ABSTRACT

The investigation of the effect of the built environment in a neighbourhood and how it impacts residents' health is of value to researchers from public health policy to social science. The traditional methods to assess this impact is through surveys which lead to temporally and spatially coarse grained data and are often not cost effective. Here we propose an approach to link the effects of neighbourhood services over citizen health using a technique that attempts to highlight the cause-effect aspects of these relationships. The method is based on the theory of *propensity score matching with multiple 'doses'* and it leverages existing fine grained open web data. To demonstrate the method, we study the effect of sport venue presence on the prevalence of antidepressant prescriptions in over 600 neighbourhoods in London over a period of three years. We find the distribution of effects is approximately normal, centred on a small negative effect on prescriptions with increases in the availability of sporting facilities, on average. We assess the procedure through some standard quantitative metrics as well as matching on synthetic data generated by modelling the real data. This approach opens the door to fast and inexpensive alternatives to quantify and continuously monitor effects of the neighborhood built environment on population health.

1 INTRODUCTION

The effects of urban neighbourhood characteristics on health outcomes of its residents is an ongoing research topic [2]. With over half of the population living in urban areas and a projected increase to 68% by 2050 [31], understanding exactly how these neighbourhood aspects impact different disease outcomes is a significant public health concern. Traditional research into the risk factors of many diseases focus mainly on 'direct causes' - those that are close to the biological mechanisms that are responsible for the development of the disease. For instance, high cholesterol and coronary heart disease. However, in order to deliver maximum impact when designing interventions that prevent diseases in the population at large, it has been argued that we should also focus on what puts people at *'risks of risks'* [15, 27] - the factors that lead people to be exposed to the direct causes of disease in the first place. These, which we call 'higher level causes', for instance social-economic status (SES) or the availability of services and amenities in a neighbourhood environment, are useful from a public health point of view, as they can be influenced directly by policy, as opposed to an individual's diet or lifestyle choices.

Previous work on neighbourhood effects on health mainly consists of observational cross-section studies, with the SES of the neighbourhood as the most studied variable, and Body Mass Index (BMI) as the most studied health outcome [2]. We find two main issues. Firstly, a large proportion of these works rely on traditional data sources such as surveys which can be quite expensive at scale and therefore lead to limited geographical and time span coverage. This focus on traditional data sources also means aspects such as the availability of services and amenities in the neighbourhood are neglected, and studies to understand its impact on residents' health are few, even though the built environment was found to have a consistent association with for example, depression [18], amongst neighbourhood structural features. Some previous work have for instance looked at food venue density and BMI [34], and tobacco store density and life expectancy [8]. Secondly, these discussions have mainly revolved around associations, and the daring leap to attempt at a causal conclusion are few. Since these physical aspects of a neighbourhood are controllable and can be planned, this has enormous potential to help inform public policy decisions. The data offered by projects such as Open Street Map (OSM), combined with the growing availability of causal methodology, turns this potential closer to a reality at scale.

In this paper we try to leverage this available open data offering fine grained spatio-temporal granularity and a causality framework which takes us closer to eliciting causal effects. There are advantages to this approach. The use of open data offers a scalable and cost effective solution in addition to the granularity in comparison with survey methodologies. Additionally, physical characteristics are better defined and quantifiable compared to measures such as SES. Specifically, and to illustrate the approach, we investigate the availability of sporting facilities and its potential causal effect on

antidepressant prescriptions across over 600 neighbourhoods in London over three years.

In summary, the contributions of this paper are:

(1) A general cost effective approach to study the influence of the built environment and neighbourhood characteristics, and the mechanisms that underlie this influence such as access to tobacco, certain types of food, or sports, over population health.
(2) We work on a specific example, exploiting urban open data to show that the effect of sporting facilities on antidepressant prescriptions in London.
(3) Our analysis, using data from Open Street Map (OSM), the UK National Health Service (NHS) prescriptions and the census, shows that the effect of sport venues over prescriptions for antidepressants follows an approximate normal distribution centred at a negative effect for prescriptions with increases in sporting facilities, on average.
(4) We assess our approach by examining the results from the procedure for balance, as well as comparing with results from the null model and of synthetic datasets modelled based on real data, where we have knowledge of the real effect.

This approach opens the door to new methodologies to study urban health and to offer urban planners mechanisms to study these geo-temporal processes at a fine grained scale. We first give a general overview and intuition behind the approach, followed by a more detailed explanation. Section 5 and 6 then describes the results of our analysis on a specific case study and our evaluation. We conclude by discussing the implications of our investigations, its limitations, and potential.

2 RELATED WORK

The study of neighbourhood effects on health has grown rapidly over the last two decades [22] [2]. This ranges from grocery store density and BMI [34] to tobacco store density and life expectancy [8]. The neighbourhood variable under study can be split largely into two categories. The tangible aspects of the neighbourhood, such as green spaces, amenities, or venues offering services, and the intangible aspects of the neighbourhood, comprising mostly of social aspects such as social cohesion, social disadvantage, to perceived safety.

The research area dates back to Durkheim's study of suicide in the 19th centuary [5] but the most recent concrete indication of any plausible causal effect is shown by a rare randomised controlled study conducted in the United States which shows that disadvantaged families moving to neighbourhoods with lower poverty rates lead to long term improvements on mental and physical health [17].

Non experimental studies in the literature predominantly feature social characteristics of a neighbourhood [2][22]. However, these intangible variables are often difficult to define, hard to measure and quantify, as opposed to the physical characteristics. Additionally, the traditional methods of surveys lends itself well to the study of social aspects as opposed to the physical, which may explain the lack of studies in the latter area.

Reviews of neighbourhood effects research suggests that apart from a few key studies such as the randomised experiment, evidence is inconclusive regarding many health outcomes [18, 22], and the literature has had its fair share of discussion around the validity of causal estimates from non experimental data [21][12]. Additionally, even though association studies are plentiful, there has been a lack of proposed mechanisms for which high level neighbourhood characteristics can influence health, and of the ones that are proposed, hardly any are related to the tangible aspects of the neighbourhood [4]. This study examines one such potential mechanism, given that the built environment is noted to be consistently associated with depression [18].

There is a glaring opportunity to leverage non-conventional data sources to help characterise neighbourhoods, and an appropriate methodology that will allow this to be done continuously at scale. Alternative data sources, such as those from mobile phone call detail records, social networks such as Twitter, Foursquare, Google Street View and other web data, have been increasingly used in a wide range of applications from estimating poverty levels [30], measuring social diversity [10], to auditing the neighbourhood environment [29].

There exists studies that investigate how these data sources can be used to understand and improve public health. For instance, the association between human lifestyles and chronic diseases, and its use in predicting diseases evolution in urban areas [34]. Another study used a model based on twitter data to predict disease prevalence, and found associations between the different geographical risk factors (e.g tobacco use, exercise) based on phone interview data, with the model prediction [24]. However these are constrained to associations and predictions. Traditional studies attempting to establish causal links on the other hand, such as that between physical activity, fast food environments, BMI, body fat percentage, and waist circumference, noted lack of data on the food environment to be a limitation [19].

In short, we see three potential improvements to the state of neighbourhood effects research: More focus on physical characteristics of the neighbourhood, a deeper investigation into the potential physical causal mechanisms by which the neighbourhood effects health, and scalability of methodology to continuously monitor effects leveraging non-traditional data sources.

This paper illustrates an alternative approach which addresses these concerns and contributes further to the discussion.

3 APPROACH OVERVIEW

We now describe the overall approach. We are interested in studying specific characteristics of neighbourhoods, say the presence of particular services - for instance sporting facilities - over a population health outcome, such as antidepressant prescriptions. The neighbourhood characteristic here is then called the *treatment*. This stems from the fact that we are adopting a causal view; we want to find the effect that applying the treatment would have on the outcome for the average neighbourhood.

Geographical Separation. The units under study are then not specific individuals, but rather neighbourhoods. The adopted definition of a neighbourhood in this study is that of a *ward*, an administrative geographical separation, of which, for instance, London has approximately 625. At the beginning of the calendar year, each ward is considered treated with a particular *dose* of treatment, where a dose is the binned value of the absolute value of the treatment variable.

Randomized Controlled Trials. In an ideal scenario, the best approach to estimate the causal effect of the neighbourhood treatment to the outcome is to conduct a randomised controlled trial (RCT). We randomly select half of the wards and strip them of the treatment variable as control, and apply the same amount of treatment to the rest. Why this is infeasible is obvious, but what is the next best alternative?

We run an *observational study*, which aims to achieve the same goal as a RCT, but without data from a randomised experiment. To do this we first look at the intuition behind why RCTs work in the first place. The key point is that randomisation of treatment assignment to each neighbourhood ensures that all of the variables that may also be influencing the outcome are equal in expectation as the number of neighbourhoods increases. This means that the outcomes of the two groups, those exposed to treatment and the control, are comparable because the only difference between the groups is the treatment status. An important point here is that we do not have to know all the variables that also affect the outcome; the randomisation ensures these are balanced even if unobserved.

The observational study conducted here attempts to achieve the same goal as the RCT - construct two groups where the outcome is comparable with the only difference being the treatment status. However, since we no longer have randomisation, two problems arise. Firstly, there could be variables that also affect the outcome, which are only balanced in the groups if the treatment assignment is randomised. Additionally, we also could have variables that also affect the treatment status of the units, as treatment is not randomly assigned. Which means even if we were able to construct two groups with balance on the variables that affected the outcome, the groups may be imbalanced with respect to the variables that determined treatment, and the effect will not be representative of the average effect on the population. The variables that potentially affects both the treatment, outcome, or each other are called *confounding variables* or *confounders*[1]. The game here is then to construct two groups such that on average, the confounding variables are balanced, but the treatment assignment is different.

Matching. To achieve this, we use a procedure called *matching*. For each control unit, if we were able to find another unit in the population with the same set of values for all confounding variables but instead has received a different treatment, then the difference between the outcomes of the pair can be calculated and averaged over all pairs in the population. This is called exact matching. However finding an exact match is not always possible, so instead we find, for each unit, a match that would minimise the overall difference between the average value for all confounders between the two groups. This is the basic idea behind the approach.

Propensity Score. There are two additional modifications. Firstly, since there could be many confounding variables, high-dimensional matching between the units could be potentially difficult, so we match instead on a single measure called the *propensity score*, which is a function of the confounding variables and is shown to achieve balance, on average, for the confounding variables [28]. Secondly, instead of a binary treatment status, treated or control, there are multiple possible treatment 'doses', where the dose is defined by the bin in which the treatment variable falls into. The two constructed groups now consists of the 'low dose' group and the 'high dose' group, because units can only be matched if they received a different dose of treatment. The balancing nature of the propensity score still applies in this case under some conditions.

At a Glance. In summary, we estimate the causal effects by emulating the results of a randomised controlled trial using a matching procedure based on propensity scores to balance the confounding variables between the high dose and low dose treatment group. The difference between the outcomes of these two groups is interpreted as the average causal effect of the treatment on the population.

[1]While in some literatures the word confounder is used to refer to a particular type of confounding variable - the common cause between treatment and outcome - here we use it interchangeably with confounding variable

4 METHODOLOGY

In this section we go into more detail on various parts of the methodology before we describe its application to a specific example.

As briefly mentioned previously, the aim is to attempt to emulate a randomised controlled experiment - which means that the confounding variables between the 'treated' and 'control' group in the binary case, or high and low dose group in the multiple treatment case, should be balanced on average.

To achieve this, the wards are matched in such a way that minimises the difference between the confounding variables over all matched pairs, and maximises the difference between the treatment 'dose' e.g the binned value of available sport venues in a ward, in each pair.

In this section we first describe matching in the case of a binary treatment, then introduce the need for the propensity score, followed by how this matching can be achieved with multiple treatment levels.

4.1 Matching with Binary Treatment

Finding a match for a treated unit with precisely the same values for all variables in the set of confounders is called exact matching. In practice, especially with more than a handful of confounders, this is infeasible.

Given a confounder x, if an exact match cannot be found, the nearest value to the confounder could be used instead. However, where there is more than one confounder, the matching procedure uses the sum of the difference between all of the confounders, and aims to find a matching that minimizes this total sum. This is called nearest neighbour matching. We find a set of pairs of units M, given a set of p confounders to minimise the distance

$$\sum_{(i,j)\in M} \sum_{p} |x_p^i - x_p^j|$$

where x_p^i denotes the pth confounder of unit i. This optimisation problem can be solved as a graph matching problem. Given a graph $G = (V, E)$ a matching is a subset $M \subset E$ such that for all $(u_1, v_1), (u_2, v_2) \in M$, $u_1 \neq v_1 \neq u_2 \neq v_2$ i.e no two edges share a common vertex.

A couple of definitions on graph matching. A *perfect matching* is a matching that includes all the vertices of a graph. This is only possible when the number of vertices are even. A near-perfect matching is a matching when only one vertex is excluded from the matching. This happens when the number of vertices are odd. A matching is called *maximum* if it contains the largest number

of edges, which in turn implies it contains the largest number of vertices. A perfect and near-perfect match is always a maximum matching. The problem of finding maximum matchings can be extended to weighted graphs, where each edge is associated with a distance. We can then ask for a maximum matching that minimises the total sum of all edge weights. Such a matching is called an *optimal matching*. Our problem can be framed as an optimal matching problem with a fully connected graph, where the vertices represent the wards, and the edge weights are the difference between the values of the confounders between each potentially matched pair.

4.2 The Propensity Score

Even with nearest neighbour matching, the high dimensionality of the confounders can still be a problem. With many confounders, the optimal match may still yield large overall distances in the matching, and the confounders in the treatment and control group could still remain imbalanced, if the sample size is small relative to the dimension of the confounders. The theory of the propensity score resolves this issue by stating that, instead of matching on all of the confounders, which may possibly be high dimensional, if the matching was performed based on a value called the propensity score, a one dimensional scalar value, then the confounders in the treatment and control group should still be balanced on average, in the limit of a large sample [28]. This was intitially shown to be true in the case of binary treatment. The estimation of the propensity score is discussed next in the context of multiple treatments.

4.3 Matching with Multiple Treatment Levels

If we let z denote the level of treatment received, the discussion so far has been constrained to the case where there are only two possible 'doses' of treatment, that is, no treatment at all $z = 0$, and a single value for treatment $z = 1$. For our particular application, we have to consider extensions of this to the case where there are many possible levels of treatment.

The propensity score is unknown, and has to be estimated. Additionally, the balancing nature of the propensity score is only proved in the case where there were two levels of treatment. Joffe et al [11] showed that the balancing property of the propensity score could be extended to the case with varying doses of treatment. This means that matching based on a scalar propensity score will still balance observed confounders when there are different doses of treatment. This is precisely the case when $P(z|x) = P(z|b(x))$, where x are the confounders and $b(x)$ is the propensity score. McCullaugh's ordered logistic model [20] would satisfy this criteria.

In light of this, the propensity score for any unit i corresponds to $\beta^T_{x_i}$ in the model

$$log\frac{P(z_i) \geq d}{P(z_i) < d)} = \theta_d + \beta^T \mathbf{x_i} \tag{1}$$

where d is the different doses of treatment, and can take values $= 2, 3, .., D$. Note that here, the distribution of treatment levels given the confounders depends only on $\beta^T_{\mathbf{x}}$, which means $P(z|x) = P(z|b(x))$, and makes it a balancing score in the case with multiple treatments. An estimate of this value can be obtained using maximum likelihood, and is denoted $\hat{\beta}^T_{\mathbf{x_i}}$.

Another difference when performing matching with doses is that we would like matched pairs to have different levels of treatment. Similar to the case with binary treatment when control units are only allowed to match with treated units and vice versa.

To maximise the difference between the treatment levels of the matched pairs, instead of matching directly with the difference of the estimated propensity score, a modified version of the distance metric that incorporates the treatment dosage, adopted from Lu et al [16] is used. The distance between two units i and j, denoted $d_{i,j}$ is then defined as

$$d_{(i,j)} = \frac{|\hat{\beta}^T_{\mathbf{x_i}} - \hat{\beta}^T_{\mathbf{x_j}}| + \epsilon}{|z_i - z_j|} \tag{2}$$

Where ϵ is an extremely small positive number. The role of ϵ is to deal with edge cases when either the potential match has the exact same confounders or treatment dosage.

In the case with two treatments, matching can be solved using an optimal bipartite matching algorithm, such as the Hungarian algorithm [13]. This is because the vertices of the graph can be divided into two disjoint sets, those which represent units who received treatment, and those which did not, as units from the same group are not allowed to match, and has no edge in the graph. Here where we have multiple doses of treatment, and each unit can potentially be matched with any other unit, and is called an optimal non-bipartite matching problem. The algorithm used to solve the this problem can be attributed to Edmonds [6]. This algorithm generalises his original blossoming algorithm that constructs maximum matchings, to construct a maximum weighted matching on a graph.

We can now construct a graph, with each vertex representing a unit, and edges connected to other units where the weight is the distance given by equation 2. Using Edmonds algorithm we then can obtain an optimal matching M. Given a set of matched pairs M, and let y denote the outcome and z the treatment, the average treatment effect (ATE) per dose can then be calculated by

$$ATE = \sum_{(i,j)\in M} \frac{y_i - y_j}{z_i - z_j} \tag{3}$$

5 PROOF OF CONCEPT APPLICATION

We demonstrate the feasibility of using the matching procedure described previously to investigate sporting facility availability and its effect on antidepressant prescriptions on the average neighbourhood in London. We first describe the datasets, then the confounding variables, apply the matching procedure and assess the results.

5.1 Datasets

To obtain the data required to perform the matching, we combine eight datasets. These include *venue*, *prescription*, *GP*, and *drug* data, *ward boundaries* and *demographics*, the *Greater London area boundary*, and finally *postcodes* in London. All of these datasets are open.

Venue Data. The OpenStreetMap (OSM) project is a crowd-sourcing platform that aims to create a freely available and editable map of the world. The map contains data on a wide array of geographical features, such as shops, cycle routes, benches to waterways, which

are contributed by users and moderated before being added to the project. These features can be given a tag, where a list of official tags are maintained [7].

Prescription Data. The UK National Health Service (NHS) maintains an open dataset that contains all of the prescriptions, broken down at the practice level, across the whole of England. This dataset specifies which drug, identified using the British National Formulary[2] Code (BNF Code), and the quantity prescribed in GP's across England.

GP and Drug Data. Each month a BNF Code to chemical name mapping is published which allows the drug prescribed to be identified. The NHS also maintains a medical practice dataset which allows a practice to be located using its postcode from the practice code.

Geographical Boundaries and Demographics. The London data store [1] is a repository for data on different geographical separations in London and contains statistics such as population, housing benefits, crime rates, access to nature, to higher education results. Additionally, the geographical separations at the ward, borough or LSOA level is also available in GeoJson format.

Finally, The office of national statistics (ONS) maintains a postcode dataset that allows mapping between a postcode and different administrative or electoral areas, or latitude and longitude.

5.2 Confounding Variables

The confounding variables considered can be broken down into three categories. First of these is the population structure. London, as with many developed cities, is a commercially active area and different parts of the city attract people at different stages of their lives. The data segregates the population into those with age 0-15 (children), 16-64 (working age) and 64+ (retired). Plotting these values as a percentage of the population of each ward on a choropleth clearly shows that central London attracts the majority of the working age group, retirees mostly occupy the outskirts and children are mostly even distributed, albeit with higher concentration in more deprived areas. This is shown in Figure 1.

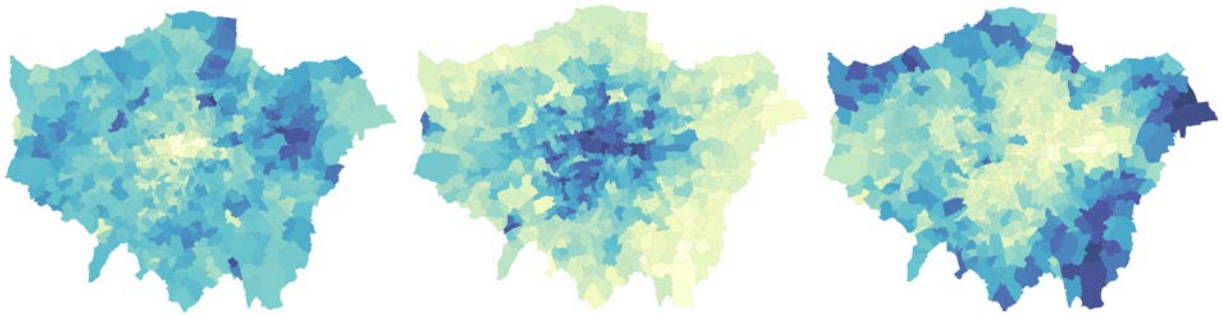
Additionally, the number of full time and part time employees in an area helps us characterise whether the area is more residential or commercial, which affects both sporting facilities and prescription numbers.

The second is the availability of green spaces. Despite London being one of the greenest capital cities on the planet, there are major discrepancies in the availability of green spaces. The demographic dataset captures this with two values, % area that is green space, and % homes with deficient access to nature. Access to nature not only has been linked with mental health [3] but its availability also determines the type of sporting venue that is available.

Finally, with SES being so commonly linked with a variety of health outcomes [2, 22], we also include several measures of deprivation, ranging from housing benefit claims to job seekers allowance claims. The full set of confounders used are shown in Table 1.

Of course, there are many points of discussion surrounding how we select confounding variables and decide on the causal structure and we defer to Section 7.1 where we touch on the key points. The results of applying the matching procedure is considered next.

Table 1: The set of considered confounders.



Population Structure
Ages 0-15
Ages 16-64
Ages 64+
Full-time Employees
Part-time Employees
Green Spaces
% Area Green Space
% Homes with Deficient Access to Nature
Deprivation
DWP [3] Working-age client group (Rates)
Employment and Support Allowance Claimants
Housing Benefit Rates
Income Support Claimants
Incapacity Benefit Claimants
Job Seeker's Allowance Claimant Rates

5.3 The Treatment Effect

In this section we apply the matching procedure as described in Section 4 using the datasets and confounders identified above, to understand the impact of sport venues over antidepressant prescription. Doing this requires the following steps:

(1) Using the OSM data dump (the 'planet file'), the open source Osmium Tool, a boundary file of the Greater London Area and boundaries for London wards, we extracted all venues related to sports between the years 2011-2013 and mapped them to each ward in London using a geometry library. The venues were identified as sports-related through a list of key:value tags, the ones which are included were distilled from the official tag page [23] and are shown in Table 2. The extracted venues and its frequency are represented using the word-cloud shown in figure 2.
(2) To determine prescriptions, the prescription data was filtered by BNF code for antidepressants, the postcode data was filtered to only those in London, the GP data is then used to filter for London GPs and obtain a list of GP IDs with its corresponding prescription numbers for 2011-2013. The GPs were then mapped to each ward similarly.
(3) For each unit (ward) we now have the treatment (sport venues), outcome (antidepressant prescriptions) and associated confounding variables from the demographic dataset. We can now estimate the propensity score, $\beta_{x_i}^T$ in equation 1, calculate the distance using equation 2 and construct a graph to perform optimal non-bipartite matching with Edmonds algorithm.
(4) Given a matching M, we could calculate the average treatment effect as in equation 3. This is shown along with the distribution of the effects in the matched pairs in Table 3.

[2] A pharmaceutical reference book published by the British Medical Association
[3] Department of Work and Pensions

(a) Ages 0-15 (b) Ages 16-64 (c) Ages 65+

Figure 1: A choropleth map revealing systematic bias in age structures in London. Darker colours indicate a higher density.

Table 2: Objects tagged with the key and values listed here were included in the extraction.

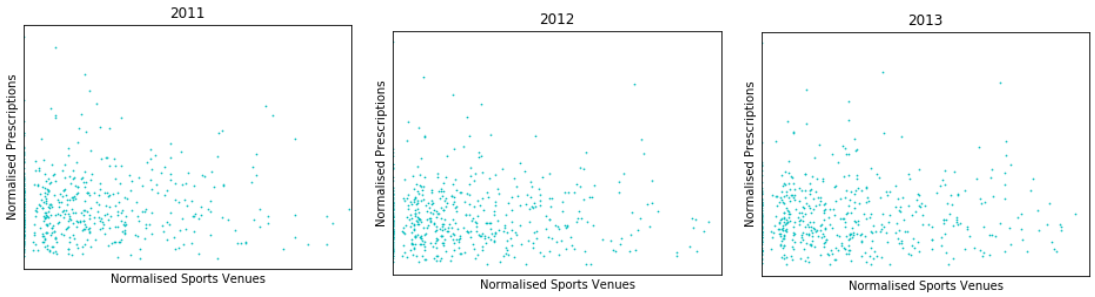
Key	Values Included
Sports	All Values
Leisure	Pitch Golf Course Swimming Pool Sports Centre Horse Riding Track
Club	Sports

Figure 2: Tag values from extracted sports venues, size is proportional to frequency

The units here are the change in antidepressant prescription per person, per dosage of sports venue in a ward in London. We can see that the ATE across all three years are negative. This suggests that there is a negative effect. If we compare this with the treatment effect distribution from matching on the null model - where the sport venue counts per wards were randomised - also shown in Figure 3, this also suggests that there is an effect in the negative direction.

Table 3: The distribution of the treatment effects in the matched pairs across 3 years, the average distribution on the null model, across ten runs, is shown below.

Year	ATE	Min	25th %	75th %	Max
2011	-0.461	-91.579	-7.651	5.774	65.911
2012	-1.117	-66.628	-7.948	7.912	55.853
2013	-0.529	-90.034	-7.573	6.454	72.320
Null Model					
2011	0.178	-62.699	-7.147	6.971	62.811
2012	0.494	-68.740	-7.245	8.495	62.291
2013	-0.085	-64.700	-8.180	8.161	71.384



Specifically, a unit increase in dosage level is expected, in the long run, to decrease the number of antidepressant prescriptions per person by anywhere between 0.461 to 1.117. With an average prescription level per person value of 23.51 across all wards across three years, this amounts to a decrease of 1.96-4.75% per year. If we looked at the simple correlation between the two variables, we could not discern as much, as shown in Figure 3.

However this result deserves a deeper discussion. With such a relatively small magnitude, a more conservative interpretation would be that of a small negative, or no effect. This is due to the many possible uncertainties, both in the data and assumptions, that will be discussed in Section 7.2. If we look at the entire distribution of effects we can see that it spans a wide range of values, with the distribution skewed towards the negative direction, albeit slightly. This is shown in Figure 4.

In the next section we will explore some more aspects related to these results and assess their validity.

6 ASSESSING THE INFERRED EFFECT

How do we assess the reliability of the inferred effects? Since we do not have the 'true' effects to compare with, the effectiveness of the matching procedure in this instance is evaluated using three metrics: the dose difference, the confounder balance, and performance on a synthetic dataset.

(a) Spearman 0.0286, p-value 0.493 (b) Spearman 0.00765, p-value 0.855 (c) Spearman 0.0155, p-value 0.712

Figure 3: Simple correlation between the normalised number of sports venues and prescription across wards in London. This paints a very different picture to the obtained effects after matching.

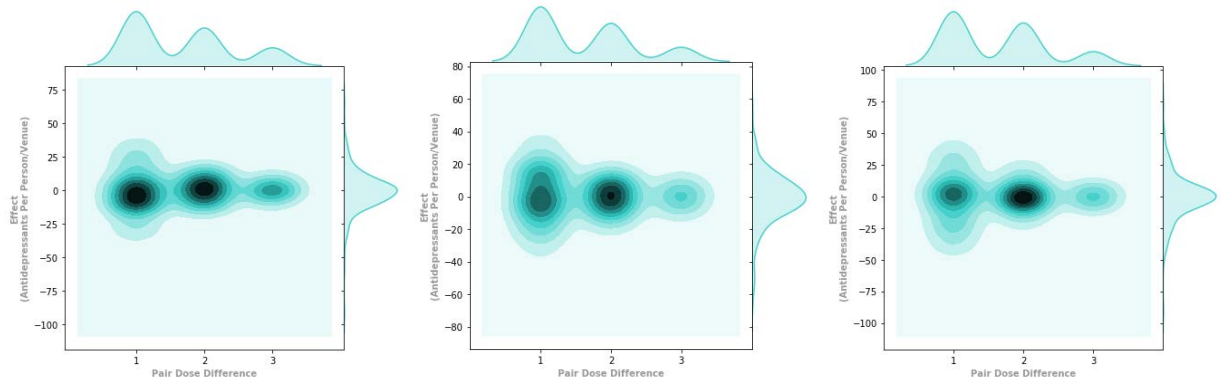


Figure 4: Plot of the joint distribution between dose difference and effect of each matched ward pair. From left to right: 2011, 2012, 2013.

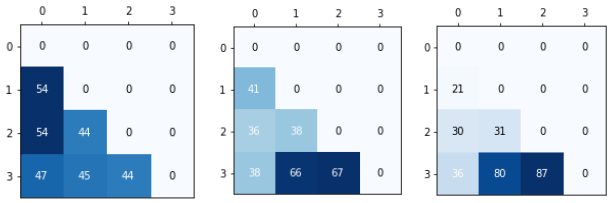

Comparing the results to alternative methods used to elicit causal effects such as difference-in-difference or regression discontinuity would also be informative, however the available data does not satisfy the conditions for their use.

6.1 Dose Difference

One of the intentions behind the form of the distance metric used, given by Equation 2, is to maximise the difference in treatment doses of each matched pair. This leads to reduced noise when computing the in-pair treatment effect.

Figure 5 shows the distribution of doses in each matched pair across the span of three years. Rows represent the dose of the unit with the higher level of treatment in the pair, and the columns represent the dose of the unit with the lower treatment. Darker colours indicate higher number of pairs with these doses.

Here one of the aims is to create pairs where the doses are not equal, we can see that this is achieved judging from the diagonals of the heatmap across three years. In fact, the difference in dosage is larger than 1 level in 50.7%, 49.0% and 51.2%, respectively. With approximately 35% of pairs having a difference in dose level of 2 and 15% with a difference of 3 dose levels across three years. The matching procedure has indeed created pairs with different treatment levels.

(a) 2011 (b) 2012 (c) 2013

Figure 5: Distribution of within-matched-pair doses between the high dose unit and low dose unit. Rows represent the high dose unit and column the low dose unit.

6.2 Confounder Balance

The original aim in any matching procedure is to produce different groups of units that have, on average, similar values for the confounders, such that the treatment effect is representative of the population. Table 4 shows the average value of the confounders between the high dose unit and low dose unit in a pair.

Here we can see that most of the confounders have successfully been balanced across the two groups. The exception is perhaps the normalised full time and part time employee rate, which has a difference of over 5 and 1.4 percent respectively. This is seen clearly

Table 4: The average normalised values of the confounders in the high dose and low dose groups across all matched pairs in 2011. Other years gave similar results.

Confounder	High	Low
Population Aged 0-15	19.611	19.760
Population Aged 16-64	68.991	69.182
Population Aged 65+	11.398	11.058
Greenspace Area	27.272	26.448
Homes with Deficient Access to Nature	25.751	25.727
Employment & Support Allowance Claims	1.034	1.026
Housing Benefit Claims	12.871	12.863
Income Support Claims	3.393	3.374
Incapacity Benefit Claims	2.882	2.807
DWP Working Age Clients	14.363	14.307
Part-Time Employees	13.229	14.688
Full-Time Employees	34.089	39.827
Job Seekers Allowance Claims	5.623	5.569

by plotting the difference between the two groups as a percentage of the average of the original values, shown in blue in Figure 6.

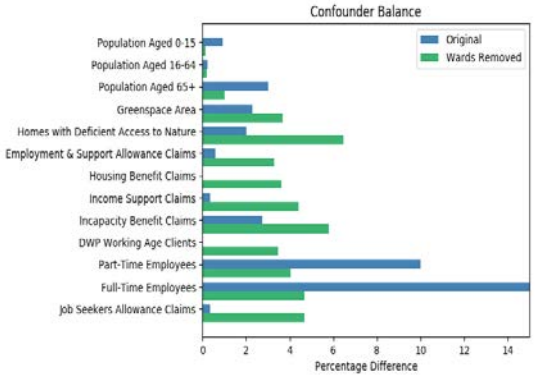

Figure 6: The percentage difference between the confounders of the high and low dose groups with respect to the average of the original values. The green bars show the balance after the wards of St James, West End, and the City of London was excluded from the matching procedure.

On further investigation this can be attributed to a couple of extreme values for these two confounders in the ward data, which can be seen clearly in Figure 7, with particular wards having over three times the value of the remaining wards.

The three wards with the highest values for both confounders were predictably large commercial areas. These were the St James and West End wards of the Westminster area, containing Mayfair, Soho, large business districts, and the City of London. We may be tempted to remove these wards in the matching procedure, in an attempt to achieve more balance within the confounders. At first glance, doing so may seem a good idea, shown in green in Figure 6.

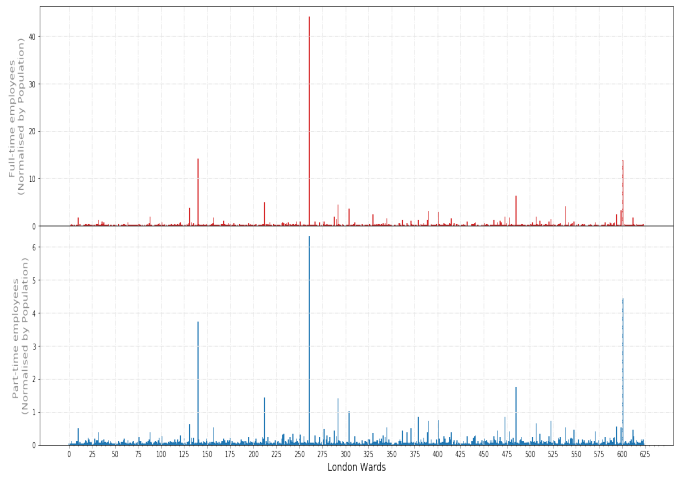

Figure 7: A plot of full time and part time employees, normalised by population, for the wards in London. Here we clearly see at least three outliers.

However, removing the wards, all of which are highly commercial areas of the city, induces a bias, as evidenced by the increased imbalance across the other confounders. The reason behind this may be that removing key business districts means that other business areas are forced to match with less similar areas, perhaps residential ones, generating additional imbalance. Additionally, remove key business districts mean that the average effect is now no longer representative of London as a whole, but rather London without the wards of St James, West End, and the City of London. Therefore for the entirety of London, we have to take into account the way that the balancing errors may have influenced the obtained effect in interpreting said effect.

6.3 Generating Synthetic Data

The most common benchmark in the literature for the evaluation of the causal effect estimate is the use of synthetic data [32][14][9][33]. Here, instead of constructing a completely arbitrary artificial dataset, we model the observed dataset and use this model to generate synthetic data. This means that we can generate datasets that mimic the real data, but where we are able to specify the underlying mechanisms - how the confounders affect both the treatment and the outcomes, and how the treatment affects the outcome. As a result, we know the 'true' causal effect of the treatment. We can then assess how well the method recovers this true effect.

More precisely, if we wanted to generate N units $i = 1, ..., N$ (these are artificial 'wards' in our case) each with p confounders (13 here) where we denote the confounders of unit i as $\mathbf{x_i} = x_{i1}, ..., x_{ip}$, we first have to generate values for all confounders for each N units. We then specify two functions, $f_Z(\mathbf{x_i})$ that takes in the confounders and generates a treatment (normalised sporting facilities) for a unit, and $f_Y(z_i, \mathbf{x_i})$ that take in the confounders and the treatment to generate an outcome (normalised antidepressant prescriptions) for that unit.

The distribution of the confounders from the real data is show in Figure 8. We model the confounders using a truncated normal

distribution except for part time employees, full time employees, and deficient access to nature, which we model using an exponential distribution. The parameters of the confounder distributions was estimated using maximum likelihood.

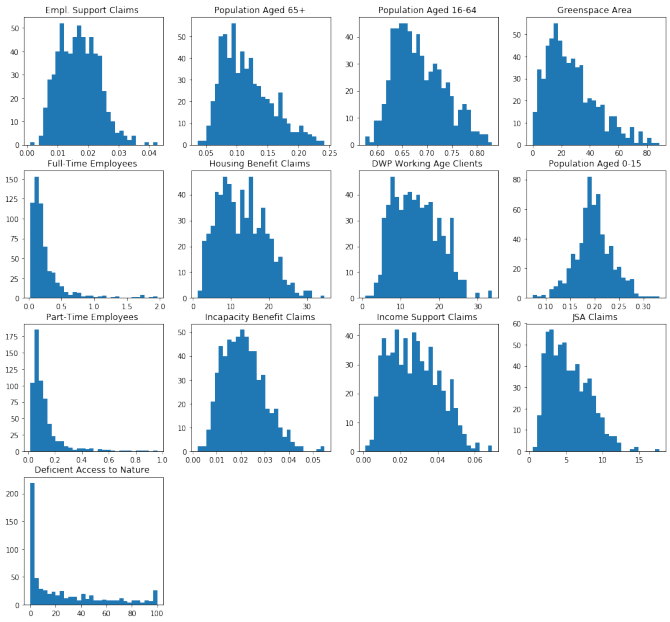

Figure 8: Distribution of normalised confounders in London wards.

Similarly looking at the distribution of sporting facilities, we then constructed $f_Z(\mathbf{x})$ as an exponential distribution:

$$f_Z(\mathbf{x}) = P(Z = z|\mathbf{x_i}) = \begin{cases} \frac{1}{f(\mathbf{x_i})} e^{\frac{z}{f(\mathbf{x_i})}} & \text{if } z \geq 0 \\ 0 & \text{if } z < 0 \end{cases}$$

where

$$f(\mathbf{x_i}) = \frac{\sum_p x_{ip}}{\alpha}$$

and α is tuned such that the treatments mimic the observed distribution.

The outcome for each unit, Y_i, is determined by $f_Y(z_i, \mathbf{x_i})$ and is constructed as a truncated normal distribution where if $Y > 0$

$$Y \sim \text{Normal}(\alpha \cdot \sum_p x_{ip}, \beta \cdot \sum_p x_{ip}) + \gamma z_i$$

where the values for α and β were tuned such that the data generated is within the observed range of outcomes in the real data, and z_i is the treatment for unit i. Here, we know that the treatment effect is γ per dose by construction.

Figure 9 shows a comparison between the observed distribution of the treatment and outcomes, and the distribution generated by the mechanism just described.

It is important to acknowledge that the functions chosen to generate the data is one of many possible functions that could potentially be the underlying mechanism behind this process. It is virtually impossible to tell which function is more likely than the other, besides the fact that it is able to generate data that closely mirrors the observed data.

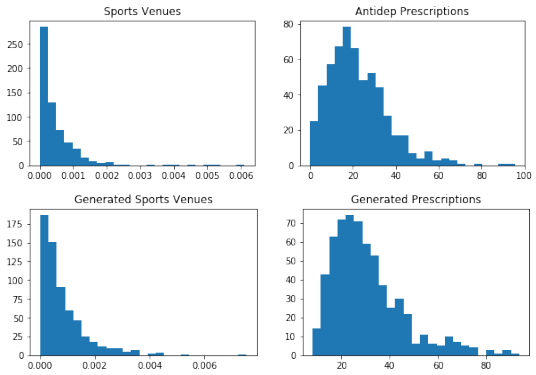

Figure 9: Comparison between normalised sports venues and antidepressant prescriptions in the data and the generated dataset.

6.4 Matching on Synthetic Data

Now that we could generate units along with its confounders, treatment, and outcome, we can run the same matching procedure used on the real dataset on the synthetic dataset. Since we know the true ATE of the synthetic dataset by construction, we can evaluate how the matching procedure performs.

The synthetic process was run to generate a total of 6250 units, each batch of 625 having a different set of confounders. This is done four times for four different 'true' ATE values, two for each direction, one with a small effect and one large effect. The results of the treatment effects calculated from the matchings are shown in Table 5.

Table 5: Treatment effects for the synthetic dataset. Each row was obtained from 6250 generated units, with each group of 625 containing a different set of confounders.

ATE	Est. ATE	Min	25th %	75th %	Max
-1	-0.292	-75.2	-7.20	6.17	63.2
-10	-9.30	-73.7	-15.9	-2.75	87.5
1	1.45	-70.5	-5.30	8.55	70.6
10	10.4	-69.9	3.48	17.3	68.5

Here we can see a similar outcome to the treatment effects obtained from the real dataset. The effects span a wide range, however the distribution is skewed towards the direction of the true effect. In the case where the magnitude of the 'true' effect is large, over 75% of all estimated effects lie in the correct direction.

The estimated effects also lie in the correct direction. We can see that in larger true effects, the matching procedure is able to give a better estimate. Where the effect is small, the inferred effects are less accurate. This gives some indication to how we should interpret the results obtained from real data, and since the obtained effects are small, we should err more on the side of a conservative interpretation.

7 DISCUSSION

We now turn our attention to discuss the potential sources of error in this approach. First we address the issue of confounding variable selection which was deferred from section 5.2 and then address the sources of error more generally.

7.1 Confounding Variable Selection

In the current causal inference literature there does not exist a method of testing which variables are relevant to a causal model for a particular problem from a set of possible variables. The closest that we have come across in this respect are methods in causal discovery [26], which at the current best can be used to find the equivalence class of directed acyclic graphs that could represent the class of models that potentially produced the observed distribution of variables, under some restricting assumptions, and given a pre-specified set of variables.

Therefore the current best option in determining confounding variables related to a causal question is to use existing subject matter knowledge, or literature relevant to the problem at hand. This is a fundamental problem of causal inference, where we cannot be certain whether we have identified all variables relevant to the cause and effect relationship at hand. It may be the case that in the future it is discovered, hypothetically, that people who smoke are severely more likely to develop depression, in which case the proportion of smokers in an area, or some variable that closes correlates with it, should additionally be considered a confounder.

An additional point to note is that of selecting key variables and edges that would have enough of an effect to be worth considering. Precisely how large is 'enough' still remains an open issue. People who have pets may indeed be slightly less prone to develop severe depression, but is the effect noticeable enough? Does the distribution of people who own pets consistently different in various areas? Systematic ways to answer these types of questions still remain unknown.

7.2 Sources of Error and Open Problems

The challenge with inferring cause is the amount of care that must be taken to eliminate all sources of errors throughout the entire process that could impact the results. In this project we by no means claim that this has been achieved, and discuss the potential sources of errors that we have conceived of here. The errors can be classified into three major categories; those that emerge from the assumptions about the causal structure, from the data itself, and from simplifying assumptions.

The most glaring source is that of the causal structure. Here the inferred effects is only a good estimate if we have included all of the confounders that are indeed relevant to the problem. This means that there are no unobserved factors that could influence the treatment and outcome. This is otherwise known as the strong ignorability assumption in Rubin's causal model, or called identifiability in Pearl's framework [25], and we have discussed above.

The second source of error are those from the data. Does the dataset of venues include all existing sports venues in London? If not, are they missing at random, or does it depends on some factor, such as the area? If it is the latter case, how do we assess this bias in exclusion from the dataset, and how do we incorporate this into an uncertainty of the estimated effect? The same issue applies with the prescription data. A potential direction forward is to assume the observed data is some fraction of reality and find the thresholds, under some additional assumptions, where the results significantly deviate from those obtained here.

Additionally, can the numbers in the dataset be taken at face value? For instance, the statistics on the demographics of a ward may have itself been generated by a statistical model. Even if we had the uncertainty attached to any particular value, how do we incorporate this uncertainty when inferring the effect?

The final major source of error are the simplifying assumptions. For instance, does the number of antidepressant prescriptions represent the rate of depression in an area well? Or does the exclusion of private prescriptions in the data create enough of a bias? The same question about incorporating uncertainties, if these were known, applies here. In general, issue of propagating uncertainties through some causal inference procedure is an interesting and open issue.

8 CONCLUSIONS

In this paper we have illustrated an approach to investigate the causal effects of the built neighbourhood environment on population health using open data at scale. This is important for several reasons. Firstly, it provides the potential to investigate the physical underlying mechanism of how a particular aspect of the neighbourhood influences health. Many higher level neighbourhood characteristics such as income or SES have been associated with multiple health outcomes, but how exactly does this affect health remains a question. Is it because people with higher SES eat healthily, exercise more often, or smoke less? Looking at the available services in a neighbourhood allows us to tackle these types of potential mechanisms. Secondly, the physical environment has the advantage of being better defined and quantifiable as opposed to more abstract measures such as general deprivation. Additionally, it provides a low cost and fast alternative to traditional methods of data collection, often with extra granularity. Lastly, these features of a neighbourhood are controllable from a policy point of view, as opposed to individual lifestyle choices, and is perhaps a more effective choice from a public health intervention standpoint.

Specifically, we have investigated the extent to which the availability of sporting venues have a causal role to play on the prescription of antidepressants in the neighbourhoods of London. Is the strength of evidence obtained and the magnitude of the indicated effect large enough to warrant a mass campaign encouraging sporting facilities? Probably not. However, it does give us insight into some important issues. With the preliminary knowledge of the possible effect size being rather modest, decision makers can now decide whether pursuing this question further, to obtain a better estimate of the effect, for example by collecting additional data or investigating to what extent the assumptions hold, is worth pursuing. It may be the case that the resources available should be put into other issues that are now known to be more cost effective, given the evidence obtained here. Or similarly, this method can be adopted to investigate related questions on venues and health.

It is hoped that this contributes to the conversation about urbanisation, and more generally, data-driven approaches in research tackling social and policy questions.

ABSTRACT

In the past few decades, there has been rapid growth in quantity and variety of healthcare data. These large sets of data are usually high dimensional (*e.g.* patients, their diagnoses, and medications to treat their diagnoses) and cannot be adequately represented as matrices. Thus, many existing algorithms can not analyze them. To accommodate these high dimensional data, tensor factorization, which can be viewed as a higher-order extension of methods like PCA, has attracted much attention and emerged as a promising solution. However, tensor factorization is a computationally expensive task, and existing methods developed to factor large tensors are not flexible enough for real-world situations.

To address this scaling problem more efficiently, we introduce `SGranite`, a distributed, scalable, and sparse tensor factorization method fit through stochastic gradient descent. `SGranite` offers three contributions: (1) *Scalability*: it employs a block partitioning and parallel processing design and thus scales to large tensors, (2) *Accuracy*: we show that our method can achieve results faster without sacrificing the quality of the tensor decomposition, and (3) *FlexibleConstraints*: we show our approach can encompass various kinds of constraints including l_2 norm, l_1 norm, and logistic regularization. We demonstrate `SGranite`'s capabilities in two real-world use cases. In the first, we use Google searches for flu-like symptoms to characterize and predict influenza patterns. In the second, we use `SGranite` to extract clinically interesting sets (i.e., phenotypes) of patients from electronic health records. Through these case studies, we show `SGranite` has the potential to be used to rapidly characterize, predict, and manage a large multimodal datasets, thereby promising a novel, data-driven solution that can benefit very large segments of the population.

1 INTRODUCTION

Increasingly large amounts of health-related data are released on the Internet and have great potential for enabling better disease surveillance and disease management. As a motivating example, search activities on diseases such as influenza can be used and correlated with actual influenza surveillance data. Estimation of influenza-like illness (ILI) rates is a well-studied task [25, 32], Google Flu Trends, while flawed, demonstrated a link between influenza related search queries and the Centers for Disease Control and Prevention's (CDC) ILI rates[19]. Similarly, programs such as the National Institute of Health's All for Us NIH [2], are looking to gather data and make it publicly available to researchers to enable precision medicine. Extracting influenza patterns or clinical characteristics from such high-dimensional data can pose challenges, even before considering whether the data has been appropriately labeled.

A vast majority of the algorithms for disease surveillance or disease prediction adopt a supervised learning approach, but the need for labels can limit the possible scope of the task. However, unsupervised learning methods such as tensor factorization have been successfully applied in many application domains including social network analysis [29, 30, 39] and health analytics [15, 16, 18, 22, 36]. Tensors can succinctly represent high-dimensional data, including various representations of time or different sources of data. For example, an existing work showed that factorizing a tensor that grouped ILI historical statistics by year, week, and region could tease out patterns that are commonly based on the weeks that influenza is highest, deliver insight into the degree to which regions are similar or different from one another in terms of influenza, and capture the changes in ILI intensity from one year to the next [13]. Moreover, a variety of constraints can be placed on the learned latent factors to extract meaningful patterns and reduce overfitting. Yet, efficient tensor decomposition of large datasets in the presence of such constraints can be challenging.

In this paper, we propose `SGranite`, a distributed tensor decomposition framework that can incorporate a variety of regularization terms to constrain the latent factors. In particular, we show that integrating three forms of regularization terms can achieve easier-to-interpret factors, provide robustness in the presence of noise, and map to existing domain knowledge. Moreover, `SGranite` is very fast and scalable. Using a Spark-based implementation, we demonstrate the ability to decrease computation time by distributing both

the data as well as the parameters without sacrificing accuracy. To promote reproducibility, our code is open-sourced and available on GitHub[1].

The contributions of our work can be summarized as follows:

- **Flexibility:** Our framework supports a variety of meaningful constraints such as sparsity, diversity, and distinguishability.
- **Scalability:** Our scalability analysis of `SGranite` on a large tensor constructed from healthcare data achieves near linearity speed-up as we scale to the number of machines. Moreover, our framework achieves at least a 4× speed-up compared to an existing state-of-the-art distributed tensor factorization method.
- **Accuracy:** Our empirical results in two health-related case studies show that incorporating the variety of constraints improves interpretability and robustness compared to the standard decomposition models.

Table 1 summarizes the contributions in the context of existing works.

2 BACKGROUND AND NOTATION

This section briefly introduces tensors and a popular tensor decomposition model. We refer the reader to [24, 34] for comprehensive overviews of practical tensor decompositions.

2.1 Tensors

Tensors are generalizations of matrices and vectors to higher dimensions. An N-way tensor is denoted as $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ and each cell of the tensor represents the interactions between N types of data. Each dimension of the tensor is referred to as a *mode*. Tensors can be unfolded or flattened as a matrix, which is called *matricization*. $\mathbf{X}_{(n)}$ denotes the matricization of tensor $\mathcal{X}$ along mode-n. Table 2 lists the operations and symbols used in this paper.

Definition 2.1. A rank-one N-way tensor is the outer product of N vector

$$\mathcal{X} = a^{(1)} \circ a^{(2)} \circ \cdots \circ a^{(N)}.$$

Each element of a rank-one tensor is the product of the corresponding vector elements (i.e., $x_{i_1 i_2 i_3 \cdots i_n} = a^{(1)}_{i_1} \circ a^{(2)}_{i_2} \circ \cdots \circ a^{(N)}_{i_N}$).

2.2 Tensor Decompositions

The CANDECOMP / PARAFAC (CP) model [7, 14] is one of the most popular and well-studied tensor decomposition method. In CP decomposition, the tensor is factored into a sum of rank-one tensors:

$$\mathcal{X} \approx \mathcal{M} = \sum_{r=1}^{R} \mathbf{A}^{(1)}(:, r) \circ \mathbf{A}^{(2)}(:, r) \circ \cdots \circ \mathbf{A}^{(n)}(:, r),$$

where $\mathbf{A}^{(n)}(:, r)$ is the rth column of $\mathbf{A}^{(n)}$. CP-decomposition can be also expressed as $[[\lambda; \mathbf{A}^{(1)}; \mathbf{A}^{(2)}; \cdots; \mathbf{A}^{(n)}]]$, where λ is a vector of the weights λ_r. Several benefits of the CP decomposition includes its intuitive output structure, uniqueness property that makes the model reliable to interpret, and the ability to learn a model even with relatively small amount of observations [24]. Figure 1 provides an example of the CP decomposition for an influenza-based tensor, where each rank-one tensor represents a pattern over time for a group of states and a set of search queries.

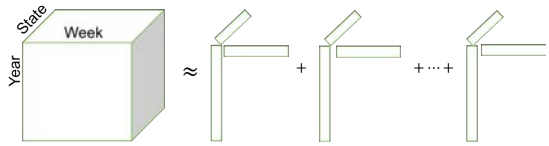

Figure 1: An example of CP decomposition for influenza search data. A tensor is constructed of time series data is decomposed into the weighted sum of rank-one tensors based on the minimization of an objective function. Each rank-one tensor, formed by taking the outer product of factor vectors, constitutes a latent factor.

The CP decomposition, $\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \cdots, \mathbf{A}^{(n)}$, is performed by minimizing the loss between $\mathcal{X}$ and $\mathcal{M}$ as defined by an objective function. The form of the objective function is determined by assumptions about how the data in the tensor was generated. A standard method of fitting a CP decomposition is the least squares formulation, which assumes the random variation in the tensor data follows a Gaussian distribution. Unfortunately, this may not be appropriate for count data, which is common in many applications including those considered in this paper [17].

A more appropriate objective function for count data assumes the underlying distribution of the data is Poisson [8]. This assumption results in an objective function that minimizes the Kullback-Leibler (KL) divergence:

$$f(\mathcal{M}) = \sum_i m_i - x_i \log m_i.$$

There have been several recent works to accelerate the computational speed of the CP decomposition. FlexiFact partitions the tensor into smaller tensors that are then decomposed in parallel using Apache Hadoop. While their method scales well with the input size, the model is not well-suited for count data and performs excessive disk operations. More recently, DisTenC, a Spark-based distributed tensor completion algorithm was proposed that regularizes the trace norm of the tensor [11]. Similar to FlexiFact, it is designed for numeric data and does not support any regularization or constraints on the factors.

3 SGRANITE

We propose `SGranite`, a distributed and flexible constrained CP model, to impose a variety of constraints on the latent factors. Our algorithm uses distributed stochastic gradient descent (DSGD) approaches to scale the CP decomposition on count data to huge datasets. `SGranite` has the following benefits:

- Simultaneously supports multiple constraints on the factor matrices.
- Learns patterns even when data cannot be stored on a single server.
- Maintains computational efficiency across a large number of workers.

Table 1: A comparison of the supported features between SGranite versus state of arts methods

Feature	SGranite	CP-APR [8]	Granite [16] (fit using SGD)	FlexiFact[6]	DisTenC [11]
Scalable	Yes	No	Yes	Yes	Yes
Memory Efficient	Yes	No	Yes	No	Yes
Time efficient	Yes	No	No	Yes	Yes
Appropriate for count data	Yes	Yes	Yes	No	No
Works with constraints	Yes	No	Yes	Yes	No

Table 2: Table of symbols and their associated definitions

Symbol	Definition
$\mathcal{X}$, $\mathbf{X}$, $\mathbf{x}$, x	Tensor, Matrix, Column Vector, Scalar
$\mathbf{X}_{(n)}$	n-mode matricization of a tensor $\mathcal{X}$
$\mathbf{X}(\mathbf{r},:)$	rth row of $\mathbf{X}$
$\mathbf{X}(:,\mathbf{r})$	rth column of $\mathbf{X}$
$\mathbf{A}^{(n)}$	nth factor matrix
$\|a\|_2$, $\|\mathbf{A}\|_F$	l_2 norm, Frobenius norm
$*$	Hadamard (elementwise) product
$\circ$	outer product
$\otimes$	Kronecker product
$\odot$	Khatri-Rao product (column-wise $\otimes$)

A distributed framework for incorporating a variety of constraints in CP decomposition is appealing for several reasons including the ability to extract patterns from large datasets that cannot be readily stored on a centralized server, to encode prior knowledge, to improve interpretability, and to democratize high-dimensional learning by running on standard commodity servers.

In this section, we will first provide a general overview and then formulate the optimization problem.

3.1 General Optimization Problem

SGranite, builds on several existing nonnegative CP decomposition algorithms to model sparse count data using the Poisson distribution [8, 16]. Let $\mathcal{X}$ denote an observed tensor constructed from count data with size $I_1 \times I_2 \times \cdots \times I_N$ and M represent a same-sized tensor of Poisson parameters for $\mathcal{X}$. In addition to KL divergence, we introduce generalized constraints on the factor matrices, $\mathcal{R}(\mathbf{A}^{(n)})$ to the objective function. Thus, the optimization problem is defined as:

$$\begin{aligned} \min f(\mathcal{M}) &= \sum_{\vec{i}} (m_{\vec{i}} - x_i \log m_{\vec{i}}) + \sum_k \underbrace{\beta_k \mathcal{R}_k\left(\mathbf{A}^{(n)}\right)}_{\text{regularization terms}} \\ \text{s.t. } \mathcal{M} &= [\![\boldsymbol{\lambda}; \mathbf{A}^{(1)}, \cdots, \mathbf{A}^{(N)}]\!] \\ \lambda_r &\geq 0, ||\mathbf{a}_r^{(n)}||_1 = 1, \ \forall r \\ \mathbf{A}^{(n)} &\in [0,1]^{I_n \times R}, \ \forall n \end{aligned} \tag{1}$$

The Poisson parameters, $\mathbf{m}$, can be determined by minimizing the negative log-likelihood of the observed data $\mathbf{x}$. We also maintain the stochasticity (i.e., elements sum to 1) and non-negativity constraints (i.e., factor elements and weights, or λ, must be non-negative) that were introduced in the original CP-APR model [8].

3.2 Example of Useful Regularization Terms

Equation 1 supports a variety of regularization items, $\mathcal{R}(\mathbf{A}^{(n)})$. While we describe three forms of special regularizations that are useful for analyzing health data, SGranite was developed to handle any regularization that is either smooth and differentiable or has an easy-to-compute proximal operator [31].

3.2.1 Diversity on $\mathcal{A}^{(n)}$. For analyzing flu patterns or clinical characteristics of patient subgroups, it is preferable for the rank-one factor components to be distinct from each other. This allows domain experts to more easily interpret the patterns. While several mechanisms for encouraging diversity have been proposed [16, 21, 36], we adopt the angular penalty term in [16] that encourages diversity between rank-one tensors by penalizing overlapping elements. There are two benefits to this regularization. It does not require prior knowledge to construct a similarity matrix that is used in [21]. Similarly, it does not require the discovered patterns to be orthogonal to one another [36], which may be too restrictive. Under angular regularization, any element that has large values in multiple columns in the factor matrix are penalized. Thus, the angular penalty for the n^{th} factor matrix, $\mathbf{A}^{(n)}$, is formulated as follows:

$$\mathcal{R}_k\left(\mathbf{A}^{(n)}\right) = \sum_{r=1}^{R} \sum_{p=1}^{r} \max\left(0, \frac{(a_p^n)^T a_r^n}{\|a_p^n\|_2 \|a_r^n\|_2} - \theta_n\right)^2$$

3.2.2 Sparsity and Smoothness on $\mathcal{A}^{(n)}$. Sparsity and smoothness constraints have been introduced in a wide range of applications to improve interpretability and increase robustness to noise. Our framework supports a general class of ℓ_p penalties including simplex constraint term ($||\mathbf{a}_r||_1 = 1, a_{ir} \in [0,1]$); ℓ_2 regularization on the weight and the first factor matrix, $\lambda\mathcal{A}^{(1)}$ to mitigate overfitting to large count data; and the ℓ_0-norm regularization which caps the number of non-zeros elements in the factor.

We first consider the simplex constraint term, which can yield sparse factors while providing a probabilistic interpretation. For the n^{th} factor matrix, $\mathbf{A}^{(n)}$, we restrict the elements to lie on the ℓ_1-ball of diameter s, where s is a user-specified parameter, such that:

$$\mathcal{R}_k\left(\mathbf{A}^{(n)}\right) = \sum_{r=1}^{R} (s - ||\mathbf{a}_r^{(n)}||_1)$$

When $s = 1$, this results in the projection of the factor onto the probabilistic (or canonical) simplex [9]. By decreasing s to be less than 1, the resulting factors will be sparser.

The ℓ_2-norm regularization was introduced in [16] to encourage terms in the factor matrix vectors to be similar-sized. Together with the simplex projection, the interaction of these two regularizations achieved further sparsity by driving specific elements to 0 more quickly in a similar manner to the elastic net regularization [41].

$$\mathcal{R}_k\left(\mathbf{A}^{(n)}\right) = \sum_{r=1}^{R} \|a_r^{(n)}\|_2$$

The ℓ_0-norm regularization, introduced in [4], is an alternative to the simplex projection that limits the number of non-zero elements. While its usage in Equation 1 results in a non-convex optimization problem, the hard thresholding properties can yield easy to interpret factors (top-k elements). To perform hard-thresholding on the n^{th} factor matrix, $\mathbf{A}^{(n)}$, the regularization term is:

$$\mathcal{R}_k\left(\mathbf{A}^{(n)}\right) = \sum_{r=1}^{R} \|a_r^{(n)}\|_0$$

3.2.3 Discriminative Factors. In some scenarios, the discovered patterns should be discriminative of a certain outcome of interest. For example, we may want to use the clinical characteristics to predict things like mortality or whether or not the patient is likely to be readmitted in 30 days. [21] introduced a logistic regression regularization that encouraged the derivation of latent factors that can distinguish in-hospital mortality outcomes. `SGranite` also adopts the regularization term to derive discriminative latent factors when such information exists. Without loss of generality, we assume that the first mode has labeled records. Then the discriminative regularization is of the form:

$$\mathcal{R}_k\left(\mathbf{A}^{(1)}\right) = \log P(\mathcal{A}^{(1)}, y|\theta)$$

The probability of a sample $\mathbf{a}(i,:)$ (i^{th} row in $\mathbf{A}^{(1)}$) having the outcome of interest, $P(\mathcal{A}^{(1)}, y|\theta)$, is obtained by training a logistic regression model on the factor matrix $\mathbf{A}^{(1)}$.

3.2.4 Sparse, Diverse, and Discriminative Patterns. To demonstrate the flexibility of `SGranite`, we introduce all three forms of regularization into our final optimization problem. Thus, the final objective function is:

$$\begin{aligned} f(\mathcal{M}) = &\sum_{\vec{i}} (m_{\vec{i}} - x_i \log m_{\vec{i}}) + \\ &\beta_1 \sum_{n=1}^{N} \sum_{r=1}^{R} \sum_{p=1}^{r} \max\left(0, \frac{(a_p^n)^T a_r^n}{\|a_p^n\|_2 \|a_r^n\|_2} - \theta_n\right)^2 + \\ &\beta_2 \sum_{n=1}^{N} \sum_{r=1}^{R} (s - ||\mathbf{a}_r^{(n)}||_2) + \beta_3 \log P(\mathcal{A}^{(1)}, y|\theta) \end{aligned} \tag{2}$$

3.3 SGD Updates

This section provides details of how to solve our optimization problem efficiently (Equation 2). `SGranite` uses an alternating minimization approach, cycling through each mode while fixing all the other modes. For each mode, the resulting subproblem is solved using stochastic gradient descent (SGD). To derive the SGD updates, we first re-write the objective function as a scalar-valued function of the parameter vector y using the same approach as [3]. The parameter vector y represents the vectorization of the factor matrices, with the weights $\boldsymbol{\lambda}$ absorbed into the first factor matrix.

$$y = \begin{bmatrix} vec(\boldsymbol{\lambda}\mathbf{A}^{(1)}) \\ vec(\mathbf{A}^{(2)}) \\ \vdots \\ vec(\mathbf{A}^{(n)}) \end{bmatrix}$$

As a result, the gradients of the objective function can be formed by vectorizing the partial derivatives with respect to each component of this parameter vector:

$$\nabla f(y) = \left[vec(\frac{\partial f}{\partial \mathbf{A}^{(1)}}) \cdots vec(\frac{\partial f}{\partial \mathbf{A}^{(n)}}) \right]$$

For notational convenience, we also represent the matricized form of the tensor decomposition as:

$$[\![\boldsymbol{\lambda}; \mathbf{A}^{(1)}, \cdots, \mathbf{A}^{(N)}]\!]_{(n)} = \boldsymbol{\lambda}\mathbf{A}^{(n)}(\mathbf{A}^{(-n)})^T$$

where

$$\mathbf{A}^{(-n)} = \mathbf{A}^{(N)} \odot \cdots \odot \mathbf{A}^{(n+1)} \odot \mathbf{A}^{(n-1)} \odot \cdots \odot \mathbf{A}^{(1)}.$$

Thus, the partial derivatives of Equation 2 with respect to the factor matrix, $\mathbf{A}^{(n)}$ are the following:

$$\begin{aligned} \frac{\partial f}{\partial A_r^{(n)}} = &\left[1 - X_{(n)} \oslash Z_{(n)}\right] a_r^{(-n)} + \\ &\beta_1 \sum_{p \neq r} \max\left(0, g(a_r^{(n)}, a_p^{(n)})\right) \frac{\partial g(a_r^{(n)}, a_p^{(n)})}{\partial \mathbf{a}_r^{(n)}} + \\ &\beta_2 \mathbf{a}_r^{(n)} + \beta_3 y \frac{1}{1 + \exp(\mathbf{y}\mathbf{A}_r^{(1)})} \theta \end{aligned} \tag{3}$$

We refer the reader to [16, 21] for the detailed derivation of the gradients.

For large datasets, the calculation of the derivatives simultaneously for all modes is computationally expensive. Thus, `SGranite` uses an SGD approach to avoid storing the entire tensor in memory. For faster convergence, we adopt a variant of SGD named Adaptive Moment Estimation (Adam) to adaptively update the learning rate [23]. Our preliminary experiments on a single machine showed that SGD with Adam converged faster and more accurately than using a fixed learning rate.

Algorithm 1 SGD updating process

1: **for** $l = 1 : L$ **do**
2: Randomly select n samples
3: Calculate the gradients for samples using Equation 3
4: Compute the decaying averages of past and past squared gradients
5: Take a step using averaged gradients
6: **end for**

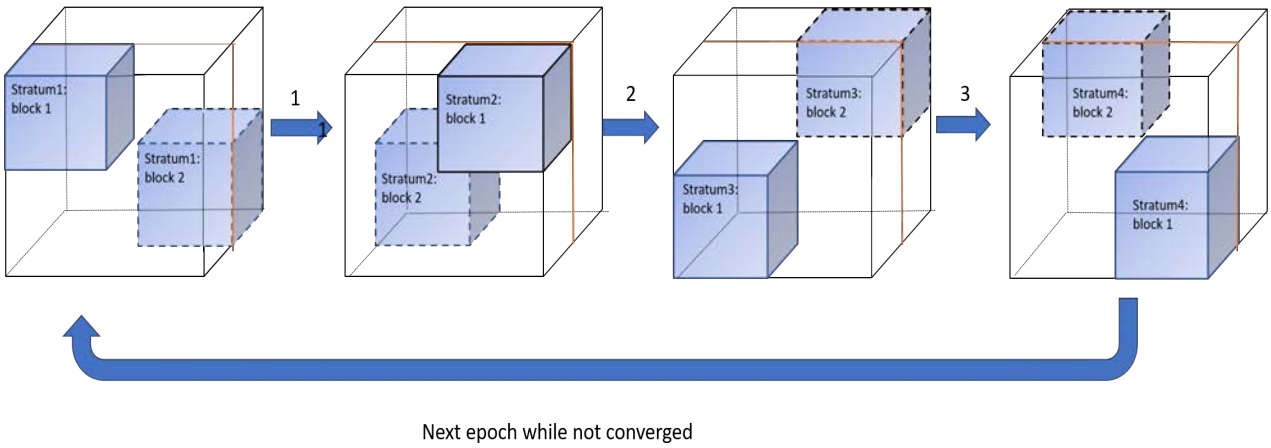

Figure 2: A graphical example of our SGranite: Suppose there are 2 workers, we will have 8 blocks and 4 strata after partition. We run this process iteratively until convergence. In each epoch, start from strata one, each worker runs SGD for its own assigned block in parallel. Check the convergence until all strata are iterated. We repeat above algorithm again if the stopping criteria is not satisfied. All intermediate results are saved as Resilient Distributed Datasets (RDD) collections and cached in memory.

3.4 Parallel Algorithm using Spark

Although SGD scales well to sparse data, we would like to distribute the computation to achieve results faster. FlexiFact proposed distributing the computation by dividing the tensor such that no two blocks share any elements (along with any dimension) [6]. Thus, the SGD algorithm can be run in parallel on each block without sacrificing accuracy. We refer the reader to [6, 12] for detailed proof of convergence. SGranite uses the same approach to distribute the non-zero elements of the count tensor using this tensor partition. However, we note several main differences between our framework and Flexifact: (1) support for sparse, count data by using an appropriate objective function (KL divergence), (2) flexibility to incorporate a variety of constraints beyond sparsity and non-negativity, and (3) distributed computation using Apache Spark.

Unlike SGranite, FlexiFact uses the Hadoop Map-Reduce platform to distribute the data collection across multiple nodes. Unfortunately, a Hadoop workflow spends an exorbitant amount of time on disk operations, as it needs to read and write intermediary results on the disk. On the other hand, Apache Spark [40] has been proposed as an alternative that eliminates unnecessary disk operations for iterative algorithms. By performing the data analytic operations in-memory and in near real-time, Spark can achieve lower computation times. Thus, SGranite is developed using Spark to distribute the computation.

3.4.1 Tensor Partition. First, we define a stratum as a set of independent blocks, and we denote the number of blocks in each stratum by d. Suppose we have d available workers, in order to iterate all regions of $\mathcal{X}$, we need d^3 blocks and thus d^2 strata. For a stratum s we have d blocks $Z_i^{(s)}$ for $i = 0, 1, \cdots, n-1$. A detailed partition function for a size of $I \times J \times K$ tensor $\mathcal{X}$ is provided below:

$$\begin{aligned} b_i &= (i\lceil I/d \rceil, (i+1)\lceil I/d \rceil) \\ b_j &= (j\lceil J/d \rceil, (j+1)\lceil J/d \rceil) \\ b_k &= (k\lceil K/d \rceil, (k+1)\lceil K/d \rceil) \\ j_{s,i} &= (j+s) \\ k_{s,i} &= (j+s) \mod d \\ Z_i^{(s)} &= \mathcal{X}_{(b_i, b_{j_{s,i}}, b_{k_{s,i}})} \end{aligned} \tag{4}$$

Figure 2 provides an example of how to divide a count tensor for 2 available workers.

3.4.2 Block Parallelization. Prior to introducing how SGranite iteratively solves the optimization problem in parallel, we introduce some definitions. A full epoch is defined as when the algorithm has seen all the d^3 blocks in the tensor. Since we need d^2 strata to cover all the blocks, we need to perform d^2 inner iterations. Therefore, we refer to each stratum training as a single inner iteration. Thus, in SGranite, the computation of each stratum is performed sequentially in each epoch. But for each stratum, we run SGD on the d^2 blocks in parallel. After each inner iteration, we update the factor matrices and use them as the initialization for the next stratum. Figure 3 provides an example of training using a single stratum. Upon the completion of an epoch (all strata have been run), the factor matrices are combined from all the workers, and then re-normalized for identifiability. The normalization can be performed for a user-specified mode, otherwise it defaults to the first mode. Convergence is checked between epochs by measuring the changes in the KL divergence to see if it is below a given tolerance. The details for the parallel-version of SGranite is described in Algorithm 2.

3.4.3 Spark Implementation Details. The non-zero elements of the count tensor are stored in a list using the coordinate format and

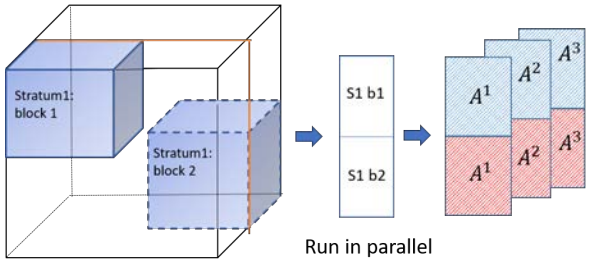

Figure 3: A graphical example of one stratum training: Given one stratum of training data and factor matrices $A^{(1)}, A^{(2)}, A^{(3)}$, we run SGD on each block in parallel. Then factor matrices $A^{(1)}, A^{(2)}, A^{(3)}$ are updated and used as the initialization for the next stratum training.

Algorithm 2 `SGranite`

Randomly initialize $[\![\boldsymbol{\lambda}; \mathbf{A}^{(1)}; \cdots; \mathbf{A}^{(N)}]\!]$
Partition the tensor and construct d^2 stratas using 4
for $m = 1 : M$ **do**
  for $l = 1 : d^2$ **do**
    Assign each block in lth strata to a worker
    Each worker runs Algorithm 1 in parallel
    Update the factors $[\![\boldsymbol{\lambda}; \mathbf{A}^{(1)}; \cdots; \mathbf{A}^{(N)}]\!]$
  end for
  Gather results from each worker
  Normalize factor matrices according to the specified mode
  if converged **then**
    break
  end if
end for
Return $[\![\boldsymbol{\lambda}; \mathbf{A}^{(1)}; \cdots; \mathbf{A}^{(N)}]\!]$

loaded as Resilient Distributed Datasets (RDDs), and then it is shared throughout our cluster as a broadcast variable. A broadcast variable in Spark is immutable, meaning that it cannot be changed later on. This may seem inconvenient but it truly suits our case since we only need to read values from the tensor to calculate gradients in each iteration.

We do not broadcast factor matrices since we need to update them in each iteration. Due to our partition function, each worker has a chance to update factors matrices with different boundaries. The best way is to partition factor matrices using Block ID. In this way, we can reduce the memory and communication cost. Specifically, we applied `map` and `aggregateByKey` functions to partition the factor matrices into blocks. The function `map` transforms each entry of the sparse tensor into an element in the RDD whose key is a block ID. Then `aggregateByKey` groups each block together and persists in memory. In each inner iteration, we use `groupWith` to build a stratum partitioned using `partitionBy` and then use `mapPartitions` to assign tasks to each node.

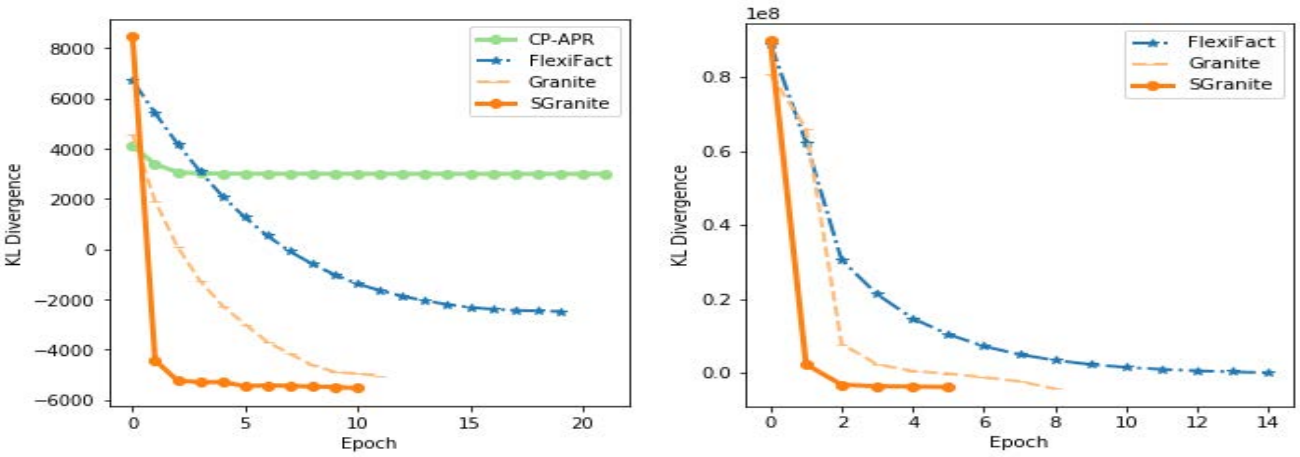
We found storing factor matrices RDDs and partitioned result in a significant acceleration, but not doing this will cause virtual memory issues in our experiments. Our experiments suggest such a design will enable us to obtain better speed-up and scalability.

4 EXPERIMENTS AND RESULTS

In this section, we first provide descriptions for two real-world health datasets. We then give an overview of baseline methods and provide qualitative and quantitative results.

4.1 Datasets

We use the following two publicly available datasets:



- Influenza: Using Google Flu Trends historical data[2] from 2003 to 2015, we generated a tensor to uncover temporal influenza patterns that are unique and similar across multiple states. For each region in the United States, we collected the number of search queries related to influenza on a weekly basis over 11 years. The resulting tensor is 12 regions × 52 weeks × 11 years. Although the data quality has been shown to be low Olson, Donald R et al. [28], this dataset is used to demonstrate the feasibility of `SGranite` on search data.
- MIMIC-III [20]: MIMIC-III is large database containing de-identified health data associated with approximately sixty thousand admissions of critical care unit patients from the Beth Israel Deaconess Medical Center collected between 2001 and 2012. For each patient, we extract medications and the International Classification of Diseases (ICD-9) diagnosis codes. ICD-9 codes are aggregated using Clinical Classification Software (CCS) categories[3], a standard preprocessing step in healthcare analysis. Similarly, medications are grouped using the Anatomical Therapeutic Chemical (ATC) Classification via the RxNorm RESTful Web API, a web service developed by the National Library of Medicine[4]. The aggregation step results in a 38159 patient × 234 diagnosis × 511 medication tensor.

4.2 Baseline Approaches

We will compare `SGranite` to both centralized and distributed CP decomposition methods.

- CP-APR [8]: The first algorithm proposed for modeling sparse count data using a Poisson distribution. There is no support for constraints, and the updates are performed using multiplicative updates. The algorithm has been ported to Python by the authors of [16].
- Granite [16]: A centralized extension of CP-APR that incorporates the angular penalty, ℓ_2, and the simplex projection as regularization terms. The authors shared a python implementation of Granite fit using SGD.
- FlexiFact [6]: A distributed algorithm based on the DSGD approach that factorizes a coupled tensor and matrix using a similar partition method. However, it uses least squares as an objective and only supports non-negativity and ℓ_1 constraints. For a fair comparison, we implemented the algorithm in Spark according to the paper.

[2] https://www.google.org/flutrends
[3] The mapping from ICD-9 to CCS can be found at https://www.hcup-us.ahrq.gov/toolssoftware/ccs/ccs.jsp.
[4] Details for the RxNorm RESTful Web API can be found at https://mor.nlm.nih.gov/download/rxnav/RxNormAPIREST.html.

(a) Influenza **(b) MIMIC**

Figure 4: Comparison of two distributed and two non-distributed CP models using KL divergence. SGranite converges in less epochs than the other methods. The negative KL divergence arises from the fact that the observed values are not probability measurements.

4.3 Implementation and Hardware Details

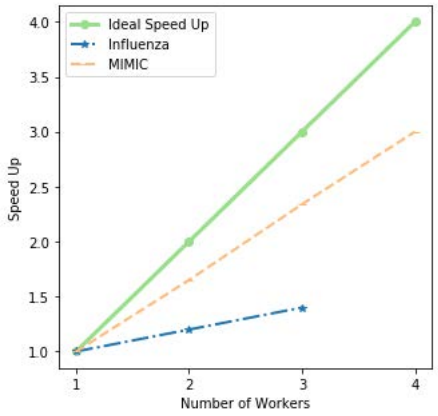
SGranite is implemented in Python and the source code is publicly available[5]. The experiments were conducted on AWS. The cluster has one master and three worker nodes. Each node has four virtual cores and 16 GB of RAM. Results in our paper were reported using 4 workers.

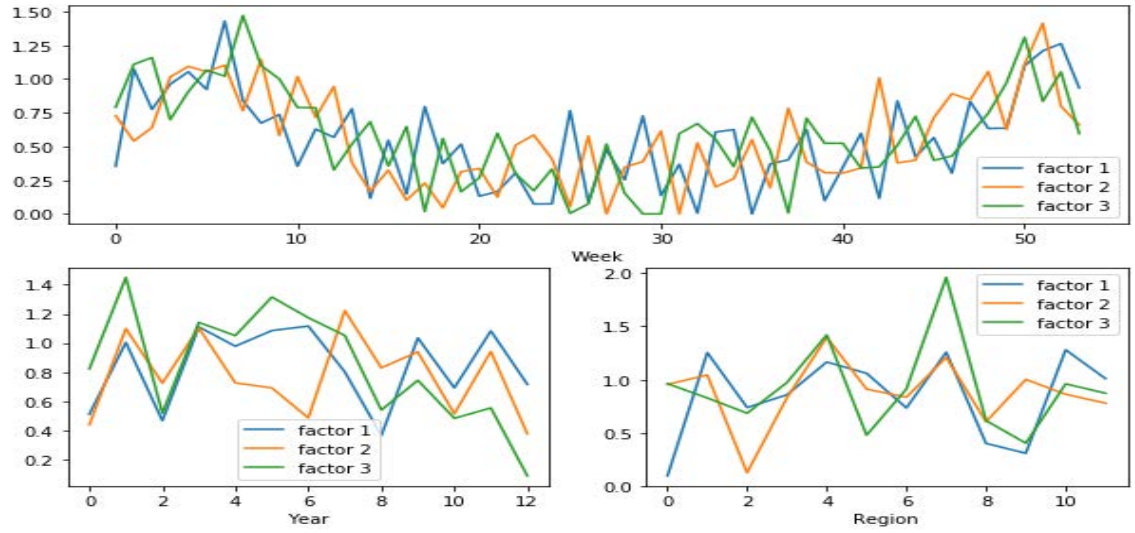
4.3.1 Hyperparameter tuning. The logistic regularization penalty β_3, simplex projection β_2 and the angular penalty β_1 were set as 0.06, 0, and 0.02, respectfully. θ_n for angular penalty for each mode, the learning rate, and batch sizes were selected as 0.9, 0.0001, and 200 respectively. All hyperparameters were chosen based on a grid search over values.

4.4 Results

4.4.1 Scalability and Accuracy. First, we assess the quality of the approximation (measured by KL divergence) for SGranite and the other baseline methods. Figure 4 shows the KL divergence as the function of the number of epochs on both datasets. For the centralized algorithms (CP-APR and Granite), each epoch corresponds to a full iteration. The plots demonstrate that SGranite converges at least 4× faster than FlexiFact and also faster than the centralized algorithms. Moreover, the quality of the approximation is better than any of the existing methods. This suggests that SGD-based methods may help escape undesirable local minima (compared to CP-APR). The figure also highlights the importance of appropriately modeling the data distribution as opposed to using the least-squares loss (FlexiFact) may not yield the best approximation.

Next, we evaluate the scalability of our algorithm with respect to the number of workers. We calculate the speed-up as the ratio between the total execution time and the sequential execution time. Figure 5 demonstrates the speed-up of SGranite with respect to the number of workers. As can be seen in the figure, the speed up for the MIMIC tensor is very close to the ideal speed-up, as it is relatively large. However, there is a limited improvement on the Influenza tensor, a small dataset. This is due to the communication cost that is incurred in coordinating the different nodes. We note that because SGranite caches the updated factor matrices in memory to minimize disk accesses between consecutive iterations, it is able to scale to a large dataset and a large number of workers. Since this speed-up would not be possible on a system like Hadoop, we do not provide a comparison with FlexiFact.





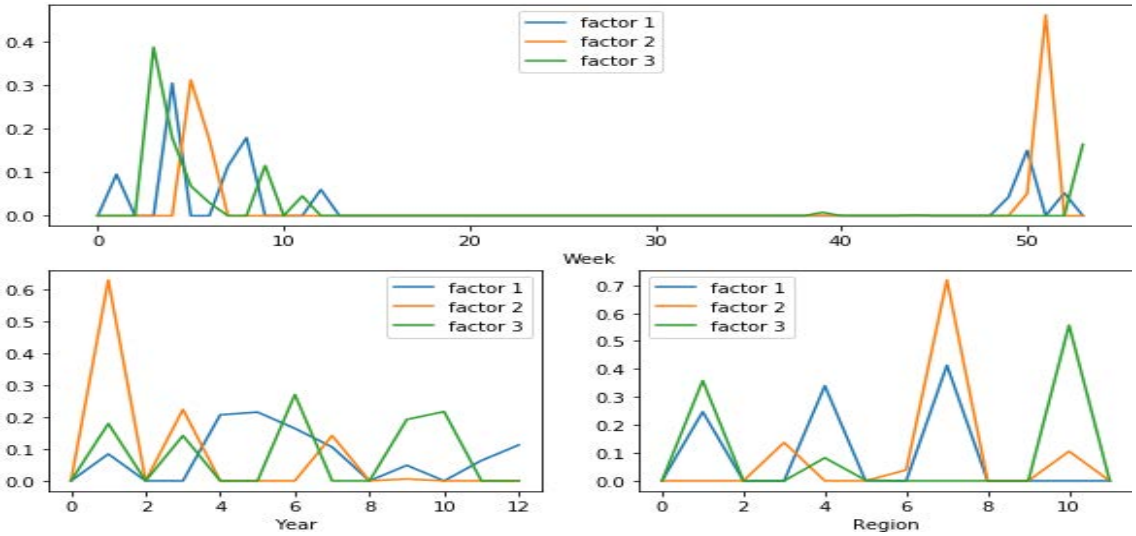


Figure 5: The speed-up curve for both datasets. It shows analysis of large datasets will gain an obvious speed up by using SGranite.

4.4.2 Qualitative and Quantitative Assessment of the Constraints. To examine the impact of the constraints, we first compare the results from SGranite on the influenza dataset both with and without the angular and simplex regularization terms. Figure 6a shows the

[5]https://github.com/hehuannb/SGranite-WWW

(a) No angular penalty and simplex projection ($\beta_1 = \beta_2 = 0$)

(b) Angular penalty and simplex projection constraints

Figure 6: A comparison of the learned latent factors with and without constraints using $R = 3$. Year from 2003 to 2015

latent factors learned without the regularization terms, and Figure 6b shows the latent factors learned with the regularization terms. From these plots, we observe that the learned factors without regularization are highly correlated and can be difficult to distinguish from one another. In Figure 6a, it is hard to discern any noticeable pattern across the weeks and the different regions. In comparison, Figure 6b demonstrates the potential of incorporating both diversity and sparsity. We can observe that factor 2 predominantly captures the peak influenza season that occurs both towards the end of December and in mid-February in region 7, whereas factor 3 is slightly delayed and captures the influenza trend in regions 1 and 10. Furthermore, all three factors capture the peak in influenza season that occurs in late December and early February through March.

Next, we quantitatively assessed the impact of the logistic regression and angular penalty on the MIMIC-III dataset. To evaluate the discriminative power and distinctiveness of the learned factors, we used the in-hospital mortality cohort similar to that proposed in [21]. We used 37,000 patients, including all 5,014 patients who died during admission. We split our dataset into 80% training and 20% testing. We measured the discrimination on the test set using the area under the receiver operating characteristic curve (AUC). Distinctiveness is measured using the average overlap or the degree of overlapping between latent factors. It is defined as the average of cosine similarities between all latent factor pairs:

$$\text{Avg Overlap} = \frac{\sum_{r_1}^{R} \sum_{r_2 > r_1}^{R} \cos(a_{r_1}^{(2)}, a_{r_2}^{(2)}) + \cos(a_{r_1}^{(3)}, a_{r_2}^{(3)})}{R(R-1)}$$

Table 3 summarizes the AUC, total computation time (or running time), and the average overlap. We observe that SGranite can not only accelerate the tensor decomposition but also provides better prediction than other baseline methods. Moreover, the average overlap is smaller than Granite even without the angular constraints. This suggests that the partition function may also have some beneficial impact in terms of reducing overlapping factors. Moreover, incorporating the angular constraints further helps the discriminative ability of the model. This suggests that adding diversity constraints to yield less correlated latent features may also help the resulting predictive model. Therefore, SGranite supports a variety of flexible constraints and yields improved predictive performance.

Model	AUC	Time	Avg Overlap
CP-APR [8]	0.63	> 1 hour	0.3
FlexiFact [6]	0.65	35 mins	0.37
Granite [16]	0.67	> 1 hour	0.3
SGranite ($\beta_1 = 0$)	0.68	**20 mins**	0.1
SGranite ($\beta_1 > 0$)	**0.71**	25 mins	**0.07**

Table 3: Table of AUC, running time, and average overlapping using different methods. The highest AUC value means extracted phenotypes have stronger discrimination. The lowest running time indicates our distributed method can significantly accelerate the computation time. Compared to CP-APR and FlexiFact, adding angular penalty improved the distinction significantly.

4.4.3 Case Study 1: Flu Patterns. We provide a further qualitative assessment of our learned latent patterns from the influenza dataset. First, we comment on the ability to capture the overall flu season trends. Although flu season can vary across region to region, the flu season is typically between October through May (week 43 to week 22) [1]. We observe this phenomenon even with and without angular penalty constraints as illustrated in Figure 6. The variance in region and slight shifts in the week are further evident when angular penalty and simplex projection constraints are present (Figure 6b). We can see that some of the regions are present only in 1 of the factors. Moreover, slight shifts along the week are observed (top chart), depending on which latent factor with the higher elements occurring between weeks 48 and 13. This provides further confirmation that each region will have slightly different times when influenza will be more prominent.

We also assessed the learned flu patterns with FlexiFact, the other distributed CP algorithm that supports non-negativity and sparsity. Figure 7 presents the learned latent factors using FlexiFact. We observe that the peak level regions that are discovered using SGranite are more consistent with the CDC influenza positive test results, shown in Figure 8. The peaks that are discovered by FlexiFact are inconsistent with the observed CDC reports. FlexiFact factors suggest two different peaks, one between weeks 8-10 and one 18-20, whereas the CDC reports note a peak around 7-9 and by week 20, it has mostly died down. Moreover, we observe that the FlexiFact latent factors are more difficult to interpret as the region and year factors are fairly correlated. We also compared with the learned factors from a previous study [13] and found our learned patterns were more consistent with the observed results. This suggests that the incorporation of constraints not only improves interpretability but also provides robustness to noise.

4.4.4 Case Study 2: Phenotypes. We conducted a second case study to examine SGranite's ability to extract discriminative and distinct clinical characteristics from the MIMIC III dataset. The identification of clinical phenotypes from EHR data can help advance our understanding of disease risk and drug response as well as support the practice of precision medicine on a national scale [33, 38].

For clinicians, diversity is important to discover rare phenotypes in a patient population. Moreover, diverse phenotypes are likely easier to implement, as a clinician may find it difficult to rank-order or apply phenotypes that have substantial overlap. In addition, discriminative phenotypes are better predictors of mortality (shown in Table 3) and thus can be used to assist the decision-making process.

Table 4 presents the learned phenotypes that are important where importance is determined based on the magnitude of the phenotypes (or λ_r). Thus, these are the three sets of patient characteristics at which diagnosis and medication are dominant. First, we observe that the learned phenotypes have limited number of overlapping elements. In table 4, the most significant phenotype (λ_1) captures acute complications with heart diseases which can be riskier. In particular, acute respiratory distress syndrome has a mortality rate of 30-50% and is associated with long hospital stays [27]. The third phenotype (λ_3) captures more chronic diseases such as heart valve disorder, leukemias, and osteoarthritis. In addition, we observe that most medication codes in Table 4 are associated with diagnosis codes above. For example, potassiuman chloride and practolol are commonly used to lower blood pressure in hypertensives [10, 37]. An ACE inhibitor is used primarily for the treatment of hypertension and congestive heart failure [26]. And magnesium carbonate has shown to be effective for chronic kidney diseases and intracranial injury [5, 35].

5 CONCLUSION

In this paper, we presented a distributed, diverse, non-negative tensor decomposition framework that supports a variety of constraints including an angular penalty to encourage diversity and a simplex projection to encourage sparsity while scaling to large tensors. By imposing such regularization terms, SGranite successfully extracts meaningful latent factors in two real-world use cases. Moreover, by using Spark, SGranite successfully reduces processing time by dramatically reducing the workload and high communication cost. In addition, SGranite improves binary prediction tasks by incorporating logistic supervision into the fitting process. In the future, we plan to develop a distributed algorithm that can handle linear regression problem and also an extension that can use outside data sources as the guidance information.

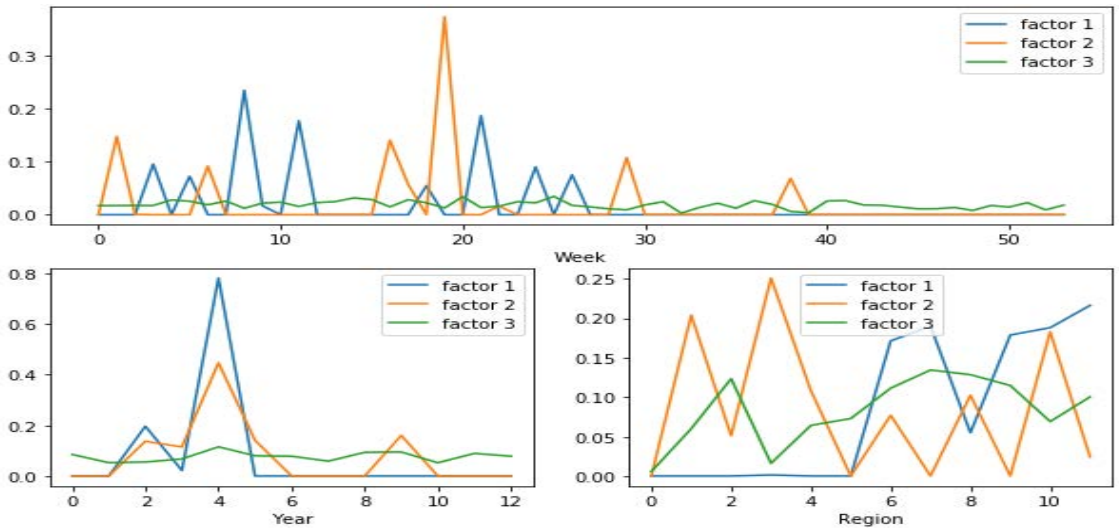

Figure 7: Latent factors obtained using Flexifact. Year from 2003 to 2015

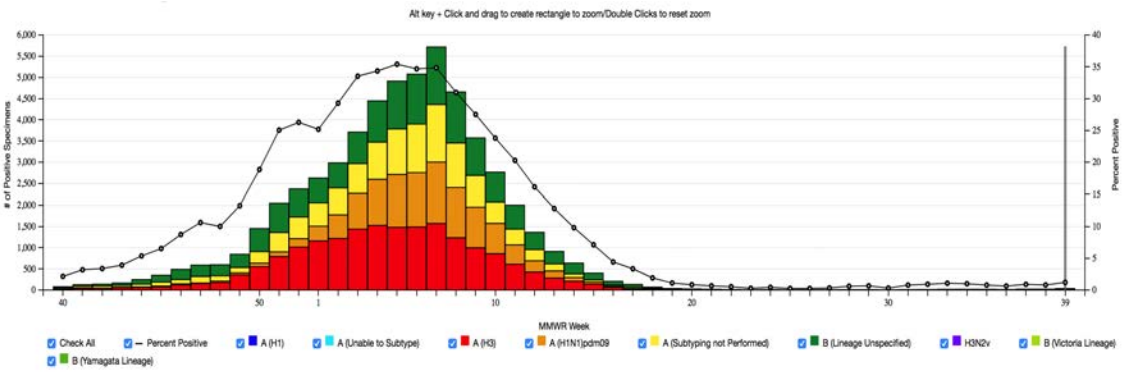

Figure 8: This figure is downloaded from CDC, it shows the actual influenza positive tests reported to CDC in 2010-2011, week ending Oct 01, 2001.

Phenotype 1: $\lambda_1 = 87$	**Phenotype 2:** $\lambda_1 = 79$	**Phenotype 3:** $\lambda_3 = 77$
Respiratory distress syndrome	Coronary atherosclerosis & other heart disease	Heart valve disorders
Acute cerebrovascular disease	Intracranial injury	Intracranial injury
Coronary atherosclerosis & other heart disease	Congestive heart failure; nonhypertensive	Leukemias
Hypertension w/ complications & secondary hypertension	Acute and unspecified renal	Osteoarthritis
Potassium chloride	Oxyphenisatine	Practolol
Sodium chloride	Adrenergics, inhalants	Magnesium carbonate
Omeprazole	ACE inhibitors	Anilides
Potassium chloride	Nitroprusside	Sodium chloride

Table 4: Table of top 3 phenotypes with high λ. Upper four rows are diagnosis codes and four rows below are medication codes correspondingly

ABSTRACT

Crowdsourced knowledge bases like Wikidata suffer from low-quality edits and vandalism, employing machine learning-based approaches to detect both kinds of damage. We reveal that state-of-the-art detection approaches discriminate anonymous and new users: benign edits from these users receive much higher vandalism scores than benign edits from older ones, causing newcomers to abandon the project prematurely. We address this problem for the first time by analyzing and measuring the sources of bias, and by developing a new vandalism detection model that avoids them. Our model FAIR-S reduces the bias ratio of the state-of-the-art vandalism detector WDVD from 310.7 to only 11.9 while maintaining high predictive performance at 0.963 ROC_{AUC} and 0.316 PR_{AUC}.

1 INTRODUCTION

Knowledge bases play an important role in modern information systems. For instance, web search engines use them to enrich search results, conversational agents to answer factual questions, and fake news detectors for fact checking. Collecting knowledge at scale still heavily relies on crowdsourcing: Google acquired the open Freebase project to bootstrap its proprietary "Knowledge Graph" until Freebase was shut down and succeeded by Wikidata, the free knowledge base of Wikimedia. Other prominent open knowledge bases like Yago and DBpedia also depend on crowdsourcing by extracting knowledge from Wikipedia. As crowdsourcing knowledge has a long history, so does the fight against damage caused by vandals and other users, which may propagate to information systems using the knowledge base, potentially reaching a wide audience.

From its humble beginnings with manual review and rule-based detection bots, damage control at Wikipedia has grown into an intricate sociotechnical system, where man and machine work together to review edits and to maintain the integrity of its articles. While Wikipedia's damage control system grew alongside the encyclopedia for more than a decade, Wikidata gained momentum at a much faster pace: Transferring Wikipedia's system to Wikidata without a second thought (see Figure 1 for an illustration), adapting its procedures and the machine learning technologies employed [27, 49], has given rise to discrimination.

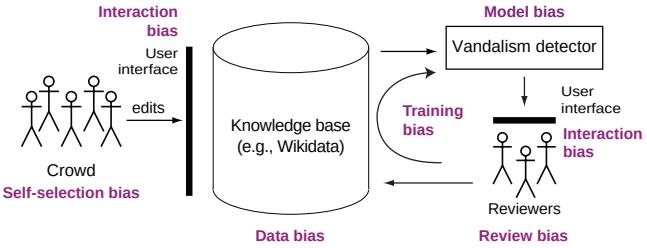

Figure 1: Wikidata's damage control system along potential sources of bias, which may accumulate in a vicious cycle.

In this paper, we reveal for the first time that state-of-the-art vandalism detectors employed at Wikidata are heavily biased against certain groups of contributors. For example, *benign* edits of new users receive vandalism scores over 300 times higher than *benign* edits of older user accounts. Such a widespread discrimination of certain user groups (especially that of anonymous editors) undermines the founding principles on which Wikimedia's projects are built:[1] maintaining a neutral point of view, the ability of anyone to edit articles, and the creation of a welcoming environment. The discrimination of anonymous users by registered users has long been recognized and the problem has been tackled through continuous community outreach.[2] But when discrimination gets encoded into automatic decision-making at Wikimedia, this aggravates the problem. For example, it has been previously found that new contributors whose edits are automatically reverted are much more likely to withdraw from the project [21, 22, 50].

Besides raising awareness, we carefully analyze different sources of bias in Wikidata's damage control system. Based on these insights, we develop two new machine learning models and demonstrate that bias can be significantly reduced compared to the state-of-the-art. Our model FAIR-E uses graph embeddings to check the content's correctness without relying on biased user features. Our model FAIR-S systematically selects the best-performing hand-engineered features under the constraint that no user features are used. Furthermore, we experiment with different transformations of the state-of-the-art vandalism detector WDVD: post-processing scores, reweighting training samples, and combining approaches via ensembles. We evaluate our approaches on a subset of the standardized, large-scale Wikidata Vandalism Detection Corpus 2016 [27], comparing our results to others from the literature.

In what follows, after discussing related work in Section 2, we analyze in Section 3 the sources of bias for Wikidata's damage control system. Section 4 introduces our new detection models designed to mitigate biases. Sections 5 and 6 detail the evaluation data and our comparative evaluation, respectively, and Section 7 discusses limitations and practical implications.

2 RELATED WORK

Despite the long-standing insight that machine learning is prone to incur bias, the body of work addressing this problem is surprisingly small. Only recently Baeza-Yates [2] compiled an overview of biases found on the web that may induce discrimination, including an analysis of Wikipedia's editor elite and its gender gap. Romei and Ruggieri [48], Zliobaite [67], and Pedreschi et al. [45] collect measures to quantify bias in machine learning models which we employ in our analysis. Otherwise, only a handful of papers explicitly attempt to mitigate biases in machine learning applications: Zhao et al. [65] and Bolukbasi et al. [5] tackle gender bias, Wang et al. [57], Wilkie and Azzopardi [59] and Yang and Stoyanovich [61] tackle biases in information retrieval systems, Torralba and Efros [53] investigate bias in image classification, and Dixon et al. [13] propose methods to measure and mitigate bias in text classification. Algorithmic attempts at bias mitigation include naive Bayes [7], SVMs [62], decision trees [30], and random forests [47]. The trade-off between accuracy and fairness is explored by Berk et al. [4], Kleinberg et al. [33], Corbett-Davies et al. [10], and Chouldechova [8], while performance measures for imbalanced datasets such as PR_{AUC} and ROC_{AUC} are not considered. Berk et al. [4], Hardt et al. [23], and Dwork et al. [16] discuss different notions of fairness including equality of opportunity and statistical parity. More closely related to our work, Halfaker et al. [21, 22] and Schneider et al. [50] find that newcomer retention at Wikimedia projects is severely affected by overzealous reversion of their edits. Passing part of the blame to automatic vandalism detectors, no remedies are proposed.

Vandalism at Wikipedia is defined as "editing deliberately intended to obstruct or defeat the project's purpose."[3] Though this definition excludes damage caused unintentionally, the task of a vandalism detector, human or other, is to identify both kinds of damage so they can be dealt with according to severity. The literature and practitioners often speak of vandalism detection while actually operationalizing damage detection in general [31]; current vandalism detectors are quite incapable of discerning user intent, which often even challenges human reviewers. Vandalism detection was first proposed for Wikipedia, employing text mining and user reputation features to detect damaging edits to articles [46]. More than a dozen approaches have been proposed since (e.g., [1, 29, 54, 56]), giving rise to a rich set of features, many of which have been transferred into the models currently at work. By comparison, vandalism detection models for Wikidata are still in their infancy [25, 27, 43, 49, 52], as evidenced by the facts that their feature sets are almost entirely the same as those employed for Wikipedia, and that hardly any feature quantifies Wikidata's actual content, i.e., the knowledge encoded as subject-predicate-object triples. Our approach omits the biased user reputation features and introduces novel graph embeddings, drawing from, and advancing related work on fact checking and link prediction.

Fact checking pertains to checking the correctness of a fact and can be divided into approaches using internal and external knowledge. Regarding the former, Ciampaglia et al. [9] compute the shortest path between a fact's subject and its object, considering different weighted (transitive) predicates. Shi and Weninger [51] determine paths between subject and object that help to distinguish correct from incorrect predicates between them, employing a one-hot encoding and logistic regression. We experimented with path features, too, but found a simpler graph embedding to be superior for debiasing. Nishioka and Scherp [43] analyze the evolution of knowledge graphs to verify changes, employing basic features like the age of entities and predicates and the in- and out-degree of entities. Approaches using external knowledge include that of Wu et al. [60], who check the correctness of facts from news articles by generating SQL queries to find contradictory information in a relational database. Lehmann et al. [37] check the correctness of a given subject-predicate-object triple via web search, taking into account the trustworthiness of websites found.

Link prediction is the task of predicting missing predicates between pairs of subjects and objects. Nickel et al. [41] survey corresponding approaches and distinguish explicit and latent features. The former category includes path rankings used to complete existing knowledge bases [36, 40, 51] and validation knowledge extracted from web sources [14, 15, 28]. Gardner and Mitchell [20] simplified and sped up path ranking. We experimented with their best features, but found a simpler graph embedding to be superior for debiasing. Other approaches do not try to complete a knowledge base but classify the local completeness of entities within [11, 18]. Link prediction approaches with latent features are based on matrix factorization [42], neural embeddings [14], and translational embeddings [6, 38, 55, 58]. Special kinds of link prediction include type prediction of the type of an entity [19, 39, 44] and predicting obligatory attributes of entities of a given type [35].

Altogether, fact checking and link prediction are complementary in that the former's goal is to identify incorrect knowledge, whereas the latter's goal is to introduce correct knowledge that is missing. Both are often evaluated on artificial data, whereas we apply them to vandalism detection at scale on real-world data from Wikidata. Moreover, both tasks typically assume a static knowledge base, while vandalism detection presumes a constant stream of edits. We adapt the methods borrowed from both tasks accordingly.

3 BIAS ANALYSIS

Wiktionary defines 'discrimination' as "*treatment* of an individual or group to their disadvantage" and 'bias' as "*inclination* towards something; predisposition, partiality, prejudice [...]." If a given system acts discriminatorily, we call it biased, and we ask which of its components cause its bias and how it can be controlled to render its behavior non-discriminatory. In this section, we carry out the first bias analysis of Wikidata's damage control system.

Several potential sources of bias can be identified (see Figure 1): *model bias* refers to the vandalism detection model used, and may result from its selection of features and its learning algorithm. The user interface of monitoring tools may introduce *interaction bias* by directing reviewer attention to high-scoring edits first, enclosing them in a "filter bubble" and reinforcing inherent *reviewer bias*, i.e., the prejudices that humans sometimes hold. Analyzing the reviewers' decisions, models are adjusted directly, by creating rules and features, or indirectly, by using their decisions as labeled training data, causing *training bias* and *data bias*. Furthermore, biased reviewer decisions may lead to *self-selection bias* among Wikidata's volunteers, ousting non-conformists.

[3] https://en.wikipedia.org/wiki/Wikipedia:Vandalism

The discriminatory nature of *Wikipedia's* damage control system has been previously shown [21, 22, 50]: the rise of (semi-)automatic reviewing tools caused more newcomer contributions to be considered damaging, severely affecting retention. Although policies have been adjusted to prevent such discrimination, the vandalism detection models have not been redesigned. Our analysis shows that, at least for *Wikidata*, this is insufficient. In what follows, we go beyond previous analyses by shedding light on the main sources of bias, the detection models and the human reviewers, and by taking into account anonymous users, the antecedents of newcomers.

3.1 Measuring Bias

Every edit of an item at Wikidata results in a new revision i of that item, and the task of a vandalism detector c is to compute a vandalism score for each new revision as soon as it arrives, so that $c(i) \approx Pr(i = \text{vandalism} \mid x_i)$, where x_i is i's feature vector. The scores are then used for two modes of operation. In fully automatic mode, the revisions exceeding a score threshold are automatically reverted without any human intervention. In semi-automatic mode, revisions are ranked by vandalism score and manually reviewed.

To measure the bias of a detector producing continuous scores, roughly following Kleinberg et al. [33] and Zemel et al. [63], we compare the average scores of *benign* edits by two disjoint user groups. The more the difference deviates from 0 or the ratio deviates from 1, the more biased the classifier is. By convention, we call one group "protected" (i.e., to be protected from discrimination). Let I denote the set of all revisions, then given the ground truth whether a revision i is vandalism or benign, we get the following contingency table, where $A, \ldots, H$ denote the corresponding subsets of I, from which we derive the difference (Diff.) and the Ratio between the protected group and the remainder as bias measures:

		Truth benign	Truth vand.	∪
Protected	yes	A	B	C
	no	D	E	F
∪		G	H	I

$$\text{Diff.} = \frac{1}{|A|}\sum_{i\in A} c(i) - \frac{1}{|D|}\sum_{i\in D} c(i)$$

$$\text{Ratio} = \frac{1}{|A|}\sum_{i\in A} c(i) \;/\; \frac{1}{|D|}\sum_{i\in D} c(i)$$

Table 1a shows examples, comparing the vandalism score of the Wikidata Vandalism Detector (WDVD) for the creation of a given subject-predicate-object triple by a registered user with that of creating the same triple anonymously. Regarding the first example, at a score difference of 0.0907, an anonymous user receives a score that is 900.2 times higher than that of a registered user.

To measure the bias of semi-automatic detection, which produces binary scores, we utilize the odds ratio, which is invariant to changes in class distribution in the dataset. Let $p_1 = \sum_{i\in A} c(i)/|A|$ be the proportion of benign revisions from protected users that are considered vandalism and let $p_2 = \sum_{i\in D} c(i)/|D|$ be the proportion of benign revisions from other users that are considered vandalism:

$$\text{Odds ratio} = \frac{p_1/(1-p_1)}{p_2/(1-p_2)}.$$

Further measures have been proposed, including the closely related risk difference and risk ratio [7, 48, 67], but also measures based on individuals instead of groups [16], the latter demanding that similar edits receive similar scores. For lack of a task-specific similarity measure, we resort to the aforementioned measures.

3.2 Biases of Vandalism Models

There are two kinds of vandalism detectors for Wikidata: (1) the rule-based Wikidata Abuse Filter (FILTER) [27], which tags revisions as per user-defined rules,[1] and (2) machine learning-based detectors. The latter include the state-of-the-art approach WDVD [27] and variants thereof developed during the WSDM Cup 2017 [24], the "Objective Revision Evaluation Service" (ORES) [49] deployed at Wikimedia, and our new approach FAIR proposed in this paper.[2] The WDVD approach outperformed all other approaches in the recent WSDM Cup 2017 in terms of PR_{AUC} [25]. Table 1b shows their distribution of features across feature categories. Apparently, all previous approaches rely on contextual, and especially user-related features, such as account age and whether an edit was made by a registered or an anonymous user. Moreover, hardly any content features capture Wikidata's statements, but only textual portions of an item. This already hints at a high potential for bias.

Analyzing the vandalism scores of all approaches applied on the Wikidata Vandalism Corpus 2016 [25] reveals that all except FAIR exhibit significant biases. Table 1c exemplifies the average vandalism scores obtained for anonymous and registered users from which we compute the bias measures found in Table 1d (top row pair). Similarly, the bias against newcomers and country of origin is computed (remainder of the table). Being anonymous or a newbie raises one's average vandalism score of benign edits by a factor of up to 311 under WDVD, and by a factor of 40-133 under ORES and FILTER. With FAIR, we reduce the bias ratio to 11.9. There is comparably small bias against country of origin, and even a bias in favor of Japanese users, which can be explained by their low vandalism prevalence [31]. These values must be taken with a grain of salt, since geolocation is available only for anonymous users, who are a priori discriminated because of this fact. In what follows, we hence focus on mitigating the bias against anonymous users.

Upon close inspection, the many user-related features employed by WDVD, ORES, and FILTER turned out to be the causes for their biases. For example, the feature `isRegisteredUser`, that is employed by both WDVD and ORES, is a simple feature with high predictive performance. But it causes *benign* edits by anonymous users to have much higher scores than *benign* edits by registered users: 9.00% of edits by anonymous users constitute vandalism and only 0.03% of edits by registered users (in the training and validation set of WDVC-2016-Links). The feature is not able to discriminate *benign* and *vandalizing* edits based on the actual content of an edit, thus assigning roughly 300 times higher scores to *all* edits by anonymous users. Similarly, ORES includes the age of a user (`userAge`), and WDVD includes the numbers of revisions and items edited by a user (`userFrequency`, `cumUserUniqueItems`), as well as geolocation of IP addresses (e.g., `userCountry`, `userCity`). Regarding FILTER's rules, Table 1e lists the top-most rules fired which exploit user information: "new user changing sth."; "new user removing sth."; and "possible vandalism." Compared to the top ones not doing so, these rules act highly biased against anonymous users. Edits to which these rules apply receive an average vandalism score of 28.8%, which is a high number given the large class imbalance; the majority of wrong decisions affect anonymous users (69.1%), again

[1] We convert tags to continuous scores by computing the empirical vandalism probability of all past revisions with a given tag.
[2] For brevity, we report only on the best variant, FAIR-S, in this bias analysis.

Table 1: Bias analyis: (a) Examples for model bias. (b) Overview of features by model. (c) Average vandalism scores for anonymous and registered users.[4] (d) Bias measurements against protected users as score difference (top rows) and score ratio (bottom rows). (e) Rules of the Wikidata Abuse Filter (FILTER) and their biases.[5] (f) Biases by Wikidata reviewers. Among 1,100 benign edits, 145 were incorrectly reverted by human reviewers with disproportionately many affecting anonymous editors.

a large number compared to the small percentage of overall edits by anonymous users. FILTER rules can only be created by Wikidata's (at the time of writing) about 60 administrators,[3] who are the most active users and who carry out lots of other maintenance tasks, too.

For the new approach FAIR-S, we omit all user features, thus significantly reducing its bias. The remaining bias can be explained by unsuspicious features that are (slightly) correlated with the omitted feature `isRegisteredUser`. This effect is referred to as *indirect discrimination* [45] or *redlining* [7]. In general, it is undesirable to make all groups have exactly the same average scores as small differences might be justified by hidden confounding variables and it would be an overreaction often called *affirmative action* [48, 66].

3.3 Biases of Wikidata Reviewers

Another potential source of bias might be the human reviewers engaged in Wikidata's semi-automatic damage control system. If a reviewer encounters a poor edit, it is reverted, and otherwise typically nothing happens. To investigate the degree to which revert decisions may be biased, we used a manually annotated dataset, compiled as part of the Wikidata Vandalism Corpus 2015 (WDVC-2015) [26]. It consists of two random samples of 1,000 edits each that were rollback reverted by Wikidata reviewers and that were not reverted, respectively. These edits were carefully annotated with respect to whether they constitute vandalism, but unlike Wikidata's reviewers, the annotator was given no knowledge about the registration status (anonymous or registered) of the editor.

Among the 2,000 edits, 1,103 are *benign* edits, 145 of which were *incorrectly* reverted. Table 1f breaks down the observed behavior of Wikidata reviewers as a contingency table of registration status over revert decision correctness. Reverting a benign edit is an incorrect decision, whereas not reverting it is correct. From the marginals of this matrix (not shown), we obtain the expected behavior under the assumption of independence. We find that revert decisions by Wikidata reviewers are heavily biased against anonymous editors, since they are disproportionately often affected by incorrectly reverted edits: 103 edits by anonymous users are *incorrectly* reverted although we would expect only 16.6 edits considering the relatively small number of 126 edits by anonymous editors. Fisher's test shows that the bias against anonymous users is statistically highly significant ($p < 0.0001$). Figure 2 shows how the reviewer bias developed over time. Choosing time intervals so that an approximately equal amount of the 1,103 benign edits fell into each interval, the odds ratio severely increased over time, suggesting that bias against anonymous users among reviewers kept growing.

Only Wikidata's administrators and a few other powerful users with the so-called rollback rights can perform rollback reverts. Even when accounting for human fallibility, it appears that, on this sample of edits, anonymous editors were discriminated. We do not suspect any malicious intent of Wikidata reviewers. Rather, the fact that many true vandalism edits originate from anonymous editors may have led them to ingest some form of prejudice whenever an anonymous edit looks odd while skipping edits by registered editors without closer inspection. However, even if more vandalism originates from anonymous editors than from registered ones, this is not a sufficient justification to treat benign anonymous editors unfairly. After all, a revert decision should be based on content alone, and not on who the content comes from.

[4] Tables c, and d were computed on the test set of the vandalism corpus WDVC-2016-Links. Vandalism scores of the models FAIR-S, WDVD, ORES, FILTER were obtained as described in Sections 4 and 6 and calibrated to approximate vandalism probabilities.

[5] Computed on the whole WDVC-2016-Links dataset.

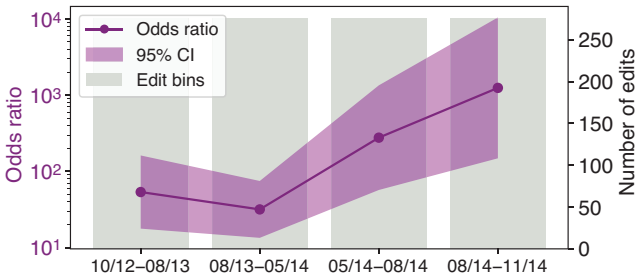

Figure 2: Reviewer bias against anonymous users as odds ratio over time, averaged over equisized edit bins.

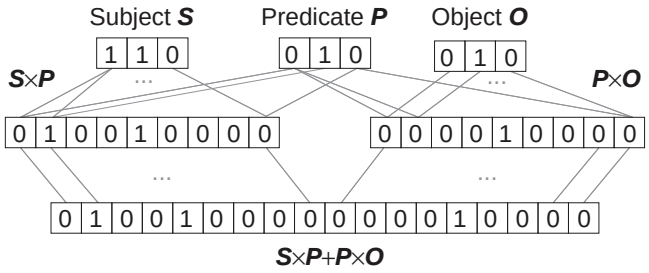

Figure 3: Example of an embedding of a subject-predicate-object triple in $n := 3$-dimensional predicate space (top), the outer products $S \times P$ and $P \times O$ (middle), and the final $2n^2 = 18$-dimensional embedding (bottom).

4 FAIR—UNBIASED VANDALISM DETECTION

Our bias analysis indicates that the main source of bias in state-of-the-art vandalism detectors are user-related features. That, together with the lack of features to characterize the actual content of Wikidata, creates a situation where bias and discrimination thrives. This section introduces FAIR, a new vandalism detector for Wikidata. We tackle the problem (1) by devising new content features based on explicit graph embeddings that protect Wikidata's primary asset, its subject-predicate-object triples between entities (FAIR-E), and, (2) by careful feature selection from the existing vandalism detectors with an eye on bias (FAIR-S).

4.1 FAIR-E: Graph Embeddings for Wikidata

Unlike for Wikipedia, where the full power of text mining can be unleashed to detect vandalism in its articles, the content of knowledge bases is much more difficult to be represented, which may explain the lack of corresponding features in Wikidata's vandalism detectors. We propose a novel graph embedding FAIR-E that results in a particularly low bias. To the best of our knowledge, this kind of graph embedding has not been used before, neither for Wikidata vandalism detection, nor elsewhere.

Editing Wikidata means editing subject-predicate-object triples. The user interface of Wikidata enforces that every edit affects exactly one triple,[6] so that representing an edit boils down to representing the edited triple. We encode the subject, predicate, and object of a triple in predicate space and capture all pairwise interactions between them (see Figure 3 for an illustration). For the subject, we encode all *outgoing* predicates as a binary vector S. The predicate is directly encoded as one-hot encoding P. For the object, we encode all *incoming* predicates as a binary vector O. The whole triple is then encoded as concatenations of pairwise combinations: $S \times P + P \times O$, where the +-operator denotes the concatenation of vectors and $\times$ the outer product, i.e., all combinations of elements. Let n be the number of predicates, then a triple vector has $2n^2$ dimensions. In Wikidata, there are about $n = 6,000$ predicates. To avoid overfitting, we restrict the set of predicates: We compute all predicates that were present in the item graph at the end of the training set and we set all other predicates in our embedding vectors to zero, thus effectively removing predicates to attributes such as strings and numbers and removing predicates that have been deleted earlier. Moreover, we restrict the representation to $n := 100$ predicates for S, P, and O, respectively. Using a suitable training dataset, we compute the top 100 predicates according to frequency for S, P, and O independently, and then proceed to computing the combined representation, yielding a 20,000-dimensional vector. As machine learning algorithm, we employ logistic regression.

To give an example how the embedding works: Suppose we want to represent the newly created triple ⟨Alejandro Cuello (Q15924626), occupation (P106), actor (Q33999)⟩. The subject is a person with predicates "date of birth" (P569), "sex or gender" (P21), and "country of citizenship" (P27), the triple predicate is "occupation" (P106), and the object has incoming predicates "occupation" (P106), "field of work" (P101), and "position held" (P39). Our model learns that the triple predicate "occupation" goes well with the incoming object predicates "occupation", "field of work" and "position held." In contrast, the triple ⟨Steve Jobs (Q19837), instance of (P31), animal (Q729)⟩ is highly unusual. Adding another "instance of" (P31) relationship to a subject with subject predicates "country of citizenship" (P27) and "sex or gender" (P21) often points to vandalism; as does adding an "instance of" relationship to an object with incoming object predicate "parent taxon" (P171).

Variants. We experimented with multiple variants of our approach, including different values for n, different interactions between subject, predicate, and object (see Section 6), and predicates to attributes. We experimented with taking the *outgoing* predicates of the object instead of the *incoming* predicates, too. However, the above encoding outperformed all other variants on the validation set in terms of predictive performance. Varying the strength of L2 regularization had little effect on predictive performance but had a large effect on bias, so we disabled regularization to minimize bias (setting scikit-learn's parameter $C = 10000$). We also experimented with the path ranking algorithm [14, 20], but the resulting model did not outperform the above model.

Limitations. If a subject-predicate-object triple uses a predicate not among the ones selected, its embedding is the zero vector, which was the case for about 15% of triples in our dataset. Our logistic regression classifier assigns the same, small vandalism probability to all these cases (determined by the intercept of logistic regression). For triples updated in a revision, we only consider the new version of the triple. Our embedding does not distinguish additions and removals of triples and we leave it for future work to incorporate such a distinction in a way that improves performance. As the set and distribution of predicates changes over time, retraining the classifier may be required from time to time.

[6] Wikidata's API allows for editing multiple triples at once, which is rather the exception. In that case, we use the main triple from Wikidata's automatically generated comment.

4.2 FAIR-S: Selecting Unbiased Features

As an alternative approach to debiasing vandalism detectors, we systematically evaluated candidate feature subsets for subject-predicate-object triples from the union of all features developed for previous detectors and call our model FAIR-S: We used the features of WDVD [27], the features of ORES [25, 49], and a few new features, including the ones from FAIR-E, while intentionally omitting user-related features and features not targeting subject-predicate-object triples between entities. Features were added to the set until predictive performance on our validation set did not improve anymore. Table 2 shows the resulting feature set, which constitutes a local optimum in the space of possible feature subsets, since removing any of the features or adding further features from our candidate set decreases performance in terms of ROC_{AUC}. Seven features from Heindorf et al. [27], three features from Sarabadani et al. [49], and four new features were selected. We use a random forest with 32 trees and a maximal depth of 16 for our experiments.[7] In a pilot study, we experimented with other algorithms including logistic regression, neural networks, and gradient boosted decision trees, carefully tuning their hyperparameters, yet, corroborating previous findings, random forests outperformed them all in this setting [27, 49]. Below, the features are described in more detail.

Subject. We characterize a subject by how many different users have edited it (`subjectLogCumUniqueUsers`), how many edits have been performed on it (`subjectLogFrequency`), how many labels and aliases it has (`subjectNumberOfLabels`, `subjectNumberOfAliases`), the number of words in its English label (`subjectLabelWordLength`), and how often the predicate has been edited for this subject (`subjectPredicateCumFrequency`). These features signal how popular a subject is (`subjectLogCumUniqueUsers`), how large a subject is (`subjectNumberOfLabels`), and how complex a subject is (`subjectLabelWordLength`). The number of words serves as a proxy for the complexity of an item. Items with one-word labels might be about organizations or places, items with two words are typically persons, and items with many words are complex topics. Other forms of encoding from our candidate features did not yield any improvement. In general, we found that subject features are prone to overfitting, since there are about 2.5 million different subjects and most subjects have never been vandalized.

Predicate. We represent each predicate by the number of times it appears in the training set (`predicateFrequency`). Other forms of encoding from our candidate feature set did not yield improvements.

Object. In contrast to subject features, object features are less prone to overfitting since objects are reused many times. We capture the popularity of an object by the number of revisions it appears in (`objectFrequency`) and the number of times an object has been edited in combination with a given predicate (`objectPredicateCumFrequency`). Moreover, one of the features of FAIR-E was included: We compute the set of all incoming predicates of an object in the knowledge graph and take this set as a feature (`objectPredicateEmbedFrequency`), the idea being that the incoming predicates of an object capture in what context and for what purposes it should be used. To avoid overfitting, we restrict this set to the top 100 most frequent predicates on the training set.

[7] We use a fixed seed for feature selection. Due to some low-performing and redundant features, the feature set is not stable for different seeds. But even slightly different feature sets yield similar predictive performance and bias values.

Table 2: Features of our vandalism detector FAIR-S and their performance scores and biases on our test dataset, computed with a random forest with 32 trees and maximal depth 16.

Feature Group / Feature	Reference	Performance ROC_{AUC}	Performance PR_{AUC}	Bias Diff	Bias Ratio
Subject	—	0.907	0.071	0.01199	4.05
`subjectLogCumUniqueUsers`	[27]	0.901	0.052	0.01005	3.51
`subjectLogFrequency`	[27]	0.880	0.042	0.00795	2.95
`subjectNumberOfLabels`	[49]	0.859	0.031	0.00321	1.76
`subjectNumberOfAliases`	[49]	0.761	0.026	0.00198	1.47
`subjectLabelWordLength`	—	0.721	0.008	0.00165	1.38
`subjectPredicateCumFrequency`	—	0.687	0.008	0.00096	1.22
Predicate	—	0.729	0.011	0.00196	1.46
`predicateFrequency`	[27]	0.729	0.011	0.00196	1.46
Object	—	0.729	0.026	0.00234	1.55
`objectPredicateEmbedFrequency`	—	0.682	0.013	0.00188	1.44
`objectFrequency`	[27]	0.650	0.010	0.00107	1.25
`objectPredicateCumFrequency`	—	0.613	0.007	0.00014	1.03
Edit Features	—	0.889	0.062	0.00926	3.32
`editProportionOfTriplesAdded`	[49]	0.866	0.022	0.00418	2.00
`editSubactionFrequency`	[27]	0.851	0.020	0.00381	1.91
`editPrevActionFrequency`	[27]	0.629	0.024	0.00297	1.70
`editActionFrequency`	[27]	0.575	0.005	0.00052	1.12

Edit. We characterize the change of an edit with four features: the edit operation, such as create, update, or remove (`editActionFrequency`, `editSubactionFrequency`), the previous action performed on the same item (`editPrevActionFrequency`), and the size of the edit operation relative to the current size of the item (`editProportionOfTriplesAdded`).

Variants. Both for the subject and the object, we experimented with using their *super types* according to Wikidata's *instance of* hierarchy as a feature. Neither of these features improved predictive performance nor bias. For the object, similar information is already captured with our predicate embedding (e.g., in `objectPredicateEmbedFrequency`). Also, a bag-of-words model of the subject's and the object's textual labels and descriptions did not help.

