactions from the records of the last 5 days as the test data, where the proportion of fraud instances to benign ones is around 1 : 30.

We provide some statistics on the preference features to give a better impression on the fraud detection problem. One key statistic is the L_1 norm of a transaction instance $\mathbf{x}$, that is, the total number of interactions recorded in the past month. We notice that in the fraud transactions, 66.8% have zero interaction, i.e., $\|\mathbf{x}\|_1 = 0$[6], while the percentage is only 3.9% in the benign transactions. According to the explanation from domain experts in TaoBao, those fraud instances with zero L_1 norms are likely to be generated by large number of simple and cheap robots or scripts by the platforms, which are also easier to detect. The remaining fraud instances with non-zero L_1 norms correspond to the sophisticated scripts, such as the one in Figure 2, which makes complicated operations to behave like humans. Table 1 presents the distribution of $\|\mathbf{x}\|_1$ of instances with non-zero L_1 norms, as well as the mean value of $\|\mathbf{x}\|_1$.

There are several points we would like to make regarding these statistics. First, though it seems reasonable to have two separate classifiers, one for instances with zero L_1 norm and the other for the remaining instances, empirical attempts show that it provides

[6]We would like to remind the reader that for simplicity, we only consider the preference features to encode an instance, while in the deployed model, there are other non-zero features.

Type	$\|\mathbf{x}\|_1 \leq 100$	$100 < \|\mathbf{x}\|_1 \leq 200$	$200 < \|\mathbf{x}\|_1 \leq 300$	$\|\mathbf{x}\|_1 > 300$	mean($\|\mathbf{x}\|_1$)
fraud	33.87%	16.43%	10.85%	38.85%	**377**
benign	45.33%	23.56%	12.8%	18.31%	**208**

Table 1: Statistics on fraud and benign instances with non-zero L_1 norms

little improvement and brings extra vulnerability to adversarial attack. Thus, we use a single classifier as the detector for all instances. Second, despite the high amount of fraud instances with zero L_1 norms, the perturbation on those instances is meaningful as it indicates the potential that the adversary improves their simple bots with extra functions. Third, we also evaluate our attacks on fraud instances with non-zero L_1 norms separately, and the slight perturbation can still bypass the detector with high chance. For example, with $q = 20$ in L_1 attack, which corresponds to the distortion ratio of only around 5% given that the mean value of $\|\mathbf{x}\|_1$ is 377 for fraud instances with non-zero L_1 norms, the adversarial examples generated by AIS_1 can fool the detector with probability over 50%.

8.1.2 Model Training and Attack Settings. The deep fraud detector model is trained with the following parameters. The training batch size is 500 and the model is trained over 30000 batches. Adam [12] optimizer is used to conduct the stochastic gradient descent and the learning rate is set to be 0.0002. The regularization parameter α is set to be 0.01. The adversarial training is conducted with adversarial examples generated by $IFCM_1$ and $IFCM_2$, with $q = 30$ and $q = 6$ respectively. To test the attacking effectiveness of various algorithms, we consider $q \in \{10, 20, 30\}$ for the L_1 attack and $q \in \{4, 5, 6\}$ for the L_2 attack. In evaluation of the detector strengthened with adversarial training, we also try larger values of q, such as $q \in \{10, 20, 30, 40, 50\}$ for the L_1 attack and $q \in \{4, 5, 6, 7\}$ for the L_2 attack.

8.1.3 Baselines. We adapt several state-of-the-art continuous attacks to generate discrete perturbations, including FGSM [8], C&W attack [4], Logit-Space attack [2], and EAD attack [5].

FGM_1: FGM_1 is a single step L_1 attack method which selects the q coordinates with the minimal partial derivatives and adds one unit perturbation on each of them.

C&W attack: C&W attack is an optimization-based method primarily for continuous L_0, L_2, and L_∞ attacks on image classifiers. We adapt it to generate L_1 attack and use rounding techniques to obtain the discrete perturbation satisfying the norm constraint. C&W uses the Change of Variables (CoV) to replace δ with $\frac{q}{2}(tanh(\mathbf{w})+1)$ (element-wise) and solves the following continuous optimization

$$\min_{\mathbf{w}\in\mathbb{R}^n} c \cdot f(\mathbf{x} + \frac{q}{2}(tanh(\mathbf{w}) + 1)) + \|\frac{q}{2}(tanh(\mathbf{w}) + 1)\|_p$$

where $f(\mathbf{x}^{adv})$ is suggested to be defined as the difference of the logits, i.e., $f(\mathbf{x}^{adv}) = \max(z_1^{adv} - z_0^{adv}, 0)$ [4] with $\mathbf{z}^{adv}$ being the output of the last hidden-layer when the adversarial example $\mathbf{x}^{adv} = \mathbf{x} + \frac{q}{2}(tanh(\mathbf{w}) + 1)$ is the input. We replace it with $f(\mathbf{x}^{adv}) = z_1^{adv} - z_0^{adv}$ as z_1 tends to be larger than z_0 in our tested detector and the suitable threshold is around 0.9, rather than 0.5. Constant c is selected with binary search to ensure that $f(\mathbf{x}^{adv})$ is minimized to the extend while $\|\frac{q}{2}(tanh(\mathbf{w}) + 1)\|_p \leq q$ is still satisfied[7]. The optimization is solved with Adam optimizer. We pick the hyper-parameters that perform the best in solving the optimization in our tests, including the learning rate of 0.1 with 1000 gradient descent steps. 16 binary searches are conducted on $c \in [0, 100]$. The continuous solution δ is rounded off in a similar way as R3 attack. After the binary search returns the optimal c, we solve the optimization with 5 random starting-points of $\mathbf{w}$ and pick the best rounded discrete solution.

C&W-LS attack: Logit-Space attack [2] uses one-hot encoding to represent the discrete feature and applies the Softmax reparameterization to approximate the one-hot encoding. Formally, δ_i is represented by $Softmax(\mathbf{w}_i) \cdot (0, 1, ..., q)$ and the optimized variable is changed to $W = [\mathbf{w}_1, ..., \mathbf{w}_n]$. The optimization is similar to C&W attack, except that an entropy penalty is imposed to penalize δ_i being fractional. That is, C&W-LS solves the following optimization

$$\min_{W\in\mathbb{R}^{n\times(q+1)}} c\cdot f(\mathbf{x}+U(0,1,...,q)^T)+\|U(0,1,...,q)^T\|_p+\beta\cdot\sum_{i\in[n]} H(\mathbf{u}_i)$$

where $U = [\mathbf{u}_1, ..., \mathbf{u}_n]$, $\mathbf{u}_i = Softmax(\mathbf{w}_i)$, i.e., $u_{ij} = \frac{e^{w_{ij}}}{\sum_{j'=0}^{q} e^{w_{ij'}}}$ for $j \in \{0, 1, ..., q\}$, and $H(\mathbf{u}_i) = -\sum_{j=0}^{q} u_{ij} \log(U_{ij})$ is the entropy for $\mathbf{u}_i$ regarded as a distribution, which is minimized when $\mathbf{u}_i$ is one-hot. The implementation follows the same settings as C&W attack. We try different values of β and choose the best one in evaluation, which is 0.1 for L_1 attack and 0.5 for L_2 attack.

EAD attack: EAD attack [5] is a continuous L_1 attack on image classifier. It is also optimization-based attack which solves the following optimization problem with elastic-net regularization

$$\min_{\delta\in\mathbb{R}^n_{0,+}} c \cdot f(\mathbf{x} + \delta) + \beta \cdot \|\delta\|_1 + \|\delta\|_2^2$$

We try different values of β and choose the best one in evaluation, which is 5.0.

We also try to round other attack algorithms such as DeepFool [17] for discrete L_2 attack. However, since DeepFool aims to find the successful attack with the smallest L_2 distortion and thus imposes no norm restriction on perturbation. The rounding solution of DeepFool performs poorly. We also implement the random attack, which has little effect on degrading the performance of the classifier. Therefore, the results of these attempts are not presented in the paper.

8.1.4 Evaluation Metrics. We evaluate various attacks and adversarial training based on two metrics, *success rate* and *Average Precision (AP)*. Success rate measures the proportion of fraud instances which are correctly recognized by the detector with pre-defined threshold η and mis-classified under the attack. AP is commonly

[7] Though in [4], the binary search on c aims to ensure the minimal value of c such that δ successfully fools the detector, it performs worse than our implementation when rounding the solution to the discrete one with L_p norm bound q. Thus, we implement C&W attack in the way explained here.

Attack	Original model			Model with adversarial training				
	$q = 10$	$q = 20$	$q = 30$	$q = 10$	$q = 20$	$q = 30$	$q = 40$	$q = 50$

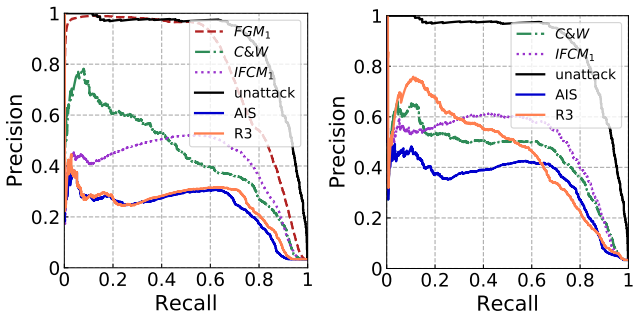
Table 5: *Success rate* of L_2 attacks



adopted to measure the performance of a classifier, which is defined by the enclosing area of the Precision-Recall curve (PR-curve). For a threshold η, the precision and recall are defined as follows [19]

$$P(\eta) = \frac{tp}{tp + fp} \quad R(\eta) = \frac{tp}{tp + fn},$$

where tp, fp and fn denote the true positive rate, false positive rate and false negative rate respectively. A higher value of AP intuitively means that the detector can recall a large proportion of fraud instances and meanwhile mis-classifies a few benign instances. A stronger attack should be able to degrade the AP to a lower value. The effectiveness of adversarial training can also be measured by AP by verifying whether the obtained model can pertain the AP under strong attacks. PR-curve is also useful for the selection of threshold in deployment. In practice, we choose the threshold η^* which equals the precision and recall, and we use η^* when evaluating the success rate of attacks. One thing to notice is that, an attack degrading the AP to a lower value doesn't mean it has higher success rate at η^*, since AP is an average measure of performance over all threshold values. We now present our key experimental results.

8.2 Average Precision

Tables 2 and 3 show the AP of the original detector and the one obtained via adversarial training under various L_1 and L_2 attacks respectively. Figure 3 shows the PR-curves of the detector under L_1 attacks with $q = 30$ and L_2 attacks with $q = 5$. We denote by *unattack* the trials without adversarial perturbation, corresponding to the performance on the original test data. The results show that (i) The deployed detector is extremely vulnerable to adversarial perturbations, as with $q = 20$ and $q = 5$ for AIS_1 and AIS_2 respectively, the AP is decreased from nearly 0.9 to 0.434 and 0.344. The numbers further decrease to 0.238 and 0.207 for AIS_1 attack with $q = 30$ and AIS_2 attack with $q = 6$ respectively. (ii) Our attack methods always achieve the largest degrade of AP in all settings, and significantly outperform baselines, especially AIS and R3, which show the similar performance. (iii) With adversarial training, the detector becomes significantly more robust to adversarial perturbations, as we consider larger q values 40, 50 for L_1 attack and 7 for L_2 attack, and the model can still achieve an AP above 0.859 in all

(a) L_1 attack, $q = 30$ (b) L_2 attack, $q = 5$

Figure 3: PR-curves.

Attack	L_1 attack			L_2 attack		
	$q = 10$	$q = 20$	$q = 30$	$q = 4$	$q = 5$	$q = 6$
FGM_1	0.005	0.005	0.005	-	-	-
IFCM	0.037	0.072	0.103	0.057	0.088	0.125
C&W	372.5	399.8	480.1	285.4	317.9	329.2

Table 6: Average runtime of generating one adversarial example (in seconds)

settings. Besides, the performance on the original test data is not degraded due to adversarial training, which shows the necessity of adversarial training[8].

8.3 Success Rate

Tables 4 and 5 show the success rates of tested L_1 and L_2 attacks respectively on the original model with threshold value η^*. To better understand the effectiveness of attacks, we separate the fraud instances based on the L_1 norm and randomly pick 1000 fraud instances with zero L_1 norm and 1000 fraud instances with non-zero L_1 norm. The results show that (i) Both types of fraud instances are highly vulnerable to adversarial perturbations. For instances with zero L_1 norm, with distortion bounds of 20 in L_1 norm and 5 in L_2 norm, our *AIS* attack can craft the instance to bypass the detector with probabilities over 84%. This shows the potential threat for the deployed system as the real-world adversaries and platforms may exploit this property and design more sophisticated scripts and bots with only tens of additional operations to bypass the detector with high changes. While for instances with non-zero L_1 norm, with distortion bounds of 20 in L_1 norm, which corresponds to an average distortion ratio of only 5% given the average L_1 norm for this type of instance being 377, our AIS_1 attack can fool the detector with probability 54.1%. (ii) Our attack methods achieve the highest success rates in all settings, and outperform baselines more significantly for instances with zero L_1 norm.