5 EVALUATION DATA

This section describes the Wikidata datasets used in our evaluation, how they have been pre-processed, split into training, validation, and test sets, as well as their characteristics. Moreover, we investigate the proportion of model bias due to data bias.

5.1 Wikidata Revision History and Graph

We derive our dataset from the Wikidata Vandalism Corpus 2016 (WDVC-2016) [25]. This dataset ranges from October 2012 to June 2016 and contains all human edits along with labels whether the edit is considered vandalism. The labels were automatically obtained by analyzing the use of the rollback tool of Wikidata, which is explicitly meant to revert vandalism [26, 27]. A manual analysis revealed that 86% of reverted revisions are indeed vandalism and only about 1% of the non-reverted revisions. We derive a subset of this dataset, called WDVC-2016-Links, that contains all edits pertaining to the knowledge *graph*, i.e., the actual content of

Table 3: Evaluation data: (a) Derivation of the new dataset WDVC-2016-Links from WDVC-2016. (b) Datasets for training, validation, and test in terms of vandalism triples, total triples, subjects, predicates, and objects. (c) The vandalism corpus WDVC-2016-Links broken down by domain. (d) Estimation of the true bias without noisy labels. We perform stratified sampling on the test dataset and manually annotate the samples to estimate the true bias. (e) Wikidata vandalism corpus WDVC-2016-Links over time by domain for all edits, and, (f) for vandalism edits only.

the knowledge base. Table 3a details the successive filtering steps we applied. We omit edit operations by semi-automatic editing tools like Wikidata Game because they perform little vandalism and we believe tailored quality checks should rather be directly built into them. Moreover, we remove edits affecting labels, descriptions, aliases, sitelinks, qualifiers, references, attributes, and special operations for item creation and item merging, yielding a dataset consisting of edits affecting links between entities.

While the Wikidata vandalism corpus contains the data in incremental form, i.e., edit by edit, for our novel content-based features, we need to represent the data as a graph. For these features, we base our computation on the static Wikidata graph from February 29, 2016, i.e., the graph capturing the data ahead of the time interval covered by the validation set.[8]

5.2 Datasets for Training, Validation, and Test

Following previous work, we split the dataset by time to enable classification of edits as soon as they arrive without exploiting information "from the future." Table 3b shows the data splits along key statistics on triples. Overall, the dataset contains 21,641 vandalism cases among 7 million edits; a class imbalance of 0.3%. Our training set ranges from April 18, 2013, to February 29, 2016, consisting of 6 million edits. For efficiency, we derive triples from Wikidata's automatically generated edit comments, which were not available before April 2013. The two-month periods for validation and testing range from March to April and May to June, respectively, each comprising more than 550,000 edits. The large number of subjects renders subject feature prone to overfitting.

[8] https://archive.org/download/wikidata-json-20160229

5.3 Corpus Analysis

Table 3c breaks down the vandalism corpus by domain. We categorize edits by domain according to Wikidata's classification system.[9] In both absolute and relative terms, the most vandalism edits occur on persons such as Barack Obama, Christiano Ronaldo, and Justin Bieber, potentially causing high vandalism scores for all edits in this category. At the same time, among all categories, persons have the highest number of *benign* edits by anonymous users which still should receive low vandalism scores. This illustrates the inherent difficulty to achieve high predictive performance and low bias at the same time. An unbiased vandalism model must discriminate vandalism from non-vandalism without discriminating certain editor groups. Biases are still relatively small in this case, compared to the abuse filter in Table 1e.

The plots (e) and (f) in Table 3 overview our corpus both in terms of time and domains. The number of edits per month increases, as does the number of vandalism cases. The drop of manual edits around March 2014 can be explained by emerging automatic tools that automate routine data import and maintenance tasks, thus temporarily reducing manual edit operations. The increasing vandalism around January 2015 coincides with the redesign of Wikidata's user interface, driving vandals from the header area of labels, descriptions, and aliases to the body area containing links and statements. The person domain grows fastest, both in terms of benign and vandalism edits. Overall, the distribution of vandalism across domains remains relatively stable over time, with the exception of two outliers: an increase of vandalism affecting the works domain in January 2013 and March 2016.

5.4 Estimating Model Bias Without Data Bias

To investigate the effect of the noisy automatic vandalism labels on bias, we carry out a manual analysis: Drawing a stratified sample of 1,000 edits with respect to registration status (anonymous vs. registered) and automatic ground truth (vandalism vs. benign), we obtain gold labels by manual review of 250 edits per stratum, enabling an estimation of the true bias. The reviewer was kept unaware to which stratum a given edit belonged. Table 3d summarizes our findings and shows the average vandalism scores of WDVD for the data subsets we found to be *truly benign* and that form the basis for the bias computation. The WDVD scores were obtained by calibrating its original scores with isotonic regression on the large-scale corpus ground truth. As a result, WDVD's estimated bias without noisy labels is a score difference of 0.083 and a score ratio of 143.4. This is about half the bias measured on the automatically annotated corpus (0.121 and 310.7, respectively), which still necessitates countermeasures to reduce it. We leave creating a larger unbiased dataset that allows for training, calibrating, and evaluating (unbiased) vandalism detectors to future work.

6 EVALUATION AND BIAS OPTIMIZATION

We carried out a series of experiments to minimize the bias of our models while maintaining a competitive predictive performance. Table 4a gives an overview of the results we obtained for FAIR-E and FAIR-S, the state-of-the-art baselines WDVD, ORES, and FILTER, and variants thereof obtained by post-processing scores, reweighting training samples, and combining models in an ensemble. FAIR-E exhibits low bias at reasonable predictive performance; FAIR-S achieves higher predictive performance at a higher bias.

The literature has investigated trade-offs between different notions of fairness and predictive performance [4, 8, 10, 33], indicating that the two optimization goals cannot be satisfied at the same time, dependent on the notion of fairness and performance measure. Nevertheless, a sustainable model must strike a balance between fairness and predictive performance to ensure the long-term success of an online community. The state-of-the-art in vandalism detection has not yet reached its full potential in this respect.

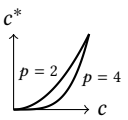
In what follows, we briefly recap the baseline models and the prediction performance measures, and then detail the aforementioned experiments. To ensure reproducibility, the code base underlying our research is published alongside this paper.[10] While feature extraction is carried out in Java, our experiments are implemented in Python using scikit-learn, version 0.19.1. To calibrate classifier scores before computing bias, we use isotonic regression.

6.1 Baselines and Performance Measures

For the final evaluation on the test set, all baselines were trained on both the training and the validation set of WDVC-2016-Links, i.e., on about 6 million revisions ranging from April 2013 to April 2016. Unless otherwise indicated, the same hyperparameters and machine learning algorithms as reported in Heindorf et al. [25] were used: WDVD employs multiple instance learning on top of bagging and random forests. It uses 16 random forests, each build on 1/16 of the training dataset with the forests consisting of 8 trees, each having a maximal depth of 32 with two features per split using the default Gini split criterion. ORES uses a random forest with 80 decision trees considering 'log2' feature per split using the 'entropy' criterion. FILTER uses a random forest with scikit-learn's default hyperparameters, i.e., 10 decision trees without a maximal depth.

We employ performance measures for both predictive performance and bias performance, the latter using the bias measures introduced in Section 3. Predictive performance is measured in terms of area under curve of the receiver operating characteristics (ROC_{AUC}) and area under the precision-recall curve (PR_{AUC}). Both curves capture predictive performance across different operating points, where each point on one of the curves has a corresponding point on the other [12]. However, corresponding points are weighted differently when computing the area under the curves: ROC_{AUC} emphasizes operating points at high recall ranges and PR_{AUC} emphasizes points at high precision ranges. Hence, ROC_{AUC} is best suited to analyze semi-automatic vandalism detectors, where revisions are ranked and manually checked by reviewers, whereas, PR_{AUC} is best suited to analyze fully automatic detection systems, where vandalism is reverted without human intervention.

6.2 Debiasing via Feature Engineering



We obtain our debiased models FAIR-E and FAIR-S via feature engineering. For FAIR-E, we employ graph embeddings capturing the content of an edit in contrast to meta data such as user reputation, thus obtaining a bias ratio of only 5.6 on the test set compared to over 300 of the state-of-the-art approach WDVD. We experimented with different variants of what feature interactions to consider and Table 4b overviews our results on the validation set. In general, we observe that, with increasing model complexity, both predictive performance and bias increase. Given the relatively low bias, we opt to optimize predictive performance and choose the model $S \times P + P \times O$ as FAIR-E, taking into account all pairwise interactions between subject and predicate as well as predicate and object.

Based on feature selection and explicitly omitting user features, FAIR-S achieves a bias ratio of only 11.9 at 0.316 PR_{AUC} and 0.963 ROC_{AUC}. Plot (c) in Table 4 shows the trade-offs between bias and predictive performance obtainable by adding or by removing single features from the set of candidate features and outlines the Pareto front on the validation set. For example, removing the feature `objectPredicateCumFrequency` from FAIR-S yields the left-most point with both lower predictive performance and lower bias. We choose the best predictive model without user features as FAIR-S. Compared to WDVD, which consists of 47 features, FAIR-S consists of only 14 features, thus simplifying the model, reducing its runtime, and rendering its decisions much more explainable.

6.3 Debiasing via Post-Processing Scores

As an alternative to feature engineering, we can obtain comparable results in terms of bias and predictive performance by post-processing the scores of WDVD. We scale uncalibrated scores $c(i)$ from sample i of the protected class, while leaving those from the unprotected class unchanged, thus obtaining $c^*(i)$:

$$c^*(i) = \begin{cases} c(i)^p, & \text{revision } i \text{ from anon. user} \\ c(i), & \text{revision } i \text{ from reg. user} \end{cases}$$

[10] http://www.heindorf.me/wdvd

Table 4: Evaluation results: (a) Performance and bias of approaches on the test set of the vandalism corpus WDVC-2016-Links. (b) Optimization of FAIR-E on the validation set by testing all pairwise feature interactions between subject (S), predicate (P), and object (O) in predicate space. (c) Optimization of FAIR-S on the validation set. The plot shows ROC_{AUC} over bias of FAIR-S (purple) after adding (green) or removing (orange) a feature. The dotted line shows non-dominated points on the Pareto front. (d) Error analysis with respect to bias on our golden dataset.

$P + O$	0.068	0.739	0.0042	1.94
S	0.020	0.643	0.0012	1.26
P	0.008	0.659	0.0008	1.17
O	0.011	0.663	0.0004	1.09

(c)

(d)

Users	Manually reviewed edits (n=1,000)			
Gold Truth:	Vandalism (n=524)		Benign (n=476)	
FAIR-S:	Vandalism (correct)	Benign (incorrect)	Vandalism (incorrect)	Benign (correct)
Anonymous	250	42	73	135
Registered	173	59	28	240

After scaling, we apply isotonic regression to calibrate the scores to represent probabilities, i.e., $c^*(i) \approx Pr(i = \text{vandalism} \mid x_i)$, in order to prevent bias being lower just due to a smaller interval of scores. By experimentally varying the parameter $p > 1$, we obtain classifiers that have approximately the same bias as our models FAIR-E and FAIR-S, allowing for performance comparisons. As Table 4a shows, we can achieve approximately the same predictive performance as with feature engineering. The advantage of post-processing scores is that the model does not have to be retrained. However, the model's decisions are also much more difficult to understand. It is less clear what effect single features have, thus hindering an intuitive explanation to Wikidata editors whose edits have been reverted. Apart from the polynomial scaling function introduced above, we experimented with other families of functions, including linear, fractional, and exponential functions. Polynomial scaling outperformed all other variants in terms of PR_{AUC}.

6.4 Debiasing via Weighting Training Samples

As another option to reduce biases, we experimented with reweighting training samples. We start by assigning each of the four groups of protected/unprotected, benign/vandalism revisions the same weight. Then we increase the weight of benign edits by protected users such that it becomes prohibitively expensive for the algorithm to make mistakes on this set of revisions. Symmetrically, we increase the weight of vandalism edits by unprotected users. Thus, using the notation from Section 3, the weight of each training sample i is obtained by:

$$w(i) = \begin{cases} \alpha \cdot \frac{1}{|A|}, & \text{revision } i \in A \\ 1 \cdot \frac{1}{|B|}, & \text{revision } i \in B \\ 1 \cdot \frac{1}{|D|}, & \text{revision } i \in D \\ \alpha \cdot \frac{1}{|E|}, & \text{revision } i \in E \end{cases}$$

		Truth benign	Truth vand.	∪
Protected	yes	A	B	C
	no	D	E	F
∪		G	H	I

By varying the constant $\alpha > 1$, we obtain classifiers with varying trade-offs between bias and predictive performance. For the weighting experiment in Table 4a, we reduce the maximal tree depth of WDVD from 32 to 16 to increase the number of training samples per leaf, giving the weighting a larger effect. We experimentally determine α to achieve approximately the same bias as our models FAIR-E and FAIR-S, allowing for performance comparisons. However, predictive performance is lower than that obtained by feature engineering or post-processing scores. We believe the reason is that reweighting leads to overfitting on certain subsets of the data and the effect on bias is rather indirect by reducing the misclassification rate on these subsets, instead of tackling bias directly. Hence, we suggest to rather use feature engineering or post-processing scores. Besides, we also tried to employ separate constants α_1 and α_2 per group, but no better bias and predictive performance was achieved, so we resorted to the basic weighting scheme.

6.5 Debiasing via Combining Models

In yet another debiasing attempt, we train ensembles of models with high predictive performance and low-bias models to derive a model with characteristics in between. A weighted average between the scores of the two models is computed. Table 4a shows the results: While it is possible to use ensembles to reconcile predictive performance with bias, this method appears to be inferior to feature engineering and post-processing scores.

6.6 Debiasing Error Analysis

Table 4d shows the results of an error analysis for FAIR-S. The continuous scores of FAIR-S were converted to binary decisions, so that predicted vandalism prevalence equals the vandalism prevalence in the golden set from Table 3d. The table shows, that 73 benign edits by anonymous users were classified as vandalism. Manually investigating these edits, we find that most of the edited triples are

updates (53), rather than removals (11) or creations (9). In most cases, the subject is a human. Predicates frequently affected are "occupation" (P106, 10 cases), "instance of" (P31, 8), "country of citizenship" (P27, 6), and "sex or gender" (P21, 6). It might be beneficial to develop vandalism detectors tailored to update operations, e.g., by comparing the old and new object of a triple. Also specific features targeting problematic predicates might help. Beyond intrinsic plausibility checks, also double-checks in external databases or web search engines seem promising.

7 DISCUSSION

Biases in machine learning are still widely neglected by researchers and practitioners in machine learning and data science, who primarily focus on optimizing predictive performance, disregarding fairness constraints that are essential for the long-term success of online communities. Approaches that discriminate against sex, race, religion, or that are otherwise biased against minorities—or even against majorities[11]—jeopardize an online community's long-term goal of promoting a feeling of fairness, security, and belonging. We hope that our endeavor helps towards increasing awareness.

Our bias definition emphasizes fair treatment of *benign* edits, which is also known as *equality of opportunity* [23], and which we believe is well-aligned to the goal of newcomer retention. Fair treatment of both *benign* and *vandalism* edits would correspond to the stricter fairness notion *equalized odds* [23], making it potentially more challenging to find a good balance between predictive performance and fairness. Another fairness notion that is sometimes mentioned by the media, lawmakers, and the literature is *statistical parity* [16, 17], requiring that the same proportions of anonymous and registered edits are classified as vandalism. This neglects that the two populations might have different vandalism prevalences, and Dwork et al. [16] argue that it is an inadequate notion of fairness. First results [4, 8, 10, 33] suggest that there is a trade-off between fairness and predictive performance for many notions of fairness, requiring difficult trade-offs when the set of features is fixed. We believe decisions about an edit should focus on the edit's "content", instead of the reputation of the user who submitted it. But even without features prone to incur bias, there can still be bias against certain groups, since seemingly harmless features might correlate with biased features. For example, in Table 2, features related to edit operations and subjects introduce (a small) bias against anonymous edits. However, forcing two groups to have exactly the same score distribution might introduce reverse discrimination, also known as affirmative action [3, 48, 66], since there might be hidden confounding variables justifying certain differences. In the future, causal modeling [32, 34, 64] might help to decide what causal relations to consider.

Wikidata makes for an interesting case study to analyze and mitigate biases as it has one of the largest online communities and provides opportunities to pay particular attention to the content rather than the user reputation. We believe some lessons learned in this project can be transferred to other projects, too. It is common practice to identify malicious edits via meta data such as geolocation of IP addresses, age of user account, or browser information such as user language. While those features are simple to obtain, they do not directly judge the quality of an edit and harm well-intentioned users. Our graph embeddings serve as an example of how features purely judging the content of an edit help to reduce unintentional biases. Perhaps surprisingly, we can obtain comparable performance-bias trade-offs by artificially scaling scores after a biased model has been trained. On the one hand, this approach might serve as an easy route to debias existing models. On the other hand, we feel that it is rather a "black-box approach" and might be less suitable for understanding predictions and explaining them to editors.

Finally, we would like to point out some limitations and directions for future research. Our model FAIR-E was specifically designed for edits affecting links between entities and extending it to attributes, labels, descriptions, and aliases might be challenging, with the exception of our model FAIR-S. Here, such an extension is rather straightforward as it selects features from WDVD which is capable of classifying all edits in Wikidata. Our analysis is based on a dataset derived from the rollback actions of Wikidata reviewers and we observed some reviewer bias in this dataset. We leave it to future work to create a large-scale, unbiased dataset. For example, the Wikimedia Foundation might decide to hide user information from Wikidata reviewers, forcing them to purely consider the content of an edit. However, this might make the review process more expensive as reviewers cannot skip or quickly skim large amounts of edits by registered users anymore. Besides fair vandalism detectors, further means to increase newcomer retention might include vandalism detectors explaining their decisions, improved user interfaces, onboarding programs for newcomers, increased social interactions, and gamification—all accompanied by data-driven processes such as A/B testing or reinforcement learning.

8 CONCLUSION AND OUTLOOK

Machine learning models ingest biases through training data and features—sometimes even aggravating them—fueling a vicious cycle of reinforcing biases in a larger system. In this work, we developed a vandalism detector for Wikidata's damage control system that does not contribute significant bias of its own. Compared to the state-of-the-art, it considerably reduces bias against edits by anonymous and newly registered editors. We achieve this result by omitting user-related features and by developing features that purely encode the content of an edit, rather than any meta information. In the future, we plan to investigate biases at further online platforms and to develop a general framework for bias mitigation, e.g., by employing evolutionary algorithms to explore the Pareto front of non-dominated models in bias-performance space.

ACKNOWLEDGMENTS

This work was supported by the German Research Foundation (DFG) within the Collaborative Research Center "On-The-Fly Computing" (CRC 901). Special thanks go to the anonymous reviewers for their helpful comments.

[11] Anonymous *edits* are a clear minority in our dataset since only about 2.4% of edits are by anonymous editors. However, anonymous *editors* might possibly be in the majority, since the number of distinct IP addresses from anonymous editors is about 2.5 times higher than the number of distinct user accounts from registered editors (our data does not reveal how often the same anonymous editor uses a different IP address).

ABSTRACT

Information diffusion is usually modeled as a process in which immutable pieces of information propagate over a network. In reality, however, messages are not immutable, but may be morphed with every step, potentially entailing large cumulative distortions. This process may lead to misinformation even in the absence of malevolent actors, and understanding it is crucial for modeling and improving online information systems. Here, we perform a controlled, crowdsourced experiment in which we simulate the propagation of information from medical research papers. Starting from the original abstracts, crowd workers iteratively shorten previously produced summaries to increasingly smaller lengths. We also collect control summaries where the original abstract is compressed directly to the final target length. Comparing cascades to controls allows us to separate the effect of the length constraint from that of accumulated distortion. Via careful manual coding, we annotate lexical and semantic units in the medical abstracts and track them along cascades. We find that iterative summarization has a negative impact due to the accumulation of error, but that high-quality intermediate summaries result in less distorted messages than in the control case. Different types of information behave differently; in particular, the conclusion of a medical abstract (i.e., its key message) is distorted most. Finally, we compare extractive with abstractive summaries, finding that the latter are less prone to semantic distortion. Overall, this work is a first step in studying information cascades without the assumption that disseminated content is immutable, with implications on our understanding of the role of word-of-mouth effects on the misreporting of science.

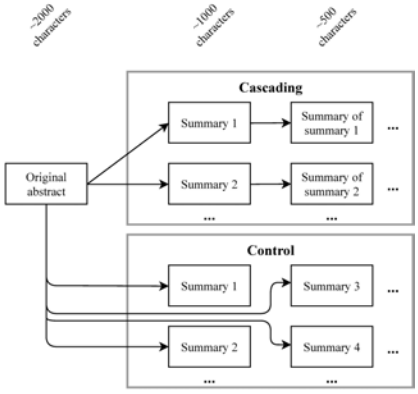

Figure 1: Schema of the crowdsourced experiment for simulating information cascades. In the cascading setting, workers summarize texts iteratively, reducing the number of characters hop by hop. In the control setting, workers always summarize the original text for all target lengths.

1 INTRODUCTION

The spread of information, online and offline, is a noisy process. As a message is passed on from person to person, or from platform to platform, errors creep in, and facts are distorted, oftentimes to an extent such that, after a few hops of propagation, downstream messages may be entirely different from—or even contradict—the original message. This way, valuable information may turn into harmful misinformation, even without purposeful interference.

Misconceptions and sensationalism add their part to compound the problem, as frequently observed in the context of health-related topics such as dieting and vaccination. For example, in 2006, the first results of the *Women's Health Initiative Dietary Intervention* trial were published. The trial found little impact of diets lower in fat and higher in fruits, vegetables, and grains in the incidence of certain diseases in women between 50 and 79 years old [25]. Shortly after its publication, a sequence of press releases and news stories increasingly distorted the nuanced and cautious findings of the study, overlooking methodological caveats and benefits found [35]. Throughout the diffusion process, news overwhelmingly reported that food and nutrition had little to do with health and disease [9].

This anecdote portrays how information may be distorted as it propagates over the news and social media. These distortion processes are overlooked in the existing literature on information diffusion [21], which treats information disseminated through a network as consisting of immutable pieces of content (e.g., *memes* [34] or topics [10]). Previous research in communication studies [14, 22] indicates, however, that the way information is altered, interpreted, or framed along its diffusion may have a significant impact.

Two orthogonal factors are at play during message propagation:

(1) **Word of mouth:** Information commonly spreads in a cascading fashion, from person to person, or from platform to platform, rather than directly from the original source to every person or platform.
(2) **Summarization:** When an original message is passed on, it is frequently compressed, focusing on the essence while omitting unnecessary details.

Both factors can introduce errors. First, word-of-mouth propagation usually takes place on noisy channels (unless messages are forwarded unmodified, e.g., via retweets), and when an error occurs, it is passed on via what we term the **telephone effect,** named after the *telephone game,* in which *"players form a line, and the first player comes up with a message and whispers it to the ear of the second person in the line. The second player repeats the message to the third player, and so on. When the last player is reached, they announce the message they heard to the entire group. The first person then compares the original message with the final version. Although the objective is to pass around the message without it becoming garbled along the way, this usually ends up happening"* [1]. Second, summarization can be seen as lossy compression and thus induces an additional loss of information, which we term the **summary effect.**

Consider, e.g., this three-hop cascade: a ten-page medical research paper is promoted in a one-page university press release, which is picked up by a half-page newspaper article, which is finally mentioned in a tweet with 280 characters. It is clear that the tweet at the end of the cascade will be different from the original research paper. What is less clear is whether the difference stems from the fact that the message was passed on three times (the telephone effect), or from the fact that ten pages were compressed to 280 characters (the summary effect). Disentangling the telephone and summary effects is difficult when working with observationally collected information cascades as studied in prior work, e.g., URLs spreading via tweets [50] or quotations spreading via news articles and blog posts [34]. Moreover, assembling an appropriate dataset in the first place is challenging, too. For instance, in the case of the aforementioned *Women's Health* trial, it is hard even to identify the structure of cascades, i.e., the graph that specifies from which other node each node received the message. If an article misreported the findings, it is unclear if the author read the original scientific report and misunderstood it, or if they read other articles that had already introduced the error. Also, the level of coverage may vary widely: a special feature on women's health in a tabloid may briefly mention the trial, whereas an editorial in *Science* may be dedicated to it entirely. Meaningfully comparing such different formats is hard.

Present work: an experimental framework for studying message distortion in information cascades. These challenges associated with observational settings motivated us to adopt an experimental approach. In our experimental design, inspired by the telephone game, we aim to track the distortion of messages as they propagate hop by hop. Starting from an original message, we simulate an information cascade by asking a crowd worker to shorten the original message to a prescribed target length while preserving the essential information. The resulting summary is then passed on to another worker, who is asked to condense it to an even shorter target length, and so forth. This way, we obtain chains of **cascading summaries.** Along the chains, the original message is distorted by the telephone and summary effects. To tease the two effects apart, we also collect **control summaries,** of the same lengths as the cascading summaries, but produced by directly summarizing the original message to the respective target length, without any intermediate summaries. This setup is depicted in Fig. 1. Cascading summaries are subject to both the telephone and the summary effects, whereas control summaries are only subject to the summary effect, so the difference in error rates in cascading vs. control summaries can be ascribed to the telephone effect.

This experimental design allows us to address the following **research questions:**

RQ1: Measuring the telephone effect. What part of information distortion is due to the cascading of messages (telephone effect), rather than to length restrictions (summary effect)?
RQ2: Information persistence. Given that a piece of information has already survived k summarization steps, how likely is it to survive one more? What factors impact its survival?
RQ3: Extractive vs. abstractive summarization. Broadly, there are two ways of summarizing text, (1) by subselecting keyphrases (*extractive*), (2) by paraphrasing essential information (*abstractive*). How effective are these strategies in mitigating distortion introduced by the telephone effect?

Application to medical information. Motivated by the importance of medical information, we apply the above framework to a scenario where original messages are abstracts of papers published in the *New England Journal of Medicine* (NEJM). Automatically identifying the key facts contained in a medical abstract is an open challenge [45], and so is determining the presence vs. absence of those facts in subsequent summaries. Hence, in order to reliably address the above research questions, we manually annotate lexical and semantic units in the abstracts and track them along cascades.

We find that, overall, cascading summarization has a detrimental effect due to the accumulation of error. High-quality intermediate summaries, however, can have a positive effect, by isolating the essential information and discarding noise, entailing less distorted subsequent messages than in the control case. Different types of information behave differently; in particular, the conclusion of a medical abstract—the most critical information —is distorted most: the conclusion is correctly represented in cascading summaries by about 25 percentage points less, compared to control summaries, for a fixed target length. Moreover, we find that the prior knowledge of the crowd workers impact the persistence of information in the control setting, but not in the cascading setting. Finally, comparing extractive with abstractive summaries, we find that extractive summaries (where more keyphrases are preserved) are less prone to semantic distortion.

Implications. Beyond the special case of medical information, our work has general implications for the study of information cascades in a setting where information is not immutable and atomic but subject to distortion and omission. In this context, modeling the distortion of content through its diffusion in a network can help us understand the nature of viral content and the processes through which biased or erroneous information arises from a correct source. Furthermore, these insights could be used to purposefully create content that is less prone to distortion as it is diffused.

2 RESEARCH DESIGN

We describe our experimental design for collecting cascading and control summaries (Sec. 2.1), the dataset of cascades of medical information (Sec. 2.2), and our method for extracting keyphrases and facts from abstracts and tracking them along cascades (Sec. 2.3).

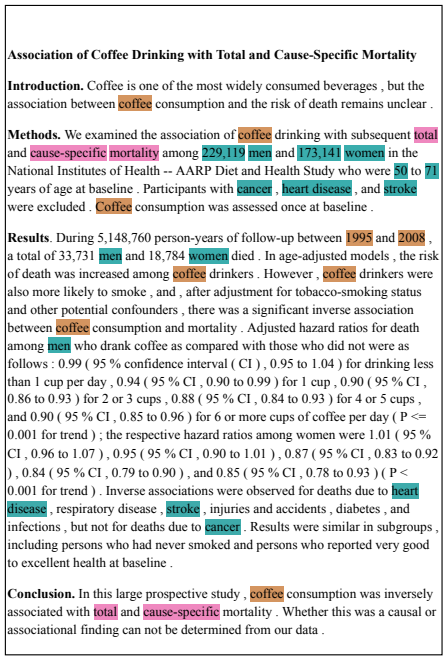
2.1 Collecting information cascades

We perform a controlled experiment to simulate an information diffusion process through text summarization tasks. Starting from an original text of length l_0, we leverage crowd workers to shorten it to a sequence of prescribed target lengths $l_1 > l_2 > \cdots > l_n$. More specifically, workers were given the following instructions:

> You will be given a short text (l_k characters) with medicine-related information. Your tasks are these:
>
> (1) Read the text carefully.
> (2) Write a summary of the text. Your summary should
> (a) convey the most important information in the text, as if you are trying to inform another person about what you just read;
> (b) contain between $l_{k+1} - \Delta_{k+1}$ and $l_{k+1} + \Delta_{k+1}$ characters.
>
> We expect high-quality summaries and will manually inspect some of them. Copy-pasting is disabled.

Cascading and control summaries differ with respect to the input given to workers. In cascading summaries, a crowd worker whose task is to produce a summary of length l_k is given as input a summary of length l_{k-1} that was previously produced by another crowd worker. Only for target length l_1 is the original text used as input. In control summaries, on the contrary, the input is always the original text, regardless of the target length.

For each original text, target length, and condition, we collect multiple summaries. Cascading summaries form a set of chains rooted in the original abstracts, whereas control summaries are flat broadcast trees. This is depicted in Fig. 1.



Cascading summaries are affected by both the telephone and the summary effect (as defined in Sec. 1), whereas control summaries are affected only by the summary effect, such that comparing the two cases allows us to quantify the telephone effect. One might argue that the telephone effect could be isolated in a more straightforward fashion by using a constant target length throughout, asking workers to simply rephrase the input, and thus eliminating the summary effect altogether. This, however, would allow for trivial solutions on behalf of crowd workers: nothing would keep them from simply copying the input, such that by eliminating the summary effect, the telephone effect would also vanish. This shortcoming could be addressed using a different research design, e.g., by showing workers the input text for a certain amount of time, then hiding it and asking them to reproduce it from memory. This setup, however, is more complex to implement, requires workers to spend idle time before finishing the task, and runs the risk of cheating (e.g., even when disabling copy–paste, users might take a screenshot or a picture). Also, for longer original texts (such as research paper abstracts), summarization is a step users would naturally perform in real cascades. For all these reasons, we adopt the summarization-based paradigm. Due to budget constraints, we create cascades such that each node has one descendant, since otherwise, the cost of the experiment would increase exponentially.

2.2 Dataset: cascades of medical information

In our concrete application of the above experimental design, we collect cascades whose root nodes consist of medical abstracts from the *New England Journal of Medicine* (NEJM). We select four research fields of public interest (vaccination, breast cancer, cardiovascular diseases, and nutrition), and choose 4 impactful papers per field, for a total of 16 abstracts, listed in Table 1. Analyzing the number of links to these papers in a large corpus of blog posts and news pieces, we select papers that were widely discussed online.

For each abstract, we generate 8 chains of cascading summaries, so that for each target length, each abstract had 8 summaries associated with it. In parallel, we collect another 8 independent control summaries per target length, totaling $16 \times 8 \times 2 = 256$ summaries per target length. Original abstracts were $l_0 \approx 2000$ characters long, and we consider five target lengths (which we also refer to as *hops*): $l_1 = 1000$, $l_2 = 500$, $l_3 = 250$, $l_4 = 125$, and $l_5 = 64$ characters. We allow slacks $\Delta_1 = 100$, $\Delta_2 = 50$, $\Delta_3 = 25$, $\Delta_4 = 13$ and $\Delta_5 = 9$, for each budget respectively.

For several reasons, we enforce that workers only summarize one text per hop per abstract. Firstly, we do not want a single worker to be involved in several summarization chains, as this would imply that a single unskilled or malicious worker could jeopardize the quality of all the chains. Secondly, we do not want information to leak from one summary to another. As different chains are related to the same paper, it could be that workers understood the text better if they summarized multiple summaries originating from the same paper. Due to the latter reason, we also limit workers to do summaries related to a paper in different hops 36 hours apart.

Association of Coffee Drinking with Total and Cause-Specific Mortality

Introduction. Coffee is one of the most widely consumed beverages , but the association between coffee consumption and the risk of death remains unclear .

Methods. We examined the association of coffee drinking with subsequent total and cause-specific mortality among 229,119 men and 173,141 women in the National Institutes of Health -- AARP Diet and Health Study who were 50 to 71 years of age at baseline . Participants with cancer , heart disease , and stroke were excluded . Coffee consumption was assessed once at baseline .

Results. During 5,148,760 person-years of follow-up between 1995 and 2008 , a total of 33,731 men and 18,784 women died . In age-adjusted models , the risk of death was increased among coffee drinkers . However , coffee drinkers were also more likely to smoke , and , after adjustment for tobacco-smoking status and other potential confounders , there was a significant inverse association between coffee consumption and mortality . Adjusted hazard ratios for death among men who drank coffee as compared with those who did not were as follows : 0.99 (95 % confidence interval (CI) , 0.95 to 1.04) for drinking less than 1 cup per day , 0.94 (95 % CI , 0.90 to 0.99) for 1 cup , 0.90 (95 % CI , 0.86 to 0.93) for 2 or 3 cups , 0.88 (95 % CI , 0.84 to 0.93) for 4 or 5 cups , and 0.90 (95 % CI , 0.85 to 0.96) for 6 or more cups of coffee per day (P <= 0.001 for trend) ; the respective hazard ratios among women were 1.01 (95 % CI , 0.96 to 1.07) , 0.95 (95 % CI , 0.90 to 1.01) , 0.87 (95 % CI , 0.83 to 0.92) , 0.84 (95 % CI , 0.79 to 0.90) , and 0.85 (95 % CI , 0.78 to 0.93) (P < 0.001 for trend) . Inverse associations were observed for deaths due to heart disease , respiratory disease , stroke , injuries and accidents , diabetes , and infections , but not for deaths due to cancer . Results were similar in subgroups , including persons who had never smoked and persons who reported very good to excellent health at baseline .

Conclusion. In this large prospective study , coffee consumption was inversely associated with total and cause-specific mortality . Whether this was a causal or associational finding can not be determined from our data .

Coarse category	Fine category	Facts	Keyphrases
Participants	Sex	The study was performed in women and men.	men; women
	Age	The participants were between 50 to 71 years of age at baseline.	50; 71
	Condition	Participants with cancer, heart disease and stroke were excluded.	cancer; heart disease; stroke
	Location	N/A	
	Sample size	There were 229,119 men and 173,141 women among the participants.	229,119; 173,141
Intervention	General	The study assessed the impact of coffee consumption.	coffee
	Duration	The study followed up individuals between 1995 and 2008.	1995; 2008
	Intensity	N/A	
	Control	N/A	
Outcomes	General	The study measured long-term total and cause-specific mortality.	total; cause-specific; mortality
	Effect strength	N/A	
	Adverse effects	N/A	
Conclusion	General	Coffee consumption was inversely associated with total and cause-specific mortality in non-smokers.	We annotate no keyphrases for this category.

Figure 2: *Left:* one of the 16 abstracts used in this study. *Right:* the categories employed, as well as facts and keyphrases associated with the abstract. Keyphrases are highlighted in the abstract.

To assess participants' level of domain knowledge, we use a questionnaire for each topic. For the topics *Breast cancer* and *Vaccination,* we use online quizzes approved by University of Rochester medical reviewers [2, 5]. For the topic *Cardiovascular diseases*, we use the sections *Epidemiology* and *Risk factors* of Bergman et al. [6]. For the topic *Nutrition,* we use the first section on expert nutrition advice of the UCL Nutrition Knowledge Questionnaire [32].

Table 2: Values used for annotating facts.

Fact value	Explanation
A	The fact is entirely captured in the text, omitting only insignificant details.
B	The essence of the fact is captured in the text, but a significant amount of detail was omitted.
C	The fact is not, or only insufficiently, captured in the text.
D	The fact contradicts the original text.

2.3 Annotating and tracking information

Studying information distortion requires quantifying the completeness and truthfulness of a summary: which facts from the original text are present in a given summary, and which facts have been omitted or even contradicted?

To address this challenge, we exploit the fact that medical abstracts are highly structured: key information can be attributed to a few main categories (e.g., *Participants* or *Intervention*), which may be further decomposed into multiple lower-level ones [45]. For example, *Participants* may be decomposed into subcategories like *Age, Sex,* and *Condition.* We develop two methods for tracking information related to these categories, which we explain in detail.

We annotate **keyphrases** (e.g., "mortality") in the abstracts with the categories they belong to (e.g., *Outcomes*). The phrases are then matched in subsequent summaries. Tracking keyphrases is computationally simple, but runs the risk of low recall: a fact may be expressed in a summary, but in words different from those in the input text. In other words, semantic completeness does not require lexical completeness. Moreover, it may be the case that the keyphrase is present, but the actual information is lost, e.g., if the summary contradicts the source text but shares keyphrases with it.

We also extract **facts,** short sentences stating the essential information a text conveys about a specific category. For example, for *Participants/Sample size,* a fact may be *"There were 229,119 men and 173,141 women among the participants"*. Facts of a given category may partially overlap with others; e.g., in the above example, it is mentioned that the study was performed with men and women, information which may also be present in the fact for the *Participants/Sex* category. We present a full abstract with annotated keyphrases and facts in Fig. 2. On the right-hand side, we show the hierarchical categories for both keyphrases and facts, inspired by the categories proposed in Nye et al. [45]. Notice that *Conclusion/General* is a category for which we have only facts but not keyphrases. This is the case as the conclusion often involves keyphrases from various categories; e.g., the statement *"Coffee consumption was inversely associated with total and cause-specific mortality in nonsmokers"* contains keyphrases about the intervention (*coffee*) and the outcome (*cause-specific; mortality*).

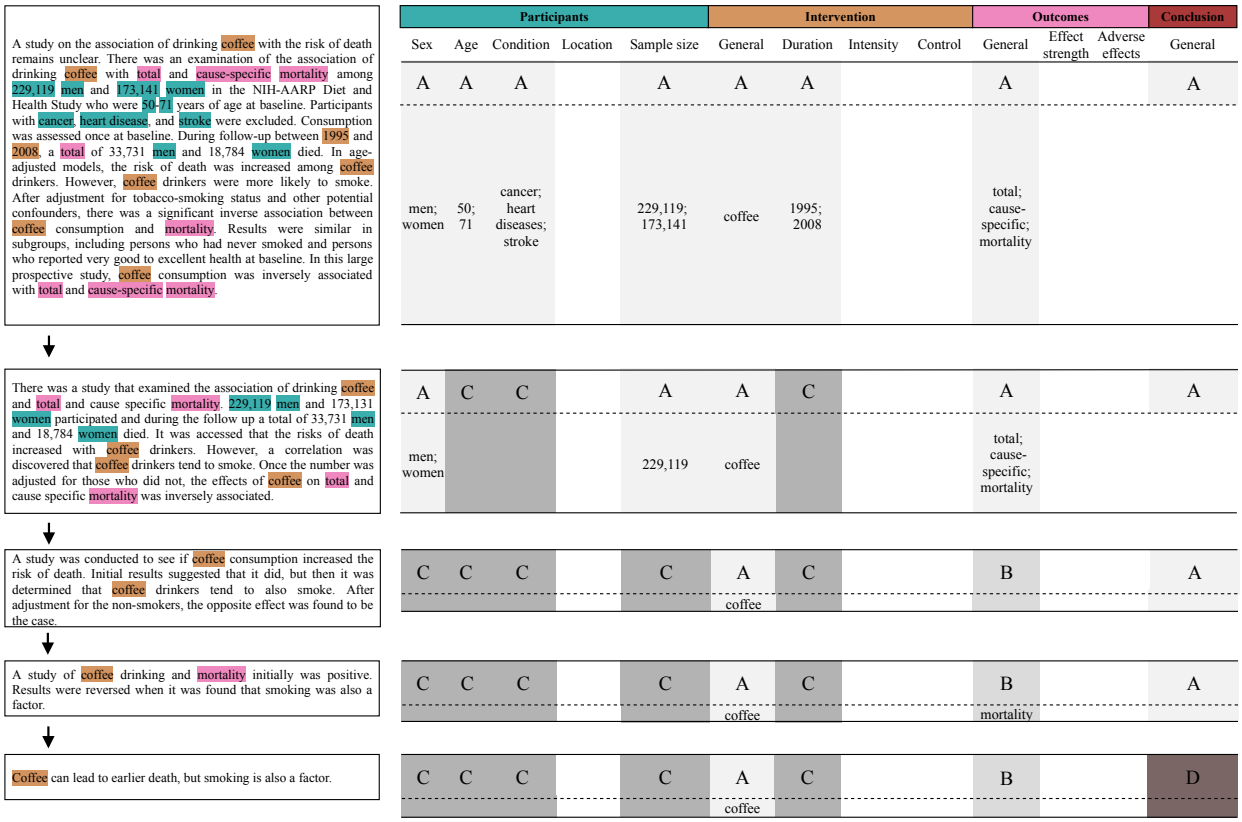


Figure 3: *Left:* a real summarization cascade obtained from crowd workers. *Right:* the annotated facts and the matched keyphrases for each of the summaries. Fact values (*A, B, C, D*) are explained in Table 2.

Tracking facts along the cascade is more complex and ambiguous than tracking keyphrases. For each summary, we assign each fact a **fact value** (*A, B, C,* or *D*). The meaning of these values is defined in Table 2. We attributed values to facts via crowdsourcing, instructing crowd workers as follows:

> You will be given several statements (around 9) and a series of short texts (of different sizes) related to medicine. Your tasks are these:
>
> (1) Read the statement and the texts carefully.
> (2) Judge how well the statement is captured by the different texts, choosing between *A, B, C,* and *D* (as explained in Table 2).
>
> The above will be repeated for several statements (the texts will be the same). Quality checks will be performed on the answers.

Attributing values to the facts is subjective: it is often not trivial to decide between *A* and *B*, or between *B* and *D*; e.g., the information that the study involved 1,067 participants can be distorted along the cascade by stating that the study involved a thousand participants. Is this fact partially preserved, as the order of magnitude is still conveyed, or does this contradict the initial fact, since $1{,}067 \neq 1{,}000$?

We take several steps to ensure annotation quality: *(i)* We add a qualification test where we explain the task thoroughly, gave examples, and assessed workers' ability to understand the subtleties of the task. *(ii)* We show texts of different sizes at once to ensure that workers could compare what a piece of information would look like in several lengths, making the annotation of a given fact consistent across several summaries. *(iii)* We introduce quality checks (facts that are wrong for all statements), allowing us to filter workers who failed often. *(iv)* Lastly, we assign three workers per fact and manually review all facts, giving emphasis to those where not all three workers had annotated a given fact with the exact same value (33% of all cases).

Example. We present a summary cascade on the left-hand side of Fig. 3. The summaries refer to the abstract from Fig. 2. The findings are nuanced: coffee is associated with an increased risk of death; yet, when accounting for confounding variables, such as smoking, the association is reversed. In the cascade, as the summaries become shorter, this subtlety becomes increasingly difficult to grasp. In the last summary, we eventually even arrive at a contradiction.

Annotated keyphrases and extracted facts are shown on the right-hand side of Fig. 3. Firstly, notice that the sudden contradiction we just described is captured, as the label *D* was assigned to the *Conclusion/General* fact in the last summary. Another interesting transition here is how the *Outcomes/General* fact shifts from *A* to *B* in the third summary: both previous summaries indicated that the summary measured total and cause-specific mortality, whereas the third one simply indicates that it measured the risk of death, which is less complete.

To see the limitations of tracking keyphrases and how they are overcome by tracking facts, consider the second summary, which

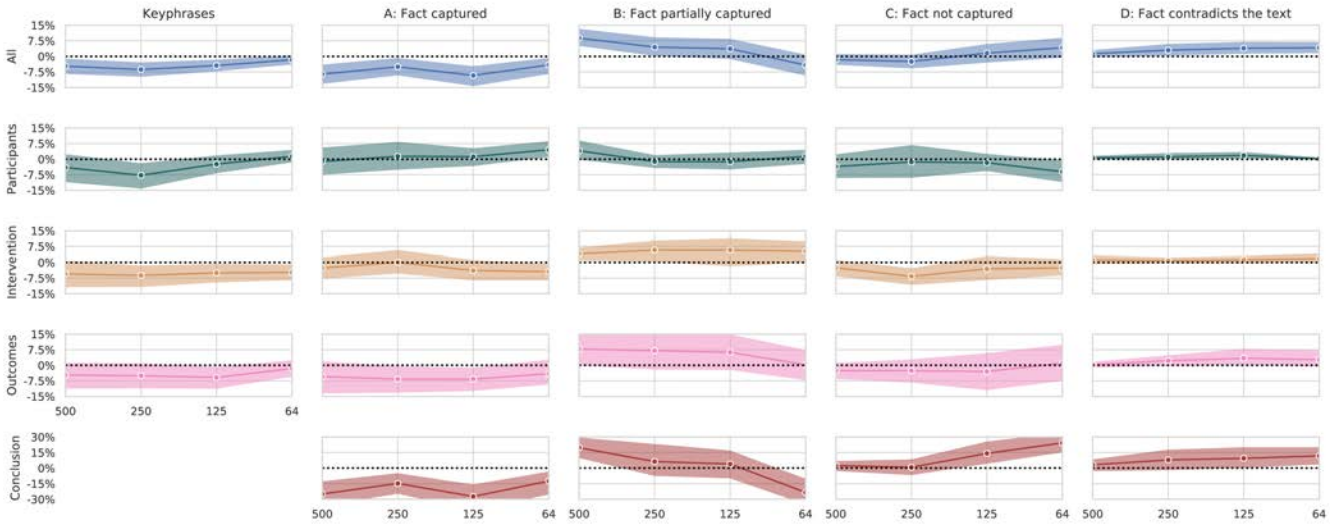

Figure 4: Differences in percentage of preserved keyphrases (column 1) and fact values (columns 2–5) between cascading and control summaries for fact categories (rows) and hops (x-axes), with bootstrapped 95% confidence intervals.

contains a typo: it says that the study was performed in 173,131 women instead of 173,141. Also, the worker used the expression "risk of death", instead of "mortality". These examples show that keyphrases can be difficult to track when there are typos or when expressions are rephrased.

3 RESULTS

3.1 RQ1: Strength of the telephone effect

In our first analysis, we compare the distortion of information in the cascading and control conditions.

Differences across hops. We calculate the percentage of keyphrases in the summaries of a given hop and the percentage of facts with a given value for all papers in the cascading and control settings. We depict the difference between the two settings in percentage points in Fig. 4. Values above 0% mean that the percentage of keyphrases, or of facts of a given value, is higher in the cascading summaries. We observe several interesting patterns. Cascading summaries preserve fewer keyphrases in all categories at all hops. This difference decreases in the last hops, perhaps because they require users to adopt more abstractive summarization strategies in both settings. The percentage of facts labeled as *A* is lower for cascading than for control summaries. This effect is particularly strong for the *Outcomes* and *Conclusion* categories. In the latter, the difference is greater than 15%. The difference in the percentage of facts labeled as *D* has an increasing trend. Here too, the effect is strongest for the *Outcomes* and *Conclusion* categories. Lastly, facts labeled as either *B* or *C* do not present a clear trend for the *Participants, Intervention,* and *Outcomes* categories. For the *Conclusion* category, however, the difference in *B*-valued facts decreases along the hops, while the percentage of *C*-valued facts increases. Overall, these differences suggest that the "telephone effect" impacts the quality of summaries significantly, particularly harming the essential facts—the outcomes and conclusion of a study.

Category distribution. We also analyze how the distribution of categories differs for the distinct settings (Table 3). Consider the percentage of facts labeled as *A* that belong to the *Participants* and *Conclusion* categories. For cascading summaries, the percentage of *Participants* facts consistently stays above 29%, while this percentage drops significantly to 14% for control summaries. For the *Conclusion* category, we have the inverse: the percentage of *A* statements in the *Conclusion* category decreases in the cascading group and remains stable (above 10%) in the control. This suggests that the type of message that ends up getting spread differs between the cascading and control summaries: cascading summaries seem to "remember" less pertinent facts about participants, whereas control summaries preserve more crucial facts about study conclusions.

Table 3: Distribution over categories (*Participants, Intervention, Outcomes, Conclusion*) for fact values (*A, B, C, D*). Results for control setting in bold.

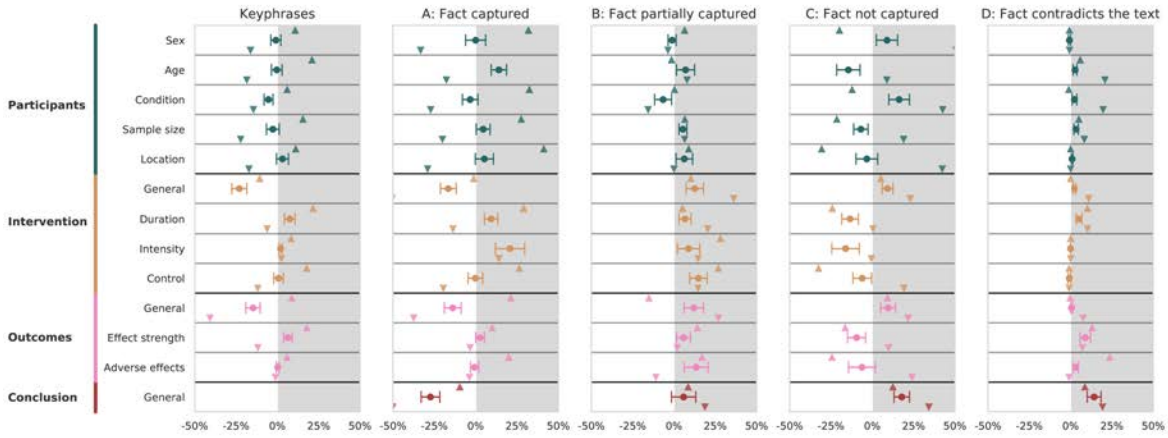

Figure 5: Differences in the percentage of facts and keyphrases between cascading and control summaries for fine-grained categories (averaged over all target lengths). On the positive side of the x-axis (in gray), the percentage of facts/keyphrases is higher in the cascading scenario. Each category is associated with three values (with bootstrapped 95% CIs): The circle ∘ represents the actual difference between the cascading and control settings. The upward △ (downward ▽) triangle represents the difference between the successor of the best (worst) cascading summary from the previous hop and control.

A closer look. We now zoom into the fine-grained categories to drill deeper with regard to the differences between the cascading and control settings. We study the difference between the percentage of keyphrases and facts, averaged across hops, as depicted by the circles (∘) in Fig. 5. We find that the differences are largest in what can be considered the most important facts. For example, the categories *Conclusion/General*, *Intervention/General,* and *Outcomes/General* have the biggest difference for facts labeled as *A* and for keyphrases (recall that there are no conclusion-related keyphrases). The percentage of facts labeled as *C* and *D* for these categories is also higher in the cascading scenario. This is interesting as one might expect that the telephone effect should impact peripheral categories such as *Duration* the most, whereas the opposite is the case. Analyzing the telephone effect from this perspective, we find that iterative summarization creates a "tunnel vision" effect, where less important information often moves to the fore when multiple summarization steps are involved.

The bright side of the telephone effect. Cascading summaries clearly have the disadvantage of propagating errors. However, they also have a potential advantage: given that one person did an excellent job at summarizing a text, it may be that the text they created is more straightforward for the next person to understand and thus to summarize. To determine the existence and strength of such a hypothetical positive effect, we proceed as follows. For each paper and each hop in the cascading setting, we consider only the summary whose source was the "best" of all summaries in the previous hop, where we consider the best summary to be the one with the largest number of *A*-labeled facts. We then compare the percentage of facts and keyphrases per fine-grained category between these summaries and the ones in the control setting as previously done. We show the values for this comparison for each fine-grained category as an upward triangle (△) in Fig. 5. Similarly, we also show the values for an analogous comparison where the source summary was the "worst" summary, depicted as a downward triangle (▽).

By inspecting facts labeled as *A*, we find that the "best-ancestor" scenario preserves facts better or similarly to the control setting (except for the *Conclusion/General* and *Intervention/General*category). This shows that a summary can, in fact, be a better reference text than the original abstract itself. A potential cause for this improvement might be that, although the telephone setting causes distortions, it also lowers the cognitive load, as summarizing jargon-filled 2000-character abstract is significantly harder than summarizing a 500-character text that was written by someone whose knowledge on the subject may be closer to one's own. On the other hand, the "worst-ancestor" scenario highlights the dangers of the telephone effect, where one sloppy summarization may distort the facts present in the text and harm subsequent summaries.

3.2 RQ2: Hop-to-hop information persistence

Next, we calculate the *conditional chance of survival* for keyphrases and facts across hops. That is, given that a fact or a keyphrase is present in a given hop k, what is the chance that it will also be present in hop $k+1$? In the case of keyphrases, for a given summarization process and category, we define the survival probability as the percentage of keyphrases that continue to exist in the summary, out of those that already exist in the reference text. For instance, if there are three keyphrases in the *Outcomes* category in hop 1, and two remain at hop 2, the probability of survival for this category from hop 1 to hop 2 is 2/3. In the case of facts, we consider the number of statements of a given category that are fully (fact value *A*) or partially (*B*) preserved in the source text and continue to be so in the resulting summary. The mean values along with a linear regression line for different categories can be seen in the first column

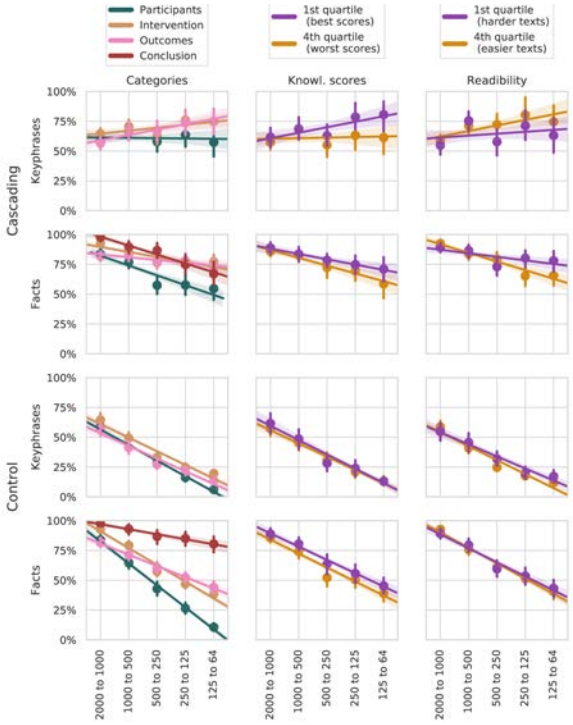

Figure 6: Probabilities of surviving one more hop for keyphrases/facts, alongside regression lines. Each row represents a combination of keyphrases/facts and a setting (cascading/control). In the first column, we compare the survival chance across different categories. In the other two, we compare it for different values of workers' questionnaire scores and of the readability index of the original abstract.

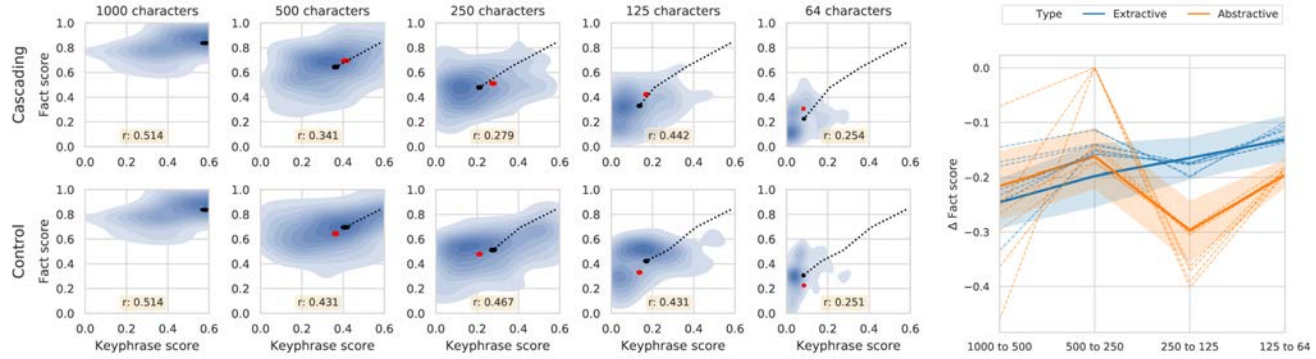
of Fig. 6. Interestingly, we observe that, while by construction the target length of texts decreases exponentially hop by hop, survival probabilities decrease or increase only linearly.

Cascading vs. control. We continue to inspect the first column of Fig. 6. The probability of survival of keyphrases increases for cascading summaries across hops for all coarse categories. This makes sense intuitively: if a keyphrase was selected for a summary, it is likely that it is relevant and thus will be selected again. In the control scenario, keyphrases always exist in the reference text (because it is the original abstract), so the probability of survival decreases as target lengths decrease. Analyzing facts, however, we find a significant difference between our experimental conditions: the probability of survival for facts in the control *and* cascading settings decreases across hops, implying that different dynamics govern distortions associated with lexical vs. semantic elements of a text. Whereas survival probabilities increase for keyphrases in cascading summaries, they decrease for facts. We conjecture that some salient keyphrases have an inherent "fitness" for survival, but that this is less true for abstract facts, which may be more or less salient, and thus "fit", in their concrete surface forms.



Categories. Moreover, we can also find differences in the dynamics of distortion across different categories. We observe that categories have different survival probabilities, especially for facts. For control summaries, the survival chance of *Conclusion* facts is higher than for the facts of other categories. Also, for *Conclusion*, the survival chance in cascading summaries is lower than for control summaries. This suggests that using the original abstract as a reference makes it more likely that the reader will understand the conclusion. Notice that this is different from what we observed in Sec. 3.1, as there, it could be the case that the conclusion prevailed in the control setting simply because it got lost in the cascade. Here we see that, even when the conclusion fact is present in a given summary in the cascading setting, it is less likely that it will survive.

Knowledge questionnaire. We consider the influence of the worker's knowledge questionnaire score (Sec. 2.2) on the level of distortion. At each hop, we rank the texts according to the score of the workers who summarized them on the questionnaire of the topic associated with the original abstract, and then compare the survival chance of facts and keyphrases of two extremes: the texts summarized by workers whose score is in the first quartile (who performed the best in the test) and the texts summarized by workers whose score is in the fourth quartile (who performed the worst). This is shown in the second column of Fig. 6. We use Chow's test [13] to assess whether the coefficients of the regression are significantly different, finding that, in the control setting, workers who scored better in the test lost significantly fewer facts than those who did poorly ($p < 0.01$). For cascading summaries, keyphrases survive more for workers that scored well in the text ($p < 0.05$), whereas the difference in the survival of facts is not significant. A hypothesis for this disparity is that in-depth knowledge on the subject is essential to read the original abstract (as in the control case), but that, once the text has been summarized by someone else (who may not possess that knowledge), the noise is already introduced, and the effect of the level of knowledge fades away.

Readability. We also consider the influence of the number of difficult words *in the original abstract* on the survival of facts and keyphrases. We order texts according to the percentage of words that *(i)* have more than one syllable and *(ii)* are not in a list of the most frequent English words (as done for readability metrics such as the Dale-Chall Readability Score [12]). We compare the cascades of the four most readable abstracts (first quartile) with the four least readable (fourth quartile). This is depicted in the third column of Fig. 6. We find a different effect to what we observed when inspecting the knowledge questionnaires: facts in more readable abstracts do not a have a significantly different of survival in any setting according to Chow's test. Keyphrases survive more for more readable abstracts in the cascading setting only ($p < 0.05$). Altogether, these results suggest that the telephone effect alters not only the facts and keyphrases of the summaries, but also how other factors influence the distortion processes over these facts and keyphrases.

3.3 RQ3: Extractive vs. abstractive strategies

Another aspect that may influence distortion effects in information cascades is the summarization strategy employed. Here we compare *abstractive* and *extractive* summarization strategies. To be able to do so, we have to distinguish abstractive and extractive summaries, as well as successful and unsuccessful ones. To this end, we define

(a) (b)

Figure 7: (a) Kernel density estimates of summaries according to their fact scores and keyphrase scores for different hops in cascading and control settings. Ellipses mark centroids (height and width: 95% CIs; black: experimental setting in question; red: other experimental setting). (b) Loss of fact score per summarization step for extractive vs. abstractive texts in the cascading setting. Lines correspond to multiple combinations of $\alpha \in [0.4, 0.7]$ and $\beta \in [0.0, 0.15]$ (95% CIs plotted for $\alpha = 0.3, \beta = 0.05$).

keyphrase scores and *fact scores* for each summary. The keyphrase score is defined as the percentage of keyphrases that the summary retained from the original abstract, whereas for fact scores we take a weighted average of the percentages of *A*- and *B*-valued facts retained from the original abstract (assigning weight 1 to *A*-valued facts and weight 0.5 to *B*-valued facts). With these definitions, we can plot summaries as points in a two-dimensional plane. We depict the kernel density estimate of these points in Fig. 7a. In this figure, we consider points with higher fact scores (y-axis) to be better summaries, and points with higher keyphrase scores (x-axis) to be more extractive. This way, the figure allows us to visually track the quality and extractiveness of summaries.

In each plot of Fig. 7a, we display a black ellipsis marking the centroid of the summary cloud (the height and width of the ellipsis represent 95% confidence intervals), and a red ellipsis marking the centroid for the other experimental setting. We also plot the hop-by-hop trajectory of the centroid as a dotted line. Notice the diagonal trajectory: summaries go from better and more extractive to worse and less extractive. Comparing the centroids for the cascading and the control settings, we also see that the centroid of the cascading setting always lies southwest of that of the control setting: cascading summaries are worse as well as less extractive.

In all scenarios, the fact scores are correlated with keyphrase scores (Pearson's r between 0.25 and 0.51), as can be seen in Fig. 7a. This makes it particularly hard for us to fairly assess summarization strategies, as it may be that the worst summaries are considered "abstractive" simply because they do not contain keyphrases (while also not containing the facts). Thus, our analysis has to condition the comparison in a way that we compare summaries that are similar in "goodness", but that differ in the level of extractiveness (which we capture using the defined scores).

We proceed as follows: for each hop and abstract in the cascading setting, we match summaries in pairs. Summaries are only matched if *(i)* the relative difference in their keyphrase score is *greater* than α and *(ii)* the relative difference in their fact score is *less* than β. We greedily match each summary once. Within each pair, we consider the summary with the higher keyphrase score to be more extractive (while of similar quality). We then compare how the fact score of each summary in the pair decreases with the subsequent summarization. The idea is that if extractive texts lose more of their fact score than abstractive texts, this is evidence that extractive summarization is less effective (and vice versa).

We show the results for each of summarization step in Fig. 7b for several values of α and β. The plot suggests that even when we account for the correlation between keyphrases and facts, we observe that extractive summaries are beneficial to latter hops, but similar in the first ones. In our data, thus, although abstracts were often full of jargon and technicalities, trying to change important lexical parts of the text (which we tagged as keyphrases) seems to be detrimental Our analysis here is limited as we are considering the survival of keyphrases to be a proxy for extractiveness, which may not necessarily hold in all cases.

4 DISCUSSION

4.1 Summary of findings and implications

In this paper, we propose an experimental framework for studying message distortion in information cascades and assess the diffusion of information from selected medical abstracts. Our analyses suggest that information cascades, as captured by iterative summarizations, distort the examined medical texts lexically and semantically. Facts and keyphrases frequently are not captured or even contradict the original text. The "telephone effect" impacts the most essential information the most, in particular the conclusion of abstracts. Overall, the content of the message after cascading summarization differs considerably from the content after direct summarization.

The telephone effect is, however, nuanced. Firstly, it is not necessarily bad: good summaries may serve as stepping stones toward better downstream summaries. Moreover, cascading summaries attenuate the impact of the complexity of the original text as well as the impact of users' topic-specific knowledge. Our findings suggest

that influential platforms or users may have a disparate impact on the quality of information being spread, resonating with the narrative that the rise of online social networks, where messages written by anyone can have far-reaching impact, has diminished the quality of the information [26].

We also investigated the success of abstractive vs. extractive summarization in information cascades. Even when accounting for the correlation between keyphrases and facts, we still find that extractive summarization performs better. This insight has implications on how scientists and the press should cooperate to convey research to the general public. Our findings suggest that scientific media coverage should make an effort not to distort the key terms with which authors use in their research.

Lastly, although keyphrases and facts are correlated, the conditional probability of survival of keyphrases increases hop by hop in information cascades, whereas it decreases for facts—a finding that should be taken into consideration when modeling the diffusion of information using keyphrases as proxies for associated facts.

4.2 Related work

Similar methodologies. Previous work has considered similar experimental settings to study distinct phenomena. Mesoudi and Whiten [38] propose a setting similar to our iterative cascades (among others) to study cultural transmission and evolution. Moussaïd et al. [40] use the equivalent of what we call a one-hop iterative cascade to study the propagation of risk information. A similar analysis of how textual content mutates was done in an observational setting by Adamic et al [3]. The researchers studied how memes evolve through Facebook analyzing the adaptation of textual features, as well as their impact on the propagation of the meme.

Word of mouth and customer behavior. Word of mouth is an important phenomenon driving customer behavior. Prior work has studied how the level of customer satisfaction impacts engagement in word-of-mouth information diffusion [4] and how effects of word of mouth together with other factors impact customer persuasion [24]. Word-of-mouth effects have also been analyzed in a networked framework to demonstrate different roles played by weak and strong social ties and the relational properties of homophily on referral behavior [23].

***Bona fide* vs. intentional information distortion.** Agents involved in word of mouth distort the information even given best intents. In contrast, a rich body of work seeks to detect, model, and prevent intentional message distortion, e.g., the dissemination of misinformation, and fake news [11, 33, 54]. Our experimental setting abstracts away from the complex social media landscape with heterogeneous agents including bots and trolls [16, 55], in order to understand the fundamental patterns that govern information distortion. On the middle ground between best intent and intentional distortion, media outlets distort information in more a more nuanced way [39]. In *agenda setting*, more attention is allocated to stories that fit a biased narrative, and in *framing*, the facts are more subtly distorted due to how they are presented.

Telephone and summarization effects. The telephone effect and the summarization effect have been studied from a linguistic standpoint. Breck and Cardie [8] note that facts, events, and opinions appearing in news articles are often known only second- or third-hand. Agents reporting them resort to using two kinds of expression that can filter information: perspective and speech expressions. They propose a learning approach that correctly determines the hierarchical structure of such information filtering expressions emerging due to the telephone effect. More recently, Gligorić et al. [18] found that length constraints cause Twitter users to summarize their content. This process significantly alters linguistic aspects of the text, such as the use of abbreviations, contracted forms, and articles.

Science communication. Media coverage of science has been investigated by communication research. The focus of the field is on scientists' attitude towards the media and on patterns of interactions with journalists and other key players such as news organizations and science information professionals [47, 56]. Evidence suggests that most scientists consider visibility in the media important and responding to journalists a professional attitude that is reinforced by universities and other science organizations. Exaggeration in the news is strongly associated with exaggeration in press releases, and improving the accuracy of academic press releases could represent a key opportunity for reducing misleading health-related news [53].

Summarization and paraphrasing. Finally, the summarization task at the heart of our experimental design is tightly related to the classic natural language processing tasks of paraphrasing [28, 49, 57] and summarization [37, 43]. Prior research introduced the distinction between abstractive and extractive summarization approaches upon which we rely in some of our analyses [27].

4.3 Limitations and future work

Our experimental setup allows us to finely measure and characterize message distortion effects, which would be difficult in observational setups. Still, it remains unclear to what extent our findings generalize to a wider spectrum of real-world information cascades, where three important distinctions are likely to have an impact: *(i)* the sequence-of-laypeople mechanism used here may differ from the way information diffuses in the real world; *(ii)* different kinds of information (e.g., news) may be subject to different dynamics; *(iii)* the assumed *bona fide* scenario may not hold in all cases.

Future work will face the challenge of tracking message distortion in real-world cascades (such as the one described in Sec. 1). By taking advantage of methods and insights developed in this paper, we plan to establish the extent to which our findings reflect the complex universe of social media, thus removing the *bona fide* assumption. Moreover, we will explore whether the observed effects can be modeled mathematically to predict which lexical and semantic units of a text that are likely to be distorted.

ABSTRACT

The text snippets presented in web search results provide users with a slice of page content that they can quickly scan to help inform their click decisions. However, little is known about how these snippets are generated or how they relate to a user's search query. Motivated by the growing body of evidence suggesting that search engine rankings can influence undecided voters, we conducted an algorithm audit of the political partisanship of Google Search snippets relative to the webpages they are extracted from. To accomplish this, we constructed lexicon of partisan cues to measure partisanship and construct a set of left- and right-leaning search queries. Then, we collected a large dataset of Search Engine Results Pages (SERPs) by running our partisan queries and their autocomplete suggestions on Google Search. After using our lexicon to score the machine-coded partisanship of snippets and webpages, we found that Google Search's snippets generally amplify partisanship, and that this effect is robust across different types of webpages, query topics, and partisan (left- and right-leaning) queries.

1 INTRODUCTION

Search engines are one of, if not the most important tool used by people seeking information on the web. Surveys have repeatedly found that people reach for search engines first when they have online information needs [18] and that this happens on a daily basis [19]. These observations are especially true with respect to breaking news, where people report getting news from search engines even more frequently than social media [51, 54]. Surveys and ethnographic studies have also observed that search engines are specifically used for "fact-checking," possibly because search engines are viewed as neutral and trusted sources of information [4, 18, 19, 30, 55, 65].

When conceptualizing the role of search engines in information seeking, it is critical to recognize that they are no longer just intermediaries that transfer users from queries to websites via "10 blue links" [46]. Instead, modern search engines are rich media platforms unto themselves, often presenting links to third-party websites alongside images, videos, maps, algorithmically curated "knowledge," and social media posts [58]. This additional control over how information is presented — beyond ranking and filtering — can further increase the capacity of search engines to shape users' behavior and preferences. For example, recent studies have found that different types of queries often return different types of results, and these different result types (e.g., embedded Twitter results) can surface partisan or low-quality links in highly ranked positions [16, 57, 58].

One particularly important feature found on modern Search Engine Result Pages (SERPs) are *search snippets*. Snippets appear below links to webpages and provide a brief summary of the content of the given page. These summaries provide users with additional context about a webpage, beyond what can be gleaned from their title. Originally, snippets were drawn from HTML `meta description` tags embedded in webpages. Over time, however, search engines have incorporated *document summarization algorithms* [64] to dynamically produce snippets for pages that lack meta-data, as well as combat intentionally misleading meta-data [24, 28, 63].

Snippets are a critical — and, we argue, under-scrutinized — facet of modern search engines. *First*, snippets have a direct influence on the links that users choose to visit. For example, an inaccurate or misleading snippet may cause a user to select a different link. *Second*, even if a user does not click a given link (or *any* of the links on a SERP), they may still read and be influenced by the snippets. In much the same way people scan the titles and opening paragraphs of newspaper articles [25, 27], users may scan the titles and snippets of webpages in a SERP.

In this study, we present the first analysis of *partisan cues* in snippets on Google Search. We define partisan cues as words or phrases that are disproportionately used by a specific political group to signal group membership and frame specific issues. For example, we observe that the phrases "gun rights" and "gun violence" are used by right- and left-leaning US politicians, respectively, to

https://doi.org/10.1145/3308558.3313654

engage with their fellow partisans and frame the gun control debate. We focus on partisan cues in SERPs returned for political queries because (1) news-seeking and fact-checking are common and socially-important use cases for Google Search, and (2) behavioral experiments have shown that the political valence of search rankings can have dramatic real-world impacts on voting behavior [22, 23].

To implement our study, we trained a lexicon of partisan unigrams and bigrams drawn from speeches given by US politicians using Natural Language Processing (NLP) techniques [26]. This lexicon serves two purposes. *First*, we manually curated a subset of the bigrams to use as queries on Google Search. In total, we chose 1,050 right- and left-leaning terms, as well as 3,520 names of US politicians, to use as queries. We queried Google Search for these terms and all of their *autocomplete* suggestions between October 13–30, 2018, ultimately producing a dataset of 88,745 SERPs and 541,437 unique webpages that were linked from the SERPs. *Second*, we used the lexicon to score the partisanship of text in our dataset from left- (-1) to right-leaning (1). We then compared the partisanship score of each snippet to the score of the webpage it was drawn from to understand whether Google Search is amplifying, dampening, or even inverting the incidence of partisan cues in snippet text relative to the original document.

Our study makes the following contributions and observations:

- We present the first large-scale analysis of machine-coded partisanship in Google Search snippets, covering 4,570 political queries and their autocomplete suggestions.
- We audit the behavior of Google Search's document summarization algorithm, and find that snippets tend to be drawn from text that is near the beginning of webpages. We further observe that the algorithm leverages visible text and textual meta-data (such as alt-text on images) from webpages.
- Overall, we find that 54–58% of snippets amplify partisanship, depending on the fraction of our lexicon that is used for scoring, i.e., the snippets contain stronger partisan cues on average than the corresponding webpage they were synthesized from. This finding remains consistent across SERPs from left- and right-leaning queries and pages with and without structured meta-data that may influence Google Search's document summarization algorithm [28, 29].
- Surprisingly, we find that 19–24% of snippets have inverse partisanship than the corresponding webpage.
- We identify 31 websites where Google Search consistently produces snippets that differ from the underlying webpages in terms of the machine-coded partisanship, with high statistical significance. These websites include prominent news and social media services.

We believe that it is highly unlikely that Google has intentionally engineered their document summarization algorithm to amplify partisan cues. Instead, a more likely explanation for our findings is that journalistic practice encourages the use of partisan terms and quotes from partisan politicians in the introduction (and meta-data) of articles, which are also the types of text favored by the summarization algorithm. We hope this study will foster additional research and public debate about the role of search snippets in web search, and foster the development of document summarization algorithms that are intentionally designed to align with societal expectations and democratic norms.

Outline. Our study is organized as follows: in § 2 we motivate our study and survey related work. In § 3 we introduce our datasets and partisan scoring metrics. We analyze our dataset in § 4 and conclude with limitations and discussion in § 5.

2 BACKGROUND AND RELATED WORK

Snippets are a ubiquitous and important feature on modern search engines like Google Search. The goal of snippets is to help users assess the relevance of linked documents without having to click through each one [64, 67]. Snippets appear below links in SERPs and typically show one to three lines of text summarizing the linked document. The sentences or fragments that compose a given snippet may be extracted from different parts of source document, including visible text and invisible meta-data such as the HTML `meta description` tag, alt-text on HTML `img` tags, and various Microformat and Microdata structured meta-data languages [28, 29]. Search engines often generate snippets dynamically at query-time to select document text that is relevant to the current user's query [3, 64].

Document Summarization. Automated snippet generation is a variant of extractive summarization (in contrast to abstractive summarization [10]) that has been actively researched for decades. The earliest text summarization algorithms relied on word frequency distributions [45], sentence location [21], and per-sentence scoring techniques [52] to select text for the summary. In 1998, methods that tailored summaries to specific queries were invented [64], which continue to influence the design of modern search engines [5, 68]. More recent research has used machine learning [36, 69] and neural network-based methods [11, 50] to achieve better summarization performance.

Studying Web Search Engines. Prior work has examined various qualitative aspects of snippets. There are studies on whether the length of snippets impact user experience and the informativeness of search results [13, 38], as well as how snippet length should be customized for mobile web search [37]. Collins-Thompson et al. studied the relationship between user experience and the reading levels, and found that dwell-time improved when the reading level of the snippet matched the underlying document [12]. In our context, this suggests that user satisfaction may be maximized when the partisan cues in a snippet accurately reflect the partisanship of the corresponding document.

To our knowledge, no prior studies have examined the partisanship of snippets. Although there are several studies that have *audited* [15, 59] Google Search, the focus of these studies has been examining how Google Search's personalization algorithm impacts the links that appear in SERPs [32, 39, 58], or the partisanship of links in SERPs [16, 57].

The Impact of Snippets. Our study of partisan cues in snippets is motivated by work that examined how people read and interpret the news. *First*, studies have shown that people often do not read news articles in full; instead, they scan the headlines [25, 27]. Eye-tracking studies suggest that the same behavior is true with respect

to snippets, since they attract a major portion of users' attention when they browse SERPs [13, 31], but ultimately users may only click a single link (if any) to view in full. *Second*, news headlines have the power to shape users' perceptions of stories, even if they read the full articles [20, 25]. We hypothesize that the same effect may be true of snippets: the partisan cues highlighted in a snippet may influence users' perceptions of the linked document even if it has a different partisan slant. Furthermore, in cases where a user does not click any links on a SERP, partisan cues in the snippets may still influence the user's perception of the query term itself.

Scoring Partisanship. Identifying ideological bias in text is difficult and many methods have been proposed to address it. Studies on political communication have revealed that subtle differences in word choice can signal an ideological leaning [9, 17, 35]. For example, US Republicans say "death tax" while Democrats say "estate tax," and there are no ideologically neutral alternative phrases [41].

Early approaches to political text analysis typically used human raters to manually code political statements [7, 8, 40] or relied on manually constructed dictionaries of terms to automatically label statements [14, 33, 34, 43, 53, 61, 62]. In this study, we leverage NLP techniques that automatically generate lexicons of partisan terms using politician's public speeches as a convenient, voluminous, and well-labeled (i.e., because the partisanship of the speaker can be determined based on their party affiliation and voting record) training dataset [26, 60]. These techniques obviate the need for tedious human labeling. Using the lexicons, the *machine-coded* partisanship of a document can be quantified by looking at the number and strength of polarized terms in the document [42, 44].

Unlike prior work on partisanship of SERPs, our goal is to examine the partisanship of text rather than of web domains [16, 57]. Thus, existing datasets that score the partisanship of web domains are not pertinent to our study [1, 2, 6, 49, 56].

3 DATASET AND METHODOLOGY

In this section, we present the datasets and methods that we use in our study. *First*, we introduce our lexicon of partisan unigrams and bigrams, including the raw data and methods we used to construct it. We use this lexicon to inform our selection of queries on Google Search, as well as score the partisanship of text. *Second*, we explain the process we used to select queries for Google Search, crawl SERPs and webpages, and extract data from these web documents. *Third*, we present our metrics for computing partisanship and comparing the partisanship between snippets and webpages.

3.1 Lexicon Construction

The basis for our study is a lexicon of unigrams and bigrams[1] that represent *partisan cues*, i.e., each phrase is primarily used by partisan people with a specific ideological stance. We use this lexicon for two purposes: to select ideological queries for Google Search (see § 3.2) and to score the partisanship of text (see § 3.3).

We use a method developed by Gentzkow and Shapiro to construct our lexicon [26]. In brief, this method counts the frequency of n-grams in documents that have reliable partisan labels (e.g., right and left), and then scores each n-gram based on the relative, normalized frequency of its use by individuals on each side of the partisan divide.

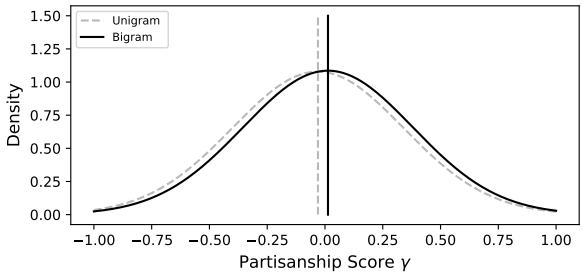

Figure 1: Distribution of partisanship scores γ of unigrams and bigrams in our Vote Smart lexicon.

For our study, we crawled a corpus of documents from votesmart.org, which is a website that catalogues information about politicians, on August 11, 2018. We chose Vote Smart because prior work has shown that its data is useful for understanding politicized language [66]. Specifically, we gathered transcripts of speeches and letters from 20 Democrats and 19 Republicans, including Donald Trump, Hillary Clinton, all congressional leaders from the US House and Senate, and several other prominent US congressional representatives. We selected this set of politicians because they generate a large volume of documents due to their public presence, and as leaders they tend to set the agendas for their respective parties.

Before constructing our lexicon, we balanced and cleaned the corpus. *First*, we chose to use documents dated between January 2008 and August 2018, as this covered the current and former US presidential administrations. We found that using older documents polluted the final lexicon with phrases and issues that were no longer salient in 2018, meaning they did not return relevant results when queried on Google Search. *Second*, we randomly downsampled the documents each year to ensure that each side had an equal number of total documents. *Third*, we cleaned (e.g., case-folding, lemmatization, etc.) and tokenized the corpus using NLTK.[2]

Next, we extracted all unigrams and bigrams from the cleaned corpus and scored them. We computed the probability of each unigram and bigram g appearing in Republican- and Democrat-authored text as $Pr_R(g)$ and $\Pr_D(g)$, respectively. We then computed the partisan bias γ of each g as

$$\gamma(g) = \frac{Pr_R(g) - Pr_D(g)}{Pr_R(g) + Pr_D(g)}. \quad (1)$$

γ scores range from $[-1, 1]$, with 1 (-1) indicating that a phrase is used exclusively by Republicans (Democrats).

Finally, we obtained our lexicon by filtering out unigrams and bigrams that appear <50 times, as these are unlikely to be recognized by people as partisan. After filtering, our lexicon contains 69,901 total terms, with 13,464 unigrams and 56,437 bigrams. Example terms and their scores include: "LGBT" (-0.92), "climate crisis" (-0.91), "equal pay" (-0.90), "gun safety" (-0.85), "burdensome regulation"

[1] We do not consider n-grams with $n > 2$ in this study because we believe that the majority of commonly used partisan cues can be expressed in one or two words.

Medicare	raid medicare, medicare trustee, care entitlement, higher copays, medicare advantage, medicaid patient, medicare negotiate, affordable child, cost prescription, cut medicaid, improve affordable, benefit affordable
LGBT	lgbt rights, lgbt american, gay bisexual, lesbian gay, lgbt people, lgbt individual, lgbt community, discrimination lgbt
Obamacare	obamacare mandate, obamacare premium, obamacare plan, problem obamacare, failure obamacare, obamacare employer, obamacare break, obamacare disaster

(0.81), "illegal immigrant" (0.86), "bureaucrat" (0.89), "obamacare" (0.91), and "death tax" (0.98).

Figure 1 shows the score distribution for terms in the lexicon. As expected, the scores are normally distributed, with most terms having low partisanship. The mean score for unigrams and bigrams are -0.03 and 0.01, respectively, demonstrating that the final lexicon is well-balanced.

3.2 Data Collection and Extraction

The next step in our methodology is constructing a dataset of snippets from Google Search SERPs along with the corresponding webpages. Constructing this dataset involved choosing the queries for Google Search, crawling, and finally extracting data from the resulting webpages.

Query Selection. Our ultimate goal in this study is to compare the prevalence of partisan cues in Google Search snippets to their corresponding webpages. To achieve this, we need a large sample of politically-relevant SERPs from Google Search, which necessitates having a set of politically-relevant queries.

We built our set of *root queries* from two sources: (1) the names of US politicians and (2) partisan bigrams from our lexicon. For the former, we gathered the names of 3,520 US politicians, including prominent members of the current and former presidential administrations, members of the US House and Senate, and state governors. For the latter, we had two independent human labelers[3] examine all bigrams in the lexicon with scores < -0.5 or > 0.5 and manually curate terms that were specific enough to be valid queries on Google Search. For example, the bigrams "spend percentage" and "defend proud" both have a score of 1 in the lexicon (i.e., exclusive use by Republicans), but the labelers felt that these bigrams (and others like them) were not useful as queries, since they were unlikely to return results that linked to news and political webpages. Additionally, the labelers expanded bigrams in cases where additional words were necessary to transform them into valid queries. For example, the labelers expanded the bigrams "sanctity life" and "operation choke" (both with a score of 1) to "sanctity of life" and "operation choke point". Because this labeling task is highly subjective, we accepted all of the labelers' suggestions and then randomly downsampled to produce an ideologically balanced set of 1,050 partisan queries.

Clustering. To facilitate analysis of how partisan cues vary by topic, we clustered the 1,050 partisan root queries using a word-embedding technique [48]. Specifically, we used the pre-trained word vector *wiki-news-300d-1M.vec* [47] to map each root query into a vector space. Then we averaged the vectors corresponding to the words in each root query and clustered the mean vectors using k-means. The authors manually examined all 41 resulting clusters and selected 24 that were well-formed, i.e., all of the included root queries were related to a single, well-defined topic. Table 1 shows a subset of these topical clusters and the queries they contained.

Crawling and Query Expansion. We queried Google Search for all 4,570 root queries between October 13–30, 2018. We also queried Google Search for all of the *autocomplete suggestions* for each root query. This is a useful technique for expanding our root queries because the suggestions are drawn from real user queries, i.e., the suggestions provide a window into an more ecologically-valid sample of queries [57, 58]. Although some of the autocomplete suggestions may not be politically-relevant, the corresponding SERPs have minimal impact our analysis because they typically do not contain terms from our lexicon. In total, we ran 88,745 queries and collected an equal number of SERPs from Google Search.

Data Extraction. Since our focus is on the relationship between search snippets and webpage content, we parsed all of the SERPs in our dataset to retrieve snippets and their associated webpage links. We filtered out links in the SERPs that did not have snippets, linked to back to *.google.com, or were part of a non-standard *component* (e.g., maps, videos, images, etc.) [57, 58]. Next, we crawled all the links. Finally, for each (snippet, webpage) tuple, we filtered out cases were the webpage contained <300 characters, which removed 114,020 tuples from our dataset. Ultimately, our dataset contained 820,795 (snippet, webpage) tuples.

In most of our analysis in § 4 we focus on the *page text* in webpages. We define page text as the string content that exists between HTML tags in the body of the HTML document. Page

[3]Both labelers were US citizens by birth and were familiar with US politics.

Table 2: Lexicon size and number of (snippet, webpage) pairs that are scorable under different thresholds.

Threshold	Unigrams	Bigrams	Scorable Pairs Count	Scorable Pairs %
5%	638	2692	43311	5.28
10%	1276	5378	137067	16.70
15%	1914	8076	272745	33.23

text excludes everything in the document head, HTML tags, tag attributes, JavaScript, and Cascading Style Sheets.

3.3 Scoring Snippets and Webpages

The next step in our methodology is computing a partisan bias score for each snippet and webpage using our lexicon. Let U and B be the sets of unigrams and bigrams in our lexicon, and $\gamma(g)$ is the partisan score of n-gram g. For a given sample of text (either a snippet or webpage) produced in response to a given query, we compute its partisan bias score Γ using the following steps:

(1) Use NLTK to clean and tokenize the text and the query, producing lists of tokens T and Q, respectively.
(2) Compute $T' = \{\forall t \in T \mid t \notin Q\}$, i.e., remove all of the tokens $q \in Q$ from T. This step ensures fairness: 1,050 of our queries are explicitly partisan, and query terms are highly likely to appear in the corresponding snippets and webpages. It would be unfair to explicitly query for partisan words then use those same words to score the resulting samples.
(3) Compute $S_B = \{\forall t \in T' \mid t \in B\}$, i.e., the list of bigrams in T'. Compute $S_U = \{\forall t \in (T' - S_B) \mid t \in U\}$, i.e., list of unigrams in T' after the bigrams have been removed (to avoid double counting cases where unigrams and bigrams have overlapping words). Compute $S = S_B \uplus S_U$. This process prioritizes bigrams over unigrams since the former tend to have stronger semantic meanings [60].
(4) Compute the partisan bias score Γ of S as

$$\Gamma(S) = \frac{\sum_{s \in S} \gamma(s)}{|S|}, \tag{2}$$

i.e., the mean bias score of all n-grams found in T'.

Γ scores range from $[-1, 1]$, with -1 (1) indicating that the partisan cues in the snippet or webpage lean heavily to the left (right).

Note that we have intentionally chosen to normalize Γ scores using the total number of partisan queues in the text, rather than the total number of tokens in the text. We chose this formulation because webpage text tends to be orders of magnitude longer than snippet text. If we normalized by the number of tokens, then webpages would be guaranteed to have much lower scores than snippets, and thus it would not be reasonable to compare the scores for a snippet and the corresponding webpage.

Relative Bias Scores. In most of the analysis in § 4, our focus is on comparing the Γ scores of (snippet, webpage) pairs. To compare the magnitude and direction of the two Γ scores, we defined a *relative political bias score* Δ computed as

$$\Delta(\Gamma_s, \Gamma_w) = \begin{cases} \Gamma_s - \Gamma_w & \text{if } \Gamma_w \geq 0 \\ \Gamma_w - \Gamma_s & \text{if } \Gamma_w < 0 \end{cases} \tag{3}$$

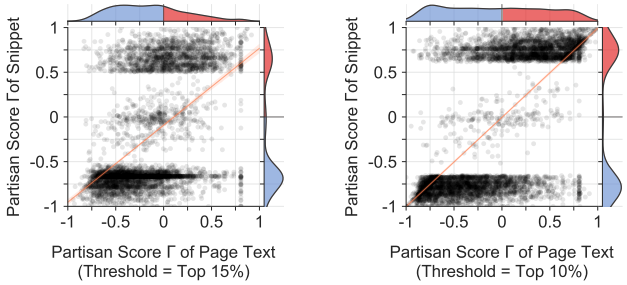

Figure 2: Partisan scores Γ of (snippet, webpage) pairs under the top 15% and top 10% lexicon thresholds.

where Γ_s and Γ_w are the Γ scores of the snippet and webpage, respectively. Δ scores exist in the range $[-2, 1]$, with three distinct subranges that have different interpretations.

- $[0, 1]$: Δ scores in this range indicate that the snippet had more partisan cues than the webpage, thus we say that the snippet *amplified* partisan bias.
- $[-2, -1]$: Δ scores in this range indicate that the snippet and webpage had opposite polarity (i.e., one was right-leaning and the other left-leaning, or vice versa), thus we say that the snippet *flipped* the partisan bias.
- $[-1, 0]$: Δ scores in this range are ambiguous. They could indicate that the snippet had fewer partisan cues than the webpage, thus the snippet *decreased* partisan bias, or they could indicate that the snippet flipped the partisan bias.

In § 4, we present both the distribution of Δ scores, as well as the percentage of cases where snippets amplified, decreased, or flipped partisan bias, to resolve ambiguity. Furthermore, to be conservative in our analysis, we also interpret Δ scores in the range $[-0.1, 0.1]$ as *unchanged*, i.e., the snippet and webpage had sufficiently similar Γ scores that a person is unlikely to notice substantive differences between their use of partisan cues.

Thresholding the Lexicon. As shown in Figure 1, the vast majority of terms in our lexicon have low γ scores, i.e., they are not strongly partisan, and are unlikely to be recognized as partisan by a human being. Since we are only interested in strongly partisan cues, we chose three thresholds $x = [5\%, 10\%, 15\%]$ to prune our lexicon. For threshold x, we select the top x left-leaning and top x right-leaning n-grams in the lexicon.

Table 2 shows the number of unigrams and bigrams that remain in the lexicon after thresholding, as well as the the number and percentage of all (snippet, webpage) pairs that are scorable at a given threshold. We say that a (snippet, webpage) pair is not scorable if Γ is undefined for either, i.e., the snippet or the webpage contains zero n-grams from the given lexicon once the words in the query itself are removed.

As expected, Table 2 shows that the percentage of our dataset that is scorable shrinks rapidly as the threshold becomes stricter. In § 4, we only analyze the datasets at the 10% and 15% thresholds because the scorable sample at 5% is too small.

4 ANALYSIS

In this section, we present our analysis comparing the partisan cues in snippets and the corresponding webpages. Throughout our analysis, we use relative political bias Δ scores to compare the partisanship of (snippet, webpage) pairs, and we present results derived from two lexicons containing the top 15% and 10% of partisan terms from our Vote Smart lexicon (see § 3.3). We begin by examining the overall distribution of Δ scores, and then examine various subsets of our full dataset to determine if Δ scores vary by search query, website, and webpage structure.

4.1 Overall Results

Figure 2 shows the Γ scores for each (snippet, webpage) pair in our dataset under the 15% and 10% lexicon thresholds. As expected, the distribution of scores for snippets is strongly bimodal because the average snippet only includes 1–2 partisan cues and they are likely to share the same polarity (e.g., both lean right or both lean left). In contrast, the distribution of scores for webpages is more evenly distributed, since the average webpage contains 30–52 partisan cues depending on the lexicon threshold. The Spearman rank correlation between the snippet's and webpage's Γ scores reveal moderate correlation with coefficients 0.50 and 0.63 at $p < 0.001$ for the top 15% and top 10% lexicon thresholds, respectively.

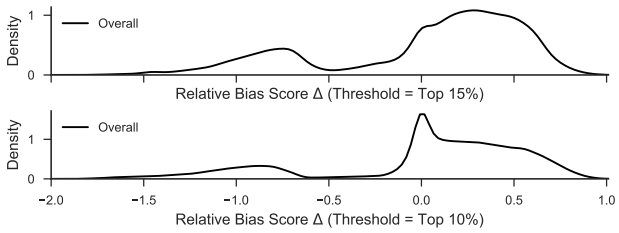

Figure 3a shows the distribution of Δ scores calculated over our entire dataset of (snippet, webpage) pairs under the top 15% and top 10% lexicons. The distributions have similar, bimodal shape regardless of lexicon: the bulk of the volume is in the $[0, 1]$ range, indicating that the snippets have stronger partisan cues than the corresponding webpages. The remaining volume tends to fall in the $[-1.5, -0.5]$, indicating snippets that either (1) have weaker partisan cues than the corresponding webpage or (2) have opposite partisan cues than the corresponding webpage (i.e., the political polarity has flipped).

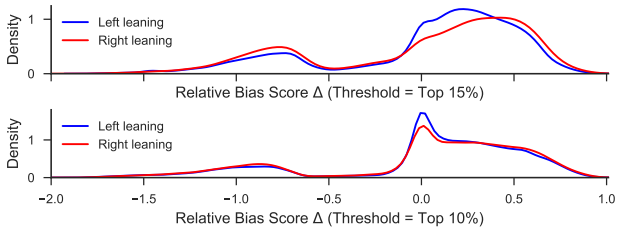
The "Overall" bar in Figure 4 presents the fractions of (snippet, website) pairs where the snippet *amplified*, *decreased*, *flipped*, or had *unchanged* partisanship relative to the corresponding webpage. Recall that we conservatively consider Δ scores in the range $[-0.1, 0.1]$ to be unchanged, since the relative difference in partisanship between the snippet and webpage are unlikely to be noticeable in practice. We observe that 54–58% of snippets amplified partisan cues, depending on the lexicon threshold. Cases where polarity flipped account for 19–24% of the total, while cases where the snippet had weaker partisan cues only account for 3–4% of the total.



4.2 By Location

The overall results in § 4.1 surprised us: they suggest that Google Search's document summarization algorithm constructs snippets that consistently amplify partisanship. To investigate why this might be the case, we examine where Google's algorithm tends to extract snippets from in webpages, and whether this relates to the use of partisan cues.

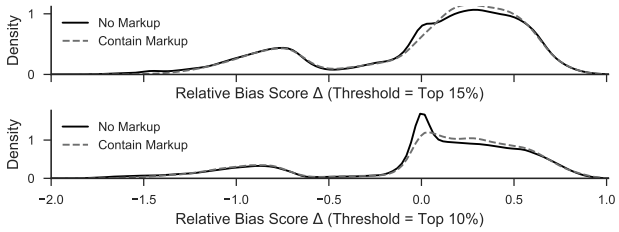


Figure 5 shows the distribution of locations within webpages that snippets were extracted from in our dataset. We split the analysis between snippets that were extracted entirely from one location, and snippets that were composed of several pieces that were extract

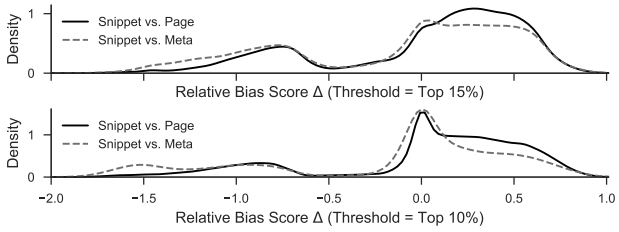

(a) All (snippet, webpage) pairs

(b) Split by query polarity

(c) Split by webpages with and without structured meta-data

(d) Snippets compared to webpage text and meta-data

Figure 3: Distribution of relative political bias scores Δ under the top 15% and top 10% lexicon thresholds. We present the overall score distribution, as well as distributions where the (snippet, webpage) pairs are split by various criteria.

from different locations in the webpage[4]. We observe that the algorithm has a strong preference for text that is earlier in documents. This may interact poorly with the "inverted pyramid" journalism

[4]In this analysis, we ignore snippets that were extracted entirely from webpage meta-data

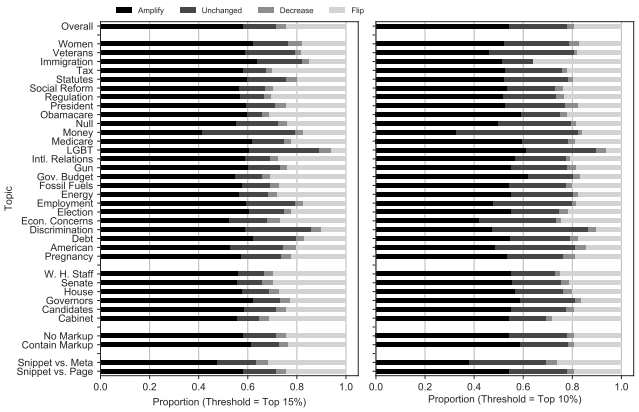

Figure 4: Fraction of cases where the snippet amplified, decreased, flipped, or had unchanged partisanship relative to the corresponding webpage. We present stacked bars for all (snippet, webpage) pairs, pairs within various query topics, pairs with webpages containing and not containing structured meta-data as well as snippets versus meta-data and versus the page text. We present results under the top 15% and top 10% lexicon thresholds.

format, which places the most specific language and jargon at the head of the story.

To further investigate the relationship between snippet location and partisanship, we calculated Δ scores between snippets and subsets of text from the corresponding webpage, where each subset contains the initial f percentage of page text. We show these results in Figure 6, varying f from 5% to 100% of the webpage text. We find that the fraction of cases where the snippet amplified the machine-coded partisanship increases as we consider larger percentages of webpage text, while the fraction of unchanged cases decreases precipitously. This suggests that either: (1) highly partisan terms at the beginning of the page, which get selected by the summarization algorithm, are eventually averaged out by less partisan terms later in the page, or (2) partisan terms of one polarity at the beginning of the page are counteracted by terms with opposite polarity later in the page. Either way, the choice to algorithmically privilege specific text snippets often leads to a mismatch between the machine-coded partisanship of the snippet versus the entire document.

4.3 By Root Query

Next, we examine how Δ scores vary by root query. To make our analysis tractable (recall that we ran 88,745 queries on Google Search), we clustered our root queries by (1) topic (see § 3.2 and Table 1) in the case of partisan phrases, and (2) job in the case of politician's names (e.g., US Senator, state governor, etc.). In total, we examine 24 topical clusters of partisan phrases and 6 clusters of politicians. Additionally, we aggregate each root query together with its associated autocomplete suggestions.

Figure 4 shows the breakdown of (snippet, webpage) relationships for different clusters of root queries. With few exceptions, the individual clusters tend to exhibit the same characteristics as the overall dataset. Notable exceptions include: the "Money" topic has

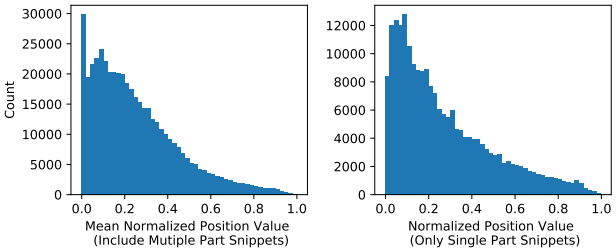

Figure 5: Distribution of the positions in webpages that snippets were extracted from, normalized over the total webpage length.

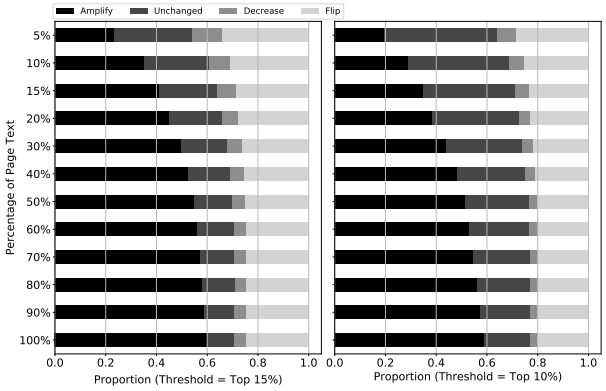

Figure 6: Fraction of cases where the snippet amplified, decreased, flipped, or had unchanged partisanship relative to subsets of text from the corresponding webpage, always starting from the top of the page. We present results under the top 15% and top 10% lexicon thresholds.

the lowest fraction of amplifying (33–41%) and highest fraction of unchanged (38–50%) snippets; under the 15% threshold, the "Immigration" and "Obamacare" topics have the largest fractions of amplifying (64%) and flipped (31%) snippets, respectively; under the 10% threshold, the "Government Budgeting" and "Immigration" topics have the largest fractions of amplifying (62%) and flipped (34%) snippets, respectively.

4.4 By Query Polarity

Next, we examine how Δ scores vary by query polarity. Specifically, we take our clusters of the root queries and divide them into left- and right-leaning queries. For partisan phrases, this is done using their γ score (see § 3.1); for politician's names, this is done using their party affiliation. Note that for this analysis, we omit six topical clusters that only contained root queries of one polarity (e.g., "LGBT", see Table 1).

Figure 3b shows the distribution of Δ scores for (snippet, webpage) pairs, split between left- and right-leaning queries. The distributions exhibit roughly the same bimodal patterns as the overall

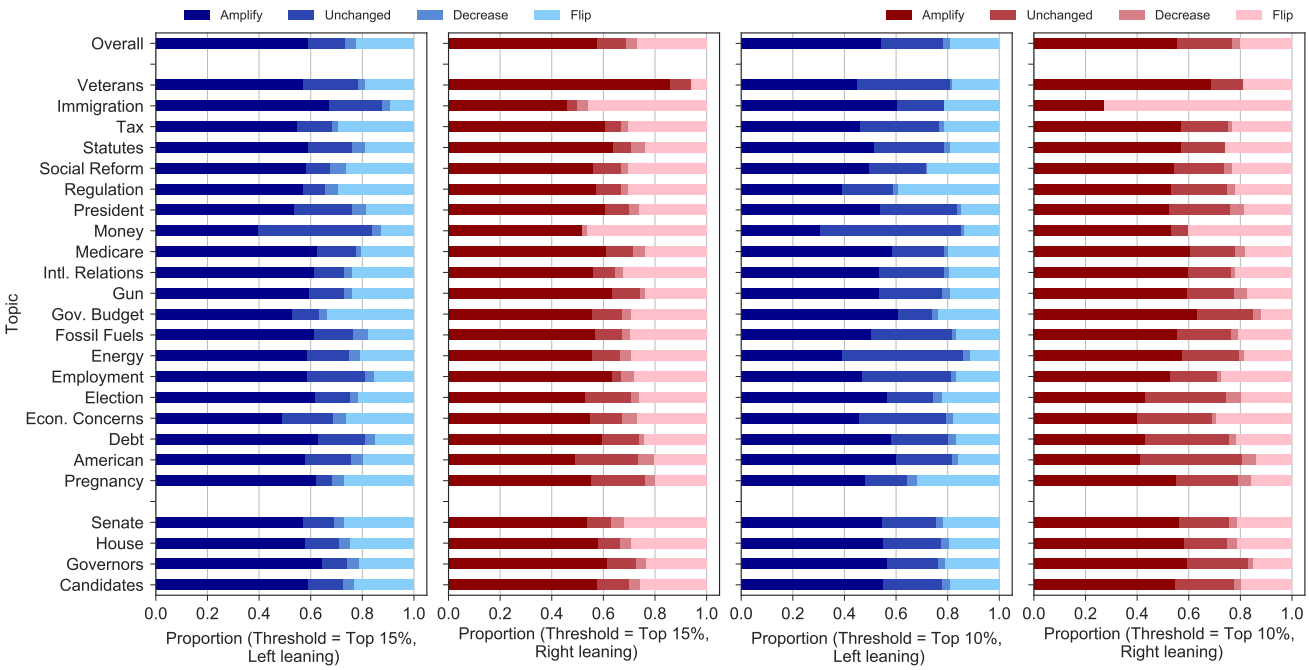

Figure 7: Fraction of cases where the snippet amplified, decreased, flipped, or had unchanged partisanship relative to the corresponding webpage, split by query polarity. We present stacked bars for all (snippet, webpage) pairs and pairs within various query topics. We present results under the top 15% and top 10% lexicon thresholds.

distributions shown in Figure 3a. With respect to each other, we used the Kolmogorov-Smirnov test to compare the left- and right-leaning distributions under each lexicon threshold, respectively, and found that they are significantly different (top 15%: $D = 0.06^{***}$; top 10%: $D = 0.03^{***}$). However, the differences between the means of the distributions are very small (top 15%: 0.02; top 10%: 0.004), meaning that the differences in the distributions have little substantive impact.

Figure 7 shows the fractions of (snippet, webpage) relationships broken down by root query and query polarity, and under different lexicon thresholds. The "Overall" bars show that left- and right-leaning queries behave similarly: 54–59% of snippets from left-leaning queries amplify partisan cues, versus 55–58% of snippets from right-leaning queries; 19–22% of snippets from left-leaning queries flip polarity, versus 20–27% of snippets from right-leaning queries. However, as we previously observed there are exceptions. For example, in the "Immigration" topic, snippets in SERPs generated by left-leaning queries amplify partisan cues 61–67% of the time, versus 27–46% of the time for right-leaning queries. Similarly, in the "Money" topic, snippets generated by left-leaning queries amplify partisan cues 30–40% of the time, versus 52–53% of the time for right-leaning queries.

4.5 By Website

Next, we analyze how Δ scores vary by website, i.e., we group the (snippet, webpage) pairs by the domain hosting the webpage. For each website that had a sample size >100, we use the Wilcoxon V signed-rank test to compare the snippets' Γ scores and webpages' Γ scores, and further applied a Boneferroni correction for multiple hypothesis testings. For the top 15% lexicon we tested 235 websites, versus 113 for the 10% threshold. Ultimately, there were 31 domains whose snippets' Γ scores were significantly different from its webpages' Γ scores under both of the lexicon thresholds. We highlight these websites in Table 3, along with the count of (snippet, webpage) pairs for each websites. We organize the websites by type, including twelve news sites, seven political websites, three social media websites, and three law-related websites. We could not categorize the last six websites.

The results in Table 3 demonstrate that there are particular websites where Google Search's summarization algorithm consistently derives snippets with different machine-coded partisanship than the webpage text. This is unsurprising in the case of social media websites, since each page may contain political content from different people, and thus a single snippet may not capture all of their views. The results are more surprising in the case of news and political websites. It is difficult to say whether these findings are caused by (1) some unanticipated, but consistent, interaction between the content or formatting on these websites and Google Search's summarization algorithm, or (2) whether this reflects an intentional effort by the authors of these websites to "optimize" their appearance on Google Search by highlighting partisan cues.

4.6 By Structured Meta-data

According to Google's documentation, its snippet generation algorithm may leverage structured meta-data from within a webpage when summarizing it [28, 29]. This meta-data can be as simple as

Table 3: Websites that have significant difference between text scores and snippet scores *Note:* $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$.

HTML `meta` tags, or as complex as structured meta-data markups like Microformats[5], RDFa, and Microdata. Google is intentionally ambiguous about when and whether meta-data is used to generate snippets to prevent gaming of the algorithm by Search Engine Optimization (SEO) services.

In this section, we examine whether pages that contain structured meta-data data have snippets that are more or less consistent with the webpage content. Page authors could use structured meta-data to help supply Google Search's snippet generation algorithm with information that is more representative of the webpage's content; alternatively, they could use meta-data to misrepresent the webpages content (e.g., by making it seem more partisan and inflammatory) to attract visitors.

To implement this comparison, we split our dataset into two sets of (snippet, webpage) pairs, based on whether the webpage contained structured meta-data. We specifically looked for ten kinds of Microformat meta-data, including specific attributes for objects like *People and Organizations*, *Blog Posts*, *Locations*, and *Events*. 17% of webpages in our dataset contained Microformat meta-data; of these webpages, the top objects included *People and Organizations* (62%), *Blog Posts* (30%), and *Locations* (2%).

Figure 3c shows the distribution of Δ scores for (snippet, webpage) pairs, split between webpages that do and do not contain structured meta-data. As above, we used the Kolmogorov-Smirnov test to compare the two distributions under each lexicon threshold, respectively, and found that they are significantly different (top 15%: $D = 0.04^{***}$; top 10%: $D = 0.06^{***}$). However, the differences between the means of the distributions was very small (0.03), again suggesting that the differences in the distributions has little substantive impact.

Figure 4 shows the fractions of (snippet, webpage) relationships broken down by webpages containing and not containing structured meta-data. Webpages with markup have a slightly greater fraction of snippets that amplify bias (59–61% versus 54–58%) and slightly lower fraction of snippets that leave partisanship unchanged (12–20% versus 14–24%). Based on these results, structured meta-data does not appear to make a widespread difference on the machine-coded partisanship of Google Search snippets.

Next, we examine the relationship between snippets and meta-data from a different perspective. Thus far, all of our analysis has compared the partisan cues in snippets to the partisan cues in the text of the webpage (see § 3.2). However, in practice we observe that Google Search's snippet generation algorithm often extracts sentences and phrases from meta-data in the webpage, such as the as the HTML `meta description` tag and alt-text on HTML `img` tags. This is an important distinction, because this meta-data is typically not visible to the user. This creates situations where the snippet for a webpage may be extracted from text that reader of that page may never see.

To analyze the differences between visible page text and invisible meta-data, we compare the Γ score of each snippet to the Γ scores of the page text and meta-data of the corresponding webpage.[6] To implement this comparison, we extracted all of the meta-data from the webpages in our corpus.

Figure 3d shows the distribution of Δ scores for (snippet, webpage) pairs when we compare snippets versus meta-data and versus the page text. We ran the Kolmogorov-Smirnov test on these distributions and found them to be significantly different (top 15%: $D = 0.11^{***}$; top 10%: $D = 0.04^{***}$). However, unlike all of our previous comparisons, in this case the differences between the means of the distributions were large (top 15%: 0.13; top 10%: 0.20), indicating that there are qualitative differences between meta-data and page text with respect to the use of partisan cues.

Figure 4 explores this further by presenting the fractions of cases where snippets amplified, decreased, or flipped partisanship relative to the webpage text and meta-data. When compared to meta-data, snippets were less likely to amplify partisan cues (38–48% versus 54–58%), more likely to leave partisanship unchanged (16–31% versus 14–23%), and more likely to flip polarity (26–31% versus 19–24%). There are two potential explanations for this finding: (1) Google Search's snippet generation algorithm may prefer to use phrases extracted from meta-data, thus leading to closer alignment between the partisan cues in snippets and meta-data; or (2) webpage authors may use more partisan cues in meta-data than in the page text (the average number of partisan cues in webpage meta-data in our dataset is 22–33, depending on the fraction of our lexicon that is used for scoring).

[5]Microformats: http://microformats.org/

[6]Note that the results for "Snippet vs. Page" in Figure 3d and Figure 4 are identical to the "Overall" results; we repeat them to make visual comparison easier.

5 DISCUSSION

In this work, we present the first evaluation of partisan cues in Google Search snippets. Our work relies on a dataset of 820,795 unique (snippet, webpage) pairs that were gathered from Google Search based on 88,745 unique queries for partisan phrases, names of US politicians, and all of their autocomplete suggestions. We quantify the partisan cues in our dataset using a lexicon of highly partisan unigrams and bigrams extracted from political speeches hosted by Vote Smart.

The main takeaway of our study is that Google Search snippets tend to amplify partisan cues relative to the original webpages (see Figure 4). This may have serious implications for how people consume political information from Google Search: if a person "scans the headlines" on a SERP, they may be left with a more partisan impression than if they read the source documents [25, 27]. Furthermore, partisan cues in snippets may prime users with a particular framing that will color their perception of the webpages if they click through and read them [20, 25]. Field-studies should be conducted to determine whether these hypothesized effects actually hold true in practice.

One important, unresolved question is *why* Google Search's snippet generation algorithm tends to produce snippets that amplify partisan cues. It is extremely unlikely that this is an intentional design decision on Google's part; rather, this is likely an unintended, emergent effect. Our analysis of the behavior of Google Search's snippet generation algorithm in § 4.2 and § 4.6 suggests that the cause may be interactions between writing style and webpage structure: the snippet algorithm prefers text at the beginning of pages and within meta-data, while page authors tend to use more partisan cues in these locations. Additional algorithm auditing work should be conducted to more fully explore the implementation of Google Search's snippet generation algorithm.

A second, equally important question is: is Google's current snippet generation algorithm acceptable, or should it be altered (and if so, how)? Generating partisan snippets is not necessarily bad design, if the objective is to make the partisan polarity of webpages that appear in SERPs very clear to users before they click the links. Arguably, altering the snippet generation algorithm to eschew or replace partisan cues will lead to snippets that fail to accurately reflect the content of the underlying page, which may worsen the user experience if it leads to users being unsatisfied with pages they visit. That said, it is unclear whether the snippet is the best place to implicitly convey the partisanship of webpages, since the domain of the website may already be sufficient (e.g., US users recognize the differences between Fox News and MSNBC, irrespective of any particular article).

Conversely, it can be argued that reducing or eliminating partisan cues in snippets may have overall benefits for democratic society, i.e., by reframing political hot-topics using non-partisan language that does immediately trigger framing effects and confirmation bias in readers. This could be accomplished by shifting from extractive to abstractive summarization. This design change may be especially important with respect to Google Search, since it is widely believed to be neutral, and it is the first place most web users go to investigate news and politics [4, 18, 19, 30, 55, 65]. We argue that Google, and other search engines, should engage in a transparent and deliberate effort to design how their summarization algorithms interact with news and political content, rather than allowing the algorithm to blindly function as-is, without reflection or critique.

Applications. Our methods for scoring partisan cues in text have applications beyond measurement and auditing. *First*, our methods could be used to help improve the quality of document summarization algorithms, e.g., by identifying snippets that are more closely aligned with the overall political valence of a document. *Second*, our methods could be used to inform the design of document summarization algorithms that are specifically tuned to increase diversity, e.g., by finding document with a particular political valence, or by intentionally extracting snippets from documents that have reduced or flipped polarity.

Limitations. Our study has several limitations. *First*, the Γ scores that we calculate for individual webpages are not strongly correlated with the overall partisanship of the associated websites, as measured using existing scales like AllSides and others [1, 2, 6, 57]. This is expected: the webpages we sample from any given website are not necessarily representative of the website as a whole.

Second, our approach for parsing text from webpages is overly permissive: text that is not relevant for our analysis (e.g., navigation bars, page footers, etc.) will also be extracted and included in our analysis. In practice, there is no perfect tool for extracting "content" from webpages. We do not expect this additional text to have a substantive impact on our analysis.

Third, our method for scoring partisan cues does not consider contextual semantics. For example, we do not consider negation or sarcasm. Unfortunately, this is a fundamental limitation of current NLP techniques that impacts many contemporaneous studies [57].

Fourth, our lexicon may be incomplete, e.g., there may be partisan cues that are used in the media but were not repeated sufficiently by politicians for them to emerge in our lexicon. The potential for false negatives informed our decision not to analyze (snippet, webpage) pairs containing zero partisan cues from our lexicon, since it would have been presumptuous to conclude that these samples contained "zero partisanship."

Fifth, our study is not longitudinal, and it is unclear whether our results generalize over time.

Finally, people may not recognize all of the n-grams in our lexicon as partisan, or they may not react to them in proportion to their γ score (i.e., people may judge them to be more partisan or less partisan). Extrapolating further, this means that people may not make the same judgments about partisan cues in snippets and webpages that we do in our analysis. Additional fieldwork is necessary to validate the n-grams in our lexicon and their scores, as well as evaluate people's perceptions of partisan cues in situ on SERPs.

ABSTRACT

With the wide adoption of multi-community structure in many popular online platforms, human mobility across online communities has drawn increasing attention from both academia and industry. In this work, we study the statistical patterns that characterize human movements in cyberspace. Inspired by previous work on human mobility in physical space, we decompose human online activities into ***return*** and ***exploration*** – two complementary types of movements. We then study how people perform these two movements, respectively. We first propose ***a preferential return model*** that uncovers the preferential properties of people returning to multiple online communities. Interestingly, this model echos the previous findings on human mobility in physical space. We then present ***a preferential exploration model*** that characterizes exploration movements from a novel online community-group perspective. Our experiments quantitatively reveal the patterns of people exploring new communities, which share striking similarities with online return movements in terms of underlying principles. By combining the mechanisms of both return and exploration together, we are able to obtain an overall model that characterizes human mobility patterns in cyberspace at the individual level. We further investigate human online activities using our models, and discover valuable insights on the mobility patterns across online communities. Our models explain the empirically observed human online movement trajectories remarkably well, and more importantly, sheds better light on the understanding of human cyberspace dynamics.

1 INTRODUCTION

In physical space, human movements follow a set of underlying principles. Much research work has been devoted to human mobility in physical space on various topics such as individual and group level mobility patterns [11, 39], the temporal-spatial properties of human mobility [17], and the relation between individual mobility and social connections [9]. With the rapid advances in information and communication technologies (ICT), especially the smartphones, the majority of the population in modern societies around the world are spending a significant and increasing amount of their daily time and activities in cyberspace, and in doing so connecting to multiple online communities.

Uncovering the statistical patterns that characterize the trajectories of human movements across online communities is not only key to many research areas such as computational sociology [4, 51], social media [19, 35], and complex networks [36], but also of great importance for the design of multi-community platforms [20]. Much work has been done on modelling online trajectories, including learning sequential patterns from user traces [31], detecting information spreading among communities [21, 43], and extracting human mobility patterns in cyberspace [18]. However, these studies are usually descriptive and limited at a coarse user-group granularity, while a finer grained understanding in the underlying rules that people follow when they move across online communities is still missing. To address the deficiency, we employ a popular framework in physics for studying individual movements across real word locations [32, 40]. To be specific, we decompose online activities to two basic types of movements across communities – ***return*** and ***exploration***. We then study based on what mechanisms individuals perform these two types of movements.

We start our work with investigating the relation between return and exploration. When an individual performs a move in cyberspace, she either returns to a previously visited online community, or explores a new community. Previous work on human online activities suggests that, at each move, users are not choosing between return and exploration randomly [2]. One evidence is that the probability of people visiting new communities shows a decreasing tendency over time instead of staying constant [54], indicating an evolving relation between return and exploration. We take a close look at this evolving relation, and quantitatively show that the probability of exploring new communities decreases exponentially with the amount of unique communities previously visited. Generally speaking, this finding implies that the more communities an individual has visited, the more likely she will return to a visited community at her next move, rather than exploring a new one. Interestingly, this relation in cyberspace is similar to the relation between human physical return and exploration in real world, which is originally reported in the preferential return model in physics [40].

With the relation between return and exploration being modelled, we proceed to investigate how humans perform return movement among visited communities. Reportedly, people visit online communities following Zipf's law [7], i.e., an individual's preferred communities receive exponentially more visits than the less preferred. This observation indicates that the probabilities of returning are not evenly distributed among visited communities. Our experiments show that the probability of an individual returning to a community is proportional to the visit frequency she pays to this community. In other words, people are more intended to return to their frequently visited communities. Consequently, the frequently visited communities get even more returns (i.e., the rich get richer), and result in the exponential imbalance. This finding, again, echos the property of people returning to offline locations in physics preferential return model. Therefore, without causing confusion, we also refer to our model for online return movement (including its relation with exploration) as the ***preferential return model***.

We then study the mechanism how humans explore the cyberspace. Usually, people explore online communities driven by their personal demands and interests [12, 53]. This suggests that people are more likely to explore new communities somewhat related to the communities they have visited before, rather than randomly select a unvisited one. In fact, previous literature indicates that the online communities an individual visits can be categorized into ***community-groups*** [13, 29]. In other words, with a high probability, a newly visited community can be classified into one of the previously explored community-groups. Following this idea, we investigate the exploration movement from a community-group perspective. To be specific, given the group label of each online community as well as a user's exploration trajectory, we study how she selects new communities from her previously explored community-groups, or opens a new community-group to explore.

Our experiments quantitatively indicate that exploration movement at community-group level share a remarkable resemblance with return movement, and also follows a ***preferential principle***. We first focus on the probability that an individual explores a community in a community-group that she has never explored before. We discover that this probability also evolves over time, and decreases exponentially with the total amount of community-groups the user has explored. Next, we examine the probability of a user exploring a new community from her previously explored community-groups. Similar to return movement, our results show that people pay more attention to their preferred community-groups. To be specific, with much higher probabilities people select new communities from the preferred community-groups to explore. To the best of our knowledge, this is the first time that such a quantitative mechanism of human exploration in cyberspace being reported. We refer to the mechanism as the ***preferential exploration model***.

Through the lens of both *preferential return* and *preferential exploration* models, we are able to not only see a big picture of how people move across online communities, but also uncover more insights in human mobility patterns in cyberspace. For example, we uncover that some communities attract more people to return. The communities of this type are usually of relatively small sizes, and concentrate on niche topics. Meanwhile, we also find that the members of some other communities are more intended to explore. The communities of this type, differently, are usually of larger sizes, and their topics are broader and more interactive. In fact, our analysis indicates that more than 67% of the variance of user intention to explore new communities can be explained using user visit history. It is also of high research value to compare human dynamics in physical space and cyberspace. Interestingly, our experiments indicate that humans are more likely to explore in the physical world, while in cyberspace they are more likely to return to their familiar communities.

The main contributions of this paper are summarized as follows.

- We systematically study human mobility in cyberspace. In particular, we present a ***preferential return model*** and a ***preferential exploration model***. The models explain empirical evidences remarkably well, and synergistically characterize the statistical patterns of human movements across online communities.
- We further investigate online activities at an individual level using our models. Our findings reveal previously undiscovered insights on human cyberspace dynamics, such as the relations between user activities and the community features, the differences between human online and offline movements, and so on.

2 DATA COLLECTION AND PREPROCESSING

We collect our data from Reddit, one of the most visited websites in the world[1]. Reddit has been used as the data sources in many computational sociology studies [47, 50], due to its high popularity and almost complete data availability[2]. In addition, we select Reddit for our study for two other reasons. 1) Multi-community structure – Reddit is organized into thousands of communities (i.e. subreddits), and users are allowed to post in any communities at will. Such a multi-community setting breeds a large amount of activities across communities [15, 21, 51], and therefore makes the data source ideal for studying human online movements. 2) Complete user traces – all the user activities (except for the ones deleted by users) on the platform are available. In other words, up to a time point, we are able to collect complete user online trajectories from their first activities. Given that human online mobility patterns are evolving over time [16], using complete user traces for our study avoids possible information lose and leads to more precise analysis.

In this work, we take a user post in a Reddit community as a "check-in" activity in the community, and a movement between communities consists of two consecutive posts. Please note that the two consecutive posts can be located in the same community. We first download all the user posts on Reddit from 2012 July to 2014 Dec. This initial dataset contains totally 1 billion records, posted by 9 million users in 0.2 million online communities. We first filter out communities with less than 100 users, resulting in 17 thousand active communities. We then find users who did not join Reddit until 2013 Jan (i.e. remove all the user who have activities (posts) in the first six months in our data), and extract the trajectories of these users across active communities. By doing so, we ensure that the extracted trajectories are complete (i.e. starting from the users'

[2] Reddit data is publicly available, and free for download at www.reddit.com/3bxlg7

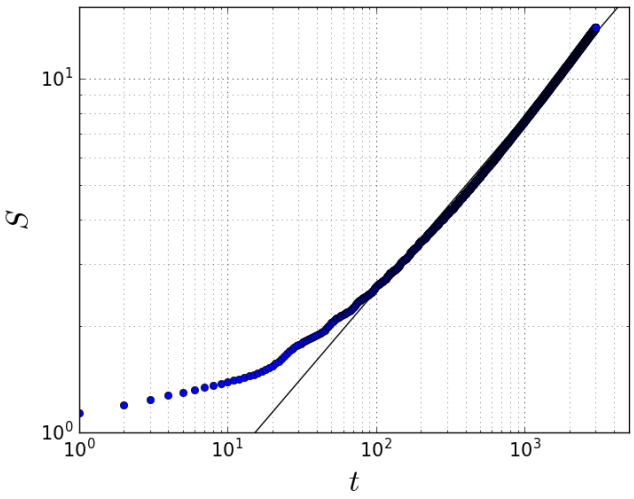

Figure 1: Distribution of the number of visited unique communities S over time t in hours. The fitted straight line indicates that $S \sim t^{\mu}$, where μ is estimated to be 0.42.

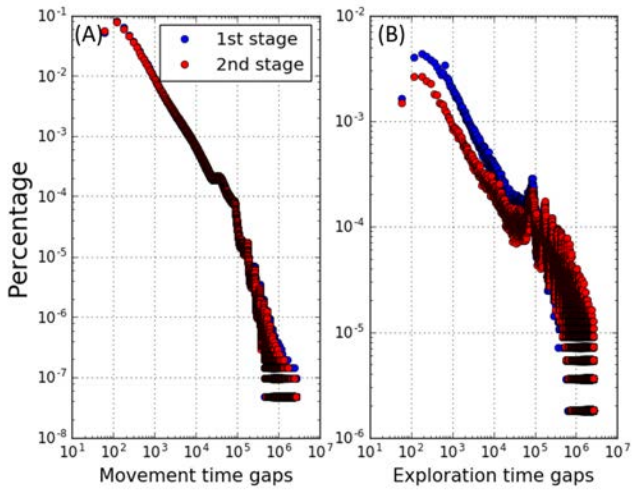

Figure 2: The distributions of time gaps in seconds between all movements (A) and explorations (B) for two stages. Both plots are shown in log-log scale. Please note that the two curves mostly overlap in plot (A), indicating little difference between the first and second stages in terms of the distribution of time gaps between all movements. While (B) reveals that the time gaps between explorations are significantly shorter in the first stage.

first activities) up to 2014 Dec[3]. We further filter out inactive users who posted less than 100 activities or joined less than five online communities. We also follow previous work to exclude non-human accounts by detecting those accounts that contain certain terms such as "Bots", "Moderator" and so on, as well as deleted users [18]. In total, our final dataset contains 16 million activities, forming the online trajectories of 57 thousand users. We will specify in the corresponding sections if more constraints are applied to the data.

3 PREFERENTIAL RETURN MODEL

In this section, we introduce our ***preferential return model***. We first model the probability that a user explores a new online community at each move, denoted as P_{new}. Since return and exploration are complementary, the probability of the user returning to a visited community is naturally $1 - P_{new}$. We find evidence that P_{new} decreases over time, and the decreasing tendency can be well modelled with the number of unique communities the user has visited. We then model, given that the user choose to return, the probability that she returns to a specific visited community i, denoted as Π_i.

3.1 Relation between Return and Exploration

According to our experiments, as well as several previous studies [8, 18, 48], the number of unique communities visited by a user, denoted as S, follows

$$S \sim t^{\mu}, \tag{1}$$

where t is the time the user has spent wandering in cyberspace (Figure 1). The parameter μ is found to be smaller than one [18], and empirically estimated to be around 0.4 from our data. The fact that $\mu < 1$ indicates that the exploration of new communities of users shows a decreasing tendency over time. Two possible reasons could cause the tendency: 1) the probability of user exploring new communities, P_{new}, decreases, or 2) P_{new} stays constant, but the user activity levels reduce over time (i.e. performing fewer movements). To find out, we evenly divide user trajectories into two stages according to the number of communities explored. In other words, given that a user has explored S unique communities in total, she explored $S/2$ in each stage, respectively. We examine the time gaps between explorations, as well as the time gaps between all the moves for each stage, respectively. Our experiments show that, in terms of the distributions of the time gaps between all the moves, little difference is observed between two stages (Figure 2 (A)). In other words, statistically, user activity levels are almost unchanged over time. However, the time gaps between explorations in the later stage are significantly longer than in the former stage (Figure 2 (B)). Clearly, these evidences suggest that although users stay active at the same level, the probabilities of exploring new communities decrease over time.

To model the decreasing probability, we associate P_{new} with S. The idea is rooted from our assumption that the more communities a user has visited, the less likely she might want to explore a new one in her next move. Therefore, we formally model P_{new} as

$$P_{new} = \rho S^{-\gamma}. \tag{2}$$

We then quantitatively validate this formula using empirical data. However, it is not practically feasible to estimate P_{new} for every move a user makes. Fortunately, P_{new} can be also viewed as the

[3]We are aware of that our filtering method could still include some users who joined Reddit before 2012 July, but we assume that the amount of such users are few and have little impact on our experiments.

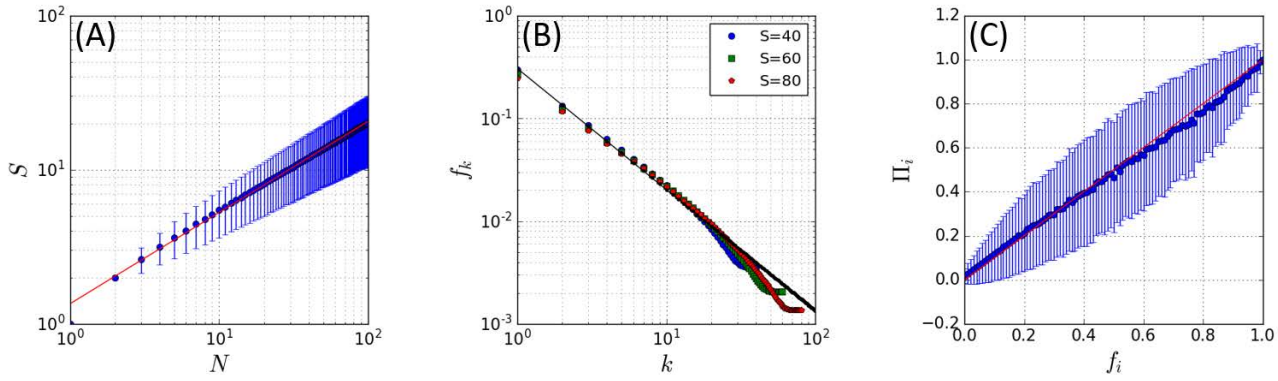

Figure 3: (A) The distribution of the number of uniquely visited communities S over the number of total movements N averaged on all the users, and the error bars indicate the standard deviations. The fitted line in log-log scale indicates that power-law distribution of S over N, as suggested in Formula (4). (B) The relation between visit frequency f_k and visit ranking k for three user groups of different S. The plot shows that Zipf's law holds true, regardless of the number of unique communities a user has visited. (C) The relation between Π_i and f_i averaged on all the user, and the error bars show the standard deviations. The fitted line has a slope of 0.96 and an intercept of 0.005, indicating the equivalence of Formula (6) holds true.

change rate of S over the total number of moves, denoted as N [40][4]. Formally, we can rewrite the equivalence as

$$P_{new} = \frac{\mathrm{d}S}{\mathrm{d}N}. \tag{3}$$

Combining Formulas (3) and (2), we can derive our hypothesized relation between S and N:

$$S = (1+\gamma)(\rho N)^{1/(1+\gamma)}. \tag{4}$$

Since both S and N can be observed from data, we therefore validate our modelling on P_{new} (i.e. Formula 2) by empirically showing that Formula (4) holds true.

Formula (4) suggests a power-law distribution of S over N, i.e. $log(S) \propto log(N)$. We calculate the Pearson Correlation Coefficient between $log(S)$ and $log(N)$ for each user in our dataset. Our experiments report that for more than 96% of the users, the coefficients are larger than 0.9 (p-values < 0.001). In other words, Formula (4) holds true for most users. We further plot this distribution averaged on all the users in Figure 3 (A), and clearly observe a straight line in log-log scale. Therefore, our hypothesis on P_{new} is validated as well. To be specific, we can conclude that, as the number of visited communities increases, the probability of an individual exploring new communities decreases exponentially. Practically, suggested by Formula (4), we are able to determine γ and ρ for each user from the parameters of the straight line in log-log scale[5], and study human mobility in cyberspace at an individual granularity (Section 6).

3.2 Probability of Returning to a Community

Modelling P_{new} allows us to predict how likely an individual would explore a new community, or return to a visited community. We next study the probability of an individual returning to a specific visited community i, i.e. Π_i. It is reported that the frequency f_k of a user's kth most visited community follows Zipf's law [18, 54], and formally,

$$f_k \sim k^{-\zeta}. \tag{5}$$

Figure 3 (B) shows that the this law also appears in our data. The Zipf's law indicates users' imbalanced probabilities of returning to visited communities. Such a "the rich get richer" observation inspires us to model Π_i as the proportion of visits paid to this community previously, denoted as f_i. Formally,

$$\Pi_i = f_i. \tag{6}$$

Theoretically, given P_{new} being modelled as $\rho S^{-\gamma}$, this hypothesis on Π_i can lead to the Zipf's law property in Formula (5), providing evidence for the rationale of Formula (6)[6]. Empirically, We further validate this formula using our data. Since it is infeasible to directly estimate Π_i for each move, we make an approximation in our experiments. To be specific, we cut user trajectories into slices of length L. Within each slice, we estimate Π_i as the percentage of visits to community i. Then within the previous slice, we compute f_i, the frequency to the same community. We set L as 100 for a robust estimate for Π_i[7], and conduct our experiments on totally 23 thousand users whose trajectories cover at least two slices (i.e. total movements N large than 200). We plot the relation between Π_i and f_i in Figure 3 (C). From the plot, we can observe that the relation is linear with a slope very close to 1, indicating that Formula (6) holds true. An interesting observation is the spindle-shaped errors of the fitted straight line – the equivalence between Π_i and f_i is more stable when f_i approaches either end (1 or 0). This is because

[4]Generally speaking, this is because the probability of visiting a new community at each move is equal to the "amount of change" of S brought by each move. For more information, please refer to the supplementary material of [40]

[5]Simply, the slope of the straight line is $1/(1+\gamma)$, and the intercept is $log(\rho)/(1+\gamma) - log(1+\gamma)$.

[6]A detailed proof is beyond the scope of this paper. Please refer to [40] for more information.

[7]Naturally, larger values of L lead to more precise estimates of Π_i. However, since Π_i and f_i are estimated within two different slices, larger L also introduces more temporal differences to the slices, and therefore, introduces larger errors to our validation. We experiment with L from a reasonable range of 50 to 200, and obtain similar results.

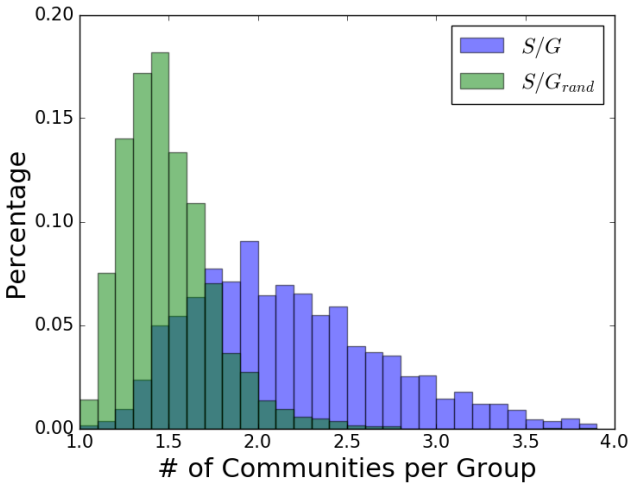

Figure 4: Histogram of the average numbers of online communities a user explored per community-group under our group assignments (S/G) versus random group assignments (S/G_{rand}).

our approximation might introduce some amounts of noises into the fitting, unless the user previously rarely visits a community ($f_i \to 0$) or visits the community very frequently ($f_i \to 1$).

4 PREFERENTIAL EXPLORATION MODEL

The preferential return model characterizes the statistic patterns of ***return*** movement in cyberspace. However, this model does not describe if a user chooses to explore, which new community she will visit. In this section, we introduce our *preferential exploration model* for characterizing ***exploration*** movement. The model is inspired by the fact that the communities a user visit usually can be categorized into several community-groups [12, 53]. Table 1 shows the exploration traces of three randomly selected users from our data. For example, the thrird user in the table explored $S = 28$ unique online communities, while most of these communities are mainly from five community-groups. To be specific, community *sushi*, *asianeats* (asian eats), *tipofmytongue* (tip of my tongue), and *ramen* are clearly related to ***Food***. Similarly, *Boxing*, *kungfu*, *loseit* (lose it), and so on are all communities on ***Exercises***. Such a grouping property suggests that the explorations of a user are not independent – previously explored community-groups could provide further information for later explorations. Following this idea, we investigate exploration movement from a community-group perspective. In particular, we first categorize all the online communities into community-groups. Then we study how users select unvisited communities from community-groups at each exploration.

4.1 Extracting Community-groups

In this work, we adopt a dendrogram-based method to extract community-groups, as suggested in many community detection studies [22, 38]. We apply Pointwise Mutual Information (PMI) as the similarity metric for clustering [42]. To be specific, for two online community C_i and C_j, let U_{C_i} and U_{C_j} denote their user sets, respectively. We compute the similarity between C_i and C_j, as $pmi(U_{C_i}, U_{C_j})$, and formally,

$$pmi(U_{C_i}, U_{C_j}) = log\frac{|U_{C_i} \cap U_{C_j}|}{|U_{C_i} \cup U_{C_j}|}, \tag{7}$$

where $|\cdot|$ denotes the size of a set. PMI computes the similarity between communities from a user co-occurrence perspective. Compared with language-based metrics that are usually adopted for measuring online community similarity [43, 45], PMI better quantifies the likelihood of users moving across communities. For example, *nyc* and *boston* are two typical city-specific communities on Reddit. Since the visitors to city-specific communities are mainly local residents [18], typical users of *nyc* or *boston* are unlikely to pay visit to the other community. Therefore, the similarity between *nyc* and *boston* should be relatively low from a movement perspective, as indicated by a low value of $pmi(nyc, boston)$. On the contrary, according to our experiments, language-based metrics, such as similarities between doc2vec embedding [23], suggest high similarity between the two communities, because of their similarly city-related topics. We set the number of community-groups as 300 for clustering[8], and extract flat group structures for online communities, i.e., each online community is assigned to only one community-group. Table 2 shows some examples of the extracted community-groups. We define that a community-group is explored by a user if the user explores one or more online communities of the group.

We further examine our community-group assignments by comparing the results with random group assignments. Specifically, we randomly cluster all the communities into the same number of groups, and the distribution of group sizes (i.e. number of online communities in each group) is also set to the same as our group assignments. Let G denote the number of community-groups a user explored under our assignments and G_{rand} denote the number of random community-groups a user explored. If our assignments capture the grouping property of user explorations, i.e., user explorations concentrate on several community-groups, then the average number of online communities a user visited per community-group, i.e. S/G, should be significantly larger than S/G_{rand}. We compute both S/G and S/G_{rand} for each user, and conduct a t-test to compare the two values. The test result indicates that a user explores significantly more online communities per community-group under our assignments than random group assignments with a p-value < 0.001. Therefore, our community-group assignments are validated (see Figure 4 for more details).

4.2 Exploring New Community-groups

With the group labels being assigned to online communities, we study the probability of a user exploring a community in a community-group that she has never explored before. We denote this probability as Q_{new}, and the probability of exploring a community in her explored community-groups is thus $1 - Q_{new}$. Similar to our inference on P_{new}, the probability Q_{new} equals to the change rate of the number of unique community-groups a user explores, G, over the number of unique communities she visits, S. Formally, the

[8]Using different settings of community-group numbers leads to same statistic patterns of exploration movement, but with slightly different parameters.

Table 1: Exploration traces of three randomly selected users from our dataset. We also indicate the community-groups each user explored. The community-groups are automatically extracted from all the online communities using a clustering method, and the titles are manually labeled. We use different colors and superscripts in the exploration traces to label which community-group an online community belongs to. The online communities that do not share group membership with any other communities in a trace are colored in black, and are not denoted with superscripts. Also, please note that *AUS.*, *RELP.*, and *EXER.* are short for Australia, Relationships, and Exercises, respectively.

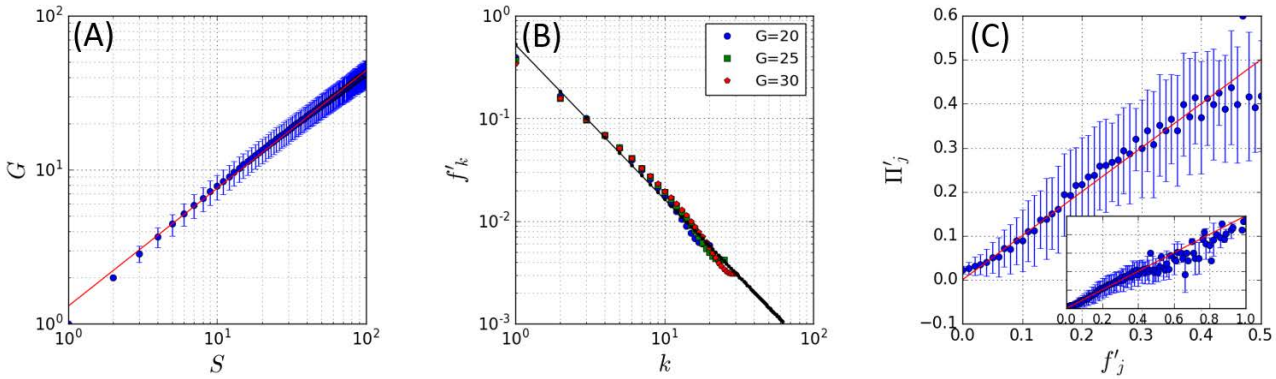

Figure 5: (A) The distribution of the number of unique explored community-groups G over the number of explored communities S averaged over all the users. The plot is in log-log scale, and the error bars indicate the standard deviations. (B) Zipf's law between the exploration frequency to community-groups, f'_k, and the exploration ranking k. (C) The relation between Π'_j and f'_j. The main plot and the inset plot shows the ranges of [0, 0.5] and [0, 1] for f'_j, respectively. Both plots are averaged over all the users, and the error bars show the standard deviations.

equivalence is

$$Q_{new} = \frac{dG}{dS}. \tag{8}$$

We therefore investigate the relation between G and S from user trajectories. Very interestingly, we also discover a power-law distribution of G over S, i.e. $log(G) \propto log(S)$. Specifically, the Pearson Correlation Coefficients between $log(G)$ and $log(S)$ of over 91% users are higher than 0.9, with p-values smaller than 0.001. We plot this distribution in log-log scale in Figure 5 (A).

Given the power-law distribution, as well as Formula (8), we are able to infer the expression of Q_{new}, and formally,

$$Q_{new} = \rho' G^{-\gamma'}. \tag{9}$$

In other words, the probability of exploring a new community-group exponentially decreases with the number of unique groups previously explored. This finding makes interesting but obvious sense – a user's exploration in cyberspace gradually converges to the several categories (i.e., community-groups) she is interested in, and consequently, the more community-groups she has explored, the less likely she will explore a new one. Furthermore, the power-law distribution of G over S can be simply parameterized as

$$G = (1 + \gamma')(\rho' S)^{1/(1+\gamma')}. \tag{10}$$

Please note that, the relation between S and G can be empirically estimated from user trajectories. Therefore, Formula (10) allows us to compute both ρ' and γ' for each user, and to quantify individual exploration patterns (Section 6).

Table 2: Five extracted community-groups using an automatic clustering method with manually labeled titles. The first three groups –*Food*, *Tech*, and *Cars* in the table, are already mentioned in Table 1, and we show more online communities from these community-groups here. We also list two new community-groups – *Wine* and *Asia* in the table.

Title	*Online Communities*

4.3 Exploring Previous Community-groups

Next, we investigate how users select new communities to explore from the community-groups explored before. We start with the exploration frequency a user exercises in each community-group, denoted as f'. For the first time, we uncover that Zipf's law also applies to f'. Generally speaking, users perform exponentially more explorations in their preferred community-groups, resulting in very imbalanced exploration frequencies among community-groups. Formally, the exploration frequency f'_k of the kth most explored community-group satisfies

$$f'_k \sim k^{-\zeta'}. \tag{11}$$

Figure 5 (B) shows the Zipf's law for the users of different numbers of explored community-groups. The exponentially uneven exploration frequency indicates that "the rich get richer" is also reflected in user exploration at the community-group level. Therefore, we naturally model the probability a user explores a community in her explored community-group j, denoted as Π'_j, as the exploration frequency of this community-group f'_j, and formally,

$$\Pi'_j = f'_j. \tag{12}$$

We empirically validate $\Pi'_j = f'_j$ by employing the same method for validating $\Pi_i = f_i$. Specifically, we divide user exploration trajectories into slices of length L'. Within a slice, we estimate Π'_j as the percentage of explorations to community-group j, and within the previous slice we compute f'_j for the same community-group. Although a large L' makes the estimations more precise for users who have sufficiently long exploration trajectories, it also significantly reduces the total number of users for our experiments. Therefore, we make a trade-off, and set $L' = 20$. We then filter out the users who explore fewer than 40 communities ($S < 40$), and retain 4 thousand users. We plot our results in Figure 5 (C). Despite the relatively large errors caused by the value of L', we still see the approximate equivalence between Π'_j and f'_j, which validates Formula (12). Note that the errors increase as f'_j increases, especially for $f'_j > 0.5$ (see the inset of Figure 5 (C)). This is due to the fact that a user can explore at most one community-group with a frequency larger than 0.5. Meanwhile, the total number of users is relatively small. Hence the errors for $f'_j > 0.5$ are relatively large.

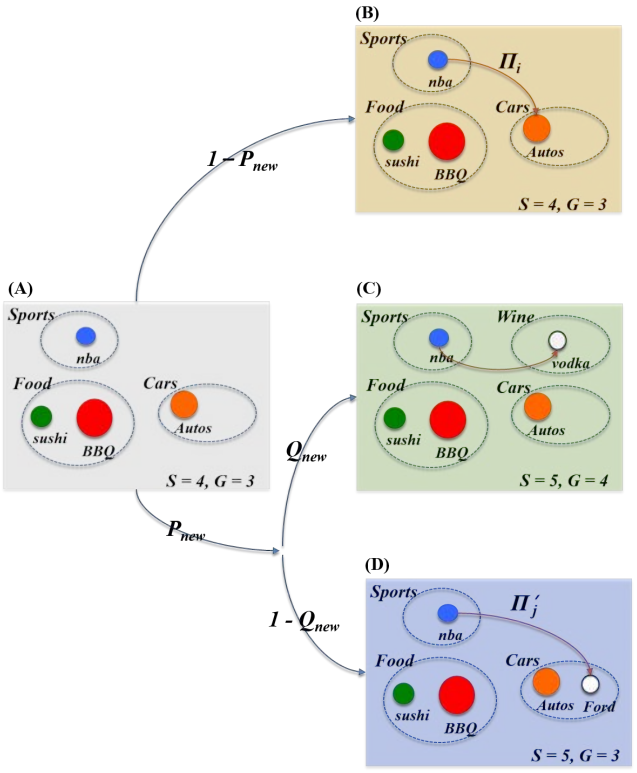

Figure 6: An example of an imaginary user's movements across online communities, illustrating our overall model. From the initial stage (A), the user first chooses between returning to a previously visited community (B) or exploring a new one. If the user chooses to explore, she further decides between exploring a new community-group (C) or selecting a new community from a previously explored community-group (D).

5 OVERALL MODEL

Combining both ***preferential return model*** and ***preferential exploration model***, we are able to cover two basic types of movements across online communities, and obtain an overall model for human mobility in cyberspace.

5.1 An illustrative example of our model

We summarize our overall model using an example of an imaginary user moving across online communities (Figure 6):

- At the initial stage (Figure 6 (A)), the user has visited four communities, belonging to three communities groups ($S = 4$ and $G = 3$): *nba* – ***Sports*** group, *sushi* and *BBQ* –***Food*** group, and *Autos* – ***Cars*** group.
- The user first chooses to perform either exploration or return, with probability P_{new} and $1 - P_{new}$, respectively. Our model indicates that probability P_{new} can be modelled as $\rho S^{-\gamma}$.
- If she chooses to return, she returns to community i with probability Π_i, and the probability can be modeled as the visit frequency to this community f_i. Figure 6 (B) illustrates that the user returns to her previously visited community – *Autos*. Both S and G are unchanged in this case.
- Otherwise, she further chooses to explore an unvisited community in a new or an explored community-group, with probability Q_{new} and $1 - Q_{new}$, respectively. We model Q_{new} as $\rho' G^{-\gamma'}$ in our model. Figure 6 (C) shows that the user explores community *vodka* in a new community-group ***Wine***. In this case, both S and G are increased by one.
- Furthermore, the probability of the user exploring a new community in a previously explored community-group j, denoted as Π'_j, is proportional to the exploration frequency of this community-group f'_j. Figure 6 (D) shows that the user explores a new community *Ford* in her explored community-group ***Cars***. Therefore, S increases to 5, and G remains 3.

5.2 The Preferential Principle

This overall model uncovers two interesting resemblances with respect to human dynamics: 1) the resemblance between human movements in cyber and physical spaces, and 2) the resemblance between online return and exploration movements. First, according to the physical preferential model [30], the relation between return and exploration in physical world shares the same form of Formula (2). Meanwhile, the probability of returning to a physical location is also proportional to the previous visit frequency of this location (Formula 6). In other words, although the two spaces are fundamentally different, people follow a similar "preferential principle" in both spaces – the probability of visiting new communities/locations decreases over time, and people pay more and more visits to the communities/locations they are fond of. Second, it is worth noting the similar mathematical forms of our preferential return and exploration models. The similarities further suggest that the "preferential principle" not only governs how people return to visited online communities, but also applies to the explorations to new communities. To be specific, people explore new community guided by their preference to community-groups – they gradually lose interests in exploring new community-groups, and perform more and more explorations to their preferred groups.

Such a "preferential principle" in both cyber and physical spaces, and for both return and exploration movements, leads to the frequently observed Matthew effect [26] ("the rich get richer" phenomenon) in human mobility patterns. Given the fact that Matthew effect is also observed in many other areas, such as economy and sociology [33, 41], it is worth questioning that if this principle is one of the fundamental rules of human dynamics, and applicable to other human activities. We will save these very interesting extensions for our future work.

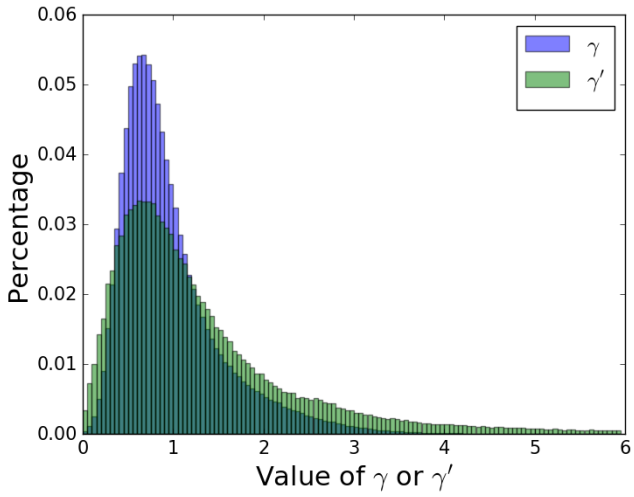

Figure 7: Histogram of γ versus γ' for all the users .

6 HUMAN DYNAMICS IN CYBERSPACE

Our models reveal that user intentions to explore new online communities and community-groups both decrease over time. From Formulas (4) and (10), we can separately derive

$$log(S) = 1/(1+\gamma)log(N) + const, \tag{13}$$

$$log(G) = 1/(1+\gamma')log(S) + const. \tag{14}$$

Apparently, parameter γ quantifies how strong users' intentions are to explore new communities. A larger γ indicates a weaker intention – the increase of number of unique communities S is slower as the total movements N increases. Similarly, parameter γ' quantifies how strong users' intentions are to explore new community-groups. Therefore, in this section, we focus on γ and γ', and study human dynamics in cyberspace.

6.1 Intentions to Explore

We compute both γ and γ' for all the users in our dataset. Our results report that the mean and median of γ are 0.97 and 0.82, respectively; and the mean and median of γ' are 2.52 and 1.17, respectively. We then conduct a t-test between γ and γ', and the test result indicates that γ' is significantly larger than γ (t-statistic = 41.9, and p-value < 0.001). Figure 7 shows the distributions of both parameters. Recall that, in physical space, the relation between return and exploration are the same as in cyberspace. According to the previous research [40], the intention to explore new places in physical space, parameterized by γ_p, is estimated around 0.2. Therefore, we have

$$\gamma_p < \gamma < \gamma' \tag{15}$$

Formula (15) reveals previously unknown insights of human intention to explore. On one hand, from $\gamma_p < \gamma$, we learn that people are more likely to explore in physical space than in cyberspace. One possible reason for the difference lies in the evolution of physical

Table 3: Top five positively and negatively correlated online communities to γ. We list the communities along with their user sizes and the values of the coefficients.

Subreddit	*User Size*	*Coefficient*

AskHistorians	836,844	-0.29

locations and online communities. Online communities are self-updating – people communicate and interact in communities, and keep posting new contents [24]. On the contrary, physical locations are usually associated with fixed functionality, and change much slower over time. Therefore, people can still be exposed to new contents even if they return frequently to a visited communities in cyberspace, but they might feel bored if they do not explore new places in physical space. On the other hand, the intention to explore new community-groups is the lowest among three, suggested by the large value of γ'. This result is consistent with the psychology theories that describe human cognitive upper limit of handling interests [27, 28]. In other words, when people have explored sufficient community-groups to fulfill their interests, they mainly focus on exploring the new communities within the explored groups instead of opening up new community-groups.

In a nutshell, human dynamics in cyberspace shares many similar principles with physical space while maintaining several unique characteristics.

6.2 Relations between Intentions and Contents

With the knowledge of user intentions to explore, a natural follow-up question is if the intentions are related to the communities or community-groups a user visits. For example, we wonder if people with lower intentions visit different communities from people with higher intentions. To answer the questions, we conduct two linear regression analyses. The dependent valuables of the analyses are γ and γ' of users, and the independent valuables are the online communities and community-groups the users visit for the two analyses, respectively. The two analyses report quite different results. The first analysis reports a high r^2 of over 0.67. This suggests that more than 67% of the variance of γ can be explained by the online communities a user visits. In contrast, the second analysis reports a quite low r^2 of 0.11, indicating that the intention of exploring new community-groups can be barely explained by users' visit histories of community-groups. The analysis results probably suggest human's different cognitive views of single online community and community-groups. We leave the investigation of such differences for the future work.

Furthermore, from the results of the linear regression analysis of γ, we are able to learn the communities that are negatively and positively correlated with γ. Specifically, for each independent valuable (i.e., online community), the linear regression calculates a coefficient and a p-value. The coefficient indicates how correlated an independent valuable is to the dependent valuable, and the p-value suggests how significant the correlation is. We first filter out all the online communities whose p-values are larger than 0.05, and obtain 381 communities positively correlated with γ, and another 427 communities negatively correlated. We list the top five most positively and negatively correlated communities in Table 3. Please note that, positive correlations to γ imply that people who visit these communities prefer to return, and oppositely, negative correlations imply that their visitors prefer to explore.

We can observe that positively and negatively correlated communities are quite different in several aspects. First, positive correlated communities are usually of smaller sizes. This difference can be directly read from the table, and is also confirmed by a t-test (t-statistic = 3.8, p-value < 0.001). Second, the two types of communities are of quite divergent topics. The positively correlated communities usually focus on specific and niche topics. For example, the first (*Albuquerque*) and the third (*tulsa*) are local communities of two American cities[9]. In fact, many other city-specific communities also appear to be positively correlated. The topics of the other three positively correlated communities are also quite specific. For example, *TankPorn* is a community for sharing pictures of tanks, and *letsgofish* focuses on Miami Marlins – an American professional baseball team based in Miami, Florida. While the topics of negatively correlated communities are broader and more interactive. For example, *TrueAskReddit* and *AskHistorians* are both Q&A communities. Meanwhile, *Needafriend* is a community for building up friendships. The contents in these communities involve much more interactions between users. The remaining two communities are both related to general topics – discussions on *poker* and *baseball*.

7 DISCUSSION & FUTURE WORK

Different from previous studies on human online activities, in this work we employ a novel mobility perspective, and decompose online activities into return and exploration movements. Our models indicate that both online return and exploration movements follow a preferential principle. Such a finding further suggests several valuable research questions. Since return movement in physical space reportedly also exhibits the same properties, a question worth studying is if humans explore physical space in a similar preferential way. Furthermore, we also wonder if the principle could extend to other types of human activities. For example, we can study if certain human daily activities, e.g., listening to music, can also be modelled the same way. To be specific, it is possible that people re-listen to their preferred music many times (similar to return movements); and the more music they have listened, the less likely they will seek for new music (similar to exploration movements).

[9]The two cities are Albuquerque, New Mexico, and Tulsa, Oklahoma, respectively.

Moreover, given the fact that the preferential returns are never observed in animal mobility [5], we are also curious if such a preferential principle is one of the fundamental, and meanwhile, unique principles of human dynamics.

Our findings in this paper also imply rich practical applications. For example, we uncover that human explorations in cyberspace are guided by an underlying group structure and related to previously explored community-groups. Meanwhile, our models quantify individual intentions to explore both online communities (γ) and community-groups (γ'). This knowledge could be applied to predicting users' next exploration, and implementing a more sophisticated recommendation system. For example, it is possible to deploy more personalized recommendations based on user exploration intentions. Specifically, for users with a low γ but a high γ', the system can focus on recommending communities within their explored groups; and for users with a low γ and also a low γ', the system may recommend more communities from new community-groups.

Furthermore, our preferential exploration model is built on a flat community-group structure in cyberspace. We extract the group structure from data using an automatic clustering method. Our experiments report that different settings of the number of groups result in slightly different parameters (i.e., γ' and ρ'), but the statistical patterns of exploration in cyberspace are consistent. It is worth noting that many previous studies suggest that the group structure revealed in human activities are in fact hierarchical and overlapping [30, 38]. Flat community-group structures with different group numbers can be regarded as rooted from the same general hierarchy but with different cutting thresholds, and are special cases of overlapping group structures. These facts suggest a more ubiquitous possibility of modelling human online exploration – humans explore communities following an implicit "road-map" of cyberspace. To be specific, in this new model, a global hierarchy defines the positional relations and the cost of moving across online communities. In other words, the hard boundaries of community-groups are replaced by continuous "distances" in cyberspace. We can then naturally associate the probability of exploration with a distance measure and obtain a more generic model without manually setting any thresholds.

8 RELATED WORK

Since Rotman et al. first suggest that people interact and share purpose in online groups, and therefore form sociological communities [37], there has been much work studying human activities across online communities. It is common that people join multiple communities on online platforms [6], and user participation in multiple communities reportedly benefits the survival of the communities [55]. Danescu-Niculescu-Mizil et al. study the interaction between users and online communities, and discover that there are different stages of users joining online communities from a linguistic perspective [10]. Following a similar approach, Tan et al. investigate the language change of users while joining multiple communities, and report that people tend to visit less and less popular communities [44]. Furthermore, how communities affect user actives are also studied. For example, Hamilton et al. study the user loyalty to multiple communities, and reveal the relation between user engagement and community characteristics [15]. Kumar et al. report that communities interact, and even conflict with each others, and most conflicts are started by a small number of specific online communities [21].

Our work is also closely related to the work studying human mobility. Many models have been developed in physics to investigate the mechanisms of the movements across locations in real word [14, 46, 49]. For example, Barabasi et al. propose a priority queue mechanism to model [1], and Ravasz et al. suggest a hierarchical organization [34] to explain the observed burstiness property of human mobility. Song et al. first propose the preferential return model for quantifying the return and exploration movements in physical world [40]. Such a model is then extended by much follow-up work [3, 25]. For example, Pappalardo et al. develop a "returner and explorer dichotomy" for differentiating people of divergent mobility patterns [32].

The similarities between human activities across online communities and movements in physical space have been discussed in some recent work [52, 54]. For example, Hu et al. introduce an analogy between physical space and cyberspace, and leverage framework designed from movements across locations in real world to study mobility patterns across online communities [18]. However, these studies mostly focus on statistical resemblances, instead of investigating the underlying rules that lead to the similarities [2]. Different from the previous work, in this work we empirically show that the mechanisms of movements in both spaces also share interesting similarities.

9 CONCLUSIONS

Given the increasing involvement and significance of cyberspace in people's daily lives, it is important to model the underlying patterns and principles of human online activities. In this work, we have systematically studied human activities across online communities from a mobility perspective. We first propose the preferential return model, which characterizes how people choose between returning to a previously visited community or exploring a new one. Then the model quantifies, if the user decides to return, how likely she is going to return to a specific community. With the return movements being modelled, we further propose the preferential exploration model. This model analyzes human online exploration movements from a novel community-group perspective, and quantitatively describes the processes of people selecting unvisited communities from community-groups. The two models are substantially validated by statistically solid evidences on a large real world data set. Combining these two models, we are able to reveal an interesting preferential principle of human cyberspace dynamics. Generally speaking, the principle suggests that people gradually lose interest in exploring new physical or cyber locations, and more and more often return to the location they are fond of. Such a principle implies a rich variety of future work (as stated in Section 7).

We have further applied our models to analyzing human online trajectories at the individual level, and reveal previously undiscovered insights about human mobility in cyberspace. We quantify user intention to explore in cyberspace and find that, interestingly, people are more likely to explore in physical world. Moreover, we investigate the relations between online communities and user intention to explore. Our experiments report that people who prefer

to return tend to visit communities of smaller size and specific topics, while people who prefer to explore tend to visit communities of larger size and interactive topics.

ABSTRACT

Citywide abnormal events, such as crimes and accidents, may result in loss of lives or properties if not handled efficiently. It is important for a wide spectrum of applications, ranging from public order maintaining, disaster control and people's activity modeling, if abnormal events can be automatically predicted before they occur. However, forecasting different categories of citywide abnormal events is very challenging as it is affected by many complex factors from different views: (i) dynamic intra-region temporal correlation; (ii) complex inter-region spatial correlations; (iii) latent cross-categorical correlations. In this paper, we develop a Multi-View and Multi-Modal Spatial-Temporal learning (MiST) framework to address the above challenges by promoting the collaboration of different views (spatial, temporal and semantic) and map the multi-modal units into the same latent space. Specifically, MiST can preserve the underlying structural information of multi-view abnormal event data and automatically learn the importance of view-specific representations, with the integration of a multi-modal pattern fusion module and a hierarchical recurrent framework. Extensive experiments on three real-world datasets, *i.e.*, crime data and urban anomaly data, demonstrate the superior performance of our MiST method over the state-of-the-art baselines across various settings.

CCS CONCEPTS

• **Information systems → Spatial-temporal systems**.

1 INTRODUCTION

Citywide abnormal events, like crimes (*e.g.*, robbery, felony assault) and urban anomalies (*e.g.*, blocked driveway, noise), may pose tremendous risks to public safety if not timely handled. According to national statistics, urban anomalies cost Americans more than $100 billion direct and indirect loss in each of recent years [39]. Hence, accurate and reliable prediction of abnormal events is in pressing need for data-driven decision makers to alleviate huge life and economic losses. For example, in disaster control, by forecasting future abnormal events, local governments can design better transportation planning and mobility management strategies to prevent severe social riots [34, 48]. Furthermore, in public order maintaining services, understanding latent occurrence patterns of abnormal events at each geographical region in a city is highly important for people's activities modeling and place recommendation tasks [20, 40]. In this paper, we aim to predict abnormal events of different categories at each region of a city ahead of time, thereby leading to significant improvement in societal welfare.

There exist prior studies on detecting geographical anomalies using spatial-temporal data [7, 17, 26]. Most of these studies identify the abnormal events by analyzing the historic traces or movement patterns of the studied objects using statistical and data mining approaches. However, instead of forecasting events in the future, these approaches typically identify them only after they have occurred, which may lead to significant information delay and lack of preparedness to handle the anomalies in an efficient way.

We identify three key challenges of modeling such abnormal event data from multiple views, which motivate the model design:

First, the distributions of abnormal events in the urban space are highly dynamic and vary greatly from one region to anther. In such cases, the abnormal event occurrences are no longer independent across different locations and it is crucial to take the spatial correlations into consideration for the abnormal event forecasting task. In addition, when modeling dynamic pairwise spatial correlations, probabilistic graphical models [23, 24] may fail due to their heavy computational cost with massive parameters based on prior assumed distributions.

Second, the occurrence pattern of abnormal events often involve underlying factors which are dynamically evolving over time. For example, crime causality on weekdays may differ from weekends. Conventional time series forecasting techniques, such as Autoregressive Integrated Moving Average (ARIMA) [29] and Support Vector Regression (SVR) [30], are mostly limited to linear models which depend solely on the single-level periodic patterns. Thus,

these methods can hardly be responsible to temporal dynamics across different time slots with respect to the occurrences of abnormal events.

Third, explicit and implicit influences among different abnormal event categories are ubiquitous in real life. For example, traffic jam at a specific region may be triggered by a robbery occurring in the same region, due to the crowd aggregation and increased patrol in response to the robbery. Therefore, the occurrence of a specific category of abnormal event may stem from not only spatial correlations between regions as well as temporal dependencies across time slots, but also the influences among different categories.

Motivated by the aforementioned challenges, this work proposes a general and flexible framework–Multi-View Deep Spatial-Temporal Networks (MiST)–for learning the predictive structure from the relationships within the multi-view abnormal event data. Specifically, at the first phase, we develop a context-aware recurrent framework to capture temporal dynamics of abnormal event data in different views and provide automatic view-specific representations. At the second phase, to jointly preserve the inter-region correlations and the cross-category influences together with the encoded temporal patterns of multi-dimensional data, we propose a pattern fusion module based on attention mechanisms to promote the collaboration of different views, and automatically capture the contribution of correlated regions, time slots and categories from the corresponding view in the predictive model. To supercharge MiST modeling of summarized occurrence patterns with time-ordered structural information and non-linearities, a conclusive recurrent network module is designed to model the sequential patterns of fused embedding vectors at the final phase. The final conclusive latent representations are fed into a fully connected neural networks to predict the abnormal events in future time slots.

In summary, we highlight our contributions as follows:

- We introduce a new multi-view and multi-modal spatial-temporal learning framework MiST for predicting abnormal events of different categories at each region of a city. MiST maps all the spatial, temporal, and semantic units into a latent space to preserve their cross-modal correlations.
- We develop a multi-modal pattern fusion module that is tailored to cooperate with a hierarchical recurrent framework for learning the latent region-time-category interactions shared in multi-view data, and automatically adjust the correlations from each view in assisting the prediction task.
- Through extensive experiments performed on three real-world abnormal event datasets collected from NYC and Chicago, we show that MiST consistently surpasses several state-of-the-art baselines across various settings.

The rest of this paper is organized as follows. We formally present the problem in Section 2. Section 3 introduces the proposed framework. The experimental results are presented in Section 4. Section 5 summarizes the related works. We finally conclude our work in Section 6.

2 PROBLEM FORMULATION

In this section, we first introduce the preliminaries and the studied problem. Then, we present the overview of our developed framework.

2.1 Preliminaries

Definition 1. **Geographical Region**. *We partition a city with a grid-based map segmentation. In particular, we divide the whole city into $I \times J$ disjointed grids which consists of I rows and J columns with the longitude and latitude information. Each grid is referred to as a geographical region denoted by $r_{i,j}$, where i and j is the index of row and column, respectively. In this work, we use regions as the minimal units to study the abnormal event forecasting problem.*

We define the geographical region set as $R = (r_{1,1}, ..., r_{i,j}, ..., r_{I,J})$, and suppose that there are L abnormal event categories ($C = (c_1, ..., c_l, ..., c_L)$), where C is the category set indexed by l. Given a time window T, we also split T as non-overlapping and consequent time slots ($T = (t_1, ..., t_k, ..., t_K)$), where K denotes the number of time slots which is indexed by k.

Definition 2. **Abnormal Event Data Source**. *Given a region $r_{i,j}$, we use $\mathbf{Y}_{i,j} = (\boldsymbol{y}^1_{i,j}, ..., \boldsymbol{y}^l_{i,j}, ..., \boldsymbol{y}^L_{i,j}) \in \mathbb{R}^{L \times K}$ to denote the observations of all categorical abnormal events during K past time slots at region $r_{i,j}$. In particular, $\boldsymbol{y}^l_{i,j} \in \mathbb{R}^K$ belongs to category c_l and represents the event observed at region $r_{i,j}$ from time slot t_1 to t_K. In $\boldsymbol{y}^l_{i,j}$, each element $y^{l,k}_{i,j}$ is set to 1 if abnormal event of category c_j is observed at region $r_{i,j}$ in time slot t_k and 0 otherwise.*

Problem Statement. Given the historical abnormal event data source of all categories across geographical regions R in a city from time slot t_1 to t_K, the objective of this work is to learn a predictive framework which infers the unknown event occurrence of each category c_l at each region $r_{i,j}$ in h future time slots. Formally, we aim to compute: $(y^{l,(K+h)}_{i,j} | \mathbf{Y}_{i,j} = (\mathbf{y}^1_{i,j}, ..., \mathbf{y}^L_{i,j}));\ i, j \in [1, ..., I], [1, ..., J]$.

2.2 Framework Overview

Our developed MiST is a multi-layer representation learning framework as shown in Figure 1. Before presenting the details, we first introduce the model input and then elaborate the motivations to design our framework MiST from spatial-temporal-categorical views.

Definition 3. **Event Context Tensor**. *Given a target region $r_{i,j}$, we model different categorical abnormal events of its spatially nearby regions in time slot t_k using an event context tensor, $\mathcal{A}^k_{i,j} \in \mathbb{R}^{I \times J \times L}$ with three dimensions denoting I grid rows, J grid columns, and L categories, respectively. Specifically, given the time slot t_k, each element in $\mathcal{A}^k_{i,j,l}$ is set as 1 if there exists abnormal events of category c_l from the corresponding region $r_{i,j}$ in the $I \times J$ grid map. Otherwise, we set the element in $\mathcal{A}^k_{i,j,l}$ as 0.*

Context-aware Recurrent Framework. To characterize intra-region correlations in terms of dynamic properties of abnormal event distributions from temporal view, we develop our context encoder based on Long short-term memory (LSTM) networks to learn latent representations for the elements of the flattened vector from event context tensor $\mathcal{A}$ in each time slot. The representations learned from our LSTM encoder give MiST the ability to model the evolving time-dependent nature of abnormal events by well capturing not only their local temporal contexts but also multi-level periodical patterns.

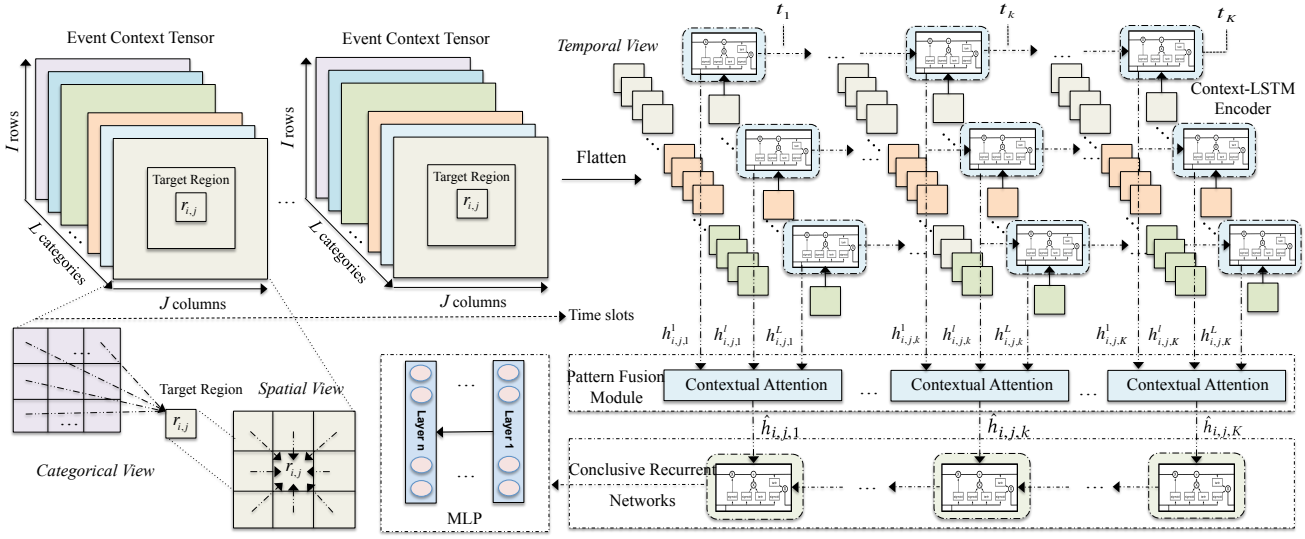

Figure 1: The Multiview and Multimodal Spatial-Temporal Learning Framework.

Multi-Modal Pattern Fusion Module. To jointly capture the inter-region and cross-category correlations in terms of abnormal event distributions, we propose a deep fusion module to model inherent occurrence patterns of abnormal events across surrounding geographical regions and different categories simultaneously. Given a specific time slot t_k, we supply the learned hidden representation vectors of each time-ordered sequence of tensor $\mathcal{A}^k_{i,j}$ to an attention mechanism in order to generate summarized embedding vectors from spatial-categorical views.

Conclusive Recurrent Networks. Relying on the hidden representations generated from spatial-temporal-categorical views, we then develop a conclusive recurrent networks to effectively capture the sequential patterns of cross-modal correlations between location, time, and event category. The final multi-view sequence representations from spatial-temporal-categorical dimensions are stored in the last states of the conclusive recurrent network cells, which provides a guidance for the prediction during the occurrence probability decoding phase.

3 METHODOLOGY

In this section, we present the details of our MiST framework.

3.1 Context-aware Recurrent Framework

In the architecture of MiST, we first employ Long Short-Term Memory (LSTM) networks to encode the complex intra-region correlations with respect to the distributions of abnormal events across time slots (from t_1 to t_K). In particular, LSTM consists of one cell state, and three controlled gates to update the cell state by performing write, read and reset operations, respectively. Formally, the updating functions for hidden states $\mathbf{h}^t_{i,j,l}$ and $\mathbf{c}^t_{i,j,l}$ corresponding to region $r_{i,j}$ and category c_l in t-th time step of input encoded sequence with length T in our LSTM encoder are presented as:

$$
\begin{aligned}
\mathbf{i}^t_{i,j,l} &= \sigma(\mathbf{W}_i \cdot \mathbf{h}^{t-1}_{i,j,l} + \mathbf{V}_i \cdot x^t_{i,j,l} + b_i) \\
o^t_{i,j,l} &= \sigma(\mathbf{W}_o \cdot \mathbf{h}^{t-1}_{i,j,l} + \mathbf{V}_o \cdot x^t_{i,j,l} + \mathbf{b}_o) \\
\mathbf{f}^t_{i,j,l} &= \sigma(\mathbf{W}_f \cdot h^{t-1}_{i,j,l} + V_f \cdot x^t_{i,j,l} + b_f) \\
\widetilde{c^t_{i,j,l}} &= \phi(\mathbf{W}_c \cdot \mathbf{h}^{t-1}_{i,j,l} + \mathbf{V}_c \cdot x^t_{i,j,l} + \mathbf{b}_c) \\
\mathbf{c}^t_{i,j,l} &= \mathbf{f}^t_{i,j,l} \odot \mathbf{c}^{t-1}_{i,j,l} + \mathbf{i}^t_{i,j,l} \odot \widetilde{\mathbf{c}^t_{i,j,l}} \\
\mathbf{h}^k_{i,j,l} &= \mathbf{o}^t_{i,j,l} \odot \phi(\mathbf{c}^t_{i,j,l})
\end{aligned} \tag{1}
$$

where $\mathbf{W}_* \in \mathbb{R}^{d_s \times d_s}$ represents the transformation matrix from the previous states (*i.e.*, $\mathbf{c}^{t-1}_{i,j,l}$ and $\mathbf{h}^{t-1}_{i,j,l}$) to LSTM cell and $\mathbf{V}_* \in \mathbb{R}^{d_x \times d_s}$ are the transformation matrices from input to LSTM cell. Here, d_x and d_s denotes the dimension of input vectors and hidden states, respectively. Furthermore, $\mathbf{b}_* \in \mathbb{R}^{d_s}$ is defined as a vector of bias term. $\sigma(\cdot)$ and $\phi(\cdot)$ represents the sigmoid and tanh function, respectively. The $\odot$ operator denotes the element-wise product. We denote the input gate, output gate and forget gate as $\mathbf{i}^t_{i,j,l}$, $\mathbf{o}^t_{i,j,l}$, and $\mathbf{f}^t_{i,j,l}$, respectively. For simplicity, we denote Eq. 1 as $\mathbf{h}^t_{i,j,l} = \text{LSTM}(*, \mathbf{c}^{t-1}_{i,j,l}, \mathbf{h}^{t-1}_{i,j,l})$ in the following subsections. While there exist other variations of recurrent neural networks, *e.g.*, gated recurrent unit (GRU), we choose LSTM for its general expressions.

3.2 Multi-Modal Pattern Fusion Module

While directly applying the recurrent neural network to solve the abnormal event forecasting problem is intuitive, the general recurrent neural network can do little to handle the complicated influencing factors from other geographical regions and event categories. Hence, we further employ an attention mechanism to adaptively capture the dynamic correlations from spatial and categorical view. Attention mechanisms are proposed to infer the importance of different parts of the training data, and let the learning algorithms focus on the most informative parts. Attention mechanism aims

to free the encoder-decoder architecture from the fixed-length internal representation by introducing a context vector to model the relevance. In addition, in order to differentiate regions and categories in the fusion process, we incorporate region embedding $\mathbf{e}_{r_{i,j}} \in \mathbb{R}^{d_e}$ and category embedding $\mathbf{e}_{c_j} \in \mathbb{R}^{d_e}$ as contextual information into the attention mechanism. Formally, the attention computation formulations in MiST are given:

$$\boldsymbol{\eta}^k_{i,j,l} = \tanh(\mathbf{W}^k(\mathbf{h}^k_{i,j,l}, \mathbf{e}_{r_{i,j}}, \mathbf{e}_{c_j}) + \mathbf{b}^k)$$
$$\alpha^k_{i,j,l} = \frac{\exp(\boldsymbol{\eta}^k_{i,j,l})}{\sum_{i,j\in G}\sum_{l=1}^{L}\exp(\boldsymbol{\eta}^k_{i,j,l})} \tag{2}$$

where we term the size of hidden representation vector in attention networks as *attention dimensionality* which is denoted as S. $\mathbf{W}^k \in \mathbb{R}^{d_s \times S}$ and $\mathbf{b}^k) \in \mathbb{R}^{d_s}$ are respectively the weight matrix and bias vector that project the input into hidden layers to get $\eta^k_{i,j,l}$ as hidden representation of $\mathbf{h}^k_{i,j,l}$. Then, we measure the importance of hidden representations of each region $r_{i,j}$ in the grid map $G = I \times J$ ($(i,j) \in G$) and category c_l ($c_l \in C$), and get a normalized importance weight $\alpha^k_{i,j,l}$ through a softmax function. The attention weights of our fusion module are jointly determined by the input spatial-categorical features and the encoded historical hidden states in the context-LSTM encoder. After obtaining the attention weights, the output hidden representation vector at time slot t_k is derived as:

$$\mathbf{q}^k = \sum_{i,j\in G}\sum_{l=1}^{L}\alpha^k_{i,j,l}\mathbf{h}^k_{i,j,l} \tag{3}$$

where $\mathbf{q}^k$ is the summarized concatenation of view-specific representations $\mathbf{h}^k_{i,j,l}$, describing what kind of influential factors will be considered as more important for abnormal event occurrences at target region $r_{i,j}$. In the training process of MiST, the developed the deep fusion module with attention mechanism is parametrized as a feed-forward neural network which can be trained with the whole neural network. Our proposed approach is very general, which can automatically learn the correlation weights of different views.

3.3 Conclusive Recurrent Network

So far we have developed two components of MiST to (i) model dynamic intra-region correlations from temporal views with the context-LSTM encoder; (ii) capture complex inter-region and cross-categorical correlations from spatial-categorical views with deep fusion module. With the above learned weights as coefficients, the summarized representation $\mathbf{q}^k$ are calculated as the weighted combinations of the view-specific representations with the voting weights (*i.e.*, $\alpha^k_{i,j,l}$) of different views.

To integrate the complex patterns encoded from spatial-categorical factors with the temporal patterns under the MiST framework, we propose to encode the multi-dimensional patterns with recurrent neural networks and model the complex location-time-category interactions with latent-space representations. In this paper, we apply LSTM as the recurrent unit and formulate it as follows:

$$\boldsymbol{\xi}_k = \text{LSTM}(\mathbf{q}_{k-1}, \boldsymbol{\xi}_{k-1}) \tag{4}$$

The joint embedding $\boldsymbol{\xi}$ maps all spatial, temporal, and categorical units into a common latent space. The developed conclusive recurrent networks provide a flexible way to let different views to collaborate with each other. By combining this spatial and categorical contextual signals with the current recurrent temporal status, our MiST framework could predict future abnormal events based on not only the sequential relation but also the spatial correlations across regions and co-occurrence relationships across categories.

3.4 Forecasting and Model Inference

Finally, we utilize the Multilayer Perceptron (MLP) component to decode the occurrence probability by capturing the non-linear dependencies between elements in hidden vectors. Formally, we represent MLP as follows:

$$\psi_1 = \phi(\mathbf{W}_1 \cdot \lambda_1 + \mathbf{b}_1)$$
$$\cdots\cdots$$
$$\psi_N = \phi(\mathbf{W}_n \cdot \lambda_n + \mathbf{b}_n)$$
$$y^{l,k}_{i,j} = \sigma(\mathbf{W}' \cdot L_n + \mathbf{b}') \tag{5}$$

where N represents the number of hidden layers in MLP (indexed by n). For the ψ_n layer, $\mathbf{W}_n$ and $\mathbf{b}_n$ represents the weight matrix and bias vector, respectively. We use *ReLU* (denoted as $\phi(\cdot)$) as the activation function of the fully connected layers and further specify the activation function as *sigmod* (denoted as $\sigma(\cdot)$) to output the abnormal event occurrence probability of category c_l at region $r_{i,j}$ in time slot t_k, *i.e.*, $y^{l,k}_{i,j}$.

In general, our abnormal event occurrence forecasting can be regarded as a classification problem. We utilize cross entropy as the metric in our loss function which is defined as follows:

$$\mathscr{L} = -\sum_{(i,j,l,k)\in S} y^{l,k}_{i,j}\log\hat{y}^{l,k}_{i,j} + (1 - y^{l,k}_{i,j})\log(1 - \hat{y}^{l,k}_{i,j}) \tag{6}$$

where $\hat{y}^{l,k}_{i,j}$ denotes the estimated probability of the l-th category of abnormal events occur at region $r_{i,j}$ in k-th time slot. Here, S is the set of abnormal events in the training process. The model parameters can be derived by minimizing the loss function. In this work, we use Adam optimizer [16] to learn the parameters of MiST.

4 EVALUATION

In this section, we conduct extensive experiments on three real-world abnormal event datasets (*i.e.*, crime and urban anomaly data) collected from New York City (NYC) and Chicago to verify the effectiveness of our developed *MiST* framework. We then analyze the experimental results and demonstrate the accuracy promotion by comparing it with various baselines. We perform experiments to answer the following questions:

- **Q1**: Compared with the state-of-the-art forecasting techniques, can our *MiST* framework achieve comparable accuracy in predicting both citywide crimes and anomalies across different cities?
- **Q2**: Does *MiST* consistently outperform other algorithms with respect to different time periods?

Algorithm 1: The Learning Process of MiST Model.

Input: Historical Abnormal Event Sequences Y, Neighbor Region Set G, Category Set L, Sequence Length T, and Batch Size b_{size}.

Paras: Embedding Matrices $e_r \in \mathbb{R}^{(I*J)\times d_e}$, $e_c \in \mathbb{R}^{C\times d_e}$, and Other Hidden Parameters θ.

Initialize all parameters;

// Sample a minibatch of size b_{size}.

foreach $\mathsf{T}_{\text{batch}} = \text{sample}(X, b_{\text{size}})$ **do**

  foreach $\langle i, j, l, t\rangle \in \mathsf{T}_{\text{batch}}$ **do**

    foreach $\langle i', j'\rangle \in G[(i, j)]$ **do**

      $R_{i,j} = e_r[(i, j) :]$;

      // Lookup region embeddings

      foreach $l' \in L$ **do**

        $C_l = e_c[l, :]$;

        // Lookup category embeddings

        $c^0_{i',j',l'} = c^0, h^0_{i',j',l'} = h^0$// init. hidden states

        for $t' \leftarrow (k - s)$ **to** $(k - 1)$ **do**

          $c^t_{i',j',l'}, h^t_{i',j',l'} = \text{LSTM}(X[i', j', l', t'], c^{t-1}_{i',j',l'}, h^{t-1}_{i',j',l'})$;

          // Eq.1

        end

      end

    end

    $\hat{T}_k = \text{Attention}(h^k_{:,:,:}, [h^k_{:,:,:}; R_{:,:}; C_{:}])$ $\hat{y}^t_{i,j,l} = \text{MLP}(\hat{T}_k)$

    $y^t_{i,j,l} = X[i, j, l, t]$ Update loss $\mathcal{L}$

  end

  Update all parameters w.r.t $\mathcal{L}$;

end

- **Q3**: How does our *MiST* model work for forecasting abnormal events with different categories compared with state-of-the-art techniques?
- **Q4**: How is the performance of *MiST* variants with different combinations of key components in the joint framework?
- **Q5**: How is the performance of *MiST* with different spatial and temporal scales?
- **Q6**: How do different hyperparameter settings affect the forecasting performance of *MiST*?
- **Q7**: How is the interpretation of our *MiST* framework in capturing dynamic importance weights across spatial and category dimensions when predicting citywide abnormal events?

4.1 Data Description

4.1.1 **Data Statistics.** We collect three abnormal event datasets with two different types from NYC and Chicago, *i.e.*, two crime data and one urban anomaly data, and separately perform experiments of predicting the occurrences of each categorical urban crimes and anomalies at each geographical region in a city. The basic statistics of the three datasets are shown in Table 1. In our experiments, we focus on several key categories and consider other categories as external type. We also show the geographical distributions of abnormal events with respect to different categories and time periods in Figure 2. Their details are introduced as follows:

Table 1: Dataset Statistics.

Data Source	**Crime Reports from NYC**	
Time Span	From Jan, 2015 to Dec, 2015	
Category	Burglary	Robbery
Number of Instances	14,967	16,886
Category	Felony Assault	Grand Larceny
Number of Instances	20,189	41,873
Data Source	**Anomaly Reports from NYC**	
Time Span	From Jan, 2014 to Dec, 2014	
Category	Noise	Illegal Parking
Number of Instances	134,690	57,374
Category	Blocked Driveway	Building/Use
Number of Instances	74,698	24,319
Data Source	**Crime Reports from Chicago**	
Time Span	From Jan, 2015 to Dec, 2015	
Category	Burglary	Robbery
Number of Instances	13,103	9,633
Category	Narcotics	Theft
Number of Instances	21,607	56,695
Category	Assault	Battery
Number of Instances	16,992	48,824
Category	Criminal Damage	Deceptive Practice
Number of Instances	28,590	14,084

- **NYC Crime Data (NYC-C)**. This crime dataset records multiple categories of crime reports (*e.g.*, burglary, robbery) in NYC and each crime record is in the format of (crime category, latitude, longitude, timestamp). This data was collected from Jan 2015 to Dec 2015.
- **NYC Urban Anomaly Data (NYC-A)**. This dataset spanning from Jan 2014 to Dec, 2014 is collected from 311 non-emergency services in New York City which records urban anomalies of different categories (*i.e.*, noise, illegal parking). Each reported anomaly record is formatted as (anomaly category, latitude, longitude, timestamp).
- **Chicago Crime Data (CHI-C)**. This crime data was collected from Chicago during 2015 to Dec 2015, which documents different categorical crime reports (*e.g.*, theft, narcotics). The data format is similar as that of NYC crime data.

4.2 Experimental Settings

4.2.1 **Parameter Settings.** In our experiments, we leverage Adam as the optimizer in the learning process of *MiST* and implemented *MiST* with TensorFlow architecture. We set the hidden state dimensionality d_s as 32 and embedding size d_e as 32. The attention dimension and the number of MLP layers is set to 32 and 3, respectively. Additionally, the batch size and learning rate is set to 64 and 0.001, respectively.

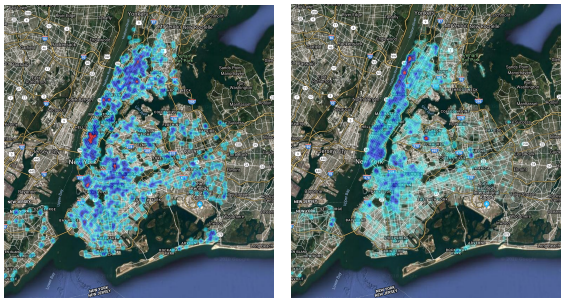

Table 2: Crime forecasting results across different categories in terms of *Macro-F1* and *Micro-F1*.

4.2.2 **Baseline Methods.** *MiST* is measured against the following baseline methods from five categories: (i) the conventional time series forecasting methods (*i.e.*, SVR and ARIMA); (ii) conventional supervised learning algorithm (*i.e.*, LR); (iii) recurrent neural network and its variants for spatial-temporal data forecasting (*i.e.*, ST-RNN and GRU); (iv) advanced neural network models for time series and sequence modeling (*i.e.*, RDN, HRN and ARM). The details are presented as follows:

- **Support Vector Regression (SVR)** [3]: it is a supervised learning model for time series regression analysis based on kernel functions which are characterized by the margin and the number of support vectors.
- **Auto-Regressive Integrated Moving Average (ARIMA)** [15]: it is a conventional time series prediction model for understanding and predicting future values in a time series which is in conjunction with stationary and linear transformations.
- **Logistic Regression (LR)** [11]: it is a statistical model which forecasts each region's abnormal event occurrences based on temporal features (e.g., the day of a week and the month of a year) extracted from historical crime logs.
- **Spatial-Temporal Recurrent Neural Network (ST-RNN)**[25]: it utilizes the recurrent neural networks to capture the spatial and periodical temporal contexts in modeling time-ordered data from each time intervals.
- **Gated Recurrent Framework (GRU)** [6]: it is a time-ordered sequence modeling approach based on gated recurrent unit and encodes the input time series into latent representations.
- **Recurrent Deep Networks (RDN)** [12]: this method is a recurrent deep network framework to consider long-term dependencies in recurrent neural networks, and aims to predict spatial events via jointly modeling normal dynamic temporal patterns.
- **Attentive Hierarchical Recurrent Networks (HRN)** [14]: it is a attention-based hierarchical recurrent framework that is capable of capturing the dynamic sequential patterns and their inherent interrelationships with other ubiquitous data.
- **Attention-based Recurrent Model (ARM)** [9]: this method leverages recurrent framework and attention mechanisms to interpret the relations between the current and past values in predicting spatial-temporal mobility data.

4.2.3 **Evaluation Protocols.** In our experiments, we chronologically split the dataset into training (6.5 months), validation (0.5 month), and test (1 month) sets. The validation set was used for tuning hyper-parameters and the final performance comparison was conducted on the test set. We partitioned New York City and

(a) Crime-Burglary-Aug (b) Anomaly-Noise-Aug

(c) Crime-Burglary-Nov (d) Anomaly-Noise-Nov

Figure 2: Distributions of abnormal events in NYC.

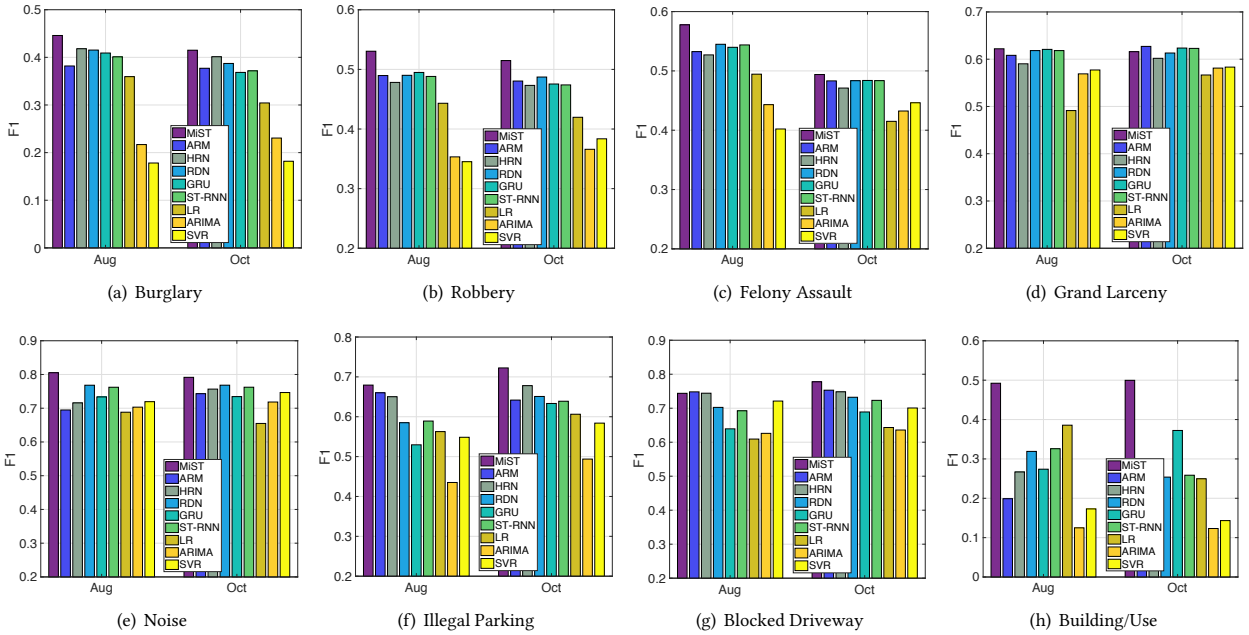
Chicago into 248 and 189 disjointed geographical regions, respectively, where each region is a $2km \times 2km$ grid, following the similar settings in [32, 43]. Based on the region partition results, we can map each abnormal event (*i.e.*, report of crime or urban anomaly) into an individual geographical region and generate the inputs for *MiST* framework. In this work, We adopted two types of evaluation metrics to fully evaluate all methods:

- (i) We use *Marco-F1* and *Micro-F1* [10, 33] to evaluate the prediction accuracy across different crime categories. These metrics indicate the overall performance across different classes. The mathematical definitions of Marco-F1 and Micro-F1 are given: Micro-F1 $= \frac{1}{J} \cdot \sum_{j=1}^{J} \frac{2 \cdot TP_j}{2 \cdot TP_j + FN_j + FP_j}$ and Macro-F1 $= \frac{2 \cdot \sum_{j=1}^{J} TP_j}{2 \cdot \sum_{j=1}^{J} TP_j + \sum_{j=1}^{J} FN_j + \sum_{j=1}^{J} FP_j}$. where J is the total number of event categories. A higher Micro-F1 and Macro-F1 score indicates better performance.
- (ii) we use *F1-score* (harmonic mean to balance precision and recall) and *AUC* [8] to evaluate the accuracy in predicting an individual category of abnormal event occurrence. A higher F1-score and AUC value reflects a better forecasting accuracy.

To ensure the fairness of performance comparison for all compared methods, our experiments are conducted by forecasting occurrences of abnormal events in consecutive days in the time period of test set. In the evaluation results, the average performance is reported across all days in the test time period.

4.3 Performance Comparison (Q1, Q2 and Q3)

4.3.1 **Overall Comparison (Q1).** Table 2 shows both the crime and urban anomaly forecasting accuracy across categories on different cities in terms of Macro-F1 and Micro-F1. From the evaluation results, we summarize three key observations as follows:



First and foremost, *MiST* is significantly better than other different types of neural network-based methods. For example, for predicting crimes in Chicago, *MiST* achieves relatively 9.6% and 30.9% improvements over the best performed baseline (*i.e.*, RDN) in terms of Macro-F1 and Micro-F1 on September. This sheds lights on the benefit of our multi-view model which jointly considers the spatial, temporal, and semantic relationships.

Second, the performance of neural network-based methods are superior to that of conventional time series forecasting techniques and supervised learning approach. This is due to the factors that: (1) conventional time series forecasting methods only emphasize one fixed temporal pattern, rather than the time-evolving temporal dependencies; (2) the neural network-based methods could capture complex inherent structures of multi-dimensional spatial-temporal data in a non-linear manner, which is more advantageous.

Lastly, there is no obvious winner among the recurrent network network variants (*i.e.*, ST-RNN and GRU) and deep sequential data modeling solutions (*i.e.*, RDN, HRN and ARM). This again confirms that only considering the data dependencies from temporal dimension is insufficient to predict both crime and urban anomaly occurrence well. In contrast, *MiST* dynamically associates weights for latent spatial, temporal and categorical correlations, which shows remarkable flexibility and superiority.

4.3.2 **Forecasting Accuracy v.s. Time Periods (Q2).** To make thorough evaluation, we conduct comparison experiment of *MiST* and all baselines across different training and test time periods. We can note that the best performance is consistently achieved by *MiST* with different forecasting time periods. In addition, another observation is that the performance gain between *MiST* and other baselines is relatively stable when sliding the training and testing time windows, which reflects the robustness of our model in learning the dynamic abnormal event distributions over time.

4.3.3 **Forecasting Accuracy v.s. Categories (Q3).** Furthermore, we investigate the effectiveness of *MiST* in predicting each individual category of abnormal events and report the evaluation results in Figure 4 and Figure 3 for crimes in Chicago and crimes as well as urban anomalies in NYC. We can observe that our *MiST* achieves the best performance in all cases. For example, *MiST* outperforms the best performed baseline (*i.e.*, RDN) by 13.2% on average in forecasting burglaries and 12.4% on average in forecasting illegal parking in NYC. Additionally, another interesting observation is that obvious improvements can also be obtained by *MiST* in predicting abnormal events of sparser categories, *e.g.*, 84.1% average relatively improvement over the state-of-the-art approach ST-RNN for building/use prediction. This observation indicates that *MiST* is capable of effectively modeling latent correlations from different contextual modalities (region, time, category), to alleviate the data scarcity problem in forecasting sparse anomalies.

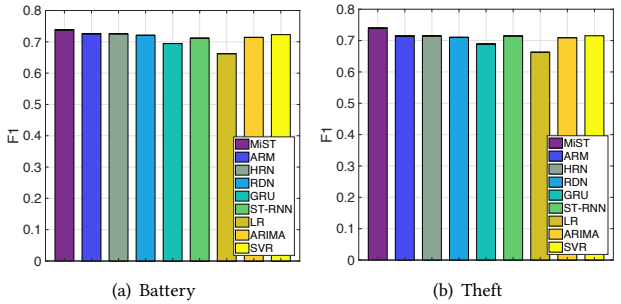
(e) Noise (f) Illegal Parking (g) Blocked Driveway (h) Building/Use

Figure 3: Forecasting results for individual category in terms of *F1-score* on NYC crime and anomaly data.

4.4 Component-Wise Evaluation of *MiST* (Q4)

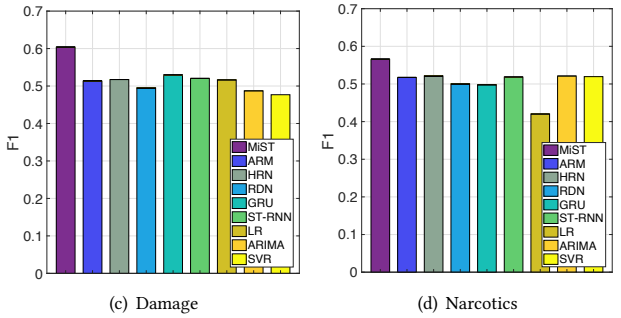
In addition to comparing *MiST* with state-of-the-art techniques, we also aim to get a better understanding of key components of *MiST* by studying the effect of different view components. We denote the full version of our method as as *MiST*.

- **Spatial-View + Temporal View** *MiST*-st: This variant captures both spatial and temporal dependencies in predicting abnormal events, *i.e.*, does not consider cross-categorical influences.
- **Category-View + Temporal View** *MiST*-ct: This variant considers both categorical and temporal views, *i.e.*, without considering inter-region spatial correlations.
- **Temporal View** *MiST*-t: For this variant, we only use LSTM with temporal attention mechanism to consider the temporal dimension of muli-view data, *i.e.*, without considering contextual signals from both spatial and categorical views.



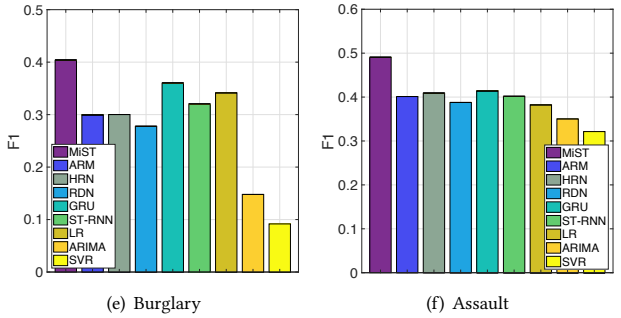
We report the evaluation results on crime dataset in Figure 5. We can notice that the full version of our developed framework *MiST* achieves the best performance in all cases. As such, it is necessary to build a joint framework to capture spatial view (inter-region spatial correlations), temporal view (intra-region temporal correlations), as well as categorical view (cross-categorical dependencies) simultaneously for forecasting citywide abnormal events.

4.5 Effect of Spatial and Temporal Scale (Q5)



In our evaluations, we further investigated the effect of spatial and temporal scale in *MiST*, *i.e.*, the geographical scale of grid map $G = I \times J$ in the event context tensor $\mathcal{A}$ ($I = J$ in our experiments) and the length of encoded sequence T in our developed recurrent framework. The evaluation results are presented in Figure 6. There are two interesting insights from the result: (i) Figure 6(a) reveals that increasing I and J improves performance, which is not surprising since we consider a larger geographical space to learn jointly representations from mutli-views. Furthermore, as the spatial scale of the event context tensor increases, the performance slightly increases but mainly remains stable when $I = J = 11$. One potential reason is that when considering larger geographical coverage, more parameters need to be learned. As a result, the training of *MiST* becomes harder. (ii) As depicted in Figure 6(b), the performance of *MiST* becomes better as the encoded sequence length T increases and tends to saturate once T reaches 10. Due to space limit, we only report the results of crime data on Oct. Similar results can be observed on urban anomaly dataset and other time periods.

4.6 Hyperparameters Studies (Q6)



To investigate the robustness of *MiST* framework, we examine how the different choices of parameters affect the performance of *MiST* in the prediction performance. Except for the parameter being tested, we set other parameters at the default values. Figure 7 and Figure 8 shows the evaluation results as a function of one selected parameter when fixing others. Overall, we observe that *MiST* is not strictly sensitive to these parameters in two tasks and is able to reach high performance under a cost-effective parameter choice, which demonstrates the robustness of *MiST*. Furthermore, we can observe that the increase of prediction performance saturates as the representation dimensionality reaches around 32. This is because: at the beginning, a larger value of hidden state dimensionality d_s and attention dimension S brings a stronger representation power for the recent framework and attention network, but the further increase of dimension size of latent representations to encode abnormal event occurrence patterns from multi-views might lead to the overfitting issue. In our experiments, we set the dimension

size as 32 due to the consideration of the trade-off between the effectiveness and computational cost.

4.7 Case Study (Q7)

Apart from the superior forecasting performance, another key advantage of *MiST* is its ability in interpreting the importance weights of spatial and categorical correlations in predicting a specific category of abnormal event at a region. To demonstrate this, we perform case studies to show the explainability of our framework by visualizing the attention weights obtained from *MiST* in predicting burglaries with a 5×5 grid map (the target region is in the middle of this map) in NYC, as shown in Figure 9. We could observe that

(a) Robbery (b) Burglary

(c) Felony Assault (d) Grand Larceny

Figure 9: The importance weights of across regions and crime categories learned from *MiST* in predicting burglaries with a 5×5 grid map in NYC.

MiST enables the dynamic modeling of correlations between the target region and other regions, as well as latent influences between the target event category (burglary) and other categories.

5 RELATED WORK

We introduce the research work which are related to our study.

Ubiquitous Sensing Applications. Ubiquitous sensing has emerged as a new sensing paradigm that empowers average people to contribute their observations and measurements about the physical world. Numerous novel applications have been developed to address various challenges in smart cities applications [4, 18, 21, 32, 36, 37, 41, 42], such as intelligent transportation [4], privacy-preserving [37], business assessment [21] and human activity modeling [41]. However, the abnormal event prediction problem in ubiquitous sensing scenario remain as a challenging problem to be solved. In this paper, we develop an end-to-end model to tackle this problem by addressing the unique challenges.

Spatial Anomaly Detection and Event Forecasting. There exists a good amount of work on the topics *geographical anomaly detection* [7, 17, 44, 46, 47]. For example, Doan *et al.* detected anomalies by modelling the behaviours of pedestrian flows across multiple locations [7]. Zheng *et al.* identified the anomalies from spatial-temporal data using multiple data sources [47]. However, all above solutions identified the geographical anomalies *after they happen* which might lead to the inefficiency to handle the anomalies beforehand. Additionally, while several recent studies aim to predict social events using social media data [27, 31, 45], these work only consider obvious social events which can be identified based on the external content (*e.g.*, keywords) from social media platforms (*e.g.*, Twitter). In contrast, this paper solves a new problem of different categories of abnormal event prediction at each region of a city with a multi-view and multi-modal deep neural network architecture.

Sequential Data Modeling. A relevant body of work in the machine learning and data mining communities have investigated modeling sequential data [9, 12, 13, 35, 38, 48]. For example, Autoregression-based models (*e.g.*, ARIMA) have been proposed to study the problem of time series prediction [19]. Compared to traditional time series data, temporally-ordered abnormal event sequence has its own characteristics, *e.g.*, complex spatial-temporal correlations and dynamic multi-dimensional interactions. Recently, Recurrent neural networks (RNNs) become an effective tool due to their success in sequence modeling [1]. For example, Hu *et al.* proposed to capture sequential structures of subevents with LSTM networks [12]. Wu *et al.* developed a RNN based model to predict future behavioral trajectories of users in online recommendation platforms [35]. However, these works can only capture temporal dependency in time series, which ignore the various characteristics of geolocation data from multi-views. To overcome this problem, our MiST framework aims to forecast the abnormal event data in urban space via modeling latent correlations from spatial-temporal-categorical views.

Attention Mechanism. The attention mechanism has been proposed to strengthen not only the ability of RNN in capturing the long-range dependencies but also the interpretability in image analysis [5] and nature language processing [22]. Later, a number of studies developed attention-based models to encode hidden states in different time series applications, such as patients' health information prediction [28] and online personalized recommendation [2]. Inspired by the above work, this work proposes a deep fusion module based on attention mechanism. Different from the above attention-based methods which only focus on sequential patterns, we propose a novel multi-view attention model which fuses view-specific representations on different dimensions.

6 CONCLUSION

This paper explored a new neural network architecture MiST to explicitly model the dynamic patterns of citywide abnormal events from spatial-temporal-categorical views. We integrated recurrent neural networks with a multi-modal pattern fusion module to model spatial-temporal correlations. We evaluated our new MiST framework on different types of real-world datasets and the results showed that our approach achieves better performance when competing with several baselines. There are several future directions for our work. *First*, we are interested in extending the current method to identify the causalities for the occurrences of different categorical abnormal events, which is useful for suggesting relevant public policy making. For future work, it is promising to explore the factors underlying abnormal event occurrences and how different categorical event propagate with respect to spatio-temporal dimensions. *Second*, in this paper, we evaluated our method on three real-world datasets, *i.e.*, crime and anomaly data, due to limited data availability. In fact, the framework of MiST is general, and it is feasible to apply our model on other multi-dimensional time-stamped sequence data.

ABSTRACT

Under increasing scrutiny, many web companies now offer bespoke mechanisms allowing any third party to file complaints (*e.g.,* requesting the de-listing of a URL from a search engine). While this self-regulation might be a valuable web governance tool, it places huge responsibility within the hands of these organisations that demands close examination. We present the first large-scale study of web complaints (over 1 billion URLs). We find a range of complainants, largely focused on copyright enforcement. Whereas the majority of organisations are occasional users of the complaint system, we find a number of bulk senders specialised in targeting specific types of domain. We identify a series of trends and patterns amongst both the domains and complainants. By inspecting the availability of the domains, we also observe that a sizeable portion go offline shortly after complaints are generated. This paper sheds critical light on *how* complaints are issued, *who* they pertain to and *which* domains go offline after complaints are issued.

CCS CONCEPTS

• **Information systems** → **World Wide Web**; *Web complaints*; Web search engines; Web indexing; Infringing content distribution; • **General and reference** → Measurement.

1 INTRODUCTION

The web has proven a powerful platform for the large-scale distribution of content. Notoriously difficult to regulate, individual web organisations have been frequently left to decide how to best handle issues related to legal, regulatory and even moral matters, *e.g.,* moderation of online discourse, removal of copyright infringing content, mitigation of online harassment. This has generated significant societal attention, with major companies like Google and Twitter coming under increasing public scrutiny [9, 24]. Consequently, large web organisations have begun to implement bespoke mechanisms to allow third parties to register complaints. For example, Google's complaint system allows anybody to issue notices requesting the removal of specific results from their search listings, whereas Twitter enables users to report posts they believe to be infringing policy. Although a valuable tool in the wider landscape of web governance, this places considerable responsibility within the hands of these organisations, who must decide which complaints are legitimate and how they should be dealt with (often referred to as self regulation [30]). Yet, to date, we have little evidence regarding how these complaint procedures are handled, how successful they are, or who they are targeted against and by whom.

We argue that the scale of these complaints and their impact on the wider society's perception of the web, warrant detailed investigation. There are multiple interesting questions, such as who generates complaints? Whom do these complaints pertain to? What are the characteristics of domains that receive complaints? Does content remain online after complaints? With these questions in mind, this paper presents the *first large-scale study of web complaints*. To this end, we have gathered complaints from hundreds of transparency reports made available by organisations including Google, Vimeo, Bing and Twitter, and reflected in the Lumen database (§2). These reports expose detailed information about web complaints covering over 1 billion URLs ranging from copyright infringement to governmental notices.

We start our analysis by characterising the nature and scale of organisations that generate notices (complainants). Despite the presence of numerous complaint categories, copyright notices largely dominate, with 98.6% of all complaints (§3.1). A critical minority of organisations play a remarkably prominent role in this, with the top 10 alone contributing 41% of all notices sent (§3.2). Our analysis reveals that the majority of *notices* are generated by large content-based organisations (*e.g.,* NBC, Fox). Despite this, we find that the majority of notice senders are occasional users of the complaint system: 94% of complainants issue fewer than 100 notices. These different groups tend to rely on different types of complaints. For example, large copyright enforcers (*e.g.,* Rivendell) generate millions of copyright notices, whereas governmental agencies (*e.g.,* Roskomnadzor) issue a far smaller set of targeted court and governmental

https://doi.org/10.1145/3308558.3313438

notices. This leads us to focus on the categories of websites that these different types of notices pertain to (§3.3). We find that notices are heavily biased towards certain types of website. For example, websites categorised as 'File Sharing' and 'Elevated Exposure' are hugely over-represented amongst our complaint dataset. Similarly, individual notice senders tend to target specific topics, *e.g.,* 60% of complaints by *Cam Model Protection* target adult websites, whereas 55% by *NBCUniversal* target Entertainment, shedding light on the priorities of organisations utilising the complaint services.

This leads us to investigate if equivalent dynamism exists on the part of the reported websites themselves (§4). We find that a small (and constantly evolving) set of websites dominate the ranking of the most reported, with a few domains that remain prominent throughout our entire measurement period: the top 1% of domains accumulate 63% of complaints (§4.1). These include many obscure websites, which are unlikely to be widely known, *e.g.,* 22 out of the top 30 most frequently reported websites are not even in the Alexa Top 100K, and the correlation between the popularity of domains in terms of notices and Alexa rank is just 0.13. Deeper analysis reveals that these trends are dictated by the activity of a small set of *extremely* aggressive notice senders (§4.3), whose 'bursty' behaviour creates high levels of instability.

We finally inspect the availability of the webpages that are complained about, with the conjecture that websites receiving many complaints may be more likely to go offline (§4.4). We confirm that many are highly ephemeral: 22% of all domain names soon get taken offline (NXDOMAIN), whereas our HTTP liveness checks show that a further 19% of all resources fail to return 200 OK responses within 1 week of a complaint. We correlate these with a number of factors to find that the 'success' rate of complainants differs dramatically, with the most successful (Rivendell) seeing 55% of its complaints acted upon in contrast to others complainants where the figure is below 1%.

2 METHODOLOGY & DATASET

This section presents our data collection methodology. This has two goals: (*i*) To provide vantage into a broad set of web complaints, covering enough domains to provide meaningful insight; and (*ii*) To annotate these complaints with sufficient metadata to shed light on domain activities and topics.

2.1 Website Complaints

First, we detail our methodology for gathering complaints issued about websites. Naturally, it is impossible to get complaints issued to *all* websites, because the vast majority do not make this information available. Hence, we focus on sites that expose transparency reports, *e.g.,* Bing, Twitter, Google, Vimeo. These reports list complaints received by the organisations, including relevant metadata. To gather these, we utilise Lumen[1] — a database run by the Berkman Klein Center for Internet & Society. It aggregates and publishes transparency report data pertaining to complaints issued towards 223 organisations. The exact purpose of each complaint differs, *e.g.,* a complaint to Bing will normally request the removal of search results, whilst complaints to Vimeo will concern the removal of videos. However, each notice (*i.e.,* complaint) includes the following standard fields:

- *Notice Type:* the category of notice which has been reported. For example, a Digital Millennium Copyright Act (DMCA), trademark or data protection *etc.*
- *Notice Sender:* or complainant, is the organisation who submitted the notice.
- *Notice Recipient:* the web publisher or service provider where the infringing notice is sent to.
- *Notice Principal:* in cases of a copyright-related notice, this is the person or organisation that holds the copyright on the content reported.
- *Infringing URL(s):* the list of URL(s) that the notice sender is requesting to be dealt with. Note that this is not necessarily a set of URLs owned by the recipient, *e.g.,* Bing may receive complaints requesting the removal of a third-party URL from its search results.

We collected all complaints from the Lumen database between 01/01/2017 and 31/12/2017 using their API. In total, we extract 1,054,248,823 URL complaints from 38,523 notice senders.

2.2 Website Metadata

Once we extract the reported URLs, we compile further metadata. This section explains the metadata collected.

Website Categorisation. We classify each domain using the VirusTotal API.[2] This API has been used in a wide set of research, and is known to provide good accuracy [14, 16, 31]. The API provides a classification for each domain in our dataset, *e.g.,* games, education, file sharing, blogs *etc.* We later use this to understand the types of complaints generated. Due to the usage limitations of the API, we only categorise the top 240K domains with the most reported URLs. Note that 22% of these could not be categorised by VirusTotal. We further annotate each domain with its Alexa ranking to gain insight into its global popularity.

DNS Probes. We utilise the Domain Name Service (DNS) to map the domains to their respective DNS records on 29/07/2018. We performed queries (IPv4), which yield 849,023 responses and 206,863 IP addresses. We use this data to check if the domain name is still live.

Webpage Probes. For each URL, we download its HTML and parse it to extract all embedded domains. This allows us to identify mirrors of websites hosted on multiple domains/URLs, by comparing the HTML contents. Tests are performed from a university campus, where we have confirmed no web filtering is performed. In total, we collect the HTML structure for 770,737 webpages.

Liveness Checks. We also perform periodic checks on the domains and URLs to verify if the websites are still active (*i.e.,* returning an HTTP 200 status code). This allows us to explore the potential efficacy of organisations seeking to remove content. Due to the sheer scale of the complaints (>1 billion URLs), we only perform checks for 2M URLs complained about between 14/07/2018 to 17/07/2018. Upon recording a complaint from Lumen, we added its URL to a queue and began weekly checks that executed between 18/07/2018

[1] https://lumendatabase.org/

[2] https://www.virustotal.com/

to 14/08/2018. We record the HTML response and HTTP status code, alongside whether or not the TCP handshake timed out. Each week, we exclude URLs that have already been deleted.

2.3 Limitations & Ethical Considerations

We emphasise that Lumen only provides vantage into 223 complaint recipients, obviously a small fraction of the world's online organisations. These consist primarily of: *Google*–79%, *Bing*–15.6%, *Twitter*–3.8%, *Periscope*–0.8% and *Vimeo*–0.4%. We do not assert that our findings generalise beyond these organisations, although the scale of these five companies indicates that the insights are highly valuable nevertheless. We should also highlight that our research covers websites that may participate in illegal activity (*e.g.*, copyright infringement). We restrict this collection to downloading the webpage HTML and checking server liveness, ensuring that *no* measurements involve participating in a websites activities, *e.g.*, registering user accounts or downloading content. Note that this may still result in advertisement revenue being generated by the website. Unfortunately, this was impossible to avoid considering the nature of our measurements. That said, we limit ourselves to accessing URLs a small number of times (< 10), minimising any potential revenue.

3 COMPLAINTS & NOTICE SENDERS

In this section, we investigate the senders and receivers of complaints. Specifically, we are interested in exploring *who* sends complaints and *what* they pertain to.

3.1 What Types of Complaints Exist?

We identify complaints from 38,523 unique senders, covering 1.05 Billion URLs, which are hosted across 1,090,173 domains. Individual complaints tend to contain multiple URLs, with an average of 560 URLs and 31 domains per notice. In terms of the *types* of notices, there is a remarkable skew towards DMCA complaints. This is partly driven by the prominence of search engine recipients within our data. Table 1 presents a breakdown of the types of complaints across the entire dataset. We find that DMCA notices make up 98.6% (1.05B URLs) of the dataset and a similar share of domains (97.8%). DMCA notices are a US-enforceable complaint which covers takedown notices for (allegedly) copyright infringing content. The senders largely appear to be third party organisations who act on behalf of the actual copyright owners: just 9% of notice senders listed are also the principal. Measured by frequency, DMCA notices are followed by Defamation (52K), Court Orders (29K) and Government Requests (2.7K), covering nearly a third of the recipients (31%). We also observe a number of less popular complaint types, such as Law Enforcement Requests, Data Protection and Trademark infringements. Whereas these make up less than 0.001% of the dataset, they cover more than 20% of the recipients.

3.2 Who Are the Notice Senders?

The previous section suggests that notice senders are more diverse than simply the owners of copyright material, and that different reporting practices coexist. To shed light on these aspects, we next inspect the entities behind the notices submitted. We find that the distribution of notices is *highly* skewed towards a few extremely

Table 1: Dataset summary with the percentages of notice types, and the corresponding share of URLs, senders, principals and domains.

Notice Type	% of notices	% of URLs	% of senders	% of principals	% of domains
DMCA	98.6	99.99	94.46	99.87	97.78
Defamation	0.95	<0.01	0.15	<0.01	1.50
Court Order	0.19	<0.01	4.87	0.07	0.41
Government Request	0.15	<0.01	0.15	0.02	0.13
Private Information	<0.01	<0.01	0.071	-	0.003
Data Protection	<0.01	<0.01	-	-	<0.001
Law Enforcement Request	<0.01	<0.01	0.02	0.03	<0.001
Trademark	<0.01	<0.01	0.02	-	<0.001
Other	0.08	<0.01	0.26	<0.01	0.16
Total	1,885,267	1,054,248,823	38,523	20,686	1,090,173

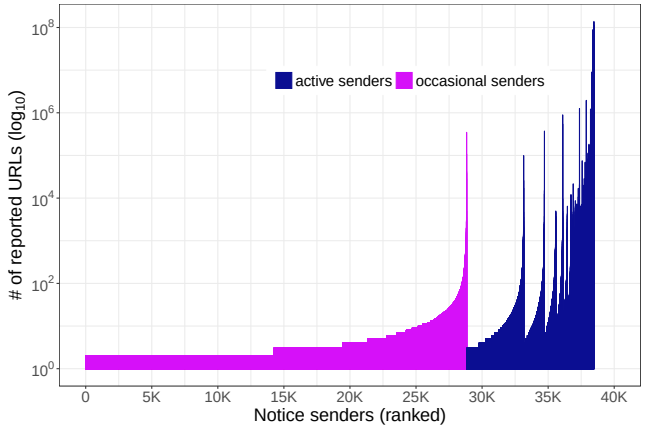

Figure 1: Number of reported URLs per complainant. The X-axis present each complainant, sorted by the two metrics: (*i*) number of days a complainant reports on; and (*ii*) notices generated by each complainant.

active senders. The top 10% of notice senders report over 1 billion URLs, in stark contrast to just 550K by the bottom 90%.

Figure 1 presents the number of reported URLs from each notice sender. The X-axis is sorted by two metrics: (*i*) the number of days that a sender generates notices on; and (*ii*) the number of notices sent (note that Y-axis is in log scale). The distribution is highly unbalanced, with a large majority of notice senders (94%) issuing fewer than 100 complaints. The figure reveals two broad categories of complainants: (*i*) *active*, who send complaints on multiple days and (*ii*) *occasional*, only generating notices on a single day. Whilst the *active* group represents just 25% of all complainants, it is responsible for almost all notices (99.92%). In contrast, the *occasional* senders, consisting of the remaining 75%, collectively contribute just 0.08% of the total number of complaints. It can also be observed that the curve in Figure 1 is not monotonic. This is because the number of notices issued each day can vary. Whereas occasional senders, by definition, *only* issue complaints on a single date, some send multiple notices. Although the daily average is just 1.4 notices, there are some occasional senders who send a large number of complaints in a single burst. For example, Idreto (an occasional sender) generated 350K notices on a single day. As a result, even

Table 2: Top 10 complainants (by # of reported URLs).

Notice Sender	% of reported URLs	% of notice	% of reported domains	# of reported days
Rivendell	13.17	1.65	4.97	357
Aiplex	9.76	1.88	1.30	364
BPI	8.60	2.52	2.72	355
Apdif Mexico	8.52	0.55	0.16	208
Mg Premium	7.77	0.47	0.49	341
Apdif Brasil	7.56	0.52	0.39	244
Remove Your Media	7.28	0.92	2.45	346
Mark Monitor	5.29	1.13	5.12	365
Fox Group Legal	4.36	0.14	2.26	355
Protek Media, S.C.	4.20	0.31	0.67	365
Total	806,358,505	188,158	224,076	

occasional senders can have a significant impact on the overall ranking of reported domains.

We now inspect the types of complaints generated by these two groups of notice senders. Table 2 presents the top 10 complainants. We find that *active* senders are dominated by copyright enforcement and trade organisations *e.g.,* the British Phonographic Industry (BPI), Apdif Brasil, Apdif Mexico, *etc.* These organisations represent hundreds of music recording companies in their respective jurisdictions. Also within this group are copyright protection agencies such as Muso, Aiplex, Mark Monitor and Entura who specialise in tracking pirated content. These companies aggregate complaints from many different copyright holders, and act as enforcers on their behalf. This partly explains their broad coverage and ability to produce large volumes of complaints. In contrast, *occasional* senders are predominantly made up of small organisations and private entities. We see that the categories of *Private Information* and *Trademark* are particularly dominated by *occasional* notice senders, making up 94% and 70% respectively. Conversely, *active* senders hold sway among other notice types, *i.e.,* DMCA. These striking differences between the categories of sender highly differing strategies based on the nature of the complaints, with the ability of a small hub of complainants to dominate the wider system.

3.3 What Topics Do Complaints Target?

To better understand the main drivers behind the complaints, we investigate which categories of websites notices senders complain about. Figure 2 presents the percentage breakdown of complaints, domains and complainants based on the reported domain category. Although it is clear that these classifications contain noise, we believe they offer useful insight into wider activity. To better understand how this relates to the general web ecosystem, we also depict the distribution of the Alexa Top 100K websites.

There is a remarkable divergence between our dataset and Alexa, highlighting a clear bias towards complaints for certain types of websites. The largest fraction of domains are categorised as business (for both Alexa and Lumen), which includes websites such as `4shared.com`, `mangapark.me` and `gorillavid.in`.[3] The most over-represented categories in the Lumen dataset are Elevated Exposure[4] (8% *vs.* 0.3% for Alexa), Entertainment (13% *vs.* 3%), File

[3]We note that this category covers a number of business facing websites, including those engaged in Hollywood copyright theft.
[4]This category refers to malicious websites that camouflage their true nature

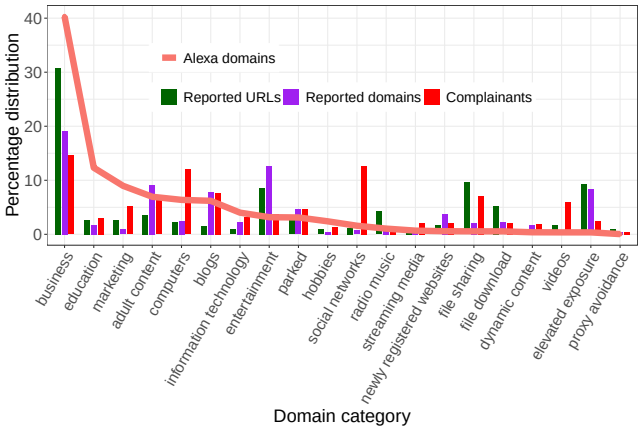

Figure 2: Percentage of reported URLs, domains and complainants for the 20 most reported domain categories *vs.* the share of Alexa Top 100K per category.

Download (2% *vs.* 0.6%), File Sharing (2% *vs.* 0.6%), Blogs (8% *vs.* 6%), and Adult Content (9% *vs.* 7%). While File downloading and sharing are expected, the other ones are less intuitive. In contrast, categories that are under-represented include Education (2% for Lumen *vs.* 12% for Alexa) and Marketing (1% *vs.* 9%).

These trends suggest that notice senders tend to focus on individual categories. To explore this, Figure 3 presents the fraction of complaints that target each of these top 20 categories for the top 30 complainants. In-line with our conjecture, several complainants exhibit significant bias towards a single category. For example, 42% of MG Premium's complaints target adult websites, 45% of NBCUniversal's focus on Entertainment, and 34% of Rico's is Business, demonstrating the prevalence of a high degree of specialisation. Considering the practice of using web crawling to collect links [29], this specialisation makes sense as it allows individual organisations to streamline their activities (based on which sites they have crawlers for).

Briefly, we also note that these categories tend to attract different *types* of notices too. For example, we find that the majority of Data Protection (60%) notices are logged against adult domains. This aligns with the well known high litigiousness of the adult content industry [21]. In contrast, 10% of complaints catagorised as Defamation pertain to news. The remaining notice types (DMCA, Government, and Private Information) are typically made about business domains, representing 31%, 33% and 60% for each category respectively; with the exception of Court Order notices where most complaints are regarding shopping domains (27%). These clear trends confirm that the majority of notice senders are quite focused in their activities, with clear specialisation.

4 WEBSITES & WEBPAGES

Whereas the previous section explored the complaints and complainants, we next inspect the websites (domains) and webpages (URLs) which the complaints pertain to. Specifically, we are interested in understanding which websites gain most attention, and their availability.

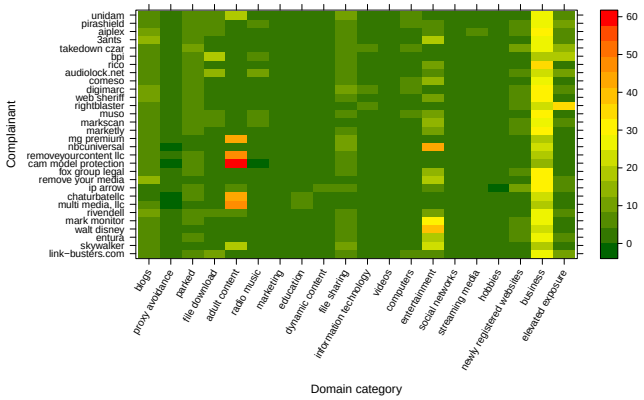

Figure 3: Distribution of (top 20) domain categories (in %) reported by (top 30) complainants.

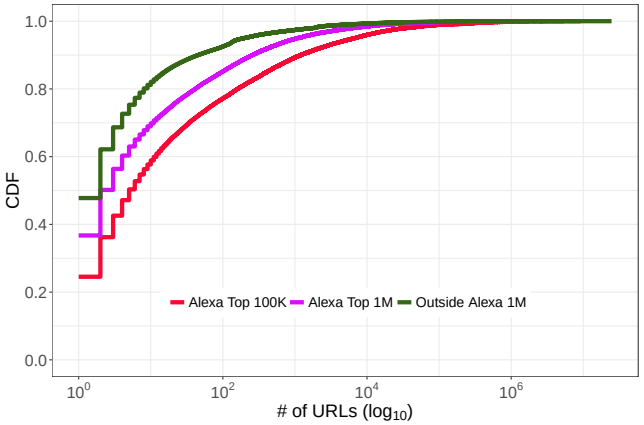

Figure 4: CDF of the number of complaints per domain. Domains are classified by their Alexa Rank.

4.1 How 'Hot' Are Websites?

We start by inspecting the number of complaints generated about each website. Figure 4 presents a CDF showing the distribution of notices per domain. We separate the data depending on the domain popularity, based on its position in the Alexa ranking. Again, we observe a noticeable skew: it is clear that there are a small number of 'hot' websites that gain the most attention from notice senders. In particular, the most reported domains (the top 1% by the number of reported URLs), receive 63% of all complaints. To provide insight into the characteristics of these domains, Table 3 summarises the Top 10 in terms of the number of complaints. A range of uncommon websites are seen within this list. Although, overall, 60% of notices relate to websites in the Alexa Top 100K, only 4 of the most reported 10 domains, and 8 out of the top 30 are within this Alexa rank (we find a Pearson correlation of just 0.13 between these two rankings). The reasons behind these relatively obscure sites gaining 'notoriety' are quite diverse, but they do share one common attribute: their position in the ranking is typically driven by a single complainant that repeatedly targets them. In fact, 9 out of the top 10 domains receive at least 50% of their complaints from a single organisation. This is a general pattern across all domains: we find that 82% of them receive at least half of their complaints from a single complaint. To visualise this dominance by a few complainants in each domain, we depict in Figure 5 the percentage of URLs reported by the top 3 complainants of each domain (in green). The rest of complainants (in red) tend to contribute little to nothing. The vast majority of domains receive nearly all complaints from just a tiny set of senders. For example, `mp3toys.xyz` receives 99.9% of complaints from a single party (Apdif Brasil). Upon closer inspection, it is clear that this organisation uses an algorithm to 'guess' potential infringing URLs based on song titles. Although we envisage that these URLs are checked for liveness before complaints are generated, we note that `mp3toys.xyz` dynamically generates 200 OK HTTP responses for *any* URL requested, likely disrupting any liveness checks. These type of bulk sending activities do not appear to be rare occurrences. For example, the same organisation reported over 17M URLs for file hosing domain `4shared.com`, despite the website only hosting 2M pages [25]. As well as confirming that these highly active senders are heavily automated, it also suggests that rigorous procedures are not always followed.

4.2 Are Domains Unique?

The above is based on unique domain counts, however, we also posit that some of these domains may actually host the same content, or even resolve to the same IP address. To test this, we turn to our DNS and webpage probes, which downloaded the HTML from all domains. We extract their `<title>` and all metadata tags. In cases, where two domains' tags match, we assume they host the same page. We term these *replicas*. The vast majority of domains host different content. Fewer than 0.01% of domains have any replicas. From those that do, 73% refer to the same IP address, indicating that the web server operator has simply created multiple domain names. Just 2% of these have matching second-level domains (with a different TLD), whereas the remainder actually are entirely distinct. We conjecture that this may be an evasion tactic to avoid DNS-based blocking schemes. We also observe certain outliers; in the most extreme case, we find that `1fichier.com` uses 3,838 different domain names, which map to 78 IP addresses. This is a file sharing service well known for hosting illegal content. Another key driving force in the case of these extreme examples is the presence on numerous unblocker websites in our dataset. These websites essentially operate as proxies, generating third level domains for any website requested. For example, `s-s.www.cats.com.prx2.unblocksites.co` provides access to `www.cats.com` via `unblocksites.co`. Table 4 presents the top 10 (in terms of reported URLs) of these unblocking services. Remarkably, `unblocksites.co` actually constitutes 10% of all reported URLs. In other words, we find that many complainants target these unblocker sites, by replicating their complaints for both the origin domain and the unblocked version. Understanding an exploring these is a key area of our future work.

4.3 How Stable are Domain Rankings?

The previous sections indicate that complaints about a domain are often dominated by a single sender. We conjecture that this

Table 3: Top 10 domains with most complaints and the number of TLDs associated with each domain, times it appeared in the top 10 (in terms of complaints) per month, domain category, major complainant (with the share of complaints), number of days receiving complaints and its Alexa ranking position.

Domain	# of TLDs	# of times in top 10	Domain category	# of complainants	Major complainant (s) (% of complaints)	# of days reported	Alexa Rank
mp3toys.xyz	10	3	elevated exposure	10	Apdif Brasil (99.9%)	109	-
4shared.com	15	4	filesharing	40	Apdif Brasil (99.8%)	246	-
googlevideo.com	1	7	entertainment	84	Comeso (78.2%), Remove Your Media (17.3%)	239	-
mangapark.me	3	4	business	18	Remove Your Media (99.1%)	28	3,901
gorillavid.in	3	3	business	16	Fox Group Legal (55%), Mark Monitor (25.2%), Vobile (17.1%)	365	6,778
tvad.me	1	2	business	14	Fox Group Legal (59.9%), Mark Monitor (39.9%)	94	45,766
israbox.vip	101	5	media file download	19	Rivendell (99.6%)	46	-
uploaded.net	3	2	filesharing	216	Rivendell (31.7%), Skywalker(18.1%) Mark Monitor (14.9%), Fox Group Legal (12.3%)	365	662
genteflowmp3.uno	11	2	media file download	6	Apdif Mexico (99.6%)	149	-
deep-warez.org	1	2	radiomusic	43	Rivendell (98%)	345	183,305

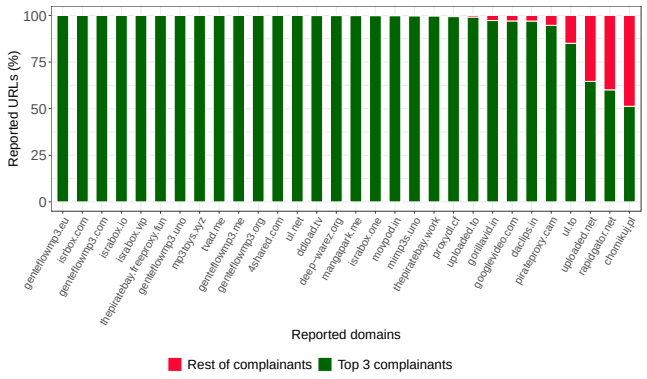

Figure 5: Percentage of reported URLs by the top 3 complainants for each domain (on X-axis) *vs.* the rest of complainants.

Table 4: Top 10 unblocking services present in our dataset.

Unblocking Site	% of Reported URLs	% of Domains	Unblocking Site Category	Alexa Rank
unblocksites.co	10	0.13	uncategorised	12,252
freeproxy.fun	2.4	0.02	webproxy	26,517
unblocked.lol	2	0.04	proxy avoidance	8,552
unblockall.xyz	0.9	0.02	proxy avoidance	820,291
proxydude.xyz	0.6	0.007	elevated exposure	-
immunicity.gold	0.5	0.03	proxy avoidance	-
unblockall.org	0.5	0.01	business	4,947
unblocked.cam	0.5	0.02	proxy avoidance	
unblocker.cc	0.4	0.009	proxy avoidance	15,535
unlockproj.club	0.4	0.02	uncategorised	

dominance may result in significant temporal instability. This can be represented as a ranked list, capturing the domains most frequently reported on each day. To explore this, Figure 6 presents the count of domains that are reported on x days. 81% of domains are complained about on fewer than 5 days, with only 0.2% being complained about on more than 300 days. This suggests a high degree of instability, with the make-up of complaints changing on a daily basis. In line with our previous findings, the majority of these infrequently complained about domains are outside the Alexa Top 1M, whereas 87% of domains which are complained about on over 300 days are within the top 1M. In Figure 6 this can be seen as an upturn on the right-hand side of the graph.

To explore this trend, We next calculate the statistical variance of each domain's daily complaint count to understand how the number of daily complaints change. Figure 7 presents a CDF showing the per domain variance over the entire dataset (for domains with complaints on multiple days). About 15% of domains have a variance of zero because they receive the same number of complaints each day they are reported; 94% of these are reported under six times. However, many remaining domains exhibit significant daily variance: 7% of domains have a variance greater than 1K and, remarkably, 0.9% of domains even have a daily variance greater than 1M. This means that the number of complaints to a domain varies heavily on a day-to-day basis.

Closer inspection reveals that this is driven by *extremely* aggressive complainants who periodically inject large sets of (sometimes repeat) notices. For example, for domains with variance greater than 1M, we find that 92% receive an average of 116 duplicates from the same sender. To better highlight this aggressive activity, Figure 8 presents timeseries measuring the number of daily complaints for several example domains. We select the top two domains with the largest variance in each Alexa ranking category (top 100K,

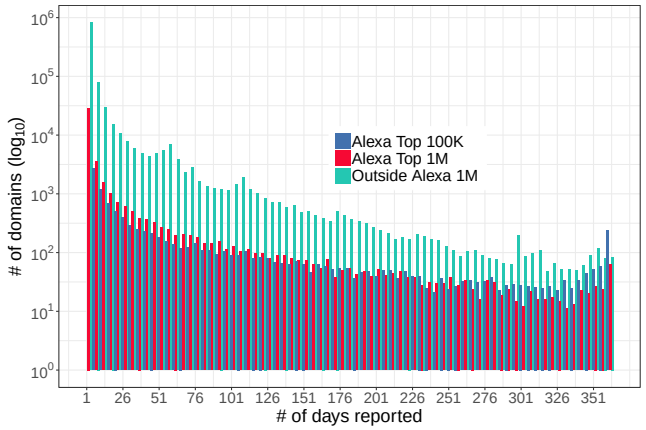

Figure 6: Number of days receiving complaints for each domain in a given Alexa rank.

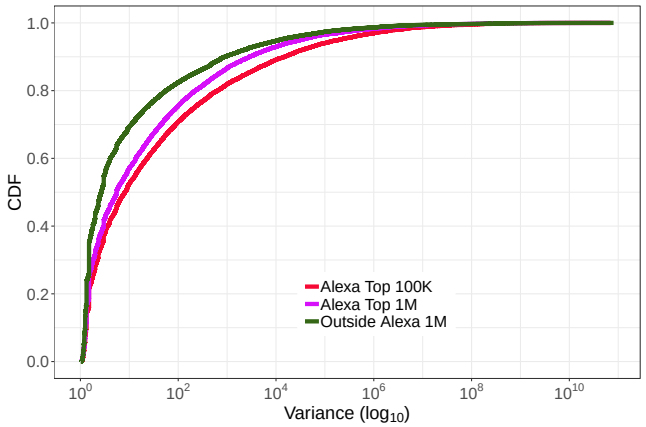

Figure 7: CDF of the variance of the number of complaints per day for each domain in a given Alexa rank.

top 1M, outside Alexa). Significant instability exists across each of these domains, with labels in the figure highlighting the individual sender causing each spike. For instance, the top ranked domain, `mp3toys.xyz`, receives an average of 500K daily complaints from Apdif Brasil between Jan & Feb, yet this collapses to below 6 per day in March. Similarly, `mp3taringa.net` receives a significant number of complaints between 03/Jan – 05/Jan by Apdif Mexico, but following this the numbers collapse to almost zero. We posit that these senders are not always careful in the complaints they generate but, rather, send bulk notices, leaving the recipient to make sense of the content.

4.4 Are Reported Websites Alive?

We finally inspect the availability of reported domains and webpage resources. As it is impossible to draw causal links between a notice being issued and the removal of content, we limit our analysis to inspecting the availability of URLs, rather than inferring the reason for their (un)availability.

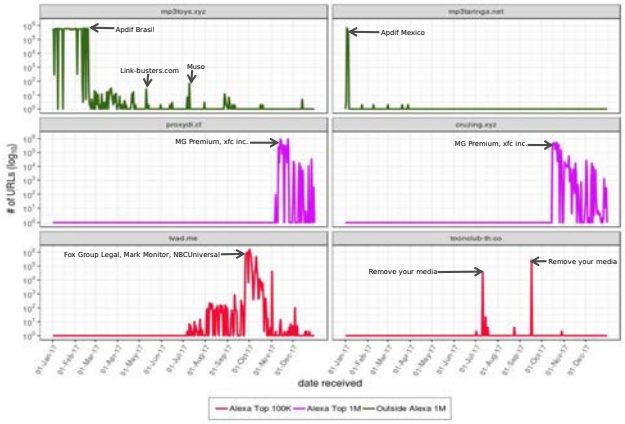

Figure 8: Timeseries with complaints to selected domains and complainants causing complaints' bursts.

Understanding Domain Liveness. We first check the liveness of each domain's DNS record using our DNS dataset. This reveals that 22% of reported domains return an NXDOMAIN response.[5] These domains account for over 183M (17%) of infringing URLs, with just 3% (1,426) of them belonging to domains that rank within Alexa's Top 1M. As different domain registrars may have differing policies regarding the removal of records, we next group domains by their TLD, and check the likelihood of domains being taken offline; Figure 9 presents the results. We plot both the number of websites (domains) that are unavailable, as well as the number of specific URLs that become unavailable (because the domain is offline). For context, we plot the density of Alexa top 1M domains that have each TLD. The majority of TLDs with a high percentage of NXDOMAIN responses do not frequently occur in the top Alexa rankings. Instead, we see that the majority of domains are from the recent wave of new generic TLDs [23]. The most extreme is `.lol`, where 98% of domains are NX; it is noteworthy that this TLD is operated by Uniregistry, which has been accused of predominantly hosting spam [1]. These trends indicate that the usage and behaviours across these TLDs are quite different, with some far more likely to contain unavailable domains.

Understanding URL Availability. Next, we turn to our periodic HTTP liveness checks to see if resources (URLs) are still alive (for those domains that do not return NXDOMAIN). We see that the number of 200 (OK) responses decline slowly but steadily over the 4 week period that we monitored. After week 4, 22% of URLs are inactive (*i.e.,* non-200). This trend, however, is relatively shallow with the majority of URLs (19%) becoming inactive in the first week after the notice has been observed in Lumen.[6] We also note that the statuses returned evolve across the four weeks. In week 1, the number of HTTP 4XX responses is 168K, yet in week 2 we only observe a further 12K webpages responding with 4XX. Instead, the

[5]This is returned when a domain name does not exist on the authoritative name server any longer.
[6]Note that it is also possible that the URL was not live when the complaint was generated. Unfortunately, we cannot check this.

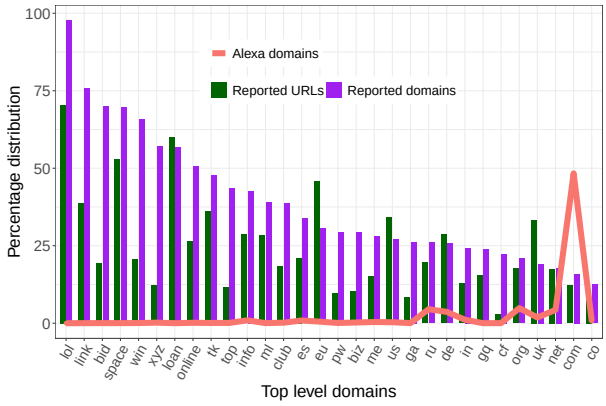

Figure 9: Unavailable domains per TLD and URLs thus becoming inaccessible (as a % from the total) *vs.* the share of Alexa domains for each TLD.

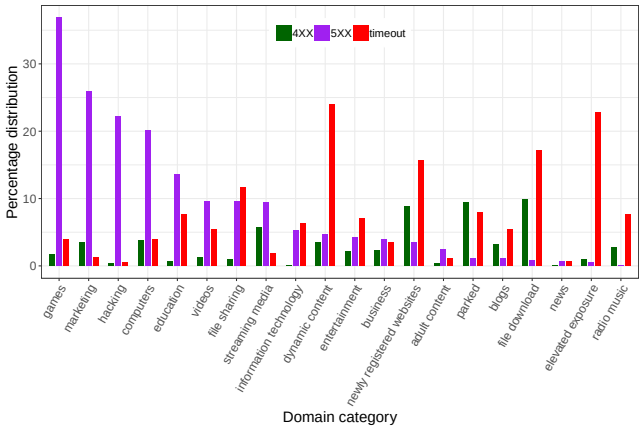

Figure 10: URLs going offline (*i.e.,* non-$2XX$ response) for the top-20 most reported domain categories (in %).

number of HTTP 5XX and TCP timeouts increase, suggesting that these websites go through several stages that start with removing of content (therefore returning a 4XX) before total shutdown of the web server. The latter makes sense, as it may be unnecessary to continue running a server if most content has been removed.

Understanding Category Availability. We continue our analysis by inspecting which category of URLs are most likely to go offline. Figure 10 breaks down all URLs into their categories and presents the share within each group that reports non-200 HTTP responses after complaints are generated. Certain categories are significantly more likely to return non-200 responses. For example, 10% of URLs classified as File Download return a 404 response; similar traits are also seen across Parked (9%) and Newly Registered Website (9%). In contrast, 24% of URLs classified as *Dynamic Content* (*i.e.,* websites that generate different material for each visit) return a TCP connection timeout, *i.e.,* the web server is no longer online. Other examples of categories with high numbers of URLs that timeout include *Elevated Exposure* (22%), and *File Download* (17%). The category which contains fewest unavailable sites is *News*, where only 1.34% of URLs become non-200. This indicates that the robustness of sites differs substantially across categories. That said, it is reasonable that domains more clearly engaging in suspicious activity are most likely to become unavailable.

Understanding Complainant Success An obvious question is which complainants are most likely to see their reported URLs deleted. To measure this, we calculate the percentage of reported URLs from each notice sender that later sees the URL resource returning a non-200 response. Figure 11 presents the weekly percentage of complaints that return a non-200 response after each weekly liveness check for the top 10 senders (based on the complainant with most not 2XX responses). The websites targeted by these different notice senders have very different availability properties. Complaints from rights enforcement organisations (*e.g.,* Rivendell, MarkScan, AudioLock.net) appear more effective compared to trade organisations (*e.g.,* British Phonographic Organisation).

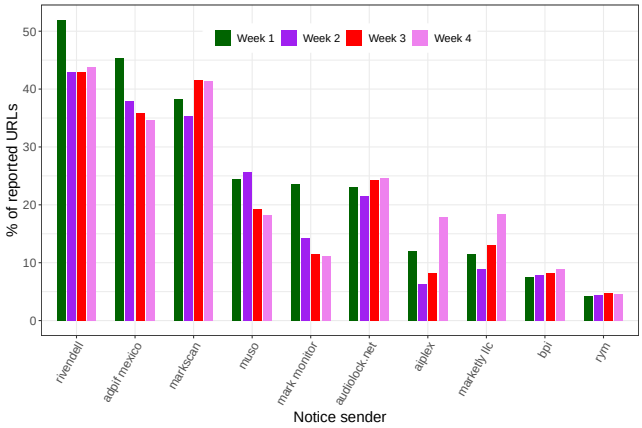

Figure 11: Weekly share (non-cumulative) of URLs with a non $2XX$ response for the top 10 complainants.

For example, about 53% of complaints in the first week of submission from Rivendell return non 2XX response code whilst just 8% from British Phonographic Organisation return same. These results confirms that the efficacy of these different organisations differs greatly, and that the websites they pursue have extremely different characteristics in terms of resilience to takedown.

5 RELATED WORK

There are two main areas of related work: (*i*) studies that rely on Lumen for exploring web complaints; and (*ii*) studies that have explored illegal online activities more generally.

Web Complaint Studies. There have been numerous studies into web complaints, however, these largely appear in legal journals, and rarely contain data-driven analysis. Those that do are mostly restricted to manual inspection of small sets of notices. For example, Heins *et al.* [10] examined 320 takedown notices to determine if the takedown process is fairly used by reporting organisations. They discovered that 20% of notice senders send weak copyright claims,

an assertion our results agree with. Urban *et al.* [28] examined nearly 900 notices in an attempt to discover the primary reporting organisations that file them. They saw that business entities and corporations were the main users of takedown notices. Our work differs significantly from these two studies. Whereas they study a small sample of notices, we offer far broader vantage into web complaints, characterising the activities across notices regarding over 1 billion URLs. Closely related is the Right To Be Forgotten (RTBF), established in 2014 within the European Union. This allows individuals to request the de-listing of personal information from search engines, which is "inaccurate, inadequate, irrelevant or excessive". Bertram *et al.* [2] inspected the RTBF requests issued to Google. This work is complementary to our own, as we focus on different complaint mechanisms, *i.e.,* Lumen does not cover RTBF. This is evident from the contrast between types of URLs in [2] *vs.* our study, *e.g.,* 33% of RTBF URLs relate to social media, and 20% to news. This can be compared against §3.3, where we find a greater propensity towards Entertainment and Business URLs (driven by the prominence of copyright enforcement notices).

Illegal Web Activities. George *et al.* [8] examined the challenges that comes with the ease of sharing User Generated Content (UGC), highlighting the roles played by hosting providers and proposing stronger legislation to address the illegal sharing of UGC. Wong [33] suggested a more flexible legislation, whilst Sawyer [22] recommended that platforms that share UGC should develop solutions to mitigate against the sharing of infringing material. Clay and Lucas discussed how a UGC platform (YouTube) has been exploited for such purpose [3, 11]. Raman *et al.* also identified pirated content being shared via Facebook Live [19]. To prevent the sharing of infringing content on such platforms, Dutta *et al.* proposed a signature-based detection to mitigate against infringing material remaining accessible online [6].

Peer-to-Peer networks and file hosters are also a frequently used to disseminate illicit or illegal material. Despite several anti-piracy efforts through the injection of fake content on BitTorrent portals [4, 5, 7, 15] and the shutdown of file hosters services [18], about 90% of files shared using BitTorrent protocol are judged to be infringing [20, 32]. Furthermore, 80% of files shared through file hosters are also in the same category [17]. Ibosiola *et al.* measured the availability of illegal content on streaming cyberlockers [13]. They found that the majority of copyright infringing content is hosted on a small number of platforms. A large portion of complaints in our data also pertain to adult content. While there have been several studies on online adult content [26, 27], few focus on illegal adult content [12]. Our work is orthogonal as we primarily focus on the complaints that are related to these activities.

6 DISCUSSION AND FUTURE WORK

This paper has explored the nature of web complaints. With increasing scrutiny on illegal and illicit web activities, and the recent ability to streamline complaints against different stakeholders, this study offers a critical input into the wider ongoing debate about web governance and the use of so-called self-regulation [30].

Summary of Findings. We have found a large and complex ecosystem dominated by a small set of complainants. While there are a large number of organisations (38,523) that generate over 1 billion reported URLs, the top 10 complainants alone contribute over 41% of all notices. It therefore appears that these complaint procedures have become the dominion of a small group of large and very active organisations. Dominant players consists of a mix of influential copyright owners (*e.g.,* Fox) and third-parties specialised in pursuing copyright infringers (*e.g.,* Rivendell). Bursts of complaints are common with most of the complaints towards each domain originating from 2–3 complainants, driving the unusual instability we see in the rankings. Complainants are highly specialised in terms of the types of notices they generate and the domains they target. This leaves some domain categories (*e.g.,* File Sharing) regularly reported, and others rarely seen (*e.g.,* Education). Surprisingly, many of the most frequently reported domains are quite obscure, and fail to score highly in popularity rankings. Finally, we find that complaints do seem to matter. Many domain names are soon taken offline and 22% of the URLs are inaccessible within just 4 weeks of us observing the complaints. Hence, it is clear that we shed light on a highly dynamic environment from the perspective of domain operators too.