8.4 Feasibility of Attacks

8.4.1 Feasibility of Adversarial Perturbations. The perturbations generated here are not artificial noises on the input. Instead, there do exist such cases where the malicious service platform intentionally creates such perturbations. Recall that in the motivating scenario, we show an automatic script (Figure 2) by a malicious service provider. The script can conduct operations to pretend it as a human. One interesting pattern noticed by domain experts is that, when the script scrolls the item list on the website or mobile Apps, it will not directly visit the target item to create fake impression. Instead, it is designated with certain probability of visiting another item from certain categories and return to the item list. Imagine that fraudulent sellers and providers recognize the adversarial perturbations to bypass the detector. They can easily design effective scripts or even hire human labors to conduct the perturbation. Furthermore, we also sample adversarial perturbations and the domain experts verify that they are doable by the fraudulent sellers or malicious service providers.

8.4.2 Scalability of Attacks. Table 6 lists the average runtime of generating one adversarial example with various attacks. Notice that different attacks have varying proportions of computations able to be parallelized. Thus, the runtime of crafting a single instance cannot reflect the runtime of processing a batch of samples. From the adversary's perspective, our attacks are feasible as they can generate an adversarial examples within several minutes. Besides, one extra note on AIS is that it belongs to the *black-box* attacks as no information of the architecture of the detector is required. Thus, we argue that AIS could generate adversarial instances that are practical for real-world adversaries to craft.

[8]The proposed adversarial training process has been adopted to train the deep fraud detector for deployment since the Double 11 Shopping Festival of 2018.

9 CONCLUSION

This paper reveals the potential risk of deploying deep learning models in the task of fraud detection. We propose a fast attack called IFCM to generate large amount of effective adversarial examples, and two novel and more powerful attacks, search-based AIS attack and optimization-based R3 attack. We conduct extensive evaluations on a deployed deep fraud detector from TaoBao, one of the largest e-commerce platforms in the world with large-scale real-world transaction data. Results show that (i) Our proposed attacks can bypass the deployed detector with a high probability and can successfully degrade the Average Precision (AP) of the detector from nearly 90% to as low as 20% with slight perturbations. (ii) Our proposed attacks significantly outperform the state-of-the-art attack methods adapted to the domain of fraud detection, with respect to both the success rate and the degrading of AP of the detector in all testing trials. (iii) Our proposed adversarial training with the mixture of adversarial examples from both the L_1 and L_2 attacks significantly improves the robustness of the model, and pertains the AP of nearly 90% on the unperturbed test data.

ABSTRACT

Web crawlers spend significant resources to maintain freshness of their crawled data. This paper describes the optimization of resources to ensure that product prices shown in ads in a context of a shopping sponsored search service are synchronized with current merchant prices. We are able to use the predictability of price changes to build a machine learned system leading to considerable resource savings for both the merchants and the crawler. We describe our solution to technical challenges due to partial observability of price history, feedback loops arising from applying machine learned models, and offers in cold start state. Empirical evaluation over large-scale product crawl data demonstrates the effectiveness of our model and confirms its robustness towards unseen data. We argue that our approach can be applicable in more general data pull settings.

1 INTRODUCTION

An important characteristic of web content is the constancy of its change. While the dynamics of change are well understood in the context of generic web pages [2, 4, 5], commercial content (e.g., product listings, e-commerce sites, etc.) dynamics are relatively less explored. We see two major differences between the generic web content and commercial content. First, commercial content tends to have different change dynamics as it is closely related to marketing and economic factors such as supply and demand. Second, commercial content contains richer domain-specific metadata, e.g., merchant and brand, which provides us with more facets to understand its change dynamics. Besides, since there are billions of products advertised and sold online, often from small independent merchants, tracking and predicting of commercial content change at scale is an important but hard research challenge. Thus, in this paper, we focus on the change dynamics for commercial content.

In particular, we study commercial content change in the context of building an effective product search service. Figure 1 illustrates a high level architecture for such service. Product search results are based on the *product offers* that are listed on *merchants'* websites. These merchants are distributed and independent, and their websites cannot be searched in real-time due to latency constraint. Thus, a local database is used to store local copies of offer attributes. This paper studies the dynamics of price changes since price is one of the most important attributes of online products. The local database is then used by the search interface when users access offer details. The crawler plays a crucial role in our search service, as it attempts to keep the local database fresh. The ultimate goal for the crawler is to ensure that the prices seen by users (from the local database) match the prices shown on merchants' websites.

To achieve this goal, we need to update the local database immediately after an offer changes its price. One potential way is encouraging merchants to push price change information through merchant feeds. Our production system indeed receives such information. This mechanism alone, however, in our experience is insufficient to maintain maximum product offer freshness. Typically, merchant feeds are pushed according to specific schedules,

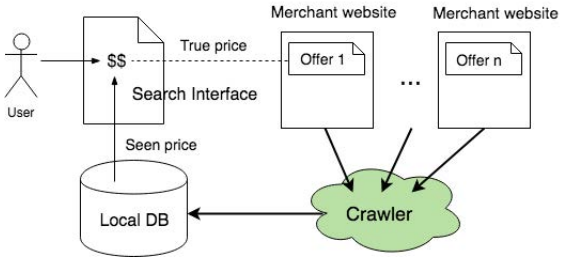

Figure 1: Overall architecture for our product search service.

but offers may change attributes regardless of the feed upload schedule. Creating a quality feed and delivering it continuously carries a substantial cost for merchants. Therefore, significant efforts are still required to build an efficient offer crawler.

An alternative solution is to repeatedly crawl merchants' websites for updates. Production crawlers often need to handle billions of offers, and scheduling frequent re-crawls for all them is impractical. To deal with that, our production crawler selects a subset of offers based on certain heuristics, and then crawls them periodically using a *Batch Scheduler*. Meanwhile, to compensate for important offers that might not be selected, we include an *InstaCrawl* component to crawl offers immediately after user clicks. Although this brings reasonable database freshness, offer selection heuristics in the *Batch Scheduler* are hard to build, and we overspend substantial resources on *InstaCrawl* because most offers do not change prices.

Previous development of generic web crawlers encounters a similar issue; researchers and practitioners try to solve it by predicting content change and schedule crawls accordingly [19, 24]. Most of existing studies developed their models based on web pages' past change frequencies [12, 13, 16, 20, 25]. There are two issues with this approach. First, it cannot handle the web pages with no or little crawl history, i.e., cold start. Second, it cannot deal with feedback loops — adjustments to the crawl strategy can distort the distribution of change frequency features so that the trained model may not work anymore. Later studies discovered that the content of a web page can help alleviate the cold start problem since similar pages share similar change patterns [28, 30].

Inspired by prior work, in this paper, we apply the predictive crawling approach to the domain of crawling commercial content. Informed by the latest advances in deep learning, we propose a state-of-the-art neural network based method to predict price change at scale. Our method combines both change dynamics as well as content and metadata information based features in a unified framework which enables us to effectively handle cold start and feedback loops of change frequency features.

We further develop new crawling strategies based on the predictive models and examine their effectiveness in the production environment. In this paper, we focus on optimizing *InstaCrawl* because the corresponding offers are more likely to be accessed by users. Particularly, we use the predictive model to reduce crawls for offers that are unlikely to change prices. Our experiments show that the new crawling strategies succeed in saving significant amount of resources. Since we use metadata and content features which are relatively static and independent from crawl history, our methods save resources even in the cold-start scenarios, for offers with little or no prior change history. In this paper, we intend to keep our models generalizable to other crawling components. For example, our price change model can also be applied to the *Batch Scheduler* for selecting more appropriate offers for periodical re-crawls.

To summarize, the main contributions of our work are as follows:

- To motivate our predictive models, we provide a comprehensive, global-scale study of factors that affect online price change – the first such published study to the best of our knowledge (Section 3).
- We develop a state-of-the-art and scalable price change prediction model that combines both price change frequency and metadata features (Section 4), and further demonstrate both its effectiveness and robustness in a cold-start setting (Section 5).
- We utilize the price change prediction model for making crawl decisions, and demonstrate that it can save a significant amount of crawl resources in production setting (Section 6).

2 RELATED WORK

A large body of work addressing freshness in pull systems has been done in the context of web crawlers (e.g. [6, 12, 23]). The topic started attracting significant interest in industry and research in the 1990s together with the rise of web search engines. Crawler optimization to address significant resource demands became an active area of research too.

A number of studies, for example [11, 13, 31], focused on change detection and estimation of frequency of change with sampling based policies. Cho and Garcia-Molina [8, 9] analyzed web content change patterns and proposed several design choices for incremental crawlers. Among them, the authors discovered that web pages changed with different frequency, and the overall freshness of a crawled corpus can be improved by 10%-23% through adjusting download frequency for different pages. Brewington and Cybenko [4] presented statistical analysis of web page modifications, introduced a freshness metric and estimated the download rate to maintain a desired level of freshness. The works [19] and [2] analyzed degree to which change correlates with other page properties, described finer-grained change statistics within different regions in the page, across various types of web pages and user visitation patterns. Tan and Mitra [30] used unsupervised learning to focus crawling within groups of pages that share similar change patterns.

Also, in the context of web page crawling, Radinsky and Bennett [28] extended the prediction model by combining change frequency features with the content of pages and their similarity to other pages. However, the use of change frequency features brings several important issues. Such features are calculated from download history and are sensitive to changes in crawl frequency. Changes to the crawling strategy will significantly affect the distribution of crawl history features, whereas the goal for change prediction is to apply such a model to reduce unnecessary crawling. Radinsky and Bennett's model can potentially avoid such issues since it also considers the content of web pages. However, the authors did not examine the performance after excluding the change frequency features. Also, they assume a full observation of crawl history when computing the change frequency which are unavailable most of the time.

Having a reliable prediction of when a web page will change is not enough for building an effective crawler. A key component in addition to estimating change probability is establishing an update policy. Optimality and scalability of such policies for various metrics under different assumptions is a subject of a number of studies. A recent work [3] presented a tractable near-optimal randomized strategy that can be computed in near-linear time. Eckstein et al. [18] studied the monitoring of web page changes under politeness constraint. Cho and Garcia-Molina [10] introduced freshness and age metrics and proposed several crawler policies assuming that change frequency follows a Poisson distribution. Also under the Poisson assumption, Coffman et al. [15] studied crawler optimality and proved an optimal formula for page refresh frequency, and Grimes et al. [20] studied optimality of a combined cost model for staleness and crawl resources when estimating refresh rates. We show, in this paper, that prices are not equally likely to change across different times of day and days of the week, thus deviating from the Poisson model. Aligned with our findings, Calzarossa and Tesser [5] analyzed temporal change patterns for news websites and showed that the changes are time dependent with significant hourly and daily fluctuations.

The work from Olston and Pandey [25] addressed crawler optimality which focused on persistent content and attempted avoiding ephemeral content likely to be obsolete by the time it reaches the index. Lefortier et al. [21], on the other hand, studied situations when engines do want to present fresh results even over ephemeral content. Wolf et al. [32] studied crawling strategies prioritized to refresh content that is more likely to surface as a result of a user query. Pandey et al. [27] presented a probabilistic change behaviour model, resource allocation and scheduling mechanism to answer continuous queries over dynamic web content and describe its more subtle differences compared to general web crawling.

A related area of research studies policies for refreshing web content caches. For example, Cohen and Kaplan [16] proposed policies for proactive validation of cache content using historic access patterns such as frequency and recency of access.

Overall, existing studies did conduct extensive research on both crawler optimization and content change prediction. However, they mainly focused on the crawling of generic web pages, and, to the best of our knowledge, very few of them studied the crawling for commercial content. Our work is the first to provide a large-scale analysis of the dynamics of commercial web content change, and develop scalable and effective content change prediction models.

3 ANALYZING PRICE CHANGE AT SCALE

Before diving into the details of building machine learning models for predictive crawling, we first provide a large-scale analysis of price change patterns for online offers. In particular, we focus on temporal, geographical and content patterns.

3.1 The Salticus Dataset

In order to conduct an unbiased analysis that avoids feedback loops [29], we sampled one million online offers and scheduled hourly crawls for all of them. The sample is a stratified mix of two sample types: (a) random uniform from the entire corpus of offers; (b) click weighted, to better represent popular offers that receive clicks. We download hourly snapshots of these offer pages from May 1st 2018 to the middle of September 2018, and use this crawl data for the following analysis, as well as for our predictive machine learning models. We refer to these snapshots as the *Salticus*[1] *dataset* in the remainder of this paper.