Societal and Legal Implications. Web governance and the (mis)use of web complaint mechanisms have important social and legal implications. Transparency is critical and, as a society, it is important to know how and why information is filtered. This is particularly the case as we have found that these mechanisms might not be always used wisely, *e.g.,* with some complainants generating hundreds of repeat notices, and seemingly auto-generated URLs (§ 4.3). We argue that this might overwhelm recipients, who will not necessarily have the resources to deal with these large numbers. As these highly centralised models of operation have the potential for misuse, understanding the activity of senders is therefore critical.

Our results further suggest that there is opportunity to improve and streamline the procedures. For notice recipients, the filtering of invalid complaints would no doubt be a valuable innovation. That said, we do not discount the veracity of many complaints, and therefore developing mechanisms to support this process from the perspective of (legitimate) notice senders would also be worthwhile. This, of course, should not be done at the expense of website operators, who should always be given paths to recourse. Developing techniques that automate the above three things is important. Arguably, Lumen and other similar transparency platforms, can play a powerful role in this process.

Future Work. There are a number of lines of future work. First, we hope to expand our access to more diverse datasets. Within the paper, we have not investigated the role that recipients might play within the nature of complaints observed. This is likely to open up new lines of interesting investigation. Our analysis has also revealed traits of a cat-and-mouse game, with complainants bulk sending notices, and websites replicating themselves across multiple domains and TLDs. Exploring the temporal attributes of this game will no doubt reveal a number of yet unseen behaviours. Last, we also wish to explore if search engines cease to index URLs that are complained about. Quantifying this forms a key strand of our future work.

ABSTRACT

Diffusions, such as the heat kernel diffusion and the PageRank vector, and their relatives are widely used graph mining primitives that have been successful in a variety of contexts including community detection and semi-supervised learning. The majority of existing methods and methodology involves linear diffusions, which then yield simple algorithms involving repeated matrix-vector operations. Recent work, however, has shown that sophisticated and complicated techniques based on network embeddings and neural networks can give empirical results superior to those based on linear diffusions. In this paper, we illustrate a class of nonlinear graph diffusions that are competitive with state of the art embedding techniques and outperform classic diffusions. Our new methods enjoy much of the simplicity underlying classic diffusion methods as well. Formally, they are based on nonlinear dynamical systems that can be realized with an implementation akin to applying a nonlinear function after each matrix-vector product in a classic diffusion. This framework also enables us to easily integrate results from multiple data representations in a principled fashion. Furthermore, we have some theoretical relationships that suggest choices of the nonlinear term. We demonstrate the benefits of these techniques on a variety of synthetic and real-world data.

1 INTRODUCTION

Diffusion methods for graph mining work by modeling a process where we conceptually inject a *dye* at a particular node or set of nodes in the graph and observe how the *dye* diffused over the edges of the graph.[1] How the *dye* diffuses reveals latent structure in the graph. For instance, if the *dye* stays nearby the source, this indicates that there is a community nearby the source. If the *dye* starts at nodes with a particular label, then under homophily (where neighbors share similar properties), the *dye* will concentrate at nodes likely to share the same label. In this way, the method can be used for semi-supervised learning. Because this conceptual view of diffusions is general, a graph diffusion can be realized in a large number of ways including smooth functions on graphs [57], random walks [38], PageRank equations [37], and linear algebra relaxations of combinatorial graph theory [15, 35]. Consequently, diffusion methods have been widely applied to a large variety of graph mining tasks [13, 18, 20, 24, 32, 38]. In the majority of these results, diffusion methods gave a performance that was comparable to the state of the art, with many possible ways to adjust the computational primitive to improve the results and to scale up to massive problems.

More recently, however, a new class of techniques emerged that raised the state of the art performance on semi-supervised learning problems. These are based on node embeddings along with subsequent machine learning algorithms [22, 39] or from more complicated graph-based variations on neural networks [26, 56]. These methods are impressive because they have established new benchmarks for performance on learning with graph-based data. A downside to these methods, however, is that they can be hard to reason about and can make it difficult to understand what may be causing poor performance on new problems.

Diffusions, on the other hand, are highly intuitive, simple procedures modeled on the *dye* description in the introduction. The vast majority of existing work on diffusions in graphs considers linear diffusions, those where the dynamics can be fully captured by a single matrix operator, such as a random-walk operator or a Laplacian matrix, or a regularized or perturbed version of either [19]. In this paper, we consider nonlinear diffusions, which arise in more

[1] We use the term *dye* here as an intuitive concept only and mimic the ideas of dyes and diffusions in medical diagnostics and physics.

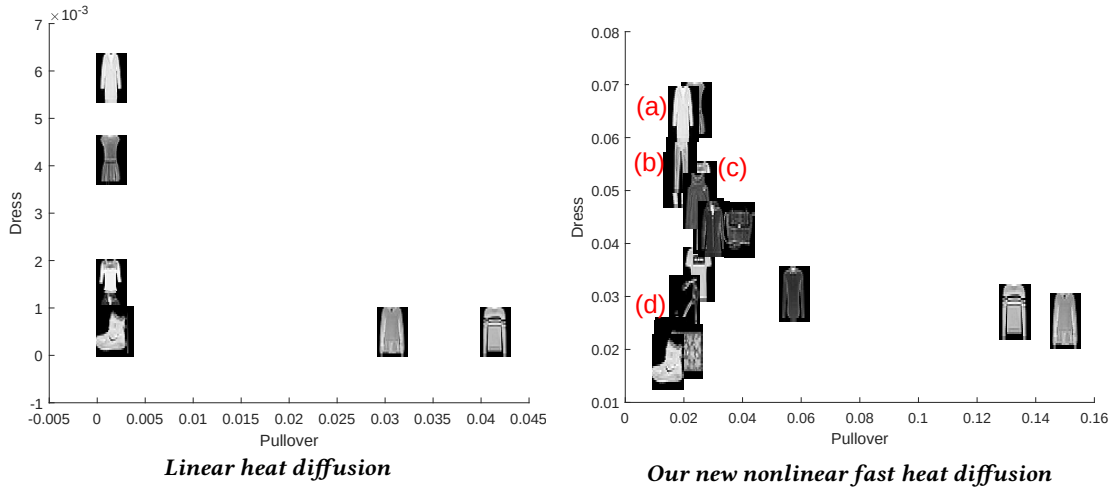

Figure 1: Comparison between linear diffusion based on the linear heat kernel diffusion (left) and our nonlinear diffusion (right) on Fashion MNIST dataset where we seeded the diffusions on a few pictures of pullover sweaters and dresses. This gives a coordinate for each image in the graph based on its diffusion value and these diffusion values reflect how much it looks like a pullover or dress. We draw the same 20 examples for linear diffusion and nonlinear diffusion. The linear diffusion concentrates the results nearby the seeds (most images are on top of each other) where the nonlinear diffusion captures our intuitive notion that there is a diversity of images that look like dresses or pullovers. For example, in the right figure, with respect to the y-axis, the sorting of the diffusion values reflect the semantic similarity between the clothes. Marker (a) points to dresses, marker (b) points to trousers (long as dress), marker (c) points to tops and finally, marker (d) points to shoes.

complicated physics and ecology settings. For instance, the porous media equation [23, 29] describes diffusion through a physical substance that can capture and store the diffusing substance (such as an isentropic gas), slowing the diffusion in a nonlinear fashion. The fast diffusion equation [48] describes diffusion in plasma's [6], and also the diffusion of materials in silicon when the medium is clustered [25]. These diffusions are fairly well understood from an abstract mathematical perspective (e.g. see [7, 48, 49]). With only a few exceptions, however, these ideas have not been applied to graph mining tasks. (See related work for more discussion of what has been done with respect to graphs and networks.) A related type of nonlinearity, which involves using a nonlinear transmission process which diffuses *dye* according to some nonlinear rule, is captured with a nonlinear Laplacian operator such as the p-Laplacian [1, 8, 9]. These have been studied as ways to generalize spectral clustering (see Section 4 for more about the differences). Additionally, it was shown in [36] that using the traditional Laplacian in semi-supervised learning results in labeling function that is spiky at the labeled points and flat everywhere else. Bridle et al. [8] solve this problem using the p-Laplacian in an energy minimization problem and we inherit this advantage when we use the p-Laplacian in the diffusion process.

In this paper, we show that by using values from these nonlinear diffusions, we are able to match state of the art performance benchmarks in semi-supervised learning. This helps to retain the intuitive reasoning behind the methods. As an example of how nonlinear diffusions help to solve problems, see Figure 1, where we show the solution of the standard heat kernel diffusion and nonlinear diffusion for a semi-supervised learning problem on the Fashion MNIST dataset [54]. In this case, we form a graph based on the images themselves (see more details in Section 6.4). Then we diffuse from a few images of a pull-over sweater and a dress with the heat kernel diffusion and our nonlinear diffusion. We show each image (node in the graph) in the after the diffusion has run for some time for the kernel diffusion compared with the nonlinear fast diffusion. As the figure shows, using the nonlinear diffusion causes the points to spread out far more than what is shown in the heat kernel. This illustrates how these advanced diffusions can give a much wider spread of values compared with standard diffusions and enable better classification. Avoiding these *spiked* solutions was also a motivation of past work on nonlinear diffusions [8].

More generally, introducing simple nonlinearities often improves the performance of other machine learning tasks. For example, nonlinear dimensionality reduction techniques [41, 46] outperforms linear techniques by assuming that the data lies in a nonlinear manifold. Nonlinear activation functions enhance the results of neural networks [16], and simple nonlinear transformations of the results of spectral clustering improve results as well [51]. Hence, our work shows yet another way that simple nonlinearities can improve the performance of graph mining tasks.

Finally, one of the great advantages to diffusion methods is that they offer theoretical guarantees of performance through Cheeger inequalities [11–13, 35, 55]. These relate the output from the diffusion to nearby bottlenecks in the graph, formalized as low conductance sets. (See [56] for examples on how general this perspective can be to capture a large number of notions of *conductance*.) In this paper, we have results that suggest using a nonlinear diffusion using the power function with power value close to 0 should give

the best performance for low-conductance set detection through new analysis of the sweepcut procedure (Theorem 5.8).

Our experimental results (Section 6) show that nonlinear diffusion outperforms heat diffusion in community detection by up to 35% in F1-measure and it outperforms related work in graph-based semi-supervised learning in most datasets. In the latter case, we show how our diffusion framework can be adapted to work on multiple datasets (Section 3.2).

Summary of contributions and outline of the paper.

- We introduce two methods for nonlinear diffusion, one using nonlinear functions and another one using nonlinear Laplacian operators (Section 2).
- We place these diffusions in a framework where we can integrate multiple data representations and to self-train itself (Section 3).
- We show that nonlinear diffusion with power function should give smaller conductance sets with p approaches 0. (Section 5).
- We experimentally compare nonlinear diffusion methods to related work in community detection and graph-based semi-supervised learning (Section 6).

2 EVALUATING NONLINEAR DIFFUSIONS

2.1 Notation and Background

We use the following notation throughout the rest of the paper. Scalars are denoted by small letters (e.g., m, n), sets are shown in capital letters (e.g., X, Y), vectors are denoted by small bold letters (e.g., $\mathbf{f}, \mathbf{g}$), and matrices are denoted by capital bold letters (e.g., $\boldsymbol{A}, \boldsymbol{L}$).

Let $G = (V, E)$ be an undirected graph, where $n = |V|$ is the number of nodes in the graph. Let $\boldsymbol{A}$ be the associated adjacency matrix of the graph G and $\boldsymbol{D}$ be the diagonal matrix of degrees, where $\boldsymbol{D}_{ii} = \mathbf{d}(i)$, is the degree of the vertex i. (In the case of a weighted graph, then the weighted degrees are the sum of the edge weights.) Additionally, $\mathbf{e}_S$ is the vector of all ones for entries $i \in S$ and zero otherwise.

Conductance. Conductance is one of the popular quality measures that quantifies how good is the set S as a partition of the graph G [43]. Given a subset S of the vertices V, we define the volume of set S as $\mathrm{vol}(S) = \sum_{v \in S} \mathbf{d}(v)$ and the cut of set S as $\mathrm{cut}(S) = \{\{u, v\} \in E : u \in S \text{ and } v \in \bar{S}\}$. Furthermore, the conductance of the set S is defined as:

$$\phi(S) = \frac{|\mathrm{cut}(S)|}{\mathrm{minvol}(S)},$$

where $\mathrm{minvol}(S) = \min(\mathrm{vol}(S), \mathrm{vol}(V - S))$. For weighted graphs, the volume uses the weighted degrees and the $|\mathrm{cut}(S)|$ is the sum of edge weights cut.

The heat kernel diffusion The heat kernel diffusion [13] from a seed set S results in a solution to the dynamical system:

$$\frac{\partial \mathbf{u}}{\partial t} = -\boldsymbol{L}\mathbf{u} \qquad \mathbf{u}(0) = \frac{\mathbf{e}_S}{|S|},$$

where $\boldsymbol{L} = \boldsymbol{I} - \boldsymbol{A}\boldsymbol{D}^{-1}$ is the random walk Laplacian with eigenvalues $\lambda \in [0, 2]$.[2]

[2] Note that the Fiedler vector used in spectral clustering is $\mathbf{f} = \boldsymbol{D}\mathbf{x}_2$, where $\mathbf{x}_2$ is the eigenvector associated with the second smallest eigenvalue of $\boldsymbol{L}$.

We can state a closed-form solution via the matrix exponential:

$$\mathbf{u}(t) = \exp(-t\boldsymbol{L})\mathbf{e}_S/|S|,$$

which has been shown to have a number of nice properties [13, 27].

In the remainder of this section, we will describe two methods to encode nonlinearity in the heat kernel diffusion. The first method is by first applying a nonlinear function g to grow or decay the values at each node and then transmitting the heat according to the heat diffusion differential equation. The second method is by using a nonlinear Laplacian operator that grows or decays the amount transferred on each edge.

2.2 Nonlinear Diffusion with Growth or Decay

The following dynamical system describes a general notion of nonlinear diffusion (e.g. [49]) when applied to a graph or network:

$$\frac{\partial \mathbf{u}}{\partial t} = -\boldsymbol{L}g(\mathbf{u}) \qquad \mathbf{u}(0) = \frac{\mathbf{e}_S}{|S|}.$$

Here g is the nonlinear function, S is the set of seed nodes, and $\mathbf{u}(t) \in \mathbb{R}^n$ is the diffusion value at each node at time t. One representative choice of g is the power function $g(\mathbf{u}) = \mathbf{u}^p$ (element-wise). Using the power function is motivated by the porous media equation ($p > 1$) [47] and the fast diffusion equation ($p < 1$) [7] (see discussion of these in the introduction). Setting $p = 1$ gives the linear heat kernel diffusion [13].

In nonlinear diffusion, each node will apply the function g to its current diffusion value before transmitting the heat to its neighbor. If the values of $\mathbf{u} \in [0, 1]$, then if $p > 1$, the diffusion at each node is reduced first according to both the parameter p and the diffusion value at the node before the node can transmit any heat. This models the diffusion medium *capturing* the value being diffused. Hence, this will keep the diffusion more localized around the seed nodes. However, if $p < 1$, then the diffusion at each node will be magnified first before the node starts transmitting the value, which will help the diffusion explore wider regions. This models settings where large values diffuse faster.

Due to the effect of the nonlinearity, nonlinear diffusion does not have a closed form solution as the heat kernel diffusion, therefore we approximate the solution of the dynamical system by using a simple forward Euler integration, which can be derived by approximating the time-derivative $\partial\mathbf{u}/\partial t \approx (\mathbf{u}(t + h) - \mathbf{u}(t))/h$.[3] Hence, we have the evolution:

$$\mathbf{u}(t + h) = \mathbf{u}(t) - h\boldsymbol{L}\mathbf{u}(t)^p.$$

Here $\mathbf{u}(t + h)$ is the diffusion value at time $t + h$. Because the notion of "time" for this system is arbitrary, we only study the solution after k steps of the evolution process with a fixed value of h. The solution $\mathbf{u}$ for the dynamical systems is non-negative as mentioned in [4] and [47]. However, as we approximate the dynamical system using forward Euler method, the values can be negative. Getting non-negative numerical solutions is difficult as discussed in [44] and therefore, to ensure that $\mathbf{u}$ values are between 0 and 1, we truncate values less than zero to be zero and values greater than one to be one. Algorithm 1 gives a simple pseudocode to do this.

[3] The forward Euler method is often problematic in dynamical systems in physics because there are conservation laws that need to be respected in the approximation. Because the diffusion framework here is an abstraction, we are less worried about accuracy in terms of the ODE, which makes forward Euler a simple, pragmatic choice.

We have ongoing analysis to study accuracy and convergence in the integration problem in more detail that are beyond the scope of this paper; among these results, our analysis gives a direct proof of non-negativity.

Algorithm 1: Nonlinear Diffusion with Growth or Decay

```
NonlinearDiffusionWithGrowthOrDecay (L, k, h, g, s)
  Input : Random walk Laplacian L, number of steps k, step
          length h, nonlinear function g and initial diffusion
          values s.
  Output: f
u = s ;
for i ← 0 to k do
    u = u − hLg(u) ;
    truncate values of u to be between 0 and 1
end
f = g(u);
```

2.3 Nonlinear Diffusion via Nonlinear Transfer

Like the heat kernel diffusion, we can also define nonlinear diffusion using nonlinear transfer. One way to do this is via the p-Laplacian [1, 8, 9]. The p-Laplacian operator [8, 9] is defined as:

$$(\nabla_p \mathbf{f})_i = \sum_{j \in V} w_{ij} \phi_p(\mathbf{f}_i - \mathbf{f}_j),$$

where $\phi_p : \mathbb{R} \to \mathbb{R}$ is

$$\phi_p(x) = |x|^{p-1}\text{sign}(x),$$

and $\mathbf{f} = \boldsymbol{D}^{-1}\mathbf{u}$. This results in a nonlinear Laplacian operator as in the following setting:

$$\frac{\partial \mathbf{u}}{\partial t} = \nabla_p \mathbf{u}.$$

We can write the result of the p-Laplacian on a vector $\mathbf{u}$ using the incidence matrix of the graph. Let $\boldsymbol{N}$ be the edges-by-nodes, unweighted incidence matrix and $\boldsymbol{W}$ be a diagonal matrix of edge-weights that corresponds to the order of edges in the incidence matrix.[4] Then

$$\phi_p(\mathbf{f}_i - \mathbf{f}_j) = |\boldsymbol{N}\boldsymbol{D}^{-1}\mathbf{u}|^{p-1}. * \text{sign}(\boldsymbol{N}\boldsymbol{D}^{-1}\mathbf{u})$$
$$\nabla_p \mathbf{f} = \boldsymbol{N}^T\boldsymbol{W}\,|\boldsymbol{N}\boldsymbol{D}^{-1}\mathbf{u}|^{p-1}. * \text{sign}(\boldsymbol{N}\boldsymbol{D}^{-1}\mathbf{u}).$$

Here, we use the element-wise multiplication .∗, absolute value and power. Additionally, we use the observation that $\phi_p(\boldsymbol{N}\boldsymbol{D}^{-1}\mathbf{u})$ has the same sign as $\boldsymbol{N}\boldsymbol{D}^{-1}\mathbf{u}$. Hence when we multiply by $\boldsymbol{N}^T\boldsymbol{W}$ the arbitrary sign of the difference of edges in the incidence matrix cancels and we scale by the appropriate weight because of $\boldsymbol{W}$. Note that if $p = 2$, then the equation corresponds to the heat kernel diffusion. Algorithm 2 shows the pseudocode for the nonlinear diffusion using the p-Laplacian.

[4]For the unweighted incidence matrix $\boldsymbol{N}$ and an unweighted graph, $\boldsymbol{L} = \boldsymbol{I} - \boldsymbol{A}\boldsymbol{D}^{-1} = \boldsymbol{N}^T\boldsymbol{N}\boldsymbol{D}^{-1}$. For a weighted graph, we have $\boldsymbol{L} = \boldsymbol{N}^T\boldsymbol{W}\boldsymbol{N}\boldsymbol{D}^{-1}$. The matrices $\boldsymbol{N}$ and $\boldsymbol{W}$ are easy to build from the raw list of edges. If `ei`, `ej`, `ew` are length $|E| = m$ arrays with the source, destination, and weight of each edge, then $\boldsymbol{N}$ = `sparse([1:m;1:m],[ei;ej],[ones(m,1);-ones(m,1)],m,n)` and $\boldsymbol{W}$ = `diag(ew)` in pseudo-Matlab or Julia notation.

Algorithm 2: Nonlinear Diffusion using the p-Laplacian

```
NonlinearTransfer (N, w, D, k, h, p, s)
  Input : Unweighted incidence N, edge weights w, degree
          matrix D, number of steps k, step length h, nonlinear
          diffusion parameter p and initial diffusion values s.
  Output: f
u = s ;
for i ← 0 to k do
    q = ND^{-1}u ;
    u = u − hN^T[w. ∗ (|q|)^{p−1}. ∗ sign(q)] ;
    truncate values of u to be between 0 and 1
end
f = D^{-1}u;
```

3 USING NONLINEAR DIFFUSIONS

Given an input graph G, we can use the solution vector $\mathbf{f}$ that results from either of the two nonlinear diffusions instead of any of the vectors used in semi-supervised learning [19, 24, 35, 57] or local community detection [13, 27, 55] as a straightforward substitution in these algorithmic pipelines. All of these pipelines feature a *diffuse-and-round* perspective where the results of multiple diffusions are turned into estimated classes in the case of semi-supervised learning or rounded to clusters in the case of community detection. We elaborate more on community detection in Section 5.

To be more precise, for semi-supervised learning, we assume we have $S_1, \ldots, S_c$ as c-seed sets that represent samples of c classes. The goal of the problem is to infer the class label $1, \ldots, c$ for the remaining nodes $V - \cup S_i$. The most interesting case is when $|S_i|$ is small and constant, such as 5 or 10 and independent of the graph size. In which case, we diffuse from S_i using our nonlinear diffusion to compute a vector $\mathbf{f}_i$. With all the vectors $\mathbf{f}_1, \ldots, \mathbf{f}_c$, we assign classes based on their rank in the diffused solutions [19]. That is, node j is the $r_1, \ldots, r_c$th largest node in $\mathbf{f}_1, \ldots, \mathbf{f}_c$, then we assign its class to $\text{argmin}_i\, r_i$. We can also pick the class based on the largest value of node j in any of the diffusions $[\mathbf{f}_i]_j$, which we call value-based rounding [57].

Complexity. The runtime complexity of our diffusions is linear in the number of edges of the graph, because the major piece of computation involves k-matrix vector products – multiplying by a Laplacian or incidence matrix is linear in the number of edges – for each of the c classes.

For the case of semi-supervised learning, our experiments and final methodology incorporate two additional ideas. First, we can use feedback from the diffusion process itself to suggest new training labels [10] (Section 3.1). Second, we show how to easily incorporate multiple data representations into our diffusion framework (Section 3.2).

3.1 Self-Training with Diffusion Methods

In semi-supervised learning, a self-trained diffusion means that the diffusion method incorporates feedback from its results. For instance, if the results of a diffusion $\mathbf{f}_i$ suggest that a subset of node R is extremely like to have label i, then we would re-run the diffusion using seeds $S_i \cup R$. This process is repeated either for a specific

number of iterations or until no significant change is observed in the diffusion method. A confidence score for each label can be calculated based on the diffusion values. The higher the diffusion value, the more confident the diffusion is about its decision. As self-training depends on the decision of the diffusion, if the diffusion yields useful results, then the quality of the diffusion will enhance over time, otherwise, the quality will decrease. Therefore, there is no guarantee that self-training will always enhance the quality of the diffusion, however, in practice it often does.

3.2 Integrating multiple data representations

In many real-world learning problems, the underlying data has multiple representations. For example in citation graphs, there is a matrix $\boldsymbol{A} \in \mathbb{R}^{n \times n}$ which captures the relationship between publications based on citations but there are also metadata associated with each paper including authors, titles, and keywords. It is essential to make use of all the available representations in order to develop a better understanding of the data. Consequently, we show how to use 2 different types of relationships between our objects to do prediction. The extension to even more types is simple.

The idea is to construct multiple graphs based on each data representation. For example in citation graphs, we would have $\boldsymbol{A}$ the citation graph, and also $\boldsymbol{B}$, which is a nearest neighbor graph based on some similarity function over the metadata features. Then, we want to run diffusions in $\boldsymbol{A}$ and $\boldsymbol{B}$ simultaneously and our goal is to have all the diffusions concentrated in the same set of nodes. In order to accomplish this goal, each diffusion will try to pull the other diffusions to be similar to it. This changes the nonlinear diffusion differential equation (and similarly the heat kernel diffusion) to:[5]

$$\mathbf{u}_{k+1}^A = \mathbf{u}_k^A - h\boldsymbol{L}_A g(\mathbf{u}_k^A) - \sigma(\mathbf{u}_k^A - \mathbf{u}_k^B)$$
$$\mathbf{u}_{k+1}^B = \mathbf{u}_k^B - h\boldsymbol{L}_B g(\mathbf{u}_k^B) - \sigma(\mathbf{u}_k^B - \mathbf{u}_k^A).$$

Here $\mathbf{u}_k^A$ is the diffusion value for the diffusion running over $\boldsymbol{A}$ at step k and we describe the update to get to the next step. The impact of the parameter σ is the strength of the coupling between the solutions. If σ is large, then we will move the solutions together. If σ is small, then they will evolve with only weak coupling.

4 RELATED WORK

Diffusion methods for clustering, semi-supervised learning, and a variety of other problems have a lengthy history, which has been extensively discussed in various surveys [10, 18, 34]. These methods are all based on linear notions of diffusion. We highlight two important connections we use in the remainder of the paper: spectral clustering and personalized PageRank. For a useful broad perspective on diffusion, we also recommend Ghosh et al. and Yan et al. [17, 55].

Spectral clustering is based on looking for minimum energy modes of the graph Laplacian. These minimum energy modes also can be interpreted as bottlenecks in a diffusion over the nodes. Since this is a linear matrix operator, these minimum energy modes correspond to the small eigenvectors. Specifically, the Fiedler vector is the second smallest generalized eigenvector $\boldsymbol{L}\boldsymbol{D}\mathbf{f} = \lambda \boldsymbol{D}\mathbf{f}$. This eigenvector gives the smallest non-trivial minimizer of the energy function $E(\mathbf{f}) = \mathbf{f}^T \boldsymbol{L}\boldsymbol{D}\mathbf{f}/(\mathbf{f}^T \boldsymbol{D}\mathbf{f})$. The Fiedler vector provably identifies a set of small conductance in the graph [15].

Personalized PageRank (PPR) is a diffusion method that models a random walk with reset process [37]. As a diffusion, it corresponds to the infinite time limit of

$$\frac{d\mathbf{x}}{dt} = (1-\alpha)(\mathbf{e}_S - \mathbf{x}) - \alpha \boldsymbol{L}\mathbf{x},$$

following results on the dynamics of PageRank [21]. PageRank can also be derived as a locally biased analogue of spectral clustering [19], and it is commonly used both for semi-supervised learning [57] and community detection [2], where it also identifies a set of small conductance in the graph. We compare against PPR in our experiments.

4.1 Nonlinear diffusions in graphs.

All of the existing work on nonlinear diffusion for graphs uses the p-Laplacian [1] and seeks to generalize spectral clustering inspired approaches. For instance, Buhler and Hein [9] seek to generalize the Fiedler vector to the p-Laplacian by finding low-energy states. Likewise, Brindel and Zhu [8] seek low-energy states of the p-Laplacian that fix the value of specific nodes to use for semi-supervised learning. Our perspective is different and we seek to generalize methods based on their diffusion interpretations rather than the energy minimization perspectives. For linear diffusions, the two are essentially equivalent because the eigenvectors determine the long-term behavior of the diffusion, but the generalizations are rather different for nonlinear operations.

4.2 Relationship to Neural Networks

Our work can also be interpreted in the context of graph-based neural networks [42]. These view a graph, or a matrix derived from a graph, as defining a layer in a neural network. Hence, we can interpret our diffusion as the output of a graph neural network with a fixed set of weights and a variable number of layers (depending on k). However, in addition to the graph structure, there are other sources of information that are not utilized in these related work like features per node. To use both the graph structure along with the feature matrix, both Planetoid [56] and Graph Convolutional Networks (GCN) [26] were proposed to allow neural networks to jointly learn from the feature matrix along with the graph structure. We compare against both of these methods in our experiments. (In this work, we extend the diffusion methods to learn from different sources of information.)

Compared to neural networks, nonlinear diffusion has two advantages, the first one is that it is more interpretable, as it follows a dynamical equation. Having a dynamical equation makes it easier to reason about its decisions and to develop theoretical results like developing Cheeger-type inequalities. The second advantage is that it reduces the number of parameters (we do no optimization over the weights of the layers) used in neural networks and therefore it is a simpler model.

4.3 Further relationships

Another line of work studies *fractional Laplacians*, which model the diffusion dynamics with fractional powers of the Laplacian matrix [40]. As such, these are still linear diffusions, albeit on a

[5] The equations for the p-Laplacian formulation are changed in an analogous fashion.

non-linear transformation of the Laplacian matrix. Our approach to integrating the results of multiple representations bears some relationship with recent work on centrality in temporal networks [45], although the motivation and applications are distinct. Finally, there are methods that use flow techniques for semi-supervised learning [50, 52]. These techniques offer fundamentally different tradeoffs. In our view, they are often best used to refine the results of diffusion algorithms to achieve better downstream performance.

5 NONLINEAR DIFFUSION ANALYSIS

The goal of this section is to prove our main theoretical result, which guides how we would pick a nonlinear diffusion to find small conductance sets in a graph. The precise method we study is as follows. We use Algorithm 1 to diffuse from a seed set S to produce a diffusion vector $\mathbf{f}$. (Note that $\mathbf{f}$ depends on the seed set, the value h, and the number of steps k.) Then we perform a sweep-cut procedure over the vector $\mathbf{f}$ to identify a set of small conductance. The sweep-cut procedure works by building a permutation $\sigma = (\sigma_1, \sigma_2, \ldots, \sigma_n)$ that sorts $\mathbf{f}$ from large elements to small elements, and then evaluates the conductance of each sorted prefix $S_i = (\sigma_1, \ldots, \sigma_i)$. We return the set $S = \operatorname{argmin}_i \phi(S_i)$ where $\phi(S_i)$ is the conductance.

This proof of our main results proceeds in two stages. First, we show a relationship between the sweep over any vector $\mathbf{f}$ and the set of minimal conductance (Section 5.2) that shows how well an "approximate indicator" vector behavior. Second, we will use the properties of nonlinear diffusion to guide our choice for nonlinear diffusion.

5.1 f-weighted Conductance

Before we begin, we fix a variety of notation that we will use throughout the proof and introduce a specialized notion of conductance, that we term f-weighted conductance. Our objective is to develop an inequality that relates the smallest conductance of any set, ϕ^*, in the graph G to the conductance of performing sweepcut over the vector $\mathbf{f}$, which results in conductance $\phi(\mathbf{f})$. Additionally, we want this inequality to maintain a linear relationship between ϕ^* and $\phi(\mathbf{f})$. This will require quantifying how well $\mathbf{f}$ looks like an indicator vector over the optimal set.

Using $\mathbf{f}$, we will direct each undirected edge $e = (u, v)$ in the graph G, such that it points from the node with higher $\mathbf{f}$ value to the node with lower $\mathbf{f}$ value. This re-direction will encode the sorted order of the nodes and will ensure that $\mathbf{f}(u) - \mathbf{f}(v) \geq 0$ for all $(u, v) \in E$. To encode this re-direction using matrices, we will define $\boldsymbol{N}_\mathbf{f} \in \{0, 1, -1\}^{m \times n}$ to be the $\mathbf{f}$-oriented incidence matrix, where for each edge $e = (u, v)$, $\boldsymbol{N}_\mathbf{f}(e, u) = 1$ and $\boldsymbol{N}_\mathbf{f}(e, v) = -1$ if and only if $\mathbf{f}(u) \geq \mathbf{f}(v)$. We will use $x \sim y$ to iterate over the directed edges. Additionally, assume that the vertices are numbered descending according to $\mathbf{f}$, so that we have $\mathbf{f}(v_1) \geq \mathbf{f}(v_2) \geq \ldots \geq \mathbf{f}(v_n)$ and let us first normalize $\mathbf{f}$ so that its values are between 0 and 1.

To accomplish our objective, we need to define a relationship between the set S^* of smallest conductance in the graph and the set obtained by performing a sweepcut over $\mathbf{f}$. Therefore, we define the f-weighted conductance $\phi^*(\mathbf{f})$ as:

$$\phi^*(\mathbf{f}) = \frac{|\mathrm{cut}_\mathbf{f}(S^*)|}{\mathrm{minvol}_\mathbf{f}(S^*)},$$

where $|\mathrm{cut}_\mathbf{f}(S^*)| = (\mathbf{e}^T_{S^* \to \bar{S}^*} + \mathbf{e}^T_{\bar{S}^* \to S^*})\boldsymbol{N}_\mathbf{f}\mathbf{f}$, $\mathbf{e}_{S \to \bar{S}}$ is the indicator vector where only edges pointing from S to $\bar{S}$ have value one and other edges have value zero, and $\mathrm{minvol}_\mathbf{f}(S^*) = \min(\sum_{u \in S^*} \mathbf{f}(u)\mathbf{d}(u), \mathrm{vol}(G) - \sum_{u \in S^*} \mathbf{f}(u)\mathbf{d}(u))$. If $\mathbf{f} = \mathbf{e}_{S^*}$, then $\phi^*(\mathbf{f}) = \phi^*$.

5.2 A General Sweepcut Inequality

To derive a general sweepcut inequality, we will derive an upper bound and a lower bound for $\phi^*(\mathbf{f})$ and using these bounds, we will be able to relate $\phi(\mathbf{f})$ to ϕ^* linearly. Additionally, let us define W as the set of nodes that have nonzero $\mathbf{f}$ values.

Lemma 5.1. *If $vol(W) \leq minvol(S^*)$, then:*

$$\phi^*(\mathbf{f}) \geq \frac{\phi(\mathbf{f})\, vol_\mathbf{f}(W) - \mathbf{e}^T_{S^* \to S^*}\boldsymbol{N}_\mathbf{f}\mathbf{f} - \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*}\boldsymbol{N}_\mathbf{f}\mathbf{f}}{minvol_\mathbf{f}(S^*)},$$

Proof. The result is largely algebraic:

$$\begin{aligned}
\phi^*(\mathbf{f}) &= \frac{|\mathrm{cut}_\mathbf{f}(S^*)|}{\mathrm{minvol}_\mathbf{f}(S^*)} \\
&= \frac{(\mathbf{e}^T_{S^* \to \bar{S}^*} + \mathbf{e}^T_{\bar{S}^* \to S^*})\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S)} \\
&= \frac{\mathbf{e}^T\boldsymbol{N}_\mathbf{f}\mathbf{f} - \mathbf{e}^T_{S^* \to S^*}\boldsymbol{N}_\mathbf{f}\mathbf{f} - \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*}\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S^*)} \\
&= \frac{\sum_{x \sim y}(\mathbf{f}(x) - \mathbf{f}(y)) - \mathbf{e}^T_{S^* \to S^*}\boldsymbol{N}_\mathbf{f}\mathbf{f} - \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*}\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S)}.
\end{aligned}$$

Note that due to numbering of the vertices descending according to $\mathbf{f}$, $(\mathbf{f}(x) - \mathbf{f}(y))$ is always a non negative number. Moreover, using $\sum_{x \sim y}(\mathbf{f}(x) - \mathbf{f}(y)) = \sum_{i=1}^{n-1}(\mathbf{f}(x_i) - \mathbf{f}(x_{i+1}))|\mathrm{cut}(S_i)|$ from [13], where S_i is the set of nodes labeled v_1 to v_i, we get:

$$\begin{aligned}
\phi^*(\mathbf{f}) &= \frac{\sum_{i=1}^{n-1}(\mathbf{f}(x_i) - \mathbf{f}(x_{i+1}))|\mathrm{cut}(S_i)| - (\mathbf{e}^T_{S^* \to S^*} + \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*})\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S^*)} \\
&\geq \frac{\phi(\mathbf{f})\sum_{i=1}^{n-1}(\mathbf{f}(x_i) - \mathbf{f}(x_{i+1}))\,\mathrm{minvol}(S_i) - \mathbf{e}^T_{S^* \to S^*}\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S^*)} \\
&\quad - \frac{\mathbf{e}^T_{\bar{S}^* \to \bar{S}^*}\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S^*)}.
\end{aligned}$$

As $\mathrm{vol}(W) \leq \mathrm{minvol}(S^*)$, we get:

$$\begin{aligned}
\phi^*(\mathbf{f}) &\geq \frac{\phi(\mathbf{f})\sum_{x \in W}\mathbf{f}(x)\mathbf{d}(x) - \mathbf{e}^T_{S^* \to S^*}\boldsymbol{N}_\mathbf{f}\mathbf{f} - \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*}\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S^*)} \\
&\geq \frac{\phi(\mathbf{f})\mathrm{vol}_\mathbf{f}(W) - \mathbf{e}^T_{S^* \to S^*}\boldsymbol{N}_\mathbf{f}\mathbf{f} - \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*}\boldsymbol{N}_\mathbf{f}\mathbf{f}}{\mathrm{minvol}_\mathbf{f}(S^*)}.
\end{aligned}$$

□

Lemma 5.2. *We also have*

$$\phi^*(\mathbf{f}) \leq \phi^* \frac{minvol(S^*)}{minvol_\mathbf{f}(S^*)}.$$

Proof. By definition,

$$\phi^*(\mathbf{f}) = \frac{|\mathrm{cut}_\mathbf{f}(S^*)|}{\mathrm{minvol}_\mathbf{f}(S^*)}.$$

Because $\mathbf{f} \in [0,1]$, then the maximum value for $\mathbf{f}(i) - \mathbf{f}(j)$ is 1 for any edge (i,j) and therefore we get:

$$\phi^*(\mathbf{f}) \leq \frac{|\text{cut}(S^*)|}{\text{minvol}_{\mathbf{f}}(S^*)} = \phi^* \frac{\text{minvol}(S^*)}{\text{minvol}_{\mathbf{f}}(S^*)}.$$

□

Theorem 5.3. *If we run a sweep-cut procedure on* $\mathbf{f}$ *where* $0 \leq f_i \leq 1$ *and* $vol(W) \leq minvol(S^*)$*, then:*

$$\phi(\mathbf{f}) \leq \phi^* \frac{minvol(S^*)}{vol_{\mathbf{f}} W} + \frac{\mathbf{e}^T_{S^* \to S^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} + \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f}}{vol_{\mathbf{f}}(W)}.$$

Proof. By using the two previous lemmas and re-arranging the terms, we can prove the theorem. □

Note that the previous generalized sweepcut inequality depends on $\mathbf{f}$, W and S^*. If $\mathbf{f}$ is far from highlighting the set S^* or $\text{vol}(W)$ is small, then this bound will reduce to the trivial bound $\phi(\mathbf{f}) \leq 1$. In the next section, we will use this generalized sweepcut inequality in addition to nonlinear diffusion properties to show that if the power function is used, then using small powers yields smaller conductance sets.

5.3 Implications for Nonlinear Diffusion

Lemma 5.4. *The sum property of nonlinear diffusion with growth or decay is:*

$$\mathbf{e}^T \mathbf{u}_t = \mathbf{e}^T \mathbf{u}_0 = 1.$$

Proof. By multiply both sides of the differential equation for nonlinear diffusion with growth or decay by $\mathbf{e}^T$ and using $\mathbf{e}^T \boldsymbol{L} = 0$, we get $\frac{\partial \mathbf{u}}{\partial t} = 0$. Therefore, the sum of the entries of $\mathbf{u}$ is always one. □

We will set $\mathbf{f} = g(\mathbf{u})$ and start our proofs using the general sweepcut inequality proposed in the previous section.

Lemma 5.5. *If* g *satisfies* $g(\mathbf{u}(x)) - g(\mathbf{u}(y)) \leq \mathbf{u}(x) - \mathbf{u}(y)\ \forall x, y \in W$*, then:*

$$\mathbf{e}^T_{S^* \to S^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} + \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} \leq |W|.$$

Proof. By noting that $\mathbf{f}$ is nonzero only at the set W, we get:

$$\mathbf{e}^T_{S^* \to S^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} + \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} \leq \mathbf{e}^T_{W \to W} \boldsymbol{N}_{\mathbf{f}} \mathbf{f}.$$

If g satisfies $g(\mathbf{u}(x)) - g(\mathbf{u}(y)) \leq \mathbf{u}(x) - \mathbf{u}(y)\ \forall x, y \in W$, then:

$$\begin{aligned} \mathbf{e}^T_{S^* \to S^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} + \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} &\leq \mathbf{e}^T_{W \to W} \boldsymbol{N}_{\mathbf{f}} \mathbf{u} \\ &\leq \sum_{x \in W} \mathbf{u}(x) |N(x) \cap W|. \end{aligned}$$

Here $N(x)$ is the set of nodes that are neighbors to x in the graph.

$$\mathbf{e}^T_{S^* \to S^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} + \mathbf{e}^T_{\bar{S}^* \to \bar{S}^*} \boldsymbol{N}_{\mathbf{f}} \mathbf{f} \leq \sum_{x \in W} \mathbf{u}(x) |W| = |W|.$$

□

Lemma 5.6.

$$vol_{\mathbf{f}}(W) \geq min_{i \in W} \mathbf{f}_i\, vol(W).$$

Proof.

$$\text{vol}_{\mathbf{f}}(W) = \mathbf{e}_W^T \boldsymbol{D} \mathbf{f} \geq \min_{i \in W} \mathbf{f}_i \mathbf{e}_W^T \boldsymbol{D} \mathbf{e}_W = \min_{i \in W} \mathbf{f}_i \text{vol}(W).$$

□

Theorem 5.7. *Sweepcut Inequality for Nonlinear Diffusion with growth or decay:*

If g *satisfies* $g(\mathbf{u}(x)) - g(\mathbf{u}(y)) \leq \mathbf{u}(x) - \mathbf{u}(y)\ \forall x, y \in W$ *and* $vol(W) \leq minvol(S^*) \leq v$*, then:*

$$\phi(\mathbf{f}) \leq \phi^* \frac{v}{min_{i \in W} \mathbf{f}_i\, vol(W)} + \frac{|W|}{min_{i \in W} \mathbf{f}_i\, vol(W)}.$$

Proof. We can prove the theorem using the two previous lemmas. □

Theorem 5.8. *If* $minvol(S^*) \leq v$*,* $g(\mathbf{u}) = \mathbf{u}^p$*,* p *tends to zero,* $\mathbf{d}_{avg}(W) \geq \frac{\alpha}{\phi^*}$*, and* $vol(W) \leq minvol(S^*)$*, then the nonlinear diffusion sweepcut inequality becomes:*

$$\phi(\mathbf{f}) \leq (\frac{v}{vol(W)} + \frac{1}{\alpha})\phi^*.$$

Proof. By noting that, as p tends to zero, $\mathbf{u}$ tends to an indicator and therefore, the condition $g(\mathbf{u}(x)) - g(\mathbf{u}(y)) \leq \mathbf{u}(x) - \mathbf{u}(y) \forall x, y \in W$ is always satisfied. In this case, $\mathbf{f}$ will tend to be $\mathbf{e}_W$ and the following properties applies for $\mathbf{e}_W$. $\min_{i \in W} \mathbf{f}_i \text{vol}(W)$ will tend to $\text{vol}(W)$ and we can observe that:

$$\frac{|W|}{\min_{i \in W} \mathbf{f}_i \text{vol}(W)} = \frac{|W|}{\text{vol}(W)} = \frac{|W|}{|W| \mathbf{d}_{\text{avg}}(W)} = \frac{1}{\mathbf{d}_{\text{avg}}(W)}.$$

As $\mathbf{d}_{\text{avg}}(W) \geq \frac{\alpha}{\phi^*}$ and re-arranging the terms, we can prove the theorem. Note that we can control $\text{vol}(W)$ using k, the number of steps, as increasing k increases $\text{vol}(W)$. □

At its heart, this theorem states that if the result of the diffusion is close to an indicator vector, then we will have some relationship between the set of smallest conductance and the result. This suggests using the power function with small power as it will tend to encourage "indicator-like" behavior for any number of time-steps. If the graph has an average degree of $\Omega(\frac{1}{\phi^*})$, then the nonlinear diffusion conductance will be close to the smallest conductance in the graph by a multiplicative factor and the larger the average degree of the graph, the smaller the multiplicative factor. Additionally, we can use this sweepcut inequality to tell us how close the nonlinear diffusion conductance is to the smallest conductance in the graph by simply computing the constants. On the other hand, this theorem only provides coarse guidance and essentially requires a large degree of knowledge of the optimal set to yield non-trivial results.

6 EXPERIMENTS

The goal of our experiments is to show the advantage of our nonlinear diffusion process in a variety of settings. We first show that it gives better F1-values in LFR synthetic graphs compared with linear diffusions, where we get the best results with small p as hinted at by our theory results. Second, in community detection on SNAP graphs, the non-linear diffusion gives consistently higher $F1$ scores on all graphs except one. Third, on graph-based semi-supervised learning, we show that nonlinear diffusion improves substantially on recently developed methods based

on neural networks in two of three tests. Finally, we conclude our experiments by trying to understand why nonlinear diffusion gives better results. Thus, we conduct a case study in the Fashion MNIST data and argue that the reason nonlinear diffusions perform better is because they produce vectors with higher dispersion than linear diffusions. Our experimental code is available at: https://github.com/RaniaSalama/Nonlinear_Diffusion

6.1 Synthetic Data

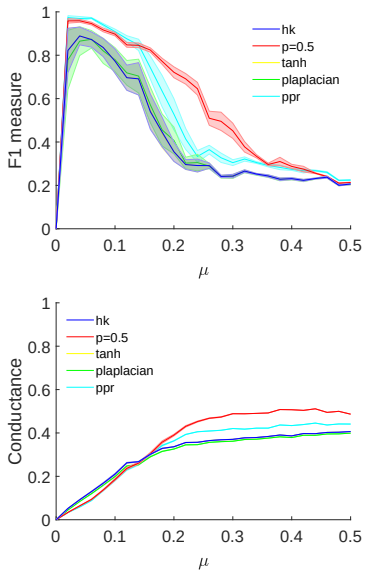

Figure 2: The F1 measure and the conductance of various techniques on LFR synthetic datasets. The bands show the variation over 100 trials.

We use the LFR model [28] to generate the synthetic datasets as it is a widely used model in evaluating community detection algorithms. The parameters used for the model are $n = 1000$, average degree is 10, maximum degree is 50, minimum community size is 20 and maximum community size is 100. LFR node degrees and community sizes are distributed according to the power law distribution, we set the exponent for the degree sequence to 2 and the exponent for the community size distribution to 1. We vary μ the mixing parameter from 0.02 to 0.5 with step 0.02 and run the heat kernel diffusion (hk), personalized PageRank (ppr), nonlinear diffusion using power function with $p = 0.5$, nonlinear diffusion using tanh function and nonlinear diffusion using p-Laplacian. In all the experiments, we set $k = 100$ and $h = 0.001$. For each graph, we start from a random seed node and we repeat the experiment 100 times. Figure 2 shows the mean and the variance for the F1 measure and the conductance while varying μ. As shown in the figure, nonlinear diffusion using power function with $p = 0.5$ has a better F1 measure than the heat kernel diffusion and has lower conductance than it for $\mu = 0.02$ to 0.14. The conductance for the nonlinear diffusion gets slightly higher after $\mu = 0.14$ but the increase in F1 measure is much higher. For example, for $\mu = 0.24$, the increase in conductance of $p = 0.5$ over the heat kernel diffusion is $\approx 9\%$, while the increase in F1 measure is $\approx 30\%$.

6.2 Local Community Detection

Local community detection is the task of finding the community when given a member of that community. In this task, we start the diffusion from the given node. Table 1 shows the community detection results for heat kernel diffusion (hk), personalized PageRank (ppr), nonlinear diffusion using the power function as the nonlinear function (power) with $p = 0.5$, nonlinear diffusion using the tanh function (tanh) and nonlinear diffusion using the p-Laplacian operator (p-Lap) with $p = 1.9$. In all nonlinear diffusions, we set $k = 10, h = 0.001$. We have followed the same evaluation settings as mentioned in [27]. In these experiments, we identify 100 communities from the ground truth such that each community has a size greater than 10, then for all algorithms, we start from each node in the community and finally report the result from the node that yields the best F1 measure. For nonlinear diffusion we truncate the diffusion values that are less than ε to be zero and the diffusion values that are greater than one to be one, where ε is designed to give 100 nodes in the final community, where we grow larger if necessary.

Table 1 shows datasets from SNAP repository [30], their characteristics, the mean F1 measure and the mean set size for the heat kernel diffusion, the personalized PageRank and the nonlinear diffusions. These results show that nonlinear diffusion can return a larger set than the heat kernel diffusion with higher or comparable F1 score. For example, in YouTube dataset, the detected communities for nonlinear diffusion have a higher F1 measure by around 35%.

6.3 Graph-based Semi-supervised Learning

Semi-supervised learning is the task of learning from a small set of labeled examples and a very large set of unlabeled examples. In these experiments, we use three citation networks, which are Cora, Citeseer and Pubmed. Table 2 shows the characteristic of these datasets. We run two coupled nonlinear diffusions as in Section 3.2, one using the adjacency matrix and another one using an r nearest neighbor graph constructed from the feature matrix using radial basis function with width equal 1. Following the exact methodology of [26], we choose the hyperparameters based on a train-validate-test split where we pick the parameters based on the ones that have the best classification accuracy on the validation set and then show the evaluation on the test set. The parameters are the number of nearest neighbors r, the number of steps k, the value of the power function p_1 for the adjacency diffusion and p_2 for the nearest neighbor diffusion, the value of σ, and value or rank rounding. For reproducibility, the parameters we find are given in a footnote.[6]

[6]For all the experiments, we set $h = 0.001$. Let r be the number of nearest neighbors used in the graph construction. For the power function, in Cora, we set the $r = 100$, $k = 400$, $\sigma = 0.55$, $p_1 = 0.6$, $p_2 = 0.45$ and used value-based rounding; in Citeseer we set $r = 200$, $k = 400$, $\sigma = 0.51$, $p_1 = 0.55$, $p_2 = 0.55$ and used rank-based rounding; and in Pubmed we set $r = 2000$, $k = 300$, $\sigma = 0.65$, $p_1 = 0.7$, $p_2 = 0.6$ and used rank-based rounding. For nonlinear diffusion using tanh function, in Cora we set $r = 100$, $k = 450$, $\sigma = 1.9$ and used value-based rounding; in Citeseer we set $r = 200$, $k = 450$, $\sigma = 1.9$ and used rank-based rounding; and in Pubmed wet set $r = 2000$, $k = 400$, $\sigma = 1.8$ and used rank-based rounding. Finally, for p-Laplacian, for Cora, we set $r = 100$, $p_1 = 1.9$, $p_2 = 1.7$, $\sigma = 0.05$, $k = 400$; for Citeseer,

Table 1: Community detection results.

	|V|	|E|	F1 measure					Set size				
			hk	ppr	power	tanh	p-Lap	hk	ppr	power	tanh	p-Lap

Table 2: Characteristics of datasets used in graph-based semi-supervised learning experiments.

	|V|	|E|	|Classes|	d	Label rate
Citeseer	3,327	4,732	6	3,703	0.036
Cora	2,708	5,429	7	1,433	0.052
Pubmed	19,717	44,338	3	500	0.003

Table 3: Classification accuracy for graph-based semi-supervised learning experiments.

	Cora	Citeseer	Pubmed
ManiReg [3]	59.5	60.1	70.7
SemiEmb [53]	59.0	59.6	71.1
LP [58]	68.0	45.3	63.0
DeepWalk [39]	67.2	43.2	65.3
ICA [33]	75.1	69.1	73.9
Planetoid [56]	75.7	64.7	77.2
GCN [26]	81.5	70.3	**79.0**
GCN + self learning [31]	80.2	67.8	76.9
hk	61.4	53.8	63.3
power	74.2	70.6	70.0
power + self-learning	71.3	68.9	70.3
tanh	77.9	**73.4**	71.0
tanh + self-learning	**82.9**	72.2	73.0
p-Lap	79.8	68.7	73.4
p-Lap + self-learning	79.2	67.8	73.4

Table 3 shows the classification accuracy of nonlinear diffusion compared to other graph-based semi-supervised learning related work. As shown in the table nonlinear diffusion using tanh function has the best classification accuracy in Cora and Citeseer. However, GCN has the best classification accuracy in Pubmed. Note that,

we set $r = 300$, $p_1 = 1.8$, $p_2 = 1.7$, $\sigma = 0.7$, $k = 1000$; and for Pubmed, we set $r = 100$, $p_1 = 1.9$, $p_2 = 1.7$, $\sigma = 0.05$, $k = 400$.

(a) Varying σ **(b) Varying p_1**

(c) Varying p_2 **(d) Varying σ in a tanh diffusion**

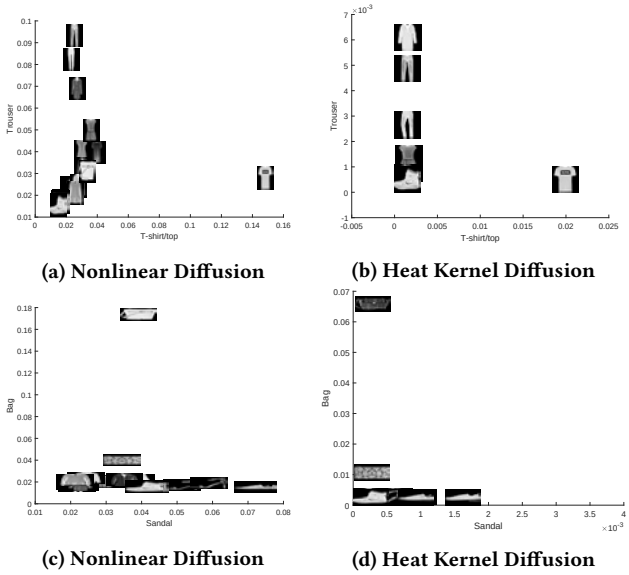

Figure 3: As we vary parameters, the accuracy remains high for many choices.

nonlinear diffusion uses less parameters as we do no optimization over the weights of the layers and therefore it is the simplest model with good accuracy. Additionally, the dynamics of the nonlinear diffusion is described by a differential equation and therefore it is easier to reason about and to develop bounds for its performance.

To further analyze the stability of nonlinear diffusion when the parameters change, Figure 3 shows changing σ, p_1 and p_2 for nonlinear diffusion using power function from 0.4 to 0.7 with step of 0.02 and changing σ for nonlinear diffusion using tanh function from 1.7 to 1.9 with step 0.02. As shown in the figure, nonlinear diffusion is robust to small changes in the parameters.

6.4 Fashion MNIST Case Study

Our final experiment is a case study of the Fashion MNIST dataset to understand why nonlinear diffusion outperforms linear diffusion. The Fashion MNIST dataset is a collection of Zalando's clothing images [54] with 70,000, 28 by 28 grayscale images. Each example is assigned a label from 10 classes, which are: T-shirt/top, Trouser, Pullover, Dress, Coat, Sandal, Shirt, Sneaker, Bag and Ankle Boot.

(a) Nonlinear Diffusion (b) Heat Kernel Diffusion

(c) Nonlinear Diffusion (d) Heat Kernel Diffusion

Figure 4: Comparison between the heat kernel diffusion and the nonlinear diffusion on Fashion-MNIST dataset.

Table 4: Heat kernel diffusion and nonlinear diffusion error rates on Fashion-MNIST dataset (k = 1000, h = 0.001, labels per class = 10, and r = 100).

	hk	power
T-shirt/top	0.466 ± 0.211	**0.362 ± 0.228**
Trouser	0.180 ± 0.084	**0.061 ± 0.017**
Pullover	0.609 ± 0.140	**0.582 ± 0.208**
Dress	0.547 ± 0.171	**0.481 ± 0.275**
Coat	0.516 ± 0.199	**0.502 ± 0.220**
Sandal	0.546 ± 0.165	**0.499 ± 0.256**
Shirt	**0.795 ± 0.109**	0.820 ± 0.098
Sneaker	0.217 ± 0.116	**0.196 ± 0.137**
Bag	0.528 ± 0.118	**0.403 ± 0.130**
Ankle boot	0.325 ± 0.138	**0.188 ± 0.190**
Total	0.473 ± 0.030	**0.409 ± 0.040**

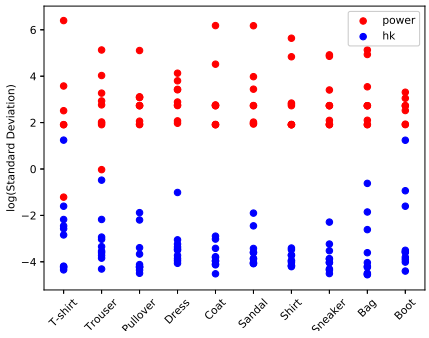

Figure 5: Dispersion comparison between the heat kernel diffusion values and nonlinear diffusion.

We construct a r-nearest neighbor graph from the data. Then, we randomly select 10 examples per class to start the semi-supervised learning task. Finally, we repeat the experiments 10 times and report the error rate over the 70,000 examples. This means that we only use around 0.14% of examples for the learning task.

Table 4 shows the error rates for the heat kernel diffusion and the nonlinear diffusion using power function with $p = 0.5$ for each different classes. These results show that nonlinear diffusion has a lower error rate than the heat kernel diffusion in all class except the Shirt class. Additionally, overall the error rate for the nonlinear diffusion was lower by around 7%.

To further study the difference between the two techniques, Figure 4 (a, b) compares values of the diffusion as in the introduction (Figure 1). Specifically, these figures are run on a random sample of 1000 images where we start from a single T-shirt/top example in the x-axis and the diffusion values when we start from a single coat example in the y-axis. Then we show 2 randomly chosen pictures from each class (so 20 pictures total). As shown in the figures, the heat kernel diffusion is extremely spiky for the different examples, while nonlinear diffusion is able to distinguish between different examples to provide more information to downstream operators. Figure 4 (c, d) shows the same comparison for Sandals and Bags.

We did one final evaluation to understand this advantage. Our conjecture is that the nonlinear diffusion produces values with far more dispersion over the range than the heat kernel. In Figure 5, we draw the log of the standard deviation of the diffusion values when we start the diffusion from each class for each trial. As shown in the figure, the nonlinear diffusion values show much higher standard deviations than the heat kernel diffusion, which supports this point.

7 DISCUSSION AND FUTURE WORK

In this paper, we have shown that nonlinear diffusion is competitive with embedding techniques and significantly outperform classical diffusions in community detection and semi-supervised learning. As a simple diffusion model, there are ample opportunities to accelerate the computation using a wide variety of techniques and we have not made that a focus of our work. For instance, there are Monte Carlo [14] and localized algorithms [2, 27] for linear diffusions that yield sublinear complexity and millisecond-level runtimes on billion edge graphs. In comparison, the complexity of our current implementation is linear (the work is k matrix-vector products). Note that, in our experience, the time required to evaluate these diffusions is dominated by the initial data load, ingestion, and r-nearest neighbor computation so we do not view this as problematic, but for large numbers of classes, faster runtime may be useful. We also note that our approach can easily be combined with recent work on higher-order analysis of graphs based on motifs [5]. Specific things we will explore in the future include how to choose the nonlinear function g in an automated fashion by studying the properties of target sets in the graph. Additionally, we hope to provide improved algorithms to evaluate the nonlinear ODEs themselves.

Acknowledgments. Both authors would like to acknowledge our colleagues who provided initial feedback on this paper. This work is supported by NSF awards CCF-1149756, IIS-1422918, IIS-1546488; NSF Center for Science of Information STC, CCF-0939370, DARPA SIMPLEX, and the Sloan Foundation.

ABSTRACT

It is common in recommendation systems that users both consume and produce information as they make strategic choices under uncertainty. While a social planner would balance "exploration" and "exploitation" using a multi-armed bandit algorithm, users' incentives may tilt this balance in favor of exploitation. We consider Bayesian Exploration: a simple model in which the recommendation system (the "principal") controls the information flow to the users (the "agents") and strives to incentivize exploration via information asymmetry. A single round of this model is a version of a well-known "Bayesian Persuasion game" from [24]. We allow heterogeneous users, relaxing a major assumption from prior work that users have the same preferences from one time step to another. The goal is now to learn the best *personalized* recommendations. One particular challenge is that it may be impossible to incentivize some of the user types to take some of the actions, no matter what the principal does or how much time she has. We consider several versions of the model, depending on whether and when the user types are reported to the principal, and design a near-optimal "recommendation policy" for each version. We also investigate how the model choice and the diversity of user types impact the set of actions that can possibly be "explored" by each type.

1 INTRODUCTION

Recommendation systems are ubiquitous in online markets (*e.g.*,Netflix for movies, Amazon for products, Yelp for restaurants, etc.), high-quality recommendations being a crucial part of their value proposition. A typical recommendation system encourages its users to submit feedback on their experiences, and aggregates this feedback in order to provide better recommendations in the future. Each user plays a dual rule: she consumes information from the previous users (indirectly, via recommendations), and produces new information (*e.g.*,a review) that benefits future users. This dual role creates a tension between exploration, exploitation, and users' incentives.

A social planner – a hypothetical entity that controls users for the sake of common good – would balance "exploration" of insufficiently known alternatives and "exploitation" of the information acquired so far. Designing algorithms to trade off these two objectives is a well-researched subject in machine learning and operations research. However, a given user who decides to "explore" typically suffers all the downside of this decision, whereas the upside (improved recommendations) is spread over many users in the future. Therefore, users' incentives are skewed in favor of exploitation. As a result, observations may be collected at a slower rate, and suffer from selection bias (*e.g.*,ratings of a particular movie may mostly come from people who like this type of movies). Moreover, in some natural but idealized examples (*e.g.*,[30, 33]) optimal recommendations are never found because they are never explored.

Thus, we have a problem of *incentivizing exploration*. Providing monetary incentives can be financially or technologically unfeasible, and relying on voluntary exploration can lead to selection biases. A recent line of work, started by [30], relies on the inherent *information asymmetry* between the recommendation system and a user. These papers posit a simple model, termed *Bayesian Exploration* in [34]. The recommendation system is a "principal" that interacts with a stream of self-interested "agents" arriving one by one. Each agent needs to make a decision: take an action from a given set of alternatives. The principal issues a recommendation, and observes the outcome, but cannot direct the agent to take a particular action. The problem is to design a "recommendation policy" for the principal that learns over time to make good recommendations *and* ensures that the agents are incentivized to follow this recommendation. A single round of this model is a version of a well-known "Bayesian Persuasion game" [24].

Our scope. We study Bayesian Exploration with agents that can have heterogenous preferences. The preferences of an agent are encapsulated in her *type*, *e.g.*,vegan vs meat-lover. When an agent takes a particular action, the outcome depends on the action itself (*e.g.*,the selection of restaurant), the "state" of the world (*e.g.*,the qualities of the restaurants), and the type of the agent. The state is persistent (does not change over time), but initially not known; a Bayesian prior on the state is common knowledge. In each round, the agent type is drawn independently from a fixed and known distribution. The principal strives to learn the best possible recommendation for each agent type.

We consider three models, depending on whether and when the agent type is revealed to the principal: the type is revealed immediately after the agent arrives (*public types*), the type is revealed only after the principal issues a recommendation (*reported types*),[1] and the type is never revealed (*private types*). We design a near-optimal recommendation policy for each modeling choice.

Explorability. A distinctive feature of Bayesian Exploration is that it may be impossible to incentivize some agent types to take some actions, no matter what the principal does or how much time she has. For a more precise terminology, a given type-action pair is *explorable* if this agent type takes this action under some recommendation policy in some round with positive probability. This action is also called *explorable* for this type. Thus: some type-action pairs might not be explorable. Moreover, one may need to explore to find out which pairs are explorable. The set of explorable pairs is interesting in its own right as they bound the welfare of a setting. Recommendation policies cannot do better than the "best explorable action" for a particular agent type: an explorable action with a largest reward in the realized state.

Comparative statics for explorability. We study how the set of all explorable type-action pairs (*explorable set*) is affected by the model choice and the diversity of types. First, we find that for each problem instance the explorable set stays the same if we transition from public types to reported types, and can only become smaller if we transition from reported types to private types. We provide a concrete example when the latter transition makes a huge difference. Second, we vary the distribution $\mathcal{D}$ of agent types. For public types (and therefore also for reported types), we find that the explorable set is determined by the support set of $\mathcal{D}$. Further, if we make the support set larger, then the explorable set can only become larger. In other words, *diversity of agent types helps exploration*. We provide a concrete example when the explorable set increases very substantially even if the support set increases by a single type. However, for private types the picture is quite different: we provide an example when *diversity hurts*, in the same sense as above. Intuitively, with private types, diversity muddles the information available to the principal making it harder to learn about the state of the world, whereas for public types diversity helps the principal refine her belief about the state.

Our techniques. As a warm-up, we first develop a recommendation policy for public types. In the long run, our policy matches the benchmark of "best explorable action". While it is easy to prove that such a policy exists, the challenge is to provide it as an explicit procedure. Our policy focuses on exploring all explorable type-action pairs. Exploration needs to proceed gradually, whereby exploring one action may enable the policy to explore another. In fact, exploring some action for one type may enable the policy to explore some action for another type. Our policy proceeds in phases: in each phase, we explore all actions for each type that can be explored using information available at the start of the phase. Agents of different types learn separately, in per-type "threads"; the threads exchange information after each phase.

[1]Reported types may arise if the principal asks agents to report the type after the recommendation is issued, *e.g.*,in a survey. While the agents are allowed to misreport their respective types, they have no incentives to do that.

An important building block is the analysis of the single-round game. We use information theory to characterize how much state-relevant information the principal has. In particular, we prove a version of *information-monotonicity*: the set of all explorable type-action pairs can only increase if the principal has more information.

As our main contribution, we develop a policy for private types. In this model, recommending one particular action to the current agent is not very meaningful because the agents' type is not known to the principal. Instead, one can recommend a *menu*: a mapping from agent types to actions. Analogous to the case of public types, we focus on explorable menus and gradually explore all such menus, eventually matching the Bayesian-expected reward of the best explorable menu. One difficulty is that exploring a given menu does not immediately reveal the reward of a particular type-action pair (because multiple types could map to the same action). Consequently, even keeping track of what the policy knows is now non-trivial. The analysis of the single-round game becomes more involved, as one needs to argue about "approximate information-monotonicity". To handle these issues, our recommendation policy satisfies only a relaxed version of incentive-compatibility.

In the reported types model, we face a similar issue, but achieve a much stronger result: we design a policy which matches our public-types benchmark in the long run. This may seem counterintuitive because "reported types" are completely useless to the principal in the single-round game (whereas public types are very useful). Essentially, we reduce the problem to the public types case, at the cost of a much longer exploration.

Discussion. This paper, as well as all prior work on incentivizing exploration, relies on very standard yet idealized assumptions of Bayesian rationality and the "power to commit" (i.e., principal can announce a policy and commit to implementing it). A recent paper [23] attempts to mitigate these assumptions (in a setting with homogeneous agents). However, some form of the "power to commit" assumption appears necessary to make any progress.

We do not attempt to *elicit* agents' types when they are not public, in the sense that our recommendation to a given agent is not contingent on anything that this agent reports. However, our result for reported types is already the best possible, in the sense that the explorable set is the same as for public types, so (in the same sense) elicitation is not needed.

Related work. Bayesian Exploration with homogenous agents was introduced in [30], and largely resolved: for optimal policy in the case of two actions and deterministic utilities [30], for explorability [34], and for regret minimization and stochastic utilities [33].

Bayesian Exploration with heterogenous agents and public types is studied in [33], under a very strong assumption which ensures explorability of all type-action pairs, and in [34], where a fixed tuple of agent types arrives in each round and plays a game. [34] focus on explorability of joint actions. Our approach for the public-type case is similar on a high level, but simpler and more efficient, essentially because we focus on type-action pairs rather than joint actions.

A very recent paper [16] (ours is independent work) studies incentivizing exploration with heterogenous agents and private types, but allows monetary transfers. Assuming that each action

is preferred by some agent type, they design an algorithm with a (very) low regret, and conclude that *diversity helps* in their setting.

Several papers study "incentivizing exploration" in substantially different models: with a social network [6]; with time-discounted utilities [10]; with monetary incentives [16, 19]; with a continuous information flow and a continuum of agents [15]; with long-lived agents and "exploration" separate from payoff generation [29, 31, 32]; with fairness [25]. Also, seminal papers [11, 27] study scenarios with long-lived, exploring agents and no principal.

Recommendation policies with no explicit exploration, and closely related "greedy algorithm" in multi-armed bandits, have been studied recently [7, 26, 36, 37]. A common theme is that the greedy algorithm performs well under substantial assumptions on the diversity of types. Yet, it suffers $\Omega(T)$ regret in the worst case.[2]

Exploration-exploitation tradeoff received much attention over the past decades, usually under the rubric of "multi-armed bandits", see books [13, 14, 21]. Absent incentives, Bayesian Exploration with public types is a well-studied problem of "contextual bandits" (with deterministic rewards and a Bayesian prior). A single round of Bayesian Exploration is a version of the Bayesian Persuasion game [24], where the signal observed by the principal is distinct from the state. Exploration-exploitation problems with incentives issues arise in several other scenarios: dynamic pricing, *e.g.*,[5, 9, 28], dynamic auctions [8], advertising auctions [3, 4, 18], human computation [20, 22, 38], and repeated actions, *e.g.*,[1, 2, 12].

2 MODEL AND PRELIMINARIES

Bayesian Exploration is a game between a principal and T agents. The game consists of T rounds. Each round $t \in [T]$ proceeds as follows: a new agent t arrives, receives a message m_t from the principal, chooses an action a_t from a fixed action space $\mathcal{A}$, and collects a reward $r_t \in [0,1]$ that is immediately observed by the principal. Each agent t has a *type* $\theta_t \in \Theta$, drawn independently from a fixed distribution $\mathcal{D}$, and an *action space* $\mathcal{A}$ (same for all agents). There is uncertainty, captured by a "state of nature" $\omega \in \Omega$, henceforth simply the *state*, drawn from a Bayesian prior $\mathcal{P}$ at the beginning of time and fixed across rounds. The *reward* $r_t = u(\theta_t, a_t, \omega) \in [0,1]$ of agent t is determined by its type θ_t, the action $a_t \in \mathcal{A}$ chosen by this agent, and the state ω, for some fixed and deterministic *reward function* $u : \Theta \times \mathcal{A} \times \Omega \to [0,1]$. The principal's messages m_t are generated according to a randomized online algorithm π termed "recommendation policy". Thus, an *instance* of Bayesian Exploration consists of the time horizon T, the sets $\mathcal{A}, \Theta, \Omega$, the type distribution $\mathcal{D}$, the prior $\mathcal{P}$, and the reward function u.

The knowledge structure is as follows. The type distribution $\mathcal{D}$, the Bayesian prior $\mathcal{P}$, the reward function u, and the recommendation policy are common knowledge. Each agent t knows her own type θ_t, and observes nothing else except the message m_t. We consider three model variants, depending on whether and when the principal learns the agent's type: the type is revealed immediately after the agent arrives (*public types*), the type is revealed only after the principal issues a recommendation (*reported types*), the type is not revealed (*private types*).

Let H_t denote the *history* observed by the principal at round t, immediately before it chooses its message m_t. Hence, it equals $\{(r_1, \theta_1), \ldots, (r_{t-1}, \theta_{t-1}), \theta_t\}$ for public types, $\{(r_1, \theta_1), \ldots, (r_{t-1}, \theta_{t-1})\}$ for reported types, and $\{r_1, \ldots, r_{t-1}\}$ for private types.[3] Formally, this is the input to the recommendation policy in each round t. Borrowing terminology from the Bayesian Persuasion literature, we will often refer to the history as the *signal*. We denote the set of all possible histories (signals) at time t by $\mathcal{H}_t$.

The recommendation policy π, the type distribution $\mathcal{D}$, the state distribution $\mathcal{P}$, and the reward function u induce a joint distribution $\mathcal{D}(\Omega, \mathcal{H}_t)$ over states and histories, henceforth called the *signal structure* at round t. Note that it is known to agent t.

We are ready to state agents' decision model. Each agent t, given the realized message m, chooses an action a_t so as to maximize her *Bayesian-expected reward*

$$\mathbb{E}[r_t] \equiv \mathop{\mathbb{E}}_{(\omega, H_t) \sim \mathcal{D}(\Omega, \mathcal{H}_t)} \left[\mathop{\mathbb{E}}_{m_t \sim \pi(H_t)} [u(\theta_t, a_t, \omega) \mid m_t = m] \right].$$

Given the instance of Bayesian Exploration, the goal of the principal is to choose a policy π that maximizes (Bayesian-expected) *total* reward, *i.e.*,$\sum_{t=1}^{T} \mathbb{E}[r_t]$.[4]

We assume that the sets $\mathcal{A}$, Θ and Ω are finite. We use ω_0 as the random variable for the state, and write $\Pr[\omega]$ for $\Pr[\omega_0 = \omega]$. Similarly, we write $\Pr[\theta]$ for $\Pr[\theta_t = \theta]$.

Bayesian-incentive compatibility. For public types, we assume the message m_t in each round is a recommended action $a \in \mathcal{A}$ which, for convenience, we sometimes write as $m_t(\theta_t)$. For private and reported types, we assume that the message m_t in each round is a *menu* mapping types to actions, i.e., $m_t : \Theta \to \mathcal{A}$. We further assume π is Bayesian incentive-compatible.

Definition 2.1. Let $\mathcal{E}_t$ be the event that the agents have followed principal's recommendations before round t, *i.e.*,$a_s = m_s(\theta_s)$ for all rounds $s < t$. The recommendation policy π is *Bayesian incentive compatible* (*BIC*) if for all rounds t and messages m such that

$$\Pr_{(\omega, H_t) \sim \mathcal{D}(\Omega, \mathcal{H}_t)} [m = \pi(H_t) \mid \mathcal{E}_t] > 0,$$

it holds that for all types θ and actions a,

$$\mathbb{E}\left[u(\theta, m(\theta), \omega) - u(\theta, a, \omega) \mid m_t = m, \mathcal{E}_t \right] \geq 0, \qquad (1)$$

where the expectation is over $(\omega, H_t) \sim \mathcal{D}(\Omega, \mathcal{H}_t)$.

The above assumptions are without loss of generality, by a suitable version of Myerson's "revelation principle".

Explorability and benchmarks. For public types, a type-action pair $(\theta, a) \in \Theta \times \mathcal{A}$ is called *eventually-explorable* in state ω if there is some BIC recommendation policy that, for T large enough, eventually recommends this action to this agent type with positive probability. Then action a is called *eventually-explorable* for type θ and state ω. The set of all such actions is denoted $\mathcal{A}_{\omega,\theta}$.

Likewise, for private types, a menu is called *eventually-explorable* in state ω if there is some BIC recommendation policy that eventually recommends this menu with positive probability. The set of all such menus is denoted $\mathcal{M}_\omega$.

[2] This is a well-known folklore result in various settings; *e.g.*,see [35, 37].

[3] For randomized policies, the history also contains policy's random seed in each round.

[4] While the principal must commit to the policy given only the problem instance, the policy itself observes the history and thus can adapt recommendations to inferences about the state based on the history. See Example 3.2.

Our benchmark is the best eventually-explorable recommendation for each type. For public and private types, resp., this is

$$\mathtt{OPT}_{\mathtt{pub}} = \sum_{\theta\in\mathbf{\Theta},\,\omega\in\mathbf{\Omega}} \Pr[\omega]\cdot\Pr[\theta]\cdot \max_{a\in\mathcal{A}_{\omega,\theta}} u(\theta,a,\omega). \tag{2}$$

$$\mathtt{OPT}_{\mathtt{pri}} = \sum_{\omega\in\mathbf{\Omega}} \Pr[\omega]\cdot \max_{m\in\mathcal{M}_\omega} \sum_{\theta\in\mathbf{\Theta}} \Pr[\theta]\cdot u(\theta,m(\theta),\omega). \tag{3}$$

We have $\mathtt{OPT}_{\mathtt{pub}} \geq \mathtt{OPT}_{\mathtt{pri}}$, essentially because any BIC policy for private types can be simulated as a BIC policy for public types. We provide an example (Example 3.2) when $\mathtt{OPT}_{\mathtt{pub}} > \mathtt{OPT}_{\mathtt{pri}}$.

3 COMPARATIVE STATICS

We discuss how the set of all eventually-explorable type-action pairs (*explorable set*) is affected by the model choice and the diversity of types. The explorable set is all information that can possibly be learned in the public-types model. All else equal, settings with larger explorable set have greater or equal total expected reward, both in benchmark (2) and in our approximation guarantees. For private types, the exploration set provides an "upper bound" on the information available to the principal, because the principal does not directly observe the agent types.

Explorability and the model choice. Fix an instance of Bayesian Exploration. Let $\mathcal{A}^{\mathtt{pub}}_\omega$ and $\mathcal{A}^{\mathtt{pri}}_\omega$ be the explorable set for a given state ω, for public and private types, respectively.[5] We will show in Section 4.3 that the explorable set for reported types is $\mathcal{A}^{\mathtt{pub}}_\omega$, too.

Claim 3.1. $\mathcal{A}^{\mathtt{pri}}_\omega \subseteq \mathcal{A}^{\mathtt{pub}}_\omega$.

The idea is that one can simulate any BIC recommendation policy for private types with a BIC recommendation policy for public types; we omit the details.

Interestingly, $\mathcal{A}^{\mathtt{pri}}_\omega$ can in fact be a *strict* subset of $\mathcal{A}^{\mathtt{pub}}_\omega$:

Example 3.2. There are 2 states, 2 types and 2 actions: $\mathbf{\Omega} = \mathbf{\Theta} = \mathcal{A} = \{0,1\}$. States and types are drawn uniformly at random: $\Pr[\omega=0] = \Pr[\theta=0] = \frac{1}{2}$. Rewards are defined as follows:

Table 1: Rewards $u(\theta,a,\omega)$ when $\omega=0$ and $\omega=1$.

	$a=0$	$a=1$
$\theta=0$	$u=3$	$u=4$
$\theta=1$	$u=2$	$u=0$

	$a=0$	$a=1$
$\theta=0$	$u=2$	$u=0$
$\theta=1$	$u=3$	$u=4$

Claim 3.3. *In Example 3.2, $\mathcal{A}^{\mathtt{pri}}_\omega$ is a strict subset of $\mathcal{A}^{\mathtt{pub}}_\omega$.*

Proof. Action 0 is preferred by both types initially. Thus in the first round, the principal must recommend action 0 in order for the policy to be BIC. Hence type-action pairs $\{(0,0),(1,0)\}$ are eventually-explorable in all models.

In the second round, the principal knows the reward of the first-round agent. When types are public or reported, the reward together with the type is sufficient information for the principal to learn the state. Moving forward, the principal can now recommend the higher-reward action for each type (either directly or, in the case of reported types, through a menu). Thus, type-action pair $(0,1)$ is eventually-explorable when $\omega=0$ and, similarly, type-action pair $(1,1)$ is eventually-explorable when $\omega=1$.

For private types, samples from the first-round menu (which, as argued above, must recommend action 0 for both types) do not convey any information about the state, as they have the same distribution in both states. Therefore, action 1 is not eventually-explorable, for either type and either state. □

Explorability and diversity of agent types. Fix an instance of Bayesian Exploration with type distribution $\mathcal{D}$. We consider how the explorable set changes if we modify the type distribution $\mathcal{D}$ in this instance to some other distribution $\mathcal{D}'$. Let $\mathcal{A}_\omega$ and $\mathcal{A}'_\omega$ be the corresponding explorable sets, for each state ω.

For public and reported types, we show that the explorable set is determined by the support set of $\mathcal{D}$, denoted $\mathtt{support}(\mathcal{D})$, and can only increase if the support set increases:

Claim 3.4. *Consider Bayesian Exploration with public types. Then:*
(a) if $\mathtt{support}(\mathcal{D}) = \mathtt{support}(\mathcal{D}')$ then $\mathcal{A}_\omega = \mathcal{A}'_\omega$.
(b) if $\mathtt{support}(\mathcal{D}) \subset \mathtt{support}(\mathcal{D}')$ then $\mathcal{A}_\omega \subseteq \mathcal{A}'_\omega$.

Proof Sketch. Consider public types (the case of reported types then follows by arguments in Section 4.3). Let π be a BIC recommendation policy for the instance with type distribution $\mathcal{D}$ and suppose π eventually explores type-action pairs $\mathcal{A}_\omega$ for this instance and state ω. Consider the instance with type distribution $\mathcal{D}'$. Extend π to a policy π' as follows: let T' be the subsequence of T for which $\mathcal{D}(\theta_t) > 0$. If $t \notin T'$, then recommend the action a that maximizes agent t's Bayesian-expected reward. If $t \in T'$, then consider the sub-history $H \equiv H_t^{T'}$ restricted to T' and recommend action $a \sim \pi(H)$. Then π' is BIC for the instance with type distribution $\mathcal{D}'$. Furthermore, π' eventually explores the same set of type-action pairs $\mathcal{A}_\omega$ for this modified instance as well (and possibly more) as every history that occurs with positive probability in the original instance occurs as a sub-history in the modified instance with positive probability as well. □

For private types, the situation is more complicated. More types can help for some problem instances. For example, if different types have disjoint sets of available actions (more formally: say, disjoint sets of actions with positive rewards) then we are essentially back to the case of reported types, and the conclusions in Claim 3.4 apply. On the other hand, we can use Example 3.2 to show that more types can hurt explorability when types are private. Recall that in this example, for private types only action 0 can be recommended. Now consider a less diverse instance in which only type 0 appears. After one agent in that type chooses action 0, the state is revealed to the principal. For example, when the state $\omega=0$, action 1 can be recommended to future agents. This shows that, in this example, explorable set increases when we have fewer types.

4 PUBLIC TYPES

In this section, we develop our recommendation policy for public types. Throughout, $\mathtt{OPT} = \mathtt{OPT}_{\mathtt{pub}}$.

Theorem 4.1. *Consider an arbitrary instance of Bayesian Exploration with public types. There exists a BIC recommendation policy*

[5] Equivalently, $\mathcal{A}^{\mathtt{pri}}_\omega$ is the set of all type-action pairs $(\theta, m(\theta))$ that appear in some eventually-explorable menu $m \in \mathcal{M}_\omega$ in state ω with private types.

with expected total reward at least $(T - C) \cdot \texttt{OPT}$*, for some constant* C *that depends on the problem instance but not on* T*. This policy explores all type-action pairs that are eventually-explorable for a given state.*

4.1 A single round of Bayesian Exploration

Signal and explorability. We first analyze what actions can be explored by a BIC policy in a single round t of Bayesian Exploration for public types, as a function of the history. Throughout, we suppress θ and t from our notation. Let S be a random variable equal to the history at round t (referred to as a *signal* throughout this section), s be a realization of S, and $\mathcal{S} = \mathcal{D}(\Omega, \mathcal{H})$ be the signal structure: the joint distribution of (ω, S). Note different policies induce different histories and hence different signal structures. Thus it will be important to be explicit about the signal structure throughout this section.

Definition 4.2. Consider a single-round of Bayesian Exploration when the principal receives signal S with signal structure $\mathcal{S}$. An action $a \in \mathcal{A}$ is called *signal-explorable for a realized signal* s if there exists a BIC recommendation policy π such that $\Pr[\pi(s) = a] > 0$. The set of all such actions is denoted as $\texttt{EX}_s[\mathcal{S}]$. The *signal-explorable set*, denoted $\texttt{EX}[\mathcal{S}]$, is the random subset of actions $\texttt{EX}_S[\mathcal{S}]$.

Information-monotonicity. We compare the information content of two signals using the notion of conditional mutual information (see [17] for background). Essentially, we show that a more informative signal leads to the same or larger explorable set.

Definition 4.3. We say that signal S *is at least as informative* as signal S' if $I(S'; \omega \mid S) = 0$.

Intuitively, the condition $I(S'; \omega_0 | S) = 0$ means if one is given random variable S, one can learn no further information from S' about ω_0. Note that this condition depends not only on the signal structures of the two signals, but also on their joint distribution.

Lemma 4.4. *Let* S, S' *be two signals with signal structures* $\mathcal{S}, \mathcal{S}'$*. If* S *is at least as informative as* S'*, then* $\texttt{EX}_{s'}[\mathcal{S}'] \subseteq \texttt{EX}_s[\mathcal{S}]$ *for all* s', s *such that* $\Pr[S = s, S' = s'] > 0$.

Proof. Consider any BIC recommendation policy π' for signal structure $\mathcal{S}'$. We construct π for signal structure $\mathcal{S}$ by setting $\Pr[\pi(s) = a] = \sum_{s'} \Pr[\pi'(s') = a] \cdot Pr[S' = s' \mid S = s]$. Notice that $I(S'; \omega_0 \mid S) = 0$ implies S' and ω_0 are independent given S, i.e $\Pr[S' = s' \mid S = s] \cdot \Pr[\omega_0 = \omega \mid S = s] = \Pr[S' = s', \omega_0 = \omega \mid S = s]$ for all s, s', ω. Therefore, for all s' and ω,

$$\begin{aligned}
&\textstyle\sum_s \Pr[S' = s' \mid S = s] \cdot \Pr[\omega_0 = \omega, S = s] \\
&\quad = \textstyle\sum_s \Pr[S' = s' \mid S = s] \cdot \Pr[\omega_0 = \omega \mid S = s] \cdot \Pr[S = s] \\
&\quad = \textstyle\sum_s \Pr[S' = s', \omega_0 = \omega \mid S = s] \cdot \Pr[S = s] \\
&\quad = \textstyle\sum_s \Pr[S = s, S' = s', \omega_0 = \omega] \\
&\quad = \Pr[\omega_0 = \omega, S' = s'].
\end{aligned}$$

Therefore π' being BIC implies that π is also BIC. Indeed, for any $a, a' \in \mathcal{A}$ and $\theta \in \mathbf{\Theta}$, by plugging in the definition of π,

$$\begin{aligned}
&\textstyle\sum_{\omega, s} \Pr[\omega_0 = \omega, S = s] \cdot (u(\theta, a', \omega) - u(\theta, a, \omega)) \cdot \Pr[\pi(s) = a] \\
&= \textstyle\sum_{\omega, s'} \Pr[\omega_0 = \omega, S' = s'] \cdot (u(\theta, a', \omega) - u(\theta, a, \omega)) \cdot \Pr[\pi'(s') = a] \\
&\geq 0.
\end{aligned}$$

Finally, for any s', s, a such that $Pr[S' = s', S = s] > 0$ and $\Pr[\pi'(s') = a] > 0$, we have $\Pr[\pi(s) = a] > 0$. This implies $\texttt{EX}_{s'}[\mathcal{S}'] \subseteq \texttt{EX}_s[\mathcal{S}]$. □

Max-Support Policy. We can solve the following LP to check whether a particular action $a_0 \in \mathcal{A}$ is signal-explorable given a particular realized signal $s_0 \in \mathcal{X}$. In this LP, we represent a policy π as a set of numbers $x_{a,s} = \Pr[\pi(s) = a]$, for each action $a \in \mathcal{A}$ and each feasible signal $s \in \mathcal{X}$.

maximize x_{a_0, s_0}

subject to:

$$\begin{aligned}
&\textstyle\sum_{\omega \in \Omega, s \in \mathcal{X}} \Pr[\omega] \cdot \Pr[s \mid \omega] \cdot \\
&(u(\theta, a, \omega) - u(\theta, a', \omega)) \cdot x_{a,s} \geq 0 && \forall a, a' \in \mathcal{A} \\
&\textstyle\sum_{a \in \mathcal{A}} x_{a,s} = 1, && \forall s \in \mathcal{X} \\
&x_{a,s} \geq 0, && \forall s \in \mathcal{X}, a \in \mathcal{A}
\end{aligned}$$

Since the constraints in this LP characterize any BIC recommendation policy, it follows that action a_0 is signal-explorable given realized signal s_0 if and only if the LP has a positive solution. If such solution exists, define recommendation policy $\pi = \pi^{a_0, s_0}$ by setting $\Pr[\pi(s) = a] = x_{a,s}$ for all $a \in \mathcal{A}, s \in \mathcal{X}$. Then this is a BIC recommendation policy such that $\Pr[\pi(s_0) = a_0] > 0$.

Definition 4.5. Given a signal structure $\mathcal{S}$, a BIC recommendation policy π is called *max-support* if $\forall s \in \mathcal{X}$ and signal-explorable action $a \in \mathcal{A}$ given s, $\Pr[\pi(s) = a] > 0$.

It is easy to see that we obtain max-support recommendation policy by averaging the $\pi^{a,s}$ policies defined above. Specifically, the following policy is BIC and max-support:

$$\pi^{\max} = \frac{1}{|\mathcal{X}|} \sum_{s \in \mathcal{X}} \frac{1}{|\texttt{EX}_s[\mathcal{S}]|} \sum_{a \in \texttt{EX}_s[\mathcal{S}]} \pi^{a,s}. \tag{4}$$

Maximal Exploration. We design a subroutine `MaxExplore` which outputs a sequence of actions with two properties: it includes every signal-explorable action at least once, and each action in the sequence marginally distributed as $\pi^{\max}$. The length of this sequence, denoted L_θ, should satisfy

$$L_\theta \geq \max_{(a,s) \in \mathcal{A} \times \mathcal{X} \text{ with } \Pr[\pi^{\max}(s) = a] \neq 0} \frac{1}{\Pr[\pi^{\max}(s) = a]}. \tag{5}$$

This step is essentially from [34]; we provide the details below for the sake of completeness. The idea is to put $C_a = L_\theta \cdot \Pr[\pi^{\max}(S) = a]$ copies of each action a into a sequence of length L_θ and randomly permute the sequence. However, C_a might not be an integer, and in particular may be smaller than 1. The latter issue is resolved

by making L_θ sufficiently large. For the former issue, we first put $\lfloor C_a \rfloor$ copies of each action a into the sequence, and then sample the remaining $L_\theta - \sum_a \lfloor C_a \rfloor$ actions according to distribution $p^{\text{res}}(a) = \frac{C_a - \lfloor C_a \rfloor}{L_\theta - \sum_a \lfloor C_a \rfloor}$. For details, see Algorithm 1.

Algorithm 1 Subroutine MaxExplore

Input: type θ, signal S and signal structure $\mathcal{S}$.
Output: a list of actions α
Compute $\pi^{\max}$ as per (4)
Initialize $Res = L_\theta$.
for each action $a \in \mathcal{A}$ **do**
  $C_a \leftarrow L_\theta \cdot \Pr[\pi^{\max}(S) = a]$
  Add $\lfloor C_a \rfloor$ copies of action a into list α.
  $Res \leftarrow Res - \lfloor C_a \rfloor$.
  $p^{\text{res}}(a) \leftarrow C_a - \lfloor C_a \rfloor$
$p^{\text{res}}(a) \leftarrow p^{\text{res}}(a)/Res$, $\forall a \in \mathcal{A}$.
Sample Res many actions from distribution according to p^{res} independently and add these actions into α.
Randomly permute the actions in α.
return α.

Claim 4.6. *Given type θ and signal S, MaxExplore outputs a sequence of L_θ actions. Each action in the sequence marginally distributed as $\pi^{\max}$. For any action a such that $\Pr[\pi^{\max} = a] > 0$, a shows up in the sequence at least once with probability exactly 1. MaxExplore runs in time polynomial in L_θ, $|\mathcal{A}|$, $|\Omega|$ and $|\mathcal{X}|$ (size of the support of the signal).*

4.2 Main Recommendation Policy

Algorithm 2 is the main procedure of our recommendation policy. It consists of two parts: *exploration*, which explores all the eventually-explorable actions, and *exploitation*, which simply recommends the best explored action for a given type. The exploration part proceeds in phases. In each phase l, each type θ gets a sequence of L_θ actions from MaxExplore using the data collected before this phase starts. The phase ends when every agent type θ has finished L_θ rounds. We pick parameter L_θ large enough so that the condition (5) is satisfied for all phases l and all possible signals $S = S_l$. (Note that L_θ is finite because there are only finitely many such signals.) After $|\mathcal{A}| \cdot |\Theta|$ phases, our recommendation policy enters the exploitation part. See Algorithm 2 for details.

There is a separate thread for each type θ, denoted $\texttt{thread}(\theta)$, which is called whenever an agent of this type shows up; see Algorithm 3. In a given phase l, it recommends the L_θ actions computed by MaxExplore, then switches to the best explored action. The thread only uses the information collected before the current phase starts: the signal S_l and signal structure $\mathcal{S}_l$.

The BIC property follows easily from Claim 4.6. The key is that Algorithm 2 explores all eventually-explorable type-action pairs.

The following lemma compares the exploration of Algorithm 2 with l phases and some other BIC recommendation policy with l rounds. Notice that a phase in Algorithm 2 has many rounds.

Lemma 4.7. *Fix phase $l > 0$ and the sequence of agent types $\theta_1, ..., \theta_T$. Assume Algorithm 2 has been running for at least $\min(l, |\mathcal{A}| \cdot |\Theta|)$ phases. For a given state ω, if type-action pair (θ, a) can be explored by some BIC recommendation policy π at round l with positive probability, then such action is explored by Algorithm 2 by the end of phase $\min(l, |\mathcal{A}| \cdot |\Theta|)$ with probability 1.*

Algorithm 2 Main procedure for public types

Initialization: signal $S_1 = \mathcal{S}_1 = \perp$, phase count $l = 1$, index $i_\theta = 0$ for each type $\theta \in \Theta$.
for rounds $t = 1$ to T **do**
  if $l \le |\mathcal{A}| \cdot |\Theta|$ **then**
    {Exploration}
    Call thread $\texttt{thread}(\theta_t)$.
    if every type θ has finished L_θ rounds in the current phase ($i_\theta \ge L_\theta$) **then**
      Start a new phase: $l \leftarrow l + 1$.
      Let S_l be the signal for phase l:
        the set of all observed type-action-reward triples.
      Let $\mathcal{S}_l$ be the signal structure for S_l
        given the realized type sequence $(\theta_1, ..., \theta_t)$.
  else
    {Exploitation}
    Recommend the best explored action for agent type θ_t.

Algorithm 3 Thread for agent type θ: $\texttt{thread}(\theta)$

if this is the first call of $\texttt{thread}(\theta)$ of the current phase **then**
  Compute a list of L_θ actions $\alpha_\theta \leftarrow \text{MaxExplore}(\theta, S_l, \mathcal{S}_l)$.
  Initialize the index of type θ: $i_\theta \leftarrow 0$.
$i_\theta \leftarrow i_\theta + 1$.
if $i_\theta \le L_\theta$ **then**
  Recommend action $\alpha_\theta[i_\theta]$.
else
  Recommend the best explored action of type θ.

Proof. We prove this by induction on l for $l \le |\mathcal{A}| \cdot |\Theta|$. Base case $l = 1$ is trivial by Claim 4.6. Assuming the lemma is correct for $l - 1$, let's prove it's correct for l.

Let $S = S_l$ be the signal of Algorithm 2 by the end of phase $l - 1$. Let S' be the history of π in the first $l - 1$ rounds. More precisely, $S' = (R, H_1, ..., H_{l-1})$, where R is the internal randomness of policy π, and $H_t = (\Theta_t, A_t, u(\Theta_t, A_t, \omega_0))$ is the type-action-reward triple in round t of policy π.

The proof plan is as follows. We first show that $I(S'; \omega_0 | S) = 0$. Informally, this means the information collected in the first $l - 1$ phases of Algorithm 2 contains all the information S' has about the state w_0. After that, we will use the information monotonicity lemma to show that phase l of Algorithm 2 explores all the action-type pairs π might explore in round l.

First of all, we have

$$\begin{aligned} I(S'; \omega_0 \mid S) &= I(R, H_1, ..., H_{l-1}; \omega_0 \mid S) \\ &= I(R; \omega_0 \mid S) + I(H_1, ..., H_{l-1}; \omega_0 \mid S, R) \\ &= I(H_1, ..., H_{l-1}; \omega_0 \mid S, R). \end{aligned}$$

By the chain rule of mutual information, we have

$$I(H_1, ..., H_{l-1}; \omega_0 \mid S, R) = I(H_1; \omega_0 \mid S, R) + \cdots + I(H_{l-1}; \omega_0 \mid S, R, H_1, ..., H_{l-2}).$$

For all $t \in [l-1]$, we have

$$\begin{aligned} &I(H_t; \omega_0 \mid S, R, H_1, ..., H_{t-1}) \\ &\quad = I(\Theta_t, A_t, u(\Theta_t, A_t, \omega_0); \omega_0 \mid S, R, H_1, ..., H_{t-1}) \\ &\quad = I(\Theta_t; \omega_0 \mid S, R, H_1, ..., H_{t-1}) \\ &\qquad + I(A_t, u(\Theta_t, A_t, \omega_0); \omega_0 \mid S, R, H_1, ..., H_{t-1}, \Theta_t) \\ &\quad = I(A_t, u(\Theta_t, A_t, \omega_0); \omega_0 \mid S, R, H_1, ..., H_{t-1}, \Theta_t). \end{aligned}$$

Notice that the suggested action A_t is a deterministic function of randomness of the recommendation policy R, history of previous rounds $H_1, ..., H_{t-1}$ and type in the current round Θ_t. Also notice that, by induction hypothesis, $u(\Theta_t, A_t, \omega_0)$ is a deterministic function of $S, R, H_1, ..., H_{t-1}, \Theta_t, A_t$. Therefore we have

$$I(H_t; \omega_0 \mid S, R, H_1, ..., H_{t-1}) = 0, \qquad \forall t \in [l-1].$$

Then we get $I(S'; \omega_0 \mid S) = 0$.

By Lemma 4.4, we know that $\texttt{EX}[\mathcal{S}'] \subseteq \texttt{EX}[\mathcal{S}]$. For state ω, there exists a signal s' such that $\Pr[S' = s' \mid \omega_0 = \omega] > 0$ and $a \in \texttt{EX}_{s'}[\mathcal{S}']$. Now let s be the realized value of S given $\omega_0 = \omega$, we know that $\Pr[S' = s' \mid S = s] > 0$, so $a \in \texttt{EX}_s[\mathcal{S}]$. By Claim 4.6, we know that at least one agent of type θ in phase l of Algorithm 2 will choose action a.

Now consider the case when $l > |\mathcal{A}| \cdot |\Theta|$. Define ALGto be the variant of Algorithm 2 such that it only does exploration (removing the if-condition and exploitation in Algorithm 2). For $l > |\mathcal{A}| \cdot |\Theta|$, the above induction proof still work for ALG, i.e. for a given state ω, if an action a of type θ can be explored by a BIC recommendation policy π at round l, then such action is guaranteed to be explored by ALGby the end of phase l. Now we are going to argue that ALGwon't explore any new action-type pairs after phase $|\mathcal{A}| \cdot |\Theta|$. Call a phase exploring if in that phase ALGexplores at least one new action-type pair. As there are $|\mathcal{A}| \cdot |\Theta|$ type-action pairs, ALGcan have at most $|\mathcal{A}| \cdot |\Theta|$ exploring phases. On the other hand, once ALGhas a phase that is not exploring, because the signal stays the same after that phase, all phases afterwards are not exploring. So, ALGdoes not have any exploring phases after phase $|\mathcal{A}| \cdot |\Theta|$. For $l > |\mathcal{A}| \cdot |\Theta|$, the first $|\mathcal{A}| \cdot |\Theta|$ phases of Algorithm 2 explores the same set of type-action pairs as the first l phases of ALG. □

Proof of Theorem 4.1. Algorithm 2 is BIC by Claim 4.6. By Lemma 4.7, Algorithm 2 explores all the eventually-explorable type-actions pairs after $|\mathcal{A}| \cdot |\Theta|$ phases. After that, for each agent type θ, Algorithm 2 recommends the best explored action: $\arg\max_{a \in \mathcal{A}_{\omega,\theta}} u(\theta, a, \omega)$ with probability exactly 1.[6]

Therefore Algorithm 2 gets reward OPT except rounds in the first $|\mathcal{A}| \cdot |\Theta|$ phases. It remains to prove that the expected number of rounds in exploration (i.e. first $|\mathcal{A}| \cdot |\Theta|$ phases) does not depend on the time horizon T. Let N_l be the duration of phase l. Recall that the phase ends as soon as each type has shown up at least L_θ times. It follows that $\mathbb{E}[N_l] \le \sum_{\theta \in \Theta} \frac{L_\theta}{\Pr[\theta]}$. So, one can take $C = |\mathcal{A}| \cdot |\Theta| \cdot \sum_{\theta \in \Theta} \frac{L_\theta}{\Pr[\theta]}$. □

[6]This holds with probability exactly 1, provided that our algorithm finishes $|\mathcal{A}| \cdot |\Theta|$ phases. If some undesirable low-probability event happens, *e.g.*,if all agents seen so far have had the same type, our algorithm would never finish $|\mathcal{A}| \cdot |\Theta|$ phases.

4.3 Extension to Reported Types

We sketch how to extend our ideas for public types to handle the case of reported types. We'd like to simulate the recommendation policy for public types, call it π_{pub}. We simulate it separately for the exploration part and the exploitation part. The exploitation part is fairly easy: we provide a menu that recommends the best explored action for each agent types.

In the exploration part, in each round t we guess the agent type to be $\hat{\theta}_t$, with equal probability among all types.[7] The idea is to simulate π_{pub} only in *lucky rounds* when we guess correctly, *i.e.*,$\hat{\theta}_t = \theta_t$. Thus, in each round t we simulate the l_t-th round of π_{pub}, where l_t is the number of lucky rounds before round t. In each round t of exploration, we suggest the following menu. For type $\hat{\theta}_t$, we recommend the same action as π_{pub} would recommend for this type in the l_t-th round, namely $\hat{a}_t = \pi_{\text{pub}}^{l_t}(\hat{\theta}_t)$. For any other type, we recommend the action which has the best expected reward given the "common knowledge" (information available before round 1) and the action $\hat{a}_t$. This is to ensure that in a lucky round, the menu does not convey any information beyond action $\hat{a}_t$. When we receive the reported type, we can check whether our guess was correct. If so, we input the type-action-reward triple back to π_{pub}. Else, we ignore this round, as if it never happened.

Thus, our recommendation policy eventually explores the same type-action pairs as π_{pub}. The expected number of rounds increases by the factor of $|\Theta|$. Thus, we have the following theorem.

Theorem 4.8. *Consider Bayesian Exploration with reported types. There exists a BIC recommendation policy whose expected total reward is at least* $(T - C) \cdot \texttt{OPT}_{\text{pub}}$*, for some constant* C *that depends on the problem instance but not on* T*. This policy explores all type-action pairs that are eventually-explorable for public types.*

5 PRIVATE TYPES

Our recommendation policy for private types satisfies a relaxed version of the BIC property, called δ*-BIC*, where the right-hand side in (1) is $-\delta$ for some fixed $\delta > 0$. We assume a more permissive behavioral model in which agents obey such policy.

The main result is as follows. (Throughout, $\texttt{OPT} = \texttt{OPT}_{\text{pri}}$.)

Theorem 5.1. *Consider Bayesian Exploration with private types, and fix* $\delta > 0$*. There exists a* δ*-BIC recommendation policy with expected total reward at least* $(T - C \log T) \cdot \texttt{OPT}$*, where* C *depends on the problem instance but not on time horizon* T*.*

The recommendation policy proceeds in phases: in each phase, it explores all menus that can be explored given the information collected so far. The crucial step in the proof is to show that:

(P1) the first l phases of our recommendation policy explore all the menus that could be possibly explored by the first l rounds of any BIC recommendation policy.

[7]We guess the types uniformly, rather than according to their probabilities, because our goal is to explore each type for certain number of rounds. Guessing a type according to its probability will only make rare types appear even rarer.

The new difficulty for private types comes from the fact that we are exploring menus instead of type-actions pairs, and we do not learn the reward of a particular type-action pair immediately. This is because a recommended menu may map several different types to the chosen action, so knowing the latter does not immediately reveal the agent's type. Moreover, the full "outcome" of a particular menu is a distribution over action-reward pairs, it is, in general, impossible to learn this outcome exactly in any finite number of rounds. Because of these issues, we cannot obtain Property (P1) exactly. Instead, we achieve an approximate version of this property, as long as we explore each menu enough times in each phase.

We then show that this approximate version of (P1) suffices to guarantee explorability, if we relax the incentives property of our policy from BIC to δ-BIC, for any fixed $\delta > 0$. In particular, we prove an approximate version of the information-monotonicity lemma (Lemma 4.4) which (given the approximate version of (P1)) ensures that our recommendation policy can explore all the menus that could be possibly explored by the first l rounds of any BIC recommendation policy.

5.1 A Single round of Bayesian Exploration

Recall that for a random variable S, called *signal*, the signal structure is a joint distribution of (ω, S).

Definition 5.2. Consider a single-round of Bayesian Exploration when the principal has signal S from signal structure $\mathcal{S}$. For any $\delta \geq 0$, a menu $m \in \mathcal{M}$ is called δ-signal-explorable, for a given signal s, if there exists a single-round δ-BIC recommendation policy π such that $\Pr[\pi(s) = m] > 0$. The set of all such menus is denoted as $\mathtt{EX}_s^\delta[\mathcal{S}]$. The δ-signal-explorable set is defined as $\mathtt{EX}^\delta[\mathcal{S}] = \mathtt{EX}_S^\delta[\mathcal{S}]$. We omit δ in $\mathtt{EX}^\delta[\mathcal{S}]$ when $\delta = 0$.

Approximate Information Monotonicity. In the following definition, we define a way to compare two signals approximately.

Definition 5.3. Let S and S' be two random variables. We say random variable S is α-approximately informative as random variable S' about state ω_0 if $I(S'; \omega_0 | S) = \alpha$.

Lemma 5.4. *Let S and S' be two random variables and $\mathcal{S}$ and $\mathcal{S}'$ be their signal structures. If S is $(\delta^2/8)$-approximately informative as S' about state ω_0 (i.e. $I(S'; \omega_0|S) \leq \delta^2/8$), then $\mathtt{EX}_{s'}[\mathcal{S}'] \subseteq \mathtt{EX}_s^\delta[\mathcal{S}]$ for all s', s such that $\Pr[S = s, S' = s'] > 0$.*

Proof. For each signal realization s, denote

$$D_s = \mathbf{D}_{\mathsf{KL}}\left(((S', \omega_0) \mid S = s) \quad \| \quad (S'|S = s) \times (\omega_0 \mid S = s) \right).$$

We have $\sum_s \Pr[S = s] \cdot D = I(S'; \omega_0|S) \leq \delta^2/8$.

By Pinsker's inequality, we have

$$\begin{aligned}
&\sum_s \Pr[S = s] \cdot \sum_{s', \omega} |\Pr[S' = s', \omega_0 = \omega | S = s] \\
&\qquad - \Pr[S' = s'|S = s] \cdot \Pr[\omega_0 = \omega | S = s]| \\
&\leq \textstyle\sum_s \Pr[S = s] \cdot \sqrt{2 \ln(2) \cdot D_s} \\
&\leq \sqrt{2 \textstyle\sum_s \Pr[S = s] \cdot D_s} \leq \delta/2.
\end{aligned}$$

Consider any BIC recommendation policy π' for signal structure $\mathcal{S}'$. We construct π for signature structure $\mathcal{S}$ by setting

$$\Pr[\pi(s) = m] = \textstyle\sum_{s'} \Pr[\pi'(s') = m] \cdot Pr[S' = s'|S = s].$$

Now we check π is δ-BIC. For any $m, m' \in \mathcal{M}$ and $\theta \in \mathbf{\Theta}$,

$$\begin{aligned}
&\textstyle\sum_{\omega, s} \Pr[\omega_0 = \omega] \cdot \Pr[S = s|\omega_0 = \omega] \\
&\qquad \cdot (u(\theta, m(\theta), \omega) - u(\theta, m'(\theta), \omega)) \cdot \Pr[\pi(s) = m] \\
&= \textstyle\sum_{\omega, s, s'} \Pr[\omega_0 = \omega, S = s] \cdot \Pr[S' = s'|S = s] \cdot \Pr[\pi'(s') = m] \\
&\qquad \cdot (u(\theta, m(\theta), \omega) - u(\theta, m'(\theta), \omega)) \\
&\geq \textstyle\sum_{\omega, s, s'} \Pr[\omega_0 = \omega, S = s, S' = s'] \cdot \Pr[\pi'(s') = m] \\
&\qquad \cdot (u(\theta, m(\theta), \omega) - u(\theta, m'(\theta), \omega)) \\
&\qquad - 2 \cdot \sum_{\omega, s, s'} |\Pr[\omega_0 = \omega, S = s] \cdot \Pr[S' = s'|S = s] \\
&\qquad - \Pr[\omega_0 = \omega, S = s, S' = s']| \\
&= \sum_{\omega, s'} \Pr[\omega_0 = \omega, S' = s'] \cdot \Pr[\pi'(s') = m] \\
&\qquad \cdot (u(\theta, m(\theta), \omega) - u(\theta, m'(\theta), \omega)) \\
&\qquad - 2 \cdot \sum_s \Pr[S = s] \cdot \sum_{s', \omega} |\Pr[S' = s', \omega_0 = \omega | S = s] \\
&\qquad - \Pr[S' = s'|S = s] \cdot \Pr[\omega_0 = \omega | S = s]| \\
&\geq 0 - 2 \cdot t \tfrac{\delta}{2} = -\delta.
\end{aligned}$$

We also have for any s', s, m such that $\Pr[S' = s', S = s] > 0$ and $\Pr[\pi'(s') = m] > 0$, we have $\Pr[\pi(s) = m] > 0$. This implies $\mathtt{EX}_{s'}[\mathcal{S}'] \subseteq \mathtt{EX}_s^\delta[\mathcal{S}]$. □

Max-Support Policy. We can solve the following LP to check whether a particular menu $m_0 \in \mathcal{A}$ is signal-explorable given a particular realized signal $s_0 \in \mathcal{X}$. In this LP, we represent a policy π as a set of numbers $x_{m,s} = \Pr[\pi(s) = m]$, for each menu $m \in \mathcal{M}$ and each feasible signal $s \in \mathcal{X}$.

maximize x_{m_0, s_0}

subject to:

$$\begin{aligned}
&\sum_{\omega \in \Omega, s \in \mathcal{X}} \Pr[\omega] \cdot \Pr[s|\omega] \cdot (u(\theta, m(\theta), \omega) - u(\theta, m'(\theta), \omega) + \delta) \\
&\qquad \cdot x_{m,s'} \geq 0 \qquad \forall m, m' \in \mathcal{M}, \theta \in \mathbf{\Theta} \\
&\textstyle\sum_{m \in \mathcal{M}} x_{m,s} = 1, \qquad \forall s \in \mathcal{X} \\
&x_{m,s} \geq 0, \qquad \forall s \in \mathcal{X}, m \in \mathcal{M}
\end{aligned}$$

Since the constraints in this LP characterize any δ-BIC recommendation policy, it follows that menu m_0 is δ-signal-explorable given realized signal s_0 if and only if the LP has a positive solution. If such solution exists, define recommendation policy $\pi = \pi^{m_0, s_0}$ by setting $\Pr[\pi(s) = m] = x_{m,s}$ for all $m \in \mathcal{M}, s \in \mathcal{X}$. Then this is a δ-BIC recommendation policy such that $\Pr[\pi(s_0) = m_0] > 0$.

Definition 5.5. Given a signal structure $\mathcal{S}$, a recommendation policy π is called the δ-max-support policy if $\forall s \in \mathcal{X}$ and δ-signal-explorable menu $m \in \mathcal{M}$ given s, $\Pr[\pi(s) = m] > 0$.

It is easy to see that we obtain δ-max-support recommendation policy by averaging the $\pi^{m,s}$ policies define above. Specifically, the following policy is a δ-BIC and δ-max-support policy.

$$\pi^{max} = \frac{1}{|\mathcal{X}|} \sum_{s \in \mathcal{X}} \frac{1}{|\mathsf{EX}_s^\delta[\mathcal{S}]|} \sum_{m \in \mathsf{EX}_s^\delta[\mathcal{S}]} \pi^{m,s}. \tag{6}$$

Maximal Exploration. Let us design a subroutine, called MaxExplore, which outputs a sequence of L menus. We are going to assume $L \geq \max_{m,s} \frac{B_m(\gamma_0)}{\Pr[\pi^{max}(s)=m]} \cdot \gamma_0$ is defined in Algorithm 5 of Section 5.2. B_m is defined in Lemma 5.7.

The goal of this subroutine MaxExplore is to make sure that for any signal-explorable menu m, m shows up at least $B_m(\gamma_0)$ times in the sequence with probability exactly 1. On the other hand, we want that the menu of each specific location in the sequence has marginal distribution same as π^{max}.

Algorithm 4 Subroutine MaxExplore

Input: signal S, signal structure $\mathcal{S}$.
Output: a list of menus μ
Compute π^{max} as per (6).
Initialize $Res = L$.
for each menu $m \in \mathcal{M}$ **do**
  $C_m \leftarrow L \cdot \Pr[\pi^{max}(S) = m]$.
  Add $\lfloor C_m \rfloor$ copies of menu m into list μ.
  $Res \leftarrow Res - \lfloor C_m \rfloor$.
  $p^{Res}(m) \leftarrow C_m - \lfloor C_m \rfloor$
$p^{Res}(m) \leftarrow p^{Res}(m)/Res, \forall m \in \mathcal{M}$.
Sample Res many menus from distribution according to p^{Res} independently and add these menus into μ.
Randomly permute the menus in μ.
return μ.

Similarly as the MaxExplore in Section 4, we have the following:

Claim 5.6. *Given realized signal S, MaxExplore outputs a sequence of L menus. Each menu in the sequence marginally distributed as π^{max}. For any menu m such that $\Pr[\pi^{max} = m] > 0$, m shows up in the sequence at least $B_m(\gamma_0)$ times with probability exactly 1. MaxExplore runs in time polynomial in L, $|\mathcal{M}|$, $|\Omega|$, $|\mathcal{X}|$ (size of the support of the signal).*

Menu Exploration. If an agent in a given round follows a given menu m, an action-reward pair is revealed to the algorithm after the round. Such action-reward pair is called a *sample* of the menu m. Let $D_m(\omega)$ denote the distribution of this action-reward pair for a fixed state ω (with randomness coming from the agent arrivals).

We compute an estimate Δ_m of $D_m(\omega_0)$. This estimate is a *triple-list*: an explicit list of (action, reward, positive probability) triples.

Lemma 5.7. *For any $\gamma > 0$, we can compute a triple-list Δ_m which is a function of $B_m(\gamma) = O(\ln 1/\gamma)$ samples of menu m such that*

$$\forall \omega \in \Omega \quad \Pr[\Delta_m \neq D_m(\omega) \mid \omega_0 = \omega] \leq \gamma.$$

Proof. Let U be the union of the support of $D_m(\omega)$ for all $\omega \in \Omega$. For each $u \in U$ (u is just a sample of the menu), define

$$q(u, \omega) = \Pr_{v \sim D_m(\omega)}[v = u].$$

Let δ_m be small enough such that for all ω, ω' with $D_m(\omega) \neq D_m(\omega')$, there exists $u \in U$, such that $|q(u, \omega) - q(u, \omega')| > \delta_m$.

Now we compute Δ_m as follows: Take $B_m(\gamma) = \frac{2}{\delta_m^2} \ln\left(\frac{2|U|}{\gamma}\right)$ samples and set $\hat{q}(u)$ as the empirical frequency of seeing u. And set Δ_m to be some $D_m(\omega)$ such that for all $u \in U$, $|q(u, \omega) - \hat{q}(u)| \leq \delta_m/2$. Notice that if such ω exists, Δ_m will be unique. If no ω satisfies this, just pick Δ_m to be an arbitrary $D_m(\omega)$.

Now let's analyze $\Pr[\Delta_m \neq D_m(\omega)]$. Let's fix the state $\omega_0 = \omega$. By Chernoff bound, for each $u \in U$,

$$\Pr[|q(u, \omega) - \hat{q}(u)| > \delta_m/2] \leq 2 \exp\left(-2 \cdot (\delta_m/2)^2 \cdot B_m(\gamma)\right) \leq \gamma/|U|.$$

By union bound, with probability at least $1 - \gamma$, we have for all $u \in U$, $|q(u, \omega) - \hat{q}(u)| \leq \delta_m/2$. This implies $\Delta_m = D_m(\omega)$. □

5.2 Main Recommendation Policy

In this subsection, we develop our main recommendation policy, Algorithm 5 (see pseudo-code), which explores all the eventually-explorable menus and then recommends the agents the best menu given all history. We pick L to be at least

$$\max_{m, s: \Pr[\pi(s)=m]>0} \frac{B_m(\gamma_0)}{\Pr[\pi(s) = m]}$$

for all π that might be chosen as π^{max} by Algorithm 5.

It is easy to check by Claim 5.6 that for each agent, it is δ-BIC to follow the recommended action if previous agents all follow the recommended actions. Therefore we have the following claim.

Claim 5.8. *Algorithm 5 is δ-BIC.*

Lemma 5.9. *For any $l > 0$, assume Algorithm 5 has at least $\min(l, |\mathcal{M}|)$ phases. For a given state ω, if a menu m can be explored by a BIC recommendation policy π at round l (i.e. $\Pr[\pi^l = m] > 0$), then such menu is guaranteed to be explored B_m times by Algorithm 5 by the end of phase $\min(l, |\mathcal{M}|)$.*

Proof. The proof is similar to Lemma 4.7. We prove by induction on l for $l \leq |\mathcal{M}|$.

Let S be the signal of Algorithm 5 in phase l. Let S' be the history of π in the first $l - 1$ rounds. More precisely, $S' = R, H_1, ..., H_{l-1}$. Here R is the internal randomness of π and

$$H_t = (M_t, A_t, u(\Theta_t, M_t(\Theta_t), \omega_0))$$

is the menu and the action-reward pair in round t of π.

Let $\mathcal{M}'$ to be the set of menus explored in the first $l - 1$ phases of Algorithm 5. By the induction hypothesis, we have $\forall t \in [l - 1]$, $M_t \subseteq \mathcal{M}'$. Then:

$$\begin{aligned} &I(S'; \omega_0 | S) = I(R, H_1, ..., H_{l-1}; \omega_0 | S) \\ =&I(R; \omega_0 | S) + I(H_1, ..., H_{l-1}; \omega_0 | S, R) = I(H_1, ..., H_{l-1}; \omega_0 | S, R). \end{aligned}$$

By the chain rule of mutual information, we have

$$\begin{aligned} &I(H_1, ..., H_{l-1}; \omega_0 | S, R) \\ =&I(H_1; \omega_0 | S, R) + I(H_2; \omega_0 | S, R, H_1) + \cdots + I(H_{l-1}; \omega_0 | S, R, H_1, ..., H_{l-2}). \end{aligned}$$

Algorithm 5 Main procedure for private types

Initialize: signal $S_1 = \mathcal{S}_1 = \perp$, phase $l = 1$.
{ S_l and $\mathcal{S}_l$ are the signal and signal structure in phase l. }
Set $\gamma_1 = \min\left(\frac{\delta^2}{16|\mathcal{M}|\log(|\Omega|)}, \left(\frac{\delta^2}{32|M|}\right)^2\right)$ and $\gamma_2 = \frac{1}{T|\mathcal{M}|}$.
Set $\gamma_0 = \min(\gamma_1, \gamma_2)$.
for rounds $t = 1$ to T **do**
  if phase $l \le |\mathcal{M}|$ **then**
    {**Exploration**}
    if $t \equiv 1 \pmod{L}$ **then**
      Start a new phase:
      $\mu \leftarrow \text{MaxExplore}(S_l, \mathcal{S}_l)$ {compute a list of L menus}
    Suggest menu $\mu[(t-1) \mod L + 1]$ to the agent.
    if $t \equiv 0 \pmod{L}$ **then**
      End of a phase:
      for each explored menu m in the previous phase **do**
        use $B_m(\gamma_1)$ samples to compute Δ_m from Lemma 5.7
      If no state $\omega \in \Omega$ is consistent with Δ_m (*i.e.,*$\Delta_m = D_m(\omega)$) for all explored menus m **then**
        pick any state ω, and
        set $\Delta_m \leftarrow D_m(\omega)$ for all explored menus m.
      {to ensure that #signals is bounded by $|\Omega|$.}
      $l \leftarrow l + 1$.
      Set $S_l = \{ \Delta_m$: all explored menus $m \}$.
      Set $\mathcal{S}_l$ to be the signal structure of S_l.
  else
    {**Exploitation**}
    if this is the first exploitation round **then**
      for each menu m explored during exploration **do**
        use $B_m(\gamma_2)$ samples to compute Δ_m from Lemma 5.7.
      Set $S_l = \{ \Delta_m$: all explored menus $m \}$.
    Suggest the menu which consists of the best action of each type conditioned on S_l and the prior.

For all $t \in [l-1]$, we have

$$\begin{aligned}
&I(H_t; \omega_0 \mid S, R, H_1, ..., H_{t-1}) \\
=&I(M_t, A_t, u(\Theta_t, M_t(\Theta_t), \omega_0); \omega_0 \mid S, R, H_1, ..., H_{t-1}) \\
=&I(A_t, u(\Theta_t, M_t(\Theta_t), \omega_0); \omega_0 \mid S, R, H_1, ..., H_{t-1}, M_t) \\
\le&I(D_{M_t}; \omega_0 \mid S, R, H_1, ..., H_{t-1}, M_t).
\end{aligned}$$

The second last step comes from the fact that M_t is a deterministic function of $R, H_1, ..., H_{t-1}$. The last step comes from the fact that $(A_t, u(\Theta_t, M_t(\Theta_t), \omega_0))$ is independent with ω_0 given D_{M_t}.

Then we have

$$\begin{aligned}
&I(D_{M_t}; \omega_0 \mid S, R, H_1, ..., H_{t-1}, M_t) \\
=&\textstyle\sum_{m \in \mathcal{M}'} \Pr[M_t = m] \cdot I(D_m; \omega_0 \mid S, R, H_1, ..., H_{t-1}, M_t = m) \\
\le&\textstyle\sum_{m \in M'} \Pr[M_t = m] \cdot I(D_m; \omega_0 \mid \Delta_m, M_t = m). \\
\le&\textstyle\sum_{m \in M'} \Pr[M_t = m] \cdot H(D_m \mid \Delta_m, M_t = m).
\end{aligned}$$

The last step comes from the fact that

$$I(D_m; (S \backslash \Delta_m), R, H_1, ..., H_{t-1} \mid \omega_0, \Delta_m, M_t = m) = 0.$$

By Lemma 5.7, we know that $\Pr[D_m \ne \Delta_m \mid M_t = m] \le \gamma_1$. By Fano's inequality, we have

$$\begin{aligned}
&H(D_m \mid \Delta_m, M_t = m) \le H(\gamma_1) + \gamma_1 \log(|\Omega| - 1) \\
&\le 2\sqrt{\gamma_1} + \gamma_1 \log(|\Omega| - 1) \le \frac{\delta^2}{16|\mathcal{M}|} + \frac{\delta^2}{16|\mathcal{M}|} = \frac{\delta^2}{8|\mathcal{M}|}.
\end{aligned}$$

Therefore we have

$$I(H_t; \omega_0 \mid S, R, H_1, ..., H_{t-1}) \le \frac{\delta^2}{8|\mathcal{M}|}, \forall t \in [l-1].$$

Then we get $I(S'; \omega_0 \mid S) \le \delta^2/8$.

By Lemma 5.4, we know that $\mathtt{EX}_{s'}[\mathcal{S}'] \subseteq \mathtt{EX}_s^{\delta}[\mathcal{S}]$. By Claim 5.6, we know that phase l will explore menu m at least $B_m(\gamma_0)$ times.

When $l > |\mathcal{M}|$, the proof follows from the same argument as the last paragraph of the proof of Lemma 4.7. □

Proof of Theorem 5.1. By Claim 5.8, Algorithm 5 is δ-BIC.

By Lemma 5.9, for each state ω, Algorithm 5 explores all the eventually-explorable menus (i.e. $\mathcal{M}_\omega$) by the end of $|\mathcal{M}|$ phases.

After that, by Lemma 5.7 and $\gamma_2 = \frac{1}{T|\mathcal{M}|}$, for a fixed state ω, we know that with probability $1 - 1/T$, $\delta_m = D_m$ for all $m \in \mathcal{M}_\omega$. In this case, the agent of type θ gets expected reward at least $u(\theta, m^*(\theta), \omega)$ where menu $m^* = \arg\max_{m \in \mathcal{M}_\omega} \sum_{\theta \in \Theta} \Pr[\theta] \cdot u(\theta, m(\theta), \omega)$. Taking average over types, the expected reward per round should be at least $(1 - 1/T) \cdot \max_{m \in \mathcal{M}_\omega} \sum_{\theta \in \Theta} \Pr[\theta] \cdot u(\theta, m(\theta), \omega)$.

The expected number of rounds of the first $|\mathcal{M}|$ phases is $|\mathcal{M}| \cdot L = O(\ln(T))$. Therefore, Algorithm 5 has expected total reward at least $T \cdot \mathtt{OPT} - T \cdot (1/T) - O(\ln(T)) = T \cdot \mathtt{OPT} - O(\ln(T))$. □

ABSTRACT

In consumer search, there is a set of items. An agent has a prior over her value for each item and can pay a cost to learn the instantiation of her value. After exploring a subset of items, the agent chooses one and obtains a payoff equal to its value minus the search cost. We consider a sequential model of consumer search in which agents' values are correlated and each agent updates her priors based on the exploration of past agents before performing her search. Specifically, we assume the value is the sum of a common-value component, called the quality, and a subjective score. Fixing the variance of the total value, we say a population is more diverse if the subjective score has a larger variance. We ask how diversity impacts average utility. We show that intermediate diversity levels yield significantly higher social utility than the extreme cases of no diversity (when agents under-explore) or full diversity (when agents are unable to learn from each other) and quantify how the impact of the diversity level changes depending on the time spent searching.