3.2 Temporal Patterns

We analyze two types of temporal patterns. First, we examine whether there are certain preferred time periods (e.g., weekday or weekend, morning or evening) for merchants to change prices. Second, we analyze how long it takes for an offer to change its price. Other temporal patterns such as changes over different days of the month and months of the year can also be interesting. However, since we only have data for a few months, such analysis might not be representative statistically.

Figure 2 illustrates the price change probability over the different days of the week and hours of the day (in merchant local time). We find that merchants are more likely to change prices at midnight. The peak of midnight change is probably due to automated updates. For days of the week, changes are more likely to happen on weekdays than on weekends. The non-uniform temporal patterns suggest that time is a useful factor to determine price change. Therefore, both day of the week and hour of the day are applied in our machine learning models. It is worth noting that our data spans from May to September which does not overlap with major holiday seasons. We expect different temporal patterns during holidays.

Figure 2: Probability of price change for different days of the week and hours of the day (local time). For each horizontal axis unit (e.g., Mon.), its probability equals to the number of downloaded offer pages with price change (on Mon.) over the total number of downloaded offer pages (on Mon.).

Figure 3 plots the distribution of time intervals between price changes. The horizontal axis denotes the time interval (in hours) for an offer to change its price; the vertical axis denotes the percentage of price changes — the amount of price changes within a given time interval over the total number of price changes in our dataset. As an example, suppose our dataset consists of two offers, A and B. Offer A changes its price at $t_0 + 1h$ and changes again at $t_0 + 3h$. Offer B changes its price at $t_0 + 1h$. Therefore, the total number of price changes is three, with two coming from A and one from B. The probability of change for $1h$ time interval is $2/3$, and the probability of change for $2h$ interval is $1/3$. Note that for an offer,

[1]Named after a spider genus, popularly known as "zebra spider".

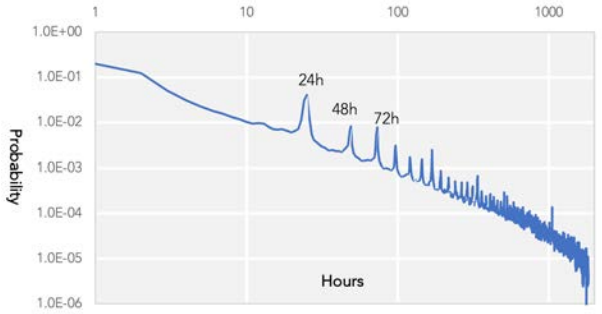

Figure 3: Distribution of time intervals between two price changes (log-log plot). The probability for a given time interval measures how many of the price changes in the Salticus dataset happened in the given interval.

the first observation of its price does not count as a change since we do not know its prior price.

Figure 3 conveys several messages. We find that among all price changes, a considerable amount of them happen within a short time. This might come from the products whose prices depend on external factors such as price fluctuations of financial instruments. One illustrative example is gold coin prices, which change dynamically together with the gold spot price. Second, we see multiple local peaks at 24 hours, 48 hours, etc. This may be due to the automatic price updates, which was also discussed in Figure 2.

3.3 Geographical Patterns

The Salticus dataset contains online product offers from across the world. This enables us to explore price change patterns for different countries. Figure 4 provides the change probability over 20 countries. Each country is represented by its ISO code.[2] The probability is computed in the same manner as described in Section 3.2. We find that different countries exhibit varying change patterns. Among the 20 countries we considered, India (IN), Mexico (MX) and Brazil (BR) are the countries with the highest price change rate whereas the United States (US), Japan (JP) and Indonesia (ID) are the lowest. This might be related to economic factors such as inflation rates in a particular country. We find a 0.4629 Pearson correlation between countries' price change rates and their inflation rates (as of October 2018). The variation of price changes across countries motivates including country as a feature in our machine learning model.

3.4 Content Patterns

This section further explores the price change patterns for different types of products. In our repository, each offer is associated with a product category.[3] A product category such as *Apparel & Accessories > Clothing* defines the product area and the subcategory of an offer. With such information, we then analyze the price change probability in each top-level category of the taxonomy. Again, the probability is computed similarly to Section 3.2.

[2]ISO codes are defined at https://en.wikipedia.org/wiki/ISO_3166-1

[3]We adopt the public Google Shopping Product Taxonomy for our online offers. A full schema is at: http://www.google.com/basepages/producttype/taxonomy.en-US.txt.

Figure 4: Price change probability in different countries. Probability is computed similarly to Figure 2.

Figure 5 presents the price change probabilities for different taxonomy categories. *Software* has the highest change rate, as it is affected by a highly dynamic *Virtual Currency* subcategory. *Electronics* (e.g., phones, tablets) and *Media* (e.g., books, music) are more dynamic than others. Offers in *Business & Industrial* and *Religious & Ceremonial* categories have the lowest change rates. Again, the non-uniform price change rate across the different categories implies that offer metadata can provide meaningful information when building machine learning models, which we take into account when designing our model as described in the next section.

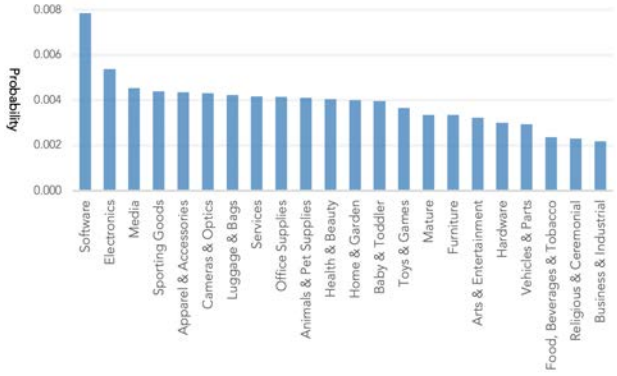

Figure 5: Price change probability over product categories. Probability is computed similarly to Figure 2.

4 METHODOLOGY

We model the price change prediction as a classification problem, for which we want to predict, for any individual offer, whether its price will change in the next K hours. Here, we do not consider the degree of change since our ultimate goal is to build an effective crawler that re-crawls an offer's page as long as there is a change. Therefore, we do not model it as a regression problem.

To build such a model, a set of training examples is required. Each example contains a list of features and a corresponding label. A positive label means that the offer's price changes within the next K hours; otherwise, a negative label is assigned. If a price x changes to y and then changes back to x, we still count it as a positive label because there are indeed price changes (twice) within the K hours. The Salticus dataset described in Section 3.1 is used for deriving our training, validation and testing examples.

4.1 Training/Testing Data

4.1.1 Generating Training Examples. The Salticus dataset contains two types of crawl events — the hourly scheduled crawls described in Section 3.1, and the regular crawls from the production system. Each crawl event is associated with a timestamp t, which allows us to split our data by time and simulate the moment we need to make a *<crawl, not crawl>* decision in the production system.

Specifically, for each simulated *prediction time* t, the future crawls after t provide full observability (on an hourly basis) of the price information in the next K hours. We use the offer information up to t to generate features, and the next K hours to generate ground-truth binary labels reflecting the price change (or lack thereof), thereby creating a single training example. By shifting t and repeating this process, we create a set of training examples.

In this paper, the *prediction time* t comes from both hourly crawls and production crawls. Using hourly crawls in addition to production crawls provides multiple benefits. First, it helps to generate enough training examples for rarely crawled offers in the production crawler. Second, it guarantees that we have an unbiased training data, with prediction times uniformly spread out over all 24 hours a day, and 7 days a week.

Finally, we observe non-uniform distributions for crawling time — crawls for popular offers are aggregated densely around the same time. To avoid generating too many similar examples, we restrict different ts to be at least 15 minutes away from each other.

The entire training generation process is illustrated in Figure 6. Instead of choosing the immediate follow-up crawl event as the next t, we skip two regular crawls and one hourly crawl since they are crawled less than 15 minutes from the last prediction time.

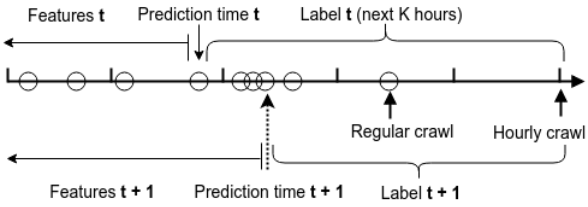

Figure 6: Training data generation process for timestamps t and $t + 1$. A vertical line denotes a Salticus hourly crawl; a circle represents a production crawl.

4.1.2 Seen and Unseen Offers. The one million Salticus offers used for model development only make up a small fraction of active offers. To understand whether our trained models can be generalized to offers that were never seen from the training data, we divide the Salticus dataset into seen and unseen offers. This is achieved by holding out 25% (i.e., 250K) of the one million offers (denoted *unseen offers*) and the remaining 750K offers are used as *seen offers*. Combining with the time-based split of training and testing data, the evaluation setup is illustrated in Figure 7. Our predictive models are only trained with the 750K offers.

Here, we use the unseen offers to simulate the production setting where our models do not observe any historical information for most of the offers. Therefore, we expect better model performances for the seen offers comparing to the unseen offers.

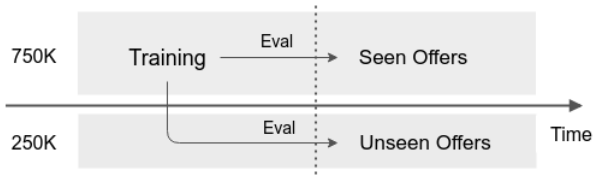

Figure 7: Overview of the training/evaluation setup.

4.1.3 Training/testing Setup. Our training/validation/testing datasets are split based on time. Particularly, crawling events from May 2018 to July 2018 are used for training, data from August 1 to August 5 is used for validation, and data from the rest of August is for testing. In total, we extract around 1.3 billion training examples, 84 million validation examples and 620 million testing examples. As expected, most of them did not contain price changes (i.e., negative price change label). In this paper, we set $K = 6$ hours, for which we observe around 1 : 48 positive/negative ratio for all training, validation and testing datasets. The validation dataset is used for model selection, and the reported results are based on the chosen model's performance on the testing data.

4.2 Features

We consider two types of features in this paper. First, we employ the historical change frequency features that are commonly adopted in previous studies [9, 28]. Second, we propose using metadata and other offer-related information that may be predictive of a price change even for offers with limited or no prior history.

4.2.1 Offer Change Frequency. We first extract a set of price change frequency features pertaining to each individual offer. We define the change frequency as the number of price changes per hour. Depending on the amount of crawling history being used, we extract the following three types of change frequency features — change frequency within the most recent day, week and month. We extract the time since the last price change and use it as a feature, as well.

4.2.2 Product Category Change Frequency. Data sparsity is a critical issue for offer-level change frequency. For new offers and rarely-crawled offers, the change frequency is either unavailable or unreliable. Radinsky and Bennett [28], in the context of web search, proposed to learn from similar web pages when encountering the sparsity issue. Similarly, in the context of commercial content, two offers may share similar change patterns if they come from the same product category. As a result, we further compute the change frequencies at the product category level and use them as features.

4.2.3 Metadata Features. The change frequency features are highly dependent on crawl history. This introduces issues when the history information is unavailable or is subject to change. To abate these issues, we introduce a number of history-independent features in our model. As shown in Section 3, offers from different product categories and different countries tend to exhibit different change patterns. This motivates us to extract the metadata information of an offer and use it as a source of features. Besides the product category and country, we include brand, condition, language, merchant and web page title of the offer. Details of the metadata features are presented in Table 1. Our previous analysis in Figure 2 illustrates

diverse price change patterns for different days of a week and hours of a day. Thus, the current day and current hour (of the prediction time) are also included as predictive features.

Compared to the offer and product change frequency features, metadata-based features have several benefits. First, they alleviate the cold-start issue since metadata is readily available for both existing and brand-new offers and product categories. Second, they are robust with respect to unexpected changes in the crawl history. Third, as we show next, metadata-based features can be combined with change frequency features for further model improvement.

Table 1: Features used in baselines and the proposed models.

Price change frequency for offer O	
Frequency (1 day)	Change frequency within last day
Frequency (1 week)	Change frequency within last week
Frequency (1 month)	Change frequency within last month
Most recent change	Time since the most recent change
Price change frequency for offers in same product category C	
Frequency (1 day)	Change frequency within last day
Frequency (1 week)	Change frequency within last week
Frequency (1 month)	Change frequency within last month
Most recent change	Avg. time since the most recent change
Metadata and related information for offer O	
Brand	Brand id
Condition	Condition: new, used or refurbished
Country	Country code
Day of Week	Day of week for the prediction time
Hour of Day	Hour of day for the prediction time
Language	Offer page language
Merchant	Merchant id
Offer title	Offer page title
Product category	Product category

4.2.4 Full Observability VS. Partial Observability. As mentioned, the change frequency features are highly sensitive to the amount of available crawl history. In the best case, if we can afford constant (e.g., hourly as in our dataset) crawls, the estimates for change frequency features will be more accurate. However, production crawlers usually cannot achieve the full observability, both due to the crawling costs as well as the politeness constraints [23].

In this paper, we experiment with two types of observability — **full observability** where we assume the observation of hourly crawls, and **partial observability** in which we only observe crawls from the existing crawling strategy. The former tells us the upper bound, whereas the latter can help us to estimate the predictive power for the change frequency features under existing crawling strategy. It is worth noting that the partial observability is sensitive to the change of crawling strategy, and adjustments to the strategy will further affect the observability, while the full observability scenario is not practical at the scale of the entire corpus.

4.3 Models

4.3.1 Baselines. In this paper, we adopt a set of baselines purely based on the change frequency features, in which we assume that the probability an offer changes its price in the next K hours equals to the historic price change frequency. Depending on the level of granularity, we include two baselines: an offer-level price change baseline and a product category level price change baseline. The former predicts an offer's price change based on its own history, whereas the latter employs the change history of its product category. Moreover, we include a third baseline combining both offer-level and category-level features in a linear model. These simple but effective baselines were commonly adopted in previous studies [8, 9, 28, 30].

4.3.2 Proposed Models. As discussed, we model the prediction task as a binary classification problem to classify whether an offer's price will change in the next K hours. To incorporate both numerical change frequency features and metadata information in one unified framework, in this paper, we adopt a feed-forward deep neural network (DNN) model.

The change frequency features, if included, are treated as numerical dense features. Metadata information is modeled by sparse features, which are embedded into a low-dimensional space [22]. Here, an embedding is a condensed vector (low-dimensional vector) representation of metadata information. Semantically, similar metadata would have similar embeddings located closely in the vector space. The combination of dense frequency features and embedded metadata features in a single neural network architecture enables both *memorization* and *generalization*, a desired property for a predictive machine learning model [7].

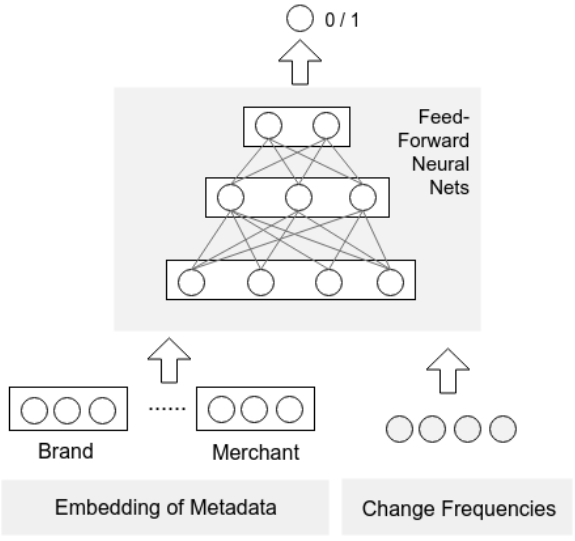

Figure 8: An illustration of our model architecture.

We use the TensorFlow DNNClassifier for model implementation [1], where we set three hidden layers with 256, 128 and 64 hidden units in each layer. We adopt ReLU (Rectified Linear Unit) as the

activation function for hidden units, and choose the Adagrad algorithm to optimize the cross-entropy loss. To deal with over-fitting, we adopt both L1 and L2 regularization and set both to 0.001.

To summarize, this paper includes the following baselines (the first three) and proposes two models for predicting price changes.

- Frequency (offer): offer-level change frequency
- Frequency (category): category-level change frequency
- Frequency (combined): combines offer-level and category-level change frequencies in a linear model
- DNN (metadata): DNN using only metadata information
- DNN (metadata + frequency): DNN using both metadata and offer + product category change frequencies.

5 PREDICTING PRICE CHANGE

This section reports the comparison results between the proposed models and baselines. Our evaluation adopts the **AUC** metric (Area Under Receiver Operating Characteristic Curve) to measure the performance of different models and baselines. A value of 0.5 means a random guess whereas 1.0 corresponds to a perfect prediction.

5.1 Evaluation on Seen Offers

Table 2 reports the testing AUCs for different predictive models on seen offers (see Section 4.1.2 for its definition). Here, we try to assess model quality on predicting the future for the offers being seen from the training set. The AUC values are obtained in the following way — firstly, we evenly split our testing data into 20 subsets; then, we evaluate on each subset; finally, we compute the averages and standard deviations over the 20 subsets. In Table 2, the top nine rows refer to baselines and the last two correspond to the proposed models. Overall, all of these models achieved AUCs above 0.5, meaning that both change frequency and offer metadata information have a predictive power. They can also be combined to further boost the prediction performance.

Table 2: Testing AUC (standard deviation) for different prediction models on seen offers.

Model \ Observability	Partial	Full
Frequency (category, 1 day)	0.560 (0.003)	0.573 (0.004)
Frequency (category, 1 week)	0.577 (0.004)	0.584 (0.004)
Frequency (category, 1 month)	0.570 (0.003)	0.583 (0.003)
Most recent (category)	0.569 (0.004)	0.582 (0.003)
Frequency (offer, 1 day)	0.642 (0.002)	0.721 (0.003)
Frequency (offer, 1 week)	0.769 (0.003)	0.815 (0.003)
Frequency (offer, 1 month)	0.791 (0.003)	0.832 (0.003)
Most recent (offer)	0.789 (0.003)	0.827 (0.003)
Frequency (combined)	0.791 (0.004)	0.847 (0.003)
DNN (metadata)	0.842 (0.005)	
DNN (metadata + frequency)	**0.875 (0.002)**	**0.883 (0.003)**

5.1.1 Full Observability VS. Partial Observability. Table 2 shows that the change frequency features computed from fully-observable crawl history outperform the ones derived from partially-observable history (details about observability are in Section 4.2.4). In terms of the baseline *Frequency (offer, 1 day)*, having fully observable history boosts AUC by as much as 12.3%. This implies the importance of collecting more crawling history. However, such an implication goes against our ultimate goal — building predictive models to lower crawling frequency. We can resonably expect that after reducing crawls from production crawlers, the performance of the partial observability baselines will decrease.

Compared to the baselines, our proposed models have the following advantages. First, the *DNN (metadata)* model does not use any price change feature and thus is not subject to the change of crawl history observability. Second, for the *DNN (metadata + frequency)* model, its performance difference under full and partial observability is small compared to the difference in the baselines. Both of them demonstrate the robustness of our proposed models.

5.1.2 Baselines VS. Proposed Models. As for baselines, we observe that offer-level price change features significantly outperform the category-level features. This is expected since the product category only provides a high-level abstraction for an offer whereas specific characteristics for each offer are missing. However, category features would be helpful when offer-level features are absent, e.g., for new offers without history. In this experiment, we only see a marginal improvement when combining offer and category features. This is because there are no new offers in the seen offers.

Comparing to the baselines, our *DNN (metadata)* model significantly outperforms the best baseline using the partial observability history, and works equivalently well as the best baseline using the full observability history. Since *DNN (metadata)* does not use any change frequency feature, it is robust towards new offers. Moreover, once the change frequency features are available, they can be simply incorporated in the *DNN (metadata + frequency)* model to yield even better performance.

5.2 Generalizability to Unseen Offers

To understand whether our models can be generalized to other offers, this section replicates the evaluation in Section 5.1 but assesses over 250K unseen offers (see its definition in Section 4.1.2). This section examines how our proposed models would generalize to the production system, which often handles billions of offers. Note that an unseen offer is different from a brand-new offer. The former refers to an offer that was not observed in the training data, whereas the latter denotes an offer without crawl history. For the unseen offers in this paper, we can still compute their offer-level and category-level price change frequency features.

Table 3 reports the AUCs of different predictive models for unseen offers. The baselines are roughly the same as Table 2, whereas the proposed models drop slightly. This aligns with our expectation since some metadata information from the unseen offers might never be observed from the training data. Surprisingly, even with partially observable history, the proposed models still outperform all baselines and maintain the AUCs above 0.80. With fully observable history, although the pure metadata feature does not achieve

the AUC as the best baseline, it can be combined with the price change features and eventually produces the best performance.

It is worth noting that although we do not specifically examine our model performances over the brand-new offers, we still expect that we can achieve reasonable performances using *DNN (metatda)* since this model does not use any crawl history information. In this case, offer level baselines would fail and the *DNN (metadata + frequency)* model will be downgraded to *DNN (metadata)*.

Table 3: Testing AUC (standard deviation) for different prediction models on unseen offers.

Model \ Observability	Partial	Full
Frequency (category, 1 day)	0.554 (0.002)	0.567 (0.002)
Frequency (category, 1 week)	0.572 (0.002)	0.579 (0.002)
Frequency (category, 1 month)	0.565 (0.002)	0.579 (0.002)
Most recent (category)	0.564 (0.002)	0.578 (0.002)
Frequency (offer, 1 day)	0.642 (0.002)	0.720 (0.003)
Frequency (offer, 1 week)	0.766 (0.003)	0.817 (0.003)
Frequency (offer, 1 month)	0.788 (0.003)	0.833 (0.003)
Most recent (offer)	0.787 (0.003)	0.828 (0.003)
Frequency (combined)	0.797 (0.003)	0.849 (0.003)
DNN (metadata)	0.803 (0.003)	
DNN (metadata + frequency)	**0.854 (0.003)**	**0.862 (0.003)**

5.3 Summary

Overall, the evaluation results from the above two sections clearly demonstrate the effectiveness of our proposed models, which not only work well on the seen offers but also show generalizability to unseen offers. Besides, we discover that metadata information is an important predictive feature. Such a feature is relatively static and easily accessible across different types of offers, effective in the cold start setting, and is not subject to the change of crawl history availability. Our proposed DNN approach provides an effective way to utilize the metadata information, and further enables the incorporation of additional features.

6 PREDICTIVE RESOURCE ALLOCATION

Experiments in Section 5 demonstrate the feasibility of building machine learning models to predict price change. However, it remains unclear how such models can be integrated with production crawlers. This section attempts to answer the question.

As mentioned in the Introduction, there are two important components in our production crawler — the *Batch Scheduler* that downloads offer pages periodically, regardless of whether or not the offers are accessed by users, and the *InstaCrawl* that follows past user clicks and downloads offer pages based on their click frequencies. The design of *InstaCrawl* relies on the observation that the past click is a good predictor of the future click [14]. Indeed, in our production crawler, 95% of user-clicked offers were also accessed in the past week. Besides, the *InstaCrawl* is also in line with previous studies which account for user experience when developing user-centric crawling quality metrics [26, 32].

In this paper, we focus on the optimization for *InstaCrawl* because the corresponding offers are more likely to be accessed by users. However, we believe that our model can also be applied to the *Batch Scheduler*, which is one of our future work directions. To be specific, our predictive models will be used for reducing unnecessary *InstaCrawl* crawls that do not yield new updates to the price information. This is achieved in the following way. For each crawl request, we skip it if our model predicts that the price will not change; otherwise, we send the request for crawling. Since our current production crawler harvests all requests and the proposed models only target to crawl a subset of them, we can use existing production logs for simulation.

It is worth noting that there is a trade-off between spending resource and improving the price information freshness. If there are unlimited resources (for both crawlers and merchant servers), one can always reach the optimal freshness. When crawling resources are limited, more stale prices will be shown. However, some approaches will be able to make better trade-offs than others. In this section, we compare the trade-offs of our proposed model with the commonly-adopted baselines in the literature.

6.1 Experimental Setup

6.1.1 Overview. As discussed, with production crawler logs, we can simulate different strategies to utilize the predictive models. To understand the effectiveness of each strategy, we need a test collection that contains all of the regular production crawls for simulation, as well as the true prices for evaluation. The Salticus dataset (see Section 3.1) is such a repository.

The simulation process is illustrated in Figure 9. Each circle denotes an *InstaCrawl* request c_i from our production crawler, and each vertical line corresponds to a Salticus hourly crawl s_k. When developing a predictive crawling strategy, we apply the decision (to crawl or not) based on a machine learning prediction for each c_i. If the decision is to crawl, the price ($\text{price}_{\text{local}}$) will be updated; otherwise, it stays unchanged. The hourly crawl s_k is used to compute the ground-truth price ($\text{price}_{\text{true}}$).

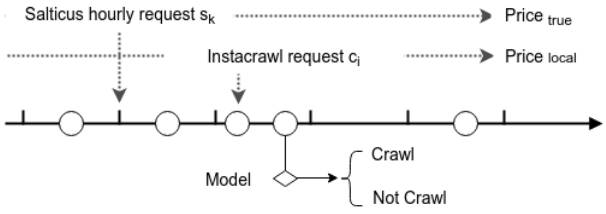

Figure 9: An illustration of applying machine learning predictions in a production crawler.