1 INTRODUCTION

Members of a society often leverage the experiences of others to inform their own choices. A high school student contemplating colleges might ask former high school students about their decision-making processes: what schools were considered, why the chosen one was selected over the others, and so on. A tourist contemplating restaurants might read reviews of former diners on review websites: what was the overall impression of the restaurant, what aspects contributed to this impression, etc. This sort of communal learning is highly valuable. By listening to experiences from the past, society can avoid repeating the mistakes of the past. However, this benefit comes at a potentially significant cost. As each individual optimizes their own choice, they might naturally select a tried-and-true option over an unknown one. As a result, unknown options, which could have great potential, are never discovered.

The classic field of *social learning*, initiated by [Ban92, BHW92], models this problem in the following way. Agents arrive sequentially and choose an action (e.g., search strategy) that results in some payoff based on the state of the world (e.g., the values of the items). Each agent receives a private signal correlated with the state of the world (e.g., priors on item values) and also observes chosen actions of past agents. The literature derives conditions under which the society may "herd" on a sub-optimal action, ignoring private signals and instead exploiting information gleaned from the history of actions.

The nascent field of *incentivizing exploration* tries to use information design or mechanism design to prevent the exploitation of historical information. In this line of work, there is a principal (the review website in the case of restaurants for instance), a sequence of agents (tourists in the restaurant example), and a set of options (the restaurants themselves). Each option has an inherent value, which is common to all agents, and the goal is to discover the highest-value option as quickly as possible. The principal either explicitly pays agents to try new options [FKKK14], or sends signals that cleverly obfuscate the past experiences in a way that convinces agents to try new options [KMP13, MSS15]. While these approaches successfully mitigate the dangers of learning from the past, they require the existence of a principal to coordinate society's search.

In this paper, we study decentralized exploration. Our central hypothesis is that societies perform sufficient search, even without a coordinating principal, when there are *sufficiently diverse preferences*. Intuitively, this diversity should be 1) high enough that agents occasionally explore even when past agents had great experiences, and 2) low enough that there is still value in observing the past. In this case, then society can perhaps learn to select good options, both by learning from each individual agent as she investigates her options before making a choice, and by learning from the sequence of agents who make different choices than their peers. We ask, is there a simple model and large range of parameters in which we can observe this effect?

We explore our hypothesis in the context of a standard model of consumer search, iterated over time. In a single round of consumer search, an agent is presented with a set of items. The agent knows the distribution of her value for each item and may pay a fixed cost to learn its instantiation. The resulting utility of the agent is her value for the item she selects minus the costs she paid to learn her values. For example, a high school student contemplating colleges might know her approximate value for each and, based on this information, pick a subset to visit prior to selecting one. In our iterated version of this model, what an agent knows about her values depends on what options previous agents considered. More precisely, before performing her search, each agent updates her priors on the values observed by previous agents during their searches. In the college choice problem, this corresponds to a high

school student listening to the trip reports of students in prior years before selecting which subset of schools to visit.

The degree to which historical information impacts an agent's search depends on the amount of correlation, or *diversity*, in the agents' preferences. In order to study the impact of diversity on average utility, we introduce a model in which each option has a common value component, drawn IID from a zero-mean Gaussian with variance $1 - \sigma^2$, and each agent/option pair has a private value component, also drawn IID from a zero-mean Gaussian with variance σ^2. Thus the total value of each option for each agent, the sum of the common and private value components, is also a zero-mean Gaussian with a fixed variance of 1. The variance parameter, σ^2, can be thought of as the diversity level. For $\sigma^2 = 0$, all the value of an option comes from the common value component, whereas for $\sigma^2 = 1$, all the value comes from the private value component. Since the distribution of option values remains constant as we change the diversity level, we are able to compare the average value obtained by societies of different diversity levels.

Our theoretical and simulation results show that diversity helps in this simple model. In particular, intermediate levels of diversity always yield higher average utilities than the extremes of zero diversity ($\sigma^2 = 0$), in which preferences are perfectly correlated, or total diversity ($\sigma^2 = 1$), in which preferences are independent across agents. We further investigate the comparison between intermediate levels of diversity. Our main result, Theorem 4.3, Theorem 4.4 and simulations, identify three distinct behaviors: For very short time horizons, less diverse societies outperform more diverse ones as the benefits of the added exploration have yet to take effect. For very long time horizons, less diverse societies again outperform more diverse ones as even the less diverse societies eventually perform sufficient exploration. But for a very large range of intermediate time horizons, we see more diverse societies outperform less diverse ones. This is because the less diverse societies tend to exploit historical information at the expense of exploration, similar to the phenomenon of herding in the social learning literature.

In addition to our aforementioned results, in Section 5, we extend our results to a more general setting that allows the quality of an item to get a very high value D with tiny probability $\frac{1}{D}$. This setting models situations where even though the society might be very diverse and agents have almost no common value, in the unlikely event that some clearly superior option with value D appears, they all agree that its value is high. We use this model to capture settings where the item values are not very concentrated, as Gaussians are, but have heavier probability tails. These happen in many natural situations where breakthroughs with significantly high value occur and the whole society agrees that they are valuable. We show that for such settings, high diversity is extremely beneficial for the social good as it increases incentives for exploration and breakthroughs occur faster. The literature on incentivizing exploration [FKKK14, HKQ15] usually refers to these settings as "Diamonds in the rough" and often uses this setting to provide lower bounds. In contrast, we show diverse societies excel in these settings.

Techniques. To establish our results, we need to be able to describe the optimal behavior of agents and bound the society's average expected utility. As we argue, the optimal behavior of the agents is characterized in [Wei79]. As shown in that paper, agents define an index for each item and then search them in decreasing order of index. Unfortunately, this index is defined implicitly, making it difficult to explicitly determine the utilities obtained by the agents. A crucial result that allows us to perform our analyses is that the average utility is approximately equal to the maximum quality of an item that agents will have explored by the end of the time horizon. This result enables us to focus on bounding the maximum quality of explored items. To provide an upper bound on this value, we consider an an alternative simpler scenario where agents, instead of following the optimal policy and computing indices of the inferred distributions of values, they use a plain threshold stopping rule. We show that there exists a coupling of the two processes such that the simpler process always explores more items and then proceed to bound the highest quality achievable when using the simple threshold stopping rule for every agent. We also give a matching lower bound by bounding the number of items that agents with a given diversity level could explore and then bound the expectation of the maximum value that these many normally distributed items may have.

We show that our bounds are asymptotically tight. This is required in order to be able to perform comparisons across different diversity levels as even a constant approximation of the expected average utility would not suffice to show a clear separation as average utilities of different diversity levels can be very close multiplicatively. To prove these sharp bounds, we rely on strong concentration results for Gaussian distributions.

2 RELATED WORK

Our work is very related to the line of work in Bayesian social learning. The classic results of [Ban92, BHW92] show that in social learning with homogeneous payoffs, agents may ignore their private signals in favor of information they infer from previous agents. When this happens, society herds on sub-optimal actions. A recent strand of literature, including [ADLO11, AMMO17, GPR06, LS15a, LS15b], explore the impact of heterogeneous preferences on social learning, generally observing that heterogeneous preferences help learning when the society is well-connected. The primary difference between these works and our paper is the structure of the actions and information sets. With the exception of [GPR06], these works assume that the action of each agent is binary and the state of world is binary. On the contrary, in our paper, the action of each agent is a search strategy and the state of world (the qualities of items) is sampled from independent Gaussian distributions. This choice allows us to study the impact of diversity in a specific setting of interest, as motivated by the literature on consumer search initiated by [Wei79]. For the dispersion of information, [ADLO11, LS15a, LS15b] assume agents observe a subset of past actions based on the social network and [AMMO17, GPR06] assume agents observe the full history or summary statistics of the reviews of past agents where a review is a discrete valued function of an agent's utility. In our paper, we assume agents observe actions of all previous agents and qualities/values of items explored by all previous agents.

Incentivizing exploration has been studied in the multi-armed bandit setting. In this line of research, it is assumed that myopic agents arrive sequentially and each pulls an arm at a time. As each agent only wants to maximize its own reward, exploration

might not be done sufficiently without a principal coordinating exploration. [KMP13, MSS15] study the setting where the outcomes of the actions are only observed by the principal and the principal convinces myopic agents to explore by sending signals containing partial information of the past outcomes. [FKKK14] considers a different setting where the myopic agents observe all the previous outcomes and the principal is allowed to use money transfers to incentivize exploration. A great amount of follow-up work has been done in various settings, including [CH15, HKQ15, MSSW16, KKM$^+$17, PBS18].

There is an emerging line of work studying "greedy algorithms" in multi-armed bandits[BBK18, KMR$^+$18, RSVW18]. Greedy algorithms can be viewed as a form of social learning and these papers show that near-optimal performance can be achieved under certain diversity conditions.

[SR17] considers myopic agents with diverse preferences in the multi-armed bandit setting. They show that if subjective preferences are known to agents beforehand, myopic agents will explore all the arms even without a principal coordinating exploration. They consider a setting of qualities and subjective preferences such that the difference between any two qualities is smaller than 1 and the subjective preferences have random binary values. For each arm, this setting guarantees the existence of agents who prefer the arm no matter what quality is. Exploration is therefore guaranteed in the long run.

[ASGM17] provides simulation results (without theoretical guarantees) showing that certain amount of preference diversity can lead to an increase in the average utility in a model that is closely related to our model. The main difference to our model is that they assume each agent searches items according to popularity levels of items and stops searching once an item has value larger than some threshold. On the contrary, we assume each agent performs the optimal search.

3 MODEL

We consider a setting with infinitely many items[1] of unknown value. Agents arrive sequentially in T rounds. The agent that arrives in round t has a value $v_{i,t}$ for item i that is the sum of two terms: an objective score q_i for the item and an individual subjective score $s_{i,t}$. The objective scores (qualities) q_i are the same for all agents and are drawn from a Gaussian $\mathcal{N}(0, 1-\sigma^2)$ with mean zero and variance $1-\sigma^2$ for some $\sigma \in [0,1]$. We refer to this score as the quality of item i. The subjective scores $s_{i,t}$ vary among agents and are drawn independently from a Gaussian $\mathcal{N}(0, \sigma^2)$ with mean zero and variance σ^2. The total value of an item, $v_{i,t} = q_i + s_{i,t}$, is thus distributed according to a Gaussian $\mathcal{N}(0,1)$ with mean zero and variance one.

Definition 3.1 (Diversity Level). *We define the* diversity *of a population of agents to be the parameter σ (the standard deviation of the subjective score).*

When the diversity is 0, all the value of an item is derived from its objective score, i.e., $v_{i,t} = q_i$, and so agents' values are perfectly correlated. When diversity is 1, all the value of an item is derived from its subjective score, i.e., $v_{i,t} = s_{i,t}$, and so agents' values are independent. Intermediate diversities interpolate between these two extremes.

Initially, the agent only knows a prior $\mathcal{F}_{i,t}$ over her value for each item i, which is a function of the initial Gaussian priors and her observations from past agents' searches. The agent may learn the objective score q_i and subjective score $s_{i,t}$ of an item i, and hence its value $v_{i,t} = q_i + s_{i,t}$, by paying a search cost c, where c is a fixed constant smaller than $\frac{1}{\sqrt{2\pi}}$ (chosen so that the agents are incentivized to explore at least one item). A search strategy of an agent is a mapping from observations to either a choice from among previously explored items, or an item to explore next. The utility $u_t(\sigma, \{\mathcal{F}_{i,t}\})$ of the agent for a given search strategy and priors is her expected value for the chosen item i^*, $v_{i^*,t}$, minus her total expected search cost, i.e., c times the expected number of items she explores. The chosen item i^* has to be an explored item.

The optimal search strategy σ^* for an agent in this setting was characterized by [Wei79] in a slightly more general setting called the *Pandora's problem*. This strategy assigns a score, called the *Weitzman index*, to every item and then explores items with positive indices in decreasing order of their indices until the observed value is greater than the following item's index.

Definition 3.2 (Weitzman Index). *The* Weitzman index $x^*_{i,t}$ *is defined as* $\mathbb{E}_{v_{i,t}\sim\mathcal{F}_{i,t}}[\max(v_{i,t} - x^*_{i,t}, 0)] = c$.

We assume that all agents use the optimal strategy and explore items in decreasing order of Weitzman index. We denote by x^* the Weitzman index of an item that has not been explored previously, i.e. the solution to $\mathbb{E}_{v\sim\mathcal{N}(0,1)}[\max(v - x^*, 0)] = c$. The choice of $c < \frac{1}{\sqrt{2\pi}}$ guarantees that $x^* > 0$ and thus every agent will explore at least one item.

Once an item is explored (but not necessarily chosen) by some agent, agents in subsequent rounds obtain information about that item. There are multiple choices we can make about exactly what information agents learn; the right choice is dictated by the setting and whether agents can infer each others' subjective biases. In this paper, we will focus on a "revealed quality" model, where, after an item i is explored by some agent, its quality q_i is revealed to all agents in future rounds. In this model, agents update their prior for a previously explored item i to $F_{i,t} = \mathcal{N}(q_i, \sigma^2)$ before computing its Weitzman index $x^*_{i,t}$. We also consider a "revealed value" model, where after an item i is explored by some agent in round t, only its value to that agent $v_{i,t} = q_i + s_{i,t}$ is revealed to future agents. In this model, the optimal strategy of the agents becomes more complicated. Given the past values of agents for a given item, the current agent forms a posterior distribution of the item's quality. This posterior can be expressed as a Gaussian distribution with mean and variance that depend on the average past observed values and the number of times that item gets explored. We can show similar results in the "revealed value" model. We omit them because of the space limit.

Our goal is to understand how the expected average utility changes depending on the diversity level σ of the society. The impact of diversity will vary with the time spent searching, and so we define the average utility with respect to a time horizon T. Let $\mathcal{H}_t$ be a history indicating the information obtained about the

[1] This assumption allows us to avoid edge cases in our analyses; our results carry over to settings with finitely many items so long as there are sufficiently many of them (in particular, more than the logarithm of the time horizon).

items explored in the first $t-1$ rounds and $\mathcal{F}(\mathcal{H}_t)$ be the induced priors for the agent arriving in round t.

Definition 3.3 (Average Utility). *We define* $A(\sigma, T) = \frac{1}{T}\sum_{t=1}^{T} E_{\mathcal{H}_t}[u_t(\sigma, \mathcal{F}(\mathcal{H}_t))]$ *to be the* average expected utility *over agents in the first T rounds when the diversity level is σ.*

3.1 Justification of Our Model

Here we provide the rationale behind the model choices.

Decomposition in Common and Private Values The assumption that agent values decompose in independent common and private components is commonly used in the empirical auction literature. Going back to the work of [LV98] who showed how to perform the decomposition based on deconvolution, it has been shown that it predicts the agent behavior quite accurately in real-world data [Kra11, Ask10].

Normally Distributed Values The choice of normal distributions for the common and private values enables expressing a wide range of diversity levels with a single parameter. The constant sum of variances property allows for fair comparisons as in all cases agents have the same distribution of values for every option. Normal distributions appear in practice; e.g., the distribution of meta-critic scores for movies on Rotten Tomatoes closely fits a normal distribution; and the distribution of the common value in the US offshore oil and gas auctions has been shown to fit a normal distribution using econometrics [STZ17].

Pandora's Box Search Model The Weitzman search strategy is the optimal policy that an agent can follow to maximize his expected utility. It has been successfully applied to real-world applications in the marketing literature [BKM16, KAB10, HC17].

4 HOW DIFFERENT DIVERSITY LEVELS COMPARE

There are two opposing forces that affect average utility – exploration and exploitation. When the society is not very diverse, agents tend to exploit previously explored options as it is quite costly for them to search for new alternatives that could potentially give them a higher value. On the other hand, diverse societies tend to explore more, but cannot exploit as much since information collected in the past is less valuable to them.

Focusing solely on exploration or exploitation can come at a significant cost. In the extreme case where the society is not at all diverse (i.e., $\sigma = 0$) and focuses on exploitation, we can show the society's average expected utility, $A(0, T)$, can be upper bounded by a constant. In particular, $A(0, T)$ does not depend on the number of rounds T.

Lemma 4.1. *For any T, $A(0, T) \leq \sqrt{\ln\left(\frac{1}{2\pi c^2}\right)} + 2$.*

To prove Lemma 4.1, we first bound by a constant the Weitzman index x^* of an unsearched item, i.e. one whose quality is not yet revealed. We then argue that once some item with sufficient quality has been identified (with quality $q_i > x^* + c$), no other item will be explored in future rounds. We conclude the proof by upper-bounding the expected quality of such an item conditional on its quality being higher than $x^* + c$. This directly gives a bound for the average utility of the agents. The proof of Lemma 4.1 is given in Appendix B.

In the other extreme case where agents are fully diverse, the society's average expected utility, $A(1, T)$, is even worse. We show that it is always the case that a fully diverse population obtains lower utility than a non-diverse population and so, in particular, its utility is also bounded by a constant independent of T.

Lemma 4.2. *For any T, $A(1, T) \leq A(0, T)$.*

To prove Lemma 4.2, we observe that the first agent in any society performs the same search no matter the diversity level and so achieves the same expected utility. When the diversity level is 0, the expected utility improves across rounds, while when the diversity level is 1, the expected utility stays the same across rounds, implying the result. The proof of Lemma 4.2 is given in Appendix B.

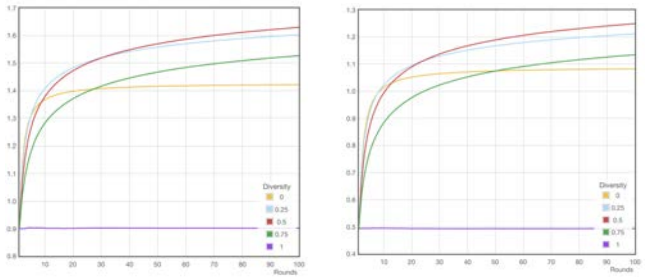
In both of these extreme cases, the average expected utility is bounded by a constant that depends on the search cost c but not on the number of rounds. However, as we show, any intermediate diversity level $\sigma \in (0, 1)$ can be significantly better than those extreme cases as the average expected utility in those cases grows with the number of rounds. Thus, it becomes clear that societies with intermediate diversity levels achieve higher average expected utility than those with extreme diversity levels.

Our main result is a characterization of how different diversity levels $\sigma, \sigma' \in (0, 1)$ compare for different numbers of rounds T. We identify three regions, depending on the number of rounds, that affect which diversity level is better than the other.

When the number of rounds T is small, the smaller diversity level σ' achieves higher average expected utility. This is because the benefit of broader past explorations is not as significant compared to knowing the values of a smaller subset of items more accurately. We show numerically in Section 4.1 that this is indeed the case and that initially, for very few rounds, almost no diversity is preferable.

When T takes intermediate values, the value of exploring a larger number of options becomes more significant than higher accuracy on fewer options and thus the higher diversity level σ is preferred. Theorem 4.3 shows the existence of this region under a technical assumption which requires a small gap between σ' and σ.

Theorem 4.3 (Intermediate T). *Let $\sigma, \sigma' \in (0, 1)$ be two diversity levels with $\sigma' < \sigma \cdot e^{-O\left(\frac{1}{1-\sigma^2}\right)}$. There exists an interval (T_1, T_2) such that $A(\sigma, T) > A(\sigma', T)$ for all $T \in (T_1, T_2)$, i.e. the large diversity level σ outperforms the small diversity level σ'. Here T_1 and T_2 depend on σ and σ'.*



When T is very large, the smaller diversity σ' level becomes again preferable to the higher level σ as in both cases a comparably large number of options have been explored in which case it is again more beneficial to know the value of the explored items more accurately. This region is described in Theorem 4.4.

Theorem 4.4 (Very large values of T). *Let $\sigma, \sigma' \in (0, 1)$ be two diversity levels with $\sigma' < \sigma$. There exists an interval (T_3, ∞) such that $A(\sigma', T) > A(\sigma, T)$ for all $T \in (T_3, \infty)$, i.e. the small diversity level σ' outperforms the large diversity level σ. Here T_3 depends on σ and σ'.*

Theorems 4.3 and 4.4 show that the diversity level σ is preferable to a small diversity level σ' for intermediate number of rounds but as the number of rounds increases the smaller diversity level becomes more socially beneficial. The proofs of the theorems are presented in Section 4.2.

We note that even though $A(\sigma', T)$ is guaranteed to be larger than $A(\sigma, T)$ for large values of T in the third region, this will happen at extremely large values of T. In fact, in all simulations presented in the next sub-section, we ran up to 10^6 rounds for different values of c, we did not observe any transition from the second region where $A(\sigma', T) < A(\sigma, T)$ to the third region where $A(\sigma', T) > A(\sigma, T)$. This is because the behavior of the $A(\sigma, T)$ is tightly characterized by the upper-bound we will show in Proposition 4.5, i.e., $\sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln(T))}$, which shows that the dependence on T is doubly-logarithmic and thus extremely large values of T are needed to reach the third region. Thus, for all practical purposes, we observe in simulations that the optimal diversity level increases monotonically with the number of rounds.

4.1 Behavior for small T - Numerical Simulations

(a) $c = 0.1$ **(b)** $c = 0.2$

Figure 1: Simulations of the average expected utility for different number of rounds and diversity levels.

Before we proceed with the proof of Theorems 4.3 and 4.4, we present some simulations that show the evolution of society's expected average expected utility with the number of rounds T in the "revealed quality" model. Figure 1, shows the plots $A(\sigma, T)$ for different number of rounds T up to 100 and different diversity levels $\sigma \in \{0, 0.25, 0.5, 0.75, 1\}$. We present two plots, one for $c = 0.1$ and one for $c = 0.2$. For each of the different scenarios, we run 10^5 independent runs.

As can be seen from the figure, all different diversity levels start at the same point for $T = 1$. The full diverse case $\sigma = 1$ remains constant at that value achieving the lowest possible utility than all diversity levels as every agent searches from scratch every time without reusing any information from the past. The case without diversity ($\sigma = 0$) on the other hand, initially has an increasing average social utility but as we've shown in Lemma 4.1, approaches a constant value after few rounds.

Diversity levels $\sigma = 0.25, 0.5$, and 0.75, achieve lower expected utility than the no-diversity case in the first rounds but eventually all outperform it as described by Theorem 4.3. The lowest diversity level $\sigma = 0.25$ manages to do this faster but also gets outperformed by the higher diversity level $\sigma = 0.5$ in later rounds. The diversity level 0.75 also outperforms 0.25 after $\sim 10^3$ rounds (not shown in the graph) but doesn't seem to outperform 0.5 even after simulating for 10^6 rounds. This is an indication that the gap in diversity levels required by Theorem 4.3 is necessary for statement to hold.

4.2 Behavior for intermediate and large values of T

We now move on to prove Theorems 4.3 and 4.4. Our main technical contribution that drives the proof of those Theorems is a sharp characterization of the average expected utility for any fixed diversity level $\sigma \in (0, 1)$. Proposition 4.5 gives a closed form expression for the average expected utility which is tight up to additive constants.

Proposition 4.5. *For any $\sigma \in (0, 1)$, and any $T > 0$,*

$$A(\sigma, T) = \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln T)} \pm O_c(1).$$

The proof of Proposition 4.5 can be found in Appendix B. The main observation in establishing the statement is that the expected utility $A(\sigma, T)$ is well approximated by the maximum quality of the revealed items after T rounds (Lemma B.3). Using this observation, we obtain the result by giving upper and lower bounds to the best item that is revealed in the end which in turn is closely related to the number of revealed items. To give the lower-bound (Lemma B.4), we bound the rate that new items are revealed by bounding the probability that all available options are unsatisfactory for a given agent, i.e. when his true value is negative for all currently explored items. For the upper-bound (Lemma B.5), we show that the probability that a new item is explored is exponentially small with the number of high quality items already known. Thus as we show, the number of items n explored after T rounds is logarithmic in T. We obtain the bound on the maximum quality of a revealed item by noting that the maximum of n gaussian random variables with variance $1-\sigma^2$ is approximately $\sqrt{1-\sigma^2} \cdot \sqrt{2\ln n}$. This gives us the approximate expression of the expected utility $A(\sigma, T)$.

Given the closed form expression of Proposition 4.5, we can easily obtain Theorems 4.3 and 4.4 as corollaries.

Proof of Theorem 4.3:

By Proposition 4.5, there exists a constant C_1 such that

$$\left| A(\sigma, T) - \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln(T))} \right| \leq C_1.$$

For notation convenience, define constant $C_2 = \sqrt{2\ln(2)}$. Set $T_1 = \exp\left(\frac{1}{\sigma^2} \exp\left(\frac{(2C_1+C_2)^2}{2(1-\sigma^2)}\right)\right)$ and $T_2 = \exp\left(\frac{1}{\sigma'^2}\right)$.

For any $T < T_2$, we can upper bound $A(\sigma', T)$ by constant $C_1 + C_2$:

$$\begin{aligned} A(\sigma', T) &\leq \sqrt{1-\sigma'^2} \cdot \sqrt{2\ln(1+\sigma'^2 \ln(T))} + C_1 \\ &< \sqrt{2\ln\left(1+\sigma'^2 \cdot \frac{1}{\sigma'^2}\right)} + C_1 \leq C_2 + C_1. \end{aligned}$$

For any $T > T_1$, we can lower bound $A(\sigma, T)$ by constant $C_1 + C_2$:

$$\begin{aligned} A(\sigma,T) &\geq \sqrt{1-\sigma^2}\cdot\sqrt{2\ln(1+\sigma^2\ln(T))} - C_1 \\ &> \sqrt{1-\sigma^2}\cdot\sqrt{2\ln\left(1+\sigma^2\cdot\frac{1}{\sigma^2}\exp\left(\frac{(2C_1+C_2)^2}{2(1-\sigma^2)}\right)\right)} - C_1 \\ &> 2C_1 + C_2 - C_1 = C_1 + C_2. \end{aligned}$$

Therefore for any $T \in (T_1, T_2)$, $A(\sigma, T) > A(\sigma', T)$. In order to make sure $T_1 < T_2$, we need $\sigma' < \sigma \cdot \exp\left(-\frac{(2C_1+C_2)^2}{4(1-\sigma^2)}\right)$. □

Proof of Theorem 4.4:

For any $\sigma' < \sigma$, we have that $\lim_{T\to\infty} \frac{A(\sigma,T)}{A(\sigma',T)} = \frac{\sqrt{1-\sigma^2}}{\sqrt{1-\sigma'^2}} < 1$. This immediately implies that for any $\sigma' < \sigma$, there exists a large enough T_3 such that $A(\sigma, T) < A(\sigma', T)$ for all $T > T_3$, as required by Theorem 4.4.

□

5 AN EXTENSION WITH RARE BUT HIGH REWARD ITEMS

We extend our results to a setting where agents' values are correlated in a more structured way. In this extension, we introduce an additional term of objective value in the quality of an item, i.e. we write q_i as $d_i + r_i$ where d_i takes value D with probability $p = \Theta(D^{-1})$ and 0 otherwise while r_i is sampled from $\mathcal{N}(0, 1-\sigma^2)$ as before. We call an item with $d_i = D$ a "diamond" due to its rarity and high value. We assume that $c \geq p \cdot D$ so that the exploration cost is larger than the expected value of an item.

In this diamond model, diversity gives significant help in early rounds. Our main result in this model is that the existence of a diamond can significantly change the behavior and average utilities of agents of different diversity levels.

Theorem 5.1. *Consider any constant diversity level $\sigma < 1$. If the number of rounds T satisfies $\omega(D) \leq T \leq \exp(o(D))$, then $A(\sigma, T) = o(1) \cdot A(1, T)$ as the diamond value D increases.*

In contrast to the previous section, where exploration in the full diverse setting is meaningless as future agents cannot benefit from the experience of their predecessors, Theorem 5.1 shows that if there is even a tiny probability that a very desirable and socially beneficial alternative is identified, diversity helps significantly. Therefore, we show that in societies where even fully diverse agents can agree on a clearly superior outcome which might occur with very small probability, larger diversity levels work in society's favor as they help identify this option faster.

The full proof of Theorem 5.1 can be found in Appendix B. Here we show some important steps of the proof.

To prove Theorem 5.1, we first show that when the diversity level is 1 and $T = \omega(1/p)$, the expected average utility is close to the diamond value D.

Lemma 5.2. *$A(1, T)$ is at least $(1 - o(1))D$ for $T = \omega(1/p)$.*

The main idea behind the proof of Lemma 5.2 is to show that at least one new item is searched in each round before a diamond is discovered and thus in $T = \omega(1/p)$, the diamond will be found. The proof of Lemma 5.2 can be found in Appendix B.

Next we proceed to bound the expected average utility for any diversity level $\sigma < 1$, when $T \leq \exp(o(D))$, $A(\sigma, T)$. We start with the extreme case when $\sigma = 0$. The proof is similar to the proof of Lemma 4.1 and is given in Appendix B.

Lemma 5.3. *$A(0, T)$ is at most $D \cdot p + O(1)$.*

The case for intermediate diversity level $\sigma \in (0, 1)$ is more complicated. We give an upper bound on the average utility in the appendix (Lemma B.9).

A TOOLS FOR GAUSSIAN DISTRIBUTIONS

In this section, we list several facts and lemmas about Gaussian distributions. Throughout this document, we use Φ to refer to the *CDF* of the Gaussian $\mathcal{N}(0, 1)$ and φ to refer to the density function of the Gassian $\mathcal{N}(0, 1)$.

Fact A.1. *Let $\Phi(t)$ be the CDF of standard Gaussian distribution then for $t > 0$,*

$$\frac{1}{\sqrt{2\pi}}\cdot\frac{t}{t^2+1}\cdot\exp(-t^2/2) \leq 1-\Phi(t) \leq \min\{\frac{1}{\sqrt{2\pi}t}, 1\}\exp(-t^2/2).$$

Fact A.2 ([Bar08]). *Let $\Phi(t)$ be the CDF of standard Gaussian distribution. Let $\varphi(t)$ be the density of standard Gaussian distribution. For any $t > 0$,*

$$\frac{\varphi(t)}{1-\Phi(t)} \leq \frac{t}{2} + \frac{\sqrt{t^2+4}}{2}.$$

The following two lemmas can be proved by standard techniques about Gaussian distributions. We omit their proofs because of space limit.

Lemma A.1. *For any $T > 0$, let $x_1, ..., x_T$ be sampled from $\mathcal{N}(0, \sigma^2)$ independently. Then we have*

$$Pr\left[\min_{i\in[T]}\frac{x_1+\cdots+x_i}{i} \leq -2\sigma\right] \leq 1/4.$$

Lemma A.2. *For any $x^*, T > 0$, let $x_1, ..., x_T$ be sampled from $\mathcal{N}(0, \sigma^2)|_{\geq x^*}$ independently. Then we have*

$$\mathbb{E}\left[\max_{i\in[T]} x_i\right] \leq \sigma\sqrt{2\ln(2T)} + x^*.$$

B OMITTED PROOFS

B.1 Ommitted Proofs of Lemma 4.1 and Lemma 4.2

Lemma B.1 (Restatement of Lemma 4.1). *For any T, $A(0, T) \leq \sqrt{\ln\left(\frac{1}{2\pi c^2}\right)} + 2$.*

Proof. The proof plan is to first bound by a constant the Weitzman index x^* of an unsearched item, i.e. one whose quality is not yet revealed. We then argue that once some item with sufficient quality has been identified (with quality $q_i > x^* + c$), no other item will be explored in future rounds. We conclude the proof by upper-bounding the expected quality of such an item conditional on its quality being higher than $x^* + c$. This directly gives a bound for the average utility of the agents.

We start by bounding the Weitzman index x^* of an unsearched item. For an unsearched item, the distribution of the value is $\mathcal{N}(0, 1)$.

The Weitzman index x^* satisfies $\mathbb{E}[\max(X - x^*, 0)] = c$ where $X \sim \mathcal{N}(0, 1)$. Using Fact A.1 on Gaussian distributions, we see

$$\begin{aligned} c &= \mathbb{E}[\max(X - x^*, 0)] \\ &= \mathbb{E}[X - x^* | X - x^* > 0] \cdot Pr[X - x^* > 0] \\ &= \left(-x^* + \frac{\varphi(x^*)}{\Phi(-x^*)}\right) \cdot \Phi(-x^*) \\ &= (-x^*)(1 - \Phi(x^*)) + \varphi(x^*) \\ &\leq (-x^*)\left(\frac{\varphi(x^*)}{x^*} - \frac{\varphi(x^*)}{(x^*)^3}\right) + \varphi(x^*) \\ &= \frac{\varphi(x^*)}{(x^*)^2} = \frac{1}{\sqrt{2\pi} \cdot (x^*)^2 \cdot \exp((x^*)^2/2)}. \end{aligned}$$

This implies an upper bound on the Weitzman index of an unsearched item:

$$x^* \leq \max\left(1, \sqrt{\ln\left(\frac{1}{2\pi c^2}\right)}\right).$$

When an item has been searched with observed quality q_i, since the diversity level is 0, the values of this item for future agents are determinstically q_i. Therefore the Weitzman index of this item is simply $q_i - c$.

Once some item has quality $q_i > c + x^*$, its Weitzman index is larger than x^* which means it will be searched before any unsearched items. And once this item is searched in a round, we know its realized value is q_i which is larger than x^*. Therefore no more unsearched items will be searched.

Let Q be the quality of the first item with quality larger than $c + x^*$. We have $\mathbb{E}[Q] = \mathbb{E}_{X \sim \mathcal{N}(0,1)}[X | X > c + x^*]$. We know that starting from the round this item is searched, each agent's utility is at most $Q - c$ and before this item is ever searched, each agent's utility is at most $c + x^* - c \leq Q - c$. Therefore we can bound the average utility as following:

$$\begin{aligned} A(0, T) &\leq \mathbb{E}[Q - c] \leq \mathbb{E}_{X \sim \mathcal{N}(0,1)}[X | X > c + x^*] - c \\ &= \frac{\varphi(c + x^*)}{1 - \Phi(c + x^*)} - c \\ &\leq \frac{x^* - c + \sqrt{(x^* + c)^2 + 4}}{2} \text{ (by Fact A.2)} \\ &\leq x^* + 1 \\ &\leq \sqrt{\ln\left(\frac{1}{2\pi c^2}\right)} + 2. \end{aligned}$$

□

Lemma B.2 (Restatement of Lemma 4.2). *For any T, $A(1, T) \leq A(0, T)$.*

Proof. First notice that when the diversity level is 1, values are completely independent of the history and have the same distributions across agents. Therefore, the expected utilities of all agents are the same. Therefore $A(1, T)$ equals the expected utility of the first agent.

When the diversity level is 0, consider the following strategy for agents except the first agent: just search the item chosen by the first agent and choose it. By using this strategy, we know all agents will get at least the utility of the first agent. By the optimality of Weitzman index strategy, we know $A(0, T)$ will be at least the expected utility of the first agent.

Finally, notice that the expected utility of the first agent does not depend on the diversity level. This implies $A(0, T) \geq A(1, T)$. □

B.2 Omitted Proof of Proposition 4.5

We proceed to show Proposition 4.5. We first relate the average expected utility $A(\sigma, T)$ to the expectation of the positive part of the highest quality explored during the first T rounds when the diversity level is σ, denoted by $M(\sigma, T)$. Here the positive part of x means $\max(x, 0)$. In Lemma B.3, we show that $A(\sigma, T)$ is sandwiched between $M(\sigma, \gamma T)$ and $M(\sigma, T)$. Subsequently, we provide sharp bounds on $M(\sigma, T)$ and show that $M(\sigma, \gamma T)$ and $M(\sigma, T)$ are very close for large T.

Lemma B.3. *For any diversity level $\sigma \in (0, 1)$ and any $\gamma \in (0, 1)$,*

$$(1 - \gamma)\left(M(\sigma, \gamma T) - c\right) \leq A(\sigma, T) \leq M(\sigma, T) + O_c(1).$$

Proof. Let's first prove the left hand side. For each agent after round γT, a sub-optimal strategy is to explore and pick the item with highest quality searched before the end of round γT and leave. This gives utility $M(\sigma, \gamma T) - c$ in expectation. By the optimality of the Weitzman index strategy, agents after round γT should at least get $M(\sigma, \gamma T) - c$ in expectation. Again by the optimality of the Weitzman index strategy, agents in the first γT rounds should get utility at least 0 in expectation. Thus, we have $A(\sigma, T) \geq (1 - \gamma)\left(M(\sigma, \gamma T) - c\right)$.

Now let's consider the right hand side. The main idea is to upper bound the expected utility of the last round T by $M(\sigma, T) + O_c(1)$.

Let n be the number of items explored in the first T rounds, with qualities $q_1, ..., q_n$. In round T, the agent's expected utility will be at least as large as the expected utility of agents in previous rounds as more information is revealed. Let j be the item where the T-th agent stops his search. We fix j, n and $q_1, .., q_n$ in this argument and expectations are taken over randomness of subjective scores of the T-th agent. T-th agent's value for any previously explored option is less than x_j^*, the Weitzman index of item j, as he chose to explore item j. Moreover, since he decided to stop at j, his value at j, $q_j + s_{j,T}$ must be higher than x_{j+1}^*, the Weitzman index of the next item to search in round T. After the search, the T-th agent might take item j or some other items with value smaller than x_j^*. Thus, his expected utility, is at most $\max(q_j + s_{j,T}, x_j^*) - c$ and $s_{j,T}$ is sampled from $\mathcal{N}(0, \sigma^2)$ conditioned on $q_j + s_{j,T} > x_{j+1}^*$.

Using Lemma A.2, we can upper bound the expected utility of the agent in round T by

$$\begin{aligned} \mathbb{E}[\max(q_j + s_{j,T}, x_j^*)] &\leq \mathbb{E}_{X \sim \mathcal{N}(0, \sigma^2)}[q_j + X | q_j + X > x_j^*] \\ &\leq q_j + \mathbb{E}_{X \sim \mathcal{N}(0, \sigma^2)}[X | X > \max(x_j^* - q_j, 0)] \\ &\leq q_j + \max(x_j^* - q_j, 0) + O(1) \text{ (by Lemma A.2)} \end{aligned}$$

Recall x^* is the Weitzman index of an unexplored item. If item j has been searched before round T, we have $x_j^* = x^*$. We can simply get

$$\mathbb{E}[\max(q_j + s_{j,T}, x_j^*)] \leq \max(q_j, 0) + x^* + O(1).$$

If item j hasn't been searched before round T, we bound the difference between x_j^* and q_j. The definition of Weitzman index

gives us,

$$c = \mathbb{E}_{X\sim\mathcal{N}(0,\sigma^2)}[\max(X-(x_j^*-q_j),0)] \le \mathbb{E}_{X\sim\mathcal{N}(0,1)}[\max(X-(x_j^*-q_j),0)].$$

Note that the last expression is strictly less than c when $x_j^*-q_j > x^*$ implying that $x_j^*-q_j \le x^*$. Then we get

$$\mathbb{E}[\max(q_j+s_{j,T},x_j^*)] \le q_j + x^* + O(1)$$

To sum up, no matter item j has been searched or not before round T, the expected utility of the agent in round T is at most $M(\sigma,T)+x^*+1$. Since the agent in round T has expected utility at least as high as expected utilities of agents in previous rounds, we conclude that $A(\sigma,T) \le M(\sigma,T)+x^*+O(1)$. □

In Lemma B.4, we give a lower bound on $M(\sigma,T)$. The main idea of the proof is to give a lower bound on the number of searched items and then show that $M(\sigma,T)$ is roughly the expected value of the maximum of that many independent Gaussians. The lower bound on the number of searched items can be achieved by considering events (indicated as W_t in the proof) when all the previously searched items have low values (caused by very negative subjective scores).

Lemma B.4. *For any diversity level $\sigma \in (0,1)$, and any $T > \exp(13/\sigma^2)$,*

$$M(\sigma,T) \ge \sqrt{1-\sigma^2}\cdot\sqrt{2\ln(\sigma^2\ln T)} - O(1).$$

Proof. To prove the statement, we fix a sufficiently large parameter n and we show that with high probability after a sufficiently large number of rounds T, two events will happen:

- The maximum quality among the first n items is at least $h = \sqrt{1-\sigma^2}\cdot\sqrt{2}\cdot(\sqrt{\ln n}-1)$,
- At least one agent will explore an item with quality higher than h.

We first bound the probability that the maximum quality of the first n items is less than h. As the qualities of all items are independent, this is a standard calculation about the maximum of independent Gaussian random variables. Setting $g = \frac{h}{\sqrt{1-\sigma^2}}$, we have:

$$\begin{aligned}
&Pr\left[\max(q_1,\ldots,q_n)\le h\right]\\
&= (Pr\left[q_1<h\right])^n = \Phi\left(\frac{h}{\sqrt{1-\sigma^2}}\right)^n\\
&\le \left(1-\frac{\exp\left(-\frac{1}{2}\cdot g^2\right)}{\sqrt{2\pi}}\cdot\frac{g}{g^2+1}\right)^n && \text{from Fact A.1}\\
&\le \exp\left(-n\cdot\frac{\exp\left(-\frac{1}{2}\cdot g^2\right)}{\sqrt{2\pi}}\cdot\frac{g}{g^2+1}\right)\\
&\le \exp\left(-\frac{\exp\left(2\sqrt{\ln n}\right)}{e\sqrt{\pi}}\cdot\frac{\sqrt{\ln n}-1}{2(\sqrt{\ln n}-1)^2+1}\right) \le \frac{1}{\sqrt{\ln n}} && \text{for } n\ge 5.
\end{aligned}$$

Assuming that there is some item with quality higher than h among the first n, we now bound the probability that some agent will explore it. Let W_t be the indicator of the event that in round t, for all items $i\in[n]$ with $q_i \le h$, $s_{i,t} < -h$. It is clear that if $W_t = 1$ for some t, $v_{i,t} < 0$ for all items with quality less than h so the agent t will keep exploring until he finds the item with quality higher than h.

We lower bound the probability that $W_t = 1$. We have that:

$$\begin{aligned}
Pr[W_t=1] &\ge \left(Pr\left[s_{i,t}<-h\right]\right)^n = \left(1-\Phi\left(\frac{h}{\sigma}\right)\right)^n\\
&\ge \exp\left(-\frac{1}{2}\cdot\left(\frac{h}{\sigma}\right)^2\cdot n\right) \ge \exp\left(-\frac{n\ln n}{\sigma^2}\right).
\end{aligned}$$

Setting $n = \frac{Z}{\ln(Z)}$ for $Z = \sigma^2\ln T$, we get that $Pr[W_t=1] \ge \frac{\ln Z}{T}$. Thus, the probability that no agent will find the high quality item is at most: $Pr[\forall t, W_t = 0] \le \left(1-\frac{\ln Z}{T}\right)^T \le \frac{1}{Z} \le \frac{1}{\sqrt{\ln n}}$.

Thus, overall we have that if $n \ge 5$

$$\begin{aligned}
M(\sigma,T) &\ge (1-\frac{2}{\sqrt{\ln n}})h \ge \sqrt{1-\sigma^2}\cdot\sqrt{2}(\sqrt{\ln n}-3)\\
&\ge \sqrt{1-\sigma^2}\cdot\sqrt{2}(\sqrt{\ln Z}-4) && \text{for } Z > n \ge 5\\
&\ge \sqrt{1-\sigma^2}\cdot\sqrt{2\ln(\sigma^2\ln T)} - 6.
\end{aligned}$$

Thus, setting T so that $n \ge 5$, we get the required bound. □

In addition to this lower bound, in Lemma B.5, we provide an upper bound on $M(\sigma,T)$. The main idea of the proof is to consider items with good qualities and show that the chance of searching a new item decreases exponentially with the number of such items. We perform the analysis using a coupling argument to an imaginary setting in which a larger number of items is always explored.

Lemma B.5. *For any diversity level $\sigma\in(0,1)$,*

$$M(\sigma,T) \le \sqrt{1-\sigma^2}\cdot\sqrt{2\ln(1+\sigma^2\ln(T))} + O_c(1).$$

Proof. Let $I(t)$ be a random variable that indicates the number of explored items after the agent in the t-th round has finished exploring, label items in the order in which they were first explored, and let $q_1, q_2, \ldots, q_{I(T)}$ be random variables that denote the quality of the items explored in the first T rounds. Then, in this notation, $M(\sigma,T)$, the expected positive part of the maximum quality of the explored items at the end of round T, is $\mathbb{E}[\max(0,\max_{i\le I(T)} q_i)]$.

To bound this expression, we define the following alternative exploration procedure that is significantly easier to analyze. We will show that there is always a coupling between the original and the alternative processes so that more items are always explored in the latter. Let x^* be the Weitzman index that satisfies $\mathbb{E}[\max(X-x^*,0)] = c$ when $X\sim\mathcal{N}(0,1)$. In our alternative process, every agent goes through every item i starting from $i=1$ and, whenever $q_i \ge x^*+c+1$, flips a coin that has probability $\Phi(1/\sigma)$ of coming heads. If the coin comes heads he stops, otherwise he continues on to the next item $i+1$. Let $I'(t)$ be the maximum number of items that have been explored by the agents in the first t rounds of this alternative procedure.

We define a coupling such that $I(t) \le I'(t)$. In the original process, we have that every agent t has value $q_i + s_{i,t}$ for item i. In the alternative process, if $q_i \ge x^*+c+1$, we couple the coin with the event that $s_{i,t} \ge -1$ which also has probability $\Phi(1/\sigma)$. Assuming inductively that $I(t-1) \le I'(t-1)$, we will show that $I(t) \le I'(t)$. This follows immediately if $I(t) \le I'(t-1)$ since we have that

$I'(t-1) \le I'(t)$. Otherwise, when $I(t) > I'(t-1)$, the original agent in the t'th round must have explored new item(s). Therefore, he must have $s_{i,t} \le -1$ for all items $i < I(t)$ for which $q_i \ge x^* + c + 1$ as he must have explored all of those first before reaching item $I(t)$. By definition of the coupling, the alternative agent will not stop in any item i such that $i < I(t)$ and thus $I'(t) \ge I(t)$.

Thus, $M(\sigma, T) = \mathbb{E}[\max(0, \max_{i \le I(T)} q_i)] \le \mathbb{E}[\max(0, \max_{i \le I'(T)} q_i)]$. We complete the proof by bounding $\mathbb{E}[\max(0, \max_{i \le I'(T)} q_i)]$ in Lemma B.6. □

Lemma B.6. *Let $I'(T)$ be as defined in the proof of Lemma B.5. Then*

$$\mathbb{E}[\max(0, \max_{i \le I'(T)} q_i)] \le \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln T)} + O_c(1).$$

Proof. For notation convenience, define $p_k = \Pr[|\{i | i \le I'(T) \wedge q_i \ge x^* + c + 1\}| = k]$. Letting m_k denote the expected maximum of k random variables distributed according to $\mathcal{N}(0, 1-\sigma^2)|_{\ge x^*+c+1}$, we have that $\mathbb{E}[\max(0, \max_{i \le I'(T)} q_i)] \le \sum_k m_k p_k$. From Lemma A.2, we have that $m_k \le \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(2k)} + x^* + c + 1 \le \sqrt{1-\sigma^2} \cdot \sqrt{2\ln k} + x^* + c + 3$ and thus we get that

$$\begin{aligned}
&\mathbb{E}[\max(0, \max_{i \le I'(T)} q_i)] \\
\le &\sqrt{1-\sigma^2} \sum_k \sqrt{2\ln k} \cdot p_k + (x^* + c + 3) \\
\le &\sqrt{1-\sigma^2} \cdot \sum_{k \ge z} \sqrt{2\ln k} \cdot p_k + \sqrt{1-\sigma^2} \cdot \sqrt{2\ln z} + (x^* + c + 3)
\end{aligned}$$

for all $z \ge 1$.

We now bound $p_k = \Pr[|\{i | i \le I'(T) \wedge q_i \ge x^* + c + 1\}| = k]$, i.e. the probability that k items with qualities higher than $x^* + c + 1$ are explored during the T rounds. We note that this can happen if in at least one round an agent manages to get k coin flips to land tails before stopping the exploration. Every agent achieves this with probability at most $(1 - \Phi(1/\sigma))^k \le e^{-\frac{k}{2\sigma^2}}$ and thus for all T rounds, the probability that k items with value higher than $x^* + c + 1$ are explored is at most $T \cdot e^{-\frac{k}{2\sigma^2}}$ by a union bound. We thus get that:

$$\begin{aligned}
&\mathbb{E}[\max(0, \max_{i \le I'(T)} q_i)] \\
\le &\sqrt{1-\sigma^2} \cdot \left(\sqrt{2\ln z} + T \sum_{k \ge z} e^{-\frac{k}{2\sigma^2}} \sqrt{2\ln k} \right) + (x^* + c + 3)
\end{aligned}$$

Setting $z = 7(1 + \sigma^2 \ln T)$ we have that

$$\begin{aligned}
T \sum_{k \ge z} e^{-\frac{k}{2\sigma^2}} \sqrt{2\ln k} &\le e^{-7} e^{\frac{z}{7\sigma^2}} \sum_{k \ge z} e^{-\frac{k}{2\sigma^2}} \sqrt{2\ln k} \\
&\le e^{-7} e^{\frac{z}{7}} \sum_{k \ge z} e^{-\frac{k}{2}} \sqrt{2\ln k} \le e^{-7} e^{\frac{z}{7}} e^{-\frac{z}{4}} \le e^{-7}
\end{aligned}$$

and we obtain

$$\mathbb{E}[\max(0, \max_{i \le I'(T)} q_i)] \le \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln T)} + x^* + c + 5.$$

□

Finally, by combining Lemma B.3, B.4 and B.5, we prove Proposition 4.5.

Proof of Proposition 4.5: Let's first prove the upper bound on $A(\sigma, T)$. By Lemma B.3 and Lemma B.5, we have

$$\begin{aligned}
A(\sigma, T) &\le M(\sigma, T) + O_c(1) \\
&\le \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln(T))} + O_c(1)
\end{aligned}$$

Now let's prove the lower bound on $A(\sigma, T)$. Notice that if $T \le \exp(13/\sigma^2)$,

$$\sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln(T))} \le \sqrt{2\ln(1+13)} = O(1),$$

and therefore the lower bound is trivial. We only need to prove the lower bound when $T > \exp(13/\sigma^2)$.

By Lemma B.3 and Lemma B.4, we have

$$\begin{aligned}
A(\sigma, T) &\ge \left(1 - \frac{1}{\sqrt{T}}\right) (M(\sigma, \sqrt{T}) - c) \\
&\ge \left(1 - \frac{1}{\sqrt{T}}\right) \left(\sqrt{1-\sigma^2} \cdot \sqrt{2\ln\left(\sigma^2 \ln\left(\sqrt{T}\right)\right)} - O(1) - c \right) \\
&\ge \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln(T)) - 2} - O_c(1) \\
&\quad - \frac{\sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln(T))}}{\sqrt{T}} \\
&\ge \sqrt{1-\sigma^2} \cdot \sqrt{2\ln(1+\sigma^2 \ln(T))} - O_c(1).
\end{aligned}$$

□

B.3 Omitted Proofs of Section 5

Lemma B.7 (Restatement of Lemma 5.2). *$A(1, T)$ is at least $(1 - o(1))D$ for $T = \omega(1/p)$.*

Proof. When diversity level is $\sigma = 1$, we have $q_i = d_i$. So q_i's realized value is either 0 or D. For each explored item, if it has quality 0, its Weitzman index will be lower than the Weitzman index of an unexplored item. This means that before an item with quality D is explored, each agent will explore at least one new item. Therefore, at round t, the probability of having seen a diamond is at least $1 - (1-p)^t$. Once a diamond has been found, each successive agent will get utility at least $D - c$. Therefore, for any t, $A(1, T) \ge (1 - (1-p)^t)(1 - t/T)(D - c)$.

We want to pick $t = \omega(1/p)$ and $t/T = o(1)$. Choosing $t = \sqrt{T \cdot (1/p)}$ suffices. We get $A(1, T) \ge (1 - o(1))(1 - o(1))(D - c) = (1 - o(1))D$. □

Lemma B.8 (Restatement of Lemma 5.3). *$A(0, T)$ is at most $D \cdot p + O(1)$ in the diamond model.*

Proof. The proof plan is similar to the proof of Lemma 4.1. We first bound by a constant the Weitzman index x^* of an unsearched item, i.e. one whose quality is not yet revealed. We then argue that once some item with sufficient quality has been identified (with quality $q_i > x^* + c$), no other item will be explored in future rounds. We conclude the proof by upper-bounding the expected quality of such an item conditional on its quality being higher than $x^* + c$. This directly gives a bound for the average utility.

We start by the Weitzman index of an unsearched item. Let x^* be its Weitzman index. Let $X \sim \mathcal{N}(0,1)$, by the defintion of Weitzman index, $c = p \cdot \mathbb{E}[\max(X + D - x^*, 0)] + (1-p) \cdot \mathbb{E}[\max(X - x^*, 0)]$.

We give upper bounds on $\mathbb{E}[\max(X + D - x^*, 0)]$ and $\mathbb{E}[\max(X - x^*, 0)]$ separately. For $\mathbb{E}[\max(X + D - x^*, 0)]$, since $x^* > 0$, we have

$$\begin{aligned}
&\mathbb{E}[\max(X + D - x^*, 0)] \le \mathbb{E}[\max(X + D, 0)] \\
=&\mathbb{E}[X + D] + (\mathbb{E}[-X | -X \ge D] - D) \cdot \Pr[-X \ge D] \\
=&D + \left(\frac{\varphi(D)}{1 - \Phi(D)} - D\right)(1 - \Phi(D)) \\
\le&D + \left(\frac{D}{2} + \frac{\sqrt{D^2+4}}{2} - D\right) \cdot \frac{1}{\sqrt{2\pi}\exp(D^2/2)D} \\
\le&D + \frac{1}{\sqrt{2\pi}\exp(D^2/2)D^2}.
\end{aligned}$$

For $\mathbb{E}[\max(X - x^*, 0)]$, we have

$$\begin{aligned}
&\mathbb{E}[\max(X - x^*, 0)] = \mathbb{E}[X - x^* | X - x^* > 0] \cdot Pr[X - x^* > 0] \\
= &\left(-x^* + \frac{\varphi(x^*)}{\Phi(-x^*)}\right) \cdot \Phi(-x^*) = (-x^*)(1 - \Phi(x^*)) + \varphi(x^*) \\
\le &(-x^*)\left(\frac{\varphi(x^*)}{x^*} - \frac{\varphi(x^*)}{(x^*)^3}\right) + \varphi(x^*) = \frac{\varphi(x^*)}{(x^*)^2} \\
= &\frac{1}{\sqrt{2\pi} \cdot (x^*)^2 \cdot \exp((x^*)^2/2)}.
\end{aligned}$$

To sum up we get $c \le p \cdot D + \frac{p}{\sqrt{2\pi}\exp(D^2/2)D^2} + \frac{1-p}{\sqrt{2\pi}\cdot(x^*)^2\cdot\exp((x^*)^2/2)}$. For notation convenience, define $\alpha = \frac{c - p\cdot D - \frac{p}{\sqrt{2\pi}\exp(D^2/2)D^2}}{1-p}$. We have $\sqrt{2\pi} \cdot (x^*)^2 \cdot \exp((x^*)^2/2) \le \frac{1}{\alpha}$. As $c - p \cdot D = \Omega(1)$ and $D = \omega(1)$, we have $\alpha = \Omega(1)$. This implies an upper bound on the Weitzman index of an unsearched item: $x^* \le \max\left(1, \sqrt{\ln\left(\frac{1}{2\pi\alpha^2}\right)}\right) = O(1)$.

When an item has been searched with observed quality q_i, since the diversity level is 0, the values of this item for future agents are determinstically q_i. Therefore the Weitzman index of this item is simply $q_i - c$.

Once some item has quality $q_i > c + x^*$, its Weitzman index is larger than x^* which means it will be searched before any unsearched items. And once this item is searched in a round, we know its realized value is q_i which is larger than x^*. Therefore no more unsearched items will be searched.

Let Q be the quality of the first item with quality larger than $c + x^*$. We have $\mathbb{E}[Q] = \mathbb{E}[q_i | q_i > c + x^*]$. We know that starting from the round this item is searched, each agent's utility is at most $Q - c$ and before this item is ever searched, each agent's utility is at most $c + x^* - c \le Q - c$. Therefore we can bound the average utility as following:

$$\begin{aligned}
A(0,T) &\le \mathbb{E}[Q - c] \le \mathbb{E}[q_i | q_i > c + x^*] - c \\
&\le D \cdot p + \frac{\varphi(c + x^*)}{1 - \Phi(c + x^*)} - c \\
&\le D \cdot p + \frac{x^* - c + \sqrt{(x^* + c)^2 + 4}}{2} \\
&\le D \cdot p + x^* + 1 \text{ (by Fact A.2)} \\
&= D \cdot p + O(1).
\end{aligned}$$

□

We proceed to show Lemma B.9 which is the main technical part behind the proof of Theorem 5.1 and gives a bound on the expected maximum quality of the items explored in T rounds, i.e. $M(\sigma, T)$. This implies an upper bound on the expected average utility $A(\sigma, T)$ using an identical argument to Lemma B.3. We omit the proof because of space limit. It is very similar to the proof of Lemma B.5.

Lemma B.9. *For any diversity level $0 < \sigma < 1$, in the diamond model,*

$$\begin{aligned}
&A(\sigma, T) \le M(\sigma, T) \\
\le&\sqrt{1 - \sigma^2} \cdot \sqrt{2\ln(1 + \sigma^2 \ln(T))} + \frac{pD(2\sigma^2 \ln(D) + 2\sigma^2 \ln(T))}{1 - \Phi\left(\frac{x^* + c + 1}{\sqrt{1-\sigma^2}}\right)} + O_c(1).
\end{aligned}$$

where x^* is the Weitzman index of an unsearched item.

Proof of Theorem 5.1: Given Lemma B.9, we can now complete the proof of Theorem 5.1. We know that x^* (the Weitzman index of an unsearched item) is constant as shown in the proof of Lemma 5.3. So for a constant $\sigma < 1$, we know that $\frac{x^* + c + 1}{\sqrt{1-\sigma^2}}$ is also a constant and therefore $\Phi\left(\frac{x^* + c + 1}{\sqrt{1-\sigma^2}}\right)$ is bounded away from 1. Plugging $T = \exp(o(D))$ into Lemma B.9, we get that $A(\sigma, T) = o(D)$. As $A(1, T) = (1 - o(1))D$ by Lemma 5.2, the theorem follows. □

ABSTRACT

Ordering take-out food (a.k.a. takeaway food) on online-to-offline (O2O) food ordering and delivery platforms is becoming a new lifestyle for people living in big cities, thanks to its great convenience. Web users and mobile device users can order take-out food (i.e. obtain *online food ordering services*) on an O2O platform. Then the O2O platform will dispatch food carriers to deliver food from restaurants to users, i.e. providing users with *offline food delivery services*. For an O2O food ordering and delivery platform, improving food delivery efficiency, given the massive number of food orders each day and the limited number of food carriers, is of paramount importance to reducing the length of time users wait for their food. Thus, in this paper, we study the food delivery task grouping problem so as to improve food delivery efficiency and alleviate the pain of waiting for users, which to the best of our knowledge has not been studied yet. However, the food delivery task grouping problem is challenging, given two reasons. First, the food delivery efficiency is affected by multiple factors, which are non-trivial to formulate and jointly consider. Second, the problem is a typical NP-hard problem and to find near-optimal grouping results is not easy. To address these two issues, we propose an effective task grouping method. On one hand, we provide formal formulations for the factors affecting the food delivery efficiency, and provide an objective to organically combine these factors such that it can better guide the task grouping. On the other hand, we propose heuristic algorithms to efficiently obtain effective task grouping results, consisting of a greedy algorithm and a replacement algorithm. We evaluate our task grouping method using take-out food order data from web users and mobile device users on a real-world O2O food ordering and delivery platform. Experiment results demonstrate that our task grouping method can save ~16% (87 seconds) of average waiting time for each user, comparing with many baseline methods. It indicates that our method is able to significantly improve the food delivery efficiency and can provide better food delivery services for users.

1 INTRODUCTION

Advance in modern web and mobile device technologies is spurring the prevalence of ordering take-out food (takeaway food) on online-to-offline (O2O) food ordering and delivery platforms (O2O platforms for short). As shown in Figure 1(a), web users or mobile device users can order take-out food on an O2O platform (step 1), through a web or an App. After receiving the food orders, the O2O platform will send them to corresponding restaurants (step 2), and will dispatch food carriers to deliver the food from restaurants to users (step 3), i.e. providing offline food delivery services for users. Thus, users are not necessary to go to restaurants in person, just waiting and enjoying the delivery of food from food carriers. Thanks to its great convenience, there are massive people ordering take-out food on O2O platforms every day. For example, in China, the number of daily food orders from users on one O2O platform has already reached 10 million [25, 26]. As a result, for O2O food ordering and delivery platforms, given the limited number of food carriers and the massive number of users each day, how to improve the food delivery efficiency such that the waiting time of the massive users can be reduced has become an urgent problem.

A feasible way to improve the food delivery efficiency is grouping delivery tasks in a city into groups (i.e. the task grouping problem). One delivery task is not one specific food order from a user, but all food orders from a region to another. For the example in Figure 1(a), there is a delivery task e from region a to region b, since there exist users in region b ordering food from restaurants in region a. A region contains many users and restaurants. If we see regions as vertices and delivery tasks as directed edges, we can construct

a delivery task graph, like the one in Figure 1(b). In Figure 1(b), tasks (edges) are grouped into four task groups, i.e. E_1, E_2, E_3 and E_4, which are highlighted using different colors. A food carrier will be assigned to only one task group such that he/she can be very familiar with the locations of users and restaurants in the task group. In other words, by task grouping, food carriers in each task group can avoid wasting time on finding the locations of users and restaurants, and the routes between them, thus improving the food delivery efficiency and reducing users' waiting time.

(a) Online-to-Offline Food Delivery Services (b) Task Graph

Figure 1: Food delivery task grouping problem.

It should be noted that the task grouping problem is not a real-time problem. For an O2O food ordering and delivery platform, delivery tasks are grouped just from time to time, e.g. once per month. For example, the task grouping result of this month can be obtained based on users' food orders in the last few months. Having the task grouping result, we can allocate food carriers to each task group and the food orders (arriving in real time) can be delivered by food carriers in corresponding task group. Clearly, *the food carrier allocation problem* (i.e. how many food carriers are needed for each task group?) and *the real-time food carrier dispatching problem* (i.e. which food carrier should be dispatched when a food order arrives in real time?) also significantly affect the food delivery efficiency. In this work, we focus on the task grouping problem since it is the foundation of the allocation and dispatching problem. These two problems will be studied in our future work.

In fact, our task grouping problem can be seen as a graph edge partition problem, i.e. a graph vertex-cut problem [5, 17, 30]. However, previous graph edge partition algorithms (heuristic algorithms mainly) are designed for distributed graph computation platforms [5, 10, 11], whose aim is to minimize the number of total replicated vertices over different edge groups. Therefore, due to the different scenarios and the different objectives, previous graph edge partition algorithms cannot work well to our task grouping problem. As a consequence, a new task grouping method is in great need for the O2O food ordering and delivery platforms.

However, our task grouping problem is challenging, due to the following two reasons.

First, to improve the food delivery efficiency, our task grouping should consider multiple factors, e.g. the *shareability* and the *empty run time* of each task group. Besides the joint consideration of these two factors, to mathematically formulate and derive the shareability and the empty run time is also non-trivial. Specifically, the *shareability* indicates to what extent food orders in a task group can be shared (jointly delivered). The *empty run time* refers to the empty cruising time before carriers deliver next food orders. For example, the task group E_4 marked by the pink color in Figure 1(b) may have high shareability, since carriers can jointly deliver orders in task e_1 together with orders in task e_2 or e_3, saving the total delivery time, if these orders come at close time. However, the task group has high empty run time. For instance, after a food carrier delivers an order to region v_3, if the next food order is in task e_1 (or e_2), the food carrier needs to go back to region v_1, *in empty*, to deliver the food order. Apparently, to improve the food delivery efficiency, we expect task groups with *high* shareability and *low* empty run time.

Second, the task grouping problem can be easily proved to be a NP-hard problem [5, 17, 30]. As a result, it is also non-trivial to design an effective and efficient algorithm to obtain near-optimal task grouping solutions.

To address these issues, in this paper, we propose a method to do the task grouping for O2O food ordering and delivery platforms. Specifically, our contributions are as below.

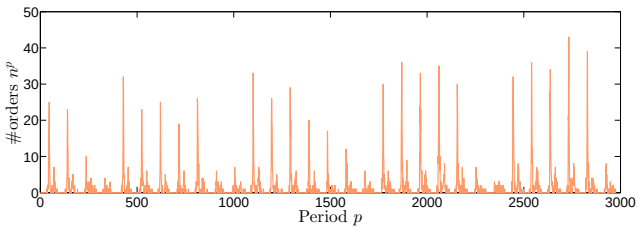
- To the best of our knowledge, we are the first to study the delivery task grouping problem for O2O food ordering and delivery platforms in real world. We formally define the food delivery task grouping problem.
- We provide formal formulations for the shareability and the empty run time. Besides, we propose a method to organically incorporate the shareability and the empty run time into one objective such that it can better guide our task grouping.
- We propose effective heuristic algorithms to solve the task grouping problem, including a greedy algorithm and a replacement algorithm. The greedy algorithm is to output a fast and good task grouping solution, while the replacement algorithm is to further refine the obtained grouping solution.
- We evaluate our task grouping method using the food order data from web users and mobile device users on an O2O food ordering and delivery platform in real world. Compared with previous graph edge partition methods, our task grouping method is able to save at least 16% (87 seconds) of average travel time for each food order, significantly reducing the waiting time of users.

2 OVERVIEW

2.1 Preliminary

Definition 1 (*Region*): A region v is a small piece of a city, containing some restaurants and users. Note that considering each individual restaurant (or user) is not necessary, given that some restaurants (or users) are geographically very close and thus can be seen as a unity. A city is comprised of many regions and we denote all regions in a city by V. Regions V in a city are obtained by region segmentation using road networks, which will be detailed later in Section 3.1. An example for the obtained regions V in a city can be found in Figure 8(b).

Definition 2 (*Delivery Task*): A delivery task, denoted by $e = (o, d, n^1, \cdots, n^P)$, is a directed edge from region o to region d, containing all food orders from restaurants of region o to users of region d. $n^p, p = 1, \cdots, P$ denotes the number of food orders in the delivery task in time period p, as demonstrated in Figure 2. A period can be with 15 minutes. P is the number of total time periods under consideration for the task grouping (e.g. one month). We can denote all delivery tasks in a city by E. The extraction of all delivery



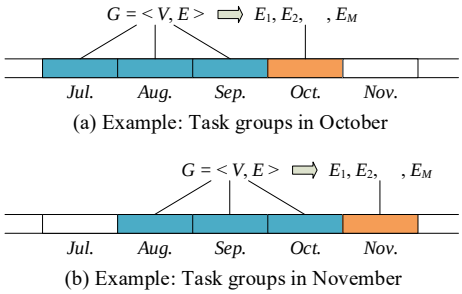


Figure 2: An example for a food delivery task's $n^1, \cdots, n^P$.

(a) Example: Task groups in October

(b) Example: Task groups in November

Figure 3: Examples for task grouping.

Different with the edges on distributed graph computation platforms [5, 10, 11], our edges (tasks) contain clear spatial and temporal properties. Specifically, o and d refer to the spatial locations of a task, while $n^1, \cdots, n^P$ denote the temporal frequency of food orders (from web users and mobile device users) from region o to region d (Figure 2). Thus, the task grouping problem in our scenario can be more difficult.

Definition 3 (*Task Graph*): A task graph is a directed graph, denoted by $G = \langle V, E \rangle$, with all regions V as vertices and all delivery tasks E as directed edges. G is naturally obtained once V and E have been extracted.

2.2 Problem Definition

M-task grouping problem: given a constructed task graph $G = \langle V, E \rangle$ and the number M of task groups, the task grouping problem aims to group all delivery tasks in E into M groups, i.e. $E_m, m = 1, \cdots, M$, such that the following conditions (or objectives) can be satisfied:

(1) Each task group E_m is a subset of E, i.e. $E_m \subset E, \forall m$;
(2) All tasks are grouped into the M groups, i.e. $\bigcup_{m=1}^{M} E_m = E$;
(3) Task groups do not overlap, i.e. $E_{m_1} \cap E_{m_2} = \emptyset, \forall m_1 \neq m_2$;
(4) Each task group E_m has high shareability;
(5) Each task group E_m has low empty run time.

As mentioned in the Introduction, our task grouping is not conducted in real time, but just from time to time. For the examples in Figure 3, the task grouping is conducted every month. Actually, since the distribution of food orders won't change dramatically, the task grouping can even be conducted every quarter/half of a year. In Figure 3(a), the task groups in October are obtained based on the task graph constructed using food order data in the previous three months, i.e. July, August and September. The obtained task groups are applied in October, i.e. each arriving food order are delivered by a food carrier in the corresponding task group. That is, the food carrier allocation and real-time dispatching (defined in the Introduction) in October are based on the obtained task groups. Similarly, in Figure 3(b), at the beginning of November, the task grouping is re-conducted based on the task graph constructed using food order data in August, September and October.

Our task grouping problem is actually a graph edge partition problem, which has already been proved to be NP-hard [2, 30]. As mentioned before, due to the spatial and temporal properties of the edges (tasks) in our task graph and the different objectives 4 and 5, our task grouping problem can be more difficult.

2.3 Framework

Figure 4 demonstrates the framework of our task grouping method, consisting of three components: pre-processing, shareability and empty run time, and task grouping algorithm. Below, we introduce each component in detail.

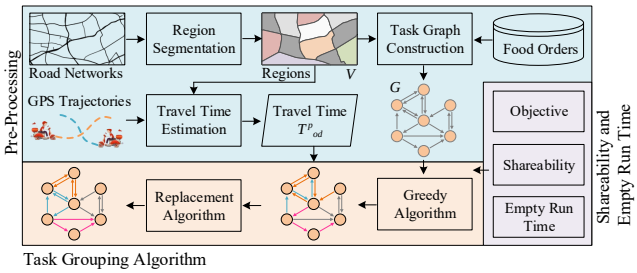

Figure 4: The framework of our task grouping method.

As shown in Figure 4, the pre-processing component has three small components: region segmentation, task graph construction, and travel time estimation. Firstly, the region segmentation is to segment a city into non-overlapping regions V. In detail, a city is segmented based on the road structure of the city (i.e. road networks), e.g. Figure 8(a, b). Next, with the segmented regions V, we construct the task graph $G = \langle V, E \rangle$. The construction process uses the historical food order records collected from web users and mobile device users in real world. From these food order records, we can know whether there are food orders from one region to another and the number of the food orders in each time period. That is, all delivery tasks E between any two regions can be extracted. Then, based on V and E, task graph G can be constructed. The constructed task graph G will be transferred to the task grouping algorithm component for grouping. The third small component is the travel time estimation, which is to estimate the travel time of food carriers between any two regions in V in each time period p. The estimation is based on the GPS trajectories of food carriers collected from real world. The estimated travel time are also necessary in the task grouping algorithm component.

The shareability and empty run time component is to formally formulate the shareability and the empty run time, which are then combined as one objective. The objective will be used to guide the grouping of tasks. In general, given a grouping result, we utilize the total delivery time of food orders to indicate the shareability of

the grouping result. The smaller the total delivery time, the higher shareability the grouping result. Thus, our objective is formulated as the sum of the delivery time and the empty run time. The delivery time and the empty run time of a grouping result will consider the number of food orders in each task in each period.

The task grouping algorithm component details our algorithms for grouping tasks into M task groups, including a greedy algorithm and a replacement algorithm. The greedy algorithm assigns tasks to each task group E_m in a greedy manner based on the objective, and will output a task grouping result $E_1, \cdots, E_m$. The replacement algorithm is to further improve the grouping result of the greedy algorithm. Specifically, we try to replace the owner (one task group) of a task with another task group, with the expectation that the total delivery time and the total empty run time can be reduced after the replacement. The replacement algorithm stops when the objective cannot be improved any more, and then our ultimate task grouping result is returned.

3 PRE-PROCESSING

3.1 Region Segmentation

In this subsection, we segment a city into non-overlapping regions V, which includes two steps. At the first step, we segment the city into regions according to the structure of road networks, using the region segmentation method proposed in [29]. By this method, the segmented regions have semantic meanings, e.g. a region can be a small block of a city. This is an important advantage of this segmentation method over the grid-based method [9, 18]. However, since road networks in a city are too dense, some regions obtained from the first step are very small, e.g. the widths and lengths of some regions are less than 200 meters. Therefore, at the second step, we recursively merge those small and geographically adjacent regions into relatively big regions, until the size of the smallest region reaches a threshold (e.g. 400 meters × 400 meters).

3.2 Task Graph Construction

With segmented regions V, we can construct the task graph based on users' food order records over a long time in real world. Specifically, for each food order (see the data format in the Section 6), we can get the location of the restaurant and the location of the user, which can be mapped into regions. For example, if the restaurant is in region o and the user is in region d, we have a task $e = (o, d, n^1, \cdots, n^P)$. Iterating over the entire food order records, we can obtain all tasks E. Besides the location information, we also have the time stamp at which a food order is ordered, which can be mapped to a corresponding time period. Thus, for each task $e \in E$, we can get the number of food orders in each period p, i.e. the $e.n^p$. Finally, based on the constructed V and E, we can then obtain the task graph $G = \langle V, E \rangle$ in a city.

3.3 Travel Time Estimation

In this subsection, we estimate the travel time $T^p_{o,d}$ of food carriers traveling from region $o \in V$ to region $d \in V$ in each period p, using the GPS trajectories of food carriers in real world. Since a period is too short (e.g. 15 minutes), we estimate the travel time from o to d in each hour, based on which we can get $T^p_{o,d}$. In detail, our estimation process has the following steps. First, we detect and remove stay points from the GPS trajectories of food carriers, using the stay-point detection algorithm proposed in [32]. In real world, food carriers may stay still to wait for users to fetch their food, or to wait for restaurants to prepare the food. Thus, we need to remove these stay points, before estimating the travel time of food carriers. Second, we map the GPS trajectories (without stay points) onto road segments, using the map-matching algorithm proposed in [28]. After the map-matching, we can obtain the travel time of carriers on each road segment. Note that there may exist some missing data, we can fill them based on the spatial and temporal correlation of travel time between road segments [4, 6, 24, 31]. Finally, the travel time between any two regions can be estimated as the minimum travel time of a path (a sequence of road segments), concatenating the centers of these two regions [24]. Note that the estimated travel time is necessary for the calculation of the shareability and the empty run time, when we conduct the task grouping.

4 SHAREABILITY AND EMPTY RUN TIME

4.1 Objective

The shareability of a grouping result $E_1, \cdots, E_M$ can be indicated by the total delivery time needed to deliver all food orders in all tasks. The smaller the total delivery time, the higher the shareability. For a simple example in Figure 5, there are four tasks. Tasks e_1, e_2 can be easily shared since their origins and destinations are both highly close, and food orders in e_1, e_2 have a similar arrival pattern (Figure 5(c)). That is, food orders in e_1, e_2 that come in the same time period can be delivered jointly, using just around one share of delivery time. So can tasks e_3, e_4. Thus, if we group e_1, e_2 as a task group and e_3, e_4 as another group, as Figure 5(a), the shareability of the grouping is high. In the meantime, the total delivery time to deliver all food orders is small, since jointly delivering food orders in e_1, e_2 (or e_3, e_4) can save a lot of delivery time. In contrast, as Figure 5(b), if we group e_1, e_3 as a group and e_2, e_4 as another group, the shareability of the grouping is low. Meanwhile, the total delivery time is large, since jointly delivering food orders in e_1, e_3 (or e_2, e_4) cannot save the total delivery time. Therefore, we can use the total delivery time to indicate the shareability. It should be noted that for a task group, in addition to the tasks' origins and destinations, the shareability is also affected by tasks' number of food orders in each time period (Figure 5(c)). The formal formulation of the shareability is in Section 4.2.

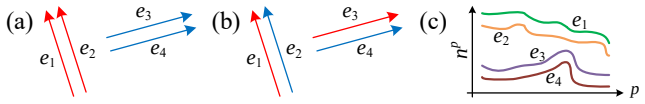

Figure 5: An example for the shareability.

The total delivery time for delivering all food orders is denoted by $DT(E_1, \cdots, E_M)$ and is actually the aggregation of delivery time in each task group E_m, i.e.

$$DT(E_1, \cdots, E_M) = \sum_{m=1}^{M} DT(E_m), \tag{1}$$

where $DT(E_m)$ refers to the total delivery time needed to deliver food orders in task group E_m.

The total empty run time of a grouping result $E_1, \cdots, E_M$ is denoted by $ET(E_1, \cdots, E_M)$, which is the aggregation of empty run time in each task group E_m:

$$ET(E_1, \cdots, E_M) = \sum_{m=1}^{M} ET(E_m), \tag{2}$$

where $ET(E_m)$ denotes the empty run time of task group E_m.

For our task grouping problem, we expect a grouping result with smaller delivery time (i.e. higher shareability) and smaller empty run time. Therefore, we can combine them as one objective, i.e. the total travel time, which is the sum of the total delivery time and the total empty run time. Thus, the total travel time $TT(E_1, \cdots, E_M)$ is

$$TT(E_1, \cdots, E_M) = \sum_{m=1}^{M} TT(E_m), \tag{3}$$

where $TT(E_m)$ is the aggregation of $DT(E_m)$ and $ET(E_m)$:

$$TT(E_m) = DT(E_m) + ET(E_m). \tag{4}$$

To obtain our objective function in Equation 3, we need to mathematically formulate the delivery time (shareability) $DT(E_m)$ and the empty run time $ET(E_m)$ in each task group E_m. Thus, for the rest of this section, we detail how to mathematically formulate the delivery time $DT(E_m)$ and the empty run time $ET(E_m)$ for each task group m.

4.2 Delivery Time $DT(E_m)$ (Shareability)

When calculating the delivery time of food orders in a task group E_m, we will consider jointly delivering (sharing) food orders, such that the delivery time can denote the shareability. However, in real world, only food orders that arrive within a time period (e.g. 15 minutes) can be shared, since jointly delivering food orders in different time periods would let users wait too long for their food. That is, jointly delivering food in different time periods is not user-friendly and will lead to poor user experience. Thus, the $DT(E_m)$ is actually the aggregation of the delivery time of food orders in each time period p. That is, $DT(E_m)$ is

$$DT(E_m) = \sum_{p=1}^{P} DT(E_m, p), \tag{5}$$

where P denotes the number of total time periods, and $DT(E_m, p)$ refers to the delivery time of food orders in task group E_m in period p. A period considered in this paper is with 15 minutes.

For food orders in a task group E_m in a period p, there may exist many strategies to jointly deliver them. For example, as shown in Figure 6, there are three tasks in task group E_m, i.e. e_1, e_2, e_3. In period p, e_1 is with one order, e_2 with two and e_3 with one. The possible joint delivery solutions include: 1) jointly delivering the order in e_1 with an order in e_2 and jointly delivering another order in e_2 with the order in e_3; 2) jointly delivering the order in e_1 with the order in e_3 and jointly delivering the two orders in e_2; etc. The problem now is to find a delivery solution such that it can be used for the calculation of our needed delivery time.

Definition 4 (*Delivery Time*): The delivery time $DT(E_m, p)$ is defined as the minimum delivery time among all possible delivery

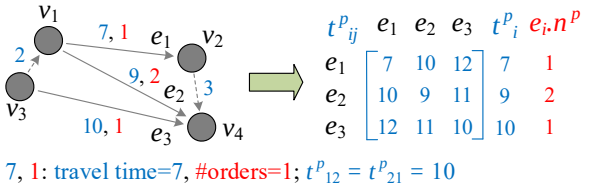

Figure 6: A simple example for delivery time $DT(E_m, p)$.

solutions such that it can indicate the shareability. As a consequence, to obtain the $DT(E_m, p)$, we need to find the optimal delivery solution. In math, it is

$$DT(E_m, p) = \min_{y_i, x_{ij}} \sum_{i=1}^{|E_m|} \left(y_i \cdot t_i^p + \sum_{j=i}^{|E_m|} x_{ij} \cdot t_{ij}^p \right)$$
$$s.t. \begin{cases} 1 \cdot y_i + \left(2 \cdot x_{ii} + 1 \cdot \sum_{j=1, j \neq i}^{|E_m|} x_{ij}\right) = e_i.n^p, \forall i \\ x_{ij} = x_{ji}, \forall i, j \\ y_i, x_{ij} \in \mathbb{Z}^+ \cup \{0\}, \forall i, j \end{cases} \tag{6}$$

y_i and x_{ij} are the decision variables. y_i refers to the number of food orders in task e_i being delivered *individually*. x_{ij} refers to the number of food orders in task e_i and e_j that are delivered jointly. t_i^p denotes the travel time needed for delivering an order in task e_i, i.e. $t_i^p = T^p_{e_i.o, e_i.d}$. For example, in Figure 6, $t_1^p = T^p_{v_1, v_2} = 7$. t_{ij}^p is the minimum travel time needed to jointly deliver an order in e_i and an order in e_j, and $t_{ij}^p = t_{ji}^p$ holds. For example, in Figure 6, $t_{12}^p = t_{21}^p = 10$ means that the minimum travel time to jointly deliver an order in e_1 and an order in e_2 is 10 minutes (by taking the route $v_1 \rightarrow v_2 \rightarrow v_4$, i.e. picking up two orders in region v_1 and then delivering the one to region v_2 and another one to v_4). $e_i.n^p$ denotes the number of orders in e_i in period p. $|E_m|$ denotes the number of tasks in group E_m.

In this optimization problem, the objective is to find the optimal delivery solution, i.e. y_i and x_{ij}, with the minimum delivery time. The first constraint requires that all orders in each task e_i should be delivered. Note that if $x_{ii} = 1$, two orders in task e_i are delivered (denoted by $2 \cdot x_{ii}$). The second constraint indicates that the sharing of orders between two tasks is symmetric. The last constraint means that y_i, x_{ij} are nonnegative integers.

From the optimization problem 6, we can find that the shareability of a task group is affected both by tasks' origins and destinations and by tasks' number of food orders in a time period, as aforementioned. The more tasks having close origins and destinations, the higher the shareability. The more food orders that come at the same time period, the higher the shareability.

The optimization problem can be efficiently solved using some off-the-shelf optimization solvers, e.g. Gurobi Optimizer [16], Microsoft Solver Foundation [13], etc. For the example in Figure 6, the solution is $x_{21} = x_{12} = 1, x_{23} = x_{32} = 1$ and thus $DT(E_m, p) = (T^p_{v_1, v_2} + T^p_{v_2, v_4}) + (T^p_{v_3, v_1} + T^p_{v_1, v_4}) = 21$. That is, the optimal delivery solution is to jointly deliver an order in e_2 with the order in e_1 (taking route $v_1 \rightarrow v_2 \rightarrow v_4$) and to jointly deliver another order in e_2 with the order in e_3 (taking route $v_3 \rightarrow v_1 \rightarrow v_4$).

4.3 Empty Run Time $ET(E_m)$

The empty run time for task group E_m is denoted by $ET(E_m)$. Similar to $DT(E_m)$, $ET(E_m)$ is also the aggregation of the empty run time $ET(E_m, p)$ in each period p, i.e.

$$ET(E_m) = \sum_{p=1}^{P} ET(E_m, p). \tag{7}$$

The empty run time $ET(E_m, p)$ is the total time intervals between the delivery units in period p.

Definition 5 (*Delivery Unit*): A delivery unit contains one food order in task e_1^s and one food order in e_2^s, and is denoted by $du = (e_1^s, e_2^s, o, d)$, where o and d denote the origin and destination of the delivery unit, respectively. For the example in Figure 6, the solution for $DT(E_m, p)$ contains two delivery units. The first unit is to jointly deliver an order in e_1 and e_2 by taking the route $v_1 \to v_2 \to v_4$. Therefore, $du_1 = (e_1, e_2, v_1, v_4)$. The second unit is to jointly deliver an order in e_2 and e_3 by taking the route $v_3 \to v_1 \to v_4$, that is, $du_2 = (e_2, e_3, v_3, v_4)$. Note that if a delivery unit contains only one food order, e_2^s is null and we denote $e_2^s = *$.

After a carrier finishes a delivery unit du_i, to deliver next delivery unit du_j, the carrier needs to spend some time traveling from du_i's destination $du_i.d$ to du_j's origin $du_j.o$, *in empty* (without carring any food). That is, the travel time from $du_i.d$ to $du_j.o$ is the empty run time. For example, as the first row in Figure 7, from delivery unit du_1 to du_2, there is empty run time $T^p_{v_4,v_3}$.

Definition 6 (*Empty Run Time*): Given the last delivery unit du_0 in period $p-1$ and the n delivery units $du_1, \cdots, du_n$ obtained from the solution for $DT(E_m, p)$ in this period p, the empty run time $ET(E_m, p)$ is the minimum time needed to travel between delivery units $du_1, \cdots, du_n$, starting from du_0. In math, it is

$$ET(E_m, p) = \min_{(i_1, i_2, \cdots, i_n) \in \text{Perm}(1,2,\cdots,n)} \sum_{j=0}^{n} T^p_{du_{i_j}.d, du_{i_{j+1}}.o} \tag{8}$$

where $\text{Perm}(1, 2, \cdots, n)$ denotes all permutations of set $\{1, 2, \cdots, n\}$ and $i_0 = 0$. $T^p_{du_{i_j}.d, du_{i_{j+1}}.o}$ is the travel time from du_{i_j}'s destination $du_{i_j}.d$ to $du_{i_{j+1}}$'s origin $du_{i_{j+1}}.o$, i.e. the empty run time between the i_j-th delivery unit and i_{j+1}-th delivery unit.

In summary, the delivery time $DT(E_m, p)$ is the total travel time of all delivery units in period p, while the empty run time $ET(E_m, p)$ is the minimum travel time needed to travel between all delivery units. For example, for the delivery units obtained in Figure 6, i.e. the $du_1 = (e_1, e_2, v_1, v_4)$ and $du_2 = (e_2, e_3, v_3, v_4)$ in Figure 7, $DT(E_m, p) = (T^p_{v_1,v_2} + T^p_{v_2,v_4}) + (T^p_{v_3,v_1} + T^p_{v_1,v_4})$. Assume that the last delivery unit in period $p-1$ is $du_0 = (e_1, *, v_1, v_2)$. We have $\text{Perm}(1, 2) = \{(1, 2), (2, 1)\}$, corresponding to the two rows in Figure 7. If the optimal solution is $(i_1, i_2) = (2, 1)$, i.e. the second row, then $ET(E_m, p) = T^p_{v_2,v_3} + T^p_{v_4,v_1}$.

The optimization problem 8 is a NP-hard problem. In fact, the problem can be seen as a traditional traveling salesman problem [19], which is to find the shortest route to visit a given list of cities. Specifically, a delivery unit in our problem can be seen as a city in the traveling salesman problem and the distance between two cities is the travel time from the destination of a delivery unit to the origin of another delivery unit. Thus, to solve the NP-hard optimization problem 8, we can apply an efficient and effective nearest neighbour

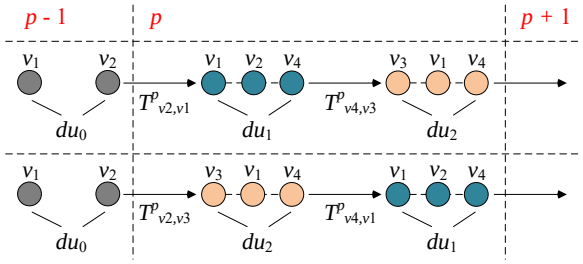

Figure 7: A simple example for empty run time $ET(E_m, p)$.

algorithm [7, 19, 20], which has been widely used in the traveling salesman problem. Specifically, assuming the current delivery unit is du_i, the algorithm selects the nearest (in terms of travel time) unvisited delivery unit du_j as the next delivery unit. That is, we select du_j such that

$$T^p_{du_i.d, du_j.o} \le T^p_{du_i.d, du_k.o}, \text{for each unvisited } du_k.$$

In this way, starting from du_0, we can obtain the solution for the optimization problem 8 efficiently and the empty run time $ET(E_m, p)$. The time complexity is $O(n)$, where n is the number of delivery units in period p.

An assumption underlying the above formulation is that there exists only one carrier in each task group E_m. This is due to that when conducting task grouping, we don't know the number of carriers in each task group E_m. The allocation of carriers to task groups is after the task grouping. Actually, if we are given the number of carriers in each task group, the problem can be formulated as a multiple travelling salesman problem [1] and corresponding empty run time can be similarly calculated.

5 TASK GROUPING ALGORITHM

5.1 Greedy Algorithm

The greedy algorithm is demonstrated in Algorithm 1. In general, the greedy algorithm is comprised of M rounds (Line 3-11) and at each round m, we assign tasks to task group E_m. Below, we detail the processes of assigning tasks to E_m at each round m.

Algorithm 1 Greedy Algorithm

```
1:  procedure GREEDY(E, M)
2:      E^u = E                                   ▷ Initial unassigned tasks
3:      for m = 1, ··· , M
4:          E_m = ∅
5:          e_* ← a random task from E^u
6:          E_m = E_m ∪ {e_*},  E^u = E^u \ {e_*}
7:          while |E_m| < α|E|/M or E^u ∩ Nei(E_m) ≠ ∅
8:              for e ∈ E^u ∩ Nei(E_m)
9:                  Compute MTR(e|E_m)            ▷ Equation 9
10:             e_** = arg min_{e∈E^u∩Nei(E_m)} MTR(e|E_m)
11:             E_m = E_m ∪ {e_**}, E^u = E^u \ {e_**}
12:     return E_1, ··· , E_M
```

Initially, E_m is an empty set and is assigned with a random task e_* selected from unassigned tasks E^u (Line 3-6). E^u is initialized

as E (Line 2) and tasks assigned will be removed from E^u. *Second*, we search each unassigned task e from E_m's neighborhood tasks $Nei(E_m)$ and compute the *marginal travel time ratio* $MTR(e|E_m)$ (Equation 9) of assigning e to E_m (Line 8-9). *Third*, the task e_{**} with the minimum marginal time ratio is assigned to E_m (Line 10-11), making E_m be with high shareability and low empty run time. We repeat the Step 2 and Step 3, until the number of tasks in E_m surpasses $\alpha|E|/M$ or there does not exist unassigned task nearby E_m (Line 7). The first stop criterion is to balance the size of each task group (e.g. $\alpha = 1.1$). The reason that we only consider the neighborhood tasks of E_m is that usually tasks not in $Nei(E_m)$ have much bigger marginal travel time ratios than tasks in $Nei(E_m)$. Thus, tasks not in $Nei(E_m)$ can be pruned and the total running time can be largely reduced. Below, we introduce the definitions of the marginal travel time ratio and the neighborhood tasks.

Definition 7 (*Marginal Travel Time Ratio*): For task group E_m and a task e, the marginal travel time ratio of assigning task e to task group E_m is defined as:

$$MTR(e|E_m) = \frac{TT(\{e\} \cup E_m) - TT(E_m)}{TT(\{e\})}, \tag{9}$$

where $TT(E_m)$ denotes the total travel time needed (including delivery time and empty run time) to deliver food orders in task group E_m as defined in Equation 4. Similarly, $TT(\{e\} \cup E_m)$ denotes the total travel time for delivering food orders in tasks $\{e\} \cup E_m$. That is, $MTR(e|E_m)$ is the marginal travel time of food orders after assigning e to E_m, divided by the original travel time needed to deliver food orders in task e. Apparently, to minimize the total travel time (our objective), we assign the task with the minimum $MTR(e|E_m)$ to the task group E_m each time, i.e. Line 10-11 in Algorithm 1.

Definition 8 (*Neighborhood Task*): A task e is a neighborhood task of task group E_m, if both e's origin $e.o$ and e's destination $e.d$ are geographically close to E_m, i.e.

$$T^p_{e.o,E_m} \le t_{nei} \text{ and } T^p_{e.d,E_m} \le t_{nei}.$$

$T^p_{e.o,E_m}$ denotes the minimum of the travel time from e's origin $e.o$ to regions in E_m. t_{nei} is a given threshold, e.g. 5 minutes.

5.2 Replacement Algorithm

The replacement algorithm, shown in Algorithm 2, is to improve the grouping result of the greedy algorithm. The main idea of the replacement algorithm is to replace the owner of a task from one task group with another task group, with the expectation that the total travel time can be reduced (our objective). The replacement algorithm stops (Line 3) when the number of continuous failed replacement attempts n_{cur} reaches the threshold n_{th} (e.g. $n_{th} = 100$). For each replacement process (Line 4-11), we have the following four steps.

First, we randomly select a task e from a random task group E_{m_1} and we remove e from E_{m_1} (Line 4-5). *Second*, for each task group E_m, we compute the *marginal travel time* $MT(e|E_m)$ (Equation 10) if assigning task e to group E_m (Line 6-7). *Third*, we find the task group E_{m^*} with the minimum marginal travel time, and assign task e to group E_{m^*} (Line 8-9). *Fourth*, if the task group E_{m^*} is exactly the task group E_{m_1}, this replacement process fails, since the total travel time is not reduced. As a result, the number of continuous failed attempts increases, i.e. $n_{cur} = n_{cur} + 1$ (Line 10). If the task group

Algorithm 2 Replacement Algorithm

```
1:  procedure REPLACE(E_1, ··· , E_M)
2:      n_cur = 0                                   ▷ Initial failed times
3:      while n_cur < n_th
4:          e ← a random task from a random E_{m_1}
5:          E_{m_1} = E_{m_1} \ {e}
6:          for m = 1, ··· , M
7:              Compute MT(e|E_m)                   ▷ Equation 10
8:          m* = arg min_{m=1,···,M} MT(e|E_m)
9:          E_{m*} = E_{m*} ∪ {e}
10:         if m* = m_1: n_cur = n_cur + 1
11:         else: n_cur = 0
12:     return E_1, ··· , E_M
```

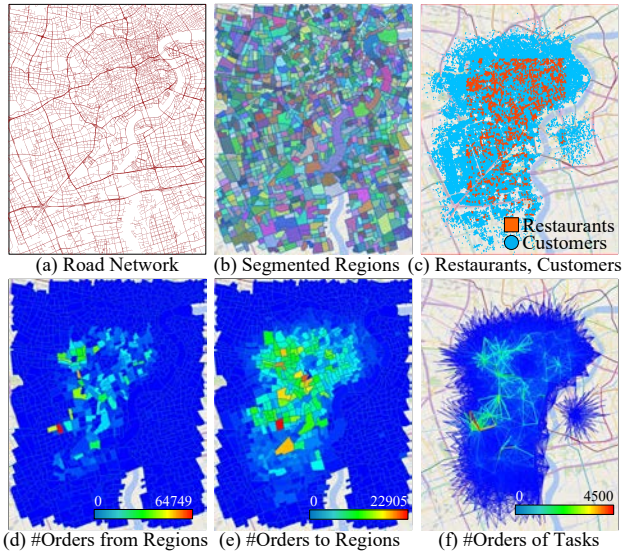
E_{m^*} is not the task group E_{m_1}, the replacement process succeeds and the total travel time has been reduced successfully. Thus, we reset the n_{cur} as $n_{cur} = 0$ (Line 11).

Definition 9 (*Marginal Travel Time*): The marginal travel time $MT(e|E_m)$ of assigning e to E_m is defined as:

$$MT(e|E_m) = TT(\{e\} \cup E_m) - TT(E_m), \tag{10}$$

where $TT(E_m)$ denotes the total travel time for task group E_m as defined in Equation 4. Thus, selecting the task group E_{m^*} with the minimum travel time for the task e is helpful for minimizing the total travel time (our objective).

6 EVALUATION



6.1 Datasets and Pre-processing Results

To evaluate our task grouping method, we use datasets collected from a real-world O2O food ordering and delivery platform. Specifically, our datasets include road network data, food order record data, and food carriers' GPS trajectory data. Below, we detail these datasets and our pre-processing results.

6.1.1 Road network. We use the road network data in city of Shanghai, China. The network contains 333,766 intersections and 440,922 road segments, as shown in Figure 8(a). As detailed before, our region segmentation is based on the road network. Specifically, using the road network, we segment the area in Figure 8(a) into regions, and after merging small and adjacent regions, we obtain 1,000 regions (i.e. $|V| = 1000$), as demonstrated in Figure 8(b). Besides, the road network data is also needed when we estimate the travel time of food carriers between any two regions.

6.1.2 Food order records. We collect one month of food order record data from users in this area. The food order records start from December 1 to December 31, 2016. For each food order record, we have the following information: 1) the time stamp at which the user ordered the food; 2) the restaurant information (ID, latitude, longitude); 3) the user information (ID, latitude, longitude); 4) the ID of the food carrier delivering the food order; and etc.

Temporal distribution of food orders. In total, our food order record dataset contains 1,852,439 food orders in total. In average, each day is with around 59,756 orders. Note that a time period is with 15 minutes, thus we have 2,976 time periods for the 31 days of food order records, i.e. $P = 2976$. The number of food orders in

(a) Road Network (b) Segmented Regions (c) Restaurants, Customers

(d) #Orders from Regions (e) #Orders to Regions (f) #Orders of Tasks

Figure 8: Regions, tasks, and food orders in an area of Shanghai city, China.

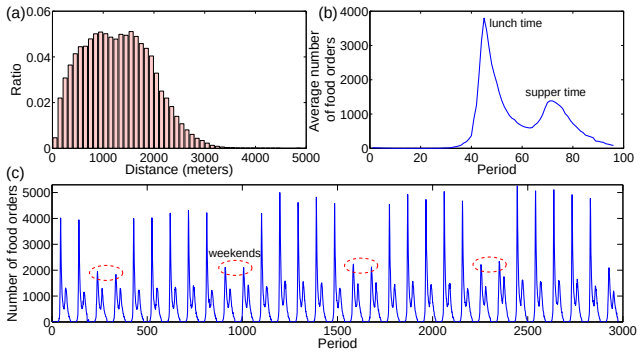


Figure 9: Statistics of food orders from real-world users.

each time period is demonstrated in Figure 9(c), and Figure 9(b) presents the average number of food orders in each period of a day. Clearly, the number of food orders has a clear daily pattern, i.e. there exist two peaks (a big one and a small one) each day. The big peak appears during the lunch time while the small peak appears during the supper time. On the other hand, there also exists a weekly pattern, i.e. weekends have much less food orders than weekdays, as shown in Figure 9(c). It implies that people more often order take-out food during their working hours, especially at noon on weekdays.

Spatial distribution of food orders. Together with the segmented regions V, the food order record data can be used to construct the task graph. Based on the food order records, using the method proposed in Section 3.2, we extract 2,980 tasks, i.e. $|E| = 2980$. And then we can construct the task graph $G = \langle V, E \rangle$, based on the obtained V and E.

The tasks (edges) are demonstrated in Figure 8(f). Task (edges) are denoted by lines in different colors based on the number of food orders in each task. That is, different colors correspond to different numbers of food orders, as the color bar shows. For example, a task denoted by red color has around 4500 food orders in the 31 days, while a task in blue color has only a few food orders.

Similar to the Figure 8(f), we can also draw the spatial distribution of food orders in each region, as shown in Figure 8(d) and (e). Specifically, Figure 8(d) demonstrates the number of food orders from each region (restaurants), while Figure 8(e) shows the number of food orders to each region (users).

Figure 8(c) shows the geographical locations of restaurants and users. Figure 9(a) presents the distribution of the geographical distances between restaurants and users. As depicted in the figure, for most food orders, the distances between restaurants and users are within 3,000 meters. This is due to that the O2O platform usually recommends restaurants within 3 kilometers to users on its web and App.

6.1.3 GPS trajectories of food carriers. The GPS trajectories of food carriers are also collected in December 2016. For each GPS record, we have a food carrier ID, a latitude, a longitude, and a time stamp. In total, there are 4,774 food carriers with 115,602,018 GPS records collected. Based on the GPS trajectory data, using the method proposed in Section 3.3, we can estimate the travel time of food carriers traveling between any two regions in V, in each time period p.

6.2 Metrics

To evaluate our task grouping method, we use four metrics, which are the average delivery time $\overline{DT}$, the average empty run time $\overline{ET}$, the average travel time $\overline{TT}$ for each food order, and the average number of regions that each task group covers. Formally, the four metrics can be formulated as

$$\overline{DT} = \frac{DT}{n_{total}}, \quad \overline{ET} = \frac{ET}{n_{total}}, \quad \overline{TT} = \frac{TT}{n_{total}}, \quad \overline{\#R} \tag{11}$$

where DT, ET and TT correspond to the total delivery time in Equation 1, the total empty run time in Equation 2 and the total travel time in Equation 3, respectively. n_{total} denotes the number of total food orders in all tasks. The smaller the first three metrics, the better a grouping result. For a task grouping result with a smaller $\overline{\#R}$, carriers in a task group can be more familiar with the locations of users and restaurants. Thus, the smaller the $\overline{\#R}$, the better.

6.3 Baselines

To demonstrate the effectiveness of our task grouping method, we compare our method with many state-of-the-art baseline methods, including NE [30], DBH [27], HDRF [17], RAND [5], and Oblivious [5, 17]. Although these baseline methods are originally designed for undirected graph edge partition problems for distributed graph computation platforms [5, 10, 11], they can be used or can be slightly modified to partition directed graph edges for our task grouping problem.

6.4 Effectiveness

We conduct extensive experiments to compare our task grouping method with the above baselines. Specifically, we use the task graph G constructed from our datasets and set $M = 300, 400, 500,$

Table 1: Comparisons with baselines (unit for $\overline{DT}, \overline{ET}, \overline{TT}$: seconds).

Task Grouping Method	$M = 300$				$M = 400$				$M = 500$			
	$\overline{DT}$	$\overline{ET}$	$\overline{TT}$	$\overline{\#R}$	$\overline{DT}$	$\overline{ET}$	$\overline{TT}$	$\overline{\#R}$	$\overline{DT}$	$\overline{ET}$	$\overline{TT}$	$\overline{\#R}$
NE	275	260	535	9.9	277	264	541	7.9	279	268	547	6.6
DBH	276	294	570	8.8	276	280	556	6.6	276	276	552	5.4
HDRF	283	267	550	7.3	285	264	549	6.0	285	258	543	5.1
RAND	292	611	903	18.4	292	603	895	13.9	292	606	898	11.3
Oblivious	284	261	545	7.5	285	252	537	5.9	285	250	535	4.9
Greedy (ours)	270	191	461	8.8	273	198	471	6.8	276	200	476	6.3
Greedy+Replace (ours)	268	180	448	8.5	271	185	456	7.0	273	186	459	6.0

i.e. grouping all tasks into 300, 400, 500 groups. To better evaluate the performance of the greedy algorithm and the replacement algorithm in our method, we first consider only the greedy algorithm (Greedy) and then add the replacement algorithm (Greedy+Replace). Experiment results are summarized in Table 1.

In terms of the first three metrics, our task grouping method defeats all baseline methods. The best baseline method is the NE method [30]. The improvement of our method over baseline methods is significant. For example, when $M = 300$, our greedy algorithm (461 seconds) has already defeated the baseline algorithms by at least 74 seconds (comparing with 535 seconds of NE method). If combined with the replacement algorithm, our method needs just 448 seconds for each food order, saving 87 seconds for each order. That is, our method can save at least 16% of average travel time for each order, comparing with the baseline methods, i.e. significantly reducing the waiting time of users.

In terms of the average number $\overline{\#R}$ of regions covered by each task group, each task group of our method covers less than 9 regions, which is a proper value. From Table 1, we can find that the smaller the M, the bigger the $\overline{\#R}$. Thus, to make carriers familiar with the locations of users and restaurants in a task group, grouping more task groups (a relatively bigger M) is better.

In the meantime, we can find that the average delivery time, empty run time, and travel time will slightly increase with the increasing of M. This is due to that the larger the M, the smaller the size of each task group, and the more difficult to improve shareability and to reduce empty run time. However, this does not mean a smaller M is better since we expect a bigger M to reduce $\overline{\#R}$. Thus, the selection of M should be a trade-off between $\overline{TT}$ and the $\overline{\#R}$ for O2O platforms in real world.

6.5 Time Efficiency

In this subsection, we study the time efficiency of our task grouping method. Our task grouping method is realized in C# and is performed on a single computer with 4 Intel Xeon E3-1225 3.31 GHz cores and 8 GB RAM. The running time of our task grouping method is presented in Figure 10. We can see that our task grouping method is efficient, using just at most 1.5 hours. It should be noted that given a city, the task grouping is only conducted from time to time, e.g. once per month or even per quarter/half of a year, as mentioned in the Introduction. Besides, our task grouping method can easily run in parallel. When more machines are used, the running time can be significantly reduced. Thus, our task grouping method is efficient enough for the applications of real-world O2O food ordering and delivery platforms.

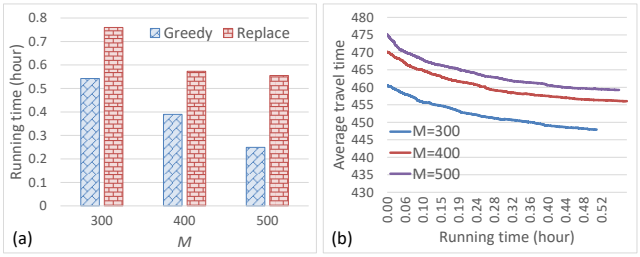

Figure 10: Running time of our task grouping method.

6.6 Balance of Task Grouping Results

The balance of each task group is also an important index. The amounts of tasks, regions, and food orders in different task groups are expected to be balancing. To this end, for a task grouping result, we use entropy to indicate the balance of tasks, regions and food orders in each task group. More specifically, we define the entropy of tasks for a task grouping result as $Ent^t = -\sum_{m=1}^{M} p_m^t \log_2 p_m^t$. p_m^t denotes the ratio of tasks in group m, i.e. the number of tasks in group m divided by the total number of tasks. Similarly, in terms of regions and food orders, we can define $Ent^r = -\sum_{m=1}^{M} p_m^r \log_2 p_m^r$ and $Ent^o = -\sum_{m=1}^{M} p_m^o \log_2 p_m^o$. p_m^r and p_m^o refer to the ratio of regions and the ratio of food orders in group m, respectively. Entropies of different task grouping methods are presented in Figure 11. As shown in the figure, our method, together with HDRF, RAND and Oblivious, achieves balancing task grouping results, with entropies approaching the optimal entropy $\log_2 300 \approx 0.829$.

7 RELATED WORK

7.1 Previous Research on Take-out Food

Previous research on take-out food (takeaway food) is conducted mainly from the socioeconomic perspective [14, 15, 23] or from the perspective of human health [21, 22]. In general, previous research mainly focuses on the influence of take-out food consumption on health. For example, in [15], Miura et al. studied the relationship between the consumption of take-out food with the socioeconomic differences in fruit and vegetable intake. Based on their analysis, they found that less educated people are more likely to consume

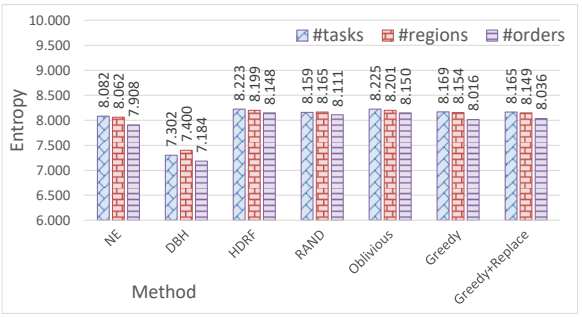

Figure 11: Entropies of tasks, regions, and orders. $M = 300$.

less healthy take-out food, containing fewer fruit and vegetables, and that consuming less healthy take-out food may result in the socioeconomic differences in fruit and vegetable intake. For another example, in literature [22], Smith et al. investigated the relationship between the take-out food consumption with diet quality and abdominal obesity. This work concluded that consuming take-out food twice a week or more may lead to poor diet quality and moderate abdominal obesity in young men and women.

Different with the above work, our work aims to improve the take-out food delivery efficiency for O2O take-out food ordering and delivery platforms, from the perspective of computer science, using data-driven methods. Consuming take-out food frequently may lead to some health concerns, however more and more healthy take-out food can be ordered. Since massive food orders are issued each day, to improve the food delivery efficiency is essential for O2O platforms. To the best of our knowledge, we are the first to study the take-out food from this perspective.

7.2 Graph Edge Partition

From the perspective of the problem formulation, our task grouping problem is formulated as a graph edge partition problem (a.k.a. graph vertex-cut problem) [2, 5, 12, 17, 27, 30]. Previous graph edge partition problems are mainly studied for large-scale distributed graph computation platforms, e.g. PowerGraph [5], GraphLab [10], Pregel [11]. Specifically, they partition a large-scale computation graph to different machines and each machine runs a part of the graph in parallel, so as to speed up the whole computation process. Their objective is to minimize the number of replicated vertices in different machines so as to lower the communication cost between machines. Many heuristic algorithms [5, 12, 17, 27, 30] have been proposed in recent years for graph edge partition problems. For example, in [30], Zhang et al. proposed a neighborhood expansion-based heuristic algorithm to do the graph edge partition. In [5], Gonzalez et al. proposed a random algorithm and some greedy algorithms. In [17], Petroni et al. presented a high-degree replicated first algorithm. Besides the graph edge partition problems, graph vertex grouping problems (a.k.a. graph edge-cut problems) [2, 3, 8] were also widely studied, which is to partition vertices (instead of edges) in a graph into a given number of groups.

As discussed before, although our task grouping problem is a graph edge partition problem, due to the different scenarios and objectives, previous graph edge partition algorithms cannot apply well to our problem. Actually, our experiment results have also validated that our proposed task grouping algorithm can achieve much better performance than the previous graph edge partition algorithms (see Table 1).

8 CONCLUSION AND FUTURE WORK

In this paper, we proposed a task grouping method for O2O take-out food ordering and delivery platforms, consisting of two main contents. First, we formulated the factors affecting the food delivery efficiency and provided a combined objective to guide our task grouping. Second, we presented effective heuristic algorithms for grouping tasks, including a greedy algorithm and a replacement algorithm. Using our task grouping method, the food delivery efficiency can be highly improved. According to the experiment results, our method is able to group tasks into task groups with high shareability (i.e. low delivery time) and low empty run time. Comparing with the previous graph edge partition algorithms, our method is able to save at least 16% (87 seconds) of average travel time for each food order, which is a significant improvement. As a result, with our research, O2O take-out food ordering and delivery platforms can largely improve their food delivery efficiency, thus providing better food delivery services for users. In the future, as mentioned in the Introduction, we plan to study the food carrier allocation problem and the real-time food carrier dispatching problem. Note that these two problems also significantly affect the food delivery efficiency of O2O food ordering and delivery platforms.

ABSTRACT

Community detection refers to the task of discovering groups of vertices sharing similar properties or functions so as to understand the network data. With the recent development of deep learning, graph representation learning techniques are also utilized for community detection. However, the communities can only be inferred by applying clustering algorithms based on learned vertex embeddings. These general cluster algorithms like K-means and Gaussian Mixture Model cannot output much overlapped communities, which have been proved to be very common in many real-world networks. In this paper, we propose CommunityGAN, a novel community detection framework that jointly solves overlapping community detection and graph representation learning. First, unlike the embedding of conventional graph representation learning algorithms where the vector entry values have no specific meanings, the embedding of CommunityGAN indicates the membership strength of vertices to communities. Second, a specifically designed Generative Adversarial Net (GAN) is adopted to optimize such embedding. Through the minimax competition between the motif-level generator and discriminator, both of them can alternatively and iteratively boost their performance and finally output a better community structure. Extensive experiments on synthetic data and real-world tasks demonstrate that CommunityGAN achieves substantial community detection performance gains over the state-of-the-art methods.

1 INTRODUCTION

Network is a powerful language to represent relational information among data objects from social, natural and academic domains [32]. One way to understand network is to identify and analyze groups of vertices which share highly similar properties or functions. Such groups of vertices can be users from the same organization in social networks [16], proteins with similar functionality in biochemical networks [12], and papers from the same scientific fields in citation networks [20]. The research task of discovering such groups is known as the community detection problem [36].

Graph representation learning, also known as network embedding, which aims to represent each vertex in a graph as a low-dimensional vector, has been consistently studied in recent years. The application of deep learning algorithms including Skip-gram [8, 19] and convolutional network [10] has improved the efficiency and performance of graph representation learning dramatically. Moreover, Generative Adversarial Nets (GAN) has also been introduced for learning better graph representation [25]. The learned vertex representation vectors can benefit a wide range of network analysis tasks including link prediction [6, 26], recommendation [34, 35], and node classification [23].

However, there still exists many limitations for the application of such embedding in overlapping community detection problems because of the dense overlapping of communities. Generally, the useful information of vertex embedding vectors is the relevant distance of these vectors, while the specific value in vertex embedding vectors has no meanings. Thus, given the representation vectors of the vertices, one has to adopt other algorithms like logistic regression to accomplish the real-world application tasks. To detect communities, a straightforward way is to run some clustering algorithms in the vector space. However, in some real-world datasets, one vertex may belong to tens of communities simultaneously [29, 30], while most clustering algorithms cannot handle such dense overlapping. In recent years, some researchers try to perform the community detection and network embedding simultaneously in a unified framework [3, 27] but still fail to solve the dense overlapping problem.

In this paper, we propose *CommunityGAN*, a novel community detection framework that jointly solves overlapping community detection and graph representation learning. The input-output overview of CommunityGAN is shown in Figure 1. With CommunityGAN, we aim to learn network embeddings like AGM (Affiliation Graph Model) through a specifically designed GAN. AGM [30, 31] is a framework which can model densely overlapping community structures. It assigns each vertex-community pair a nonnegative factor which represents the degree of membership of the vertex to the community. Thus, the strengths of membership from a vertex to all communities compose the representation vector of it.

Moreover, in recent years, motifs have been proved as essential features in community detection tasks [11]. Thus in this paper, unlike most previous works considering relationship between only

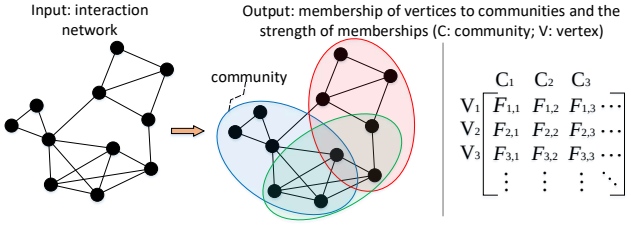

Figure 1: The input-output overview of CommunityGAN.

two vertices (the relationship between a center vertex and one of the other vertices in a window), we try to generate and discriminate motifs. Specifically, CommunityGAN trains two models during the learning process: 1) a generator $G(s|v_c)$, which tries to generate the most likely vertex subset s to compose a specified kind of motif; 2) a discriminator $D(s)$, which attempts to distinguish whether the vertex subset s is a real motif or not. In the proposed CommunityGAN, the generator G and the discriminator D act as two players in a minimax game. Competition in this game drives both of them to improve their capability until the generator is indistinguishable from the true connectivity distribution.

The contributions of our work are threefold:

- We combine AGM and GAN in a unified framework, which achieves both the outstanding performance of GAN and the direct vertex-community membership representation in AGM.
- We study the motif distribution among ground-truth communities and analyze how they can help improve the quality of detected communities.
- We propose a novel implementation for motif generation called *Graph AGM*, which can generate the most likely motifs with graph structure awareness in a computationally efficient way.

Empirically, two experiments were conducted on a series of synthetic data, and the results prove: 1) the ability of CommunityGAN to solve dense overlapping problem; 2) the efficacy of motif-level generation and discrimination. Additionally, to complement these experiments, we evaluate CommunityGAN on two real-world scenarios, i.e., community detection and clique prediction, using five real-world datasets. The experiment results show that CommunityGAN substantially outperforms the state-of-the-art methods in the field of community detection and graph representation learning. Specifically, CommunityGAN outperforms baselines by 7.9% to 21.0% in terms of F1-Score for community detection. Additionally, in 3-clique and 4-clique prediction tasks, CommunityGAN improves AUC score to at least 0.990 and 0.956 respectively. The superiority of CommunityGAN relies on its joint advantage of particular embedding design, adversarial learning and motif-level optimization.

2 RELATED WORK

Community Detection. Many community detection algorithms have been proposed from different perspectives. One direction is to design some measure of the quality of a community like modularity, and community structure can be uncovered by optimizing such measures [17, 28]. Another direction is to adopt the generative models to describe the generation of the graphs, and the communities can be inferred by fitting graphs to such models [9, 36]. Moreover, some models focus on the graph adjacency matrix and output the relationship between vertices and communities by adopting matrix factorization algorithms on the graph adjacency matrix [14, 31]. These models often consider the dense community overlapping problem and detect overlapping communities. However, the performance of these methods are restricted by performing pair reconstruction with bi-linear models.

Graph representation learning. In recent years, several graph representation learning algorithms have been proposed. For example, DeepWalk [19] shows the random walk in a graph is similar to the text sequence in natural language. Thus it adopts Skip-gram, a word representation learning model [15], to learn vertex representation. Node2vec [8] further extends the idea of DeepWalk by proposing a biased random walk algorithm, which provides more flexibility when generating the sampled vertex sequence. LINE [24] first learns the vertex representation preserving both the first and second order proximities. Thereafter, GraRep [2] applies different loss functions defined on graphs to capture different k-order proximities and the global structural properties of the graph. Moreover, GAN has also been introduced into graph representation learning. GraphGAN [25] proposes a unified adversarial learning framework, which naturally captures structural information from graphs to learn the graph representation. ANE [5] utilizes GAN as a regularizer for learning stable and robust feature extractor. However, all of the above algorithms focus on general graph representation learning. For community detection tasks, we have to adopt other clustering algorithms on vertex embeddings, which cannot handle the dense community overlapping problem. Compared to above mentioned methods, our CommunityGAN can output the membership of vertices to communities directly.

Unified framework for graph representation learning and community detection. In recent years, some unified frameworks for both graph representation learning and community detection have been proposed. Wang et al. [27] developed a modularized nonnegative matrix factorization algorithm to preserve both vertex similarity and community structure. However, because of the complexity of matrix factorization, this model cannot be applied on many real-world graphs containing millions of vertices. Cavallari et al. [3] designed a framework that jointly solves community embedding, community detection and node embedding together. However, although the community structures and vertex embeddings are optimized together, the community structures are still inferred through a clustering algorithm (e.g., Gaussian Mixture Model) based on the vertex embedding, which means the dense community overlapping problem cannot be avoided.

3 EMPIRICAL OBSERVATION

In this section, data analysis of the relationship between motifs and communities is presented, which motivates the development of CommunityGAN. We first describe the network datasets with

Table 1: Dataset statistics. V: number of vertices, E: number of edges, T: number of 3-clique (triangle), C: number of communities, A: community memberships per vertex.

Amazon	6E-6	0.53	0	0.18	0	0.05

ground-truth communities and then present our empirical observations.

3.1 Datasets

We study the five networks proposed by Yang and Leskovec [30], where LiveJournal, Orkut and Youtube are all online social networks, while DBLP and Amazon are collaboration network and product network respectively. Table 1 provides the statistics of these networks.

3.2 Empirical Observations

Now we present our empirical observations by answering two critical questions. How do the communities contribute to the generation of motifs? What is the change in motif generation with communities overlapping?

First, we investigate the relationship between motif generation and community structure. For each time, we randomly select one community. Then we sample 2/3/4 vertices from this community and judge whether they could compose a motif or not. We repeat this process for billions of times and get the occurrence probability of motifs in one community. We compare this value with the motif occurrence probability in the whole network. Because, in this paper, we mostly focus on a particular kind of motifs (clique), we only demonstrate the occurrence probability of 2/3/4-vertex cliques. As shown in Table 2, the average occurrence probabilities of cliques for vertices in one community are much higher than that for vertices randomly selected from the whole network. This observation demonstrates that the occurrence of motifs is strongly correlated to the community structure.

Next, we study the influence of community overlapping on the generation of motifs. Yang and Leskovec [31] have conducted the

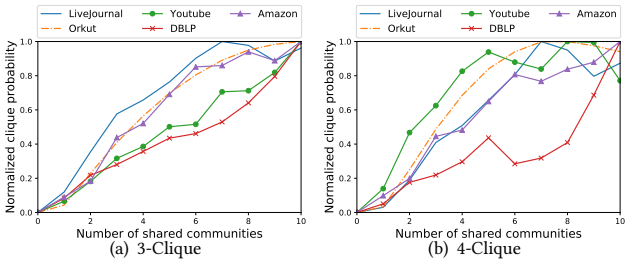

Figure 2: Normalized probability for vertices to be a clique as a function of number of shared communities. Probabilities are scaled so that maximum value is one.

relationship of 2-clique (edge) probability with community overlapping that the more communities two vertices have in common, the higher probability for them to be 2-clique. In this paper, we further study the influence of community overlapping on the generation of 3-clique and 4-clique. As shown in Figure 2, similar to 2-clique, the probability curve increases in the overall trend as the number of shared communities increases. Such observation accords with the base assumption of AGM framework that vertices residing in communities' overlaps are more densely connected to each other than the vertices in a single community. So we can extend the AGM from edge generation to clique generation, and the details will be explained in §4.4.

4 METHODOLOGY

Notation. In this paper, all vectors are column vectors and denoted by lower-case bold letters like $\mathbf{d}_v$ and $\mathbf{g}_v$. Calligraphic letters are used to represent sets like $\mathcal{V}$ and $\mathcal{E}$. And for simplicity, the corresponding normal letters are used to denote their size like $V = |\mathcal{V}|$. The details of notations in this paper are listed in Table 3.

In this section, we introduce the framework of CommunityGAN and discuss the implementation and optimization of the generator and discriminator in CommunityGAN.

4.1 CommunityGAN Framework

Let $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{M})$ represent the studied graph, where $\mathcal{V} = \{v_1, \ldots, v_V\}$ is a set of vertices, $\mathcal{E} = \{e_{ij}\}_{i,j=1}^{V}$ is the set of edges among the vertices, and $\mathcal{M}$ is the set of motifs in graph $\mathcal{G}$. In this paper, notably, we only focus on a particular kind of motifs: cliques. Moreover, the D and G are also designed to discriminate and generate cliques. For a given vertex v_c, we define $M(v_c)$ as the set of motifs in the graph covering v_c, whose size is generally much smaller than the total number of vertices V. Moreover, we define conditional probability $p_{true}(m|v_c)$ as the preference distribution of motifs covering v_c over all other motifs in $\mathcal{M}$. Thus $M(v_c)$ can be seen as a set of observed motifs drawn from $p_{true}(m|v_c)$. Given the graph $\mathcal{G}$, we aim to learn the following two models: **Generator** $G(s|v_c; \theta_G)$, which tries to approximate $p_{true}(m|v_c)$, and generate (or select) subsets of vertices from $\mathcal{V}$ covering v_c most likely to be real motifs; and **Discriminator** $D(s, \theta_D)$, which aims to estimate the probability that a vertex subset s is a real motif, i.e., comes from $\mathcal{M}$.

Table 3: Notations used in this paper

Symbol	Description
$\mathcal{G}$	The studied graph
$\mathcal{V}$, $\mathcal{E}$, $\mathcal{M}$, $\mathcal{C}$	Set of vertices, edges, motifs, communities in graph $\mathcal{G}$
V, E, M, C	Number of vertices, edges, motifs, communities in graph $\mathcal{G}$
$M(v_c)$	Set of motifs covering v_c in graph $\mathcal{G}$
$N(v_c)$	Set of neighbors of vertex v_c in graph $\mathcal{G}$
s	The subset of vertices from $\mathcal{V}$
$p_{true}(m\|v_c)$	The preference distribution of motifs covering v_c over all other motifs in $\mathcal{M}$
$G(s\|v_c;\theta_G)$	Generator trying to generate vertex subsets from $\mathcal{V}$ covering v_c most likely to be real motifs
$D(s,\theta_D)$	Discriminator aiming to estimate the probability that a vertex subset s is a real motif
$\mathbf{d}_v$, $\mathbf{g}_v \in \mathbb{R}_+^C$	Nonnegative C-dimensional representation vector of vertex v in discriminator D and generator G, respectively
θ_D, $\theta_G \in \mathbb{R}_+^{V\times C}$	The union of all $\mathbf{d}_v$ and $\mathbf{g}_v$, respectively
$F_{uc} \in \mathbb{R}_+$	The nonnegative strength for vertex u to be affiliated to community c used in AGM
$p_c(v_1, v_2, \ldots, v_m)$	The probability of m vertices v_1 to v_m to be a clique through of community c
$p(v_1, v_2, \ldots, v_m)$	The probability of m vertices v_1 to v_m to be a clique through of any one community
$\odot(F_{v_1}, F_{v_2}, \ldots, F_{v_m})$	Sum of the entrywise product from F_{v_1} to F_{v_m}, i.e., $\sum_{c=1}^{C}\prod_{i=1}^{m} F_{v_i c}$
$G_v(v_{s_m}\|v_{s_1}, \ldots, v_{s_{m-1}})$	The vertex generator based on selected vertices $v_{s_1}, \ldots, v_{s_{m-1}}$ in vertex subset generation process
$p_{v_v}(v_i\|v_c)$	The relevance probability of v_i given v_c with root v_v in random walk process

The generator G and discriminator D are combined by playing a minimax game: generator G would try to perfectly approximate $p_{true}(m|v_c)$ and generate the most likely vertex subsets similar to real motifs covering v_c to fool the discriminator, while discriminator D would try to distinguish between ground-truth motifs from $p_{true}(m|v_c)$ and the ones generated by G. Formally, G and D act as two opponents in the following two-player minimax game with the joint value function $V(G, D)$:

$$\min_{\theta_G}\max_{\theta_D} V(G,D) = \sum_{c=1}^{V}\Big(\mathbb{E}_{m\sim p_{true}(\cdot|v_c)}[\log D(m;\theta_D)] + \mathbb{E}_{s\sim G(s|v_c;\theta_G)}[\log(1-D(s;\theta_D))]\Big). \tag{1}$$

Based on Eq. (1), the optimal G and D can be learned by alternatively maximizing (D) and minimizing (G) the value function $V(G, D)$. The CommunityGAN framework is illustrated in Figure 3. Discriminator D is trained with positive samples from $p_{true}(\cdot|v_c)$ and negative samples from $G(\cdot|v_c;\theta_G)$, and generator G is updated with policy gradient technique [22] under the guidance of D (detailedly described later in this section). Competition between G and D drives both of them to improve until G is indistinguishable from the true motif distribution p_{true}.