6.1.2 Crawl Decisions. Converting a model prediction to a crawl decision is a critical component in Figure 9. The simplest way is to define a threshold. A request with prediction score above the threshold will be crawled; otherwise, it will be skipped. However, a hard decision may result in some offers never being crawled. Therefore, we adopt a probabilistic decision strategy — the crawl decision is made stochastically and proportionally to the prediction

score. In this way, offers with low prediction scores but high click rate still have a chance to be crawled.

The skewedness of prediction scores makes it difficult to directly use the original scores. As a result, we rank scores and map them into n quantiles (with the first quantile mapping to the lowest score). For the i-th quantile, we use the probability in Equation 1 for making the stochastic decision. This is a simple heuristic that makes the probability linearly proportional to its quantile — a larger quantile will result in a higher probability. We do believe that there are more principled ways to determine the probability; however, we only seek for the simplest way for the proof of concept in this paper. Here, γ is a resource factor, which can be tuned to achieve different resource saving percentages.

$$p_i = \min\left(1.0, \frac{i}{n} \cdot \gamma\right), \quad \gamma \geqslant 0 \tag{1}$$

6.1.3 Compared Models. We compare the following crawling strategies. First, we include a baseline that makes uniform-probability (p_u) decisions for all *InstaCrawl* requests. Different p_u can yield different resource consumption rates. For example, setting $p_u = 0.8$ will crawl any request with the probability of 0.8, and thus can save 20% of resources. The uniform baseline provides us with a basic understanding of the task difficulty.

Based on the evaluation results from Section 5, we further include the following three models: the best baseline *Frequency (combined)*, the best model *DNN (metadata + frequency)* and *DNN (metadata)*. *DNN (metadata)* does not use crawl history and thus can handle cold-start and the change of crawl history observability. The change frequency features are sensitive to crawl history observability, different observability levels will yield different feature values (see Section 5.1.1). In this section, we use partially observable history, i.e., downloaded pages from *InstaCrawl*, but not the hourly Salticus crawls. Note that when a new crawling strategy is applied, observability will change further since earlier no-crawl decisions will affect the availability of crawl history. Despite that, *DNN (metadata + frequency)* still gives us the upper bound performance.

6.1.4 Evaluation Metrics. Our project operates on the trade-off between resource and performance. When crawling resources are reduced within the same strategy, the performance will always drop. However, some models might be able to make better trade-offs than others. Therefore, comparing the trade-offs among different strategies is the primary focus for evaluation. Of course, with saved resources, one can schedule more crawls for unpopular pages, which may further improve the overall performance. However, we mainly focus on evaluating *resource savings* in this paper, and leave the *resource re-allocation* evaluation for future work.

In our evaluation, resource usage (denoted by R) within a time period $[t_s, t_e]$ is defined to be proportional to the number of crawling requests that are eventually sent for page download at this time period. To be specific, suppose that we have N *InstaCrawl* requests and C ($C \leq N$) of them are finally sent for crawling. R will be proportional to C. Since N is a constant during our evaluation of different crawling strategies, we use it for normalization, i.e., $R = C/N$. Note that reducing crawls will not only reduce the load of our production crawler but also significantly reduce the load for the merchant servers. Too many requests at the same time might even cause our production crawlers to be blocked.

For performance, we adopt the commonly-used freshness metric (denoted by F) [9, 28]. A page is considered to be fresh if its latest local copy of crawl result aligns with its real-world content. Since the *InstaCrawl* requests are correlated with the number of user clicks, we can treat each c_i in Figure 9 as a user click. Then, we compute the freshness for each click c_i **before** we actually crawl it. This way, we actually examine whether a user will see the right content after click. As shown in Equation 3, the overall freshness F is computed by aggregating the freshness of all clicks in $[t_s, t_e]$.

$$f(c_i) = \begin{cases} 1, & \text{if price}_{\text{local}} = \text{price}_{\text{true}} \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

$$F(t_s, t_e) = \frac{1}{N} \sum\nolimits_{t_{c_i} \in [t_s, t_e]} f(c_i) \tag{3}$$

6.2 Resource Savings

In this section, we first describe a resource-freshness trade-off for the uniform baseline, aiming to provide a basic understanding of the problem space. Then, we show how the trade-off can be improved using different machine learning based crawling strategies.

6.2.1 Freshness-Resource Trade-offs. Unlike the evaluation in Section 5, this section attempts to assess the accumulated effects of a number of machine learning decisions over time. However, first we will forego machine learning, and try to better understand the trade-off between freshness and resource utilization in our application. On one side of the spectrum, will the freshness be 100% if we harvest every regular crawl request in Figure 9? On the other side of the spectrum, what level of freshness can be maintained if we always decide *not to crawl*. Between these extremes, we can control the freshness-resource trade-off based on the uniform probability p_u (i.e., the uniform baseline in Section 6.1.3).

Accordingly, we continuously compute the freshness for different uniform crawling strategies every six hours (i.e., t_e - t_s = 6h) starting from August 1st, and plot them in Figure 10. Here, our experiments assume everything is synchronized at the beginning, so each line starts from freshness 1.0. In Figure 10, $p_u = 0.0$ (the bottom line) denotes that we never crawl, and thus the resource consumption is 0%. $p_u = 1.0$ (the topmost line) means that we crawl at every click c_i and the resource consumption is 100%.

We observe that the first 10% of resource (p_u from 0.0 to 0.1) improves freshness significantly by 0.381, whereas a further resource investment only provides a marginal increase — an additional 90% of resources (p_u from 0.1 to 1.0) only lifts the freshness by 0.029. This clearly shows that uniform crawling heavily overspends resources, particularly after $p_u > 0.1$. To reach the same level of crawl quality, other strategies might require much less resource. Therefore, the major focus of the following section is to explore the ways of optimizing resource utilization using our proposed models.

6.2.2 Resource Saving at Different Freshness Levels. To align with Section 5, we also evaluate on both seen and unseen offers. For each offer type, we compare resource utilization at fixed freshness levels for different crawling strategies. Instead of reporting values from one specific time period, we aggregate and report evaluation

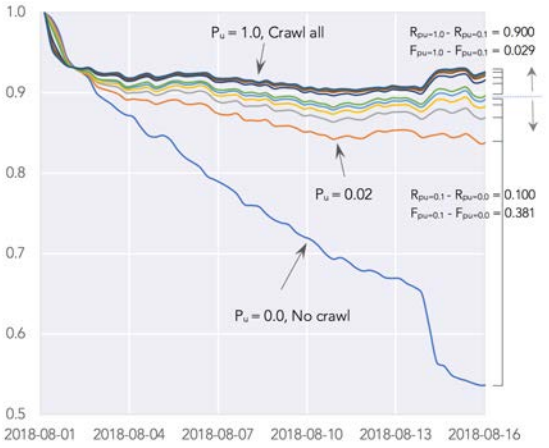

Figure 10: The change of freshness over time for a set of uniform crawling strategies. Each line denotes a p_u, which corresponds to 0.0, 0.02, 0.04, 0.06, 0.08, 0.1, 0.3, 0.5, 0.7, 0.9 and 1.0, respectively (bottom to top).

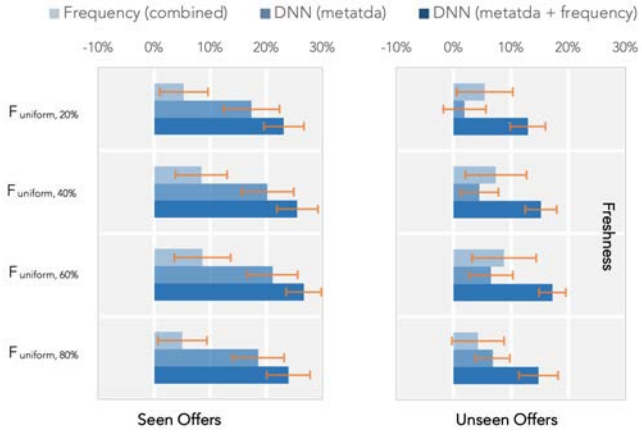

Figure 11: Resource savings (with 95% confidence interval) for different crawl strategies at target freshness levels. The horizontal axis denotes % of resources saved compared to the uniform strategy; the vertical axis denotes freshness. Freshness levels ($F_{uniform,\ X\%}$) are selected to cover 20%, 40%, 60% and 80% resource for the uniform strategy.

metrics over ten time periods five days each, i.e., August 5 to August 9, August 10 to August 14, and so on. Here, we start from August 5 because the impact from initialization fades away (we assume a freshness of 1.0 in the beginning of our simulation) and the performance becomes more stable.

In our evaluation, the freshness levels are chosen based on the uniform strategy, where we cover the freshness corresponding to the resource usage of 20%, 40%, 60% and 80% for the uniform strategy. We name them as $F_{uniform,\ 20\%}$, $F_{uniform,\ 40\%}$, $F_{uniform,\ 60\%}$ and $F_{uniform,\ 80\%}$. For each predictive crawling strategy, the amount of resources needed for a freshness level is obtained through tuning γ in Equation 1. Then, for the given crawling strategy, we measure its *resource saving* using the relative percentage of resources that can be saved compared to the uniform strategy.

Figure 11 plots the resource savings for each crawling strategy. Here, 0% means that a crawling strategy utilizes the same resource as the uniform strategy. Compared to the uniform baseline, all other models show the ability of spending less resources while maintaining the same freshness. In particular, *DNN (metadata + frequency)* achieves the best performance, which saves as much as 27% resources for seen offers and 17% for unseen offers. *DNN (metadata)* also outperforms the *Frequency (combined)* baseline on seen offers and performs equivalently on unseen offers. This aligns with our findings in Section 5.2, demonstrating the effectiveness of our proposed machine learning models. Note that there remains a big discrepancy between the seen and unseen offers for our proposed models. This is consistent with our findings in Section 5.2 and is due to the mismatch of metadata in these two different types of offers. In the future, we will explore more effective ways to bridge this gap between seen and unseen offers.

Again, as discussed in Section 5.2, since *DNN (metadata)* does not use any crawl history information, we expect that the resource saving performance for the unseen offers can be generalized to cold-start offers with no or very little history information. Overall, in this case, *DNN (metadata)* model can still save around 5% of resources whereas all frequency baselines will fail.

7 CONCLUSIONS AND FUTURE WORK

7.1 Conclusions

In this paper, we study predictive resource allocation in the context of building a production crawler for commercial content. In particular, we focus on the problem of price change prediction for commercial offers. We start our study in Section 3 via a detailed analysis of price changes on a global scale. To the best of our knowledge, this is the first such publicly available analysis. In addition, the predictability of price change dynamics that we discover, motivates the further development of predictive price change models.

In Section 4, we propose a deep neural network based approach for predicting future price changes. The model goes beyond the change frequency features commonly used in prior work, by incorporating metadata information of online offers. There are multiple contributions of this approach. First, to the best of our knowledge, this is the first published attempt to build predictive crawlers in the context of commercial web content and price change prediction. Second, we update the existing predictive models [28, 30] with a state-of-the-art machine learning approach, which incorporates both numerical frequency features and content-based sparse features within a unified framework. Experimental results in Section 5 demonstrate the effectiveness of our approach. Moreover, the incorporation of metadata enables our model to deal with the cold-start problem and avoid feedback loops.

Beyond simply predicting price changes, we further study models integration with a production crawler in Section 6. Evaluation with production crawl logs demonstrate that our models can make better resource-freshness trade-off decisions than the frequency-only baselines both for seen and unseen offers. Furthermore, through

the use of metadata information, our models can save resources even for offers with no prior price change history.

7.2 Future work

Despite the promising results we obtained, our study still has several limitations, which will be the focus of our future work.

First, we observe that models built with solely metadata information perform less well on unseen offers. This can be partially solved by increasing the size of the full-observability Salticus dataset. However, for truly new offers, an exploration of more advanced approaches for a better modeling of metadata information will be required. Besides, we see evidence that more frequent model retraining increases the wins and plan to adopt it in the future.

Second, our use of machine learning scores for predictive resource allocation may be sub-optimal. Our experiment adopts a simple quantile-based conversion from prediction score to sampling probability (see Equation 1). This can be improved by adopting a more direct optimization approach. In addition, we may also explore ways to productively re-allocate the crawl resources saved by our methods in future work.

Finally, in this paper, we made the simplifying assumption that price changes (and crawls) can be modeled independently, and do not utilize any sequence information. This allows for simpler model deployment, and, as demonstrated in Sections 5 and 6, already outperfoms the existing baselines. Thus, an interesting direction for future work is applying sequence based deep learning models (e.g., RNN, LSTM [17]), to further improve the model performance.

ABSTRACT

Descriptive titles provide crucial context for interpreting tables that are extracted from web pages and are a key component of search features such as tabular featured snippets from Google and Bing. Prior approaches have attempted to produce titles by selecting existing text snippets associated with the table. These approaches, however, are limited by their dependence on suitable titles existing *a priori*. In our user study, we observe that the relevant information for the title tends to be scattered across the page, and often—more than 80% of the time—does not appear verbatim anywhere in the page. We propose instead the application of a sequence-to-sequence neural network model as a more generalizable approach for generating high-quality table titles. This is accomplished by extracting many text snippets that have potentially relevant information to the table, encoding them into an input sequence, and using both copy and generation mechanisms in the decoder to balance relevance and readability of the generated title. We validate this approach with human evaluation on sample web tables and report that while sequence models with only a copy mechanism or only a generation mechanism are easily outperformed by simple selection-based baselines, the model with both capabilities performs the best, approaching the quality of crowdsourced titles while training on fewer than ten thousand examples. To the best of our knowledge, the proposed technique is the first to consider text-generation methods for table titles, and establishes a new state of the art.

1 INTRODUCTION

Modern search engines no longer simply return links to relevant web pages. Where possible, they enhance the search experience by extracting and directly displaying the information that a user is seeking. Often, this information is best displayed in a semi-structured form, such as a table or list; for example, in response to the query "U.S. states by population 2018," a relevant table showing population by state is more effective than a sentence with the same information. It is now a major feature in mainstream search engines, e.g., [27, 29] and Figure 1 shows examples of tabular results in Google and Bing.

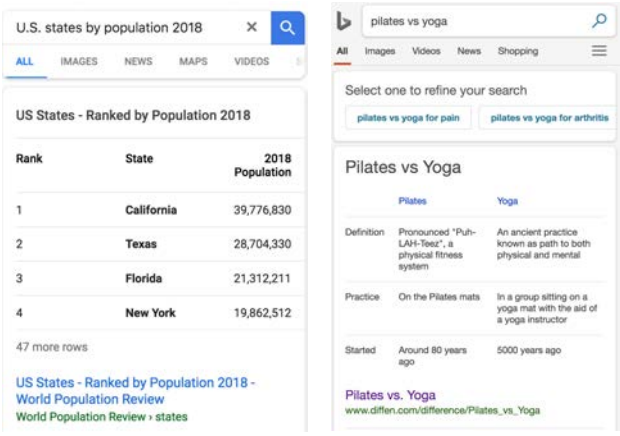

Figure 1: Example tabular results in search engines

However, separating a table from its original context removes important clues that help a user interpret its contents and trust its relevance. In our experience, the most effective way of providing this crucial context is by accompanying the tables with corresponding descriptive titles.

Consider, for example, the table shown in Figure 2. If this table were shown in isolation, it would be difficult to say for certain what it is about. If the search query that led to this table being returned is known (e.g., "Rocky Franchise Awards"), this helps with interpretation but still leaves many questions unanswered, such as: Does this table provide the exact information I was looking for or is it just the most relevant table that could be found? Are the awards in the table for one *Rocky* film or the entire *Rocky* franchise? Are these all from the same award source or from many sources? When a descriptive title is added, understanding of the table's contents improves, as does trust in the table's relevance to the query. The goal is for the user to have enough information from the displayed result (including the title) to know whether or not it is relevant to his or her information need.

Beyond user experience, the ability to generate titles for or otherwise summarize the content of semi-structured data enables other use cases as well. In a search engine, it plays a crucial role in supporting web applications such as table snippets [2]. From an information extraction standpoint, titles generated offline may be used as an

Figure 2: A descriptive title provides crucial context for understanding the contents of a table when it is displayed out of its original context. Consider, for example, the experience of trying to interpret or assess the relevance of this extracted table with versus without its title: "*Rocky* Academy Award Nominations (1977)."

additional signal when assessing the relevance of the summarized content with respect to user queries. With the increasing popularity of hands-free interfaces such as Google Home [17] and Amazon Echo [12], descriptive titles also provide a way for such devices to summarize a table's content in a more understandable way than reading the data row-by-row.

1.1 Challenges

In practice, automatically producing descriptive titles is quite challenging. First of all, the semantics of a table tend to be distributed among a variety of elements on a web page. For example, consider the table shown in Figure 3: the page title includes the name of the person being discussed, the section headings describe the topic of the table, and the column headers give the schema of the table contents. Any single one of these text strings would be insufficiently precise to serve as a table title, but together they include all the necessary information for a human to interpret its contents. This raises the question of how to best represent this collection of text snippets for machine learning.

Second, a title must sound natural; i.e., it should sound like something a human would write and not a "keyword soup." Clearly for the example in Figure 3, simply concatenating the text from each of the table metadata components would result in a title with poor readability.

Third, tables tend to describe specific relationships between specific entities, much more so than unstructured data such as free text. Consequently, descriptive titles for tables tend to include many proper nouns and rare or out-of-vocab (OOV) tokens, which are well-documented stumbling blocks for natural language generation algorithms [1, 19, 28].

Finally, the variety of tables on the web is immense [8, 14]. Some tables are relational ("horizontal") while others are entity-based ("vertical") [2]. A table may have five rows or 50. It may have an explicit caption and three section headings or none of either. It may contain the primary content of a web page or be purely supplemental, or it may be used entirely for formatting purposes and not actually be expressing any relationship at all. This tremendous diversity renders many heuristic-based approaches inadequate, as evidenced in part by the unsuccessful attempts to heuristically bootstrap training data which we report in Section 3.

Ultimately, a generated title must satisfy two properties: relevance and readability. A **relevant** title is one which correctly describes what information the table contains; it should be neither too vague ("Scores") nor too specific ("The box score of the baseball game that the Houston Astros won against the Los Angeles Dodgers in 10 innings in Game 5 of the 2017 World Series"). A **readable** title is one which sounds natural to a human reader. It need not be a complete sentence (indeed, most natural titles are not), but it should be fairly straightforward for a human to parse.

1.2 Conventional Approaches

To address readability, a common approach is to treat the title production task as a selection problem–given all the text snippets on the page, identify the one most likely to make a good title for a table in question. By selecting existing text, such approaches avoid the complexity of learning a language model for concatenating words and phrases in a natural way. However, to succeed, these approaches require a high quality title to appear somewhere verbatim on the web page, which is rarely the case. As will be discussed in Section 3, in more than 80% of cases in our user study, users did not consider any extracted text snippets as the best representation of the table. The caption tag, which is supposed to provide a title of the table, is used in widely different ways across table authors, and moreover, is present in only less than a few percentage of web tables.

When existing text snippets *are* relevant to a table, they often each contain only a portion of the ideal title for that table. Consider, for example, the titles shown in Figure 3 and Figure 5—all three titles contain text from at least three separate locations on the page. This highlights the need for compositionality in any title generation approach, which most IR-based approaches do not support.

Another approach for title production would be to mine query logs for past user queries that led to that table and use these as candidate titles [5]. Using human-generated text increases the likelihood of the title being compositional (since it is not restricted to text snippets from the page), but once again, the success of the approach is dependent on a high quality title existing *a priori* for selection. For tables with few corresponding queries, success is unlikely. Furthermore, for web pages with multiple tables in them, the task of linking a query that led to that page with the most relevant table on the page (if any) is non-trivial.

1.3 Proposed Approach

In this paper, we propose a new framework for generating high quality table titles. Our approach utilizes a sequence-to-sequence neural network model with both a copy mechanism and a generation mechanism. By generating titles instead of selecting or ranking existing text strings, this approach is capable of composing high quality title strings even when none exist in the source text. At the same time, rare and OOV tokens are retrievable thanks to the copy mechanism (see Figure 3, for example). Furthermore, as a high-capacity machine learning model, with sufficient training data the model is able to learn and utilize more nuanced patterns than most

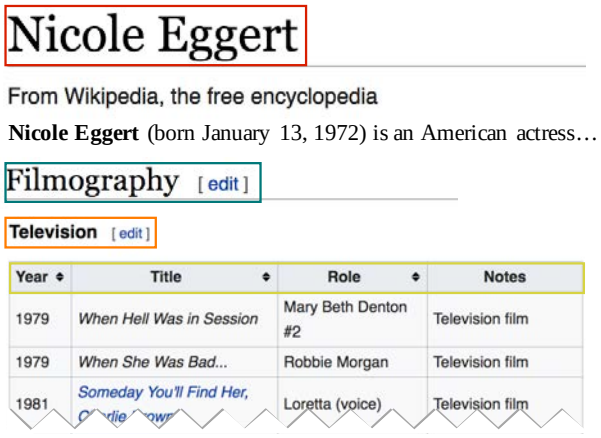

Figure 3: On the left is the top portion of a table from the web along with preceding section headings (some content has been removed for clarity). On the right are the input string (split into multiple lines for readability) and output of the trained title generation network. The double underscores around "nicole" and "eggert" denote that these are out-of-vocab (OOV) tokens (i.e., they were not present in the training data, and can therefore only be copied, not generated). Note that the generated title is composed from multiple fields (but not all fields), irrelevant tokens such as "[edit]" and "- wikipedia" are not copied, and while "role" may help to suggest the schema of this table, the token "roles" was actually generated, reflecting a learned pattern that titles tend to refer to plural objects.

heuristic-based approaches, making it more robust to the variety of tables.

The contributions of this paper are as follows:

(1) We identify the key components for successful table title generation (semi-structured data representation, composition from multiple sources, and handling rare and OOV tokens) and propose techniques for dealing with each in the context of web tables.
(2) We explore qualitatively and quantitatively the value of having both copy and generation mechanisms in a model for table title generation, finding that both are necessary to surpass simple baseline performance.
(3) We propose a framework for generating high quality titles for web tables and find that both by automated metrics (ROUGE scores) and human evaluation on a held-out test set, our model outperforms selection-based baselines and sequence-to-sequence models with either a generation mechanism or a copy mechanism, falling just slightly below human-generated titles on relevance and readability.

2 WEB TABLE TITLE GENERATION

2.1 Web Tables

The web is filled with tables. In a seminal 2008 study, researchers at Google extracted 14.1 billion HTML tables from Google's general-purpose web crawl and released initial findings on the properties and challenges associated with this corpus [4]. Since that publication, hundreds of papers have been published on various applications associated with web tables, including table detection, table classification, relation extraction, knowledge base construction, data cleaning, query answering using tables, and many others [2, 16, 23, 33, 36, 37, 39]. To this important body of work we add our own contribution of title generation for web tables.

Figure 3 shows excerpts from the top portion of a web page that has a table in it. As a human, it is easy to recognize that this table shows television appearances by Nicole Eggert. Note, however, that only one of the words in the target title for this table actually occurs within the table. Instead, the meaning of the table is distributed among many different elements on the page. This raises the important question of what context should be considered when creating a title for a table.

One option would be to include the entire web page. This would be guaranteed to include any text that could possibly be relevant for titling a table; unfortunately, it would almost certainly also include a significant amount of unrelated text, decreasing the signal-to-noise ratio of the input. The task of identifying pertinent information in a document is its own open research problem of significant complexity. Additionally, the sequential nature of encoding information with a sequence-to-sequence models means that training time is proportional to the length of the sequence being encoded. Computation overheads for encoding tens or hundreds of thousands of tokens as input is likely prohibitive for our task.

Empirically, we know that the most relevant information for titling a table tends to come from a relatively small set of potential text sources. One obvious source of such text is the contents of the *caption* tag within a table element. However, less than 5% of tables for which we would like to generate titles have explicit captions (including the one in Figure 3). Other relevant sources outside the table itself include the page title or section headings. While these certainly have greater coverage than captions, they also introduce new sources of ambiguity. Both page titles and section headings

Table 1: Metadata fields considered for inclusion in the input to the title generation model. Field names followed by * were included for the experiments reported in Section 4. Where multiple values are found, we maintain the list of values in reading order.

Field	Description
Page title*	Tokens inside the <title> tag nested in the <head> tag of the web page
Section headings*	Tokens in <h1>, <h2>, etc. tags with increasing priority, starting with the nearest
Table captions*	Captions inside <caption> tags
Spanning headers*	Headers in <th> tags that span all columns
Column headers*	Headers in <th> tags
Prefix text	Up to 200 tokens preceding the table until a new table or section boundary
Suffix text	Up to 200 tokens following the table until a new table or section boundary
Table rows	Text inside a <tr> tag, comma delimited with other tags (e.g., <td>) removed

may be only loosely related to the content of an associated table or they may refer to multiple tables on the page which actually have important distinctions between them.

In addition to these text snippets which tend to show up in their own set of HTML tags (e.g., <title> or <h1>), spans of unstructured text in sentences surrounding a table may also include important contextual clues. For example, in Figure 3, the first sentence on the page mentions that Nicole Eggert is an actress, which clearly pertains to the displayed table that lists television shows in which she has performed. While relevant text that alludes to the table may theoretically appear anywhere in the document, to reduce complexity and runtime, we use the heuristic of looking only at the unstructured text immediately preceding or following a table.