4.2 CommunityGAN Optimization

Given positive samples from true motif distribution p_{true} and negative samples from the generator G, the discriminator aims to maximize the log-probability of correctly classifying these samples, which could be solved by gradient ascent if D is differentiable for θ_D, i.e.,

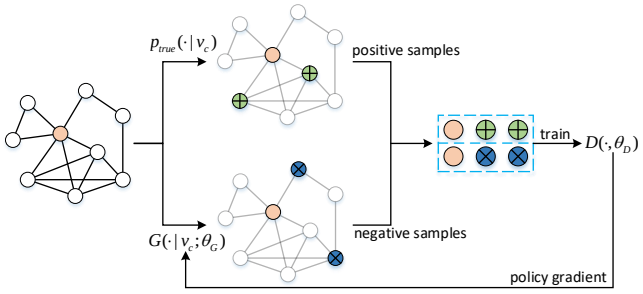

Figure 3: Framework of CommunityGAN

$$\nabla_{\theta_D} V(G,D) = \sum_{c=1}^{V}\Big(\mathbb{E}_{m\sim p_{true}(\cdot|v_c)}[\nabla_{\theta_D}\log D(m;\theta_D)] + \mathbb{E}_{s\sim G(s|v_c;\theta_G)}[\nabla_{\theta_D}\log(1-D(s;\theta_D))]\Big). \tag{2}$$

In contrast to the discriminator, the objective of the generator is to minimize the log-probability that the discriminator correctly distinguishes samples from G. Because the sampling of s is discrete, we follow [21, 25, 33] to compute the gradient of $V(G, D)$ with respect to θ_G by policy gradient:

$$\begin{aligned}\nabla_{\theta_G} V(G,D) &= \nabla_{\theta_G}\sum_{c=1}^{V}\mathbb{E}_{s\sim G(\cdot|v_c)}[\log(1-D(s))] \\ &= \sum_{c=1}^{V}\mathbb{E}_{s\sim G(\cdot|v_c)}[\nabla_{\theta_G}\log G(s|v_c)\log(1-D(s))].\end{aligned} \tag{3}$$

4.3 A Naive Implementation of D and G

A naive implementation of the discriminator and generator is based on sigmoid and softmax functions, respectively.

For the discriminator D, intuitively we can define it as the multiplication of the sigmoid function of the inner product of every two vertices in the input vertex subset s:

$$D(s) = \prod_{(u,v)\in s,\, u\neq v}\sigma(\mathbf{d}_u^{\top}\cdot\mathbf{d}_v), \tag{4}$$

where $\mathbf{d}_u, \mathbf{d}_v \in \mathbb{R}^k$ are the k-dimensional representation vectors for discriminator D of vertices u and v respectively, and θ_D is the union of all $\mathbf{d}_v$'s.

For the implementation of G, to generate a vertex subset s covering vertex v_c, we can regard the subset as a sequence of vertices $(v_{s_1}, v_{s_2}, \ldots, v_{s_m})$ where $v_{s_1} = v_c$. Then the generator G can be defined as follows:

$$\begin{aligned}&G(s|v_c) \\ =&G_v(v_{s_2}|v_{s_1})G_v(v_{s_3}|v_{s_1}, v_{s_2})\cdots G_v(v_{s_m}|v_{s_1}, \ldots, v_{s_{m-1}}).\end{aligned} \tag{5}$$

Notably, in Eq. (5), the generation of v_{s_m} is based on vertices from v_{s_1} to $v_{s_{m-1}}$, not only on $v_{s_{m-1}}$. Because if we generate v_{s_m} based only on $v_{s_{m-1}}$, it will be very likely that vertex v_{s_m} and the other vertices belong to different communities. For example, vertices from v_{s_1} to $v_{s_{m-1}}$ are students in one university, while vertex v_{s_m} is the parent of $v_{s_{m-1}}$. Simply, we can know the probability of the vertex subset s being a clique will be very low. Thus, we generate v_{s_m} based on all the vertices from v_{s_1} to $v_{s_{m-1}}$.

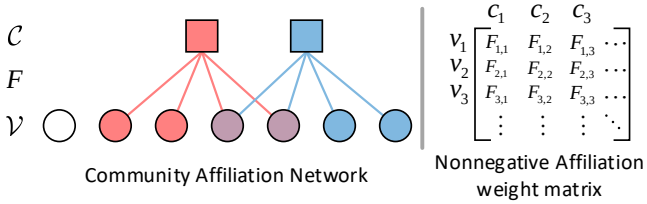

Figure 4: AGM framework. $\mathcal{V}$: vertices; C: communities; F: affiliation of vertices to communities.

For the implementation of the vertex generator G_v, straightforwardly, we can define it as a softmax function over all other vertices, i.e.,

$$G_v(v_{s_m}|v_{s_1},\ldots,v_{s_{m-1}}) = \frac{\exp(\sum_{i=1}^{m-1}\mathbf{g}_{v_{s_m}}^\top \mathbf{g}_{v_{s_i}})}{\sum_{v\notin(v_{s_1},\ldots,v_{s_{m-1}})}\exp(\sum_{i=1}^{m-1}\mathbf{g}_v^\top \mathbf{g}_{v_{s_i}})}, \tag{6}$$

where $\mathbf{g}_v \in \mathbb{R}^k$ is the k-dimensional representation vectors for generator G_v of vertex v, and θ_G is the union of all $\mathbf{g}_v$'s.

4.4 Graph AGM

Sigmoid and softmax function provide concise and intuitive definitions for the motif discrimination in D_s and vertex generation in G_v, but they have three limitations in community detection task: 1) To detect community, after learning the vertex representation vectors based on Eq. (4) and (6), we still need to adopt some clustering algorithms to detect the communities. According to [29], the overlap is indeed a significant feature of many real-world social networks. Moreover, in [30], the authors showed that in some real-world datasets, one vertex might belong to tens of communities simultaneously. However, general clustering algorithms cannot handle such dense overlapping. 2) The calculation of softmax in Eq. (6) involves all vertices in the graph, which is computationally inefficient. 3) The graph structure encodes rich information of proximity among vertices, but the softmax in Eq. (6) completely ignores it.

To address these problems, in CommunityGAN we propose a novel implementation for the discriminator and generator, which is called Graph AGM.

AGM (Affiliation Graph Model) [30, 31] is based on the idea that communities arise due to shared group affiliation, and views the whole network as a result generated by a community-affiliation graph model. The framework of AGM is illustrated in Figure 4, which can be either seen as a bipartite network between vertices and communities, or written as a nonnegative affiliation weight matrix. In AGM, each vertex could be affiliated to zero, one or more communities. If vertex u is affiliated to community c, there will be a nonnegative strength F_{uc} of this affiliation. For any community $c \in C$, it connects its member vertices u, v with probability $1-\exp(-F_{uc}\cdot F_{vc})$. Moreover, each community c creates edges independently. If the pair of vertices u, v are connected multiple times through different communities, the probability is $1-\exp(-\sum_c F_{uc}\cdot F_{vc})$. So that the probability that vertices u, v are connected (through any possible communities) is $p(u,v) = 1-\exp(-F_u^\top \cdot F_v)$, where F_u and F_v are the nonnegative C-dimensional affiliation vectors for vertices u and v respectively.

We extend AGM from edge generation to motif generation. For any m vertices v_1 to v_m, we assume that the probability of them to be a clique through of community c is defined as $p_c(v_1, v_2, \ldots, v_m) = 1-\exp(-\prod_{i=1}^m F_{v_i c})$. Then the probability that these m vertices compose a clique through any possible communities can be calculated via

$$\begin{aligned} p(v_1, v_2, \ldots, v_m) &= 1-\prod_c (1-p_c(v_1, v_2, \ldots, v_m)) \\ &= 1-\exp(-\odot(F_{v_1}, F_{v_2}, \ldots, F_{v_m})), \end{aligned} \tag{7}$$

where $\odot(F_{v_1}, F_{v_2}, \ldots, F_{v_m})$ means the sum of the entrywise product from F_{v_1} to F_{v_m}, i.e., $\sum_{c=1}^C \prod_{i=1}^m F_{v_i c}$.

Then the discriminator, which was defined as the product of sigmoid in a straightforward way, can be redefined as

$$D(s) = 1-\exp(-\odot(\mathbf{d}_{v_1}, \mathbf{d}_{v_2}, \ldots, \mathbf{d}_{v_m})), \tag{8}$$

where $\mathbf{d}_v \in \mathbb{R}^C$ is the nonnegative C-dimensional representation vectors of vertex v for discriminator D, and θ_D is the union of all $\mathbf{d}_v$'s.

Moreover, the generator G_v can be redefined as the softmax function over all other possible vertices to compose a clique with $m-1$ chosen vertices:

$$\begin{aligned} &G_v(v_{s_m}|v_{s_1},\ldots,v_{s_{m-1}}) \\ &= \frac{1-\exp(-\odot(\mathbf{g}_{v_{s_1}},\ldots,\mathbf{g}_{v_{s_m}}))}{\sum_{v\notin(v_{s_1},\ldots,v_{s_{m-1}})} 1-\exp(-\odot(\mathbf{g}_{v_{s_1}},\ldots,\mathbf{g}_{v_{s_{m-1}}},\mathbf{g}_v))}, \end{aligned} \tag{9}$$

where $\mathbf{g}_v \in \mathbb{R}^C$ is the nonnegative C-dimensional representation vectors of vertex v for generator G_v, and θ_G is the union of all $\mathbf{g}_v$'s. With this setting, the learned vertex representation vectors $\mathbf{g}_v$ will represent the affiliation weight between vertex v and communities, which means we need no additional clustering algorithms to find the communities and the first aforementioned limitation is omitted.

To further overcome the other two limitations, inspired by [25], we design graph AGM as follows. To calculate $G_v(v_{s_m}|v_{s_1},\ldots,v_{s_{m-1}})$, we first assume there is a virtual vertex v_v which is connected to all the vertices in the union of neighbors of vertices from v_{s_1} to $v_{s_{m-1}}$, i.e., $N(v_v) = N(v_{s_1}) \cup \cdots \cup N(v_{s_{m-1}})$ where $N(v)$ represents the set of neighbors of vertex v. Moreover, we assign $\mathbf{g}_{v_v} = \mathbf{g}_{v_{s_1}} \circ \cdots \circ \mathbf{g}_{v_{s_{m-1}}}$, i.e., the representation vector of v_v is the entrywise product of the representation vectors of vertices from v_{s_1} to $v_{s_{m-1}}$. For simplicity, we substitute $G_v(v_{s_m}|v_{s_1},\ldots,v_{s_{m-1}})$ with $G_v(v_{s_m}|v_v)$. Then we adopt random walk starting from the virtual vertex v_v based on a well designed probability distribution (Eq. (10)). During the process of random walk, if the currently visited vertex is v and generator G decides to visit v's previous vertex, then v is chosen as the generated vertex and the random walk process stops. The whole process for generating a vertex subset with the size of 3 is illustrated in Figure 5.

Moreover, in the random walk process, we wish the walk path is always relevant to the root vertex v_v for maximizing the probability of the generated vertex subset to be a motif. So that for a given vertex v_c and one of its neighbors $v_i \in N(v_c)$, we define the relevance probability of v_i given v_c as

$$p_{v_v}(v_i|v_c) = \frac{1-\exp(-\odot(\mathbf{g}_{v_i}, \mathbf{g}_{v_c}, \mathbf{g}_{v_v}))}{\sum_{v_j\in N(v_c)} 1-\exp(-\odot(\mathbf{g}_{v_j}, \mathbf{g}_{v_c}, \mathbf{g}_{v_v}))}, \tag{10}$$

which is actually a softmax function over $N(v_c)$ for composing clique with vertices v_v and v_c.

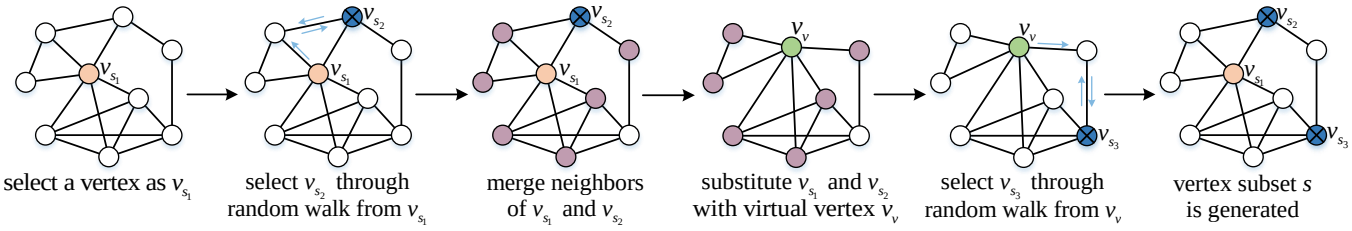

Figure 5: The generation process for vertex subset s. Blue arrows indicate the path of random walk. At the two blue vertices, because the vertex generator decides to visit the previous vertex, the random walk finishes and the blue vertices are selected.

Algorithm 1: CommunityGAN framework

Input: number of communities c, size of discriminating samples m, size of generating samples n.
Output: generator $G(s|v_c;\theta_G)$, discriminator $D(s,\theta_D)$.

```
Initialize and pre-train G(s|v_c;θ_G) and D(s,θ_D);
while CommunityGAN not converge do
    for G-steps do
        Generate n vertex subsets from G(s|v_c;θ_G) for each vertex v_c based on the random walk process;
        Update θ_G according to Eq. (3), (5), (10) and (11);
    end
    for D-steps do
        Sample m positive vertex subsets from p_true and s negative vertex subsets from G(s|v_c;θ_G) for each vertex v_c;
        Update θ_D according to Eq. (2) and (8);
    end
end
return G(s|v_c;θ_G) and D(s,θ_D);
```

If we denote the path of random walk as $P_r = (v_{r_1}, v_{r_2}, \ldots, v_{r_n})$ where $v_{r_1} = v_v$, the probability for selecting this path will be $p_{v_v}(v_{r_{n-1}}|v_{r_n}) \cdot \prod_{i=1}^{n-1} p_{v_v}(v_{r_{i+1}}|v_{r_i})$. In the policy gradient, we regard the selection of this path as an action and the target is to maximize its reward from D. Thus, although there may be multiple paths between v_{r_1} and v_{r_n}, if we have selected the path P_r, we will optimize the policy gradient on it and neglect other paths. In other words, if we select the path P_r, we assign $G_v(v_{s_m}|v_v)$ as follows:

$$G_v(v_{s_m}|v_v) = p_{v_v}(v_{r_{n-1}}|v_{r_n}) \cdot \prod_{i=1}^{n-1} p_{v_v}(v_{r_{i+1}}|v_{r_i}). \tag{11}$$

Finally, the overall solution of CommunityGAN is summarized in Algorithm 1.

4.5 Other Issues

Model Initialization. We have two methods to initialize the generator G and the discriminator D. The first is that we can deploy AGM model on the graph to learn a community affiliation vector F_i for each vertex v_i, and then we can set $g_{v_i} = d_{v_i} = F_i$ directly. The second is that we can use locally minimal neighborhoods [7] to initialize θ_G and θ_D. We can regard each vertex v_i along with its neighbors $N(v_i)$, denoted as $C(v_i)$, as a community. Community $C_(v_i)$ is called locally minimal if $C_(v_i)$ has lower conductance than all the $C_(v_j)$ for vertices v_j who are connected to vertex v_i. Gleich and Seshadhri [7] have empirically showed that the locally minimal neighborhoods are good seed sets for community detection algorithms. For a node v_i who belongs to a locally minimal neighborhood c, we initialize $F_{v_i c} = 1$, otherwise $F_{v_i c} = 0$.

The second method can save the training time of AGM on the graph. However, we find that the performance of such initialization is a little lower than the first initialization. To achieve best performance, in this paper, we choose to adopt the first initialization method. Moreover, in the efficiency analysis experiment (refer to §6.4), the training time of CommunityGAN includes the time of the pre-training process.

Determining community membership. After learning parameters θ_G and θ_D, we need to determine the "hard" community membership of each node. We achieve this by thresholding θ_G and θ_D with a threshold δ. The basic intuition is that if two nodes belong to the same community c, then the probability of having a link between them through community c should be larger than the background edge probability $\epsilon = 2E/V(V-1)$. Following this idea, we can obtain the threshold δ as below:

$$1 - \exp(-\delta^2) = \epsilon \Rightarrow \delta = \sqrt{-\log(1-\epsilon)} \tag{12}$$

With δ obtained, we consider vertex v_i belonging to community c if $\mathbf{g}_{v_i c} \geq \delta$ or $\mathbf{d}_{v_i c} \geq \delta$ for generator G and discriminator D respectively.

Choosing the number of communities. We follow the method proposed in [1] to choose the number of communities C. Specifically, we reserve 20% of links for validation and learn the model parameters with the remaining 80% of links for different C. After that, we use the learned parameters to predict the links in validation set and select the C with the maximum prediction score as the number of communities.

5 SYNTHETIC DATA EXPERIMENTS

In this section, in order to evaluate the effectiveness of CommunityGAN, we conduct a series of experiments based on synthetic datasets. Specifically, we conduct two experiments to prove: 1) the ability of CommunityGAN to solve the dense overlapping problem; 2) the efficacy of motif-level generation and discrimination. To simulate the real-world graphs with ground-truth overlapping communities, we adopt CKB Graph Generator - a method that can generate large random social graphs with realistic overlapping community structure [4] - to generate such synthetic graphs. The

Table 4: Synthetic Graphs statistics. V: number of vertices, E: number of edges, C: number of communities, A: average number of community memberships per vertex, P: percentage of communities that have overlapping with others

Graph	V	E	C	A	P

ckb-267	1123	65813	381	4.57	100%

code of CommunityGAN (including pre-training model) and demo datasets are available online[1].

5.1 Evaluation Metric

The availability of ground-truth communities allows us to quantitatively evaluate the performance of community detection algorithms. Given a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{M})$, we denote the set of ground-truth communities as C^* and the set of detected communities as $\hat{C}$, where each ground-truth community $c_i^* \in C^*$ and each detected community $\hat{c}_i \in \hat{C}$ are both defined by a set of their member nodes. We consider the average F1-Score as the metric to measure the performance of the detected communities $\hat{C}$. To compute the F1-Score between detected communities and ground-truth communities, we need to determine which $c_i^* \in C^*$ corresponds to which $\hat{c}_j \in \hat{C}$. We define final F1-Score as the average of the F1-score of the best-matching ground-truth community to each detected community, and the F1-score of the best-matching detected community to each ground-truth community:

$$F1(C^*, \hat{C}) = \frac{1}{2}\left(\frac{1}{C^*}\sum_{c_i^* \in C^*} \max_{\hat{c}_j \in \hat{C}} F1(c_i^*, \hat{c}_j) + \frac{1}{\hat{C}}\sum_{\hat{c}_i \in \hat{C}} \max_{c_j^* \in C^*} F1(c_j^*, \hat{c}_i)\right) \tag{13}$$

The higher F1-Score means that the detected communities are more accurate and have better qualities.

5.2 Datasets

To prove CommunityGAN's ability to solve the dense overlapping problem, we utilize the CKB Graph Generator to generate synthetic graphs with ground-truth communities of different overlapping levels. All the parameters of CKB are set as default except two: 'power law exponent of user-community membership distribution (β_1)' and 'power law exponent of community size distribution (β_2)' [4]. By setting $\beta_1 = \beta_2 = 2.9, 2.8, 2.76, 2.73, 2.7, 2.67$, we can get a series of graphs with different levels of community overlapping. The detailed statistics of these graphs are shown in Table 4. We can see that the percentages of overlapped communities (denoted by P) are all 100%, indicating that all the communities overlap more or less with others. Besides, with the decrease of β_1 and β_2, the average number of community memberships per vertex (denoted by A) increases, which means the density of community overlapping is becoming higher and higher.

[1]https://github.com/SamJia/CommunityGAN

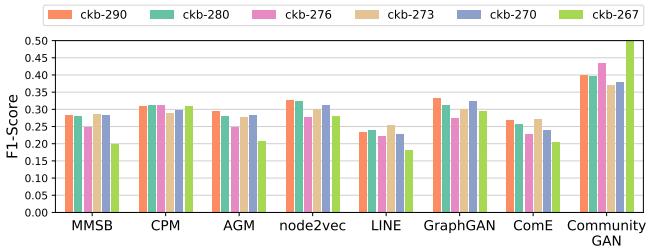

Figure 6: Performance of methods on the synthetic graphs.

5.3 Comparative Methods

We compare CommunityGAN with 7 baseline methods, of which 3 are traditional overlapping community detection methods (MMSB, CPM and AGM), 3 are recent graph representation learning methods (node2vec, LINE and GraphGAN), and 1 combines graph representation learning as well as community detection (ComE).

MMSB [1] is one of the representatives of overlapping community detection methods based on dense subgraph extraction.

CPM [18] builds up the communities from k-cliques and allows overlapping between the communities in a natural way.

AGM [31] is a framework which can model densely overlapping community structures.

Node2vec [8] adopts biased random walk and Skip-Gram to learn vertex embeddings.

LINE [24] preserves the first-order and second-order proximity among vertices in the graph.

GraphGAN [25] unifies generative and discriminative graph representation learning methodologies via adversarial training in a minimax game.

ComE [3] jointly solves the graph representation learning and community detection problem.

5.4 Experiment Setup

For all the experiments, we perform stochastic gradient descent to update parameters with learning rate 0.001. In each iteration, m and n are both 5, i.e., 5 positive and 5 negative vertex subsets will be sampled or generated for each vertex (refer to Algorithm 1), and then we update G and D on these vertex subsets for 3 times. The final learned communities and vertex representations are $\mathbf{g}_v$'s. Hyperparameter settings for all baselines are as default.

For CommunityGAN, CPM, AGM, MMSB and ComE, which directly output the communities for vertices, we fit the network into them to detect communities directly. For node2vec, LINE and GraphGAN, which can only output the representation for vertices, we fit the network into them and apply K-means to the learned embeddings to get the communities. Because of the randomness of K-means, we repeat 5 times and report the average results. Moreover, the number of ground-truth communities is set as the input parameters to the community detection models and K-means.

5.5 Ability of CommunityGAN to Solve Dense Overlapping Problem

For each method and each dataset, we calculate the average value of F1-Score. The performance of 8 methods on the series of graphs is

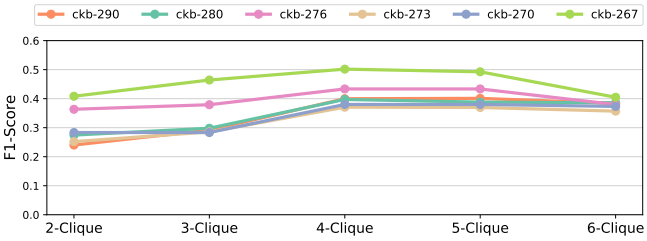

Figure 7: Performance of CommunityGAN with different size of cliques on the synthetic graphs.

shown in Figure 6. As we can see: 1) CommunityGAN significantly outperforms all the baselines on all the synthetic graphs. 2) Although CommunityGAN is based on AGM and utilizes AGM as the pre-train method, with the minimax game competition between the discriminator and generator, CommunityGAN achieves huge improvements compared to AGM. 3) On the whole, the performance of 4 graph representation learning methods (node2vec, LINE, GraphGAN, ComE) falls with the increase of overlapping density among communities, while 3 traditional overlapping community detection methods (MMSB, CPM, AGM) keep relatively steady. Among these 3 methods, the only exception is that the performance of MMSB and AGM drops largely on ckb-267. One possible reason is that the average degree of ckb-267 increases significantly compared to other graphs, and thus the performance of the two methods are affected. However, although based on AGM, CommunityGAN still performs very well on the graph ckb-267 with the well designed positive/negative sampling and the minimax game between the generator and discriminator.

5.6 Efficacy of Motif-Level Generation and Discrimination

To evaluate the efficacy of the motif-level generation and discrimination, we tune the size of cliques in the training process of CommunityGAN. Figure 7 shows the performance of CommunityGAN with different sizes of cliques on the series of synthetic graphs. We can find that, generally, cliques with a size of 4 or 5 can reach the best performance. It means that, compared to edges and triangles, the larger cliques in graphs correspond more to the community structure. In other words, community detection methods should not only focus on the edges in the graph, but also pay more attention to the motifs, especially larger motifs. However, we can see that in most graphs the performance falls when CommunityGAN generates and discriminates 6-vertex cliques. Our explanation is that too-large cliques are rare in graphs, which can only cover a relatively small number of nodes. Because of these uncovered nodes, few positive samples can be used in the training process, which in turn causes CommunityGAN to fail to learn appropriate representation vectors.

To prove such an explanation, we have counted the number of cliques and number of vertices covered by such cliques, as shown in Table 5. We can see that no matter whether the number of cliques increases or not, the number of covered vertices does not change very much from 2-clique to 5-clique. Thus CommunityGAN can benefit from the larger cliques to gather better community structure, and then reaches the best performance when clique size is 4 or 5. However, when the size of clique reaches 6, the number of covered vertices drops dramatically, and thus the performance of CommunityGAN decreases.

Table 5: Statistics of cliques in the synthetic graphs.

Number of cliques

Model	2-clique	3-clique	4-clique	5-clique	6-clique

ckb-267	1123	1123	1123	1120	907

5.7 Discussion

With the two experiments on the series of synthetic graphs, we can draw the following conclusions:

- With the same special vector design as AGM, CommunityGAN holds the ability to solve the dense overlapping problem. With the increase of overlapping among communities, the performance of CommunityGAN can maintain steadiness and does not fall like the baseline methods.
- With the minimax game competition between the discriminator and generator, CommunityGAN gains significant performance improvements based on AGM.
- With proper sizes, the motif-level generation and discrimination can help models learn better community structures compared to edge-level optimization.

6 REAL-WORLD SCENARIOS

To complement the previous experiments, in this section, we evaluate the performance of CommunityGAN on a series of real-world datasets. Specifically, we choose two application scenarios for experiments, i.e., community detection and clique prediction.

6.1 Datasets

We evaluate our model using two categories of datasets, one with ground-truth communities and one without.

Datasets with ground-truth communities.[2] Because of the training time of some baselines, we only sample three subgraphs with 100 ground-truth communities as the experiment networks from these three large networks.

CommunityGAN	**0.853**	**0.091**	**0.153**

Amazon is collected by crawling Amazon website. The vertices represent products; the edges indicate the frequently co-purchase relationships; the ground-truth communities are defined by the product categories in Amazon. This graph has 3,225 vertices and 10,262 edges.

Youtube is a network of social relationships of Youtube website users. The vertices represent users; the edges indicate friendships among the users; the user-defined groups are considered as ground-truth communities. This graph has 4,890 vertices and 20,787 edges.

DBLP is a co-authorship network from DBLP. The vertices represent researchers; the edges indicate the co-author relationships; authors who have published in a same journal or conference form a community. This graph has 10,824 vertices and 38,732 edges.

Datasets without ground-truth communities.[3]

arXiv-AstroPh is from the e-print arXiv and covers scientific collaborations between authors with papers submitted to the Astro Physics category. The vertices represent authors, and the edges indicate co-author relationships. This graph has 18,772 vertices and 198,110 edges.

arXiv-GrQc is also from arXiv and covers scientific collaborations between authors with papers submitted to the General Relativity and Quantum Cosmology categories. This graph has 5,242 vertices and 14,496 edges.

6.2 Community Detection

The community detection experiment is conducted on three networks with ground-truth community memberships, which allows us to quantify the accuracy of community detection methods by evaluating the level of correspondence between detected and ground-truth communities.

[3]http://snap.stanford.edu/data/#canets

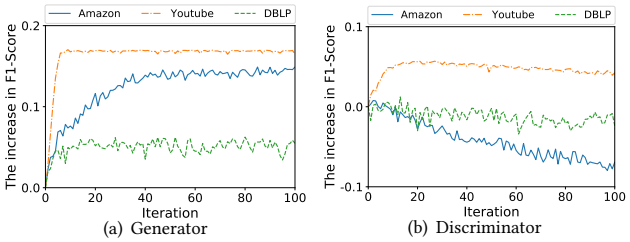

Figure 8: Learning curves of the generator and the discriminator of CommunityGAN in community detection.

Setup. In the community detection experiment, all the baselines and setups are the same as the synthetic data experiments, whose details refer to §5.4.

Evaluation Metric. Besides the F1-Score described in synthetic dataset experiments (refer to §5.1), to comprehensively evaluate the performance of methods, we also introduce the Normalized Mutual Information (NMI) in the community detection experiment. NMI is a measure of similarity borrowed from information theory. Later, it is extended to measure the quality of overlapping communities. Similar to F1-Score, the higher NMI means the better performance. Please refer to [13] for details.

Results. Table 6 shows the F1-Score and NMI of 8 methods on 3 networks, respectively. As we can see: 1) Performance of CPM, MMSB and LINE is relatively poor in community detection, which means they cannot capture the pattern of community structure in graphs well. 2) Node2vec, ComE and GraphGAN perform better than CPM, MMSB and LINE. One possible reason is that node2vec and GraphGAN adopt the random walk to capture the vertex context which is similar to community structure in some way, and ComE solves the network embedding and community detection task in one unified framework. 3) CommunityGAN outperforms all the baselines (including its pre-train method AGM) in community detection task. Specifically, CommunityGAN improves F1-Score by 7.9% (on Youtube) to 21.0% (on Amazon) and improves NMI by at most 34.3% (on Amazon). Our explanation is that the consideration of dense community overlapping provides CommunityGAN a higher learning flexibility than the non-overlapping or sparse overlapping community detection baselines. Moreover, the minimax game between the generator and discriminator drives CommunityGAN to gain significant performance improvements based on AGM.

To intuitively understand the learning stability of CommunityGAN, we further illustrate the learning curves of the generator and the discriminator on the three datasets in Figure 8. Because the F1-Score on the three datasets differs very much, we only demonstrate the relative increase in the score. As we can see, the generator performs outstandingly well after convergence, while the performance of the discriminator falls a little or boosts at first and then falls. Maybe it is because that the discriminator aims to distinguish

ground truth from generated samples better. However, the generated samples are all around the center vertex, which causes the discriminator to lose some global discrimination ability.

6.3 Clique Prediction

In clique prediction, our goal is to predict whether a given subset of vertices is a clique. Therefore, this task shows the performance of graph local structure extraction ability of different graph representation learning methods.

Setup. In the clique prediction experiment, because some traditional community detection methods (including MMSB and CPM) cannot predict the existence of edges among vertices, these methods are omitted in this experiment. To analyze the effect of motif generation and discrimination in CommunityGAN, in this experiment, we have evaluated the prediction for 2-clique (same to edge), 3-clique and 4-clique. With the size of cliques determined, we randomly hide some cliques, which cover 10% of edges, in the original graph as ground truth, and use the left graph to train all graph representation learning models. After training, we obtain the representation vectors for all vertices and use logistic regression method to predict the probability of being clique for a given vertex set. Our test set consists of the hidden vertex sets (cliques) in the original graph as the positive samples and the randomly selected non-fully connected vertex sets as negative samples with the equal number.

Results. We use arXiv-AstroPh and arXiv-GrQc as datasets, and report the results of AUC in Table 7. As we can see, even though in 2-clique (edge) prediction CommunityGAN does not always get the highest score, CommunityGAN outperforms all the baselines in both 3-clique and 4-clique prediction. For example, on arXiv-GrQc, CommunityGAN achieves gains of 0.40% to 74.52% and 4.60% to 79.03% in 3-clique and 4-clique prediction, respectively. This indicates that though CommunityGAN is designed for community detection, with the design of motif generation and discrimination,

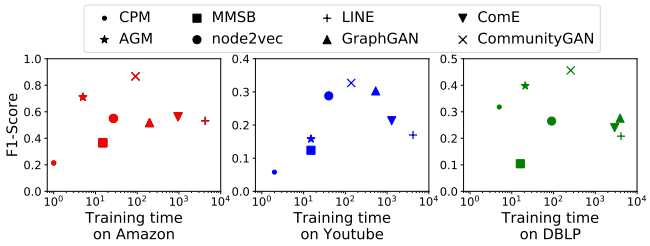

Figure 9: Performance as training time (Sec.).

it can still effectively encode the information of clique structures into the learned representations.

6.4 Efficiency analysis

In this paper, we propose Graph AGM for efficiently generating the most likely motifs with graph structure awareness. Because of the random walk process, in which the exact time complexity is not easy to infer, we evaluate the efficiency of CommunityGAN by directly comparing the training time with baselines. In this evaluation, the number of threads is set as 16 if the model supports parallelization and other parameters for baselines are as default. Figure 9 illustrates the performance and training time. Notably, the training time of CommunityGAN includes the time of the pre-training process. Even though CommunityGAN is not the fastest model, the training time of CommunityGAN is still acceptable and its performance significantly outperforms the faster models.

7 CONCLUSION

In this paper we proposed CommunityGAN that jointly solves the overlapping community detection and graph representation learning. Unlike the embedding of general graph learning algorithms in which the vector values have no meanings, the embedding in CommunityGAN indicates the membership strength of vertices to communities, which enables CommunityGAN to detect densely overlapped communities. Then a specifically designed GAN is adopted to optimize such embedding. Through the minimax game of motif-level generator and discriminator, both of them can boost their performance and finally output better community structures. We adopted CKB Graph Generator to create a series of synthetic graphs with ground-truth communities. Two experiments were conducted on these graphs to prove the ability of CommunityGAN to solve dense overlapping problem and its efficacy of motif generation and discrimination. Additionally, to complement the experiments on the synthetic datasets, we did experiments on five real-world datasets in two scenarios, where the results demonstrate that CommunityGAN substantially outperforms baselines in all experiments due to its specific embedding design and motif-level optimization.

ABSTRACT

Semantic text matching is one of the most important research problems in many domains, including, but not limited to, information retrieval, question answering, and recommendation. Among the different types of semantic text matching, long-document-to-long-document text matching has many applications, but has rarely been studied. Most existing approaches for semantic text matching have limited success in this setting, due to their inability to capture and distill the main ideas and topics from long-form text.

In this paper, we propose a novel Siamese multi-depth attention-based hierarchical recurrent neural network (SMASH RNN) that learns the long-form semantics, and enables long-form document based semantic text matching. In addition to word information, SMASH RNN is using the document structure to improve the representation of long-form documents. Specifically, SMASH RNN synthesizes information from different document structure levels, including paragraphs, sentences, and words. An attention-based hierarchical RNN derives a representation for each document structure level. Then, the representations learned from the different levels are aggregated to learn a more comprehensive semantic representation of the entire document. For semantic text matching, a Siamese structure couples the representations of a pair of documents, and infers a probabilistic score as their similarity.

We conduct an extensive empirical evaluation of SMASH RNN with three practical applications, including email attachment suggestion, related article recommendation, and citation recommendation. Experimental results on public data sets demonstrate that SMASH RNN significantly outperforms competitive baseline methods across various classification and ranking scenarios in the context of semantic matching of long-form documents.

1 INTRODUCTION

Semantic text matching estimates semantic similarity between a source and a target text pieces (e.g., query-to-document match, question-to-paragraph match, etc.). Correctly modeling semantics in text matching has long been the "holy grail" of textual information retrieval. The difficulties of semantic matching are two-fold: first, semantics of words and phrases can be ambiguous; second, when the text is long, semantics of individual words, phrases and sentences can be buried in complex document structures. While the prior research mainly focuses on the first set of difficulties, in this paper we tackle the second challenge; namely that of dealing with complex long-form documents.

To better understand the effects of document length in semantic text matching, in Figure 1 we show applications of semantic text matching across the length spectrum of source and target texts. As shown on the upper left of this figure, ad-hoc retrieval tasks like web search [7] use short source queries while targeting long-form documents; on the lower left, short text retrieval tasks like Twitter search [9, 41] use short source queries and target short documents; on the lower right, the tasks of document classification like sentiment analysis aim to categorize long-form documents into a limited set of classes [25, 30]. Interestingly, the upper right part of the figure is relatively less explored in the semantic text match setting, and, as we empirically demonstrate, many of the previously proposed semantic matching methods deteriorate when source and target documents become longer. This poses an important research challenge, since semantic text matching for long-form documents

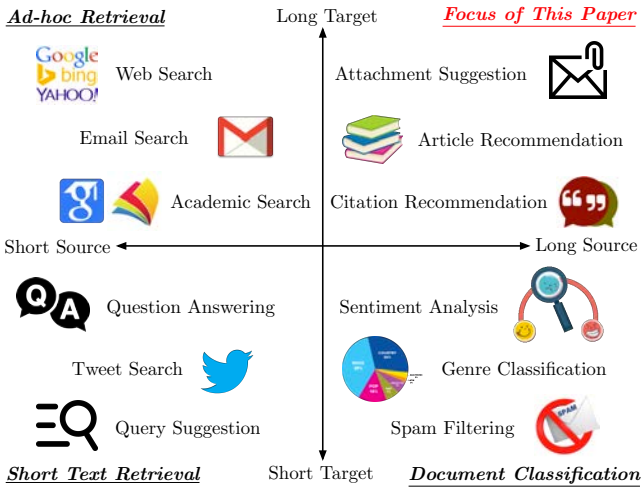

Figure 1: Applications across different lengths of source and target documents in text retrieval. In this work, we focus on the tasks with long sources and long targets.

can benefit a myriad of applications, such as related article recommendation, email attachment suggestion, citation recommendation, etc.

One of the most conventional approaches to semantic text matching is to compute a vector as the representation for each document, such as bag-of-words and latent Dirichlet allocation models [5, 18], and then apply typical similarity metrics to compute the matching scores. Unfortunately, the performance of traditional approaches is unsatisfactory, as they often fail to capture the semantic document structure. The advances in deep learning in recent years provide the opportunity to understand complex natural language and to learn better long-form document representations. For instance, recurrent neural networks (RNNs) treat a document as a sequence of words and derive a document representation based on the information along the sequence [32, 33]; convolutional neural networks (CNNs) obtain document representations by preserving local patterns [23, 38, 54].

However, although existing deep learning approaches significantly advanced the field of semantic text matching, they mainly focus on short documents and have apparent drawbacks when dealing with long-form documents. First, the core topic or idea can be hard to identify and extract from a complex narrative of a long-form document. Some of the previous studies [10, 52, 54] exploit attention mechanism [29] to distill important words from sentences, but valuable information can still be diluted within a large number of sentences and paragraphs in long-form documents. Second, the complex structural information of long-form documents have not yet been taken into account. Most of the existing approaches rely on word-level knowledge to compute text similarity. Structural information like relations among sentences and paragraphs is often disregarded. Third, the semantics of a document can drift over the course of a long narrative. For example, it is not uncommon to find documents in which the writer moves across a spectrum of subjects in the span of several passages. Neither RNN or CNN can naturally capture or follow semantic drifts like this. RNN-based approaches can attain confusing document representations by sequentially processing sentences with different semantics. CNN-based approaches can deteriorate when trying to pool and filter different semantics.

Natural language documents generally follow hierarchical structures [35] to help people read and understand them. Therefore, it is vital to utilize these structures in order to train machine learning models which can fully capture the semantics of long-form documents. Most generally, a document can be represented as a hierarchy of paragraph, sentence and word sequences. Different paragraphs and sentences in a document can have different semantic meaning and importance. The most similar research to this work is to use sentence-level information for document classification [10, 52]. As we will show in the experimental section, for long-form documents, sentence-level based document representations are still unsatisfactory because sentences in the same document may be associated with different importance and diverse semantics. On the contrary, a deep understanding of document structure can effectively boost semantic text matching.

In this paper, we propose Siamese multi-depth attention-based hierarchical RNN (SMASH RNN) to address the problem of long-form document semantic matching. Under the two-tower structure of Siamese network [32], each tower of the proposed model is a multi-depth attention-based hierarchical RNN (MASH RNN). MASH RNN, as the major component of our model, can derive comprehensive document representations from multiple levels of document structure. For example, word-, sentence-, and paragraph-level knowledge of a document can be derived by three attention-based hierarchical RNNs with different depths. To generate comprehensive document presentations, MASH RNN concatenates representations from all of these document levels, aiming to capture both concrete low-level observations and abstract high-level insights. Combining the document representations for both source and target documents from MASH RNN, SMASH RNN estimates semantic matching scores based on the representations of the source and the target documents, and an extra fully connected layer.

Our contributions can be summarized as follows:

- To the best of our knowledge, this paper is the first work to extensively exploit document structure for better document representations, in the context of improving the state-of-the-art performance of the long-form document semantic text matching models.
- We propose the SMASH RNN framework for long-form document semantic text matching. MASH RNN, the major component of SMASH RNN, learns document representations from multiple abstraction levels of the document structure.
- Experiments were conducted on publicly available datasets for three different applications: email attachment suggestion, related article recommendation, and citation recommendation. Experiment results demonstrate the effectiveness of SMASH RNN. We also provide an in-depth experiment analysis to prove the robustness of our proposed framework.

The rest of the paper is organized as follows. First, we present related work in Section 2. Then, the problem statement and SMASH RNN are described in Section 3. We show experiment results and provide an in-depth analysis in Section 4. Finally, some conclusions are given in Section 5.

2 RELATED WORK

In this section, we first give the background of semantic text matching and indicate the difference between our approach and previous studies. Deep document classification is then introduced as a related task. Last but not least, we discuss the attention mechanism in deep learning, which plays an important role in SMASH RNN.

2.1 Semantic Text Matching

To measure the similarity between documents, it is intuitive for traditional approaches to compare the words in the documents. For example, Mihalcea et al. [31] compute the word-to-word similarity while Wu et al. [49] exploit the vector space model with the term frequency-inverse document frequency (TF-IDF). However, words in the documents are extremely sparse. In addition, the semantics between individual words also cannot be captured, so these approaches usually obtain unsatisfactory results. Although some works attempt to leverage the semantics in external resources such as knowledge bases [42] or alleviate the data sparseness by Latent Semantic Analysis (LSA) [53], traditional approaches are still limited by discrete words.

The recent development of deep learning in natural language processing provides a new opportunity for semantic text matching. After using deep learning models to encode the documents in distributed representations, the Siamese structure [8] for metric learning is usually applied to learn the similarity information. There is a plethora of deep learning models for encoding documents. For instance, some studies [2, 27, 32, 33, 45, 46] exploit RNNs to model the sequential information of documents while other work [19, 38, 46, 54] applies CNNs to capture the important local messages in documents for semantic text matching.

However, most of the previous studies are not designed for long-form documents. For example, RNNs can lose important messages while passing information along a very long sequence of words. The local features learned by CNNs can be inadequate to represent the complex semantics of long-form documents.

Another line of work maps the term positions of the source and the target texts to create a matching matrix [27, 45, 46, 50, 54] or computes local interactions with the target text for each word in the source text [16]. This works well for scenarios like ad-hoc retrieval, where the source queries are short. For a scenario where both the source and the target are long documents, a matching matrix would be time-consuming to compute, and is too large to fit in memory.

In addition, the document structures that could be much beneficial are generally ignored by most of the previous semantic text matching approcaches. Note that although Liu et al. [27] mention the term "hierarchical structure," they focus on the structures in sentences so that long-form documents still cannot be handled. In other words, their proposed methods are incapable to deal with long-form documents. Our approach differs from this work in that the hierarchical document structures with different depths are explicitly considered in the model, thereby directly benefiting the model to learn the semantics of different levels in the document structure.

2.2 Deep Document Classification

Instead of simultaneously modeling two documents, deep document classification that considers a single document at a time with deep learning models can be considered as a related task. Similar to semantic text matching, deep learning models can also be utilized to encode documents into distributed representations for document classification. For example, both CNNs [13, 25, 39] and RNNs [10, 28, 52] can do document classification for many applications such as sentiment analysis. Devlin et al. [12] propose bidirectional encoder representations from transformers (BERT). However, all of these works focus on short text classification, especially for sentences and documents with few sentences. Even though BERT quickly became the state-of-the-art for many NLP tasks, its multi-head attention component requires an unrealistically enormous amount of both memory and computation time for long-form documents. Moreover, most of their approaches only take word-level information into account and ignore the structure of long-form documents. HAN [52] and NSC [10] with the exactly same architecture are the only two studies using a two-layer RNN with attention to consider sentence-level information for document classification. On one hand, a document narrative can contain a large sequence of loosely related sentences. Grouping of those sentences into paragraphs or sections is not handled by these models. On the other hand, these models only consider the sentence-level knowledge, but the word-level information that would be diluted in the two-layer model structure can be also important. Therefore, existing approaches of deep document classification cannot appropriately capture the semantics of long-form documents.

2.3 Attention Mechanism in Deep Learning

The attention mechanism [4, 29] has already become one of the most important techniques in deep learning since its huge success in machine translation [44]. Given an input sequence, the attention mechanism infers the importance of each position with a learnable context vector. Besides machine translation, the attention mechanism benefits many applications, such as caption generation [51], document classification [10, 52], and question answering [40]. In this paper, the attention mechanism is exploited to extract the important knowledge in each individual branch of the hierarchical structure for a long-form document.

3 SEMANTIC TEXT MATCHING FOR LONG-FORM DOCUMENTS WITH SMASH RNN

In this section, we first formally define the objective of this paper, and then present the proposed framework, Siamese multi-depth attention-based hierarchical RNN (SMASH RNN), to address the problem of long-form document semantic text matching.

3.1 Problem Statement

In this paper, we focus on long-form documents that can be represented as a hierarchical compositions of word. Note that hierarchy depths for documents can be vary, depending on the highest level of abstraction for a document structure. To facilitate readability, we assume that there are three levels in hierarchy – paragraphs,

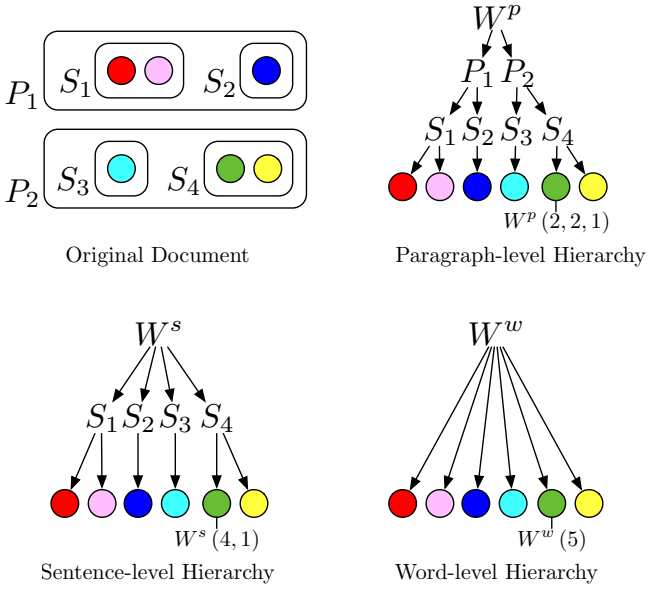

Figure 2: The illustration of hierarchical structures with different depths for an example document. P_k and S_j are the structures of paragraphs and sentences. The positions of a word in the structures depend on the depths of hierarchies.

sentences and words. However, it is important to note that our proposed method is general enough to handle variable depths of hierarchies. Figure 2 gives an illustration of hierarchical structures with different depths for a document d. Words in the d can be fitted into three hierarchical structures, i.e., W^p, W^s, and W^w, with depth 3 (paragraph-level), depth 2 (sentence-level), and depth 1 (word-level) respectively. More precisely, $W^p\,(k, j, i)$ is the i-th word in the j-th sentence of the k-th paragraph given a paragraph-level hierarchy; $W^s\,(j, i)$ is the i-th word in the j-th sentence given a sentence-level hierarchy; $W^w\,(i)$ is the i-th word for the word-level hierarchy with a depth of 1, which is just a long sequence. Note that the bottom level words in the three different hierarchies are exactly identical while their annotations vary according to hierarchy depth and document structure.

Given a source document d_s and a set of candidate documents D_c, our goal is to estimate semantic similarity $\hat{y} = Sim(d_s, d_c)$ between the source document d_s and every candidate document $d_c \in D_c$ so that the target documents semantically matched to the source document have higher semantic similarity scores.

3.2 Framework Overview

Figure 3 and 4 illustrate the framework of our proposed Siamese multi-depth attention-based hierarchical RNN (SMASH RNN). Under the Siamese structure [32], each SMASH RNN has two multi-depth attention-based hierarchical RNN (MASH RNN) towers. For each document, MASH RNN derives an informative representation based on the knowledge from different levels of document structure. For each level, an attention-based hierarchical RNN (with corresponding level depth) is constructed as an encoder to generate representations for that level. For example, the paragraph-level encoder produces paragraph-level representations with a depth-3 encoder while the sentence-level encoder produces sentence-level representations with a depth-2 encoder. The final document representation is then acquired by concatenating the representations of different levels, comprehensively covering the knowledge in all document structure levels. To estimate semantic similarity for semantic text matching, SMASH RNN adopts the Siamese structure with two MASH RNN towers. Given representations generated by MASH RNN for both the source and target documents, a fully-connected layer with nonlinearity infers a probabilistic score to examine the semantic relation between two documents with a sigmoid function [34].

In Section 3.3, we formally define MASH RNN. In Section 3.4, we put two MASH RNN towers together to define SMASH RNN.

3.3 MASH RNN for Document Representation

Most of the previous studies only exploit word-level information to represent documents [25, 32, 38, 54]. To investigate deeper structures, some work [10, 52] uses sentence-level information to represent documents. However, only using sentence-level information could lead to a loss of word level information. More than that, a long-form document usually contains quite a number of sentences, and its structure is usually deeper than sentence level. The deeper document structure was not modeled in previous studies for semantic text matching.

In this paper, we propose to model documents with information from different document structure levels. To ease the discussion, we focus on three levels of document structure – paragraph, sentence, and word-level, as mentioned in Section 3.1.

The computation of encoders in MASH RNN follows a bottom-up principle with bidirectional recurrent neural networks (Bi-RNNs) with attention. Take the paragraph-level encoder as an example. Given the j-th sentence in the k-th paragraph in the paragraph-level hierarchy W^p, we first embed words in sentence to vectors through a word embedding layer as follows:

$$\boldsymbol{x}^{\boldsymbol{p}}_{\boldsymbol{k,j,i}} = emb(W^p(k, j, i)), 1 \le i \le L^p_{k,j},$$

where $L^p_{k,j}$ is the length of the sentence, and the word embedding layer $emb(\cdot)$ embeds the words into vectors with an embedding matrix. To encode the sentence, a Bi-RNN reads the sequence of embedding vectors during both the forward pass and the backward pass. In the forward pass, the Bi-RNN creates a sequence of forward hidden states

$$\overrightarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j}}} = \left[\overrightarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,1}}}, \overrightarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,2}}}, \cdots, \overrightarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,L^p_{k,j}}}}\right],$$

where $\overrightarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,i}}} = \text{RNN}\left(\overrightarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,i-1}}}, \boldsymbol{x}^{\boldsymbol{p}}_{\boldsymbol{k,j,i}}\right)$ is generated by a dynamic function such as LSTM [21] or GRU [11]. Here we use GRU instead of LSTM because it requires fewer parameters [24]. The backward pass processes the input sequence in reverse order and generates the backward hidden states as

$$\overleftarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j}}} = \left[\overleftarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,1}}}, \overleftarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,2}}}, \cdots, \overleftarrow{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{k,j,L^p_{k,j}}}}\right],$$

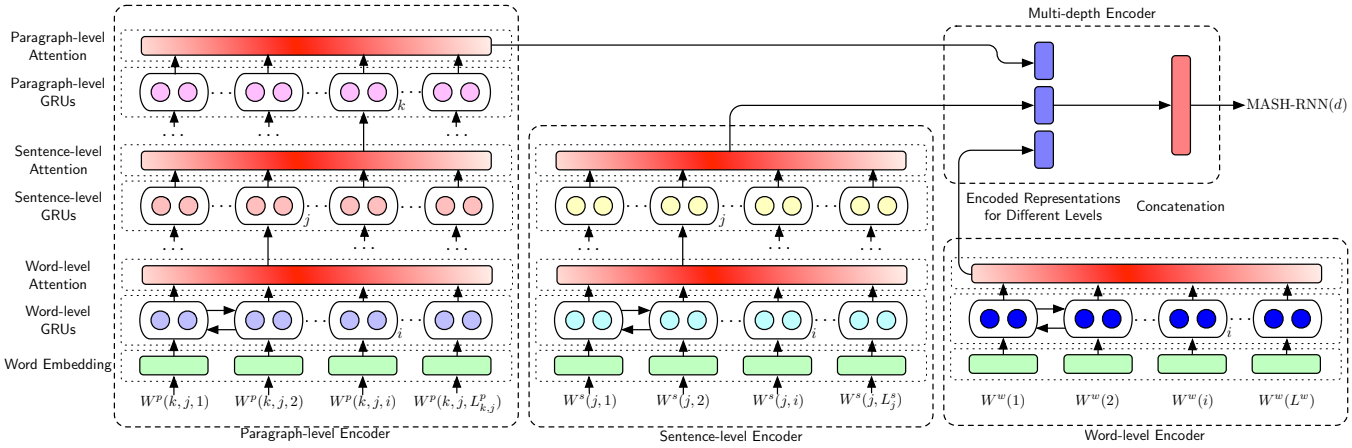

Figure 3: The schema of multi-depth attention-based hierarchical RNN (MASH RNN).

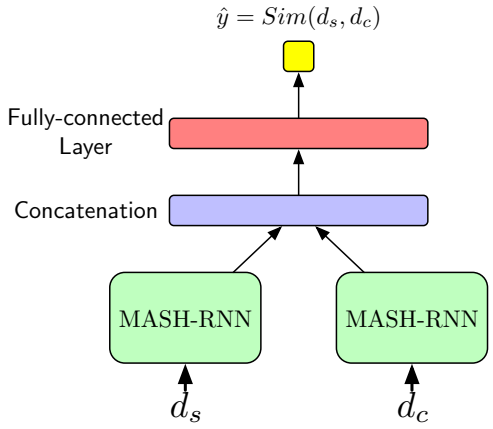

Figure 4: The architecture of Siamese multi-depth attention-based hierarchical RNN (SMASH RNN).

where $\overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,j,i}}} = \text{RNN}\left(\overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,j,i+1}}}, \boldsymbol{x}^p_{\boldsymbol{k,j,i}}\right)$. The forward and backward hidden states are concatenated as a hidden representation for words in the sentence

$$\boldsymbol{h}^p_{\boldsymbol{k,j}} = \left[\boldsymbol{h}^p_{\boldsymbol{k,j,1}}, \boldsymbol{h}^p_{\boldsymbol{k,j,2}}, \cdots, \boldsymbol{h}^p_{\boldsymbol{k,j,L^p_{k,j}}}\right],$$

where $\boldsymbol{h}^p_{\boldsymbol{k,j,i}} = \left[\overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k,j,i}}}; \overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,j,i}}}\right]$.

Since each word can have unequal importance in the sentence, the attention mechanism [4] is applied to extract and aggregate hidden representations that are more important. More precisely, the representation $\boldsymbol{h}^p_{\boldsymbol{k,j,i}}$ will be transformed by a fully-connected hidden layer to measure the importance $\alpha^p_{k,j,i}$ as follows:

$$\alpha^p_{k,j,i} = \frac{\exp\left(\boldsymbol{u}^p_{\boldsymbol{k,j,i}} \cdot \boldsymbol{u}^p_{\boldsymbol{w}}\right)}{\sum_{i'} \exp\left(\boldsymbol{u}^p_{\boldsymbol{k,j,i'}} \cdot \boldsymbol{u}^p_{\boldsymbol{w}}\right)},$$

in which $\boldsymbol{u}^p_{\boldsymbol{k,j,i}} = \tanh\left(\mathcal{F}^p_w\left(\boldsymbol{h}^p_{\boldsymbol{k,j,i}}\right)\right)$; $\mathcal{F}^p_w(\cdot)$ is a fully-connected layer; tanh is the activation for the convenience of similarity computation; $\boldsymbol{u}^p_{\boldsymbol{w}}$ is a vector to measure the word importance. The normalized importance $\alpha^p_{k,j,i}$ can be further obtained through a softmax function. Finally, the representation of the j-th sentence in the k-th paragraph can be represented as the weighted sum of the hidden representations as follows:

$$\boldsymbol{s}^p_{\boldsymbol{k,j}} = \sum_i \alpha^p_{k,j,i} \boldsymbol{h}^p_{\boldsymbol{k,j,i}}.$$

With the representations of sentences, the Bi-RNN is applied again to learn the paragraph representations because a paragraph can be considered as a sequence of sentences. Given the representations of sentences in the k-th paragraph $\boldsymbol{s}^p_{\boldsymbol{k,j}}$, a Bi-RNN generates the forward and backward hidden states of sentences as follows:

$$\overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k}}} = \left[\overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k,1}}}, \overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k,2}}}, \cdots, \overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k,L^p_k}}}\right], \overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k}}} = \left[\overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,1}}}, \overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,2}}}, \cdots, \overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,L^p_k}}}\right],$$

where L^p_k is the number of sentences in the k-th paragraph; $\overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k,j}}} = \text{RNN}\left(\overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k,j-1}}}, \boldsymbol{s}^p_{\boldsymbol{k,j}}\right)$; $\overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,j}}} = \text{RNN}\left(\overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,j+1}}}, \boldsymbol{s}^p_{\boldsymbol{k,j}}\right)$. The hidden representations for the sentences in the paragraph can then be represented as

$$\boldsymbol{h}^p_{\boldsymbol{k}} = \left[\boldsymbol{h}^p_{\boldsymbol{k,1}}, \boldsymbol{h}^p_{\boldsymbol{k,2}}, \cdots, \boldsymbol{h}^p_{\boldsymbol{k,L^p_k}}\right],$$

where $\boldsymbol{h}^p_{\boldsymbol{k,j}} = \left[\overrightarrow{\boldsymbol{h}^p_{\boldsymbol{k,j}}}; \overleftarrow{\boldsymbol{h}^p_{\boldsymbol{k,j}}}\right]$. With the attention mechanism, the importance of each sentence can be measured as follows:

$$\alpha^p_{k,j} = \frac{\exp\left(\boldsymbol{u}^p_{\boldsymbol{k,j}} \cdot \boldsymbol{u}^p_{\boldsymbol{s}}\right)}{\sum_{j'} \exp\left(\boldsymbol{u}^p_{\boldsymbol{k,j'}} \cdot \boldsymbol{u}^p_{\boldsymbol{s}}\right)},$$

where $\boldsymbol{u}^p_{\boldsymbol{k,j}} = \tanh\left(\mathcal{F}^p_s\left(\boldsymbol{h}^p_{\boldsymbol{k,j}}\right)\right)$; $\mathcal{F}^p_s(\cdot)$ and $\boldsymbol{u}^p_{\boldsymbol{s}}$ are the fully-connected layer and the vector for the importance measurement. Finally, the representation of the k-th paragraph can be represented as

$$\boldsymbol{p}^p_{\boldsymbol{k}} = \sum_j \alpha^p_{k,j} \boldsymbol{h}^p_{\boldsymbol{k,j}}.$$

As the top structure in the paragraph-level hierarchy, the document can be treated as a sequence of paragraphs, so we can also utilize the Bi-RNN to generate paragraph-level document representations. Given the representations of paragraphs in the document $\boldsymbol{p}_{\boldsymbol{k}}^{\boldsymbol{p}}$, the forward and backward hidden states of paragraphs in the Bi-RNN are generated as follows:

$$\overrightarrow{\boldsymbol{h}^{\boldsymbol{p}}} = \left[\overrightarrow{\boldsymbol{h}_1^{\boldsymbol{p}}}, \overrightarrow{\boldsymbol{h}_2^{\boldsymbol{p}}}, \cdots, \overrightarrow{\boldsymbol{h}_{L^p}^{\boldsymbol{p}}}\right], \overleftarrow{\boldsymbol{h}^{\boldsymbol{p}}} = \left[\overleftarrow{\boldsymbol{h}_1^{\boldsymbol{p}}}, \overleftarrow{\boldsymbol{h}_2^{\boldsymbol{p}}}, \cdots, \overleftarrow{\boldsymbol{h}_{L^p}^{\boldsymbol{p}}}\right],$$

where L^p is the number of paragraphs in the document; $\overrightarrow{\boldsymbol{h}_{\boldsymbol{k}}^{\boldsymbol{p}}} = \text{RNN}\left(\overrightarrow{\boldsymbol{h}_{\boldsymbol{k-1}}^{\boldsymbol{p}}}, \boldsymbol{p}_{\boldsymbol{k}}^{\boldsymbol{p}}\right)$; $\overleftarrow{\boldsymbol{h}_{\boldsymbol{k}}^{\boldsymbol{p}}} = \text{RNN}\left(\overleftarrow{\boldsymbol{h}_{\boldsymbol{k+1}}^{\boldsymbol{p}}}, \boldsymbol{p}_{\boldsymbol{k}}^{\boldsymbol{p}}\right)$. The hidden representations for the paragraphs can be represented as

$$\boldsymbol{h}^{\boldsymbol{p}} = \left[\boldsymbol{h}_1^{\boldsymbol{p}}, \boldsymbol{h}_2^{\boldsymbol{p}}, \cdots, \boldsymbol{h}_{L^p}^{\boldsymbol{p}}\right],$$

where $\boldsymbol{h}_{\boldsymbol{k}}^{\boldsymbol{p}} = \left[\overrightarrow{\boldsymbol{h}_{\boldsymbol{k}}^{\boldsymbol{p}}}; \overleftarrow{\boldsymbol{h}_{\boldsymbol{k}}^{\boldsymbol{p}}}\right]$. The importance of each paragraph can then be measured with the attention mechanism as follows:

$$\alpha_k^p = \frac{\exp\left(\boldsymbol{u}_{\boldsymbol{k}}^{\boldsymbol{p}} \cdot \boldsymbol{u}_{\boldsymbol{p}}^{\boldsymbol{p}}\right)}{\sum_{p'} \exp\left(\boldsymbol{u}_{\boldsymbol{k}'}^{\boldsymbol{p}} \cdot \boldsymbol{u}_{\boldsymbol{p}}^{\boldsymbol{p}}\right)},$$

in which $\boldsymbol{u}_{\boldsymbol{k}}^{\boldsymbol{p}} = \tanh\left(\mathcal{F}_p^p\left(\boldsymbol{h}_{\boldsymbol{k}}^{\boldsymbol{p}}\right)\right)$; $\mathcal{F}_p^p(\cdot)$ and $\boldsymbol{u}_{\boldsymbol{p}}^{\boldsymbol{p}}$ are the fully-connected layer and the vector for the importance measurement. The paragraph-level document representation can finally be represented as the output of the paragraph-level encoder as follows:

$$\boldsymbol{d}^{\boldsymbol{p}} = \sum_k \alpha_k^p \boldsymbol{h}_{\boldsymbol{k}}^{\boldsymbol{p}}.$$

Besides the paragraph-level encoder and paragraph-level representation $\boldsymbol{d}^{\boldsymbol{p}}$, with shallower depths of hierarchy W^s and W^w, we create sentence-level and word-level encoders and generate sentence-level and word-level representations $\boldsymbol{d}^{\boldsymbol{s}}$ and $\boldsymbol{d}^{\boldsymbol{w}}$.

In order to capture both concrete low-level observations and abstract high-level insights, MASH RNN uses representations from different document levels. Specifically, MASH RNN returns final document representation as a concatenation of representations generated by multi-depth encoders:

$$\boldsymbol{d} = \left[\boldsymbol{d}^{\boldsymbol{p}}; \boldsymbol{d}^{\boldsymbol{s}}; \boldsymbol{d}^{\boldsymbol{w}}\right].$$

3.4 SMASH RNN for Semantic Text Matching

The Siamese structure associated with two identical sub-networks were shown to be effective in measuring the affinity between representations of two documents modeled in the same hidden space [32, 38, 47, 54]. To address the problem of semantic text matching for long-form documents, we propose the Siamese multi-depth attention-based hierarchical RNN (SMASH RNN) using a Siamese structure that fuses the outputs of two MASH RNNs.

Figure 4 illustrates the structure of SMASH RNN for estimating the semantic similarity between a source document d_s and a candidate document d_c. To tackle two sub-networks, there are several approaches, such as using an attention matrix [54] or a similarity matrix [38]. However, long-form documents require an enormous number of parameters with these methods. Here we propose to utilize the concatenation of representations with a fully-connected layer to learn an appropriate way for computing the semantic similarity. More formally, given $\boldsymbol{d}_{\boldsymbol{s}}$ and $\boldsymbol{d}_{\boldsymbol{c}}$, which are the representations generated by MASH RNN for two documents, the final feature vector can be represented as $\boldsymbol{x}_{\boldsymbol{f}} = [\boldsymbol{d}_{\boldsymbol{s}}; \boldsymbol{d}_{\boldsymbol{c}}]$. The semantic similarity between two documents can be computed as follows:

$$\boldsymbol{u}_{\boldsymbol{f}} = \text{ReLU}\left(\mathcal{F}_d\left(\boldsymbol{x}_{\boldsymbol{f}}\right)\right),$$

$$\hat{y} = \sigma\left(\mathcal{F}_f\left(\boldsymbol{u}_{\boldsymbol{f}}\right)\right),$$

where $\mathcal{F}_d(\cdot)$ and $\mathcal{F}_f(\cdot)$ are two fully-connected hidden layers; ReLU$(\cdot)$ is the activation function for the hidden layer; $\sigma(\cdot)$ is the logistic sigmoid function for generating probabilistic scores as similarities [17].

Note that although some of the previous studies [23, 33, 38, 53] suggest to exploit predefined similarity functions, such as the Manhattan distance and the cosine similarity, to directly measure the affinity between representations, we found that predefined similarity functions do not work with long-form documents. This can be because the predefined functions are too simple to estimate the complex semantic relations among long-form documents.

3.5 Learning and Optimization

The task of semantic text matching can be modeled as a binary classification problem. Given a tuple of training data (d_s, d_c, y), where y is a Boolean value showing whether two documents are semantically matched, SMASH RNN optimizes the binary cross-entropy [20] between the estimated probabilistic score $\hat{y}$ and the gold standard y. More formally, the loss function can be written as

$$-(y \log(\hat{y}) + (1 - y) \log(1 - \hat{y})).$$

Moreover, the architecture of SMASH RNN allows end-to-end learning [55] that directly trains the full model from scratch using the existing data for a given task. Neither additional data engineering nor multi-step optimization are required.

4 EXPERIMENTS

In this section, we conduct extensive experiments and in-depth analysis with large-scale real-world datasets.

4.1 Experimental Settings

In the experiments, we verify the performance of SMASH RNN in three real-world applications of semantic text matching for long-form documents, including (1) email attachment suggestion, (2) related article recommendation, and (3) citation recommendation. More precisely, these experimental tasks are not only practical but also involving different types of long-form documents for validating the robustness of SMASH RNN. The experimental settings about the datasets employed in each task are described in the following corresponding subsection.

Evaluation. The performance of semantic text matching is mainly evaluated with standard classification metrics, including accuracy, precision, recall, and F1-score [15]. For the task of email attachment suggestion, following prior work [43], we also conduct a ranking experiment, which is evaluated with three standard information

retrieval metrics, including precision at 1 (P@1), mean reciprocal rank (MRR), and mean average precision (MAP) [3].

Implementation Details. The model is implemented in Tensorflow [1]. The Adam optimizer [26] is applied to optimize the parameters with an initial learning rate of 10^{-5}. The batch size is set as 32. Note that

a large batch size can lead to enormous memory consumption because long-form documents consists of

Note that because a long-form document can have an enormous amount of words, the size of a batch cannot be so large due to the limitation of memory usage. The number of hidden neurons in GRUs and hidden layers is set as 128, and the number of dimensions for word embeddings is 256.

Baseline Methods. For all of the tasks, we compare with the following baseline methods with and without using document structures to evaluate the performance of SMASH RNN.

- *RNN-based approach* (RNN) [32, 33] exploits an RNN to model each document as a word sequence. The Siamese structure is then applied to measure the relations between documents. It is the representative of the approaches based on word-level RNNs.
- *CNN-based approach* (CNN) [25] integrates the word embeddings into an embedding matrix and applies several convolutional filters to extract representative features with a pooling layer that covers the whole document. More precisely, a Siamese structure infers the semantic similarity with local features learned by convolutional filters. It can be also treated as the representative of the approaches based on word-level CNNs.
- *CNN with a matching matrix* (DeepQA) [38] enhances the CNN-based approach for question answering. In addition to the convolutional features, DeepQA uses a matching matrix [6] to measure an asymmetric similarity between the features of two documents with a noisy channel [14]. After joining the convolutional features of two documents and their asymmetric similarity, a fully-connected layer generates the semantic similarity. It can also be treated a CNN-based method using word-level information.
- *Hierarchical Attention Network* (HAN) [52] is the only baseline method that considers the document structure information. For each sentence, HAN applies an attention-based RNN to generate a feature vector, thereby deriving the sentence-level document representations with the other RNN. Note that HAN only obtains the sentence-level features for a document. The paragraph-level information is ignored, and the word-level knowledge can be diluted after being passed in the hierarchical model. More specifically, HAN is a special case of MASH RNN using only sentence-level encoders.

For the Siamese structure, although many studies use similarity functions to combine features, such as Manhattan distance [32] and cosine similarity [33], we found all of these methods perform worse than the methods using concatenation with a hidden layer for measuring the relations between long-form documents. Hence, we simply modify the baseline models by applying the Siamese structure shown in Section 3.4 instead of similarity functions to aggregate two document representations. Note that we do not compare with previous works incapable of processing long-form documents, such as ABCNN [54], DRMM [16], and BERT [12]. ABCNN learns an attention matrix for arbitrary position mappings, which is too large to be fitted in memory for long-form documents. DRNN requires an enormous amount of both memory and computational time to compute the local interaction between every words in the source document and the target document. BERT is also memory-inefficient and time-consuming for long-form documents, and its pretraining can only handle at most 512 tokens for a document.

For simplicity, our proposed framework SMASH RNN is denoted as SMASH in experimental results. In addition, P, S, and W in the tables indicate paragraph-, sentence-, and word-level hierarchies utilized in MASH RNN.

Table 1: The statistics of examples in the training, validation, and testing datasets for email attachment suggestion.

Dataset	Training	Validation	Testing
Period of Emails	18 months	2 months	1 month
Number of Examples	49,102	6,950	3,650

4.2 Task 1: Email Attachment Suggestion

The first application of semantic text matching for long-form documents in the experiments is email attachment suggestion. Given the content of an email and a candidate document, the goal of email attachment suggestion to classify whether the document should be an attachment for the email. If the system can precisely discriminate the attachments, the system will be able to automatically suggest those attachments, thereby saving users from spending lots of time on searching and attaching documents. This task is also evaluated as a ranking problem that aims to rank candidate documents for a given email.

Experimental Datasets. We adopt the largest publicly available Avocado Research Email Collection [36] as the experimental dataset for email attachment suggestion. The dataset is a collection of emails and attachments taken from a defunct information technology company. The emails sent within the densest 21-month period from January 2000 to September 2001 are selected for experiments. To partition the emails into training, validation, and testing sets, the first 18-month emails are the training data while the following 2-month emails are utilized for validation. The remaining 1-month emails are treated as the testing set. For attachments, we simply remove non-natural language attachments such as programming code or electronic business cards, to construct a pool of candidate attachments. For each pair of an email and its attachment, we extract the pair as a positive example. For each positive example, we randomly sample an irrelevant document from the candidate pool as a negative example to form a balanced dataset. Finally, there are 26,589 attachments in the pool of candidate attachments after filtering non-retrievable files. Table 1 shows the statistics of examples in the experimental datasets for email attachment suggestion.

Experimental Results. Table 2 shows the classification performance of the baseline methods and the proposed SMASH method with combinations of hierarchies used in MASH RNN.

For the baseline methods, the methods using only the word-level knowledge, i.e., RNN, CNN, and DeepQA, have similar performance. HAN surpasses all of the other baseline methods because it considers the sentence-level knowledge. As the proposed method in this

Table 2: The classification performance of email attachment suggestion. All improvements of our methods denoted as (*) are significant differences over the HAN method at 99% level in both of a paired t-test and a permutation test.

Method	Accuracy	Precision	Recall	F1
RNN [32, 33]	0.5594	0.5772	0.4439	0.5018
CNN [25]	0.5612	0.5694	0.5024	0.5338
DeepQA [38]	0.5618	0.5990	0.3740	0.4605
HAN [52]	0.5900	0.6096	0.5003	0.5496
SMASH (P)	0.5878	0.5895	0.5783*	0.5839*
SMASH (P+S)	0.6363*	0.6225*	0.6927*	0.6557*
SMASH (P+S+W)	**0.6718***	**0.6440***	**0.7686***	**0.7008***

Table 3: The ranking performance of email attachment suggestion. All improvements of our methods denoted as (*) are significant differences over the HAN method at 99% level in both of a paired t-test and a permutation test.

Method	P@1	MRR	MAP
RNN [32, 33]	0.1571	0.3557	0.3515
CNN [25]	0.1451	0.3499	0.3475
DeepQA [38]	0.1774	0.3634	0.3567
HAN [52]	0.1827	0.3724	0.3658
SMASH (P)	0.1534	0.3653	0.3638
SMASH (P+S)	0.2444*	0.4537*	0.4480*
SMASH (P+S+W)	**0.2692***	**0.4900***	**0.4845***

paper, SMASH significantly outperforms all of the baseline methods. More precisely, SMASH using all-level knowledge achieves 13.86% and 27.51% improvements against HAN in the metrics of accuracy and F1-score. While using only the paragraph-level hierarchy, SMASH (P) has a similar accuracy and a better F1-score compared to HAN. After accordingly adding sentence- and word-level knowledge, SMASH (P+S) and SMASH (P+S+W) have further improved performance. It demonstrates that all of the hierarchies in different levels are beneficial for email attachment suggestion. In addition, each of the hierarchies holds different information, so they can jointly enhance SMASH.

Aside from classification, the predicted semantic similarity as a numeric value can be also utilized for ranking candidate attachments. For each email, we randomly sample irrelevant documents to construct a list with ten candidate attachments. Table 3 demonstrates the ranking performance of different methods. The experimental results are consistent with the classification experiments. As a result, SMASH achieves 47.35% and 32.45% improvements of P@1 and MAP against HAN. It indicates that the semantic similarities generated by SMASH not only discriminate the attachments but are also predictive of their relative relevance scores.

4.3 Task 2: Related Article Recommendation

The second application in the experiments is related article recommendation. Given a pair of long-form articles, the goal of related article recommendation is to classify if the target article is relevant to the source article. This application can contribute to many real-world scenarios. For example, when a user reads a long Wikipedia page, the system can automatically push other related pages for a more comprehensive coverage of the topic; it can be also helpful for recommending news articles about related events.

Table 4: The statistics of examples in the training, validation, and testing datasets for related article recommendation.

Dataset	Training	Validation	Testing
% of Source Articles	80%	10%	10%
Number of Examples	65,948	8,166	8,130

Table 5: The classification performance of related article recommendation. All improvements of our methods denoted as (*) are significant differences over the HAN method at 99% level in both of a paired t-test and a permutation test.

Method	Accuracy	Precision	Recall	F1
RNN [32, 33]	0.7430	0.7328	0.7647	0.7484
CNN [25]	0.6714	0.7204	0.5601	0.6302
DeepQA [38]	0.7366	0.7197	0.7749	0.7463
HAN [52]	0.8089	0.7521	**0.9234**	0.8290
SMASH (P)	0.8047	0.7499	0.9120	0.8230
SMASH (P+S)	**0.8219***	**0.7987***	0.8677	**0.8318***
SMASH (P+S+W)	0.8144*	0.7626*	0.9137	0.8313*

Experimental Datasets. The Wikipedia [48] is adopted for the experiments on related article recommendation. 10% of the entity pages in Wikipedia are randomly sampled to build the corpus. Since there is no gold standard about the relatedness of Wikipedia articles, we use links as a source of weak supervision. First, we assume that similar articles have similar sets of outgoing links. Based on this assumption, the Jaccard similarity [22] between the outgoing links of two articles measures their *pseudo similarity*. The article pairs with pseudo similarities greater than a threshold 0.5 are considered as the positive examples. Moreover, we define the article that has the lexicographically smaller URL as the source article of the pair, for the convenience of partitioning datasets and avoiding duplicate examples. For each positive example, we randomly sample a mismatched article from the outgoing links of the source article to generate a negative example. Note that the mismatched articles are not sampled from the entire corpus because those pages will be too irrelevant to make the task challenging enough for differentiating the performance of the various methods. The examples with 80% of the source articles are the training set when each of the validation and testing sets is generated by 10% of the articles. Table 4 shows the statistics of the experimental datasets for related article recommendation.

Experimental Results. Table 5 demonstrates the performance of the different methods for related article recommendation. CNN-based methods, i.e., CNN and DeepQA, perform worse than other methods using RNNs. It may be due to the fact that Wikipedia articles are more structural so that convolutional features and the pooling layer cannot capture the document organization. RNN is slightly better than DeepQA since it captures the word dependencies in documents. HAN that considers the sentence-level structure

Table 6: The statistics of examples in the training, validation, and testing datasets for citation recommendation.

Dataset	Training	Validation	Testing
% of Source Papers	80%	10%	10%
Number of Examples	169,346	20,742	20,358

Table 7: The performance of citation recommendation. All improvements of our methods against the HAN method are significant differences at 99% level in both of a paired t-test and a permutation test.

Method	Accuracy	Precision	Recall	F1
RNN [32, 33]	0.7352	0.7358	0.7339	0.7348
CNN [25]	0.7309	**0.8048**	0.6097	0.6938
DeepQA [38]	0.7410	0.7579	0.7084	0.7323
HAN [52]	0.7813	0.7454	**0.8544**	0.7962
SMASH (P)	0.7739	0.7532*	0.8149	0.7828
SMASH (P+S)	**0.8068***	0.8019*	0.8150	**0.8084***
SMASH (P+S+W)	0.8058*	0.8038*	0.8092	0.8065*

is still the best baseline method for the task. Similar to the results of the previous task, the performance of HAN and SMASH with only the paragraph-level hierarchy is similar. When SMASH considers multi-level knowledge, it outperforms all of the baseline methods. It is also worth mentioning that although SMASH (P+S+W) is better than HAN, it does not improve SMASH (P+S) by adding the word-level hierarchy. It indicates the limitations of word-level information for capturing the semantics of long articles in Wikipedia.

4.4 Task 3: Citation Recommendation

Last but not least, the third application in the experiments is citation recommendation for academic papers. Given the content of an academic paper and the other paper as a candidate citation, we aim to classify if the candidate should be cited by the paper. This application can benefit researchers in exploring relevant studies for the paper. It not only accelerates the process of doing research and paper-writing but also prevents missing related works.

Experimental Datasets. Here we adopt the AAN Anthology Network Corpus [37] for the experiments. The corpus consists of the descriptions of 23,766 papers written by 18,862 authors in 373 venues and 124,857 citations in a citation network. In addition, the text of some papers are available in the corpus. For each paper with available text, the paper and each of its citations with text in the corpus is treated as a positive example. For each positive example, a irrelevant paper is randomly sampled to create a negative example for constructing a balanced dataset. To prevent the leakage of ground truth, the *References* sections are manually removed. We also remove the abstract sections to increase the difficulty of the task. The dataset is partitioned by the source papers of examples. The training set includes the examples generated by 80% of the source papers when each of the validation and testing sets is generated by 10% of the source papers, respectively. Table 6 demonstrates the statistics of the experimental datasets for citation recommendation.

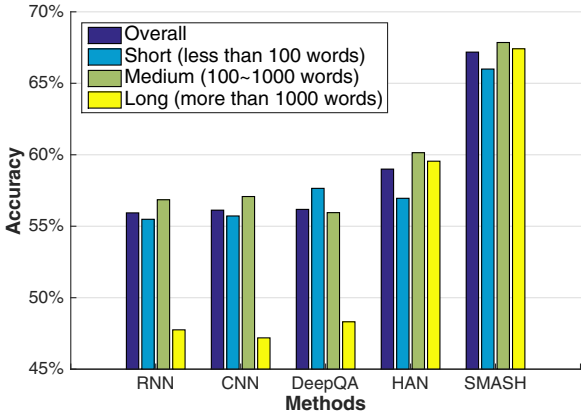

Figure 5: The classification performance of different methods across different document lengths in email attachment suggestion. SMASH uses all-level hierarchies.

Experimental Results. Table 7 shows the performance of the methods for citation recommendation. The experimental results are consistent with the results of the previous two tasks. Three baseline methods with only word-level knowledge have similar performance; CNN without using the asymmetric similarity matrix and considering word dependencies performs slightly worse than the other methods. HAN with the sentence-level information still outperforms all of the other baseline methods. After exploiting the knowledge of multi-level hierarchies, SMASH surpasses all of the baseline methods. Similar to the results for related article recommendation, the word-level hierarchy does not enhance the performance after considering the paragraph- and sentence-level knowledge. It depicts that high-level structural information is much more important for the task of citation recommendation.

4.5 Robustness Analysis and Discussion

After evaluating the effectiveness of SMASH RNN in different real-world applications, we analyze its robustness in this section.

4.5.1 Document length analysis. First, we verify that the improvements achieved by SMASH are consistent across different lengths of documents with the task of email attachment suggestion. Here we simply categorize document lengths into three groups, including short (less than 100 words), medium (100 to 1,000 words), and long (more than 1,000 words). For each testing example, we classify the example into the three length groups based on the maximum of the length of the source and candidate documents. Figure 5 and 6 show the classification and ranking performance of different methods for email attachment suggestion. Although HAN has a similar performance to other baseline methods for short and medium documents, it significantly improves both accuracy and MAP for the long-form documents by taking the sentence-level knowledge into account. It demonstrates the importance of understanding the document structure to deal with long-form documents. The improvements of SMASH against the baseline methods, including HAN, are significant and consistent across different document lengths. This demonstrates that hierarchies utilized in SMASH faithfully capture

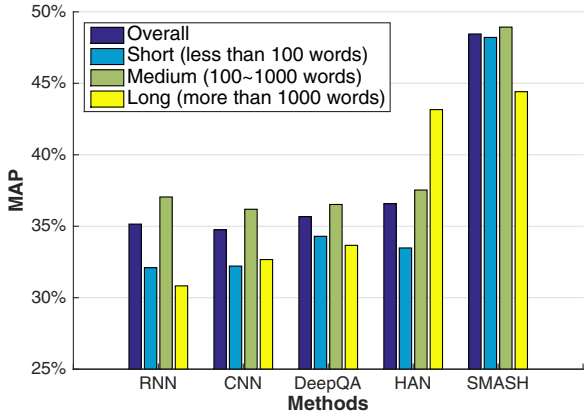

Figure 6: The ranking performance of different methods across different document lengths in email attachment suggestion. SMASH uses all-level hierarchies.

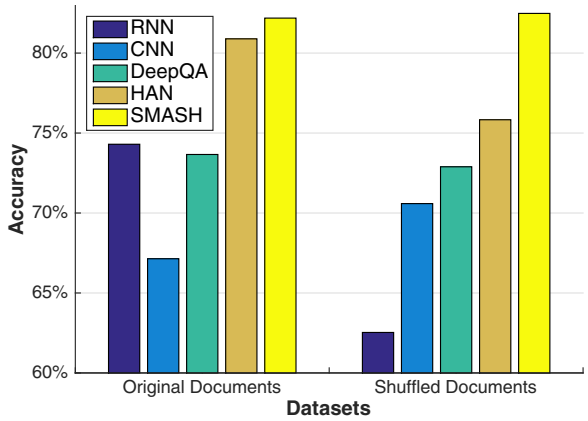

Figure 7: The classification performance of different methods with the original and shuffled documents in related article recommendation. SMASH uses the paragraph- and sentence-level hierarchies.

the document structure and semantics through multiple levels of abstraction. Hence, SMASH is robust across the spectrum of document lengths, and is capable of modeling both short as well as long-form documents.

4.5.2 Robustness to document perturbation. An interesting observation is that although SMASH achieves a 13.86% improvement of accuracy against HAN for email attachment suggestion, the improvements for the other two tasks, while statistically significant, are much smaller (1.6% and 3.1%, respectively). We assume this is because the opening words in Wikipedia pages (descriptions) and academic papers (introductions) are highly informative, and therefore the baselines can solve the problem using only positional information. To verify the assumption, we shuffle the paragraphs of Wikipedia articles to make the important texts randomly distributed in the documents for related article recommendation. Figure 7 shows the performance for related article recommendation with original and shuffled documents. RNN and HAN perform worse with shuffled documents because they cannot identify the critical parts in different positions. CNN and DeepQA have consistent performances because the convolutional features are independent to positional information. These improvements are also consistent in several trails with different random seeds for shuffling documents.

The performance of SMASH is also consistent because the model diagnoses the documents at different levels with attention. Moreover, the improvement against the best baseline method, HAN, increases significantly for the shuffled documents, and is more in line with the improvements achieved for the email attachment suggestion task. This leads us to conclude that SMASH is robust to the positioning of the core document information, and can perform equally well both for documents with well-defined introductions, as well as for complex, non-linear narratives.

5 CONCLUSIONS

In this paper, we propose to address the problem of semantic text matching for long-form documents, which has been less explored in the previous studies. In order to model the complex semantics of long-form documents, MASH RNN is introduced to generate document representations with hierarchical structures at different levels, as well as the attention mechanism in deep learning. Our model, SMASH RNN, is then formulated as a Siamese structure that aggregates the representations of the source and candidate documents derived by two MASH RNNs.

In addition to formulating the theoretical framework, we also demonstrate the practical potential of semantic text matching for long-form documents by providing three real-world applications, including email attachment suggestion, related article recommendation, and citation recommendation. Extensive experiments demonstrate that our proposed approach significantly outperforms several competitive baseline methods within different categories in both of the classification and ranking tasks. Moreover, we also show the robustness of SMASH RNN across the spectrum of documents lengths and perturbations.

Our conclusions can be summarized as follows: (1) semantic text matching for long-form documents is impactful, with numerous useful applications; (2) the usage of hierarchical document structure is essential for semantic text matching, especially for modeling long-form documents; (3) SMASH RNN can accurately capture the complicated semantics of long-form documents, even if the important messages may occur at any position, and at any level of the document structure.

ABSTRACT

As the size of real-world graphs has drastically increased in recent years, a wide variety of graph engines have been developed to deal with such big graphs efficiently. However, the majority of graph engines have been designed without considering the power-law degree distribution of real-world graphs seriously. Two problems have been observed when existing graph engines process real-world graphs: inefficient scanning of the sparse indicator and the delay in iteration progress due to uneven workload distribution. In this paper, we propose RealGraph, a single-machine based graph engine equipped with the hierarchical indicator and the block-based workload allocation. Experimental results on real-world datasets show that RealGraph significantly outperforms existing graph engines in terms of both speed and scalability.

1 INTRODUCTION

Graphs are widely used data structures for representing relationships between objects in various real-world domains, such as the web, social networks, protein networks, etc. Recently, with their increasing usage, the size of real-world graphs has increased rapidly. Such real-world graphs are called *big graphs*. To meet the demand for efficient handling of real-world big graphs, various graph engines have been developed [1, 6, 18, 25, 30]. These graph engines provide a simple programming interface to help programmers easily develop and execute graph algorithms for big graphs [14, 21].

Since all graph algorithms could be iteratively performed, existing graph engines adopt an *iterative processing* method, where an iteration starts to proceed *after* all the nodes to be processed at its previous iteration are completely processed [8, 19, 24]. Each iteration consists of two phases. At the first phase, the graph engine scans the *indicator* consisting of a bit vector [14, 29] to identify the nodes to be processed. At the second phase, it processes the identified nodes in parallel through multi-threading. Both phases of the iteration in existing graph engines, however, have been developed without careful considerations on the degree distribution of real-world graphs.

Most real-world graphs follow the *power-law degree distribution*, which is characterized by very few nodes having a very high degree (i.e., *hub nodes*), while most nodes (i.e., non-hub nodes) having a low degree [15]. The power-law degree distribution of real-world graphs causes following two phenomena when existing graph engines execute graph algorithms. First, the distribution of the nodes processed at iterations is skewed where the majority of nodes are processed at less than first half iterations while only a small number of nodes are processed at the remaining iterations[1]. Second, at some iterations, the nodes with very large degree disparity (i.e., hub and non-hub nodes) are processed together.

These phenomena cause the following two problems, which slows down the performance of the graph engines. The problem related to the first phase of the iteration is *inefficient scanning of the indicator*. Existing graph engines use a single flat indicator [14, 25, 29, 30]. They scan the whole indicator *linearly* at each iteration to identify the nodes to be processed. In the majority of iterations, the number of nodes to be processed tends to be very small, which makes the indicator very sparse in those iterations. Linear scanning of the very sparse indicator causes unnecessary computations and leads to the performance degradation of the graph engines.

The problem related to the second phase of the iteration is the delay for the progress of the next iteration due to *uneven workload*

[1]Note that this phenomenon does not happen in the graph algorithms that processes *all nodes* at each iteration, such as PageRank.

allocation over threads. Existing graph engines adopt the node-based workload allocation, where each thread processes an individual node with its edges [6, 14, 18, 30]. Since the workload of each thread is proportional to the number of edges, the node-based allocation produces huge difference in the workload between the threads that process hub nodes and the others that process non-hub nodes. This causes the threads that process non-hub nodes to wait for the ones that process hub nodes to complete, which delays the start of the next iteration.

To solve these two problems, we propose a new single-machine based graph engine[2] called *RealGraph*. RealGraph is designed based on the principles of well-known database systems [3, 4, 7] to manage big data efficiently. Furthermore, When storing graph data, RealGraph preserves *data locality* by adopting *efficient data layout* [12] that stores the data accessed together in adjacent storage space. In addition, we propose two new techniques considering the characteristics of real-world graphs to execute the graph algorithms efficiently.

First, we propose the *hierarchical indicator* that consists of multi-level bit vectors designed to skip easily the ranges of the indicator to be unnecessarily scanned. The lowest-level bit vector is the same as the flat indicator in existing graph engines. A higher-level bit vector compresses some range of its lower-level bit vector using a single bit. A bit set as 1 of each level bit vector denotes that a corresponding range at its lower-level bit vector should be scanned. The process starts from the highest-level bit vector; it scans the range of the lower-level bit vector corresponding to the bit (if each higher-level bit vector has a bit set as 1). Unlike the existing flat indicator, the hierarchical indicator reduces unnecessary scanning of the sparse indicator dramatically.

Second, we propose the block-based workload allocation which assigns *a block* to each thread, instead of a node and its edges in the node-based one. A block is a fixed-size standard I/O unit of the graph engine, which stores multiple nodes and their edges together. Since the block size is fixed, the total number of edges stored in each block is almost the same. Thus, the graph engine can allocate almost the same workload to each thread. This reduces the waiting time among threads at every iteration, which eventually accelerates the start of the next iteration.

We show the effectiveness of the proposed techniques through extensive experiments. The results indicate that RealGraph improves the performance considerably when using the proposed techniques together rather than individually. We also demonstrate the performance of RealGraph by comparing it with five well-known single-machine based graph engines [14, 21, 25, 29, 30] and four distributed-system based graph engines [1, 9, 16, 26]. For experiments, we used seven graph algorithms and six real-world graphs. For all graph algorithms and datasets, RealGraph shows the best performance in terms of processing speed and scalability compared with existing graph engines.

The contributions of this paper are as follows.

- First, we point out the problems that occur when existing graph engines deal with real-world graphs.
- Second, we propose two techniques for efficient processing of real-world graphs: (1) the hierarchical indicator to reduce unnecessary scanning and (2) the block-based workload allocation to balance the workload among threads.
- Third, we propose RealGraph, a single-machine based graph engine employing with these techniques.
- Finally, we verify the superiority of RealGraph through extensive experiments.

The organization of the paper is as follows. Section 2 addresses our motivation. Section 3 overviews our RealGraph. Section 4 explains the hierarchical indicator. Section 5 describes the block-based workload allocation. Section 6 shows experimental results. Finally, Section 7 summarizes and concludes the paper.

2 MOTIVATION

This section describes the execution procedure of a graph algorithm in existing graph engines, explains the characteristics of real-world graphs, and points out the problems when existing graph engines process real-world graphs.

The graph engine is a general-purpose software framework that aims to process various graph algorithms, rather than targeting specific graph algorithms [6, 9, 13, 14, 16–19, 21, 25, 26, 29, 30]. Although some graph algorithms could be processed asynchronously without synchronization between threads, all graph algorithms can be executed synchronously where threads are synchronized at regular intervals [8]. Therefore, most graph engines adopt *iterative processing* based on synchronous execution[3], where all the nodes to be processed at each iteration are processed completely and then the next iteration starts [24].

At each iteration, the graph engine executes a graph algorithm with two phases [13, 14, 25]: (1) identifying the nodes to be processed and (2) processing the identified nodes and their edges. In the first phase, the graph engine identifies the nodes to be processed by scanning the *indicator* consisting of a bit vector[4] of the length equal to the number of nodes [14, 25, 30]. If the bit is set as 1, it means that the node corresponding to the bit is to be processed at the current iteration. In the second phase, threads process the identified nodes and their edges in parallel. The existing graph engines adopt the node-based workload allocation that assigns a node and its edges to each thread [6, 18, 30].

However, both phases were designed without careful consideration of the degree distribution of real-world big graphs. Note that most real-world graphs show the power-law degree distribution, consisting of a small number of hub nodes and a very large number of non-hub nodes [15].

[2]Existing graph engines can be classified into two categories: single-machine based ones and distributed-system based ones.

[3]Some graph engines adopt an asynchronous execution based processing [10, 24].

[4]For the indicator composed of a bit vector, the space required for representing a node is a single bit. Therefore, even when dealing with a big graph with a large number of nodes, the graph engine requires only a small, fixed space. The downside of using a bit vector is that many bits are left unused when only a small number of nodes are processed in an iteration. A *linked list* may be considered as an alternative data structure. The linked list, however, requires much more space to represent a single node (e.g., 4 bytes in the case of using an integer for a node). In the iteration that processes only a small number of nodes, there is an advantage of using only a very small space for the nodes. But there would be a significant overhead of allocating and releasing a number of nodes for a linked list at each iteration. In particular, if the number of nodes that need to be processed in an iteration exceeds the given memory space, the graph engine could not run. This is the reason why most graph engines employ the simple and small bit vector for the indicator.

For example, Figure 1 shows the degree distribution of the Yahoo dataset used in our experiments, where the x-axis represents the degree of a node, and the y-axis does the number of nodes having the degree. We observe this dataset also follows the power-law degree distribution. This power-law degree distribution of the real-world graph causes the following phenomenon at each phase, which degrades the performance of graph engines.

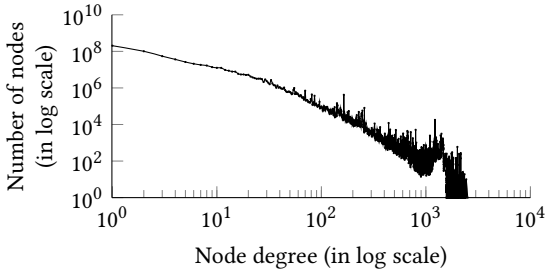

Figure 1: Degree distribution of the Yahoo dataset.

First, the distribution of the nodes processed at iterations is skewed. Since hub nodes are connected to many other nodes, they are highly likely to be accessed at early iterations in general regardless of the starting node. Also, a large number of nodes connected to the hub nodes are accessed together in the following iteration. As a result, the majority of nodes tend to be processed at early iterations, and only a small number of nodes that are multiple hop away from the hub nodes are likely to be handled at remaining iterations.

Figure 2 shows the cumulative number of the nodes processed up to each iteration, when the breadth first search (BFS) is performed on all the datasets used in experiments. Since the total number of iterations is different for each dataset, the x-axis represents the ratio of the number of processed iterations to that of the entire iterations. The y-axis indicates the cumulative percentage of the processed nodes. At early 30% or less of iterations, almost 90% of nodes are processed, and fewer than 10% nodes are processed over the remaining 70% of iterations. It is also observed that only a few nodes are processed across at more than half of the remaining iterations.

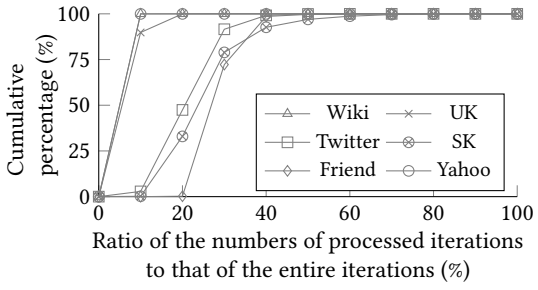

Figure 2: Cumulative number of the nodes processed up to each iteration when BFS is performed.

This phenomenon makes the indicator *very sparse in most iterations*. Since the existing graph engines linearly scan the entire indicator, the scanning becomes very inefficient. As the graph size increases, this linear scanning becomes even more impractical. In fact, with 1.4 billion nodes in the Yahoo dataset, the largest dataset used in our experiments, the scanning overhead for the indicator takes up to 50% of the total BFS execution time.

Secondly, the degrees of the nodes processed at each iteration vary significantly. In particular, the degree difference between nodes is very large at the iterations where hub nodes and non-hub nodes are processed together. Figure 3 shows the degree difference between the nodes processed at each iteration, when BFS is performed on all the datasets. The results for the first 100 iterations are shown[5]. The x-axis represents the iteration number, and the y-axis shows the ratio of the minimum node degree to the maximum node degree in log scale. We observe the existence of significant degree difference at every iteration, and in extreme cases the difference is up to 10^6 times more.

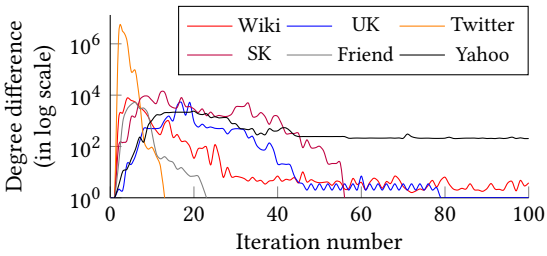

Figure 3: Degree difference between the nodes processed at each iteration when BFS is performed.

The degree difference between nodes causes uneven distribution of workload among threads in existing node-based workload allocation. Because the workload of threads is proportional to the degree of the assigned node in the node-based allocation [14, 25, 29] the workload among threads varies, which in turn delays the completion of the iteration. This is particularly true at the iteration which processes the hub nodes, because the threads with non-hub nodes should wait until the ones with the hub nodes to complete their executions. This delays the start of the next iteration, which eventually slows down the graph engine.

These observations motivate us to develop our RealGraph, a graph engine equipped with our two novel techniques: (1) efficient scanning of the sparse indicator and (2) uniform workload allocation over threads to minimize the delay for the progress of the next iteration.

3 OVERVIEW OF REALGRAPH

In this section, we describe the general architecture of our RealGraph and the efficient data layout for graph storage in RealGraph. In the following Sections 4 and 5, we describe how RealGraph solves the problems mentioned in Section 2.

3.1 Architecture

RealGraph employs, as a programming model, the *vertex-centric programming model* [14, 30] that performs a graph algorithm per the node with its edges. As a memory model, RealGraph employs the *external-memory model* [21, 29] that utilizes external storage when graph data exceeds the main memory.

[5]We show the results for the first 100 iterations, since the numbers of total iterations are different across datasets.

As shown in Figure 4, RealGraph consists of four layers: storage management layer, buffer management layer, object management layer, and thread management layer. The lower three layers manage memory and storage space. They are designed on the basis of well-known database storage systems, such as WiSS [7], Exodus [4], and Shore [3]. The thread management layer executes graph algorithms and is implemented with two techniques proposed in this paper. On top of them, we also provide a web-based user interface[6]. Using the user interface, anyone could execute a graph algorithm provided by RealGraph on their own graphs and download its result. The roles and components of each layer except for the interface are as follows.

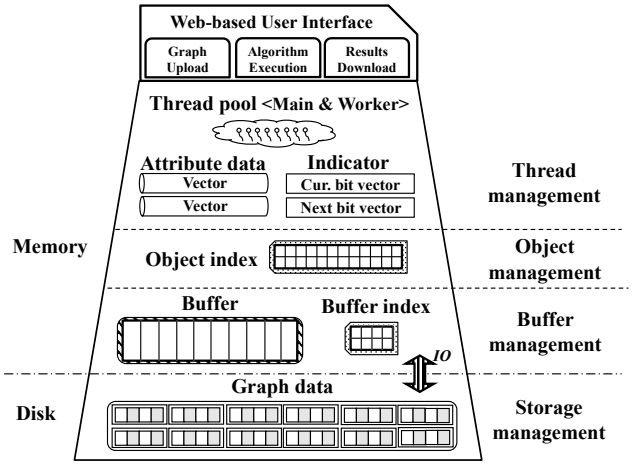

Figure 4: Architecture of RealGraph.

The storage management layer manages storage space. The graph data is divided into blocks and stored in storage space. A block is the standard I/O unit, and each block contains one or more objects. Here, an object is composed of a node and its edges[7]. If the size of an object exceeds the block size, it is stored across several blocks. This layer also manages I/Os of these blocks.

The buffer management layer manages the space for blocks in the main memory. It consists of a buffer and a buffer index. A buffer is a space with a given size in main memory and keeps blocks within that space. The buffer index has the indices for blocks loaded in buffer, which helps to access the blocks in the buffer quickly. This index is always loaded in the main memory.

The object management layer manages the location information for blocks and objects of the graph data. There is an object index which contains the indices of objects and blocks stored in storage device. It is always loaded in the main memory.

The thread management layer performs a graph algorithm. It consists of three components: thread pool, attribute data, and two indicators (i.e., current and next). The thread pool has two types of threads: worker threads that actually perform graph algorithms and one main thread that manages worker threads. The attribute data stores intermediate and final results for either nodes or edges obtained when performing a graph algorithm (e.g., nodes visited in BFS, node ranks in PageRank). The attribute data consists of several attribute vectors, each of which has the same number of elements as that of nodes. The element of each vector is the attribute corresponding to the node. If the size of the attribute data exceeds that of a given memory, they are divided into several chunks and stored in the secondary storage; each chunk required by a graph algorithm is loaded into memory. The current/next indicator stores the information about the nodes to be processed at the current/next iteration. Both indicators are always loaded in the main memory.

On the basis of the above architecture, each iteration of a graph algorithm is executed as follows. First, the main thread identifies the nodes to be processed at the current iteration by scanning the *current* indicator. Next, using the object index, the main thread finds the locations of the blocks including the objects corresponding to the identified nodes, and checks if the block exists in the buffer. Then, the main thread assigns each block to be processed to each worker thread in order. If it does not, the worker thread requests the block to the storage management layer and loads it into the buffer. After loading, the worker thread executes the function of a graph algorithm and updates the results in the corresponding attribute data. Then, it sets the next indicator such that the nodes connected to the processed nodes in the current iteration are to be processed at the next iteration. Finally, before the start of the next iteration, the next indicator is switched to the current indicator, and the current indicator is initialized to be used as the next indicator.

3.2 Efficient data layout

A good placement of nodes and edges in storage (i.e., data layout) would improve both CPU and I/O performances of a graph engine. Existing graph engines, however, have aimed at maximizing the utilization of computing resources through system optimization, overlooking the importance of data layout [14, 25].

Recognizing this, we have borrowed the concept of efficient data layout [12] and applied it to RealGraph. The main idea for this data layout is, the data accessed together in executing graph algorithms are placed in the same or adjacent storage space. Since RealGraph stores objects (each having a node and its edges) in blocks in the ascending order of node IDs as other graph engines [21, 29], we assign consecutive node IDs to the nodes likely to be accessed together at the same or successive iteration(s) by a graph algorithm. This idea makes the objects accessed together in a graph algorithm to be stored in the same or adjacent block(s).

Based on reference [12] to assign consecutive node IDs to nodes to be accessed together in various graph algorithms, breadth first search (BFS) is used as follows: BFS is performed from an arbitrary starting node in a graph given; the nodes accessed by BFS are recorded one by one in the order; the node ID used in a graph engine is determined by this order. The data layout obtained by this idea makes the nodes and edges accessed together at the same or successive iteration(s) of graph algorithms placed in the same or adjacent block(s) successfully.

This data layout transformation is performed at the preprocessing step where RealGraph stores a graph[8]. The data layout transformation is required only once for each graph to be stored in

[6] http://166.104.110.75:20080

[7] Since RealGraph uses the adjacency list, each object is stored as a node and the edges pointing to its adjacent nodes.

[8] Most graph engines also perform the preprocessing step when storing a graph. For example, GraphChi divides a graph into shards and then stores them in its preprocessing step.

RealGraph, and the graph stored in this new data layout is beneficial to the performance of many graph algorithms running on RealGraph. This implies that the transformation overhead is shared by many graph algorithms running on RealGraph.

Reference [12] reports that the data layout determined by BFS enables a graph engine not only to reduce the number of block accesses but also to face more sequential accesses of blocks, rather than random accesses, thereby improving its performance considerably.

Figure 5 shows two data layouts. A data layout has nine blocks represented by rectangles. A circle represents a node and its edges in a block. The numbers in circles indicate the order of access requests by a given graph algorithm. For processing, a graph engine should load 8 nodes into the main memory in Figure 5. In this case, by changing into the efficient data layout from existing data layout, we improve the I/O and CPU performances of RealGraph.

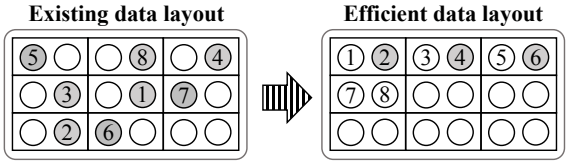

Figure 5: Data layout transformation.

When performing graph algorithms, worker threads need frequent access to blocks and attribute data. Even when it is not possible to load all of the blocks into memory, since the objects to be processed together are more likely to be located in the same or successive blocks, the number of I/O requests would be decreased and the sequential access rate could be increased. In Figure 5, RealGraph accesses only four blocks sequentially, instead of 8 blocks randomly. Similarly, the I/O performance would be increased when entire attribute data could not be loaded into memory, since the same or successive chunks of attribute data are more likely to be updated. In both cases, it is more likely to re-access the data already loaded in the main memory, which results in the increased cache hit ratio and improves the CPU performance. In addition, since adjacent bits are more likely to be set at each iteration in the current indicator, the cache hit ratio for the indicator would be increased.

Through experiments, we evaluate the performance of the efficient data layout when applied to RealGraph and also examine the synergy effects when the efficient data layout is used in combination with our two techniques in the following sections.

4 HIERARCHICAL INDICATOR

As explained in Section 2, linear scanning of the sparse indicator is very inefficient. For efficient scanning, we propose a hierarchical indicator that skips efficiently the ranges that do not need to be scanned.

The hierarchical indicator is made up of two or more bit vectors, where the upper-level bit vector determines the ranges to be scanned in the lower-level bit vector. Each level bit vector is divided into a set of ranges with a fixed length. The lowest-level bit vector is the same as the flat indicator used in existing graph engines. Each higher-level bit vector consists of a number of bits as many as the number of ranges in each lower-level bit vector. Each bit of the higher-level bit vector refers to the corresponding range of its lower-level bit vector. Both the current and next indicators are configured in the same way.

Figure 6 shows the hierarchical indicator consisting of three level bit vectors with a range length of 3. The top-level bit vector consists of three bits. The middle-level bit vector has three ranges with 9 bits. The bottom-level bit vector has a total of 9 ranges with 27 bits.

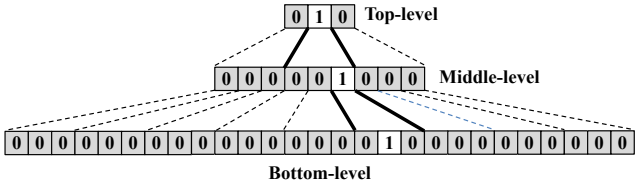

Figure 6: 3-level hierarchical indicator.

The current and next hierarchical indicators are used as follows. At each iteration, the main thread identifies the nodes to be processed in the *top-down manner* from the current hierarchical indicator. It scans each higher-level bit vector to identify the bits set as 1, and determines the ranges to be scanned of the lower-level bit vector. Then, it scans those ranges only. The main thread repeats this process and finds the nodes to be processed corresponding to the bits set as 1 in the lowest-level bit vector. By using the current hierarchical indicator, the main thread in RealGraph could skip all the ranges of the lower-level bit vector corresponding to the bits with 0 of the higher-level bit vector.

In Figure 6, the main thread scans the top-level bit vector and identifies the second bit set as 1. Only the second range of the middle-level bit vector is scanned, and the sixth bit with 1 is found. The sixth range of the bottom-level bit vector is scanned, and node 17 is identified as the node to be processed at the current iteration. In this example, the main thread scans only 9 bits, instead of all 27 bits of the bottom-level bit vector.

For the next hierarchical indicator, the worker threads set the nodes to be processed at the next iteration in the *bottom-up manner*. Each worker thread sets the bits corresponding to the nodes to be processed in the lowest-level bit vector as 1. Then, it sets the bit of the higher-level bit vector corresponding to the range including the bit set as 1 of the lower-level bit vector. This process is repeated until the top-level bit vector is reached.

Suppose Figure 6 is the next hierarchical indicator where the worker thread sets the 17th bit in the bottom-level bit vector. It also sets the sixth bit in the middle-level bit vector corresponding to the sixth range including the 17th bit in the bottom-level bit vector. Finally, it sets the second bit of the top-level bit vector corresponding to the second range containing the sixth bit in the middle-level bit vector.

To construct the hierarchical indicator, two parameters are required: the range length and the height of the hierarchical indicator. Since the height is automatically determined once the range length is fixed, the hierarchical indicator could be configured by determining the range length.

Figure 7 shows the result of BFS by changing the range length on the Yahoo dataset. Figure 7-(a) shows the scanning time, and Figure 7-(b) shows the memory usage and the height of the hierarchical indicator in levels. The experimental results show that as

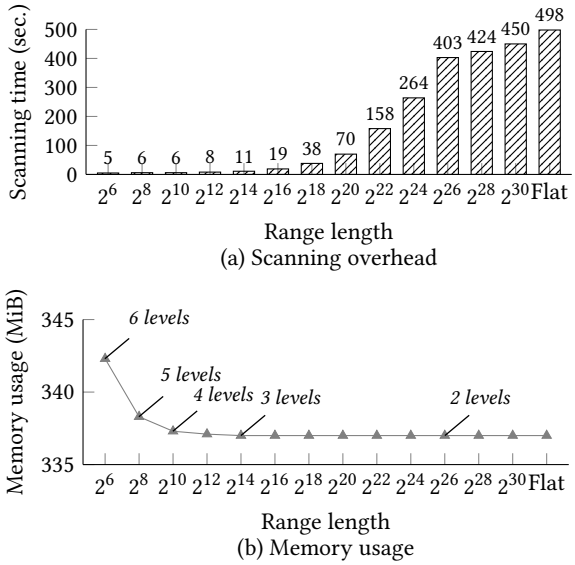

Figure 7: Scanning overhead and memory usage of the hierarchical indicator.

the range length increases, the scanning time increases, and the memory usage decreases. When considering both scanning time and memory usage, the range length of 2^{10} bits is the most efficient. The hierarchical indicator with the range length of 2^{10} bits uses only 0.1% more memory than the flat indicator employed in existing graph engines and reduces the scanning time dramatically to one-hundredth. In subsequent experiments, therefore, we use 2^{10} bits for the range length of the hierarchical indicator.

5 BLOCK-BASED WORKLOAD ALLOCATION

As mentioned in Section 2, the degree difference at each iteration causes uneven workload distribution among threads in the node-based workload allocation. This delays the progress of an iteration, which leads to degradation of the overall performance of the graph engine.

To solve the delay for the progress of the next iteration, we propose the block-based workload distribution which assigns a *block* to each thread, rather than an object (i.e., a node with its edges). A block may contain multiple objects of different sizes, but the sum of their sizes is almost the same. In RealGraph, threads are given with almost equal workloads due to the block-based workload distribution, which reduces the disparity of the completion times between threads.

Since the block size affects the performance of RealGraph, we examine the appropriate block size for RealGraph.

Figure 8 shows the execution time of PageRank[9] with 20 iterations, starting at 64KiB and increasing the block size by 4 times on the Yahoo dataset. The x-axis represents the block size, and the y-axis represents the execution time. The result confirms that the 1024KiB block shows the best performance. Thus, we use 1024KiB as the block size for RealGraph in the following experiments.

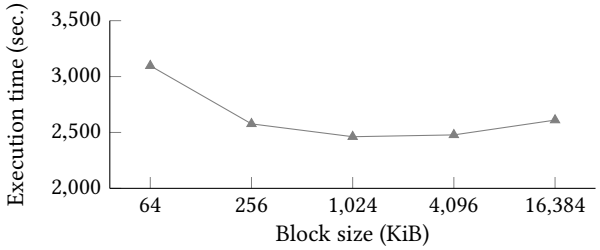

Figure 8: Execution time of PageRank with different block sizes.

To verify the superiority of the block-based workload allocation compared to the node-based one, we apply both node and block allocation techniques to RealGraph and measure the workload of each thread (i.e., the number of processed edges) at each iteration while performing PageRank on the Yahoo dataset. Figure 9 shows the result where the x-axis represents the iteration number, and the y-axis represents the standard deviation of the workload among threads. There exist a few cases where the standard deviation of the workload in the block-based allocation is larger than that in the node-based allocation. In overall, however, the block-based allocation has a much smaller standard deviation than the node-based one. This indicates the block-based allocation distributes the workload more evenly across threads.

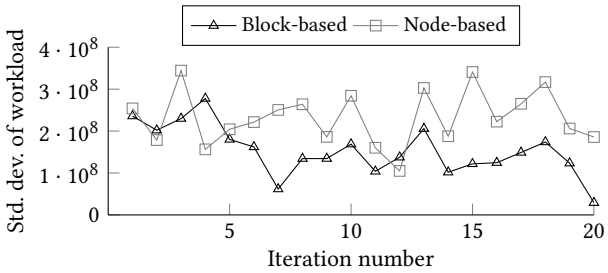

Figure 9: Standard deviation of workload over threads at each iteration

Note that the block-based workload allocation requires additional *thread synchronization* when handling a large object. A single object stored across *multiple blocks*, such as the object for a hub node, is handled by *multiple threads* in RealGraph. If multiple threads that handle a single object need to update the result of the same attribute, thread synchronization is required, making the threads progress in sequence. Since thread synchronization is an operation with large overhead, frequent thread synchronization could degrade the performance of the graph engine. If many objects are stored over several blocks, the performance of RealGraph could slow down.

Fortunately, in real-world graphs, these objects occupy only a small fraction. For all the datasets used in the experiment, when the block size is 1024KiB, only 0.0003% of the objects are stored in several blocks on average. Because the frequency of thread synchronization is very rare during the execution of the graph algorithm,

[9]BFS accesses *part of* nodes at each iteration, which results in random accesses to blocks. The random access of blocks influences some other factors such as buffer replacement policy to affect the performance of the graph algorithm. PageRank, on the other hand, causes sequential accesses to blocks, because it sequentially accesses all the nodes at each iteration. With the sequential access of blocks, other factors are less likely to affect the performance of the graph algorithms. Therefore, in this experiment, we use PageRank to observe the change of performance according to the block size as much as possible.

the performance degradation of RealGraph due to the thread synchronization is negligible.

6 PERFORMANCE EVALUATION

This section demonstrates the superiority of RealGraph through experiments. Section 6.2 validates the techniques applied to RealGraph. Section 6.3 compares the performance of RealGraph with existing single-machine based graph engines. Section 6.4 compares the performance of RealGraph with those of existing distributed-system based graph engines.

6.1 Experimental Setup

We employed five state-of-the-art single-machine based graph engines: GraphChi [14], TurboGraph [25], GridGraph [30], FlashGraph [29], and X-Stream [21]. These engines and RealGraph were performed on PCs with Intel i7-7700K, 1TiB SSD, and 64GiB memory. We also compared RealGraph with four distributed-system based graph engines: PowerGraph [9], GraphLab [16], GraphX [26], and Giraph [1].

As experimental datasets, we used six real-world graphs of varying sizes. Table 1 shows the specifications of each dataset, where *#Nodes* is the number of nodes, *#Edges* is the number of edges, and *Size* is the data size. The descriptions of datasets are as follows[10]. *Wiki* is the hyperlinked data of wiki pages in English Wikipedia. *UK* is the dataset representing the relationships of web pages having the .uk domain. *Twitter* is the dataset with the relationships of tweets collected on Twitter. *SK* is the dataset with the relationships of web pages having the .sk domain. *Friend* is the dataset with all links among users in the online gaming social network, Friendster. *Yahoo* is the hyperlinked data of web pages in Yahoo! AltaVista.

Table 1: Graph datasets

Datasets	Real-world graphs					
	Wiki	UK	Twitter	SK	Friend	Yahoo
#Nodes (M)	12	39	61	50	68	1,413
#Edges (B)	0.37	0.93	1.4	1.9	2.5	6.6
Size (GiB)	5.7	16	24	32	44	114

We employed seven graph algorithms widely used in various fields: breadth first search (BFS) [22], weakly connected component (WCC) [23], betweenness centrality (BC) [2], PageRank [20], random walk with restart (RWR) [28], belief propagation (BP) [11], and sparse matrix and vector multiplication (SpMV) [27]. Since BFS, WCC, and BC are the algorithm that accesses *part of* nodes at each iteration, the indicator is used. For the remaining four graph algorithms (i.e., PageRank, RWR, BP, and SpMV), the indicator is not used, because they access all the nodes at each iteration [11]. Since BFS, WCC, and BC differ in the number of iterations according to the datasets, they are performed until their termination conditions are satisfied. For the other four graph algorithms (i.e., PageRank, RWR, BP, and SpMV), the number of iterations is fixed as 20.

[10] Wiki: http://konect.uni-koblenz.de/networks/wikipedia_link_en, UK: http://law.di.unimi.it/webdata/uk-2005, Twitter: an.kaist.ac.kr/traces/WWW2010, SK: http://law.di.unimi.it/webdata/sk-2005, Friend: https://archive.org/details/friendster-dataset-201107, Yahoo: http://webscope.sandbox.yahoo.com

[11] There are many other graph algorithms, such as single source shortest path, depth first search, community detection, and triangle counting that use indicators for their executions. However, since existing graph engines do not provide them, we were not able to include them in our experiments.

6.2 Evaluation of proposed techniques

In this section, we verify the effectiveness of the techniques applied to RealGraph: Hierarchical indicator (H), Block-based workload allocation (B), and efficient Data layout (D). We performed two algorithms — BFS as a representative algorithm for accessing *part of* nodes at each iteration and PageRank as a representative algorithm for accessing *all* nodes at each iteration — on the Yahoo dataset, the largest one in experimental datasets. We set the number of threads of RealGraph as 8. The memory size is limited to 16GiB for the executions of out-of-core algorithms.

Figure 10 shows the results. The *x*-axis represents RealGraph with each technique applied. In the *x*-axis, Null means RealGraph with none of the proposed techniques (i.e., employing the flat indicator and node-based workload allocation), and each alphabet represents RealGraph equipped with the technique referring to its initial. For example, HB indicates RealGraph with the hierarchical indicator (H) and the block-based workload allocation (B). Ω represents RealGraph with all techniques applicable to each algorithm. The *y*-axis represents the execution time. And now, we describe the result in a way that compares the performance of RealGraph including any proposed technique with that of Null.

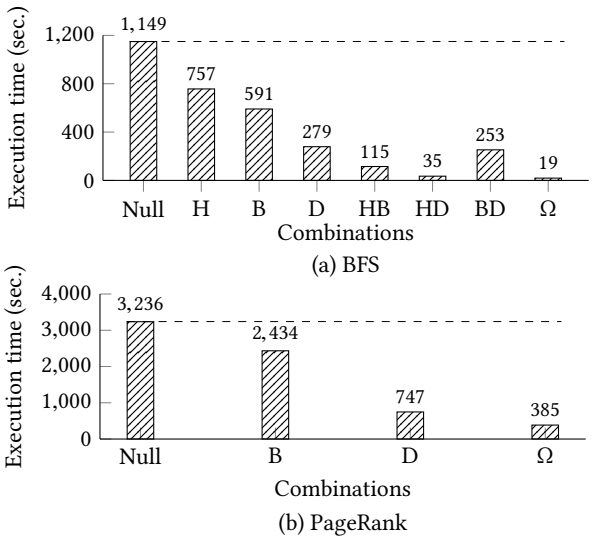

Figure 10: Performance of proposed techniques.

Figure 10-(a) shows the result of BFS. The hierarchical indicator (H) improves the performance about 1.5 times by reducing the scanning overhead, the block-based workload allocation (B) about 1.9 times by the nice load balancing, and the efficient data layout (D) about 4 times by increasing the degree of sequential access and the cache hit for attribute data and blocks, respectively.

When using both the hierarchical indicator and the block-based workload allocation (HB), the performance of RealGraph is improved 9.9 times. This is because the scanning overhead of the indicator at each iteration is reduced and the delay of the progress for the next iteration is prevented by even workload distribution. In addition, the main thread communicates with worker threads

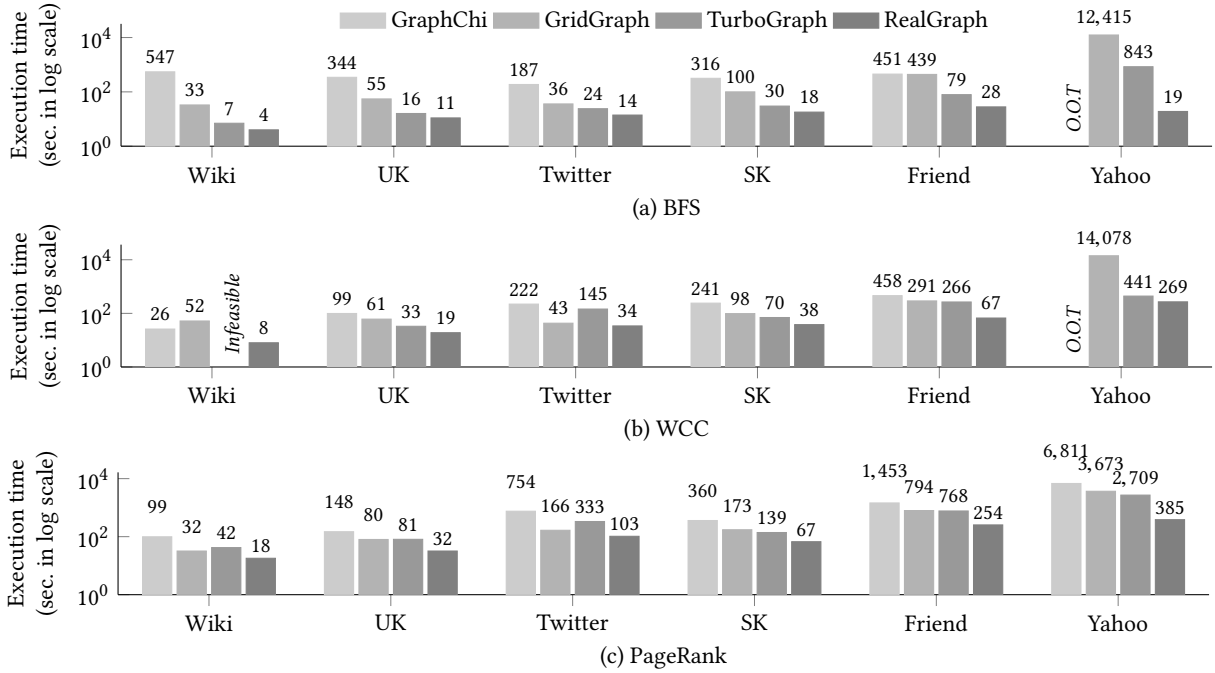

Figure 11: Performance comparison with graph engines with the same model.

per each block (rather than each node), which reduces the communication overhead. This further improves the performance of RealGraph.

The synergy is greater when combining the hierarchical indicator and the efficient data layout (HD). As mentioned in Section 3.2, the performance of RealGraph is improved by the efficient data layout when handling attribute data and graph data. Moreover, the number of ranges to be scanned in the current indicator decreases when efficient data layout is employed, because the bits corresponding to nodes to be processed tend to be clustered in a few ranges with efficient data layout. The cache hit ratio in the next indicator is also increased, because the bits in the same or adjacent ranges are likely to be set. This results in the *dramatic* performance improvement of RealGraph by 32.8 times.

The combination of the block-based workload allocation and the efficient data layout (BD) also shows synergy, improving the performance of RealGraph by 4.4 times. The magnitude, however, is somewhat smaller than the previous two cases (HB and HD). The reason is as follows. The efficient data layout aggregates the nodes to be processed into one or adjacent blocks. If an iteration processes a small number of nodes, the number of blocks to be processed may be less than the number of threads in RealGraph. Since each thread processes a block by the block-based workload allocation, all the given threads could have not been fully utilized in this case.

Finally, the combination of all three technologies (Ω) enhances the performance of RealGraph by 60 times.

Figure 10-(b) shows the results of PageRank. In PageRank where the indicator is not used, we could apply the block-based workload allocation (B) and the efficient data layout (D) to RealGraph. Each technique improves the performance by 1.3 and 4.3 times, respectively. The performance of RealGraph is improved 8.4 times when using both techniques together (Ω). The efficient data layout increases the probability that the nodes with sequential node IDs and the nodes connected to them take adjacent node IDs. If these nodes are processed by a single thread, the cache hit ratio for attribute data can be further increased. Because the block-based workload allocation assigns each thread the nodes in a single block with sequential node IDs, the performance is further improved by the synergy between the block-based allocation and the efficient data layout.

Through above experiments, we showed that each technique of RealGraph is effective, and that their combinations create a significant synergy effect. We also demonstrated that these techniques are all effective regardless of the type of graph algorithms.

6.3 Comparisons with single-machine based graph engines

In this experiment, we evaluate the performance of RealGraph by comparing it with existing single-machine based graph engines. Section 6.3.1 evaluates the performance of the single-machine based graph engines following the *same model* as RealGraph. Section 6.3.2 evaluates the performance of the single-machine based graph engines adopting *different models* from RealGraph. In these two sections, we used BFS, WCC, and PageRank, which are commonly provided by all graph engines. Section 6.3.3 shows the performance of other graph algorithms provided by different graph engines such as BC, RWR, BP, and SpMV.

6.3.1 Single-machine based graph engines with the same model. We employed TurboGraph [25], GridGraph [30], and GraphChi [14], all of which follow the same model as RealGraph. They adopt the vertex-centric model and the external-memory model. Since

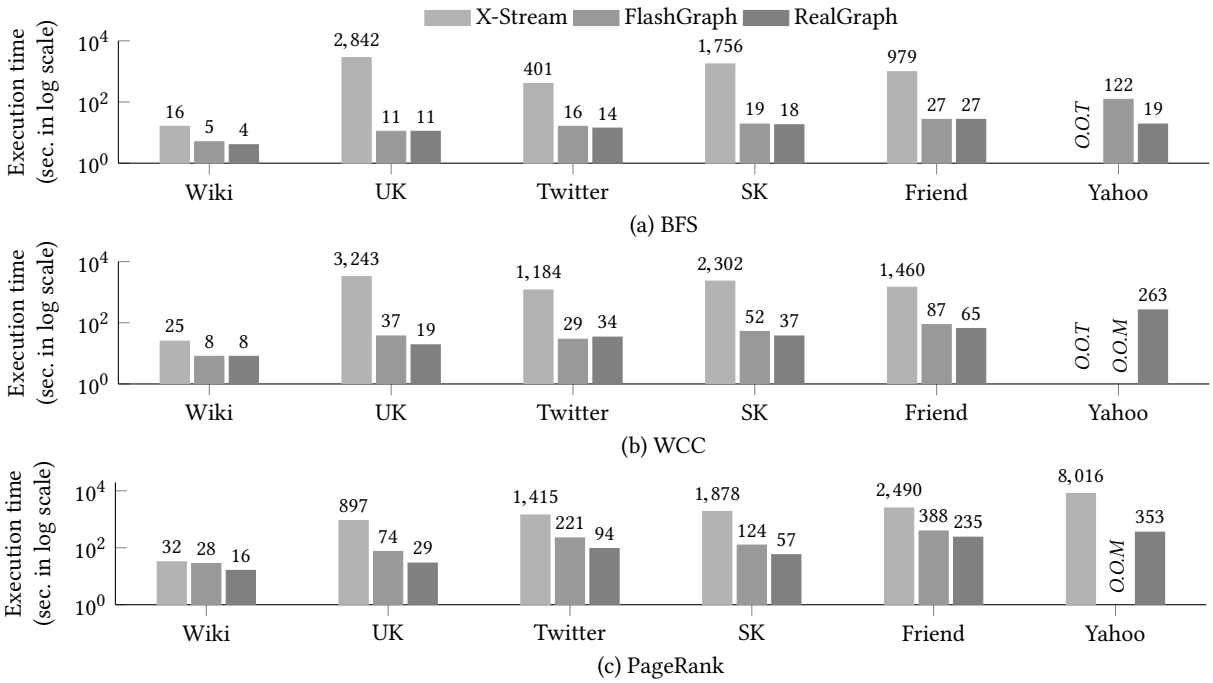

Figure 12: Performance comparison with graph engines with the different models.

TurboGraph fixed the number of threads identically as six, we set the number of threads of all the graph engines to six.

Figure 11 shows the results. The x-axis represents the graph datasets, and the y-axis represents the execution time in log scale. The experimental results show that overall execution time is in order of GraphChi, GridGraph, TurboGraph, and RealGraph. RealGraph provides the best performance *universally* for all graph algorithms and for all datasets. In particular, RealGraph is better than TurboGraph, the best performer among existing ones, up to about 44 times in the best case (i.e., BFS on the Yahoo dataset). We note that TurboGraph does not work in the Wiki dataset (i.e., infeasible), and GraphChi could not get the results of BFS and WCC on the Yahoo dataset within 24 hours (i.e., out of time, O.O.T).

6.3.2 Single-machine based graph engines with different models. In this experiment, we employed two graph engines with different models from that of RealGraph: FlashGraph [29] and X-Stream [21]. FlashGraph adopts the vertex-centric model and the semi-external memory model. X-Stream adopts the edge-centric model and the external-memory model. The number of threads was set identically as 8. We performed BFS, WCC, and PageRank, as in the previous experiments.

Figure 12 shows the experimental results. The x-axis represents the graph datasets, and the y-axis represents the execution time in log scale. RealGraph has the same or better performance than FlashGraph except for WCC on the Twitter dataset. In particular, the performance of RealGraph is up to six times better than that of FlashGraph (i.e., BFS on the Yahoo dataset). Since the graph engine with the semi-external memory model does not work if whole attribute data cannot be loaded into the given memory, FlashGraph could not perform PageRank and WCC on the Yahoo dataset (i.e., out of memory, O.O.M), while RealGraph performs all the algorithms.

Compared with X-Stream, RealGraph has always better performance for all graph algorithms and all datasets. In the case of PageRank on the Yahoo dataset, RealGraph outperforms X-Stream up to 250 times. Since the graph engines with the edge-centric model sequentially read the entire graph data at each iteration, it is inefficient for the algorithms that need to process only a few nodes at each iteration such as BFS and WCC. X-Stream does not work on BFS and WCC on the Yahoo dataset within 24 hours (i.e., O.O.T), while RealGraph works in maximum 360 seconds. These results show that RealGraph has superior scalability and better performance compared to two graph engines with different models.

6.3.3 Performance on other graph algorithms. This experiment shows that RealGraph is effective for other graph algorithms provided by different graph engines. BC is provided by RealGraph, GraphChi, and X-Stream; RWR is provided by RealGraph, FlashGraph, and X-Stream; BP is provided by RealGraph, GridGraph, and X-Stream; SpMV is provided by RealGraph, GraphChi, and X-Stream. TurboGraph does not provide any additional graph algorithms except for the common graph algorithms (i.e., BFS, PageRank,

Table 2: Execution times of other graph algorithms

Graph engines	Graph algorithms			
	BC	RWR	BP	SpMV
RealGraph	125.7	313.9	3017.3	112.2
TurboGraph	-	-	-	-
GridGraph	-	-	-	226.9
GraphChi	-	6082.6	8418.3	-
FlashGraph	O.O.M	-	-	-
X-Stream	O.O.T	8016.3	O.O.M	538.3

(Execution time unit: sec.)

Table 3: Performance comparison of RealGraph with distributed-system based graph engines

Graph engines	Graph algorithms		System environment			
	WCC	PageRank	Machine	#Cores	Mem. Size	Storage
RealGraph	34	94	Single PC with Intel i7	4	16G	SSD
PowerGraph	-	72	64 Amazon EC2 cc1.4xlarge	8	23G	HDD
GraphLab	244	249	16 Amazon EC2 m2.4xlarge	8	68G	HDD
GraphX	251	419	16 Amazon EC2 m2.4xlarge	8	68G	HDD
Giraph	200	596	16 Amazon EC2 m2.4xlarge	8	68G	HDD

(Execution time unit: sec.)

and WCC). The number of threads of all graph engines was identically set as 8. We performed the algorithms on the largest Yahoo dataset.

Table 2 shows the execution times of the algorithms on the graph engines. The hyphen (-) means that the execution time is not measured because the graph engine does not provide the corresponding algorithm. The experimental results show that RealGraph has the best performance for all graph algorithms, which proves that RealGraph are effective in various domains using real-world graphs.

6.4 Comparisons with distributed-system based graph engines

Finally, we compared RealGraph with four distributed-system based graph engines: PowerGraph [9], GraphLab [16], GraphX [26], and Giraph [1]. Since prior research [9, 26] has evaluated the performance of these four distributed-system based graph engines, we *quote* their results for comparison while measuring the performance of our RealGraph. Table 3 presents the performance comparison between RealGraph and distributed-system based graph engines for WCC and PageRank which are the only graph algorithms whose performances on the four distributed-system based graph engines are commonly reported [9, 26]) on the Twitter dataset. Table 3 also shows the system environment of each graph engine. where *Machine* indicates the number of and type of the machines, and for each machine, *#Cores* means the number of cores, *Mem. Size* does the size of memory, and *Storage* does the type of storage. The hyphen (-) means that no result is available.

Under typical configuration, the distributed-system based graph engine uses 16 or more machines, each of which has 8 cores and 20GiB or more memory. In other words, they have computing power *much* higher than RealGraph. Nonetheless, the result shows that RealGraph equipped with low computing power performs better than distributed-system based engines except PowerGraph.

When executing PageRank, PowerGraph employs 64 machines, each of which is equipped with 8 cores, while RealGraph uses a single machine with 4 cores. That is, PowerGraph uses 128 times more cores than RealGraph, notwithstanding other computing resources. The performance of PowerGraph, however, is only 25% better than that of RealGraph. Simply put, RealGraph achieves reasonable performance using much smaller computing resources.

The reasons are as follows. The graph algorithm is performed through multiple iterations, producing intermediate results proportional to the number of nodes at each iteration. To proceed to the next iteration, each machine in the distributed graph engine should maintain the same intermediate results. Thus, intermediate results should be synchronized through communication among machines, which may cause more overhead than processing of the graph algorithm [5]. We claim that RealGraph is more effective if multiple machines are not required and the given a graph can reside within a single machine.

7 CONCLUSIONS

Most real-world graphs follow the power-law degree distribution, which with a small number of hub nodes having a high degree and most nodes having a low degree. We have observed two important problems that occur when existing single-machine based graph engines process such real-world graphs: (1) inefficient scanning of the sparse indicator and (2) the delay for the progress of the iterations due to uneven workload distribution.

In order to solve these problems, we developed a new graph engine, RealGraph, designed on the basis of well-known database systems. We applied not only an efficient data layout with good data locality, but also following two techniques that efficiently process real-world graphs into RealGraph.

First, we proposed a *hierarchical indicator* where the higher-level indicator compresses a range of a lower-level indicator using a single bit. This helps to skip unnecessary ranges of each lower-level indicator by scanning each higher-level indicator, which provides efficient indicator scanning at every iteration.

Second, we devised a *block-based workload allocation* where RealGraph assigns blocks to threads. Since a block is a fixed-size standard I/O unit, the total size of objects in each block is almost the same. This prevents the delay for the progress of the next iteration.

Through extensive experiments, we verified the superiority of RealGraph. We first evaluated the effectiveness of each proposed technique. Each technology improves the performance of RealGraph, and the combination of technologies further improves its performance with synergy. For various graph algorithms and real-world graphs, RealGraph has the best performance in terms of speed and scalability compared to existing single-machine based and distributed-system based graph engines.

ABSTRACT

WhatsApp has revolutionized the way people communicate and interact. It is not only cheaper than the traditional Short Message Service (SMS) communication but it also brings a new form of mobile communication: the group chats. Such groups are great forums for collective discussions on a variety of topics. In particular, in events of great social mobilization, such as strikes and electoral campaigns, WhatsApp group chats are very attractive as they facilitate information exchange among interested people. Yet, recent events have raised concerns about the spreading of misinformation in WhatsApp. In this work, we analyze information dissemination within WhatsApp, focusing on publicly accessible political-oriented groups, collecting all shared messages during major social events in Brazil: a national truck drivers' strike and the Brazilian presidential campaign. We analyze the types of content shared within such groups as well as the network structures that emerge from user interactions within and cross-groups. We then deepen our analysis by identifying the presence of misinformation among the shared images using labels provided by journalists and by a proposed automatic procedure based on Google searches. We identify the most important sources of the fake images and analyze how they propagate across WhatsApp groups and from/to other Web platforms.

1 INTRODUCTION

WhatsApp is a world-wide popular messaging app with more than 1.5 billion active users [2] which is currently the main messaging app in many countries, including India, Brazil, and Germany. Nearly everyone with a smartphone uses WhatsApp in Brazil (about 120 million active users [15]) to keep in touch with friends and family, do business, as well as read the news.

There are key features in WhatsApp that make this app unique. First, any communication within the app is end-to-end encrypted, meaning that messages, photos, videos, voice messages, documents, status updates, and calls are only seen by those involved in the communication. Second, WhatsApp allows users to easily create and organize chat groups. These groups, which are limited to 256 members, are by default private, as group administrators decide who can join them. However, a group manager may choose to share the link to join it in websites or social networks. In such a case, anyone with access to the link can join the group, which becomes, from a practical perspective, publicly accessible. Finally, WhatsApp provides features for viral spreading, allowing users to broadcast an initial message to 256 contacts or groups or forward content to 20 contacts or groups[1].

[1]The message forwarding was limited to 5 groups in India and 20 in the rest of the world along the period this work was developed. Currently, the limit has been updated to 5 worldwide.

Recent events have raised serious concerns that WhatsApp can become a fertile ground for groups interested in disseminating misinformation, especially as part of articulated political campaigns. In 2018, unfounded allegations disseminated over WhatsApp have fueled mob lynching in India that killed more than 20 people in a two-month window [9]. The 2018 Brazilian elections experienced an information war organized within WhatsApp where false rumors, manipulated photos, decontextualized videos, and audio hoaxes have become campaign ammunition and went viral on the platform with no way to monitor their full reach or origin [15].

This paper provides a large scale investigation of information dissemination within *WhatsApp groups*. We focus on *political-oriented* publicly accessible groups as we expect greater user engagement in topics of stronger social impact. We also offer a first look into *misinformation* dissemination within *WhatsApp*. More specifically, we tackle the following research questions.

RQ1: What kind of content is shared in WhatsApp *publicly accessible* groups? Are there fake news or misinformation in these messages? **RQ2:** What is the interplay between WhatsApp and other Web platforms (i.e. social networks such as Twitter, forums, and websites) in the dissemination of political content and, in particular, misinformation?

To answer these questions, we first identify publicly accessible groups related to Brazilian politics in WhatsApp, by searching the Web and other social networks such as Twitter and Facebook for invitation links to WhatsApp groups. These groups are suitable for activism and political engagement, making them a potential target of misinformation campaigns that might attempt to maximize the audience of a story with misinformation by sharing it with people that are engaged in supporting political candidates. We joined those groups and gathered the content shared within them for time periods corresponding to two major social mobilization events in Brazil: (i) a national truck drivers' strike[2] (May 21^{st} to June 2^{nd}, 2018); and (ii) the first round of the 2018 Brazilian general elections campaign (August 16^{th} to October 7^{th}, 2018), with 141 and 364 groups monitored, respectively.

We start our investigation by first analyzing the content shared and the user interactions within the monitored WhatsApp groups to understand how users disseminate information in such environments. Our results show that images are often the most shared type of media, and they usually carry satires, news, and activism-related content. We also show that WhatsApp has a network configuration similar to many other online social networks (e.g., Twitter or Facebook) which connects thousands of users. Thus, it has the potential to make any information become viral. Moreover, we analyze how the content dissemination crosses the boundary between WhatsApp and other Web platforms.

Further, we explore the presence of misinformation campaigns in the monitored groups. We identify misinformation in image content by relying on two sources: (i) a Brazilian fact-checking agency; and (ii) a proposed automatic procedure that exploits the results of Google searches to identify images that appear in well-known fact-checking websites. Our results show a considerable number of images checked as containing misinformation, which was largely disseminated in the monitored groups. We assess the occurrence of such images in Web domains and Twitter accounts then analyze the network of misinformation propagation. Our analyses reveal that a few groups are the most responsible for disseminating images with misinformation. Moreover, by comparing the timestamps when an image first appeared on WhatsApp (as captured by our data) and on other Web applications, we find that WhatsApp was the primary source of 30% of the identified images containing misinformation.

The remainder of the paper is organized as follows. Next section discusses related work. Then, Section 3 details our methodology and summarizes the data gathered. Section 4 characterizes the content, the network structure of the groups we monitored and how information propagates in such groups. Section 5 presents our main results on the dissemination of misinformation in those groups. Finally, Section 6 concludes the paper.

2 RELATED WORK

Fake news have encountered a suitable means for fast, cheap, and easy dissemination in social media systems. Indeed, these platforms have been a main vehicle for public opinion manipulation and fake news dissemination [19, 21, 25]. Studies during the 2016 U.S. presidential election campaign observed a strong correlation of the number of visits to fake news websites (i.e., sites that deliberately publish hoaxes and misinformation) and aggregate voting patterns at state and county levels [7].

Social bots are one of the most common types of manipulation attack, emulating real users, posting content and interacting with real users and other bots [5, 16]. They were used on Twitter during the 2016 U.S. presidential campaign to manipulate discussion [1] reaching about 20% of all posts about presidential elections. Another misinformation campaign was observed during the 2017 French presidential election, in which bots' posts with unauthentic documents about a candidate quickly spread on Twitter two days before the final voting [4]. Facebook was also a target of misinformation spread aiming at influencing American voters during the 2016 presidential campaign. Using Facebook Ads platform, groups linked to the Russian Intelligence Research Agency (IRA) bought about 3,000 ads linked to 470 user accounts targeting voters from the swing states [12, 21]. Since then, Facebook has performed measures to mitigate fake news dissemination such as removing fake accounts related to political movements and working directly with fact-checking websites [13]. However, fake news is not only disseminated exclusively by social bots or through ads but also by real users. A recent study analyzed over 126,000 cascades of fact-checked news stories on Twitter, finding that fake news was 70% more likely to be retweeted than true stories, and humans are more likely to spread fake news than bots [25].

More recently, WhatsApp has also become a powerful tool to influence people during political campaigns, especially in countries in South America, Africa, and Southeast Asia. In these locations, WhatsApp groups constitute the majority of online communication, enabling politicians to reach a larger share of voters, even those residing in areas with precarious Internet connectivity. Other features that make communication via WhatsApp attractive for this kind of marketing are: it is cheaper, messages are often not contextualized and it can be used to target small groups with specific messages

[2]This was a massive event, with strong political connotation, that affected the whole country, paralyzing many economic and social sectors of the nation.

[20, 23]. This was observed in Brazil, where family groups were responsible for 51% of the dissemination of fake news on WhatsApp during the period of the 2018 presidential elections [10]. Because of the end-to-end encryption, it is hard to track the dissemination of misinformation in such platforms. Yet, recent efforts have gathered and analyzed data from WhatsApp chat groups [8, 20], focusing on textual interactions in these groups. Our present effort provides a deeper understanding of the content exchanged in WhatsApp, unveiling, among other findings, the spread of misinformation campaigns through images in the platform.

3 METHODOLOGY

In this section, we present how we gathered data of WhatsApp groups and the methods used to process and analyze it.

3.1 Data Collection

As a first step of our data collection, we had to identify a considerable number of publicly accessible groups. To that end, we used the URL pattern `"chat.whatsapp.com"`, which is commonly used in invitations to join WhatsApp groups, as a search query and submitted it to Google, Twitter, and Facebook search engines. We restricted our search space to groups related to Brazilian politics, by including in each search query a word from a dictionary related to the 2018 Brazilian elections[3]. This dictionary contains the name of politicians, political parties, as well as words associated with political extremism. Finally, we performed a manual inspection of the collected group names to filter out those unrelated to politics. In total, we found 3,444 distinct links for publicly accessible groups, out of which only 1,828 were valid (i.e., unbroken).

As a second step, we selected a number of valid groups to monitor. This monitoring involves joining each group using a cell phone. Thus, the number of groups (see Section 3.3) monitored was constrained by the available devices and their resources (memory). We joined each selected group using our available cell phones and a tool developed by Garimella *et al.* [8]. We then periodically downloaded all data shared in each group and stored them in a database. Specifically, stored data can be grouped into: images, videos, audio messages, external links, and text messages. From each message, we extracted its group name (i.e., the group the message was posted), a group ID, a user ID, and timestamp. That is, we mapped telephone numbers and user names onto unique user identifiers[4], discarding the original information afterwards. For the media messages, we also downloaded their respective files and used their filenames as a reference to the message.

As we will show in Section 3.3, images are the most frequent type of *media* content in our collected data, as well as an important source of misinformation. Thus, we delved further into the images shared on the monitored groups and developed a tool to collect Web pages in which those images have appeared. The tool exploits the capability of searching for images provided by Google search, where a user can submit an image as query, and obtain as result webpages that include matching images along with their post dates. As will be discussed in Section 4, this information allows us to analyze temporal sharing patterns such as the time interval between first appearance of an image on WhatsApp and on the Web.

In order to explore the content veracity of the images shared in the groups, we extended the tool to automatically identify whether each image had been previously checked as *fake* by a number of fact-checking websites. We further elaborate on this process in Section 5.2.

Table 1: Overview of our datasets.

	Truck Drivers' Strike	Election Campaign
#Groups	141	364
#Total Users	5,272	18,725
#Total Messages	121,781	789,914
#Text Messages	95,424	591,162
#Images	11,610	110,954
#Videos	9,752	73,310
#Audios	4,995	14,488
#URLs	11,728	92,654

3.2 Data Limitation

To our knowledge, this work is the first effort that aims to explore the political debate in WhatsApp. Also, it proposes a methodology to infer which identified publicly accessible groups are related to politics. Unfortunately, we are not aware of an approach that would allow us to assess the representativeness of our data as even the total number of groups available in the country is *not* of public knowledge. We emphasize, though, that all sensitive information (i.e., user names and phone numbers) were *not* stored in our dataset.

3.3 Events Captured in our Dataset

Our data collection focuses on the time period of two major social mobilization events in Brazil: (i) a national truck drivers' strike (May 21^{st} to June 2^{nd} 2018); and (ii) the first round of the 2018 Brazilian presidential elections campaign (August 16^{th} to October 7^{th} 2018). The truck drivers' strike was a stoppage of autonomous truck drivers all over Brazil. The strikers began a mobilization through their leaders in social networks, expressing against frequent adjustments and without minimum predictability in fuel prices, especially diesel, made by the state-owned company Petrobras[5]. The shutdown and blockades of highways in 24 states and in the Federal District caused the unavailability of food and medicine around the country, shortages and high gasoline prices, with long queues to fuel. We analyze the data collected for each aforementioned period as a separate dataset, contrasting our findings across periods.

Table 1 provides an overview of our two datasets, showing the total number of messages shared as well as the number of messages per type of content (text[6], image, video and audios). Note that most shared messages are indeed textual content, but image is the most frequent type of *media* content in both datasets, reaching roughly 10% and 15% of all content shared in the monitored groups during the strike and election period, respectively. Note also the large number of links to websites (last row) present in the text messages.

[3] https://goo.gl/PdwAfV

[4] Throughout the paper we refer to such identifiers as users. Yet, they are indeed unique telephone numbers, as we are not able to identify multiple devices of the same user.

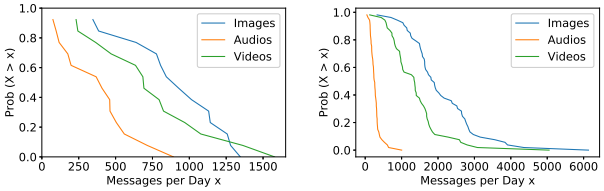
[5] http://www.petrobras.com.br/en/

[6] Only messages that are entirely composed of textual content are counted as text messages.

We shared a sample of our dataset to a set of journalists which led to wide press coverage. Particularly, a BBC story[7] manually analyzed the popular content from the truck drivers' strike data and suggested that it was organized in a decentralized way through WhatsApp groups. Audios were often used to call truck drivers to join and remain in the strike, while videos and images were used to disseminate scenes of the strike and its consequences in different cities. Similarly, another BBC story[8] analyzed popular content collected during a week of the electoral period, reporting presence of misinformation in different kinds of content, but mainly in images. They reported audios describing conspiracy theories, manipulated photos, fake polls, attacks to the traditional media and to famous personalities, as well as the instigation of hate, especially against LGBT and feminists.

4 MESSAGE CONTENT AND DISSEMINATION

In this section, we characterize the content of the messages, the network structure of the groups as well as the temporal patterns of message sharing in our datasets.



4.1 Media Content and URLs

As our first analysis, we focus on the content shared, notably media content (audios, videos, and images). We also briefly discuss the presence of URLs in textual messages. The discussion is based on Table 1 as well as on Figure 1, which shows the complementary cumulative distribution of the number of messages of different media types shared per day, across all monitored groups.

4.1.1 URLs and Webpage domains. As shown in Table 1, a total of 11,728 URLs were shared (as part of text messages) in the monitored groups during the truck drivers' strike period. During the election campaign, this number reached 92,654 URLs. They correspond to 8% and 9% of the total amount of messages we gathered for each period, respectively. The nature of these URLs varies from links to news websites, blogs, entertainment, and other social networks to even links to other WhatsApp groups. Also, 69% of all URLs shared during the truck drivers' strike period are unique. This fraction drops to 45% during the election campaign, indicating less diversity and more repetition of the links during that period.

4.1.2 Audios. Our datasets contain 4,995 and 14,488 audio messages during the truck drivers' strike and election campaign periods, respectively, which correspond to 4% and 2% of all messages gathered during each respective period. As shown in Figure 1, audio is the least frequent media type shared in the monitored groups. For example, during the truck drivers' strike, up to 450 audios were shared daily, in 60% of the days (see Figure 1(a)). During the election campaign period, up to 500 audios were shared in the same fraction of the monitored days. Note however that, this number reached a peak two days before the election day, with 1,002 audio messages shared on all monitored groups.

4.1.3 Videos. In total, 9,752 videos were shared during the truck drivers' strike, which corresponds to 8% of all messages shared during the period. Also, according to Figure 1, up to 800 videos were shared daily in 60% of the days, reaching up to 1,578 videos on a single day. During the election campaign period, 73,310 videos (9% of all messages) were shared in total, with 1,300 videos being shared daily in 60% of the days (up to 5,052).

(a) Truck Drivers' Strike (b) Election Campaign

Figure 1: Numbers of daily messages with media content shared on all groups.

4.1.4 Images. As mentioned, images represent the most popular media content shared on the monitored groups, with a total of 11,610 images (almost 10% of all messages) and 110,954 images (15%) shared during the truck drivers' strike and election campaign periods, respectively. According to Figure 1, this higher frequency happens on a daily basis. Up to 1,000 and 2,000 images were shared in 60% of the days during the truck drivers' strike and during the election campaign, respectively. Even more, in about 5% of the days, the number of images shared on the groups on a single day exceeded 1,350 and 6,100 in the two periods. For the election campaign (the latter), these days are in the week before the election day.

Given the popularity of images, we next deepen our analysis of the dissemination of type of content in the monitored groups.

4.2 Characterizing WhatsApp Images

A WhatsApp group is usually meant to be a space for discussions about a specific subject such as politics, education, games. However, the content shared itself may diverge from the group subject given the will of their participants. For example, as in other Web systems, WhatsApp groups are susceptible to spam activity (e.g. advertisements or inappropriate content). To understand the kinds of images shared on our selected groups, we first categorize the images by performing content labeling and analyze the distribution of images across categories. We also discuss the appearance of the same images on other websites and social networks.

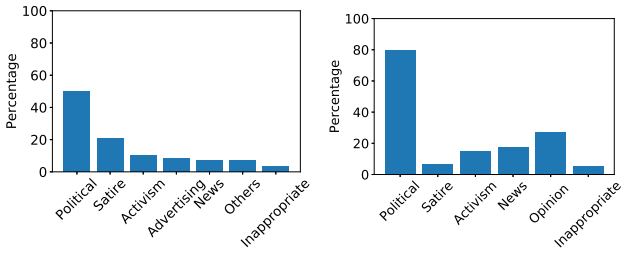
4.2.1 Content Labeling. We asked three volunteers to label a sample of the most shared images during each period. The sample from the truck drivers' strike period contains a selection of the top-20 most shared images on each day, with a total 220 images. For the election campaign period, the sample contains the top-100 most shared images, considering the whole monitored period. In order to identify duplicates of the same image, we used the *Perceptual Hashing (pHash)* algorithm [17] to calculate a fingerprint for each image. We were then able to group images having the same hash-values based on human eye perception as duplicates.

A taxonomy guideline document with instructions was given to the volunteers with the following directions: (i) observe an image and, read the text on it, if available; (ii) if there is a text, check the existence of any citation to a website or other source; (iii) check if the following content types are present in this post: *Political*

[7] https://www.bbc.com/portuguese/brasil-44325458
[8] https://www.bbc.com/portuguese/brasil-45666742

Table 2: Image categories used to label the sampled images.

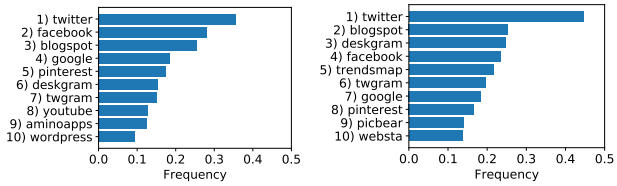
Category	Description
Political	Information about a candidate or party
News	News information with a quote
Advertising	Advertisement of product, service or company
Satire	Humorous content regarding current events
Inappropriate	Illicit products, violence, hate speech or pornographic content
Activism	Popular movements and protests
Opinion	Expression of a personal opinion or comment
Others	Image does not fit in any other category



Content; News; Advertising; Opinion; Satire; Activism; (iv) identify possible inappropriate, offensive or even illegal content by checking for the presence of *Dissemination of Hate; Violence; or Promotion of Illicit Products as Inappropriate Content*; (v) you can classify a post with more than one category (e.g., News and Political Content) or none of them; and finally (vi) if you cannot fit the image in any of the listed categories or are unable to establish its category, label the image as *Others*. Table 2 lists the categories used to label the sampled images.

After each of the three volunteers annotated each image according to the categories in Table 2, we measured the inter-annotator agreement in terms of the *Fleiss's* κ [6]. We assumed that consensus was reached if the null hypothesis of negative or no agreement $\kappa = 0$ can be rejected. Since the same image may fit more than one category, we applied the test individually for each category, averaging the κ scores obtained. The test result for the *Others* category indicated a poor agreement for the sample collected during the election campaign period. This result was then disregarded. Overall, we obtained moderate agreement among the annotators for both periods, with average κ equal to 0.6 and 0.42 for the truck drivers' strike and election campaign samples, respectively. This result is reasonable given that some categories are very broad and distinctions are somewhat blurred. In the following, we assume that an image belongs to a category if at least two of the annotators agreed upon that category.

Figure 2 shows the distributions of the image categories in each sample. In both periods, most images are related to politics (50% during the truck drivers' strike and 80% during the election campaign). The large fractions of satire and activism during the truck drivers' strike are also worth noting: we observed a lot of memes about the movement and messages supporting the truck drivers. A small fraction of images shared during that period contains advertisement. In contrast, images with opinions from personalities were much more popular during the election campaign, corresponding to 20% of all images in our sample. News and images with activism were also frequently shared during that period, but no image in our sample contain explicit advertisements.



4.2.2 WhatsApp Images on other Websites. We now analyze the extent to which the images shared on our monitored WhatsApp groups have also appeared on other websites including social networks and blogs. We do so by searching for the observed images using the Google Images search engine, as discussed in Section 3.1.

Figure 3 shows the most popular domains returned by Google Images for the images shared in each monitored period. Notice that online social networks like Twitter, Facebook, Aminoapps, and Pinterest are among the most frequent domains where the images were

(a) Truck Drivers' Strike (b) Election Campaign

Figure 3: Most popular domains for images shared on WhatsApp publicly accessible groups.

Table 3: Sharing of images on monitored WhatsApp groups.

	Truck Drivers' Strike			Election Campaign		
	Mean	Std. Dev	Max	Mean	Std. Dev	Max
#Images per Group	91	143.250	1,011	345	580.531	4,320
#Users per Group	17	21.745	110	34	41.347	211
#Images per User	5	10.831	197	10	32.322	1,612
#Shares for Image (total)	1	1.978	58	1	4.512	125

also posted, for both periods. Similarly, image apps like Deskgram and Twgram as well as Blogspot are popular domains, especially the latter, suggesting that a large fraction of image content shared on WhatsApp groups may indeed have blogs as possible sources. TrendsMap, a website that shows visualizations of the trends on Twitter, was popular for images shared during the election campaign period, while more than 10% of the images shared during the truck drivers' strike period also appeared on YouTube, as thumbnails of videos.

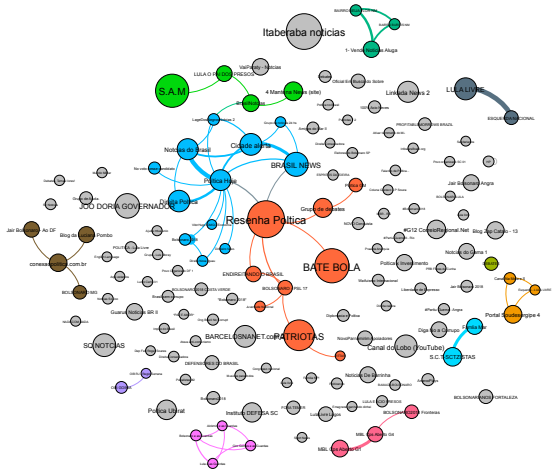
4.3 Network Structure

In this section, we analyze sharing patterns of images on the selected WhatsApp groups by studying the structure of the networks that emerge from the participation of users in different groups. To better understand this network structure, we first discuss some key measures related to the sharing of images within each group. For each period, Table 3 presents averages, standard deviations, and maximum values of the numbers of images shared by each user and within each group as well as number of users sharing images in each group and the total number of times each image was shared (across all groups). Overall, all averages are larger for the election campaign period. Although some differences may be (partially) credited to a longer monitoring period, we note that the intensity of image sharing per user was indeed higher during the campaign, with an average twice as larger and a peak eight times as larger than in the strike period. Similarly, we do observe a significant

Table 4: Network metrics for WhatsApp graphs.

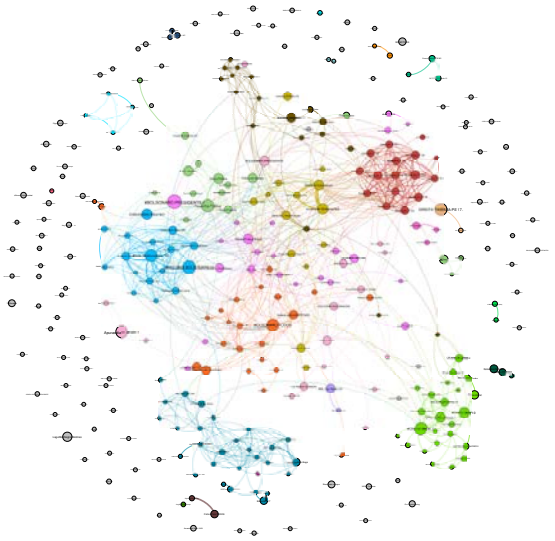
	#Nodes	#Edges	Avg. Degree	Diameter	APL*	Density	LCC**
Group Network Truck Drivers' Strike	136	55	0.809	8	2.975	0.006	25
Group Network Election Campaign	333	842	5.057	8	3.459	0.015	206
User Network Election Campaign	10,860	492,217	90.91	9	3.952	0.008	8,934

*Average Path Length. **Largest Connected Component.



increase in the number of users sharing images in the groups. Note however that most images are shared only a few times (once, on average), as only a few images are widely shared. Interestingly, we found that the groups with the largest number of images shared during the strike (*"Resenha Política"* with 1,011 images) and during the election campaign (*"#BOLSONARO PRESIDENTE"* with 4,320 images) are indeed the groups with the largest numbers of users sharing this type of content (110 and 211, respectively).

We modeled the interactions across groups by means of two network models, one at the group level and one at the user level. That is, we built a *group network* where each node represents one monitored group and edges are added connecting groups that have at least one member in common sharing image content. Figure 4 shows the group networks built for each monitored period. The size of each node represents the number of users who shared image content in the group. Although many groups are somewhat isolated or weakly connected to the rest, we do note the presence of several clusters of groups which are strongly interconnected by sharing many members in common. This may facilitate the flow of information across group boundaries.



We also modeled the relationship between users by building a *user network* where each node is a user and an edge is added between two nodes if the corresponding users have shared image content in at least one group in common. Node size represents the number of groups in which the user shared images. The user networks are naturally larger and harder to visualize. For illustration purposes, Figure 5 shows a subgraph of the network built for the election campaign, with 5,700 nodes. The network structure of the groups is evidenced by the clusters formed. We note a large number of users blending together connecting to each other inside those groups. Most users indeed form a single cluster, connecting mostly to other members of the same community. On the other hand, there are also a few users who serve as bridges between two or more groups linked by multiple users at the same time. Furthermore, a few users work as big central hubs, connecting multiple groups simultaneously. Lastly, some groups have a lot of users in common, causing these groups to be strongly inter-connected, making it even difficult to distinguish them.

To better understand the properties of these graphs, Table 4 shows various network metrics computed for the group and user networks. It presents numbers of nodes and edges, average node degree, network diameter, average path length (APL), network density, and the size of the largest connected component (LCC).

Focusing on the group networks, we see that the graph for the election campaign is more complex and more densely connected, with more clusters (i.e., communities) of groups and edges emerging

(a) Truck Drivers' Strike Network

(b) Election Campaign Network

Figure 4: Group networks (nodes are groups and edges connect groups with users in common).

between them, and a larger fraction of nodes belonging to the largest connected component (62%). Despite such differences, the average path length between the groups is only slightly larger (3.46, against 2.97 in the strike period). Also, although network density (ratio of number of edges in the graph to the maximum number of edges possible) is low for both periods (under 2%), it is higher during the election campaign. We observe similar properties in the user network with a small average shortest path length (3.95) and higher largest connected component (82% of the users).

Therefore, as illustrated in Figures 4 and 5 and in Table 4, WhatsApp is more than just a mobile network that provides end-to-end encrypted communication between two users. It exhibits network properties very similar to many other social networks such as Twitter or Facebook, connecting thousands of users and having the potential to make a piece of information become viral.

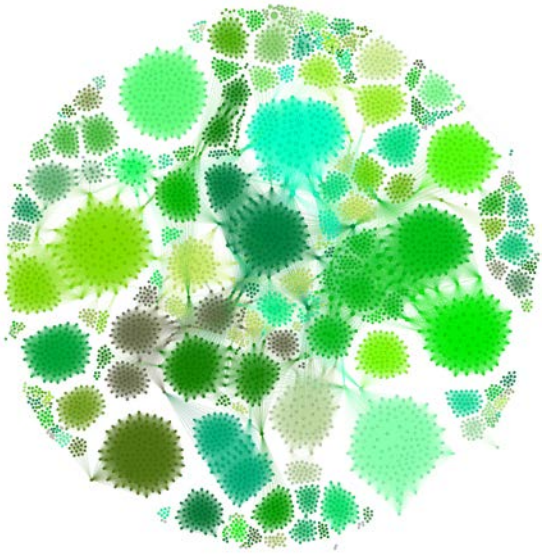


Figure 5: User network (nodes are users and edges connect users with group in common. Subgraph of election period).

4.4 Propagation Dynamics

We analyze the propagation dynamics of images within the monitored WhatsApp groups by means of two metrics, namely lifetime and burst time. The lifetime of an image is the time interval between the first and the last time the image was shared, as captured by our datasets. Burst time is the time interval between consecutive shares of the same image, irrespective of the group. In our analysis, we first identify the set of images shared during each monitored period and then compute their lifetimes and burst times considering an extended monitored period from April 23^{rd} to October 22^{nd} 2018. We also analyze the propagation dynamics of images as they cross the boundaries of WhatsApp, appearing elsewhere on the Web.

4.4.1 Lifetimes. As shown in Figure 6(a), the distributions of lifetimes are mostly similar[9]: around 20% of the images have lifetimes under 1 hour, and 40% of them have lifetimes under 20 hours. Yet, many images last quite longer on the system: more than 30% of the images have lifetimes exceeding 100 hours.

4.4.2 Burst Times. Figure 6(b) shows the distributions of burst times. Once again, both distributions are mostly similar, although there is a tendency of images being reshared within shorter time intervals during the election campaign. For example, in 40% of the cases, images were reshared within up to 120 and 100 minutes during the strike and election campaign periods, respectively. Yet, some images were reshared very sporadically: in around 20% of the cases, burst times exceed 5 and 2 days during the same periods.

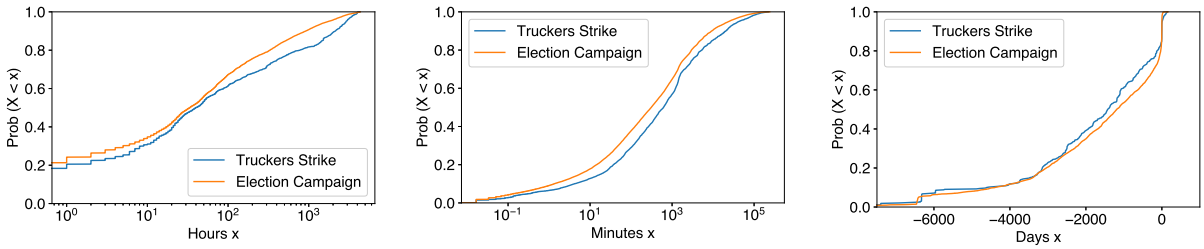
4.4.3 Propagation to and from the Web. We also analyze the propagation of images across the boundaries between WhatsApp and the Web. Specifically, we analyze the difference between the time an image was first shared on a monitored group and the time when it was indexed by Google. The latter is taken as an estimate of the time it first appeared on the Web. A positive difference suggests that the image was first shared in one of the monitored groups and then published on the Web. A negative difference may suggest the image was first posted on the Web[10]. Figure 6(c) shows the cumulative distribution of such time differences for images shared during the two monitored periods. Note that, in both cases, the time differences are indeed negative for most images (80%). Yet, 14% of the images were posted on the same day on the Web and on the WhatsApp groups, and 6% were first shared on WhatsApp.

[9]We note that the somewhat shorter lifetimes for images shared during the election campaign may be a side effect of the interruption of monitoring.

5 MISINFORMATION ON WHATSAPP

In this section, we look at the presence of misinformation in the images shared on WhatsApp groups. First, we discuss two techniques used to identify misinformation in the images in our datasets. We analyze their characteristics and propagation, and compare these images with the rest of our WhatsApp data.

5.1 Labeling with a Fact-Checking Agency



We created a list of the most shared images during the election campaign period and gave them to one of the most important fact-checking agencies in Brazil, *Lupa* [11]. They checked the veracity of each of these images following a methodology similar to other fact-checking agencies around the world (e.g., the American *Politifact*[12] and the Argentinian *Chequeado*[13]). They first analyzed where these images contained factual information as opposed to opinions since it is not possible to check the latter. Out of a total of 61 images, 47 were marked as factual. Out of these factual images, they found that 22 had already been checked by other fact-checking agencies: 17 images had been checked as containing misinformation, and only 5 images had been checked as true. These results show an expressive number of images with misinformation in WhatsApp during the 2018 Brazilian elections. In terms of percentages, 36.2% of the images with factual information where checked as containing misinformation, whereas 53.2% of them include misleading and inconclusive content (not supported by public information), and only 10.6% were verified as true. Examples of images checked as misinformation are shown in Figure 7.

Figure 7(a) is an edited image of the Brazilian former president Dilma Rousseff, who was impeached in 2016 [22], alongside Fidel Castro, former president of Cuba. At the time this picture of Castro was taken, Dilma was 11 years old. Thus, the image is clearly fake. It was the most popular image in the analyzed period. Figure 7(b) is an edited image of the former Brazilian president Lula, imprisoned for corruption at the time of monitoring [3, 24], meeting the aggressor responsible for stabbing the then presidential candidate Jair Bolsonaro during a campaign rally [18]. The intention of the image was to associate Lula with the attack against Bolsonaro.

5.2 An Automatic Methodology for Finding Misinformation

Recently, Facebook has announced partnerships with many third-party fact-checking organizations, through which Facebook demote or reduce the visibility of links rated as false [14]. This kind of

[10]Our analysis is constrained by the view of WhatsApp provided by our datasets.

Figure 7: Images checked as containing misinformation by both fact-checking methodologies.

partnership neglects misinformation in images, as fact-checkers only provide rates to links containing stories with misinformation. Next, we provide a strategy to connect the false stories found in images shared with external links that appear on the Web, providing a simple way for Facebook to demote links containing images with misinformation identified on WhatsApp.

First, we identified the main fact-checking agencies in Brazil[14]. We then automatized the process of searching each image shared on the WhatsApp groups on the Web by using the Google Image search. Given the search results for an image, we checked whether any of the returned pages belong to one of the fact-checking domains. If so, we parsed the fact-checking page and automatically labeled the image as fake or true depending on how the image was tagged on the fact-checking page.

We applied this methodology to all images in both datasets. We found only 2 images with misinformation in the truck drivers' strike dataset and 70 images containing misinformation in the elections dataset. Thus, we restricted our focus to the election campaign period. We compared the 70 images with misinformation identified by the automatic process with the 17 images checked as fake by Lupa (see previous section), obtaining an overlap of only 2 images. Thus we built a single dataset of 85 images with misinformation identified by official fact-checking agencies.

In the following, we analyze the images in this dataset, focusing on other websites where they also appear. We also compare properties of these images with those of the other images shared during the election campaign period. To distinguish between them we refer to the former as misinformation and to the later as unchecked, since the veracity of their content was not necessarily checked. We cannot guarantee the absence of misinformation in the unchecked images, given that such an assertion is restricted by the availability of checked facts. Yet, we expect that we were able to catch most images containing misinformation in our dataset, especially those with greater impact on users, as they most probably were identified by the fact checkers.

[14]Fact-checking agencies: *Boatos.org*: https://www.boatos.org; *e-Farsas*: http://www.e-farsas.com; *Comprova*: https://projetocomprova.com.br; *Lupa*: https://piaui.folha.uol.com.br/lupa; *Globo G1*: http://g1.globo.com/fato-ou-fake; and *Aos Fatos*: https://aosfatos.org.

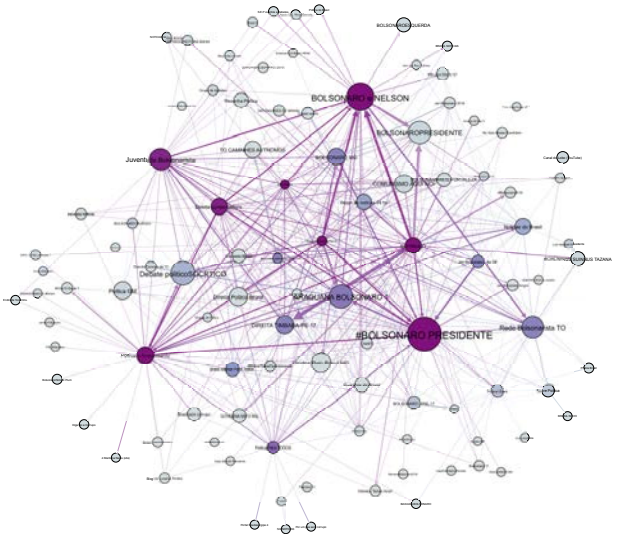
Table 5: Overview of images shared during election campaign period: misinformation versus unchecked content.

	Misinformation	Unchecked
#Groups in which images were shared	157	351
#Users who shared images	624	10,339
#Unique images	85	69,590
#Total shares of images	1,168	109,791

5.3 Images with misinformation on WhatsApp and on the Web

Table 5 presents a comparison of the images with misinformation and with unchecked content shared during the election campaign, showing the numbers of distinct images, users who shared those images, groups in which those images were shared and total number of shares. Note that, even though the number of distinct images with misinformation is small (85), these images summed up 1,168 shares posted by 624 different users in 157 different groups. Despite representing less than 1% of all images shared, these images appeared in 44% of the monitored groups in the period of the election campaign, effectively reaching a large user population. Also, note that nearly 5.7% of all users shared images with misinformation.

5.3.1 Network of propagation in WhatsApp groups. We analyzed the propagation of images with misinformation on the WhatsApp groups by building a network model representing the groups in which the images with misinformation *first appeared*. Specifically, we built a directed graph where each node represents a group and a directed edge from node A to node B was added if the same image with misinformation was first shared in group A and then appeared in group B. To build this graph we considered only groups in which at least 2 distinct images with misinformation were shared during the period. The weight of an edge is defined as the number of images containing misinformation that were first shared in a group and



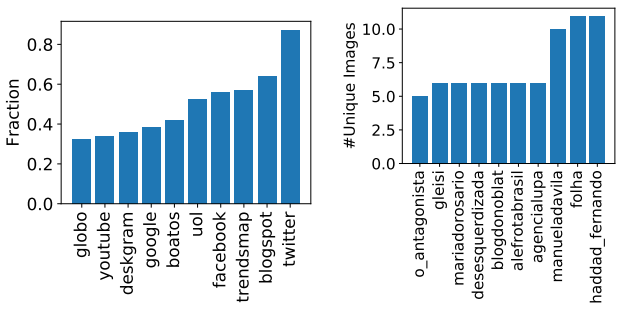


Figure 8: Network of misinformation propagation on WhatsApp groups (election campaign period).

then co-occurred in the other. The size of a node represents the number of images with misinformation posted on that particular group while the color represents the sum of the outgoing edges, that is, the total number of images that were "first seen" in that group and then spread to the rest of the network.

Figure 8 shows the network of propagation of images with misinformation in the monitored WhatsApp groups during the election campaign. Note that some nodes are darker (larger out-degree) than others, suggesting they are the main "seeds" of the images with misinformation in the graph. It is worth noting that the group in which the largest number of images with misinformation first appeared (largest node) is indeed the group with the largest number of users and largest number of images shared in general. Yet, we note that some large nodes have very light colors (e.g. *"ARAGUANA BOLSONARO 1"* and *"BOLSONAROPRESIDENTE"*), meaning that although many images containing misinformation were shared in them, they acted more as receptors than seeds, since their out-degrees are small. These results seem to suggest that fewer groups are responsible for the spreading of a large fraction the images with misinformation in WhatsApp.

5.3.2 Presence on the Web. We also analyzed the presence of images with misinformation on the Web. Figure 9(a) shows that these images frequently appeared in other social networks and blogs, notably Twitter, as also observed for images in general (Figure 3). Figure 9(b) shows the Twitter accounts that most shared these images, presenting the number of different images with misinformation tweeted by each account. Among them, there are some official journalistic accounts (*folha* and *agencialupa*) and official accounts of the presidential candidate Fernando Haddad and his vice, Manuela d'Avila. We note these profiles posted images containing misinformation with the purpose of repudiating them, acting as fact-checking accounts. Yet, some other accounts acted as misinformation broadcasters by spreading it further through the network.

5.3.3 Propagation Dynamics. Recall that, in Section 4.4 we analyzed image propagation dynamics by characterizing their lifetimes

(a) Most popular domains. (b) Most popular Twitter accounts.

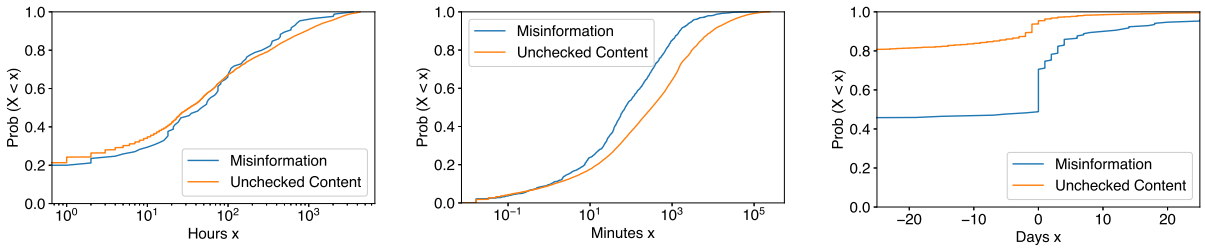

Figure 9: Images with misinformation on the Web.

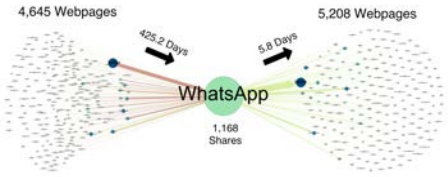
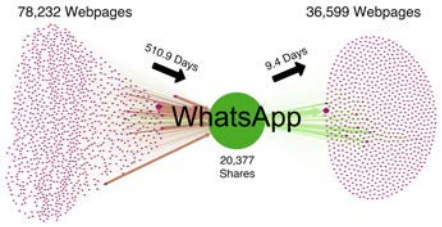
and burst times within WhatsApp groups as well as the time interval between their first appearance in WhatsApp and on the Web. We here revisit this analysis comparing the same metrics for images with misinformation and images with unchecked content, focusing on the election campaign period. The results are shown in Figure 10. For each metric, we compared the two distributions using the Kolmogorov-Smirnov test [11] with 95% confidence level, with the null hypothesis that two samples have the same distribution.

We found no statistical difference between the distributions of lifetimes of images with misinformation and images with unchecked content (p-value of 0.78). For both types of content, around 70% of the images remain in the system for up to 100 hours. In contrast, the distributions of burst times are statistically different (p-value of 2e-30). Burst times tend to be shorter for images with misinformation, suggesting a faster propagation of this type of content. For example, in 60% of the cases, an image with misinformation is reshared within 100 minutes. The fraction of such burst times reduces to 40% for images with unchecked content.

Similarly, the distributions of the time interval between first appearance on WhatsApp and on the Web are also clearly different (p-value of 2.4e-47). The vast majority (95%) of images with unchecked content were first posted on the Web (negative intervals). Only 3% of them were shared first on the monitored groups (positive intervals) whereas 2% appeared on both Web and WhatsApp on the same day. In contrast, only 45% of the images with misinformation were shared first on the Web, 20% of them were shared on both platforms on the same day, and 35% were shared first on the WhatsApp group. These results seem to suggest that WhatsApp acted as a source of images with misinformation during the election campaign period.



To further investigate the sharing of image content on the monitored WhatsApp groups and on the Web, we propose a visualization by means of a directed network, as shown in Figure 11. The network contains a central node representing WhatsApp (i.e., the monitored groups); the other nodes represent Web domains in which the images shared on WhatsApp also appeared. A directed edge from a node/domain to the central node implies that an image first appeared on that domain and later it was shared on WhatsApp. A directed edge from the central node to a node/domain implies the opposite. Thus, to improve readability, we plot nodes representing domains in which the images appeared before being shared on WhatsApp to the left of the central node, and nodes representing domains in which the images appeared after being shared on



(a) Lifetime (b) Burst Time (c) Interval between first share on WhatsApp and Web

Figure 10: Temporal properties of propagation of images with misinformation versus images with unchecked content.

WhatsApp to its right. The size of a node representing a domain captures the number of webpages in that domain in which images shared on WhatsApp appeared. The color of an edge represents the average time difference between the first appearance of an image on WhatsApp and on the specific domain, considering all images posted on that domain (green is faster than red). We emphasize that this representation captures the temporal ordering of the first appearance of an image within WhatsApp and on the Web, as captured by our dataset. Although it may provide hints about the propagation of image across the boundaries between WhatsApp and the Web, we cannot claim they map exactly the actual information flow.

(a) Images with misinformation.

(b) Images with unchecked content.

Figure 11: Network representation of images shared on WhatsApp and on the Web.

Figure 11 shows the network representations for images with misinformation and images with unchecked content. In addition to the network itself, each figure shows, for each group of domains, the total numbers of pages containing shared images as well as the average time interval between the first appearance of an image on the Web and on WhatsApp. We note that images that were first published on the Web take much longer to reach the WhatsApp groups (more than a year) than the other way around (only a few days) for both types of images. The average time interval is 73 times longer for images with misinformation and 54 times longer for images with unchecked content. Also, in general, images with misinformation cross the boundaries between WhatsApp and the Web much more quickly: 425 days from the Web to WhatsApp and less than 6 days from WhatsApp to the Web, on average (as opposed to 511 and 9 days, respectively, for images with unchecked content). Moreover, the numbers of domains (and webpages) on both sides of the central node are much more balanced for images with misinformation. This suggests, once again, that images with misinformation are much more often spread from the WhatsApp groups to the rest of the Web than images with unchecked content.

6 CONCLUDING REMARKS

This work presents an analysis of messages shared on publicly accessible WhatsApp groups related to politics during two major events in Brazil. We found that images are the most popular type of media content shared on this platform during both periods analyzed. Moreover, by manually labeling these images, we found the frequent presence of satire, activism, and personal opinions, and much of this content came from other social networks. We also analyzed the temporal patterns of the propagation of these images within WhatsApp groups, finding that a large fraction of images remained being shared on the platform for quite some time (more than 4 days), and often within short time intervals (a couple of hours). We also found that most images shared on WhatsApp were actually posted first elsewhere on the Web. As a complement, we characterized the network structure of the monitored WhatsApp groups, showing how they connect with each other and offering insights into how information may propagate across them and to/from the Web.

We also proposed a methodology to automatically identify images with misinformation, and used it to investigate the sharing of this type of content in the monitored groups. We characterized the propagation dynamics of these images, contrasting it with the patterns observed for the other (unchecked) image contents. We found that images with misinformation tend to be reshared within shorter time intervals and are much more often shared first on WhatsApp and then on the Web. This observation suggests that WhatsApp may have been a relevant source of images with misinformation to the Web during the analyzed period.

As a final contribution, we also designed and deployed the **WhatsApp Monitor**[15], a Web-based system to help the top Brazilian official fact-checking agencies and journalists. Our system displays the most popular content shared in the monitored publicly

[15] http://www.whatsapp-monitor.dcc.ufmg.br

accessible groups on a daily basis. This allows journalists to get an idea about critical content that is worth being fact-checked. We emphasize that sensitive information such as user names and phone numbers are discarded and thus are not shown by our system.

To our knowledge, this is the first effort to build a system of its kind. Our system has already been used by more than a hundred journalists with an editorial line and by three fact-checking agencies which explicitly mentioned our system as a data source. We hope this system can be useful during future election campaigns and other major events in Brazil and other countries.

More broadly, we expect this study to drive follow-up investigations covering other types of content as well as delving further into the interplay between WhatsApp groups and the Web as channels for information propagation.

ABSTRACT

We consider the problem of analyzing timestamped relational events between a set of entities, such as messages between users of an on-line social network. Such data are often analyzed using static or discrete-time network models, which discard a significant amount of information by aggregating events over time to form network snapshots. In this paper, we introduce a block point process model (BPPM) for continuous-time event-based dynamic networks. The BPPM is inspired by the well-known stochastic block model (SBM) for static networks. We show that networks generated by the BPPM follow an SBM in the limit of a growing number of nodes. We use this property to develop principled and efficient local search and variational inference procedures initialized by regularized spectral clustering. We fit BPPMs with exponential Hawkes processes to analyze several real network data sets, including a Facebook wall post network with over 3,500 nodes and 130,000 events.

1 INTRODUCTION

Many application settings involve analysis of timestamped relational event data in the form of triplets (sender, receiver, timestamp), as shown in Figure 1a. Examples include analysis of messages between users of an on-line social network, emails between employees of a company, and transactions between buyers and sellers on e-commerce websites. These types of data can be represented as dynamic networks evolving in continuous time due to the fine granularity on the timestamps of events and the irregular time intervals at which events occur.

Statistically modeling these types of relations and their dynamics over time has been of great interest, especially given the ubiquity of such data in recent years. Most prior work has involved modeling these relations using network representations, with nodes representing senders and receivers, and edges representing events. Such representations often either discard the timestamps altogether, which transforms the dynamic network into a static network, or aggregate events over time windows to form network snapshots evolving in discrete time as in Figure 1b. There have been numerous statistical models proposed for static networks dating back to the 1960s [12, 18], and more recently, for discrete-time networks [5, 15, 17, 26, 32, 39–42], but comparatively less attention has been devoted to continuous-time networks of timestamped relations.

The development of such continuous-time or point process-based network models [2, 7, 8, 11, 27, 38] appears to have progressed separately from recent advances in static and discrete-time network models. There have been many recent developments on estimation

for static network models such as the stochastic block model (SBM), including the development of consistent estimators such as regularized spectral clustering [31, 34]. Although some continuous-time models have drawn their inspiration from static network models, to the best of our knowledge, there has not been prior work connecting the two types of models, and in particular, examining whether provably accurate estimators for static network models can be used to estimate continuous-time models.

In this paper we introduce the block point process model (BPPM) for continuous-time event-based dynamic networks, inspired by the SBM for static networks. Our main contributions are as follows:

- We demonstrate an asymptotic equivalence between our proposed BPPM and the SBM in the limit of growing number of nodes, which allows us to use provably accurate and efficient estimators for the SBM, such as regularized spectral clustering, as a starting point to fit BPPMs.
- We develop efficient local search and variational inference procedures for the BPPM initialized by regularized spectral clustering on an aggregated adjacency matrix.
- We fit the BPPM to several real network data sets, including a Facebook network with over 3,500 nodes and 130,000 events and demonstrate that it is more accurate at predicting future interactions compared to discrete-time SBMs.

2 BACKGROUND

We consider dynamic networks evolving in continuous time through the observation of events between pairs of nodes at recorded timestamps, as shown in Figure 1a. We assume that events are directed, so we refer to the two nodes involved in an event as the sender and receiver (although the model we propose can be trivially modified to handle undirected events by reducing the number of parameters). Such event data can be represented in the form of a matrix E where each row is a triplet $\mathbf{e} = (u, v, t)$ denoting an event from node u to node v at timestamp t. Let N denote the total number of nodes in the network, and let T denote the time of the last interaction, so that the interaction times are all in $[0, T]$.

From an event matrix E, one can obtain an adjacency matrix $A^{[t_1,t_2)}$ over any given time interval $[t_1, t_2)$ such that $0 \leq t_1 < t_2 \leq T$. To simplify notation, we drop the time interval from the adjacency matrix, i.e. $A = A^{[t_1,t_2)}$. In this adjacency matrix, $a_{ij} = 1$ if there is at least one event from node i to node j in $[t_1, t_2)$, and $a_{ij} = 0$ otherwise. For example, Figure 1b shows two adjacency matrices constructed by aggregating events from the event table shown in Figure 1a over $[0, 1)$ and $[1, 2)$.

2.1 The Stochastic Block Model

Most statistical models for networks consider an adjacency matrix rather than event-based representation; many commonly used models of this type are discussed in the survey by Goldenberg et al. [12]. One model that has received significant attention is the *stochastic block model* (SBM), which is defined as follows (adapted from Definition 3 in Holland et al. [18]):

Definition 2.1 (Stochastic block model). Let A denote a random adjacency matrix for a static network, and let $\mathbf{c}$ denote a class membership vector. A is generated according to a stochastic block model with respect to the membership vector $\mathbf{c}$ if and only if,

(1) For any nodes $i \neq j$, the random variables a_{ij} are statistically independent.
(2) For any nodes $i \neq j$ and $i' \neq j'$, if i and i' are in the same class, i.e. $c_i = c_{i'}$, and j and j' are in the same class, i.e. $c_j = c_{j'}$, then a_{ij} and $a_{i'j'}$ are identically distributed.

The classes in the SBM are also commonly referred to in the literature as blocks. The class membership vector $\mathbf{c}$ has N entries where each entry $c_i \in \{1, \ldots, K\}$ denotes the class membership of node i, and K denotes the total number of classes. Recent work has focused on estimating the class memberships from the adjacency matrix A. In this setting, spectral clustering (and regularized variants) has emerged as an efficient estimator that has theoretical accuracy guarantees [22, 31, 33–35], scales to large networks with thousands of nodes, and is generally not sensitive to initialization.

2.2 Related Work

Most existing work on modeling dynamic networks has considered a discrete-time representation, where the observations consist of a sequence of adjacency matrices. This observation model is ideally suited for network data collected at regular time intervals, e.g. weekly surveys. In practice, however, dynamic network data is often collected at much finer levels of temporal resolution (e.g. at the level of a second or millisecond), in which case it likely makes more sense to treat time as continuous rather than discrete. In order to apply discrete-time dynamic network models to such data, it must first be pre-processed by aggregating events over time windows to form network snapshots, and this technique is used in many real data experiments [15, 27, 40–42]. For example, an aggregated representation of the network in Figure 1a with time window of 1 is shown in Figure 1b.

Aggregating continuous-time network data into discrete-time snapshots presents several challenges. One would ideally choose the time window to be as short as possible for the maximum temporal resolution. However, this increases the number of snapshots, and accordingly, the computation time (typically linear in the number of snapshots). More importantly, models fit using shorter time windows can lead to worse predictors than models fit using longer time windows because the models often assume short-term memory, such as the Markovian dynamics in many discrete-time SBMs [17, 26, 39–42]. We demonstrate some of these practical challenges in an experiment in Section 6.2.2.

Another line of research that has evolved independently of discrete-time network models involves the use of point processes to estimate the structure of a latent network from observations at the nodes [10, 13, 16, 24, 36]. These models are often used to estimate networks of diffusion from information cascades. Such work differs from the setting we consider in this paper, where we directly observe events *between pairs of nodes* and seek to model the dynamics of such event sequences.

There have been several other models proposed using point processes to model continuous-time event-based networks [2, 7, 8, 11, 23, 27, 38], which is the setting we consider in this paper. These models are typically fit using Markov chain Monte Carlo (MCMC) methods, which do not scale to large networks with thousands of nodes. The BPPM that we propose in this paper is a simpler version of the Hawkes IRM [2]. The relational event model (REM) [7] is

Algorithm 1 Generative process for BPPM

1: **for** node $i = 1$ **to** N **do**
2: Sample class c_i from categorical distribution with parameter vector $\boldsymbol{\pi}$
3: **for** block pair $b = 1$ **to** p **do**
4: **loop**
5: Sample next event time t_b from bth point process
6: **if** $t_b > T$ **then**
7: **break**
8: Randomly select nodes $i \in b_1, j \in b_2$ to form an edge from node i to node j at time t_b

related to the BPPM in that it is also inspired by the SBM and shares parameters across nodes in the network in a similar manner. We discuss the Hawkes IRM and REM in greater detail and compare them to our proposed model in Section 3.4.

3 THE BLOCK POINT PROCESS MODEL

3.1 Model Specification

We propose to model continuous-time dynamic networks using a generative point process network model. Motivated by the SBM for static networks, we propose to divide nodes into K classes or blocks and to associate a univariate point process with each pair of node blocks $b = (b_1, b_2) \in \{1, \ldots, K\}^2$, which we refer to as a *block pair*. Let $p = K^2$ denote the total number of block pairs. Let $\boldsymbol{\pi} = \{\pi_1, \ldots, \pi_K\}$ denote the class membership probability vector, where π_q denotes the probability that a node belongs to class q. We call our model the *block point process model* (BPPM). The generative process for the BPPM for a network of duration T time units is shown in Algorithm 1.

The BPPM is a very general model—notice that we have not specified what type of point process to use in the model (we discuss this in Section 3.3). The proposed BPPM is less flexible than existing point process network models such as the Hawkes IRM and the REM (we compare the BPPM to these models in Section 3.4), but its simplicity enables theoretical analysis of the model. We then use the findings of our analysis to develop principled and efficient inference procedures that scale to large networks with thousands of nodes and hundreds of thousands of events. The proposed inference procedures, which we discuss in Section 4, take advantage of the close relationship between the BPPM and the SBM, which we discuss next.

3.2 Asymptotic Equivalence with the Stochastic Block Model

The BPPM is motivated by the SBM, where the probability of forming an edge between two nodes depends only the classes of the two nodes. Given the relation between the point process and adjacency matrix representations discussed in Section 2, a natural question is whether there is any equivalence between the BPPM and the SBM. Specifically, does an adjacency matrix $A = A^{[t_1, t_2)}$ constructed from an event matrix E generated by the BPPM follow an SBM? As far as we know, this connection between point process and static network models has not been previously explored in the literature.

We first note that A meets criterion 2 (identical distribution within a block pair) in Definition 2.1 due to the random selection of node pair for each event in step 8 of Algorithm 1. To check criterion 1 (independence of all entries of A), we first note that entries a_{ij} and $a_{i'j'}$ in different block pairs, i.e. $(c_i, c_j) \neq (c_{i'}, c'_j)$, depend on different independent point processes (unlike in the Hawkes IRM), so a_{ij} and $a_{i'j'}$ are independent.

Next, consider entries a_{ij} and $a_{i'j'}$ in the same block pair $b = (c_i, c_j) = (c_{i'}, c_{j'})$. In general, these entries are dependent so that criterion 1 is not satisfied.[1] For example, if a Hawkes process [21] is used in step 5 of Algorithm 1, then $a_{i'j'} = 1$ indicates that at least one event was generated in block pair b, i.e. there was at least one jump in the intensity of the process. This indicates that the probability of another event is now higher, so the conditional probability $\Pr(a_{ij} = 1 | a_{i'j'} = 1)$ should be higher than the marginal probability $\Pr(a_{ij} = 1)$. Thus a_{ij} and $a_{i'j'}$ are *dependent*, so A does *not follow* an SBM!

We denote the *deviation from independence* using the terms δ_0 and δ_1 defined by

$$\delta_0 = \Pr(a_{ij} = 0 | a_{i'j'} = 0) - \Pr(a_{ij} = 0) \tag{1}$$

$$\delta_1 = \Pr(a_{ij} = 0 | a_{i'j'} = 1) - \Pr(a_{ij} = 0). \tag{2}$$

If $\delta_0 = \delta_1 = 0$, then the two adjacency matrix entries are independent. If $\delta_0 \neq 0$ or $\delta_1 \neq 0$, then the two entries are dependent, with smaller values of $|\delta_0|, |\delta_1|$ indicating less dependence. The following theorem bounds these values.

Theorem (Asymptotic Independence Theorem)**.** *Consider an adjacency matrix A constructed from the BPPM over some time interval $[t_1, t_2)$. Then, for any two entries a_{ij} and $a_{i'j'}$ both in block pair b, the deviation from independence given by δ_0, δ_1 defined in* (1), (2) *is bounded in the following manner:*

$$|\delta_0|, |\delta_1| \leq \min\{1, \mu_b / n_b\} \tag{3}$$

where μ_b denotes the expected number of events in block pair b in $[t_1, t_2)$, and n_b denotes the size of block pair b. In the limit as $n_b \to \infty$, $\delta_0, \delta_1 \to 0$ provided μ_b grows at a slower rate than n_b. Thus a_{ij} and $a_{i'j'}$ are asymptotically independent for growing n_b.

The proof of the Asymptotic Independence Theorem is provided in Appendix A. We evaluate the tightness of the bound in (3) via simulation in Section 5.1. Since it depends only on the expected number of events μ_b and not the distribution, it is likely to be loose in general but applies to any choice of point process.

The Asymptotic Independence Theorem states that the deviation given by δ_0, δ_1 is non-zero in general for fixed n_b, so the entries a_{ij} and $a_{i'j'}$ are dependent, but the dependence decreases as the size of a block (and thus, a block pair) grows. This can be achieved by letting the number of nodes N in the network grow while holding the number of classes K fixed. In this case, the sizes of block pairs would be growing at rate $O(N^2)$, so the asymptotic behavior should be visible for networks with thousands of nodes. Thus, an adjacency matrix constructed from the BPPM approaches an SBM in the limit of a growing network! To the best of our knowledge, this is the first such result linking networks constructed from point process models and static network models. It is also practically useful in

[1] An exception is the case of a homogeneous Poisson process, for which the entries are independent by the splitting property.

that it allows us to leverage recent work on provably accurate and efficient inference on the SBM for the BPPM.

3.3 Choice of Point Process Model

Any temporal point process can be used to generate the event times in the BPPM. We turn our attention to a specific point process: the Hawkes process [21], which is a self-exciting process where the occurrence of events increases the probability of additional events in the future. The self-exciting property tends to create clusters of events in time, which are empirically observed in many settings. Prior work has suggested that Hawkes processes with exponential kernels provide a good fit to many real social network data sets, including email and conversation sequences [14, 25] and re-shares of posts on Twitter [43]. Hence, we also adopt the exponential kernel, which has intensity function

$$\lambda(t) = \lambda^{\infty} + \sum_{t_i < t} \alpha e^{-\beta(t - t_i)},$$

where λ^{∞} denotes the background rate that the intensity reverts to over time, α denotes the jump size for the intensity function, β denotes the exponential decay rate, and the t_i's denote times of events that occurred prior to time t. We refer to this model as the *block Hawkes model* (BHM).

3.4 Relation to Other Models

The block Hawkes model we consider is a simpler version of the Hawkes IRM, which couples a non-parametric Bayesian version of the SBM called the infinite relational model (IRM) [20] with mutually-exciting Hawkes processes. By utilizing mutually-exciting Hawkes processes, the Hawkes IRM allows for reciprocity of events between block pairs. Similar to the BHM, node pairs in a block pair are selected at random to form an edge. The authors use MCMC-based inference that scales only to very small networks.

The BHM simplifies the Hawkes IRM by using a fixed number of classes K and univariate rather than multivariate Hawkes processes. The use of univariate Hawkes processes is crucial because it allows for independence between block pairs, which we used in the analysis in Section 3.2 to demonstrate an asymptotic equivalence with an SBM. We use this asymptotic equivalence in Section 4 to devise an efficient inference procedure that scales to networks with thousands of nodes.

The BHM also has similarities with the relational event model (REM) [7], which associates a non-homogeneous Poisson process with each pair of nodes, where the intensity function is piecewise constant with knots (change points) at the event times. Different node pairs belonging to the same block pair are governed by the same set of parameters. The REM also incorporates other edge formation mechanisms within block pairs such as reciprocity and transitivity, similar to an exponential random graph model. The authors also use MCMC for inference.

4 INFERENCE PROCEDURE

The observed data is in the form of triplets $\mathbf{e}_s = (u_s, v_s, t_s)$ for each event s denoting the nodes u_s, v_s involved and the timestamp t_s. Consider an event matrix E where each row corresponds to an event in the form of a triplet $\mathbf{e}_s$. Fitting the BPPM involves estimating both the unknown classes or blocks for each node and the point process parameters θ_b for each block pair b from E. In the case of an exponential Hawkes process, the parameters are given by

$$\theta_b = \left(\alpha_b, \beta_b, \lambda_b^{\infty}\right)$$

for each block pair b. Let $\theta = \{\theta_b\}_{b=1}^{p}$ denote the set of point process parameters over all p block pairs.

Exact inference is impractical for all but the smallest networks due to the discrete class memberships $\mathbf{c}$. Thus, we consider two approximate inference methods: a greedy local search (Section 4.1) and variational inference (Section 4.2). Both approaches are iterative and converge to a local maximum and are thus sensitive to the choice of initialization, which we discuss in Section 4.3.

4.1 Local Search

Consider a conditional likelihood function for the point process parameters θ given the values of the class memberships $\mathbf{c}$ that determine the block pairs. Let $E^{(b)}$ denote rows of E corresponding to events involving block pair $b = (b_1, b_2)$; that is, rows $\mathbf{e}_s$ where $u_s \in b_1$ and $v_s \in b_2$. The p row blocks $E^{(b)} = [\mathbf{u}^{(b)}, \mathbf{v}^{(b)}, \mathbf{t}^{(b)}]$ form a partition of the rows of matrix E. Let m_b denote the number of events observed in block pair b. Let n_b denote the size of block pair b, i.e. the number of node pairs or possible edges in block pair b, which is given by $|b_1|(|b_1| - 1)$ if $b_1 = b_2$ and $|b_1||b_2|$ otherwise. The conditional log-likelihood function is given by

$$\begin{aligned}
\log \Pr(E|\theta, \mathbf{c}) &= \log \prod_{b=1}^{p} \Pr\left(\mathbf{u}^{(b)}, \mathbf{v}^{(b)}, \mathbf{t}^{(b)} \middle| \theta_b, \mathbf{c}\right) \\
&= \log \prod_{b=1}^{p} \Pr\left(\mathbf{t}^{(b)} \middle| \theta_b\right) \prod_{s \in b} \Pr(u_s, v_s | \mathbf{c}) \\
&= \log \prod_{b=1}^{p} \Pr\left(\mathbf{t}^{(b)} \middle| \theta_b\right) \left(\frac{1}{n_b}\right)^{m_b} \\
&= \sum_{b=1}^{p} \left[\log \Pr\left(\mathbf{t}^{(b)} \middle| \theta_b\right) - m_b \log n_b\right] \qquad (4)
\end{aligned}$$

where the expression for $\Pr(u_s, v_s|\mathbf{c})$ follows from the random selection of nodes in step 8 of the BPPM generative process. The term $\log \Pr\left(\mathbf{t}^{(b)}|\theta_b\right)$ is simply the log-likelihood of the point process model parameters given the timestamps of events in block pair b. For the block Hawkes model, this term can be expressed in the following form [21, 30]:

$$\begin{aligned}
\log \Pr\left(t_{(1)}, \ldots, t_{(m)} | \alpha_b, \beta_b, \lambda_b^{\infty}\right) = \sum_{s=1}^{m} \Bigg\{ & \frac{\alpha_b}{\beta_b}\left[e^{-\beta_b\left(t_{(m)} - t_{(s)}\right)} - 1\right] \\
& + \log\left[\lambda_b^{\infty} + \alpha_b \sum_{r=1}^{s-1} e^{-\beta_b\left(t_{(s)} - t_{(r)}\right)}\right] \Bigg\} - \lambda_b^{\infty} t_{(m)}, \qquad (5)
\end{aligned}$$

where $t_{(s)}$ denotes the sth event corresponding to block pair b. (5) can be written in a recursive form as shown in [29].

The conditional log-likelihood (4) requires knowledge of class memberships $\mathbf{c}$, which are used to partition the event matrix into row blocks $E^{(b)}$ and thus affect both terms in (4) through $\mathbf{t}^{(b)}$, m_b, and n_b. However, in practice, class memberships are unknown, so we must maximize (4) over all possible class assignments.

We use a local search (hill climbing) procedure, which is also often referred to as label switching or node swapping in the network science literature [19, 44] to iteratively update the class assignments to reach a local maximum in a greedy fashion. Recent work has found that such greedy algorithms are competitive with more computationally demanding estimation algorithms in both the static SBM [4] and discrete-time dynamic SBM [5, 41] while scaling to much larger networks. At each iteration, we swap a single node to a different class by choosing the swap that increases the log-likelihood the most. For each possible swap, we evaluate the log-likelihood by partitioning events using to the new class assignments, obtaining the maximum-likelihood estimates of the point process model parameters, and substituting these estimates along with the new class assignments into (4). For the block Hawkes model, we maximize (5) with respect to $(\alpha_b, \beta_b, \lambda_b^\infty)$ for each block using a standard interior point optimization routine [3].

Each iteration of the local search considers $N(K-1)$ possible swaps. Computing the log-likelihood for each swap involves iterating over the timestamps of all M events. Thus, each iteration of the local search has time complexity $O(KMN)$, which is linear in both the number of nodes and events, allowing it to scale to large networks. We verify this time complexity experimentally in Section 5.3. The local search is easily parallelized by evaluating each possible swap on a separate CPU core. We terminate the local search procedure when no swap is able to increase the log-likelihood, indicating that we have reached a local maximum.

4.2 Variational Inference

Variational inference is commonly used as an optimization-based alternative to MCMC and scales to much larger data sets. We implement a mean-field variational inference approach for the BPPM to approximate the intractable posterior distribution by a fully factorizable variational distribution. To reduce the Kullback-Leibler (KL) divergence between the true posterior and the mean-field approximation, we derive the evidence lower bound (ELBO) using an approach similar to the derivation in [6] for a static SBM.

Let Z denote an $N \times K$ class membership matrix, where the notation $z_{iq} = 1$ is equivalent to $c_i = q$, both denoting that node i is in class q. We use a K-dimensional multinomial distribution for each row $\mathbf{z}_i = [z_{i1}, z_{i2}, \ldots, z_{iK}]$ of Z resulting in the following variational distribution:

$$R_E(Z) = \prod_{i=1}^{N} \text{Multinomial}(\mathbf{z}_i | \boldsymbol{\tau}_i), \tag{6}$$

where $\boldsymbol{\tau}_i$ denotes the variational parameter for node i. Unlike for a static SBM, we don't have a closed-form update equation for the block Hawkes model, so we optimize the ELBO using coordinate ascent. The derivation of the ELBO and the variational expectation-maximization algorithm are provided in Appendix B.

4.3 Spectral Clustering Initialization

In order to ensure that the local search or variational inference procedures do not get stuck in poor local maxima, it is important to provide a good initialization. Methods used to initialize class estimates in static and discrete-time SBMs include variants of k-means clustering [4, 26, 27] and spectral clustering [40, 41]. Variational inference is often executed with multiple random initializations, although some structured approaches have been used successfully in practice for certain models. Given the close relationship between the proposed BPPM and the SBM discussed in Section 3.2, we use a spectral clustering initialization, which is much faster and more principled than the typical approach of multiple random initializations. Spectral clustering is an attractive choice because it scales to large networks containing thousands of nodes and has theoretical performance guarantees applicable to the BPPM, as we discuss next.

Algorithm 2 Regularized spectral clustering algorithm used to initialize the local search in the BPPM inference procedure

Require: Adjacency matrix A, number of classes K, regularization parameter $\tau \geq 0$ (Default: τ = average node degree)

1: Compute diagonal matrices O^τ with entries $o_{ii}^\tau = \sum_j a_{ij} + \tau$ and P^τ with entries $p_{jj}^\tau = \sum_i a_{ij} + \tau$
2: Compute regularized graph Laplacian $L = (O^\tau)^{-1/2} A (P^\tau)^{-1/2}$
3: Compute singular value decomposition of L
4: $\tilde{\Sigma} \leftarrow$ diagonal matrix of K largest singular values of L
5: $(\tilde{U}, \tilde{V}) \leftarrow$ left and right singular vectors for $\tilde{\Sigma}$
6: $\tilde{Z} \leftarrow [\tilde{U}, \tilde{V}]$ {concatenate left and right singular vectors}
7: Normalize each row of $\tilde{Z}$ to have magnitude of 1
8: $\hat{\mathbf{c}} \leftarrow$ k-means clustering on rows of $\tilde{Z}$
9: **return** $\hat{\mathbf{c}}$

Recent work has demonstrated that applying spectral clustering (or a regularized variant) to a network generated from an SBM results in consistent estimates of class assignments as the number of nodes $N \to \infty$ [22, 31, 33–35]. These theoretical guarantees typically require the expected degrees of nodes to grow polylogarithmically with the number of nodes so that the network is not too sparse. Networks that satisfy this requirement belong to the polylog degree regime. On the other hand, the Asymptotic Independence Theorem shows an asymptotic equivalence between the BPPM and SBM provided that there are not too many events, i.e. the network is not too dense.

In the polylog degree regime, the ratio

$$\frac{\mu_b}{n_b} = O\left(\frac{N \,\text{poly}(\log N)}{N^2}\right) \to 0 \text{ as } N \to \infty,$$

so the network is not too dense, and the Asymptotic Independence Theorem holds. Thus, spectral clustering should provide an accurate estimate of the class assignments in the polylog degree regime, which is commonly observed in real networks such as social networks. Since we consider directed relations, we use a regularized spectral clustering algorithm for directed networks (pseudocode provided in Algorithm 2) to initialize the local search. It is a variant of the DI-SIM co-clustering algorithm [34] modified to produce a single set of clusters for directed graphs by concatenating scaled left and right singular vectors in a manner similar to Sussman et al. [35]. For variational inference, we require an initialization on the variational parameters $\boldsymbol{\tau}_i$ rather than a hard clustering solution, so we set $\boldsymbol{\tau}_i$ to the ith row of $\tilde{Z}$ to represent a soft clustering initialization.

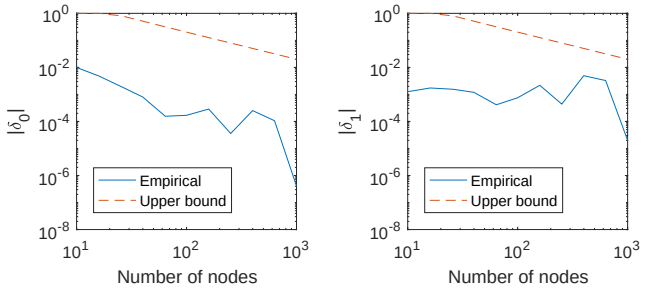

Figure 2: Comparison of empirical deviation from independence with theoretical upper bound. Empirical deviations are well within the theoretical bound.

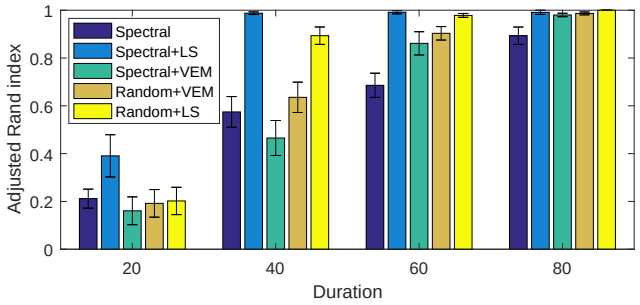

Figure 3: Mean adjusted Rand indices (± standard error) for class estimation simulation experiment with varying durations. Spectral clustering with local search produces the most accurate class estimates, while the spectral initialization for variational EM does not appear to work well.

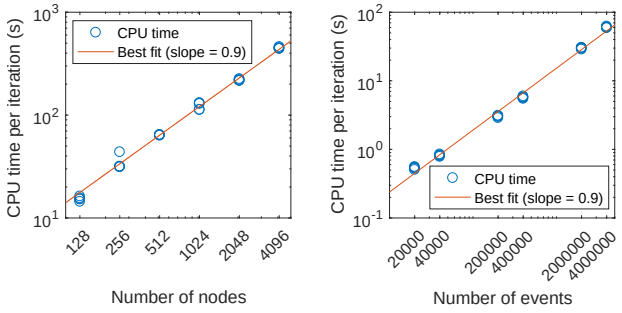

Figure 4: CPU time per iteration of local search inference in seconds with varying number of nodes and events.

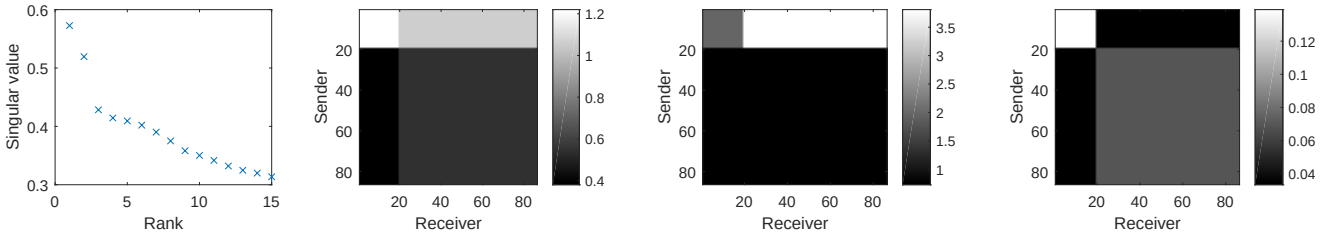
5 SIMULATED DATA EXPERIMENTS

5.1 Deviation from Independence

The Asymptotic Independence Theorem demonstrates that pairs of adjacency matrix entries in the same block pair are dependent, but that the dependence is upper bounded by (3), and that the dependence goes to 0 for growing blocks. To evaluate the slackness of the bounds, we simulate networks from the block Hawkes model (BHM). Since δ_0 and δ_1 depend only on the size of the blocks, we simulate networks with a single block and let the number of nodes N grow from 10 to 1,000. For each number of nodes, we simulate 100,000 networks from the block Hawkes model for a duration of $T = 20$ time units. We choose the Hawkes process parameters to be $\alpha = 5N$, $\beta = 10N$, and $\lambda^{\infty} = 0.5N$. The expected number of events $\mu = NT = 20N$, which grows with N and is slower than the growth of the size $n = N(N-1)$ of the block pair, so the Asymptotic Independence Theorem applies.

We evaluate the absolute difference between the empirical marginal probability $\widehat{\Pr}(a_{ij} = 0)$ and the empirical conditional probabilities $\widehat{\Pr}(a_{ij} = 0|a_{i'j'} = 0)$ and $\widehat{\Pr}(a_{ij} = 0|a_{i'j'} = 1)$. The empirical deviation from independence is shown to be well below the upper bound in Figure 2. The bound (3) in the Asymptotic Independence Theorem depends only on the mean number of events, so it is somewhat loose when applied to the block Hawkes model.

5.2 Class Estimation



This simulation experiment is based on the synthetic network generator from Newman and Girvan [28], where all the diagonal block pairs have the same parameters, and the off-diagonal block pairs have the same parameters, but different from the diagonal block pairs. We generate networks with 128 nodes and 4 classes from the block Hawkes model using Algorithm 1 with varying durations from 20 to 80 time units. We generate 10 networks for each duration, with Hawkes process parameters α and β being 0.6 and 0.8, respectively, for all block pairs. The baseline rates λ^{∞} are 1.8 for diagonal block pairs and 0.6 for off-diagonal block pairs. Classes are estimated using 5 methods: spectral clustering, local search initialized with spectral clustering, variational EM initialized with spectral clustering, variational EM with 10 random initializations, and local search with 10 random initializations.

The results shown in Figure 3 demonstrate that local search initialized with spectral clustering (Spectral+LS) is the most accurate. Conversely, the spectral clustering initialization for variational EM (Spectral+VEM) results in significantly worse results. Variational EM and local search using 10 random initializations (Random+VEM and Random+LS) take significantly longer than Spectral+LS; however, they are also less accurate, so we use Spectral+LS in the remainder of this paper.

5.3 Scalability of Local Search

We evaluate the scalability of the proposed local search inference procedure by generating networks with varying number of nodes and events from the block Hawkes model. When varying the number of nodes, we choose a time duration of 1,200 time units and set the Hawkes process parameters $(\alpha, \beta, \lambda^{\infty})$ to $(1.6, 2, 1.2)$ for diagonal block pairs and $(0.6, 0.8, 0.6)$ for off-diagonal block pairs. When varying the number of events, we choose a network with 128 nodes and set the Hawkes process parameters $(\alpha, \beta, \lambda^{\infty})$ to $(0.6, 0.8, 1.8)$ for diagonal block pairs and $(0.6, 0.8, 0.6)$ for off-diagonal block pairs. We keep the number of classes fixed to be 4 in both settings and simulate 5 networks for each configuration.

The CPU times per iteration for both varying number of nodes and events are shown in Figure 4 along with best-fit lines for a

(a) Singular values (b) α: Jump sizes (c) β: Jump decay rates (d) λ^{∞}: Background intensity

Figure 5: Block Hawkes model fit on Reality Mining data with 2 blocks. Nodes 1-15 belong to block 1 and the rest to block 2. (a) First 15 singular values of the adjacency matrix. (b)-(d) Hawkes process parameter estimates.

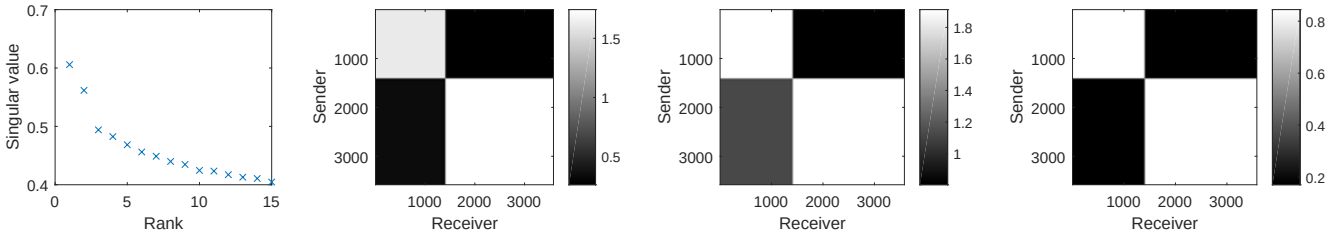
power law relationship (beginning with 512 nodes for the varying nodes experiment). The best-fit line has slope 0.9 in both cases, confirming the linear time complexity both in terms of the number of nodes N and the number of events M, which is as expected according to the computed time complexity in Section 4.1. All CPU times are recorded on a Linux workstation using 18 Intel Xeon processor cores operating at 2.8 GHz.

6 REAL DATA EXPERIMENTS

6.1 MIT Reality Mining

We analyze the MIT Reality Mining data [9], using start times of phone calls as events from the caller to the recipient. Nodes in this data set correspond to students and staff at MIT. The data were collected over approximately 10 months beginning in August 2004. We remove all nodes who do not either make or receive a call at any point in the data trace, resulting in a network with 86 nodes.

We observe a significant gap after the second largest singular value of the regularized graph Laplacian, as shown in Figure 5a so we choose $K = 2$ blocks. From examining the block Hawkes model parameter estimates shown in Figure 5b-5d, block pair $(1, 1)$ has both higher background intensity λ^{∞} and longer bursts due to high α and low β. Thus, not only does it appear to be a community, but phone calls within the community tend to happen in prolonged bursts. On the other hand, block pair $(2, 2)$ has higher background intensity than the off-diagonal block pairs but without the large jump sizes, indicating a lack of bursty behavior compared to block pair $(1, 1)$. Block pair $(1, 2)$ has high values for both α and β, indicating large bursts of short duration. However, since block pair $(1, 2)$ has a lower background intensity than $(2, 2)$, the overall density of the block pair in the aggregated adjacency matrix is not necessarily higher. Indeed, block pair $(2, 2)$ has a density of 0.041, while block pair $(2, 1)$ has a density of 0.034. Thus, the continuous-time model of the network enables greater analysis of the dynamics of interactions over both short and long periods of time, and the findings may be quite different from those of static and discrete-time network representations.



6.2 Facebook Wall Posts

6.2.1 Model-Based Exploratory Analysis. We analyze the Facebook wall post data collected by Viswanath et al. [37], which contains over $60,000$ nodes. We consider events between January 1, 2007 and January 1, 2008. We remove nodes with degree less than 10, resulting in a network with $137,170$ events among $3,582$ nodes.

We select a model with $K = 2$ blocks, as suggested by the singular values of the regularized graph Laplacian shown in Figure 6a. The parameters inferred from the BHM fit on the Facebook data are shown in Figure 6b-6d. The diagonal block pairs have larger values of background intensity λ^{∞}, indicating that the blocks form communities. This finding could also have been yielded by static and discrete-time SBMs. The diagonal block pairs also have higher values of jump sizes α, indicating that wall posts between members of a community are more bursty. A portion of the Hawkes process intensity function for block pair $(1, 1)$ is shown in Figure 7. In addition to diurnal patterns, one can observe bursty periods of wall posts throughout the day. This finding could not have been obtained from static and discrete-time SBMs. From the values of α on the diagonal block pairs, we see that wall posts within block 2 are more bursty, with higher jump sizes and roughly equal jump decay rates compared to posts within block 1. By observing the values of α on off-diagonal block pairs, we notice that there isn't much asymmetry, but the decay rate β exhibits asymmetry. Specifically, events from block 1 to 2 have longer sustained bursts than events from block 2 to 1 due to the lower value of β_{12} compared to β_{21}.

6.2.2 Comparison with Discrete-Time SBM. To compare our proposed continuous-time BHM with a discrete-time SBM [41], we consider the task of predicting the time to the next event in each block pair. We believe that this is a fair comparison because both the BHM and discrete-time SBM require that pairs of nodes in the same block pair have identical edge probabilities. We split the data into two sets, with the first 8 months of data for training and the last 4 months for testing. During each week of the test set, we attempt to predict the time to the next event in each block pair. Afterwards, we update the model with all events during that week. This results in 16 predictions in the test set for each block pair.

The BHM directly models event times, so we use the expected next event time for each block as the prediction. The discrete-time SBM does not directly model event times, so we multiply the expected number of time snapshots that will elapse before the next edge formation, which is geometrically distributed, by the snapshot length and then subtract half the snapshot length (to center the prediction within the snapshot) to get a prediction for the next event time. Since the prediction for the discrete-time SBM is dependent on the snapshot length, we test several different snapshot lengths.

(a) Singular values (b) α: Jump sizes (c) β: Jump decay rates (d) λ^{∞}: Background intensity

Figure 6: Block Hawkes model parameter estimates on Facebook wall post data with 2 blocks. Nodes 1-1421 belong to block 1 and the rest to block 2. (a) First 15 singular values of the adjacency matrix. (b)-(d) Hawkes process parameter estimates.

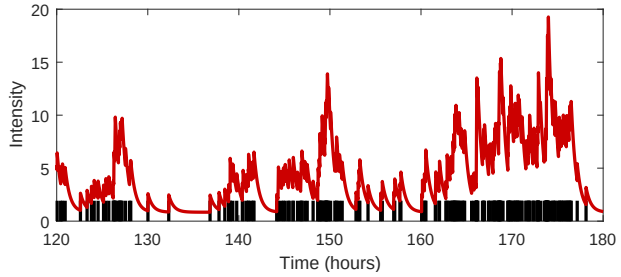


Figure 7: Hawkes process intensity function for events in block pair (1,1) of the Facebook data. Event times are denoted by black ticks along the horizontal axis.

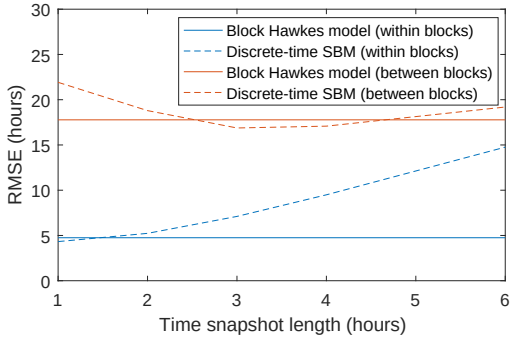

Figure 8: Prediction RMSE in hours for block Hawkes model and discrete-time SBMs on Facebook data.

We estimate class assignments for both models using regularized spectral clustering with 2 classes (with no local search iterations) so that differences in class estimates between the two models do not play a role in the accuracy. We believe this is a valid comparison because spectral clustering is used as the initialization to local search in the inference procedure for both models, as discussed in Section 4.1 for the BHM and in [41] for the discrete-time SBM.

We evaluate the accuracy of the predictions by computing the root mean-squared error (RMSE) between predicted event times and actual event times for the first event in each block pair during a week. Since the blocks form communities, we expect events to arrive much more frequently within blocks. Thus we separate the evaluation into within-block and between-block prediction RMSE. As shown in Figure 8, the accuracy of the discrete-time SBM is highly dependent on the snapshot length. For snapshots of 6 hours and longer, the loss in temporal resolution is the main contributor to the high RMSE. The shorter snapshots such as 1 hour and 2 hours have excellent temporal resolution for within-block prediction but are less accurate for between-block prediction. Choosing 3-hour long snapshots results in the most accurate between-block predictions. Due to the different rates of events within and between blocks, the discrete-time representation must trade off between within-block and between-block prediction accuracy when choosing the snapshot length. Using our continuous-time BHM, we avoid this complex problem of choosing the snapshot length and produce more accurate predictions (in total RMSE) than the discrete-time model for any snapshot length, as shown in Figure 8.

7 CONCLUSION

In this paper, we introduced the block point process model (BPPM) for dynamic networks evolving in continuous time in the form of timestamped events between nodes. Our model was inspired by the well-known stochastic block model (SBM) for static networks and is a simpler version of the Hawkes IRM. We demonstrated that adjacency matrices constructed from the BPPM follow an SBM in the limit of a growing number of nodes. To the best of our knowledge, this is the first result of this type connecting point process network models with adjacency matrix network models. Additionally we proposed a principled and efficient algorithm to fit the BPPM using spectral clustering and local search that scales to large networks and apply it to analyze several real networks.

A PROOF OF ASYMPTOTIC INDEPENDENCE THEOREM

We begin with a well-known lemma on the difference of powers that will be used both to upper and lower bound the deviation from independence.

Lemma A.1 (Difference of powers). *For a real number $x > 1$ and integer $m \geq 1$, we have the following identity:*

$$m(x-1)^{m-1} \leq x^m - (x-1)^m \leq mx^{m-1}. \tag{7}$$

Proof. The proof follows straightforwardly from factorizing a difference of powers. Specifically, for real numbers $x > y > 0$ and

integer $m \geq 1$,

$$x^m - y^m = (x-y)\sum_{i=0}^{m-1} x^{m-1-i}y^i. \tag{8}$$

If $x > 1$ and $y = x - 1$, then (8) becomes

$$x^m - (x-1)^m = \sum_{i=0}^{m-1} x^{m-1-i}(x-1)^i.$$

There are m terms in the summation. The largest term is x^{m-1}, and the smallest term is $(x-1)^{m-1}$. Thus, we can upper and lower bound the sum by mx^{m-1} and $m(x-1)^{m-1}$, respectively, to arrive at (7). □

The next lemma will be used in the upper bound.

Lemma A.2. *For a real number $x > 1$ and integer $m \geq 1$,*

$$\left(\frac{n-1}{n}\right)^m \geq 1 - \frac{m}{n}.$$

Proof.

$$\begin{aligned}
\left(\frac{n-1}{n}\right)^m - 1 &= \frac{(n-1)^m - n^m}{n^m} \\
&= -\frac{n^m - (n-1)^m}{n^m} \\
&\geq -\frac{mn^{m-1}}{n^m} \qquad (9) \\
&= -\frac{m}{n}, \qquad (10)
\end{aligned}$$

where (9) follows from applying Lemma A.1. Adding 1 to both sides of (10), we arrive at the desired result. □

We now prove the Asymptotic Independence Theorem.

Proof of Asymptotic Independence Theorem. First compute the marginal probability $\Pr(a_{ij} = 0)$. $a_{ij} = 0$ implies that no events between nodes i and j occurred. To compute this probability, we first compute the conditional probability given that the number of events in block pair b is m_b. To simplify notation, we drop the subscript b from m_b and n_b in the remainder of the proof, so the conditional probability can be written as

$$\Pr(a_{ij} = 0|m) = \left(\frac{n-1}{n}\right)^m,\ m \geq 0,$$

where the equality follows by noting that, conditioned on m total events in block pair b, the number of events between nodes i and j follows a binomial distribution with m trials and success probability $1/n$. The $1/n$ success probability is due to step 8 of the generative process of the BPPM, which involves selecting node pairs randomly to receive an event. By the Law of Total Probability, the marginal probability is

$$\begin{aligned}
\Pr(a_{ij} = 0) &= \sum_{m=0}^{\infty} p(m)\Pr(a_{ij} = 0|m) \\
&= \sum_{m=0}^{\infty} p(m)\left(\frac{n-1}{n}\right)^m, \qquad (11)
\end{aligned}$$

where the probability mass function $p(m)$ denotes the probability that m events in block pair b occurred.

Next consider the joint probability $\Pr(a_{ij} = 0, a_{i'j'} = 0)$. As before, condition on the number of events m. The conditional joint probability is

$$\Pr(a_{ij} = 0, a_{i'j'} = 0|m) = \left(\frac{n-2}{n}\right)^m,\ m \geq 0,$$

because the number of events for each node pair in block pair b follow a multinomial distribution with m trials and all event probabilities equal to $1/n$. By the Law of Total Probability,

$$\Pr(a_{ij} = 0, a_{i'j'} = 0) = \sum_{m=0}^{\infty} p(m)\left(\frac{n-2}{n}\right)^m. \tag{12}$$

We first lower bound δ_0 by noting that

$$\begin{aligned}
\delta_0 &= \Pr(a_{ij} = 0|a_{i'j'} = 0) - \Pr(a_{ij} = 0) \\
&\geq \Pr(a_{ij} = 0, a_{i'j'} = 0) - \Pr(a_{ij} = 0) \\
&= \sum_{m=0}^{\infty} p(m)\left[\left(\frac{n-2}{n}\right)^m - \left(\frac{n-1}{n}\right)^m\right] \qquad (13) \\
&= -\sum_{m=0}^{\infty} p(m)\frac{(n-1)^m - (n-2)^m}{n^m} \\
&\geq -\sum_{m=0}^{\infty} p(m)\frac{m(n-1)^{m-1}}{n^m} \qquad (14) \\
&= -\frac{1}{n}\sum_{m=0}^{\infty} mp(m)\left(\frac{n-1}{n}\right)^{m-1} \\
&\geq -\frac{1}{n}\sum_{m=0}^{\infty} mp(m) \qquad (15) \\
&= -\frac{\mu}{n}, \qquad (16)
\end{aligned}$$

where (13) follows from (11) and (12), (14) follows from Lemma A.1, and (15) follows by observing that $\left(\frac{n-1}{n}\right)^{m-1} \leq 1$.

We now upper bound δ_0 by noting that

$$\begin{aligned}
\delta_0 &= \Pr(a_{ij} = 0|a_{i'j'} = 0) - \Pr(a_{ij} = 0) \\
&\leq 1 - \Pr(a_{ij} = 0) \\
&= 1 - \sum_{m=0}^{\infty} p(m)\left(\frac{n-1}{n}\right)^m \\
&\leq 1 - \sum_{m=0}^{\infty} p(m)\left(1 - \frac{m}{n}\right) \qquad (17) \\
&= 1 - \sum_{m=0}^{\infty} p(m) + \frac{1}{n}\sum_{m=0}^{\infty} mp(m) \\
&= 1 - 1 + \frac{\mu}{n} \\
&= \frac{\mu}{n}, \qquad (18)
\end{aligned}$$

where (17) follows from Lemma A.2.

Next we lower bound δ_1 by noting that

$$\begin{aligned}
\delta_1 &= \Pr(a_{ij}=0|a_{i'j'}=1) - \Pr(a_{ij}=0) \\
&= \frac{\Pr(a_{ij}=0, a_{i'j'}=1) - \Pr(a_{ij}=0)\Pr(a_{i'j'}=1)}{\Pr(a_{i'j'}=1)} \\
&\geq \Pr(a_{ij}=0, a_{i'j'}=1) - \Pr(a_{ij}=0)\Pr(a_{i'j'}=1) \\
&= \Pr(a_{ij}=0) - \Pr(a_{ij}=0, a_{i'j'}=0) \\
&\quad - \Pr(a_{ij}=0)[1-\Pr(a_{i'j'}=0)] \\
&= -[\Pr(a_{ij}=0, a_{i'j'}=0) - \Pr(a_{ij}=0)\Pr(a_{i'j'}=0)] \\
&= -\Pr(a_{i'j'}=0)[\Pr(a_{ij}=0|a_{i'j'}=0) - \Pr(a_{ij}=0)] \\
&= -\Pr(a_{i'j'}=0)\delta_0 \\
&\geq -\delta_0 \\
&\geq -\frac{\mu}{n}, \qquad (19)
\end{aligned}$$

where (19) follows from (18).

Finally we upper bound δ_1 using the same approach as for δ_0:

$$\begin{aligned}
\delta_1 &= \Pr(a_{ij}=0|a_{i'j'}=1) - \Pr(a_{ij}=0) \\
&\leq 1 - \Pr(a_{ij}=0) \\
&\leq \frac{\mu}{n}, \qquad (20)
\end{aligned}$$

where the final inequality is obtained from (18).

Combining (16), (18), (19), and (20), and noting that the maximum deviation between two probabilities is 1, we arrive at the desired result $|\delta_0|, |\delta_1| \leq \min\{1, \mu/n\}$, which completes the proof. □

B VARIATIONAL INFERENCE DETAILS

We begin by deriving the complete-data log-likelihood for the block point process model.

$$\begin{aligned}
&\log \Pr(E, Z|\theta, \boldsymbol{\pi}) \\
&\quad = \log \Pr(Z|\boldsymbol{\pi}) + \log \Pr(\mathbf{u}, \mathbf{v}, \mathbf{t}|Z, \theta) \\
&\quad = \log \Pr(Z|\boldsymbol{\pi}) + \log \Pr(\mathbf{u}, \mathbf{v}|Z) + \log \Pr(\mathbf{t}|\mathbf{u}, \mathbf{v}, Z, \theta) \qquad (21)
\end{aligned}$$

The first term in (21) represents the prior class probability and is given by

$$\log \Pr(Z|\boldsymbol{\pi}) = \log\left(\prod_{i=1}^{N}\prod_{q=1}^{K} \pi_{iq}^{z_{iq}}\right) = \sum_{i=1}^{N}\sum_{q=1}^{K} z_{iq}\log(\pi_{iq}).$$

The second term in (21) represents the uniform distribution of events to nodes inside a block pair and is given by

$$\begin{aligned}
\log \Pr(\mathbf{u}, \mathbf{v}|Z) &= \log\left[\prod_{q=1}^{K}\prod_{l=1}^{K}\left(\frac{1}{n_{ql}}\right)^{m_{ql}}\right] \\
&= -\sum_{q=1}^{K}\sum_{l=1}^{K} m_{ql}\log(n_{ql}) \\
&= -\sum_{q=1}^{K}\sum_{l=1}^{K} \mathbf{z}_{:q}^T W \mathbf{z}_{:l}\log(\mathbf{z}_{:q}^T\mathbf{z}_{:l}),
\end{aligned}$$

where m_{ql} and n_{ql} are defined in the same manner as m_b and n_b in Section 4.1. The last equality represents these two terms as a function of Z, where $\mathbf{z}_{:q}$ denotes the qth column of $\mathbf{z}$, and a weighted adjacency matrix W where the weight w_{ij} corresponds to the total number of events from node i to node j. The third term in (21) depends on the choice of point process; for the block Hawkes model, it is given by

$$\begin{aligned}
\log \Pr(\mathbf{t}|\mathbf{u}, \mathbf{v}, Z, \theta) = \sum_{q=1}^{K}\sum_{l=1}^{K}\Bigg(\sum_{s=1}^{M}\Bigg\{ & z_{u_s q} z_{v_s l}\frac{\alpha_{ql}}{\beta_{ql}}\left[e^{-\beta_{ql}(t_M - t_s)} - 1\right] \\
& + \log\left[\lambda_{ql}^{\infty} + \sum_{r=1}^{s-1} z_{u_r q} z_{v_r l}\alpha_{ql} e^{-\beta_{ql}(t_s - t_r)}\right]\Bigg\} - t_M \lambda_{ql}^{\infty}\Bigg),
\end{aligned}$$

where u_s and v_s denote the sender and receiver nodes for event s. The complete-data log-likelihood (21) is intractable since changing the class membership of one node might affect the class memberships of other nodes, so all possibilities of Z need to be considered.

We derive a mean-field variational inference procedure in which we approximate the posterior with the fully factorizable variational distribution given by (6). We now try to find the best distribution from the family of multinomial distributions that can get us closest in KL divergence to the posterior. But calculating KL divergence requires calculating the intractable posterior, so we instead maximize the evidence lower bound (ELBO), which is equivalent to minimizing KL divergence [1]. The ELBO is given by

$$\text{ELBO}(R_E) = \mathbb{E}\left[\log \Pr(E, Z|\theta, \boldsymbol{\pi})\right] - \mathbb{E}\left[\log R_E(Z)\right].$$

Now expand and calculate expectation of individual terms in the complete-data log-likelihood (21). The expectation of the log of the summations in the second and third terms in (21) can be bounded using Jensen's inequality:

$$\mathbb{E}[f(x)] \geq f(\mathbb{E}(x)).$$

After bounding the log sums using Jensen's inequality and calculating the expectations with respect to R_E, we arrive at the simplified expression for the ELBO:

$$\begin{aligned}
\mathcal{E}(R_E) = & \sum_{i=1}^{N}\sum_{q=1}^{K}\tau_{iq}\log(\pi_{iq}) - \sum_{q=1}^{K}\sum_{l=1}^{K}\boldsymbol{\tau}_{:q}^T W \boldsymbol{\tau}_{:l}\log(\boldsymbol{\tau}_{:q}^T\boldsymbol{\tau}_{:l}) \\
& + \sum_{q=1}^{K}\sum_{l=1}^{K}\Bigg(\sum_{s=1}^{M}\Bigg\{\tau_{u_s q}\tau_{v_s l}\frac{\alpha_{ql}}{\beta_{ql}}\left[e^{-\beta_{ql}(t_M - t_s)} - 1\right] + \log\Bigg[\lambda_{ql}^{\infty} \\
& + \sum_{r=1}^{s-1}\tau_{u_r q}\tau_{v_r l}\alpha_{ql}e^{-\beta_{ql}(t_s - t_r)}\Bigg]\Bigg\} - t_M\lambda_{ql}^{\infty}\Bigg) + \sum_{i=1}^{N}\sum_{q=1}^{K}\tau_{iq}\log(\tau_{iq}) \qquad (22)
\end{aligned}$$

where $\boldsymbol{\tau}_{:q}$ denotes the vector of variational parameters for class q over all N nodes. The variational expectation-maximization (VEM) algorithm alternates between a variational E step, in which we use coordinate ascent to optimize the ELBO (22) over the variational parameters $\boldsymbol{\tau}_i$ for each node i, and an M step, in which we optimize the ELBO over the Hawkes process parameters $\left(\alpha_{ql}, \beta_{ql}, \lambda_{ql}^{\infty}\right)$ for all block pairs $(q, l) \in \{1, \ldots, K\}^2$.

ABSTRACT

In-browser cryptojacking is a form of resource abuse that leverages end-users' machines to mine cryptocurrency without obtaining the users' consent. In this paper, we design, implement, and evaluate OUTGUARD, an automated cryptojacking detection system. We construct a large ground-truth dataset, extract several features using an instrumented web browser, and ultimately select seven distinctive features that are used to build an SVM classification model. OUTGUARDachieves a 97.9% TPR and 1.1% FPR and is reasonably tolerant to adversarial evasions. We utilized OUTGUARDin the wild by deploying it across the Alexa Top 1M websites and found 6,302 cryptojacking sites, of which 3,600 are new detections that were absent from the training data. These cryptojacking sites paint a broad picture of the cryptojacking ecosystem, with particular emphasis on the prevalence of cryptojacking websites and the shared infrastructure that provides clues to the operators behind the cryptojacking phenomenon.

1 INTRODUCTION

The financial success of cryptocurrencies, which are valued at over 280 billion USD in market capitalization[1], has drawn the attention of malicious actors, who attempt to accumulate wealth through illegitimate means. One such method is cryptojacking, which entails hijacking of a victim's processing power to mine cryptocurrency without consent. Cryptojacking has been reported in several forms, including botnets [21, 55] and compromised cloud computing infrastructure [43] that mine cryptocurrencies to benefit the attackers.

Recently, a new strain of cryptojacking has emerged: in-browser cryptojacking, where JavaScript cryptocurrency miners are deployed through websites. In-browser cryptojacking can be enabled primarily by two developments. First, researchers designed specialized proof-of-work mining algorithms (e.g., Cryptonight [6]) that make CPU mining reasonably competitive. Second, in-browser JavaScript performance has been improved through new web standards (e.g., WebAssembly) and general increases in end-user computational power. These advances, coupled with the broad deployment capabilities of the web, have led to reports of in-browser cryptojacking on vulnerable websites [36], public Wi-Fi networks [10], ad-networks [37], and a popular news site [35].

Existing detection mechanisms for in-browser cryptojacking (henceforth simply referred to as cryptojacking) are nascent and primarily centered around blacklisting [1, 12, 49] and CPU usage profiling [45]. Blacklisting is a reactive technique that struggles to keep up with rapidly evolving web threats [32]. CPU usage profiling is imprecise and can mislabel online games, videos, and other processing intensive JavaScript web applications. As we demonstrate in Section 3.4.2, this method suffers from high false positive rates of up to 13% on a small-scale dataset. Recently, L1 cache measurements have been utilized to effectively detect cryptojacking incidents [30]. While this technique is an improvement over the status quo, it is limited by the need for manual, case-by-case reverse engineering of WebAssembly code. Furthermore, reliance on the state of the L1 cache is prone to noise from other running processes and would affect overall detection accuracy.

This paper presents OUTGUARD, an open-source[2] cryptojacking detection system that uses a machine learning classifier to identify

[1] Market cap for the top 100 cryptocurrencies as of July 2018, according to [11].
[2] Both code and data are available at https://github.com/teamnsrg/outguard

cryptojacking at scale. As a first step to building OUTGUARD, we systematically constructed a labeled dataset by scanning the Alexa Top 1M domains with a specially instrumented browser and recording each site's resources, provenance, and JavaScript execution traces. Applying existing cryptojacking detection tools to the scan data yielded a set of 3,006 cryptojacking execution traces from 12 different families. We assembled these cryptojacking traces into two datasets: a balanced dataset with equal numbers of cryptojacking and benign website traces, and an imbalanced dataset that more closely represents the real-world frequency of cryptojacking.

Starting with a wide range of features that pertain to JavaScript execution, network behavior, and DOM characteristics, we carefully analyzed the labeled data to ultimately narrow down to seven features in four feature categories: browser-based, mining-based, load-based, and network-based. We tested two different types of machine learning models, Support Vector Machines (SVM) and Random Forests (RF), and ultimately chose SVM as the classifier for OUTGUARDbecause it achieves 97.9% TPR and 1.1% FPR.

Effective threat detection systems inevitably prompt malicious actors to adopt detection evasion techniques. We examined the resilience of OUTGUARDto multiple forms of adversarial evasion by removing each feature category and measuring the overall detection accuracy. Our analysis showed that while an adversary can potentially evade some of the features used in the learning process, such evasion techniques severely cripple cryptojacking operations and curtail an adversary's profits. For instance, removing mining-based and network-based features (e.g., WebAssembly) is feasible, but their removal makes cryptojacking less attractive to adversaries.

We deployed OUTGUARDin the wild on the Alexa Top 1M domains and discovered 6,302 cryptojacking sites, of which 3,600 had not been detected by existing techniques. Since in-browser cryptomining, in theory, is not necessarily malicious if user consent is obtained, we performed additional analysis to verify that, in reality, nearly all cryptomining sites did not ask for user consent.Through the lenses of both the Alexa Top 1M domains and passive DNS data, cryptojacking appears predominantly in the long tail of lower popularity sites that promote illicit content such as torrents or copyrighted video streaming. Our analysis also exposed 69 incidents of cryptojacking loaded through advertisement web pages. These incidents constituted unintentional cryptojacking, which occurred without the direct involvement of website owners/publishers.

We examined the delivery of cryptojacking and coordination of cryptojacking monetization. We classified cryptojacking incidents into 14 major families based on their source code origin and found a competitive blend of five families that, in total, accounted for more than 70% of cryptojacking occurrences. We also detected 486 cryptojacking incidents using 24 less well-known cryptomining services. These services provide pool mining services that charge as little as 1% of total mining revenue. Finally, we conducted a campaign analysis and identified 35 cryptojacking campaigns which ranged in size from 2 to 121 websites. These websites deliver different types of cryptojacking libraries such as CoinHive, JSeCoin, and Crypto-loot.

Given the extent of the identified cryptojacking websites, we envision multiple deployment scenarios for disrupting cryptojacking operations in the wild. The output of OUTGUARDcould be used to augment blacklists or anti-malware mechanisms in popular browsers. The proposed detection model could also be used as a browser extension that preemptively monitors the content of the visited websites and notifies the user if the website loads a cryptojacking library.

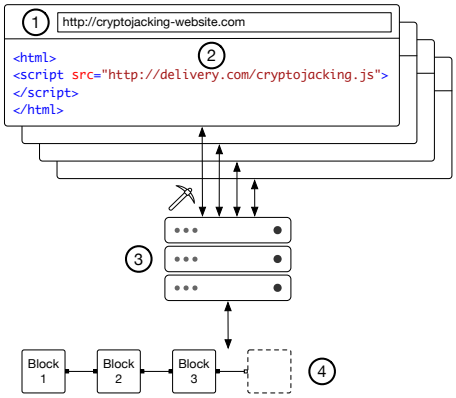

Figure 1: Cryptojacking overview. Websites (1) include cryptojacking code from a delivery server (2). Victim browsers execute mining tasks assigned from a mining pool/proxy (3), which ultimately adds new blocks to the blockchain (4).

2 BACKGROUND AND RELATED WORK

2.1 Cryptojacking Workflow

Modern cryptocurrencies are based on blockchain consensus, which was first presented and popularized by Bitcoin [41]. The blockchain is maintained and extended by miners, which typically compete to compute a proof-of-work puzzle that must be satisfied by new blocks. This proof-of-work serves as both a denial-of-service deterrent and an economic indication of commitment to the consensus protocol. Initial proof-of-work protocols, such as Bitcoin's Hashcash, benefit substantially from custom hardware optimizations, and most mining now occurs on custom mining rigs.

The development of Cryptonight [6], a new proof-of-work algorithm that significantly reduces the advantages of custom hardware, positioned GPUs, custom FPGAs/ASICs, and CPUs back into the same ballpark. In fact, Hashcash relies on brute-forcing SHA-256, which is easily parallelized and reliant on computational bandwidth, making it amenable to customized ASIC hardware. Cryptonight, on the other hand, is a memory-bound protocol (2Mb per core) that relies on random access to slow memory and each new block relies on the results of the prior block. One likely side effect of this development is cryptojacking, which allows an adversary to exploit a victim's computing power to mine cryptocurrencies without consent. Figure 1 outlines the cryptojacking workflow, which involves several entities, starting with user-facing cryptojacking websites. These websites are loaded through a user's JavaScript-enabled web browser and embed a cryptojacking JavaScript library, either through intentional design or hacker injection. The cryptojacking library is delivered from a delivery server, which can reside on the same domain as the base website or, more commonly, is loaded through a separate delivery server host.

Once the cryptojacking code has begun execution, it connects to a mining pool proxy in order to receive mining tasks. A proxy server

is often employed between the mining pool and cryptojacking miners to limit the number of connections and further subdivide mining tasks assigned by the mining pool. Prior to mining, each mining operator (who may control more than one miner) will have registered a mining account with the mining pool, so that she can receive payments for her cryptojacking efforts. Some form of account identifier is usually transmitted from the cryptojacking client to the mining pool to correctly map mining output to the correct mining account. These communications typically occur via Stratum [2], a JSON RPC protocol for mining pool coordination that is cryptocurrency-agnostic. The mining pool monitors the blockchain and assigns mining tasks to each miner that connects to it. These tasks are a low threshold version of the actual proof-of-work puzzle, so that the mining pool can record and reward incremental mining effort. Occasionally, when one of the completed tasks constitutes a successful block, the mining pool adds the block to the blockchain and claims the associated mining reward for itself. Then, periodically, the mining pool will distribute a portion of this reward among its mining accounts in proportion to the work accomplished; the rest is kept as a mining pool fee. These fees are typically around 10–30%, but can be as low as 1% or 2% [50].

The description provided thus far has focused on the components involved in the cryptojacking workflow. In reality, many of these components are controlled by a shared operator. To elucidate the common mappings between components and operators, we present two scenarios: full-service cryptojacking and do-it-yourself (DIY) cryptojacking. For full-service cryptojacking such as CoinHive, a website owner or hijacker only needs to create a CoinHive account and then insert a script inclusion tag her website. In this scenario, CoinHive operates the delivery server and the mining pool / proxy. For a DIY use case, the publisher may host her own delivery server and have the cryptojacking code connect to a public mining pool.

2.2 Related Work

Techniques seeking to gain financial profit through unauthorized access to a victim computer are numerous. There is a large body of work studying adversarial attempts to profit from end-user machines. Ransomware [25, 27, 29, 44], malicious advertisements [7, 34, 56], click fraud [19], web-based social engineering attacks [5, 8, 9, 26, 33, 51, 53], online scams [28, 39], and Potentially Unwanted Programs (PUPs) [31, 42, 48] are only a few examples of these activities in the wild. In the following paragraphs, we explain more closely related work on cryptojacking operations.

A subset of prior work on cryptojacking [16, 40, 46] mainly focuses on the impacts of unwanted mining on user machines (e.g., CPU utilization), and provides an estimate of network size and revenue for CoinHive. In this paper, we mainly focus on less noisy features that can facilitate automatic detection. Very recently, Konoth et al. [30] and Hong et al. [20] concurrently and independently performed systematic analyses on cryptojacking incidents. Hong et al. [20] proposed two techniques by statically searching for a set of fixed signatures in cryptojacking code as well as identifying patterns in the execution stack. The authors demonstrated the insufficiency of blacklists and provide insight on a set of techniques (e.g., obfuscation) that are currently used by adversaries to bypass blacklists. While there are some similarities between their detection approach and ours (e.g., identifying specific patterns), OUTGUARDmainly relies on dynamic behaviors of cryptojacking libraries that are the core components of in-browser cryptojacking, and that are quite unlikely to be used in the same way in benign programs. We elaborate on the feature set in Section 3, and show that the system still achieves high detection coverage if adversaries utilize different levels of obfuscation techniques.

The prior work most relevant to ours is MineSweeper [30], which introduces a static analysis technique to study the wasm code used by cryptojacking code. While this approach is an improvement over the status quo, it would be desirable to complement it with a more generic approach that requires minimal human intervention. OUTGUARDdoes not require manual analysis, and does not rely on cryptographic primitive identification. This was a conscious design choice to avoid possible false positive cases, as acknowledged by the authors [30]. MineSweeper also shows that CPU cache L1 event monitoring can be quite useful in detecting cryptojacking websites by analyzing two cryptojacking families with 100% CPU usage. While WebAssembly provides significant freedom to manage the memory layout, an adversary may not be able to selectively load mining operations in the L1 or L3 cache in order to bypass the proposed detection. However, our analysis reveals that cryptojacking libraries impose different L1 cache event loads as a function of the CPU threshold, leaving threshold-based approaches still vulnerable to future evasion. Furthermore, measuring CPU cache events is a very expensive operation, as the entire process of inferring the state of the CPU cache is very sensitive to noise and to the global status of other active applications on the test machine. This makes approaches similar to MineSweeper less likely to scale. OUTGUARDdoes not have this limitation, and the detection accuracy of OUTGUARDis not impacted by the type of cryptographic function or CPU-related features (see Section 3). Thus, OUTGUARDis a more generic solution to the same problem space.