2.2 Representing Semi-Structured Data

Once we know what information we would like to include in the input to our model, the question arises of how to represent this information. Drawing on the rich and rapidly expanding body of work on encoder-decoder frameworks, we chose to model these structured fields as a sequence and found that table title generation lends itself well to such an approach. The output—a title in natural language—is clearly sequential in nature. And the input, a combination of textual elements associated with the table, exhibits a sequential nature on a couple different levels. First, the text within each field is ordered as it reads left to right. And second, as demonstrated in Figures 3 and 5, the metadata fields that we collect for each table tend to increase in specificity as they get nearer to the table. Just as they were intended to be read in that order on the web page, they tend to remain in that order in high quality titles.

For each table in our dataset, we collected the following metadata fields (which are also listed in Table 1 and described in greater detail below): page title, section headings, table captions, spanning headers, column headers, prefix text, suffix text, and table rows (the contents of the table, one row at a time). Then, to convert these fields (key-value pairs) into a sequence, we iterated through the fields in the order just given and concatenated their contents, preceding each value (one or more tokens) with a special field token of the form "#[field name]". The model treats these field tokens the same as any other, eventually learning to encode information differently based on what field it is reading and to never generate these field tokens in the decoder, since they never appear in the training data titles. We now describe in greater detail how each of these fields were collected.

Page title: Page titles are found inside the <title> tag in the <head> section of a web page. This title is not directly displayed on the web page in a browser, so many web pages repeat the page title as a section heading for the user to see (as in Figure 3). Given their applicability to the contents of the entire page, page titles proved to be one of the most consistently relevant fields for generated titles. While each page has only one page title, many page titles effectively concatenate multiple titles with delimiters, as in "Chocolate Gifts | Artisan Truffles | Gourmet Chocolate".

Section headings: We chose to rely primarily on explicit header tags (<h1>, <h2>, etc.) for section headings, using the numeric levels of the headers as proxies for parent-child and sibling relationships between sections. Rather than storing all headers preceding a table, we worked backward through the document, starting at the beginning of the table and ending at the beginning of the document. In this traversal, we saved only the first header (closest to the table) at each level that had higher priority (lower numeric value) than any headers collected so far (i.e., if a heading of type <h3> had already been observed, then all section headings of type <h#> where # $\geq$ 3 were skipped from then on). Because not all web pages use these tags to denote headers, however, (relying instead on font size, bold formatting, centering, etc.), not all section headings that a human might identify were always collected. The problem of identifying document structure from visual information is an open research problem.

Table captions: While table captions (in explicit <caption> tags) tended to be highly relevant, they were relatively rare ($< 5\%$[1] of tables) and rarely sufficient as a title. Instead, captions often either provided the final piece of information in a long chain of text snippets that together form an adequate title (as in Figure 5), or they represented a long caption (sometimes multiple sentences) as in, for example, scientific literature. Regardless, if a table had a caption, some portion of it tended to show up in both crowd-sourced and generated titles.

Column headers: Column headers are table cells denoted with <th> tags (instead of the <td> tags for table data). Most tables had only one row of column headers, but not all. Column headers tended to be short, often just one or two words each.

[1]The statistics in the paper are from samples in our internal corpus unless specified.

2016 Olympic Medal Count

5	Netherlands	17.0

Figure 4: The contents of non-header rows of tables contribute surprisingly little information toward their titles tables. Consider these three tables with very similar non-header contents but very different topics and titles.

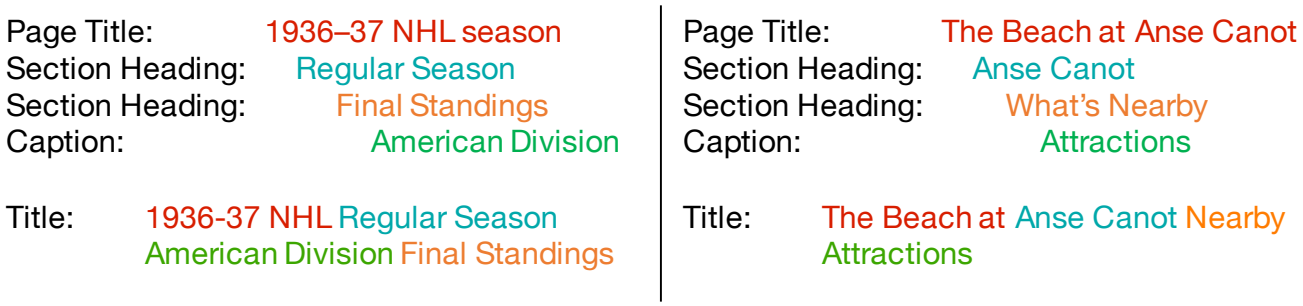

Figure 5: For the majority of tables, the ideal title is composed from multiple associated text snippets, rather than selected from among them.

Spanning headers: Spanning headers are a special type of column header—one which spans all columns in the table. Some tables use these effectively as table titles, just placed inside the table instead of above it. Spanning headers were even rarer than captions, showing up in < 1% of tables.

Prefix/suffix text: Prefix and suffix text are the tokens immediately before and after the table, respectively. They consisted of up to 200 tokens, stopping short at the boundary of another table or another section, since such boundaries tend to signal a change in topic. In practice, we found the prefix and suffix text to be quite noisy, rarely providing relevant title components not already included in the other fields, while significantly increasing the size of the input sequence. Consequently, these fields were not included in the dataset used to train the models for which we report results.

Table rows: Table rows refer to contents of all non-header rows in a table. We were surprised at first to observe that including table rows actually hurt model performance, but upon closer inspection, we recognized that individual table records rarely include unique information that appears in a good title, and topical information expressed in the columns is generally captured by the column headers. Thus, the final dataset did not include the table rows field. Figure 4 illustrates this finding with three tables that have very similar contents in their non-header rows, none of which contribute much to their respective titles.

2.3 Supporting Compositionality

Because of the inherent complexity of generating new text, our initial attempts to solve the problem of titling tables were selection-based. However, we soon found that the upper bound of such an approach was far too low, due to the frequency with which no adequate title could be found in a single continuous span of text. This observation was further confirmed during the collection of the crowdsourced dataset we describe in Section 3. For each human-generated title that we collected, we had the worker denote whether the optimal title that they generated occurred anywhere on the page in its entirety; 83% of the time, it did not.

As an illustration of this trend, consider the two collections of text snippets shown in Figure 5. Each corresponds to a single table whose human-generated title is also given. For both tables, all four snippets are relevant, but it is only when these pieces are composed that a sufficiently correct title is created.

2.4 Handling Rare and OOV Tokens

Successfully handling rare and OOV tokens is a challenge for most text generation tasks. This problem is exacerbated for the task of table title generation, due to the relational nature of tables; Tables tend to describe specific entities and quantities rather than abstract ideas. A generic description like "people shopping at an outdoor

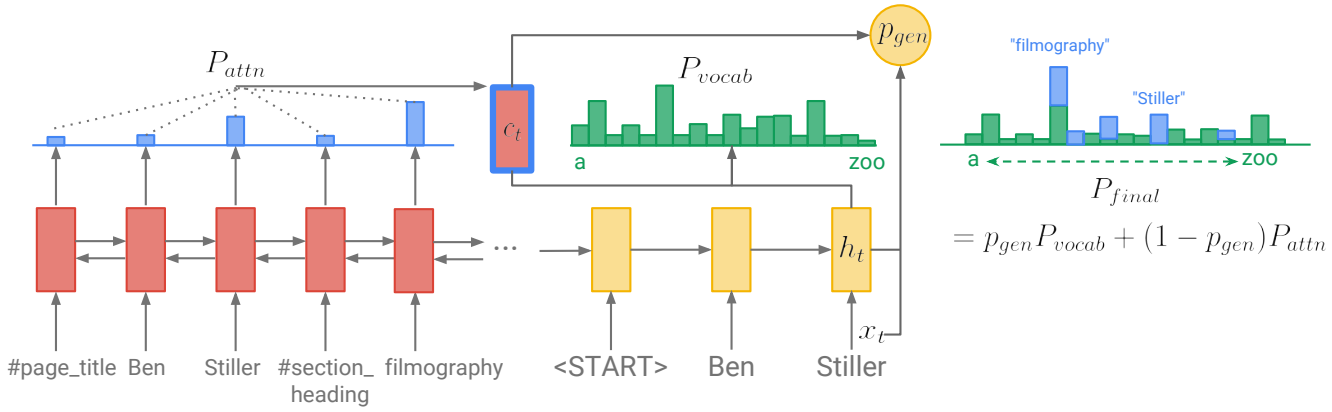

Figure 6: At each decode step, the pointer-generator network calculates the scalar value p_{gen}, which determines the relative contributions of the *vocabulary distribution* (tokens that can be generated) and the *attention distribution* (tokens that can be copied from the input sequence). Beam search is performed over the *final distribution*.

market" may work well for images, but generic titles like "countries and numbers" for tables in Figure 4 would not be helpful. We observe the proportion of specific entities to generic terms is much higher in the very information-dense format of tables. For example, in the validation split of our crowdsourced dataset (approx. 1000 titles), 90% of titles contained one or more proper nouns, and 45% contained one or more OOV words (for a vocab based on over 8000 tables plus titles).

To overcome this stumbling block, we included a copy mechanism in the decoder of our sequence-to-sequence model. A copy mechanism allows a decoder network to not only generate tokens from a known vocabulary, but also occasionally copy a token directly from the input. The parameters controlling when a token is copied versus generated are also learned. Consequently, the model is able to learn specific patterns from the training data that suggest that the following word in a title is likely to be a rare or OOV word that should be copied rather than generated. For example, after producing the tokens “Action Films Starring,” with high probability, the next generated token will be the name of an actor or actress, of which there are many, and whose embeddings are likely very close to one another. However, that actor’s or actress’s name will almost certainly appear in the metadata associated with the table (e.g., in the page title or a section heading). In this case, copying over one of the unknown tokens that is being used like a name in the input (where “being used like a name” is a soft pattern the network naturally learns) is far more likely to succeed than generating a token.

2.5 Model Selection

The model architecture we used was a pointer-generator network, first introduced by [25] as a tool for abstractive summarization of documents into a few sentences. The pointer-generator network utilizes a bi-LSTM encoder and LSTM decoder with attention. At each decode step, the scalar value $p_{gen} \in (0, 1)$ is calculated with a linear layer as follows:

$$p_{gen} = \sigma(W_c c_t + W_h h_t + W_x x_t) \quad (1)$$

where c_t is the context vector (a weighted sum of encoder hidden states, using the attention distribution), h_t is the decoder hidden state, x_t is the decoder input, and W_c, W_h, and W_x are learnable parameters. The scalar p_{gen} is used to weight the relative contributions of the vocabulary distribution P_{vocab} (i.e., the distribution that is sampled in a traditional sequence-to-sequence generation model) and the attention distribution P_{attn} to the final distribution P_{final}, which is defined for each token w in the union of the vocabulary and the input tokens:

$$P_{final}(w) = p_{gen}P_{vocab}(w) + (1 - p_{gen})P_{attn}(w) \quad (2)$$

From this distribution, the decoder samples with beam search the next token to produce (as shown in Figure 6).

Our loss function was the average negative log likelihood of the generated sequence. We used the Adagrad optimizer [9] with an initial learning rate of 0.15, gradient clipping of 2.0, and early stopping on a validation set to control overfitting. Word embeddings (128-dimensional) were randomly initialized and learned as the model was trained. LSTM hidden states (256-dimensional) were initialized with random uniform initialization up to magnitude 0.02. We trained with mini-batch size of 64 and decoded using beam search (beam size = 8) with a minimum decode length of 4 tokens and a maximum of 20 tokens. The input text was truncated at 150 tokens. We did not threshold the vocabulary, which was approximately 18k in size. During training we calculated ROUGE-1, ROUGE-2, and ROUGE-L scores as proxies for title quality. We report these numbers as well as readability and relevance scores provided by human evaluators in Section 4.

2.6 Reducing Token Duplication

An artifact of using the negative log-likelihood objective function is that we often saw the same token being generated back-to-back. Intuitively, we can understand this as the algorithm being quite confident that a particular token will show up somewhere in the true title, but because there are many ways to paraphrase a functionally equivalent title, it does not know precisely where to place that token to minimize loss. Consequently, it generates the same

token in multiple places to increase its chance of being correct in one of them (e.g., it generates "Highest Salaries NBA NBA NBA" instead of "Highest Salaries in the NBA" or "Highest Salaries of NBA Players"). While this may decrease the loss function, it also decreases readability.

The original pointer-generator network paper proposed a *coverage* mechanism for reducing duplication of phrases in generated summaries [25]. The coverage mechanism works by summing the attention distribution over all previous decoder timesteps and penalizing those tokens with high values. We find that with titles being much shorter than article summaries, a simple heuristic serves the same purpose while simplifying the model and requiring fewer parameters to learn: we simply forbid the algorithm from generating the same token twice in one title by zeroing out its probability in the final distribution in all future decode steps. While this heuristic is not foolproof (e.g., "La La Land Awards"), we find that over 95% of the titles in our dataset have no repeated tokens, and many with repeated tokens can easily be paraphrased by the model to avoid the repetition while remaining relevant. Including this heuristic yielded an instant 4.5 point boost in ROUGE score. With more training data, a more sophisticated approach for reducing token duplication may yield further improvements.

3 DATASET CREATION

3.1 Crowdsourced Dataset

The crowdsourced dataset consists of 10,102 web tables scraped from the tables returned as featured snippets [27] to user queries on Google over a span of five months from January-May 2017.

The tables were each shown in their original context to three trained crowdworkers, who were asked to provide a descriptive title for that table and to mark whether that title occurred verbatim anywhere on the page or was composed. Based on a manual inspection of the candidate titles for 100 random tables in our dataset, we found qualitatively that the most informative and relevant title (of the three provided by crowdworkers) was composed 83% of the time. The three candidate titles for each table were then aggregated using the following heuristic: if two or more of the title are identical, accept that title; otherwise, select the title with the most tokens (since the most common failure mode for generated titles was a lack of detail). From a sample of 50 tables, this heuristic chose what we considered the best title 67% of the time. Finally, the titled dataset was split 80/10/10 into train/validation/test splits.

The dataset contains tables from 1384 different domain names, where two major domains were wikipedia.org (72.6%), and espn.com (0.8%). The dataset covers diverse topics including news (e.g., bbc.co.uk, times.com), health (e.g., webmd.com, nih.gov), entertainment (e.g., boxofficemojo.com, allmusic.com), and corporations (e.g., microsoft.com, ibm.com). The average accepted title length is 40.9 characters or 6.8 tokens. The total vocabulary size is 17,862.

3.2 Heuristic-based Datasets

The first heuristic-based approach we tried was proposed in [5]: mining *query logs* for queries that led to pages with tables on them and using the queries as candidate titles for those tables. In addition to general quality issues with the queries as titles, we found it difficult to reliably link a given query to the precise table on a page it is most relevant to when multiple tables are found on the same page. Restricting the dataset to those tables that are the dominant tables on a page biased the dataset toward tables that are the central topic of the page, introducing an over-reliance on the page title as a source of title tokens.

Next we tried using *table captions* as titles for those tables that had them, but as discussed in Section 2.3 and demonstrated in Figure 5, these often contained only the last link in chain of necessary text spans for generating a good title. Hoping to identify a set of more specific captions, we tried filtering the dataset to *captions with three or more entities*. This had the result of overrepresenting certain domains (e.g., scientific papers, code documentation, large online catalogs) that dominated the training set. With all of these caption-based approaches, we faced the additional issue that by removing the caption from the training input (to prevent the model from learning to simply copy over the caption word-for-word), we sometimes removed the only mention of essential information required to generate a proper title. Our last attempt was to use as titles the *table captions with non-stopwords from multiple different sources* on the page and all of whose tokens could be found in at least one other input field. This, unfortunately, resulted in a dataset that was too small to use.

From these attempts, it became clear to us that given the immense variety of web tables, we would be hard-pressed to find any heuristic that could generate a training set of sufficient size without introducing significant harmful bias. We consequently commenced with collecting the crowdsourced dataset described above.

4 EXPERIMENTAL EVALUATION

We validated the quality of our approach with a human evaluation on 200 tables from the held-out test split of the dataset. We created two baselines that simply select the page title or nearest section heading, respectively, with a few obvious post-processing steps, such as removing "[edit]" from wikipedia section headings. We ran the pointer-generator network in *Copy Only* mode (p_{gen} hardcoded to 0 so no tokens are generated), *Generate Only* mode (p_{gen} hardcoded to 1 so all tokens are generated, as in a standard sequence-to-sequence model), and without modification (*Copy + Generate*). Finally, we also evaluated the quality of the best crowdsourced title for each table as an effective upper bound.

Evaluators assessed the readability and relevance of each title on a 3-point scale with the following interpretations: for readability, 1 = Poor, 2 = Medium, 3 = Well. For relevance, 1 = Needs Not Met, 2 = Needs Somewhat Met, 3 = Needs Fully Met. Experimental results are shown in Table 2.

Prior to collecting a dataset via crowdsourcing (Sec. 3.1), we attempted to bootstrap a training dataset using four different heuristics (Sec. 3.2). In each case, we found that the heuristic we used biased the training data enough to significantly hinder its ability to generalize. Consequently, the results reported in this paper all correspond to models trained with the crowdsourced data. Interestingly, while *Copy + Generate* had the strongest performance, *Copy Only* and *Generate Only* had the weakest, with each performing much better in one of the two metrics than the other, as shown in Figure 2. Since both readability and relevance are required in any real-world use case, it makes sense that historically, simpler selection-based

Table 2: Comparison of relevance and readability (from human evaluation) and ROUGE metrics for 200 titles. Results are grouped by category (baselines, neural networks, crowdsourced) and shown graphically in Figure 7. The crowdsourced titles have no ROUGE scores because they are the ground truth.

Model	Relevance	Readability	ROUGE-1	ROUGE-2	ROUGE-L
Page Title	2.25	2.41	0.510	0.369	0.461
Section Heading	2.29	2.56	0.476	0.315	0.411
Generate Only	1.08	2.25	0.168	0.064	0.151
Copy Only	1.97	1.26	0.384	0.221	0.240
Copy + Generate	**2.56**	**2.66**	**0.647**	**0.485**	**0.574**
Crowdsourced	2.72	2.74			

approaches have been preferred to generation-based ones. Combining the two mechanisms, however, results in a model that performs better than both single-mechanism models in all metrics.

Generate Only: We observe that the *Generate Only* model produced much more readable output than *Copy Only*, but scored extremely low on relevance. The failure of *Generate Only* seems to stem from the fact that because of the prevalence of rare and OOV tokens, the model was unable to learn sufficiently precise embeddings to convey the required information to the decoder. It did, however, appear to capture general topics. For example, when trying to produce the title "Jyotii Sethi Filmography," it produced "List of Movies with Sue Perkins" instead—both describe a list of a particular actress's movies, but clearly the model lacked the exposure to the tokens "Jyotii Sethi" to either include them in its vocabulary or learn precise enough embeddings for them.

Copy Only: On the other hand, the *Copy Only* model produced more relevant output—often producing very specific words pertaining to the table at hand—but had a much harder time composing text snippets in a readable way. Intuitively, this is because the metadata (e.g., section headings, column headers) associated with semi-structured data such as lists and tables often lack the prepositions, conjunctions, and other transition words necessary to combine multiple pieces of information. As a result, titles often consisted of snippets concatenated in unnatural ways.

Copy + Generate: Examining the output of the *Copy + Generate* model, we found many instances where a combination of both copied tokens and generated tokens was used to great effect. For example, many tables in our dataset report movie or television appearances of an individual. A common title pattern for these is "Ash King Filmography" (if the table is about Bollywood singer Ash King). Instead, for that table, the *Copy + Generate* model produced the title "Filmography of Ash King". While it may have been a mistake to generate "Filmography" first in the title, because it can generate filler words and had learned a reasonable language model, the model was able to recover from this misstep by adding the preposition "of", which actually did not occur anywhere in the input. This simple example illustrates the power of combining these two mechanisms in a single model.

It is worth noting that while the absolute difference between *Copy + Generate* and the *Section Heading* baseline is not large, the learned model cuts the gap to human-generated performance by more than 50% in both readability and relevance. This corresponds to a quite noticeable difference from a reader's standpoint. Additionally, the task of generating focused natural language is one in which performing moderately is not too difficult, but performing well enough to produce genuinely usable text is very challenging.

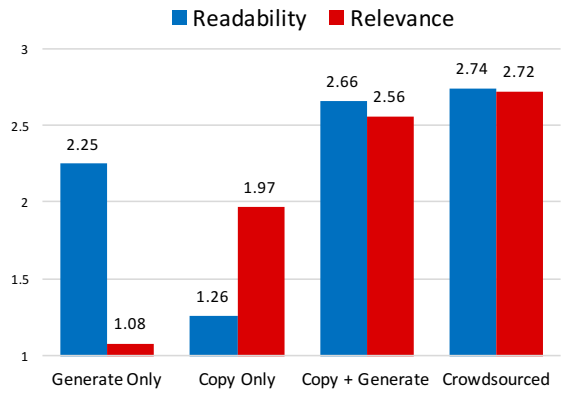

Figure 7: The poor performances of the *Generate Only* and *Copy Only* variants highlight the necessity of having both mechanisms in a single model to produce high quality titles.

5 RELATED WORK

The approach of flattening structured fields into a sequence was also recently taken by [6], who used it for the related task of generating one-sentence biographies from Wikidata facts. Instead of employing a copy mechanism, they add an autoencoder objective to their sequence-to-sequence model to encourage relevance in generated text. Other attempts to summarize structured web content include generating text summaries from individual knowledge base triples [32], generating descriptions of restaurants from structured attributes using rule-based [24] or learned [34] templates, and generating titles for web pages with e-commerce search results given a set of attributes shared by all items on the page [20].

In addition to pointer-generator networks, multiple other types of networks with copy mechanisms have been proposed [10, 11, 15, 31], each with minor differences affecting when and how the network chooses to generate versus copy.

Another way to attempt to deal with rare and OOV words is to learn over sub-word units, using character-level embeddings [7, 13, 18], byte-pair encodings [26], or WordPieces [35], for example. One reason why these methods often work well is because they are somewhat robust to variation in prefixes or suffixes of words, making it easier to recognize the similarity between words like "slower" and "slowly" compared to a word-based approach with independent embeddings for each. In the table title domain, however, we found that the most common source of OOV words was uncommon named entities, which reduces the benefit of sub-word embeddings.

For long document summarization, [22] also reduced repetition by forbidding duplicate n-grams (in their case, trigrams). They also add decoder attention (to increase awareness of which tokens have already been generated) and intra-temporal attention on the input (similar to the coverage mechanism of [25]), which penalizes input tokens that have received high attention scores in the past in hopes of limiting the number of time steps that a given token can influence.

The question of how to best evaluate Natural Language Generation (NLG) systems is one of ongoing debate. While automated methods such as BLEU and ROUGE scores are fast and cheap, these have been found to show surprisingly weak correlation with human ratings [21] for many tasks and domains. (We see this in our own dataset as well, where the *Page Title* baseline outperforms *Section Heading* in all three ROUGE metrics, yet underperforms it in both human evaluation metrics). In general, human evaluation is still the preferred method for assessing final system quality where possible [3]. Nevertheless, as they are a standard point of comparison, we report ROUGE scores as well.

6 FUTURE WORK

Surprisingly, the pointer-generator network produces effective titles when trained with just 8k examples, a much smaller dataset than is typically used in text generation tasks. Empirically, this appears to be because the model focuses more on learning when and where to "copy and paste" than it does on learning accurate embeddings for all words in the vocabulary. Using the fact that words of similar parts of speech or entity types will tend to be used in the same ways in titles, in follow-up work we intend to explore the benefits of injecting extra syntactic/semantic information (such as part of speech or named entity tags) directly into the input stream. We anticipate that this will further improve performance while maintaining low training data requirements.

As we reported in this paper, we found prefix text and suffix text to have too low signal-to-noise ratios (i.e., too many irrelevant words compared to relevant ones) to justify their presence in the input to our model. However, certain key phrases in these fields seem to strongly indicate that the surrounding words will be relevant for the title—phrases such as "the following table" and "as shown below". We suspect that a model better equipped to handle long input sequences (such as an LSTM with skipping [38] or a Transformer [30]) may be able to better utilize fields such as these, resulting in a richer input sequence from which to generate a title. Additionally, one might take advantage of the increasingly prevalent structured metadata embedded in webpages in formats such as RDFa, Microdata and JSON-LD.

7 CONCLUSION

In this work, we presented a new framework for generating titles for web tables. We found that for the majority of web tables, the ideal title must be composed, rather than selected, from the text snippets associated with the table. We trained a sequence-to-sequence model to generate titles from input sequences consisting of the flattened key-value pairs of metadata associated with web tables. The best performing model utilized a copy mechanism to make titles relevant (often copying rare and OOV words directly from the input), and a generation mechanism to make titles readable (drawing on a learned language model for titles). In a human evaluation, the model with both copy and generation mechanisms outperformed all other models, approaching the quality of crowdsourced titles. We believe this establishes a new state of the art for table title generation.