3 OUTGUARD

Because cryptojacking is still in its infancy, existing detection mechanisms are still sparse and relatively naive: NoCoin [45], minerBlock [4], and CoinBlockerLists [1] rely on open-source, user-updated blacklists to match domains or filenames. Building of an automated cryptojacking detection system in this nascent landscape requires a full construction process: building a ground-truth dataset, creating features, selecting features, training a classification model, and finally evaluating the model under benign and adversarial inputs. In this section, we describe OUTGUARD's architecture, shown in Figure 2, and detail its implementation and performance.

3.1 Building Ground Truth

Currently, no reliable labeled datasets for cryptojacking websites exist. To begin building our training dataset, we first aggregated the frequently updated public blacklist patterns in CoinBlockerLists [1] as well as the blacklist patterns used in popular browser extensions NoCoin [45] and minerBlock [4]. We scanned the Alexa Top 1M websites using our instrumented Chromium browser and collected 3,006 websites that contained JavaScript libraries or delivery servers matching the blacklist patterns.

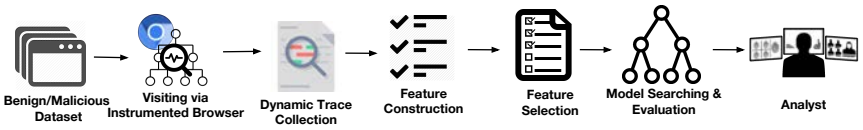

Figure 2: A high-level view of OUTGUARD's architecture.

Table 1: The training set of cryptojacking libraries we collected. Wappalyzer recognized all the libraries collected, but lacks market share (MS%) data for most of the families at the time of writing. Our labeled dataset of 3,006 websites covers 12 of 14 (85%) cryptojacking libraries.

Code Family	Currency	MinerBlock	Wappalyzer (MS%)	Labeled Dataset (%)
JSEcoin	JSECoin	✓	✓(30.6%)	1,358 (45.2%)
CoinHive	Monero	✓	✓(48.2%)	1,124 (37.4%)
CoinHive Captcha	Monero	✓	✓	132 (4.4%)
DeepMiner	Monero	✓	✓	88 (2.9%)
Coinimp	Monero	✓	✓	68 (2.3%)
Crypto-Loot	Monero	✓	✓	55 (1.8%)
ProjectPoi	Monero	-	✓(19.2%)	43 (1.4%)
Coinlab	Monero	✓	✓	43 (1.4%)
Cloudcoins	Monero	✓	✓	42 (1.4%)
Moneromine	Monero	✓	✓	28 (0.9%)
Coinhave	Monero	-	✓	15 (0.5%)
Monero.cc	Monero	✓	✓	10 (0.3%)
Webmine	Monero	-	✓	-
Inwemo	Monero	-	✓	-
Total	-	10 families	14 families (100%)	3,006 (100%)

To further label the cryptojacking libraries, we used Wappalyzer [52] version 5.2, a web technology detection tool that lists the libraries used by a given website. Wappalyzer labels cryptojacking JavaScript (JS) code by examining its origin. To create our labeled dataset, we incorporated the same methodology by mapping URLs to cryptojacking family names. For example, if the code originated from `http//cdn.cloudcoins.co`, we labeled the code as an instance of the Cloudcoin family. As shown in Table 1, we found 12 cryptojacking families in our labeled data, which cover 100% of the cryptojacking libraries known to MinerBlock. We did not find any instances of two out of the 14 total cryptojacking libraries known to Wappalyzer: *Inwemo* and *Webmine*. Inwemo is a seemingly defunct advertising replacement product [22], and Webmine is a similar product based in the Czech Republic.

To build a ground-truth set of non-cryptojacking websites, we randomly selected websites from the Alexa Top 100K. Even though there have been a few reported cases of high popularity sites exhibiting cryptojacking [13, 35], these websites are generally well-maintained and less likely to be subject to new security incidents (as later indicated in Section 5). The non-cryptojacking dataset covers a variety of real-world websites, including dynamic and high-profile websites such as news, legitimate video streaming, and popular companies' websites as well as static websites. This also contains a wide range of JS usage, including high-usage sites (e.g., cnn.com). We combined the ground truth cryptojacking and non-cryptojacking websites into two training datasets: a balanced dataset and an imbalanced dataset. The balanced dataset (BD) contains equal numbers of 2,000 cryptojacking and 2,000 benign websites. The cryptojacking websites were selected randomly and include members of all the 12 labeled cryptojacking families. The motivation behind the imbalanced dataset (ID) is that, in reality, there are significantly more benign websites than cryptojacking websites, and a balanced distribution may bias the accuracy of the classifier. To analyze the performance of the classifier, we built the ID with an imbalance ratio of 1 to 10, such that it contains 2,700 cryptojacking websites and 27,000 benign pages.

3.2 Feature Selection

After carefully examining a variety of cryptojacking websites in our labeled data, we developed a set of features that are broadly characteristic of cryptojacking libraries. Starting with the raw trace data from our data collection, we considered almost all the related features in rendering and JavaScript engine that could be useful in attributing the runtime behavior of JS code. However, we narrowed down our list to 12 features, as we observed those 12 features can potentially reflect cryptojacking behaviors more accurately. We investigated the following features, which we suspected would be strong indicators of cryptojacking, but that did not prove to be distinctive cryptojacking features.

- *JS engine execution time*: We expected JS execution time to dominate a cryptojacking website, but found that this feature is very noisy; many websites continuously execute JS.
- *JS compilation time*: Cryptojacking did not display significant differences in JS compilation time.
- *Garbage collection*: Garbage collection is often a loose proxy for memory usage, but we didn't find differentiating behavior for cryptojacking libraries.
- *Iframe resource loads*: Cryptojacking code is often loaded in an iframe, but rampant advertising iframes drowned out meaningful data.
- *CPU usage*: Cryptomining relies directly on CPU resources, but many cryptojacking libraries throttle CPU usage and are hard to distinguish from JavaScript-heavy sites.

Ultimately, by applying our domain knowledge and evaluating different potential features, we converged on seven features that represent the JS runtime execution, networking, JS event loads, and cryptomining properties of cryptojacking libraries. These features, with the potential exception of WebSockets, are essential for the profitable operation of cryptojacking campaigns. We show that all seven features are nearly ubiquitous across all 12 families of cryptojacking libraries in our labeled training set. We expand on each feature below.

Web Workers. Web workers are a modern JS feature first specified by W3C in 2009 [23] for executing JS files in background threads, independent of a site's main execution thread. Compared to non-cryptojacking usage of web workers for processor-intensive tasks (e.g., image processing during photo upload), we found that cryptojacking libraries are more likely to utilize *multiple* web worker threads for running several mining tasks concurrently. We observed that almost all 12 families utilize at least 3 web workers to perform mining. OUTGUARD's instrument browser dynamically extracts the number of threads as a feature for cryptojacking detection.

Parallel Tasks. We observed that benign websites typically create threads for specific purposes (e.g., caching or streaming video). Our analysis shows that in all the cryptojacking websites, in addition to running multiple web worker threads, cryptojacking libraries tend to run the *same* tasks in each thread, repeatedly invoking the same sequence of method calls. OUTGUARDoutputs the number of identical tasks as a numeric value for detection.

WebAssembly. WebAssembly, or wasm [54], is a new web standard introduced in 2015 that allows web developers to specify assembly-like code that executes on modern browsers at near-native speeds. The performance of WebAssembly makes it an attractive target for processing intensive cryptomining, and we found that all cryptojacking libraries in our training set use WebAssembly. OUTGUARDdetects the usage of WebAssembly by monitoring the exchange of wasm modules between the main execution thread and web workers. This detection technique, which is oblivious to the communication obfuscation found in some variants of CoinHive, results in a boolean feature that indicates the presence or absence of WebAssembly.

WebSockets. WebSockets are a low-overhead, full-duplex communication channel over TCP that was standardized in 2011. Our analysis shows that most mining modules in a browser establish a WebSocket connection to a remote mining pool/proxy. In addition to overcoming some limitations of JavaScript APIs in accessing the TCP socket, WebSocket provides a faster communication channel than standard TCP, as it eliminates the sending of additional HTTP headers for each client-side request. We also observed that cryptojacking libraries use WebSocket APIs to receive data from the mining pool which reduces bandwidth usage. OUTGUARDsearches for `webSocketCreate` events in its JS execution traces and outputs a numeric feature value for the number of WebSocket connections.

Hash Algorithms. As shown in Table 1, Monero is the most common cryptocurrency mined by cryptojacking libraries. Monero mining is a proof-of-work (PoW) task that requires the repeated calculation of the CryptoNight hashing algorithm, which can be calculated efficiently on consumer CPUs. OUTGUARDidentifies CryptoNight hashing by searching for specific function names and binary signatures in JS execution call stacks. For instance, *JSECoin* and some *CoinHive* variants call functions named `module._cryptonight_hash` and `CryptonightWASMWrapper.hash`, respectively. On the other hand, CoinHave embeds and executes binary wasm hashing functions inline for which we also developed detection signatures. This detection mechanism outputs a boolean feature.

PostMessage Event Load. Web workers constantly have to send the results of mining operations to the main process by sending the job id, the nonce, and the result of each operation. This information is then sent to mining proxies over WebSocket connections in order to manage mining tasks. The communication between the renderer process and the web workers is handled via PostMessage. As the number of web workers is significantly high in cryptojacking websites, and PostMessages are the only form of communication with web workers in most modern browsers, a large number of PostMessage events in site visits can be an indication of cryptojacking. We report the total number of PostMessage events as a numeric feature.

MessageLoop Event Load. Chromium performs task management among threads by using MessageLoop. When a WebAssmebly module is loaded into a web worker thread, it starts cryptographic operations inside loops. These operations are pushed to the MessageLoop of the thread to be sequentially processed. While use of MessageLoop does not by itself necessarily mean that a website is performing cryptojacking operations, a significantly large number of MessageLoop events during a short site visit, along with other features, can be an indication of cryptojacking. We report the number of MessageLoop events as a numeric value.

3.3 Prototype Implementation

Automatic recording of the dynamic behavior of client-side JavaScript code, such as resource usage, code provenance, and network communication, is a non-trivial challenge. In order to extract these features from websites, we instrumented Chromium and leveraged the Chromium Debugging Protocol [17] to access nearly all the functionality of DevTools [18]. More specifically, the crawler collected browser request and response traces, JavaScript execution traces, and the source code of both inline and dynamically loaded JavaScript code. This set of information was sufficient to attribute specific JavaScript code to the requested computational

Table 2: 10-fold cross-validation on Support Vector Machines (SVM) and Random Forest (RF), using balanced (BD) and imbalanced (ID) datasets. We selected SVM as the classifier for OUTGUARDbecause of its superior 96.2–97.9% TPR and 0.2–1.1% FPR.

Metric	SVM		Random Forest	
	BD	ID	BD	ID
TPR	96.2%	97.9%	95.6%	97.1%
FPR	0.2%	1.1%	1.3%	2.8%
AUC	97.8%	98.4%	96.9%	98.1%

resources, the functions being executed, any external code referenced by the function, and the execution time spent per function. This trace data includes all features we discussed with respect to the feature selection phase. We deployed the OUTGUARDcrawler on 40 virtual machines. For each website, the crawler stayed on the visited website for 45 seconds and interacted with the page by programmatically scrolling to the bottom of the page to simulate user behavior. We empirically found that 45 seconds was sufficient time for a cryptojacking website to load a cryptojacking library, communicate with a mining pool, and run mining tasks. Our analysis on 1,000 randomly selected websites shows that the run-time overhead of the instrumentation layer is approximately 2%.

The second module of OUTGUARDis a classifier that analyzes the collected data and detects cryptojacking websites by incorporating the features described in Section 3.4. To construct the detection model, we tested multiple classification algorithms and found that an SVM classifier produced the best detection results on the training dataset. To construct the classification model, we used the SVM implementation provided by scikit-learn [47]. We evaluate the classifier in Section 3.4.

3.4 Evaluation

In this section, we examine OUTGUARD's detection accuracy on the ground-truth training dataset and compare it with CPU utilization, an existing cryptojacking detection heuristic. To identify the best machine learning algorithm for automatic classification of cryptojacking libraries, we ran a 10-fold cross-validation on our BD and ID training datasets by using the scikit-learn [47] implementations of Support Vector Machines (SVM) and Random Forests (RF), based on prior work that showed these two classification algorithms work well on balanced and imbalanced datasets [28]. As shown in Table 2, both models perform above 95% TPR and below 3% FPR. We selected SVM as the default classifier for OUTGUARDbecause it slightly outperforms the RF model across both training sets.

The SVM model chosen for OUTGUARDis highly selective, achieving TPR rates of 96.2% and 97.9% for our BD and ID datasets, respectively. Our analysis of the detected cases revealed that OUTGUARDachieved a false positive rate (FP) of 1.1% (with 32 false detections) on an imbalanced dataset. Further manual analysis revealed that all the false positive cases were a set of parked domains that inserted 29 JavaScript scripts, on average, including trackers and advertisements. These websites were falsely labeled as cryptojacking because multiple trackers were using WebSocket connections for communications, and some of these scripts created multiple threads for client-side data processing. Our manual analysis of the false negative cases revealed that OUTGUARDwas unable to detect some variants of CoinImp because they did not contain indicative function calls in their execution traces, and they used fewer than three web workers.

3.4.1 Feature Analysis. We divided the features we selected in Section 3.2 into four categories in order to reason about subsequent analysis, such as feature ranking and classification evasion, from a feature function perspective. The categories are (1) runtime execution-based features such as WebAssembly usage; web worker quantity, and running of parallel tasks for mining activities; (2) a network-based feature which describes the type of communication between the mining module and the mining pool; (3) event load-based features such as MessageLoop and PostMessage Load, and (4) a mining-based feature that looks for hash algorithm fingerprints.

To determine the significance of each incorporated feature, we performed *recursive feature elimination* (RFE) using OUTGUARD's SVM model on the BD dataset. The ranking procedure begins with all seven features. At each subsequent step, a feature with the minimum weight is removed, and the FP and TP rates are re-calculated to measure the contribution of the removed feature. Table 3 displays the ranks of all features, in descending order of importance. For convenience, we derived a score ratio by dividing each feature score with the maximum score. We found that the five most predominant detection features target the dynamic characteristics of cryptojacking, making the system more resilient to common evasions such as code obfuscation. This matches our intuition that such behaviors contribute to successful mining operation – avoiding these techniques would likely impact revenue generation.

3.4.2 Evaluating the Effectiveness of CPU Utilization. We compared OUTGUARD's classification model against a CPU usage model which is a detection heuristic utilized by several reports [14, 38]. We collected the traces of all websites in our BD training dataset that consumed at least 50% of the total CPU capacity. One might expect a 50% CPU usage threshold to be reasonable for detecting cryptojacking given that we observed cryptojacking libraries from all 12 families establish CPU thresholds of at least 50% of the total CPU capacity. The CPU usage heuristic was applied to the BD. Out of the 2,000 non-cryptojacking websites in BD, CPU usage heuristic misclassified 263 as cryptojacking websites (false positive rate = 13.1%). Manual inspection of a handful of these cases revealed non-cryptojacking websites that introduced high CPU overhead due to a large number of requests and responses, constant JavaScript compilation, and frequent dynamic changes in the DOM during script loads. For example, a visit to cnn.com, a high-profile news website, generated an execution trace with 151 unique domain names that were used to retrieve JavaScript resources and other content (e.g., fonts, images, and styles).

Our comparative analysis demonstrates that it is not uncommon for non-cryptojacking websites to exhibit high CPU utilization, even for websites that typically do not require elevated CPU usage in order to function. CPU utilization can be a helpful feature for analysis of cryptojacking at small scales, but it is a less effective

Table 3: Feature importance ranking in OUTGUARD. Features are grouped into categories based on runtime execution (E), mining (M), Event Load (L), and network (N) behavior.

Rank	Feature	Category	Score Ratio	New?
1	No. Web Workers	E	100%	✓
2	Creating Identical Tasks	E	93.7%	✓
3	PostMessage Event Load	L	91.2%	✓
4	Using WebAssembly	E	85.8%	[20, 30]
5	MessageLoop Event Load	L	82.3%	✓
6	Using Hash Functions	M	76.4%	[20]
7	No. WebSocket Connections	N	48.2%	[30]

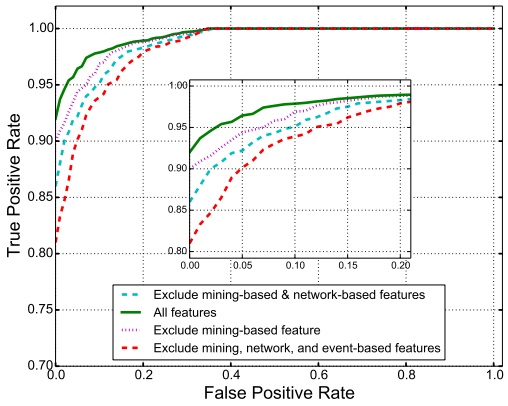

Figure 3: Detection results of OUTGUARDon the labeled dataset when different evasive scenarios were used.

feature for automatic detection at scale. CPU usage is a noisy signal—relying on this heuristic increases the likelihood of false positive cases when hundreds of thousands of websites are being analyzed.

3.5 Adversarial Considerations

Cryptojacking operators, like malware authors, are likely to exercise techniques to evade OUTGUARDby changing their implementation strategies. To address potential evasion scenarios, we evaluated the efficacy of OUTGUARD's SVM model with specific feature categories selectively removed. Figure 3 summaries the results of the experiment. The solid green curve shows the ROC curve of OUTGUARDwhen it incorporates all the features into the detection model. The dotted purple curve represents the ROC curve in the absence of mining-based features. Evasion of this feature from the detection model is a realistic possibility as our approach to detect hashing algorithm usage is somewhat brittle because it is based on collecting in-line binaries that are statically included in cryptojacking libraries or on finding references to a specific hash function in execution traces. Cryptojacking operators can re-generate cryptojacking binaries by adding dead code or by renaming functions, much as evasive malware does, to bypass mining-based feature. In this scenario, the detection performance of OUTGUARDdegrades, but it still achieves a relatively high detection accuracy, with 93% TPR and 1.2% FPR. The mining-based feature is important, but as suggested by the RFE analysis, it is not precariously important, since OUTGUARDstill achieves high detection results without it.

In the next step, we excluded the network-based feature with the assumption that a cryptojacking library may forgo a websocket connection to the mining pool/proxy server and connect through other means instead. For instance, the code may use standard TCP connections or JSONP or other communication techniques. In this case, OUTGUARDwill rely on event loads and runtime execution features to identify cryptojacking activity. The dashed blue ROC curve illustrates OUTGUARD's performance with mining-based and network-based features excluded. The system still achieves 92% TPR and 1.5% FPR. In the final experiment, we removed the event load features under the assumption that adversaries may try to limit the number of threads, and thereby impact the generated events between the web workers and the host process. The red ROC curve illustrates OUTGUARD's performance. In this case, OUTGUARDrelies solely on runtime execution features to identify cryptojacking activity. Use of runtime features (e.g., WebAssembly) in cryptojacking libraries is vital from profitability perspective, as these libraries have to incorporate such browser functionalities to use system resources effectively. Failing to do so would make the in-browser cryptomining not practical or less attractive for generating revenue. So in this final scenario, the classification accuracy has decreased significantly with the loss of networking features, down to 87% with 1.1% FPR.

Note that while an adversary can evade network or event load features, doing so will likely have a significant effect on the efficacy of mining operations, as the mining module requires low-overhead connections in order to communicate with mining pools. Furthermore, as discussed in Section 2, in-browser cryptojacking relies on multiple external parties to operate. Consequently, network-level changes requires compatibility with the rest of the parties involved in the ecosystem (e.g., pools and proxies). Moreover, minimizing of JS event loads to evade the corresponding feature set is not a trivial task, as the entire operation, including task management and task execution, significantly depends on the communication between the host process and the mining threads. Overall, we argue that a tool similar to OUTGUARDcan provide robust detection of cryptojacking websites and potentially increase the operational costs of cryptojacking or reduce the generated revenue of such operations.

4 REAL-WORLD DEPLOYMENT

We demonstrated the feasibility of real-world deployment of OutGuardby performing an analysis of the Alexa Top 1M websites. OutGuarddetected 5,873 instances of cryptojacking. Using this data, we characterized the broader cryptojacking ecosystem by examining the websites on which cryptojacking occurs, and the infrastructure supporting its mining and monetization. We later performed a scan of the Alexa Top 600K websites to supplement the case study.

For the real-world application of OutGuard, we enabled Google Safe Browsing in our instrumented browser to avoid falsely reporting cryptojacking that might be prevented by default browser protection mechanisms. That allowed us to represent realistically the cryptojacking exposure of an end-user browsing the web. We also modified OutGuardto access 3 random links on each Alexa Top webpage to simulate user interaction/navigation on the page. The measurements were conducted over two time ranges: the first scan took place from February 12 to April 15, 2018, on the Alexa Top 1M websites, and the second scan took place from October 20 to October 30, 2018, on the Alexa Top 600K websites. In total, OutGuardreported 6,302 cryptojacking websites across 5,128,117 URLs, as shown in Table 4.

4.1 Obtaining User Consent

Mining cryptocurrency in a browser is not inherently malicious, and in-browser cryptomining has been presented as a justifiable business model alternative to advertising and captcha services. The lack of user consent is the distinguishing factor between legitimate in-browser cryptomining from cryptojacking.

We performed a manual analysis of 100 randomly selected websites that contained the JSECoin library by visiting the websites and checking whether the opt-in system was enabled on them. 22% of the websites were not reachable during the manual check (e.g., `mxqproject.com, masir.us`). We found that in the remaining 78% of websites, the JSECoin cryptojacking library was automatically executed without user consent (e.g., `media9.pk, seriesenlinea.net`). Furthermore, on late 2017, CoinHive introduced a version of cryptomining code called AuthedMine, which requires user permission to turn the browser into a Monero miner. We did not find any instance of this library either in the training or in the large-scale deployment of OutGuard, which mirrors other reports [24]. This experiment suggests that website operators are likely to be reluctant to use libraries with explicit opt-in forms, and that most detected cases do, in fact, constitute cryptojacking.

4.2 Detection Coverage Evaluation

In total, OutGuarddetected 6,302 cryptojacking websites. 3,600 of the detected sites in our two experiments were newly detected websites not observed in the training dataset. Since we do not have ground truth labeled data in the large-scale experiment, we cannot provide precision-recall analysis of the detection results. However, manual analysis shows that OutGuardfalsely reported 14 websites as cryptojacking because they were loading several frames and iframes to embed videos and pop-ups. In addition to creating multiple threads, we observed several WebSocket connections with remote servers to load streaming content in these websites. We consider these cases false positives. The manual analysis of the trace files indicated that the remaining newly detected websites were true positives. We cross-checked the output of OutGuardagainst dedicated security solutions such as MinerBlock [12] and Antiminer [49]. Table 4 summarizes the results of the experiment. Our examination of the filtering lists in these extensions showed that these extensions are not specifically designed to identify cryptojacking websites. Rather, they primarily look for addresses of known mining pool proxies (e.g., `xmrpool.net`). As shown in Table 4, OutGuardhad approximately 40% more coverage than MinerBlock and 41.5% more coverage than AntiMiner.

While disrupting the communication between the cryptojacking libraries and the mining pools is an effective mitigation technique, this approach is less likely to be very successful in identifying different variants of cryptojacking families. For example, the naive versions of cryptojacking families make queries to a specific address that can easily be detected and blocked. However, we observed several cases of Crypto-loot, JSECoin, and CoinImp, which use legitimate cloud deployment services (e.g., `now.sh`) for this purpose. Unsurprisingly, it is impractical to block a domain name or IP address that belongs to cloud services without affecting a large number of other legitimate applications. Consequently, these extensions are limited to domains that do not map to cloud services, and can therefore be evaded fairly easily. We posit that a solution such as OutGuardthat monitors the dynamic behavior of websites and JavaScript libraries is more likely to prevent cryptojacking incidents in practice. With that being said, these dedicated security solutions can benefit from using OutGuardby automatically updating their corresponding filter lists.

5 CHARACTERIZING CRYPTOJACKING WEBSITES

Armed with the results of OutGuard's deployment in the wild, we first seek to answer the question of where cryptojacking occurs. Reports of cryptojacking websites have painted a myriad landscape of sites infected via web vulnerabilities [36], popular websites with cryptojacking advertisements [13], and suspicious e-commerce websites [15]. We will now take a comprehensive look at the 6,302 detected cryptojacking websites, investigating their popularity, categories, and lifetimes.

5.1 Website Popularity and Type

We look up each cryptojacking website's Alexa ranking as a metric for the relative number of visits for each cryptojacking website. 220 websites (3.5%) fall within the top 100K, 602 (9.6%) appear between the top 100K and top 1M, and the remaining 5,480 (87%) are outside of the top 1M. This suggests that cryptojacking occurs primarily in the long tail of lower-popularity websites, as hypothesized in Section 3.1 during the discussion of training data construction.

In order to better address the 5,480 sites outside of the Alexa Top 1M, we also explored passive DNS data as a means to estimate the relative popularity of the cryptojacking domains. Through the lens of one of the largest U.S. ISPs, we collected the contents and daily lookup volume of DNS resource records (RRs) for all successful DNS resolutions. We extracted all passive DNS RRs that match the

Table 4: Number of cryptojacking incidents detected by Outguard. 3,600 (57%) of the detected cryptojacking websites were new detections.

Results	Experiment 1	Experiment 2	Total
Target crawl size	Alexa 1 Million	Alexa 600K	-
URLs visited	3,798,433	1,329,684	5,128,117
Unique cryptojacking domains	5,873	429	6,302
New detections	3,171	429	3,600 (57%)
Overlap with MinerBlock	-	-	3,776 (60%)
Overlap with AntiMiner	-	-	3,684 (58.5%)

seed list of 5,873 cryptojacking domains from the initial Alexa Top 1M real-world deployment and also included RRs with subdomains of the seed list. This dataset consisted of 595.6 million RRs collected from April 2016 to March 2018.

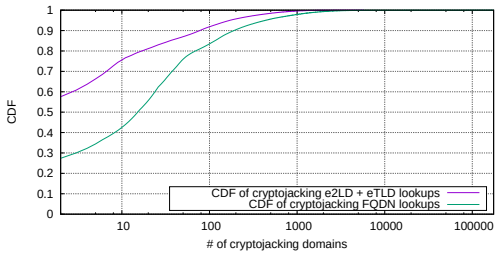

Figure 4: Distribution of passive DNS lookups for cryptojacking FQDNs and e2LD+eTLD. By both metrics, `coinhive.com` accounts for the most lookups, 21.5% and 51.7%, respectively.

We constructed the initial seed domain list for passive DNS data collection from websites that have embeded cryptojacking; however, some domains and their subdomains (e.g. `coinhive.com`) are also used for cryptojacking delivery servers or mining pool/proxy servers that coordinate cryptojacking miners. This muddles the passive DNS dataset with multiple use cases, but grouping passive DNS by effective second-level domain (e2LD) and effective TLD (eTLD), as shown in Table 5, makes it easier to distinct between cryptojacking websites and cryptojacking delivery servers or mining pools.

To characterize the ecosystem of websites that have embeded cryptojacking, we categorized the top 100 e2LD+eTLDs, which accounted for 92% of all passive DNS lookups. Granted, domains dually purposed to be both cryptojacking websites and cryptojacking administration sites have inflated lookup counts, so we examined only the number of domains for each category and did not evaluate the lookup-weighted category composition. In Table 6 we found that the top cryptojacking domains were typically sites with illicited content such as torrent hosting sites, video download/streaming sites, and malicious websites. Assuming that most of these cryptojacking incidents were not the result of website compromise, these results suggest that cryptojacking is used by criminal actors more successfully than lawful actors.

One particularly interesting mechanism for cryptojacking delivery is inclusion through an advertisement on a website through an embedded iframe. Through this form of indirect delivery, cryptojacking can achieve broad distribution, as demonstrated by DoubleClick's reported inclusion of cryptojacking on Youtube [13].

While we did not detect cryptojacking directly included in advertisements, we did find 69 cryptojacking incidents in landing pages that resulted from clicking on an advertisement. We measured these occurrences by cross-referencing the provenance of websites derived from clicked links with a list of ad domains provided by EasyList (`easylist.to`) and Ghostery (`www.ghostery.com`). We observed several instrances of *crypto–loot* and *JSECoin* libraries in our dataset. These instances were mainly delivered via specific ad-networks such as `adnxs.com` (33%),`spotxchange.com` (23.1%), and `stickyads.com` (14.5%). While the number of advertisement-based cryptojacking incidents is relatively small, they represent a fundamentally different type of cryptojacking: *unintentional* cryptojacking incidents that are dynamically loaded during page loads.

5.2 Website Lifetime

We continuously monitored all cryptojacking websites from our first deployment, which observed 5,873 websites by crawling them every ten days for 3 months to approximate their active lifetime. We labeled a cryptojacking website as inactive if we did not observe any sign of cryptojacking operations in a given trace file. We performed 9 crawls over 3 months from May 20 to July 25, 2018 and found that 32% of the cryptojacking websites became inactive in less than 10 days. These websites were mainly hosted on a set of cloud servers and were likely managed by the same group of operators. While we observed a steady decrease in the number of active cryptojacking operations over time, there were 619 (10.5%) websites—mostly video streaming, gaming, and application download sites—that stayed active for the entire measurement period. An additional 1,552 (26.4%) websites hosted cryptojacking libraries for a moderate duration of 3–9 weeks. In total, 68 (3.1%) of the 2,171 active cryptojacking websites were among the Alexa Top 100K websites, which impact thousands of users. In fact, this analysis suggests that current preventions solutions are unable or unwilling to blacklist active cryptojacking websites including the ones with higher ranking for several weeks.

6 OPERATIONAL INSIGHTS

As a second case study, we dig into the operations of cryptojacking. We cluster the identified cryptojacking families, reveal previously unknown CoinHive-like services, extract mining account identifiers to group cryptojacking incidents. This aggregated data begins to

Table 5: Grouping the top passive DNS lookups by FQDN and e2LD+eTLD highlights that the expanded passive DNS dataset includes two types of domains: cryptojacking administration domains (*) and cryptojacking website domains(†).

FQDN	Lookups (%)	e2LD+eTLD	Lookups (%)

reveal the higher-level behavior of the individual and organizational actors that run cryptojacking.

6.1 The Prevalence of Cryptojacking Families

To identify cryptojacking families that each cryptojacking website belongs to, we analyzed the downloaded wasm modules to see whether we can link cryptojacking families together. Although the names of wasm modules might vary for different cryptojacking operators, the content of the wasm module is less likely to differ for a given family. This suggests a relatively stagnant set of wasm binaries, which are typically compiled from C/C++. To assign a label to a given website, we considered two features: (1) the address of the server that hosted the cryptojacking library (similar to Wappalyzer), and (2) the hash of the wasm module used by the library. As displayed in Table 7, we found that these two metrics were sufficient to label 5816 (92.3%) of the detected websites into the 14 known cryptojacking families encountered during training data labeling. We utilized the raw number of discovered cryptojacking domains for each cryptojacking family as a proxy for the family's market share and found a broad spectrum of cryptojacking families with significant deployment. There is no single dominant entity, with the top 3 libraries, CoinHive, JSECoin, and Crypto-loot, accounting for 60.7% of the market. In total, 50% of all cryptojacking sites used non-standard hosts for their cryptojacking libraries, suggesting that the hosting server regexes found in certain blacklists are inherently reactive in their detection capabilities, and even if updated regularly, they can be easily thwarted.

We performed another experiment on the remaining 486 (7.7%) cryptojacking incidents and clustered them based on the address of the remote server that hosted the cryptojacking library. For example, Moonify (e.g., `moonify.min.js`) or Grindcash (`gridcash.js`) are CoinHive-like mining services which were not in our training dataset, but OUTGUARDidentified instances of these libraries in our large-scale experiment. We identified 24 previously unseen coinhive like mining services. Table 8 shows a subset of these mining services as well as the main mining pool.

Table 7: The number of cryptojacking websites and their associated cryptojacking families in the Alexa Top 1 Million websites in 50% of the cases, the cryptojacking library was loaded from a remote server.

Cryptojacking Family	Occurrences	Dynamically Loaded
CoinHive	2,206 (35%)	227 (10.3%)
JSEcoin	1,271 (20.2%)	839 (66%)
Crypto-loot	766 (12.2%)	737 (96.3%)
ProsectPoi	348 (5.5%)	228 (65.5%)
CoinHave	321 (5.1%)	170 (53%)
CoinImp	227 (3.6%)	207 (91%)
CoinLab	202 (3.2%)	202 (100.0%)
DeepMiner	176 (2.8%)	162 (92%)
WebMine	139 (2.2%)	111 (80%)

6.2 Campaign Analysis

Our analysis show that obtaining the *Site Key* is possible by searching in network traces and JS source code. While mining services allow generating several Site Keys per user, in practice, we found several instances of individual Site Keys being used on multiple websites simultaneously. We found 386 cryptojacking websites under 35 clusters based on unique Site Keys ranging in size from 2 domains to 121 domains. Table 9 illustrates a subset of these Site Keys. Our analysis shows that 16 out of 35 detected campaigns were using less expensive or free CoinHive-like mining services.

To get a flavor for the behavior of a cryptojacking campaign, we took a closer look at the largest CoinHive campaign. The 121 clustered domains were all registered under anonymous WHOIS services and pointed to a set of 23 IP addresses found in 15 ASes, which were mostly cloud-hosting services. The IPs were globally distributed in 7 countries including the US, Germany, Australia, Great Britain, China, Canada, and Switzerland. From Censys.io [3] we were able to determine that all IPs pointed to HTTP webservers running either openresty, nginx, or apached. The campaign's usage of multiple anonymous WHOIS services, globally distributed cloud hosting, and large number of fungible, human-meaningless domains (e.g. 5565925.com, 2zo.xyz, jipa.gdn,etc.) hint at evasion techniques characteristic of other web-based malware or PUPs.

7 DISCUSSION AND LIMITATIONS

In this paper, we construct and evaluate Outguard, a resilient system for detecting cryptojacking that finds nearly twice as many cryptojacking websites as existing blacklist solutions. As we demonstrated, a large fraction of websites have short-lived cryptojacking operations. Therefore, regular scans of the Alexa Top 1M or other domain lists using a system similar to Outguardcan automatically update blacklists with the latest cryptojacking domains and remove stale domains.

While the evaluation of Outguardon real-world dataset shows that it works well in practice, it has three potential limitations. First, Outguardis subject to bias due to the degree of completeness of the public blacklists. Like other machine learning approaches, the effectiveness of Outguarddepends on the quantity of the dataset that we used to generate the model. The hash function detection mechanism currently relies on static function name/fingerprints that can be circumvented by an evasive cryptojacking operator. We expect this to have limited impact based on our feature ranking

Table 9: A subset of cryptojacking campaigns and their corresponding mining pools. 16 out of 35 detected cryptojacking campaigns were using less expensive or free CoinHive-like mining services.

analysis. In general, OUTGUARDshould be viewed as a lower bound estimate of the the full cryptojacking ecosystem.

Second, note that OUTGUARDis a supervised learning technique. Cryptojacking operators may be able exploit this fundamental limitation and change their strategies to evade some of the features of the detection model. For example, the operators may find alternatives to using web sockets or web worker services. We plan to explore the practicality and profitability costs of these evasions to cryptojacking operators in future work. While not foolproof, OUTGUARDis likely to detect a large number of evasion scenarios as shown in Section 3.5. We believe that OUTGUARDraises the bar for adversaries to avoid cryptojacking detection and increases the development cost required to carry out these operations.

Finally, as mentioned earlier, cryptojacking occurs in many forms beyond in-browser mining. In this paper, we focused on in-browser cryptojacking as it is very easy for cryptojacking operators to develop and deploy. In contrast to other common attacks, in-browser cryptojacking does not require building specific binaries or creating drive-by download websites, which are more likely to be flagged by modern anti-malware solutions. Other forms of cryptojacking operations, such as cryptojacking browser extensions, desktop software, and mobile apps, are outside the scope of this study.

8 CONCLUSION

We find that in-browser cryptojacking libraries use browser resources in a very similar way. We show that if these traits are accurately modeled, it is possible to automatically identify a large number of in-browser cryptojacking operations. Towards that end, we developed a tool called OUTGUARD, which is able to detect a significant number of cryptojacking websites and potentially disrupt the malicious operations of cryptojacking operators. Consequently, we conclude that defending against cryptojacking operations at scale is possible with minimal human intervention.

ABSTRACT

Neural network models have achieved impressive results in the field of text classification. However, existing approaches often suffer from insufficient training data in a large-scale text classification involving a large number of categories (e.g., several thousands of categories). Several neural network models have utilized multi-task learning to overcome the limited amount of training data. However, these approaches are also limited to small-scale text classification. In this paper, we propose a novel neural network-based multi-task learning framework for large-scale text classification. To this end, we first treat the different scales of text classification (i.e., large and small numbers of categories) as multiple, related tasks. Then, we train the proposed neural network, which learns small- and large-scale text classification tasks simultaneously. In particular, we further enhance this multi-task learning architecture by using a gate mechanism, which controls the flow of features between the small- and large-scale text classification tasks. Experimental results clearly show that our proposed model improves the performance of the large-scale text classification task with the help of the small-scale text classification task. The proposed scheme exhibits significant improvements of as much as 14% and 5% in terms of micro-averaging and macro-averaging F1-score, respectively, over state-of-the-art techniques.

1 INTRODUCTION

Large-scale text classification seeks to classify arbitrary texts into a few semantically relevant classes or categories. There is a wide range of applications of large-scale text classification, including web search personalization [6], contextual advertising [5, 23], topical web search [4], recommender systems [2, 33], etc. The success of these applications is highly dependent on the quality of text classification. Usually, large-scale text classification requires a sufficiently large taxonomy of topical categories to capture various topics in arbitrary texts. In addition, it is necessary to collect a large amount of training data for each category in the taxonomy.

Although neural network models have shown promising results on text classification tasks [17, 21, 42], they perform poorly in large-scale text classification [16], which is often involved in a few or several thousands of categories. This is largely attributed to the fact that the training data for each category is relatively insufficient and distributed unevenly among classification categories.

To handle the large-scale text classification, several works [23, 34] have represented categories in large-scale taxonomy by using an explicit representation model [38] based on bag-of-words or bag-of-phrases. They exhibit a robust performance in the large-scale text classification. One advantage of the explicit representation model used in these studies [23, 34] is that it easily utilizes the taxonomy structure to share training data among categories with "is-a" relationships. However, it may be difficult to apply this method in a neural network that implicitly represents text. In addition, the performance of these approaches is limited to associated knowledge bases.

In the neural network-based text classification, several studies often utilize a multi-task learning framework with other related classification tasks to cope with the limited amount of training data [24–26, 39, 41]. Multi-task learning learns multiple related tasks simultaneously to extract common features and significantly improves the performance of a single task. One characteristic of these multi-task architectures is they share some lower layers to catch common features. Non-shared layers, the remaining layers are split into multiple specific tasks.

In this paper, we propose a multi-task learning framework based on the convolutional neural network (CNN) to handle the large-scale text classification. We apply multi-task learning by treating

Table 1: Statistics of taxonomies

	Original ODP taxonomy	Large-scale taxonomy	Small-scale taxonomy
No. categories	802,379	2,735	13
No. webpages	3,624,444	76,167	1,032,411
Avg. webpages	4.5	27.8	79,416
Min. webpages	1	2	18,021
Max. webpages	1,276	915	171,955

small- and large-scale text classification tasks as two related tasks. The multi-task framework converts the large-scale text classification task to a small-scale text classification task and jointly learns both tasks. This multi-task learning framework with different scales is motivated by our hypothesis that the useful features learned from the small-scale classification task are highly expected to be useful for the large-scale classification task. In particular, the large-scale classification task is further enhanced by task-dependent features from the small-scale classification task through a gate mechanism.

We demonstrate the efficacy of our model on a group of text classification tasks with different scales. Experimental results show that the joint learning of small- and large-scale classification yields significantly improved results in the large-scale text classification task with the help of the small-scale text classification task. In summary, our contributions are three-fold:

- We propose a convolutional neural network (CNN) based multi-task learning framework to handle the large-scale text classification, which shares useful features between small- and large-scale classification.
- We incorporate a gate mechanism into the proposed CNN-based multi-task learning, which helps to selectively utilize useful features of a small-scale classification task in large-scale classification task.
- We demonstrate the efficacy of the proposed methodology through extensive experiments. The performance evaluation clearly shows that our approach significantly outperforms strong baselines in terms of micro- and macro-averaging F1-score.

The remainder of this paper is organized as follows. We briefly describe the knowledge taxonomy and convolutional neural networks for text classification in Section 2. Section 3 describes the multi-task learning framework for large-scale text classification. We present the performance evaluation results and in-depth analysis in Sections 4 and 5, respectively. We discuss related work in Section 6 and conclude the paper in Section 7.

2 PRELIMINARY

2.1 Building Taxonomy

For the large-scale text classification, the first step of our methodology is to build the taxonomy of topics by utilizing the Open Directory Project (ODP) [1]. The ODP is a large-scale and tree-structured web directory with a maximum of 15 levels, where approximately 4 million webpages are classified into 0.8 million categories by volunteer editors. We utilize only subsets of ODP categories rather than entire sets of them to build the large-scale taxonomy, since we observe that there are many useless or too-specific categories. Specifically, we apply three heuristic rules suggested in the work [23] to remove those categories. To construct the small-scale taxonomy, we use only top-level categories from the large-scale taxonomy.

The large-scale taxonomy is well organized to classify arbitrary documents into various topics (e.g., *Top/Sports/Baseball/Major_League/Teams/Los_Angeles_Dodgers/News_and_Media*). However, the training data for each category in large-scale taxonomy is relatively insufficient and distributed unevenly among categories. On the other hand, the small-scale taxonomy represents highly abstracted topics (*Top/Sports*, *Top/Health*, *Top/Computers*, *Top/Business*, etc.), but has sufficient training data (i.e., containing the training data of all descendant categories from the top-level category to the leaf category) whose distribution is relatively balanced. Table 1 shows the statistics of taxonomies.

2.2 Convolutional Neural Network for Text Classification

For the text classification, many studies have utilized neural network models, such as recurrent neural networks [15] and convolutional neural networks [17, 37, 42]. In particular, long short-term memory network (LSTM) [12], which is a type of recurrent neural networks, has achieved impressive results on various natural language processing tasks [13, 28, 36]. However, due to the large number of parameters, LSTM usually requires sufficient training data. Therefore, LSTM may perform poorly in large-scale text classification where training data is insufficient. We adopt convolutional neural networks (CNN) which have been very successful on text classification tasks [17, 37, 42] and need relatively small parameters. The component of CNN-based text classifier usually consists of four layers (i.e., embedding layer, convolution layer, pooling layer and fully connected layer).

2.2.1 Embedding Layer. The embedding layer transforms the document into a vector of embeddings, denoted as $\mathbf{w}_{1:n} \in \mathbb{R}^{nk}$ as the input of the network, where n and k are the number of words and the dimension of word embedding, respectively. A document of length n is represented as follows:

$$\mathbf{w}_{1:n} = \mathbf{w}_1 \oplus \mathbf{w}_2 \oplus \ldots \oplus \mathbf{w}_n \tag{1}$$

where $\oplus$ is the concatenation operator. $\mathbf{w}_i \in \mathbb{R}^k$ is the word vector corresponding to the i-th word in the document. We insert zero-paddings to the both sides of these word representations to handle variable-sized documents and circumvent the border effect [8].

[1] https://curlie.org

2.2.2 Convolution Layer. The function of the convolution layer is to extract features from the input. Using a filter $\mathbf{f} \in \mathbb{R}^{hk}$, a convolution operation on h consecutive word vectors starting from i-th produces a feature. For example, a feature c_i is generated from a window of words $\mathbf{w}_{i:i+h-1}$ as follows:

$$c_i = \mathbf{ReLU}(\mathbf{f} \cdot \mathbf{w}_{i:i+h-1} + \mathbf{b}) \tag{2}$$

where $\mathbf{ReLU}(\cdot)$ is the element-wise rectified linear unit function [31] and $\mathbf{b} \in \mathbb{R}$ is a bias term. Repeating the convolution operations for each possible window of words in the document $\mathbf{w}_{1:h}, \mathbf{w}_{2:h+1}, ..., \mathbf{w}_{n-h+1:n}$, we obtain a feature map $\mathbf{c}$ as follows:

$$\mathbf{c} = [c_1, c_2, ..., c_{n-h+1}] \tag{3}$$

2.2.3 Pooling Layer. The function of the pooling layer is to further abstract the features $\mathbf{c} \in \mathbb{R}^{n-h+1}$ by aggregating the scores for each filter. There are two choices for the pooling operation, i.e., average and max. In this paper, we apply a max-over-time pooling operation [8] over the feature map and take the maximum value $\hat{\mathbf{c}} = max\{\mathbf{c}\}$ as the feature corresponding to this particular filter. The idea behind max pooling is to capture the most important feature, which has the highest value, for each feature map. With pooling layers, we induce a fixed-length vector from feature maps. To obtain multiple features, we use multiple filters with different window sizes. For m different filters, we simply concatenate the results of each filter and obtain the output vector of the pooling layer $\mathbf{z} \in \mathbb{R}^m$ as follows:

$$\mathbf{z} = [\hat{\mathbf{c}}_1, \hat{\mathbf{c}}_2, ..., \hat{\mathbf{c}}_\mathbf{m}] \tag{4}$$

2.2.4 Fully Connected Layer. The features from the pooling layers are passed to a fully connected softmax layer whose output is the probability distribution over labels. We apply dropout [35] as a mean of regularization by randomly setting to zero a proportion of elements of the feature vector. The parameters of the network are trained to minimize the cross-entropy of the predicted and true distributions.

$$L(\hat{y}, y) = -\sum_{i=1}^{N}\sum_{j=1}^{M} y_i^j log(\hat{y}_i^j), \tag{5}$$

where y_i^j and $\hat{y}_i^j$ are the ground-truth label and prediction probabilities, respectively, while N and M denotes the number of training samples and the class number, respectively.

3 METHODOLOGY

3.1 Multi-task Learning Framework for Large-scale Text Classification

Most neural network methods often suffer from large-scale text classification [16], since training documents for each category are insufficient. Motivated by the success of multi-task learning on text classification [25, 26, 39, 41], we propose a new CNN-based multi-task learning framework for the large-scale text classification. We apply multi-task learning by treating small- and large-scale classification tasks as two related tasks. The proposed framework leverages supervised data from the small-scale classification task, which has relatively sufficient training data whose distribution is balanced. Figure 1 shows our proposed model.

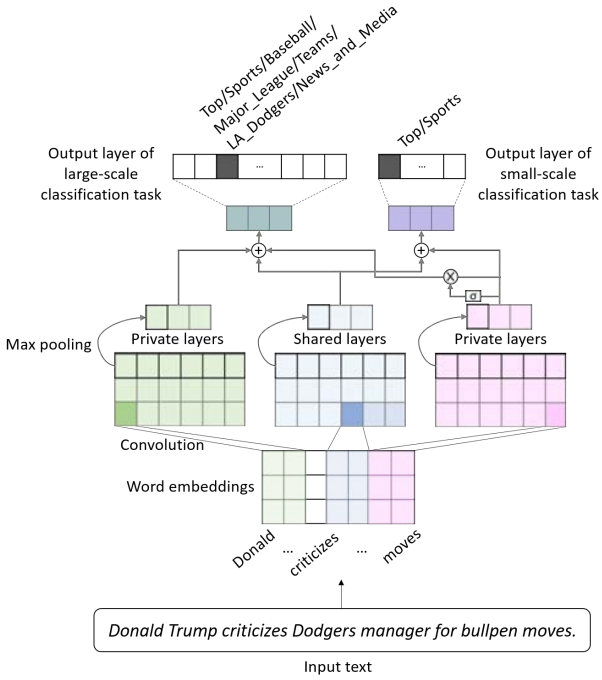

Figure 1: Illustration of architecture for multi-task CNN

In the proposed CNN architecture, the small- and large-scale classification tasks share the same embedding, convolution, and pooling layer. Each task, however, keeps its own private convolution, pooling and fully connected layer as well. Thus, the proposed model maintains two feature spaces: private (i.e., task-dependent) and shared (i.e., task-invariant) feature spaces. We denote the features obtained from the shared pooling layer as $\mathbf{z}_{sh}$. The features obtained from the private pooling layers of the small- and large-scale classification tasks are denoted as $\mathbf{z}_s$ and $\mathbf{z}_l$, respectively.

Although the shared layers help small- and large-scale classification tasks share useful common features, some useful and shareable features may be unidentified. In addition, the private features of small-scale classification task may be higher quality than the private features of large-scale classification task, because the small-scale classification task has relatively sufficient training data. Therefore, we propose a gate mechanism, which enables the large-scale classification task to borrow private features from the small-scale classification task. The gate mechanism controls the flow of features from the small-scale classification task to the large-scale classification task (we shall investigate both symmetric and asymmetric gate mechanisms through experiments in Section 4). When the large-scale classification task l borrows the features from the small-scale classification task s, a gate $\mathbf{g}$ selects the helpful features as follows:

$$\mathbf{g} = \sigma(\mathbf{W}_{s\to l}\mathbf{z}_s + \mathbf{b}_{s\to l}) \tag{6}$$

where σ denotes the non-linear activation of sigmoid, which guarantees the values of $\mathbf{g}$ in the range [0,1]. $\mathbf{W}_{s\to l}$ is the weight which needs to be learned, $\mathbf{b}_{s\to l}$ is a bias term. For the large-scale

Table 2: Statistics of datasets

		Training dataset	Test dataset	Development dataset
ODP (large-scale)	No. categories	2,735	2,735	2,477
	No. webpages	50,246	23,444	2,477
ODP (small-scale)	No. categories	13	13	13
	No. webpages	996,531	23,354	12,526
NYT	No. articles	-	120	-

classification task, the final features $\mathbf{z}'_l$ is calculated by fusing $\mathbf{z}_{sh}$, $\mathbf{z}_s$ and $\mathbf{z}_l$ as follows:

$$\mathbf{z}'_l = \mathbf{z}_l + \mathbf{z}_{sh} + \mathbf{g} \odot \mathbf{z}_s \tag{7}$$

where $\odot$ denotes element-wise multiplication. The features from the small-scale classification task are merged into the large-scale classification task after the selection by gates.

For the small-scale classification task, the final features $\mathbf{z}'_s$ are calculated by adding $\mathbf{z}_{sh}$ and $\mathbf{z}_s$ as follows:

$$\mathbf{z}'_s = \mathbf{z}_s + \mathbf{z}_{sh} \tag{8}$$

In the last layer of each task, vector representations $\mathbf{z}'_l$ and $\mathbf{z}'_s$ are ultimately fed into corresponding fully connected softmax layers to fit the number of classes, which emits the prediction of probability distribution for tasks l and s, respectively.

$$\hat{y_l} = softmax(\mathbf{W}_l \mathbf{z}'_l + \mathbf{b}_l) \tag{9}$$

$$\hat{y_s} = softmax(\mathbf{W}_s \mathbf{z}'_s + \mathbf{b}_s) \tag{10}$$

where $\hat{y_l}$ and $\hat{y_s}$ are predictive results, $\mathbf{W}_l$ and $\mathbf{W}_s$ are the weights of the fully connected layers, while $\mathbf{b}_l$ and $\mathbf{b}_s$ are the bias terms.

Given the predictions of all tasks, a global loss function forces the model to minimize the cross-entropy of the predicted and true distributions for all the tasks as follows:

$$\Phi = \lambda_l L(\hat{y_l}, y_l) + \lambda_s L(\hat{y_s}, y_s) \tag{11}$$

where λ_l and λ_s are the weights for the large- and small-scale classification task, respectively.

3.2 Training

3.2.1 Joint Training. Following [7, 25], the training of the small- and large-scale text classification tasks is achieved in a stochastic manner by looping over the tasks:

(1) Select a random task.
(2) Select a random training example from this task.
(3) Update the parameters for this by taking a gradient step with respect to this example.
(4) Go to 1.

3.2.2 Fine Tuning. For the proposed model, there are shared layers for the small- and large-scale text classification tasks. Thus, after the joint learning phase, we use a fine tuning strategy to further optimize the performance for the large-scale text classification task.

3.2.3 Over-sampling. The distribution of the ODP training dataset for the large-scale text classification task is highly skewed. We apply an over-sampling, which duplicates instances of under-represented classes until the dataset gets balanced, to lessen the impact of the imbalanced dataset [11, 20].

4 EXPERIMENTS

We experiment with a large-scale text classification task to verify the efficacy of the proposed multi-task learning framework.

4.1 Datasets

4.1.1 ODP. We use the RDF dump from the original ODP dataset released on January 8, 2017. As previously mentioned, to obtain a well-organized ODP taxonomy, we apply heuristic rules and build our own large-scale taxonomy with 2,735 categories. Thus, the final training dataset used in our experiments consists of 50,246 webpages. To construct the small-scale classification dataset, we use only 13 top-level categories from the large-scale taxonomy by excluding two categories, *Top/News* and *Top/Adult*, which contain fewer than 100 webpages. Thus, the training dataset used in the small-scale classification task consists of 996,531 webpages.

The ODP test dataset consists of webpages collected from the original ODP. The webpages in each category are randomly divided into a training set, a test set and a development set. In particular, we build two kinds of ODP test datasets. In the large-scale classification task, we collect 23,444 webpages from 2,735 ODP categories in large-scale taxonomy, while collecting 23,354 webpages from 13 ODP categories in the small-scale classification task.

4.1.2 NYT. In addition to the ODP test datasets, we select six categories related to the New York Times as the source for our second test dataset: *art*, *business*, *food*, *health*, *politics*, and *sports*. We randomly collect 20 news articles from each of these categories. Table 2 shows the statistics of datasets.

4.2 Evaluation Metrics

For the ODP datasets, we use the F_1 measure [40] as the classification performance metric, which is the balanced harmonic mean of precision and recall. We use two averaging methods to compute the F_1 measure: macro-averaging (Ma-F_1) and micro-averaging (Mi-F_1). In macro-averaging, F_1 value is measured for each category and then a simple average of all F_1 measures is computed. Conversely, micro-averaging computes the F_1 measure over all test documents. That is, macro-averaging gives equal weight to each category, whereas micro-averaging gives equal weight to each document classification decision. Thus, Mi-F_1 measure depends on the performance of categories with a large number of test documents,

while Ma-F_1 measure is strongly influenced by the performance of categories with fewer test documents.

For the NYT test dataset, we use precision at k. Three participants manually assess the top-k ODP categories obtained by the text classifiers according to three scales: relevant, somewhat relevant, and not relevant. For example, if two categories from the top-5 categories are relevant and one category is somewhat relevant, then the precision at 5 is measured as 0.6.

4.3 Comparisons with State-of-the-art Models

We evaluate the performance of eleven methods. We first adopt the explicit representation-based text classification [23] as the state-of-the-art for large-scale text classification. Other baselines include CNN, LSTM, fastText, and paragraph vector-based text classifiers, which are state-of-the-art methods on multi-class text classification. We also choose four baselines for neural network-based multi-task learning. In our experiments, we compare the following methods:

- *MC* (baseline): This is a text classification method using the explicit representation model based on bag-of-words, called merge centroid, which utilizes enriched training data for each category based on documents classified into their descendants [23].
- *CNN* (baseline): This is the convolutional neural network-based text classification method [17]. We set the hyperparameters to be the same as those of the proposed model.
- *LSTM* (baseline): This is the long short-term memory network-based text classification method [15]. We set the hidden dimension of the LSTM layer to 800, while the other hyperparameters (i.e., mini-batch size, dropout rate, regularization weight, and learning rate) are set to be the same as those of the proposed model.
- *BiLSTM* (baseline): This is the bidirectional long short-term memory network-based text classification method. We set the hidden dimension of each LSTM layer to 800, while the other hyperparameters are set to be the same as those of the proposed model.
- *PV* (baseline): This is the text classification method using paragraph vectors [22]. The learned vector representations have 300 dimensions. We represent categories by averaging the document embeddings for each document in a category.
- $fastText$ (baseline): This is a simple n-gram based neural network model for text classification [14]. The learned vector representations have 300 dimensions.
- *MT-DNN* (baseline): This is a multi-task learning model with DNN, in which a hidden layer is shared [27]. We set the hidden dimension of a shared layer to 300, while the other hyperparameters are set to be the same as those of the proposed model.
- *MT-CNN* (baseline): This is a multi-task learning model with CNN, in which lookup-tables are shared partially while other layers are task-specific [7]. We set the number of filters of private convolution layers to 300, while the other hyperparameters are set to be the same as those of the proposed model.
- *FS-LSTM* (baseline): This is a multi-task learning model with LSTM, in which a single LSTM layer is shared [26]. We set the hidden dimension of a shared LSTM layer to 300, while the other hyperparameters are set to be the same as those of the proposed model.
- *SP-LSTM* (baseline): This is a multi-task learning model with LSTM, in which each task has a private LSTM layer and shares a shared LSTM layer [26]. We set the hidden dimension of both the shared and private LSTM layers to 300, while the other hyperparameters are set to be the same as those of the proposed model.
- *SPG-CNN*: This is our proposed multi-task learning with CNN, in which each task has a private convolution layer and shares a shared convolution layer. In addition, the large-scale classification task borrows private features from the small-scale classification task through a gate mechanism.

Table 3: Detail of word embeddings

	Corpus	Dimension	|V|
Word2Vec [30]	Google News	300	3,000,000
GloVe [32]	Wikipedia	300	400,000
fastText [3]	Wikipedia	300	∞
GWR [18]	Google News	300	∞

4.4 Hyperparameters and Training

We implement the proposed model and competitor methods using TensorFlow frameworks [1] and train models in a single machine equipped with an Intel Core i5 processor, 32GB of RAM, and an NVIDIA GeForce GTX 1080 Ti with 11GB of RAM.

The networks are trained with backpropagation and the gradient-based optimization is performed using the Adam update rule [19]. The embedding layers for all of the neural networks based models (i.e., apart from *MC*) are initialized with the four pre-trained word embeddings, which are summarized in Table 3. We adopt the publicly available Word2Vec [2] and GloVe [3] models, which are popular word embeddings techniques. However, Word2Vec and GloVe models cannot represent out-of-vocabulary (OOV) words, which do not appear in the pre-trained word embedding. Thus, we additionally adopt fastText [3] (this is a word representation technique, being different from $fastText$ [14] that belongs to the baselines) and GWR [18], a character-based word representation approach, to handle OOV words. These approaches allow our framework to effectively expand the vocabulary in the large-scale text classification. The word embeddings are fine-tuned during training to improve performance. The other parameters are initialized by Xavier [9].

The hyperparameters that achieve the best performance on the development set will be chosen for the final evaluation. The final hyperparameters are as follows. For all datasets we use the ReLU, filter windows of 2, 3 and 4 with 300 filters each, mini-batch size of 64, dropout rate of 0.6, regularization weight of 0.001, and learning rate of 0.001. We set both λ_l and λ_s to 0.5.

4.5 Experimental Results

We first compare a few gate mechanisms with the ODP dataset (2,735 categories). In Table 4, *SP-CNN* denotes the multi-task learning model with CNN by the shared and private layers architecture without the gate mechanism. *SPG-CNN*$_{s2l}$ denotes *SP-CNN* using the gate mechanism that controls the flow of features from the small- to the large-scale text classification task, while the gate mechanism in *SPG-CNN*$_{l2s}$ controls the flow of features from the large- to the small-scale classification task. In *SPG-CNN*$_{bi}$, the gate mechanism is used in two-way. We observe that *SPG-CNN*$_{s2l}$ outperforms *SP-CNN*, *SPG-CNN*$_{l2s}$, and *SPG-CNN*$_{bi}$. In particular, our experimental results show that *SPG-CNN*$_{l2s}$ performs worse than *SP-CNN*. These results demonstrate that only the flow of features from the small- to the large-scale classification task is effective at the large-scale text classification. Thus, we adopt *SPG-CNN*$_{s2l}$ in the rest of experiments, which is simply denoted as *SPG-CNN* hereafter.

Table 4: Comparison of symmetric and asymmetric gate mechanisms on the ODP dataset (2,735 categories)

	Mi-F_1	Ma-F_1
SP-CNN	0.550	0.430
SPG-CNN$_{s2l}$	**0.556**	**0.448**
SPG-CNN$_{l2s}$	0.509	0.429
SPG-CNN$_{bi}$	0.551	0.442

We also compare the performance of different pre-trained word embeddings in *SPG-CNN*. Table 5 shows the results of various word embeddings. We observe that *SPG-CNN* performs the best when the embedding layer is initialized with fastText. The publicly available Word2Vec and GloVe embeddings are 4.3% and 2.8% behind fastText embeddings in terms of Ma-F_1, respectively. GWR embeddings perform close to fastText embeddings. One possible reason that fastText and GWR, character-based word embedding approaches, perform better than other popular word-based embeddings is that a large number of OOV words in pre-trained word embeddings lead to the suboptimal performance of large-scale text classification. In the remaining experiments, the embedding layers of all the neural networks based models are initialized with fastText.

Table 5: Comparison of different word embeddings on the ODP dataset (2,735 categories)

	Word embedding	Mi-F_1	Ma-F_1
SPG-CNN	Word2Vec [30]	0.525	0.405
	GloVe [32]	0.530	0.420
	fastText [3]	**0.556**	**0.448**
	GWR [18]	0.550	0.435

Table 6 summarizes the experimental results for large-scale text classification on the ODP test dataset with 2,735 target classes. We observe that *SPG-CNN* outperforms all the baselines. *SPG-CNN* performs better than *MC* over 14% and 5% on average in terms of Mi-F_1 and Ma-F_1, respectively. We also observe that *SPG-CNN* exhibits

Table 6: Large-scale classification performance on the ODP dataset (2,735 categories)

	Mi-F_1	Ma-F_1
MC [23]	0.486	0.426
CNN [17]	0.528	0.413
LSTM [15]	0.430	0.316
BiLSTM	0.495	0.376
PV [22]	0.337	0.234
$fastText$ [14]	0.460	0.371
MT-DNN [27]	0.373	0.260
MT-CNN [7]	0.512	0.435
FS-LSTM [26]	0.545	0.413
SP-LSTM [26]	0.541	0.418
SPG-CNN	**0.556**	**0.448**

Table 7: Small-scale classification performance on the ODP dataset (13 categories)

	Mi-F_1	Ma-F_1
MC [23]	0.757	0.689
CNN [17]	0.804	0.754
LSTM [15]	0.810	0.763
BiLSTM	0.824	0.779
PV [22]	0.738	0.612
$fastText$ [14]	0.727	0.568
MT-DNN [27]	0.793	0.731
MT-CNN [7]	0.800	0.739
FS-LSTM [26]	0.826	0.781
SP-LSTM [26]	**0.828**	**0.782**
SPG-CNN	0.804	0.755

improvement compared to *MT-DNN*, *MT-CNN*, *FS-LSTM* and *SP-LSTM* by over 72%, 3%, 8%, and 7% in terms of Ma-F_1, respectively. Our experimental results show that neural network-based single-task methods except CNN (i.e., *LSTM*, *BiLSTM*, *PV*, and $fastText$) perform worse than *MC* in terms of Mi-F_1 and Ma-F_1. It turns out that *CNN* performs the best among the single-task neural models and better than *MC* over 9% on average in terms of Mi-F_1. However, *CNN* performs worse than *MC* in terms of Ma-F_1. The average performance of multi-task learning models with different scales (i.e., *MT-DNN*, *MT-CNN*, *FS-LSTM*, *SP-LSTM*, and *SPG-CNN*) achieves an improvement of 10.8% and 10.9% over the average performance of single-task learning models in terms of Mi-F_1 and Ma-F_1, respectively. This experimental result indicates that the utilization of multi-task learning with different scales is indeed effective in the large-scale text classification.

Table 7 shows the evaluation results for small-scale text classification on the ODP test dataset with 13 target categories. We observe that *SP-LSTM* outperforms *SPG-CNN*, as well as other baselines. These results are consistent with the results of previous work [24–26], reporting the superior performance of LSTM-based text classifier trained on sufficient training data whose distribution is balanced. We observe that all deep neural network-based

single-task methods (i.e., *CNN*, *LSTM*, and *BiLSTM*) exhibit better performances than *MC* in the small-scale text classification. From Table 6 and 7, we confirm that neural network-based single-task methods are indeed limited to the small-scale text classification. We also observe that the average performance of multi-task learning models with different scales achieves the improvement of 4% and 10% over that of single-task learning models in terms of Mi-F_1 and Ma-F_1, respectively. This result demonstrates that multi-task learning is also helpful to the small-scale text classification task.

Table 8 shows evaluation results on the NYT test dataset. Again, *SPG-CNN* outperforms *CNN*, *LSTM*, *BiLSTM*, *PV*, *fastText*, *MT-DNN*, *MT-CNN*, *FS-LSTM*, and *SP-LSTM* by over 49%, 86%, 52%, 122%, 34%, 18%, 6%, 34%, and 29% in terms of precision at k on average, respectively. We also observe that the average performance of multi-task learning models with different scales achieves the improvement of 41% over that of single-task learning models on average. We also perform the t-test for the classification results, and find that *SPG-CNN* results are statistically significant with $p < 0.01$.

Table 8: Classification performance on the NYT dataset (2,735 categories)

	Precision at k				
	1	2	3	4	5
CNN [17]	0.325	0.279	0.231	0.208	0.193
LSTM [15]	0.225	0.221	0.189	0.177	0.175
BiLSTM	0.308	0.275	0.219	0.204	0.200
PV [22]	0.208	0.171	0.161	0.150	0.138
fastText [14]	0.292	0.296	0.281	0.260	0.242
MT-DNN [27]	0.383	0.317	0.300	0.285	0.272
MT-CNN [7]	0.417	0.354	0.333	0.325	0.310
FS-LSTM [26]	0.292	0.296	0.281	0.260	0.242
SP-LSTM [26]	0.325	0.288	0.281	0.267	0.262
SPG-CNN	**0.458**	**0.392**	**0.353**	**0.325**	**0.312**

We measure the training time for *SPG-CNN* and other neural network-based multi-task learning models. For a fair comparison, we use the same hardware resources, and record the training time for a single epoch on ODP dataset. In Table 9, we observe that *SPG-CNN* has better classification performance while learning faster than *FS-LSTM* and *SP-LSTM* by 1.2x and 1.26x, respectively. Although *MT-DNN* and *MT-CNN* are 1.98x and 1.18x faster than *SPG-CNN*, respectively, *MT-DNN* and *MT-CNN* perform worse than *SPG-CNN*. These results confirm that *SPG-CNN* is effective with a reasonable cost of training time.

5 ANALYSIS

We qualitatively examine the classified categories to analyze why the utilization of the small-scale classification task with the gate mechanism improves the performance of large-scale text classification. We take the NYT articles related to topics "Health care policies" and "Nutritions" as examples. First, from Table 10, we observe that *SPG-CNN* and *SP-CNN* classify the given documents into highly relevant categories. More specifically, from Table 10(a),

Table 9: Training time for a single epoch on ODP dataset compared to multi-task learning models

	Training time	Mi-F_1	Ma-F_1
MT-DNN [27]	**2h 7m**	0.373	0.260
MT-CNN [7]	3h 34m	0.512	0.435
FS-LSTM [26]	5h 3m	0.545	0.413
SP-LSTM [26]	5h 17m	0.541	0.418
SPG-CNN	4h 12m	**0.556**	**0.448**

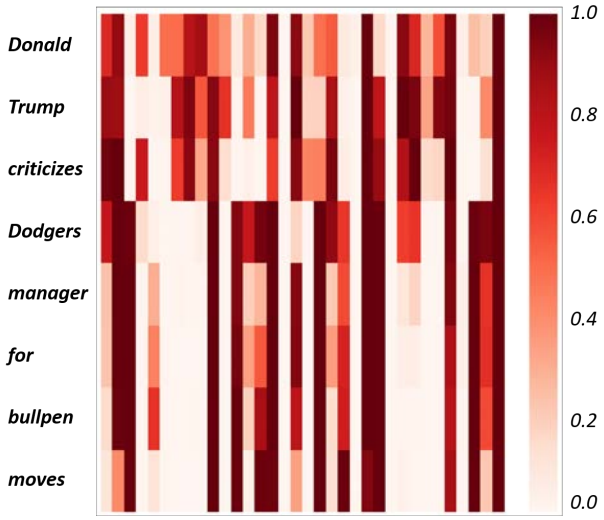

Figure 2: Visualization of the gate's activation. Y-axis represents the input words in chronological order, while X-axis represents gates.

we observe that *SPG-CNN* returns the "Social issues" related categories in top-3. *SP-CNN* also returns two "Social issues" related categories and a category related to "Insurance" that are somewhat associated with the article. In contrast, *CNN* often misclassifies top-level category (e.g., *Top/Computers/...*). In Table 10(b), we also observe that all the categories in top-3 returned by *SPG-CNN* are about "Nutritions" or "Medicine research", while *SP-CNN* returns two relevant categories and an irrelevant category. *CNN* returns a relevant category only on top-1.

We also observe that *SP-CNN* has the same small-scale classification results as *SPG-CNN* (i.e., *Top/Society*, *Top/Kids_and_Teens*, and *Top/Health* in Table 10(a), while *Top/Shopping*, *Top/Health*, and *Top/Science* in Table 10(b)). Nevertheless, it often returns categories that are not related to small-scale classification results (e.g., *Top/Business/Financial_Services/Insurance/Carriers*) and produces worse classification results than *SPG-CNN*. These results clearly demonstrate that the proposed gate mechanism successfully improves the performance of the large-scale text classification by effectively utilizing useful features of the small-scale classification task.

Table 10: Illustrations of Classified Categories

(a) "States' Policies on Health Care Exclude Some of the Poorest. The refusal by about half the states to expand Medicaid will leave millions of poor people ineligible for government-subsidized health insurance under President Obama's health care law even as many others with higher incomes receive federal subsidies to buy insurance." in NYT dataset

Method	Scale	Rank	Category

In addition, we analyze the gate activation in *SPG-CNN*, which controls the flow of features from small-scale classification task to large-scale classification task. We select an article title "Donald Trump criticizes Dodgers manager for bullpen moves", which is related to both "Issues" and "Sports". In Figure 2, we plot the gate activation as each word is processed. The small- and large-scale classification tasks of *SPG-CNN* return *Top/Society* and *Top/Society/Issues/Warfare_and_Conflict* when processing up to the third word (or criticizes), while *Top/Sports* and *Top/Sports/Baseball/Major_League/Teams/ Los_Angeles_Dodgers/News_and_Media* when the last word is processed. Interestingly, from Figure 2, we observe that different neurons are activated as predicted categories get changed. These results show how the large-scale text classification task in *SPG-CNN* selectively utilizes useful features of the small-scale classification task in practice.

6 RELATED WORK

For the large-scale text classification, many works have been proposed to handle data sparsity on knowledge bases. McCallum et al. firstly addressed data sparsity on a hierarchical taxonomy [29]. They adopted a statistical technique, called *shrinkage*, to estimate the parameters of data-sparse child categories with their data-rich

ancestor categories. In [10, 23], they proposed a large-scale text classification method called merge-centroid (MC). MC utilizes enriched training data for each category based on webpages classified into their ancestor and/or descendants in the ODP. In another line of work [34], they enriched semantic information, such as phrases and related terms, in the ODP documents by utilizing another knowledge base, Wikipedia. However, these approaches only consider term weighting approaches, without considering the importance of semantic similarity between words.

Neural network based models have utilized multi-task learning to overcome the problem of insufficient training data. In [7], they proposed multi-task learning with convolutional neural networks for several traditional NLP tasks. This study utilized a shared representation for input words, while we utilize a shared convolution layer and private convolution layers to construct the multi-task learning framework. A related work [25] proposed three different models of sharing information with recurrent neural networks (RNN). In another line of work [26], the authors augmented RNN-based multi-task learning by using adversarial training. Another work [39] proposed a CNN-based architecture for multi-task learning, which shares features via a gated sharing unit instead of a shared layer. However, none of the above research deals with the large-scale text classification. To the best of our knowledge, our current work is one of only a few works that apply multi-task learning to the large-scale text classification by treating different scales of text classification.

7 CONCLUSION

In this paper, we have proposed a novel CNN-based multi-task learning framework to handle the large-scale text classification. Specifically, we have incorporated the gate mechanism into the multi-task CNN to selectively utilize useful features of small-scale classification task. Our approach involves two steps. We first convert the large-scale classification task to a small-scale classification task. Secondly, we train the proposed CNN-based multi-task learning model, which simultaneously learns small- and large-scale classification tasks with the gate mechanism. We have verified the large-scale text classification performance of our methodology using real-world datasets. The experimental results confirm that our scheme significantly outperforms several strong baseline methods. We plan to integrate explicit and implicit representation techniques to further enhance the large-scale text classification.

ABSTRACT

Implicit user feedback is a fundamental dataset for personalized recommendation models. Because of its inherent characteristics of sparse one-class values, it is challenging to uncover meaningful user/item representations. In this paper, we propose *dual neural personalized ranking* (*DualNPR*), which fully exploits both user- and item-side pairwise rankings in a unified manner. The key novelties of the proposed model are three-fold: (1) DualNPR discovers mutual correlation among users and items by utilizing both user- and item-side pairwise rankings, alleviating the data sparsity problem. We stress that, unlike existing models that require extra information, DualNPR naturally augments both user- and item-side pairwise rankings from a user-item interaction matrix. (2) DualNPR is built upon deep matrix factorization to capture the variability of user/item representations. In particular, it chooses raw user/item vectors as an input and learns latent user/item representations effectively. (3) DualNPR employs a dynamic negative sampling method using an exponential function, further improving the accuracy of top-N recommendation. In experimental results over three benchmark datasets, DualNPR outperforms baseline models by 21.9–86.7% in hit rate, 14.5–105.8% in normalized discounted cumulative gain, and 5.1–23.3% in the area under the ROC curve.

1 INTRODUCTION

With the enormous success of e-commerce and online streaming service (*e.g.*, Amazon, eBay, Spotify, and Netflix), recommendation systems have gained much attention in academia and industry [24, 27, 35]. As one of the most successful techniques, collaborative filtering (CF) has been widely used for building a personalized recommendation model. The underlying goal of CF is to predict user preferences on unrated items by discovering hidden correlations among users/items. Concretely, CF is formulated to address either *rating prediction* or *top-N recommendation*. While rating prediction minimizes the error of predicting a user's ratings for her unrated items, top-N recommendation finds a ranked list of the favorite top-N items among unrated items.

Depending on the inherent characteristics of datasets, the recommendation models exploit *explicit* or *implicit* feedback. Earlier approaches have employed user's explicit feedback (*e.g.*, 5-star ratings). While explicit feedback is useful to understand relative user preferences among rated items, it is not always available in practice. By contrast, implicit feedback (*e.g.*, purchase histories, bookmarks, and browsing logs) does not require a user to annotate ratings but is naturally obtained from the user's behavior. Therefore, it is much easier to collect than explicit feedback, and thereby it is more feasible for real-world applications. In this paper, we aim to develop a new recommendation model for the top-N recommendation from implicit feedback.

Existing recommendation models with implicit feedback commonly suffer from the following challenges: (1) Implicit feedback is extremely sparse (*i.e.*, *data sparsity*). In most real datasets, the sparsity is about 96–99%, which leads to it being difficult for the recommendation models to learn meaningful latent user/item representations. (2) The latent user/item representations are usually induced from simple matrix factorization, which assumes that a user-item interaction matrix is represented by a linear combination of latent user vectors/item vectors. When handling highly complicated real-life datasets, this linear model might be too simple to disentangle the latent user/item vectors. (3) While implicit feedback only provides positive data for labling positive experiences, the correct label of unknown feedback is ambiguous (*i.e.*, *data ambiguity*). Unknown feedback is interpreted as a mixture of negative and unlabeled positive feedback. Therefore, it is necessary to distinguish negative feedback from unknown feedback.

To overcome these challenges, various recommendation models have been proposed in the past decade [24]. Among them, Bayesian personalized ranking (BPR) [23] is one of the most representative recommendation models. Unlike previous approaches [10, 14, 19, 25] that directly predict user preferences for unrated items, BPR minimizes a pairwise ranking loss between positive and negative feedback. In this way, it adequately addresses the data sparsity problem. Because BPR still relies on simple matrix factorization, it is incapable of correctly disentangling complex latent user/item representations. In addition, it does not pay much attention to how to distinguish negative feedback from unknowns; BPR regards all unknowns as negative feedback.

Recent studies attempt to inherit the advantage of BPR at handling data sparsity while improving the modeling power. Several

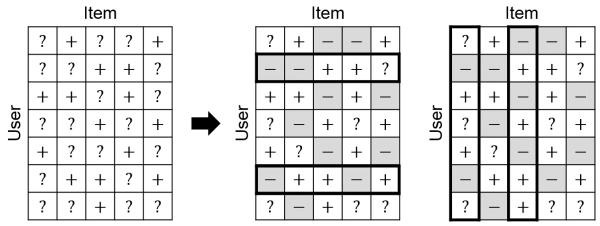

Figure 1: Example of user- and item-side pairwise rankings (center and right) elicited from a user-item interaction matrix (left), where gray color indicates negative feedback from unknown feedback. For instance, user 2 prefers item 3 to item 1 (center) and item 1 is preferred by user 3 over user 6 (right).

studies [4, 6, 18] have integrated the BPR model with deep neural networks (DNNs) to provide more expressiveness (*i.e.*, additional parameters) and flexibility (*i.e.*, non-linear activation functions) in discovering hidden correlations among users/items. Most recently, neural personalized ranking (NPR) [18] has been proposed to generalize the BPR model using DNNs. However, it focused solely on incorporating auxiliary information into DNNs and has not yet studied deep matrix factorization (DMF) to learn latent user/item representations as well as negative sampling to choose negative items from unknown feedback.

In this paper, we propose *dual neural personalized ranking* (*DualNPR*), which incorporates both user- and item-side pairwise rankings into DMF. (Figure 3 depicts the detailed architecture of the proposed model.) The key novelties of the proposed model are summarized as follows.

(1) **Utilizing dual pairwise rankings**: To alleviate the data sparsity problem, we introduce a novel data representation to *fully* exploit both user- and item-side pairwise rankings in a unified manner. Figure 1 illustrates the user- and item-side pairwise rankings collected from a toy user-item interaction matrix. While original BPR only utilizes user-side pairwise ranking, it is intuitive to employ both user- and item-side pairwise rankings to better understand correlations among users/items; it is particularly beneficial to investigate their *mutual* correlations. The use of item-side pairwise ranking is also attractive because we can augment pairwise rankings without requiring any side information. To the best of our knowledge, none of the existing work utilizes both user- and item-side pairwise rankings. Moreover, the idea of adding item-side pairwise ranking can be easily extended to improve the performance of BPR and its variants such as BPR with heterogeneous implicit feedback [20] and NPR [18].

(2) **Incorporating BPR into DNNs**: Motivated by DMF [34], our model adopts multiple hidden layers in DNNs to increase the model capacity, and learns more meaningful latent user/item representations. We believe that our model architecture helps capture the variability of user/item representations and mutual correlations among users/items. In particular, our model takes *raw* user/item vectors as an input. Although this idea is simple, user/item vectors with similar patterns are enforced to be placed as close as possible in latent space. Moreover, we can leverage a denoising method [16, 33, 36] for raw input vectors to make our model more generalized.

(3) **Dynamic negative sampling**: We design *dynamic negative sampling* using an exponential function to distinguish negative items from unknown feedback. Without much computational overhead, our negative sampling dynamically maximizes the gradient gap between positive and negative feedback in training our model. Consequently, it helps improve the quality of our model as well as achieve stable learning convergence.

We conduct extensive experiments with public benchmark datasets including Amazon and MovieLens datasets. Experimental results show that the proposed model significantly outperforms competitive models by 21.9–86.7% in terms of hit rate (HR), 14.5–105.8% in normalized discounted cumulative gain (NDCG), and 5.1–23.3% in the area under the ROC curve (AUC). Furthermore, our model shows an improvement of 35.3–43.3% in HR when both using user- and item-side triplets. In addition, our dynamic negative sampling outperforms existing sampling methods by 3.3–4.6% in HR.

2 PRELIMINARIES

In this section, we first introduce basic notations and formulate the top-N recommendation problem. Then, we review the most relevant existing work such as BPR [23] and NPR [18].

Problem Statement. Let $\mathcal{U}$ be a set of m users, and $\mathcal{I}$ be a set of n items. We are given a user-item interaction matrix $\mathbf{R} \in \{0,1\}^{m \times n}$, where $r_{ui} \in \mathbf{R}$ indicates implicit feedback from user $u \in \mathcal{U}$ for item $i \in \mathcal{I}$. Specifically, $r_{ui} = 1$ means that user feedback is *observed* (or *known*), and it is interpreted as positive feedback. Meanwhile, $r_{ui} = 0$ indicates *unobserved* (or *unknown*) feedback, and it is interpreted as a mixture of negative and unlabeled positive feedback. Given user u, $\mathcal{I}_u^+ = \{i \in \mathcal{I} | r_{ui} = 1\}$ is defined as a set of items with positive feedback by user u. Likewise, $\mathcal{U}_i^+ = \{u \in \mathcal{U} | r_{ui} = 1\}$ is defined as a set of users with positive feedback for item i. For unobserved feedback, $\mathcal{I}_u^- = \mathcal{I} \backslash \mathcal{I}_u^+$ and $\mathcal{U}_i^- = \mathcal{U} \backslash \mathcal{U}_i^+$ denote a set of items and a set of users, respectively.

In this paper, we aim to optimize a top-N recommendation list using pair-wise user/item preferences (*i.e.*, a pair of positive and negative users/items). To formalize this problem, a set D_u of *user-side triplets* is defined as follows:

$$\mathcal{D}_u = \{(u,i,j) | u \in \mathcal{U} \wedge i \in \mathcal{I}_u^+ \wedge j \in \mathcal{I}_u^-\}, \tag{1}$$

where (u,i,j) represents that user u prefers i to j. The pairwise relationship is denoted as $i \succ_u j$. Likewise, a set of *item-side triplets* is defined as follows:

$$\mathcal{D}_i = \{(i,u,v) | i \in \mathcal{I} \wedge u \in \mathcal{U}_i^+ \wedge v \in \mathcal{U}_i^-\}, \tag{2}$$

where (i,u,v) means that item i is preferred by user u over user v, denoted as $u \succ_i v$. Although these relationships are useful resources for learning recommendation models, existing studies [4, 6, 18, 23] built upon BPR solely leverage user-side triplets from a user-item interaction matrix.

Bayesian Personalized Ranking (BPR). Because implicit user feedback only provides sparse one-class values for positive feedback, it is inherently difficult to uncover the relative preferences of users. This is also known as the one-class collaborative filtering (OCCF) problem [10, 19]. To address this problem, BPR [23] is formulated to

minimize a pairwise ranking loss such that all items with positive feedback from a target user are ranked higher than the rest of the items.

Specifically, BPR aims to maximize the posterior probability $p(\Theta|i \succ_u j)$, where Θ is a set of learning parameters. According to Bayes' rule, the posterior probability is defined as:

$$p(\Theta|i \succ_u j) \propto p(i \succ_u j|\Theta)p(\Theta). \tag{3}$$

Then, the likelihood function for Θ is defined as:

$$p(i \succ_u j|\Theta) = \sigma(\hat{r}_{ui} - \hat{r}_{uj}), \tag{4}$$

where $\sigma(\cdot)$ is the sigmoid function and $\hat{r}_{ui}$ and $\hat{r}_{uj}$ are the predicted scores for items i and j by user u, respectively. In BPR, $\hat{r}_{ui}$ is computed by a linear combination of latent user vectors and item vectors [10, 14, 19, 25].

$$\hat{r}_{ui} = \mathbf{p_u}^T \mathbf{q_i}, \tag{5}$$

where $\mathbf{p_u} \in \mathbb{R}^{d \times 1}$ is a latent user vector and $\mathbf{q_i} \in \mathbb{R}^{d \times 1}$ is a latent item vector. (Symbols in bold font are vectors and matrices.) In other words, the model parameters of BPR are $\Theta = \{\mathbf{P}, \mathbf{Q}\}$; $\mathbf{P}$ and $\mathbf{Q}$ indicate a set of latent user vectors and a set of latent item vectors, respectively. The prior density follows a normal distribution $p(\Theta) \sim \mathcal{N}(0, \lambda_\Theta \mathbf{I})$, where λ_Θ is a model-specific parameter and $\mathbf{I}$ is the identity matrix.

Because of the monotone transformation property of the natural log function, maximum likelihood estimation is equivalent to minimizing the negative log likelihood. Finally, based on Bayesian inference, the objective function of BPR aims to minimize a pairwise ranking loss for all user-side triplets.

$$\underset{\Theta}{\operatorname{argmin}} \sum_{(u,i,j) \in \mathcal{D}_u} -\ln\left(\sigma(\hat{r}_{ui} - \hat{r}_{uj})\right) + \Omega(\Theta), \tag{6}$$

where Ω is Frobenius regularization for parameters Θ.

Neural Bayesian Personalized Ranking (NPR). To benefit from the great success of DNNs [15], there are several extensions of BPR using DNNs. First, visual BPR [6] combines the BPR model with auxiliary visual features learned from convolutional neural networks (CNN). Also, Bayesian personalized ranking deep neural network [4] introduces CNN to infer latent user representations from social graphs. In other words, DNNs have been exploited as a feature extractor for additional contexts and inputs for graphs, but have not been extended to BPR to learn complex user/item representations.

Most recently, NPR [18] is proposed to generalize BPR using DNNs. Figure 2 illustrates the architecture of NPR by integrating BPR with DNN. Specifically, it takes a user-side triplet (u, i, j) as an input, where user u and a pair of items i and j are represented by *one-hot* vectors. For instance, in Figure 1, user 2 prefers item 3 to item 1. In this case, $\mathbf{u}$, $\mathbf{i}$, and $\mathbf{j}$ are represented by $[0, 1, 0, 0, 0, 0]$, $[0, 0, 1, 0, 0]$, and $[1, 0, 0, 0, 0]$, respectively. Because there are m users and n items in $\mathbf{R}$, one-hot input vectors $\mathbf{u}$, $\mathbf{i}$, and $\mathbf{j}$ are represented by m-, n-, and n-dimensional vectors, respectively, and the three embedding vectors are computed by:

$$\mathbf{p_u} = \mathbf{W}\mathbf{u}, \quad \mathbf{q_i} = \mathbf{W}'\mathbf{i}, \quad \mathbf{q_j} = \mathbf{W}''\mathbf{j}, \tag{7}$$

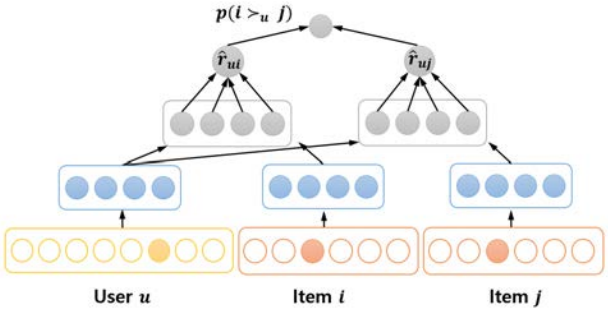

Figure 2: Model architecture of neural personalized ranking (NPR). Note that the user/item is represented by an one-hot vector.

where $\mathbf{W}$, $\mathbf{W}'$, and $\mathbf{W}''$ are embedding matrices for user u and items i and j, respectively. Because they transform the input vector to latent user/items vectors, they can correspond to learning parameters $\mathbf{P}$ and $\mathbf{Q}$ in Eq. (5).

As NPR is vertically symmetric for a user-item pair, we mainly explain the substructure for user u and item i in Figure 2. Unlike existing simple matrix factorization, $\hat{r}_{ui}$ is calculated by a non-linear matrix factorization model.

$$\hat{r}_{ui} = a(\mathbf{w}^\mathbf{T}(\mathbf{p_u} \odot \mathbf{q_i}) + b), \tag{8}$$

where $\odot$ is an element-wise product and $\mathbf{w} \in \mathbb{R}^{d \times 1}$ is a d-dimensional weight vector for latent dimensions and b is the bias term. In addition, $a(\cdot)$ indicates the activation function. In [18], the ReLU function is used as the activation function to capture non-linear user-item interactions. It is reported that Eq. (8) not only identifies the variability of user-item interactions by relaxing an equal weight requirement but also offers non-linear flexibility.

Except for computing $\hat{r}_{ui}$ and $\hat{r}_{uj}$ in Eq. (8), the objective function of NPR is very similar to Eq. (6) in original BPR. It is expected that non-linear matrix factorization used in NPR is effective for representing user/item vectors in a more flexible manner. As a result, NPR can achieve a better quality for top-N recommendation than BPR. However, it does not address the following issues: (1) item-side triplets are also a useful training resource, (2) more generalized DMF can be incorporated to represent latent user/item vectors, and (3) negative sampling is one of the key components for learning BPR and its variants.

3 PROPOSED MODEL

In this section, we propose *dual neural personalized ranking* (*DualNPR*), which complements the drawbacks of BPR and its variants. The key technical contributions of DualNPR can be summarized as follows: (1) We adopt a novel data representation to unify both user- and item-side triplets. Such a unified representation can be utilized for all pairs in user- and item-side rankings. Because the representation can also capture mutual correlations among users/items, we can effectively alleviate the data sparsity problem. (2) Our model is built upon a DMF model with multiple hidden layers to obtain the variability of user/item representations. In this process, raw user/item vectors are taken as an input. The input vectors encode

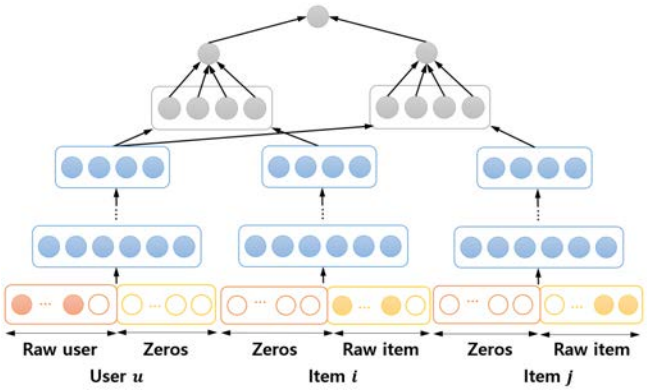

Figure 3: Model architecture of DualNPR. The user/item is represented by a raw vector concatenated with a zero vector.

richer information than conventional one-hot vector representations. Additionally, it is advantageous to apply a denoising scheme for input vectors. (3) We employ a new dynamic negative sampling strategy to choose negative feedback from unknown feedback effectively. This sampling method helps to improve the quality of our model as well as achieve stable learning convergence. In short, DualNPR can be interpreted as a more generalized BPR model built upon DNN without any additional information.

3.1 Model Architecture

Figure 3 illustrates the network architecture of DualNPR, integrating both user- and item-side triplets. Specifically, it consists of the following components: *input layer*, *embedding layer*, *scoring layer*, and *output layer*.

Input Layer: As depicted in Figure 3, while the NPR model uses a one-hot vector representation for user u, our model defines each user u by a *raw* vector across all items. Similarly, each item i is represented by a raw vector across all users. In Figure 1, for instance, when $user_2$ prefers $item_3$ to $item_1$, $\mathbf{u}$, $\mathbf{i}$, and $\mathbf{j}$ are represented by $[0, 0, 1, 1, 0]$, $[0, 1, 0, 1, 0, 1, 1]$, and $[0, 0, 1, 0, 1, 0, 0]$, respectively. While the similarity between two one-hot vectors is difficult to quantify, the similarity between two raw vectors is intuitive and able to be measured by distance metrics. That is, we can expect that the distance between latent vectors should have a similar tendency to the distance between corresponding raw vectors; the similar raw vectors result in similar latent vectors. Moreover, we can apply a denoising scheme for the input layer to increase the robustness of the proposed model as in existing work [16, 33, 36]. Formally, each input vector for a user-side triplet (u, i, j) is represented by:

$$\mathbf{u} = \mathbf{R}_{u*}, \quad \mathbf{i} = \mathbf{R}_{*i}, \quad \mathbf{j} = \mathbf{R}_{*j}, \tag{9}$$

where $\mathbf{R}_{u*} \in \{0,1\}^{n\times 1}$, $\mathbf{R}_{*i} \in \{0,1\}^{m\times 1}$, and $\mathbf{R}_{*j} \in \{0,1\}^{m\times 1}$ are a row vector for user u and column vectors for items i and j in a user-item matrix $\mathbf{R}$, respectively.

We now explain a *dual* data representation to exploit both user and item vectors in a unified manner. To represent user/item vectors, existing recommendation models [7, 8, 18, 34, 36] using DNN usually define user/item representation by different layers with user/item embedding matrices. In contrast to existing models, we adopt a single, unified input vector representation, which is defined by the following $(m + n)$-dimensional concatenated vector.

$$[\mathbf{u}; \mathbf{i}] \in \{0, 1\}^{m+n}. \tag{10}$$

To represent user vector $\mathbf{u}$ with the concatenated vector, the elements for the item vector are set as zeros. Likewise, to represent item vector $\mathbf{i}$, the elements for the user vector are set as zeros. Formally:

$$\mathbf{u} = [\mathbf{R}_{u*}; \mathbf{0}], \quad \mathbf{i} = [\mathbf{0}; \mathbf{R}_{*i}], \quad \mathbf{j} = [\mathbf{0}; \mathbf{R}_{*j}]. \tag{11}$$

This dual representation is capable of sharing one embedding layer instead of using two embedding layers for users/items. We believe that such unified embedding is a key factor to better formulate the personalized ranking problem because it learns mutual correlations across users/items.

Embedding Layer: To learn latent user/item vectors, we use one or multiple hidden layers as used in DMF [34]. For a user-side triplet (u, i, j), the first layer is represented by:

$$l_1 = a(\mathbf{W_1} x + b_1) \ \text{ for } \ x \in \{\mathbf{u}, \mathbf{i}, \mathbf{j}\}, \tag{12}$$

where $\mathbf{W_1} \in \mathbb{R}^{(m+n)\times d}$ is an embedding matrix for users/items, b_1 is the bias term, and $a(\cdot)$ is the activation function. Given (u, i, j), we have three input vectors, $\mathbf{u}$, $\mathbf{i}$ and $\mathbf{j}$. Each is a $(m+n)$-dimensional vector and all three vectors share the same embedding layer. We can also employ multiple intermediate hidden layers.

$$l_i = a(\mathbf{W_i} l_{i-1} + b_i) \ \text{ for } \ i = 2, \ldots, L. \tag{13}$$

Through the multiple hidden layers, (u, i, j) is represented by three low-dimensional vectors in a latent space. We denote the three embedding vectors as $\Phi(\mathbf{u})$, $\Phi(\mathbf{i})$, and $\Phi(\mathbf{j})$.

$$\Phi(\mathbf{u}) = a(\ldots a(\mathbf{W}_2 a(\mathbf{W_1}[\mathbf{R}_{u*}; \mathbf{0}] + b_1) + b_2) \ldots), \tag{14}$$

$$\Phi(\mathbf{i}) = a(\ldots a(\mathbf{W}_2 a(\mathbf{W_1}[\mathbf{0}; \mathbf{R}_{*i}] + b_1) + b_2) \ldots), \tag{15}$$

$$\Phi(\mathbf{j}) = a(\ldots a(\mathbf{W}_2 a(\mathbf{W_1}[\mathbf{0}; \mathbf{R}_{*j}] + b_1) + b_2) \ldots), \tag{16}$$

where $a(\cdot)$ is used as the ReLU function at each layer. From Eq (7) in NPR, $\Phi(\mathbf{u})$, $\Phi(\mathbf{i})$, and $\Phi(\mathbf{j})$ correspond to $\mathbf{p_u}$, $\mathbf{q_i}$, and $\mathbf{q_j}$, respectively, indicating a latent user vector and two latent item vectors.

The key advantage of sharing one embedding layer for both users and items is to being able to leverage an item-side triplet (i, u, v) in a unified manner. That is, one embedding layer through concatenated input vectors can be used for both user- and item-side triplets. As a result, the embedding layer can model mutual information among users/items, which effectively increases the modeling capacity with a smaller number of parameters in comparison with NPR.

Scoring Layer: Similar to traditional latent factor models [10, 14, 19], the scoring layer is used to predict a preference score for user-item interactions. Formally:

$$\hat{r}_{ui} = g\Big(\Phi(\mathbf{u}), \Phi(\mathbf{i})\Big), \tag{17}$$

where $g(\cdot, \cdot)$ is the scoring function for a user-item pair. In general, this function can be represented by a (non-linear) inner product and cosine similarity. In this paper, we investigate the following scoring functions:

- **Inner product**: As the simplest method, this is computed by the inner product between two vectors.

$$\hat{r}_{ui} = \Phi(\mathbf{u})^T \Phi(\mathbf{i}). \tag{18}$$

- **Cosine similarity**: This is computed by the normalized inner product. This function is also used for a deep structured semantic model (DSSM) [11] and a DMF model [34].

$$\hat{r}_{ui} = \frac{\Phi(\mathbf{u})^T \Phi(\mathbf{i})}{||\Phi(\mathbf{u})||\ ||\Phi(\mathbf{i})||}. \tag{19}$$

- **Non-linear inner product**: As in NPR [18], this is computed with a non-linear weighted inner product by appending weights for latent dimensions.

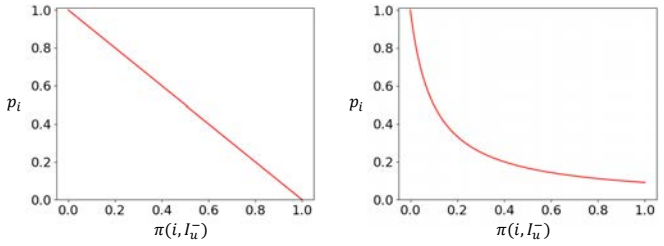
$$\hat{r}_{ui} = a(\mathbf{w}^T (\Phi(\mathbf{u}) \odot \Phi(\mathbf{i})) + b). \tag{20}$$

One might ask whether we should consider more complex scoring functions to improve the modeling power. One of the representative recommendation models using DNNs, neural collaborative filtering [8] successfully employs a complex scoring function using multi-layer perception. Such a deeper network can be useful for capturing non-linear and complex relationships between latent user/item vectors. However, in the current form of our model, we have kept relatively simple scoring functions. This is because we can employ multiple hidden layers for learning latent user/item vectors. Having a complex scoring model may deteriorate the overall quality of the proposed model by incurring the overfitting problem of DNN. Therefore, we skip using complex scoring functions. (In future work, we will study how to optimize the scoring function.)

Output Layer: Given two predicted scores $\hat{r}_{ui}$ and $\hat{r}_{uj}$, we minimize a pairwise ranking loss for Θ. For user- and item-side triplets, the likelihood functions are defined as:

$$p(i >_u j|\Theta) = \sigma(\hat{r}_{ui} - \hat{r}_{uj}) = \sigma\Big(g\big(\Phi(\mathbf{u}), \Phi(\mathbf{i})\big) - g\big(\Phi(\mathbf{u}), \Phi(\mathbf{j})\big)\Big), \tag{21}$$

$$p(u >_i v|\Theta) = \sigma(\hat{r}_{iu} - \hat{r}_{iv}) = \sigma\Big(g\big(\Phi(\mathbf{i}), \Phi(\mathbf{u})\big) - g\big(\Phi(\mathbf{i}), \Phi(\mathbf{v})\big)\Big). \tag{22}$$



Objective Function: Finally, we introduce the objective function to deal with both user- and item-side pairwise rankings. Similar to classical BPR, our objective function aims to minimize the relative loss for pairwise rankings. In clear contrast, our objective function is to minimize both user- and item-side ranking losses.

$$\begin{aligned} \underset{\Theta}{\text{argmin}} \sum_{(u,i,j)\in\mathcal{D}_u} & -\ln\left(\sigma(\hat{r}_{ui} - \hat{r}_{uj})\right) + \\ \lambda \sum_{(i,u,v)\in\mathcal{D}_i} & -\ln\left(\sigma(\hat{r}_{iu} - \hat{r}_{iv})\right) + \Omega(\Theta), \end{aligned} \tag{23}$$

where $\sigma(\hat{r}_{ui} - \hat{r}_{uj})$ and $\sigma(\hat{r}_{iu} - \hat{r}_{iv})$ are computed by Eq. (21) and Eq. (22), respectively, and λ is the weight to control the importance of item-side triplets. $\Omega(\Theta)$ is the Frobenius regularization term for our parameters $\Theta = \{\mathbf{W}_1, \ldots, \mathbf{W}_L, b_1, \ldots, b_L\}$.

3.2 Dynamic Negative Sampling

One of the main components in BPR is to choose negative items from unknown feedback. The original BPR model [23] is based on a *uniform* negative sampling method. Given user u, it first determines the number of negative items. In general, the number of negative items is proportional to the number of positive items for user u, *i.e.*, $|\mathcal{I}_u^-| = \alpha \cdot |\mathcal{I}_u^+|$. (Usually, α is set to 2–5.) Then, negative items are randomly selected from a set of all unrated items with an *equal* probability. Although this is straightforward, the uniform sampling method is ineffective for improving the quality of BPR.

(a) Linear function (b) Exponential function ($\beta = 10$)

Figure 4: Comparison of linear and exponential functions in the Amazon Music dataset.

To address this problem, a dynamic negative sampling strategy [22, 37] is proposed to maximize *gradient gaps* between positive and negative items. Intuitively, it chooses the negative items that have a substantial prediction loss at each learning step. For the current model, the probability of choosing a negative item is based on a ranked list of all unrated items. That is, the importance $\pi(i, \mathcal{I}_u^-)$ of negative item $i \in \mathcal{I}_u^-$ for dynamic negative sampling is derived by the ranking of negative items.

$$\pi(i, \mathcal{I}_u^-) = \frac{rank(i)}{|\mathcal{I}_u^-|}, \tag{24}$$

where $rank(i)$ is the ranking order of item i in $\mathcal{I}_u^-$. If item i has the highest ranking in $\mathcal{I}_u^-$, $\pi(i, \mathcal{I}_u^-)$ is $1/|\mathcal{I}_u^-|$. That is, when an item is ranked highest, $\pi(i, \mathcal{I}_u^-)$ is lowest. Then, the probability p_i of selecting negative item $i \in \mathcal{I}_u^-$ is computed by a *linear* function.

$$p_i \propto 1 - \pi(i, \mathcal{I}_u^-). \tag{25}$$

We modify this dynamic negative sampling by replacing the linear function with an exponential function. Figure 4 illustrates the linear and exponential function for dynamic negative sampling. Under this adaption, the items with high rankings have a much higher probability than negative items. The probability of selecting item i is rewritten as follows:

$$p_i \propto \frac{1}{\exp(\beta\pi(i, \mathcal{I}_u^-))}, \tag{26}$$

where β is the parameter used to control the slope of the exponential function. Note that our dynamic sampling can also be performed for both user- and item-side triplets.

3.3 Training and Prediction

Algorithm 1 describes the detailed procedure for training the proposed model. To update the parameters on each layer, we use back-propagation by adopting mini-batch gradient descent. For each epoch, we shuffle a training dataset for the user- and item-side triplets. In Section 4.1, we will explain the detailed parameter settings for training our model.

Algorithm 1: Training procedure of DualNPR.

Input: A user-item matrix $\mathbf{R}$, the number of epochs T
Parameters: $\Theta = \{\mathbf{W}_1, \ldots, \mathbf{W}_L, b_1, \ldots, b_L\}$

Randomly initialize parameters Θ.
for $t \leftarrow 1$ **to** T **do**
  for $u \in \mathcal{U}$ *and* $i \in \mathcal{I}$ **do**
    Set negative samples from $\mathcal{I}_u^-$ and $\mathcal{U}_i^-$ using Eq. (26).
  end
  Randomly sample a mini-batch $\mathcal{S} \subseteq \mathcal{D}_u$ and $\mathcal{S}' \subseteq \mathcal{D}_i$.
  for $(u, i, j) \in \mathcal{S}$ **do**
    Compute $\sigma(\hat{r}_{ui} - \hat{r}_{uj})$ using Eq. (21).
  end
  for $(i, u, v) \in \mathcal{S}'$ **do**
    Compute $\sigma(\hat{r}_{iu} - \hat{r}_{iv})$ using Eq. (22).
  end
  Update Θ with the pairwise ranking error in Eq. (23).
end

After training our model, we need to calculate the scores for all unrated items $\mathcal{I}_u^-$ for user u for top-N recommendation. Given user u and every unrated item $i \in \mathcal{I}_u^-$, the user's preference score $\hat{r}_{ui}$ is computed from the proposed model. In this case, we simply feed a user-item pair (u, i) to a substructure of the proposed model. Because our model shares the same learning parameters for a triplet input, we can simply obtain predicted score $\hat{r}_{ui}$ by using the substructure. After all unrated items for user u are passed through our model, they are sorted by descending order. Finally, we select the top-N items with the highest scores.

3.4 Extensions to BPR Variants

We explain how to extend our dual representation to several BPR variants. First, BPR with confidence (BPRC) [31] adds a confidence weight for each implicit feedback on top of the BPR framework. The objective function is defined as:

$$\underset{\Theta}{\operatorname{argmin}} \sum_{(u,i,j)\in\mathcal{D}_u} -\ln\left(c_{uij}\sigma(\hat{r}_{ui} - \hat{r}_{uj})\right) + \Omega(\Theta), \tag{27}$$

where c_{uij} is a confidence weight for (u, i, j). Our idea of dual representation can be extended to BPRC; adding the confidence for user- and item-side triplets can effectively achieve such an extension. Let c_{uij} and c_{iuv} denote confidence weights for (u, i, j) and (i, u, v), respectively. The objective of BPRC with our dual representation is formulated as:

$$\begin{aligned}\underset{\Theta}{\operatorname{argmin}} &\sum_{(u,i,j)\in\mathcal{D}_u} -\ln\left(c_{uij}\sigma(\hat{r}_{ui} - \hat{r}_{uj})\right) + \\ &\lambda \sum_{(i,u,v)\in\mathcal{D}_i} -\ln\left(c_{iuv}\sigma(\hat{r}_{iu} - \hat{r}_{iv})\right) + \Omega(\Theta).\end{aligned} \tag{28}$$

We further extend our model to adaptive BPR (ABPR) [20] with different implicit feedback. The objective of ABPR with our dual representation is written as follows:

$$\begin{aligned}\underset{\Theta}{\operatorname{argmin}} &\sum_{(u,i,j)\in\mathcal{D}_u} -\ln\left(c_{uij}\sigma(\hat{r}_{ui} - \hat{r}_{uj})\right) + \\ &\lambda_{\mathcal{E}} \sum_{(u,i,j)\in\mathcal{E}_u} -\ln\left(c'_{uij}\sigma(\hat{r}_{iu} - \hat{r}_{iv})\right) + \Omega(\Theta),\end{aligned} \tag{29}$$

where $\mathcal{E}_u$ is a set of user-side triplets collected from another implicit feedback dataset, and $\lambda_{\mathcal{E}}$ is the regularization term for $\mathcal{E}_u$. Analogous to Eq. (28), we simply add item-side triplets to two different implicit feedback datasets in Eq. (29).

Lastly, we discuss how to apply our dual representation to NPR and contextual NPR. For NPR, we can replace input vectors in Eq. (7) with concatenated user-item vectors. Then, their input vectors are modified by:

$$\mathbf{p_u} = \mathbf{W}[\mathbf{u}; \mathbf{0}], \quad \mathbf{q_i} = \mathbf{W}[0; \mathbf{i}], \quad \mathbf{q_j} = \mathbf{W}[0; \mathbf{j}], \tag{30}$$

where $\mathbf{W}$ indicates one embedding matrix for users/items. (In Section 4, we will evaluate the extension of NPR by adding our dual representation.)

Similarly, our dual representation can also be extended to contextual NPR. Let $\mathbf{e}_u^c$ and $\mathbf{e}_i^c$ denote a user context vector and an item context vector, respectively. For input vectors in Eq. (10), we append two contextual vectors to a user-item input vector, *i.e.*, $[\mathbf{u}; \mathbf{e}_u^c; \mathbf{i}; \mathbf{e}_i^c]$. Then, a user vector is represented by setting an item vector and its context as zeros. Likewise, an item vector is represented by setting a user vector and its context as zeros.

$$\mathbf{u} = [\mathbf{R}_{u*}; \mathbf{e}_u^c; \mathbf{0}; \mathbf{0}], \quad \mathbf{i} = [\mathbf{0}; \mathbf{0}; \mathbf{R}_{*i}; \mathbf{e}_i^c], \quad \mathbf{j} = [\mathbf{0}; \mathbf{0}; \mathbf{R}_{*j}; \mathbf{e}_j^c] \tag{31}$$

Under this dual representation, we can also share one embedding layer for users/items with contexts.

Table 1: Statistics of three real-world datasets.

Statistics	AMusic	MLLatest	ML1M
# of users	2,831	671	6,040
# of items	13,410	9,066	3,706
# of ratings	63,064	100,004	1,000,208
Sparsity (%)	99.83%	98.36%	95.53%

4 EXPERIMENTS

In this section, we conduct extensive experiments to evaluate the effectiveness of the proposed model. First, we describe the data preparation and experimental setup. Then, we compare DualNPR with several competitive models, including the state-of-the-art recommendation model. Also, we carry out an ablation study to investigate the effect of dual representation, that of negative sampling, that of scoring functions, and finally that of DMF.

4.1 Experimental Setup

Datasets. We perform extensive experiments over three real-world datasets including Amazon Music (AMusic), MovieLens Latest (MLLatest) and MovieLens 1M (ML1M). These are all publicly available

on their websites [1] [2]. Because we are interested in the recommendation models with implicit feedback, all of the observed feedback was regarded as positive feedback. For Movielens datasets, we do not apply any preprocessing. For AMusic, because it is notorious for high sparsity, we filtered out unreliable ratings; users who had less than 10 ratings and items that had been rated by less than five users were eliminated as has been done in existing studies [8, 33, 34]. Table 1 reports the detailed statistics of the three datasets.

Competitive Models. We compared DualNPR with two existing models and NPR with our dual representation.

- **BPR** [23]: This model minimizes a pairwise ranking loss for user-side triplets using simple matrix factorization.
- **NPR** [18]: This is a state-of-the-art BPR variant that combines BPR with DNNs.
- **Dual+NPR**: Using our dual representation, we extend NPR to utilize both user- and item-side triplets.

Although several models [7, 8, 34, 36] utilize DNNs for personalized ranking, these models belong to the point-wise approach, which directly predicts the absolute rating. In this paper, we choose BPR and NPR as the competitive models because both of them aim to optimize a pairwise ranking loss. Also, because some BPR variants [4, 6] have exploited DNNs as a feature extractor for additional contexts and inputs for graphs, it is inappropriate to compare our model with them.

Evaluation Protocol. To assess the accuracy of top-N recommendation, we adopted the *leave-one-out evaluation*, which has been widely used in the literature [7, 8, 34]. We held-out one random user-item interaction as the test item for each user, and the rest of user-item interactions were used for the training dataset. Unlike sampling-based evaluation tasks [7, 8, 34] that randomly choose 100 items that have not been rated by the user, we choose all items unrated by each user as the candidate items for top-N recommendation. Because there are many unrated items for each user, our evaluation protocol should handle much more challenging cases for top-N recommendation. We believe that our evaluation protocol is more suitable for conducting a fair evaluation for top-N recommendation because it essentially prevents sampling bias during evaluation.

Evaluation Measures. For each model, we reported the accuracy of top-N recommendation with three metrics: hit rate (HR), normalized discounted cumulative gain (NDCG) and area under the ROC curve (AUC). These metrics have been widely used in existing studies [7, 8, 23, 34, 36]. The size of the ranked list N is chosen as 25, 50, and 100. While the HR@N intuitively measures whether a test item is present in the top-N list, the NDCG@N puts more weight on highly ranked hit items than others in the top-N list. Lastly, AUC accounts for the relative rank of the test item among all unrated items. Essentially, AUC is optimized by BPR [23]. Note that all three measures are averaged across all users. The higher they are, the more accurate a recommendation model is.

Implementation Details. We implemented DualNPR and other existing models using TensorFlow. We randomly initialized model parameters with Xavier initializer [5]. For all baseline models, the number of latent dimensions was set to 128. The optimizer for the baseline models was mini-batch Adagrad. We optimized the models by adjusting the batch size of 32 and the learning rate of 0.005. The regularization term for the learning parameters was set to 0.0001. For DualNPR, the weight λ of user-item triplets was set to 0.6 (AMusic) and 0.8 (MLLatest and ML1M). All experiments were performed on a desktop with 128 GB memory and 2 Intel Xeon Processors (E5-2630 v4, 2.20 GHz, 25M cache), and all models were trained using 4 Nvidia GeForce GTX 1080Ti.

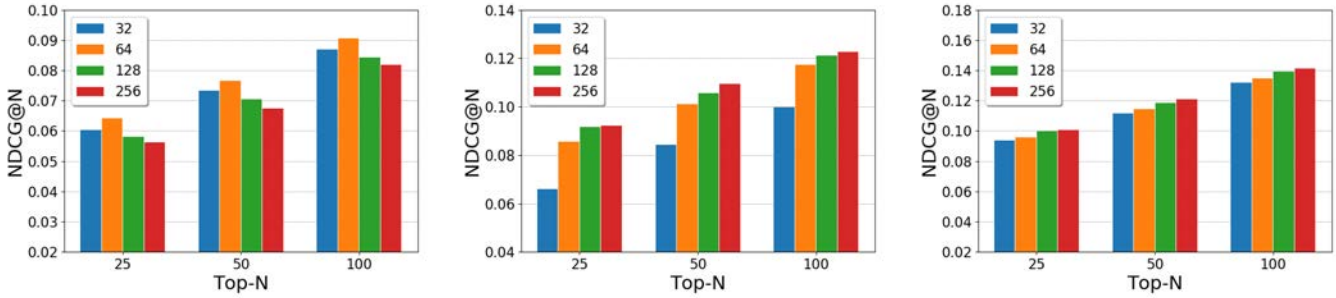
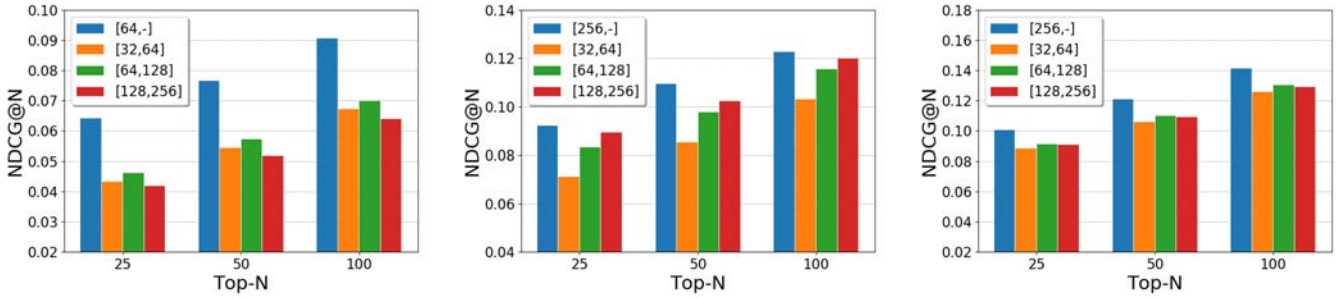
4.2 Experimental Results



DualNPR vs. Other Competitors. We evaluate the effectiveness of DualNPR in comparison with two baseline models and NPR with dual representation. In DualNPR, by default, while we used cosine similarity as the similarity function for AMusic, we used inner product as the similarity function for MLLatest and ML1M. As shown in Table 2, we found three key observations: (1) Regardless of datasets and measures, DualNPR significantly outperformed the baseline models. DualNPR was consistently better than the baseline models by 21.9–86.7% in HR, 14.5–105.8% in NDCG, and 5.1–23.3% in AUC. For the experimental results of NPR and BPR, our results show a similar tendency as reported in [18]. This achievement is meaningful in the sense that we have not added any auxiliary information. (2) Modifying NPR with our dual representation is beneficial at improving the accuracy of the original NPR. In AMusic, we observed that Dual+NPR was improved by 43.1–49.3% in HR and 49.6–57.4% in NDCG, and 12.3% in AUC, respectively. Although Dual+NPR is less accurate than DualNPR, it significantly outperformed NPR. (3) Lastly, DualNPR consistently outperforms Dual+NPR: 36.5–57.6% in HR, 50.2–70.5% in NDCG, and 10.6–39.2% in AUC. This improvement comes from DMF and negative sampling. Therefore, we can conclude that our choice of DMF and negative sampling is effective to improve the accuracy of top-N recommendation.

Effects of Dual Representation. We investigated the effects of dual representation in DualNPR. For three datasets, we consistently used inner product as the similarity function. As shown in Table 3, item-side triplets are useful to improve the accuracy of DualNPR: 7.6–50.8% in HR, 12.6–60.1% in NDCG, and 0.8–7.4% in AUC. Analyzing the results across multiple datasets, we found that the improvement owing to dual representation varies on the characteristics of the datasets. To demonstrate the significance of improvement, we computed the gain, which is the absolute difference of accuracy divided by the baseline accuracy. On average, the gain of MLLatest was 41.1% in HR, 52.9% in NDCG, and 3.1% in AUC. Likewise, the average gain of AMusic was 39.3% in HR, 49.6% in NDCG, and 7.4% in AUC. Meanwhile, the average gain of ML1M was 8.6% in HR, 14.0% in NDCG, and 0.8% in AUC. We observed that the performance gain in AMusic and MLLatest were much higher than those of ML1M. We believe that such a gap in improvement is strongly correlated with the sparsity of the datasets; AMusic (99.83%) and MLLatest (98.86%) are much more sparse than ML1M (95.53%). Therefore, we confirmed that our dual representation is beneficial to address the data sparsity problem.



(a) AMusic (b) MLLatest (c) ML1M

Figure 7: Comparisons of varying the depth of hidden layers in DualNPR.

Effects of Negative Sampling. Our dynamic negative sampling method using an exponential function was compared with two baselines: random sampling and dynamic negative sampling using a linear function. As shown in Table 4, our sampling strategy is most effective at improving the accuracy of DualNPR for all three different datasets: 1.0–5.8% in HR, -2.9–8.6% in NDCG, and 0.3–0.8% in AUC. This means that our dynamic sampling with an exponential function tends to increase the gradient gap between positive and negative items, by selectively choosing negative items with high rankings from unobserved feedback. Compared to random sampling, our sampling method shows significant improvement gains by 7.3–50.6% in HR, 15.7–55.1% in NDCG, and 1.7–3.4% in AUC. Investigating these results over different datasets, we observe that our sampling strategy is more useful in handling the sparser dataset, such as AMusic. This justifies our choice of using the exponential function as it handles the sparse dataset more adequately, and improves the accuracy of top-N recommendation.

Effects of DMF. To determine the main components of DMF, we investigated various scoring functions, the size of embedding dimensions for users/items, and the depth of hidden layers. We observed several interesting results that were opposed to our expectations.

First, Figure 5 depicts the accuracy over three scoring functions in three datasets. It was observed that both inner product (MLLatest and ML1M) and cosine similarity (AMusic) are better than a non-linear inner product. We find that the choice of optimal scoring function varies on the dataset; it significantly influenced the accuracy. Although the non-linear scoring function is less useful in the three datasets, we still believe that the non-linear scoring function can be useful for other large-scale datasets.

Next, Figure 6 illustrates the accuracy at four different sizes of embedding dimension over the three datasets. The higher the dimension, the lower the accuracy. When the dimension was 64 in AMusic and 256 in both MLLatest and ML1M, we achieved the highest accuracy. The optimal size of the embedding dimensions tends to be closely related to the number of model parameters and the amount of positive feedback for each dataset. Note that the size of input representation multiplied by the size of embedding dimension decides the number of parameters in our model. Hence, when the size of input vector for three datasets was 16k, 9.7k, and 9.7k, respectively, the number of model parameters for three datasets and ML1M is 1M, 2.4M, and 2.4M, respectively. The optimal model parameters for AMusic are much less than MLLatest and ML1M because the amount of positive feedback is much less than other datasets. In other words, this is because, given the limited amount of positive feedback, increasing the model parameters can incur an overfitting problem.

Lastly, Figure 7 depicts the accuracy at various depths of hidden layers over the three datasets. The deeper the layer's depth, the lower the accuracy of DualNPR. From these observations, we conjecture that the correlations among users/items may not be highly complex and non-linear. In future work, we will investigate the effects of DMF over various large-scale datasets.

5 RELATED WORK

Much of the attention on personalized recommendation systems [24, 27] has shifted toward collaborative filtering (CF) utilizing implicit user feedback for top-N recommendation. Because an implicit dataset provides extremely sparse one-class feedback, it is inherently challenging to infer hidden user preferences from implicit feedback. This is also known as the one-class collaborative filtering (OCCF) problem [19]. To address this problem, existing work can be categorized into two groups: *point-wise* and *pair-wise* approaches.

5.1 Point-wise Approach

The point-wise approach aims at minimizing the absolute differences between actual values and predicted values. One of the popular models is weighted matrix factorization [10, 19]. Recently, with the success of DNNs [15], several studies [12, 35] have attempted to combine matrix factorization with DNNs such as autoencoders (AE) [16, 26, 28, 33], multi-layer perceptions (MLP) [1, 2, 8, 34, 36], convolutional neural networks (CNN) [7, 13], and recurrent neural networks (RNN) [9, 32]. Specifically, Wang et al. [28] combined a latent factor model with the autoencoders and Kim et al. [13] proposed a hybrid CF model by extracting textual features using CNN. Besides, Cheng et al. [1] and Covington et al. [2] proposed a wide-and-deep model where user features, item features, and additional contents are concatenated as input vectors. For sequential recommendation, Hidasi et al. [9] and Wu et al. [32] proposed RNN-based recommendation models. Although they outperform existing simple matrix factorization models, they have not optimized pairwise ranking for top-N recommendation.

5.2 Pair-wise Approach

The pair-wise approach aims to minimize a pairwise ranking loss in the ranked list. This approach is also used in other research domains such as computer vision [29, 30], information retrieval [11] and, natural language processing [3, 17]. Among recommendation models, the most representative model is BPR [23]. The objective function of BPR is to minimize a pairwise ranking loss of user-side triplets elicited from implicit user feedback. We categorize the variants of BPR into the following two groups.

BPR from Multiple Implicit Feedback. Pan et al. [20] extended BPR to accommodate different implicit feedback by adapting the confidence level of pairwise preferences. Later on, Qiu et al. [21] investigated the correlation between auxiliary feedback and target feedback and proposed an integrated model by considering the characteristics of different implicit feedback. Although this is valid for improving the quality of original BPR, they did not necessarily require heterogeneous implicit feedback. In contrast, our model naturally augments user- and item-side pairwise rankings from a user-item interaction matrix.

Integrating BPR with DNNs: As a hybrid approach, He et al. [6] proposed a visual BPR, where CNN is used for extracting visual features. Ding et al. [4] combined BPR with DNNs by extracting user features from social networks using CNN. Most recently, Niu et al. [18] proposed NPR by combining BPR with DNNs, and extended NPR to incorporate contextual information. These existing studies in this category [4, 6, 18] are most relevant to ours because they also utilize DNNs to improve the modeling power of BPR. However, we believe that our model can be viewed as a more generalized BPR model in the sense that we handle both user- and item-side pairwise rankings without any additional information. In particular, our model can be easily extended to other BPR variants.

6 CONCLUSION

In this paper, we have introduced a new CF model that uses implicit user feedback for top-N recommendation. To achieve this goal, we have proposed DualNPR that fully exploits both user- and item-side pairwise rankings using DNNs. The proposed model addresses the following key challenges faced in the existing work. (1) DualNPR overcomes the data sparsity problem by leveraging both user- and item-side triplets collected from a user-item interaction matrix. (2) DualNPR leverages DMF to learn the variability of latent user/item representations. (3) DualNPR effectively chooses negative feedback from unknowns by introducing dynamic negative sampling with an exponential function.

ABSTRACT

People receive dozens, or hundreds, of notifications per day and each notification poses some risk of accidental information disclosure in the presence of others; onlookers may see notifications on a mobile phone lock screen, on the periphery of a desktop or laptop display. We quantify the prevalence of these accidental disclosures in the context of email notifications, and we study people's relevant preferences and concerns. Our results are compiled from a retrospective survey of 131 respondents, and a contextual-labeling study where 169 participants labeled 1,040 meeting-email pairs. We find that, for 53% of people, at least 1 in 10 email notifications poses an information disclosure risk, and the real or perceived severity of these risks depend both on user characteristics and the meeting or email attributes. We conclude by exploring machine learning for predicting people's comfort levels, and we present implications for the design of future social-context aware notification systems.

1 INTRODUCTION

Estimates suggest that people receive dozens, or hundreds, of notification messages per day [21, 30, 31] delivered to a range of connected devices that people carry with them, or that are ever-present in the environment (e.g., wearables, smartphones, computers or – increasingly – internet of things devices). Extensive prior research has explored the productivity costs of mal-timed notifications [13, 20, 21], but little is known about the privacy cost of such messages; people are frequently in the presence of others when notifications arrive, and, in these contexts, each notification poses some risk of accidental information disclosure. For example, email notifications often reveal the sender and subject fields of messages, and may be visible above the lock screen of a mobile phone (Figure 1a), on the periphery of a co-located desktop or laptop (Figure 1b), on a projection screen during a presentation, or on a smart TV [38]. As Susan Farrell writes in [9]:

> "By making smart devices ubiquitous, we've exposed ourselves to computer-assisted embarrassment. We must expand our usability methods to cover not only the isolated user in one context of use, but also the social user, who interacts with the system in the presence of others."

With the ultimate goal of designing more contextually-relevant notification strategies, we sought to understand the information disclosure risks arising from notifications received when people are in the presence of others. Specifically, we ask the following research questions:

- **RQ1:** How often do email notifications pose an information disclosure risk? I.e., How often are emails received while in the presence of others, and how often do these emails contain sensitive information?
- **RQ2:** To what degree are people's preferences and concerns dependent on user characteristics (personal preferences, job role, etc.) versus being context-dependent with respect to the content disclosed by the notification, and the people in the room?

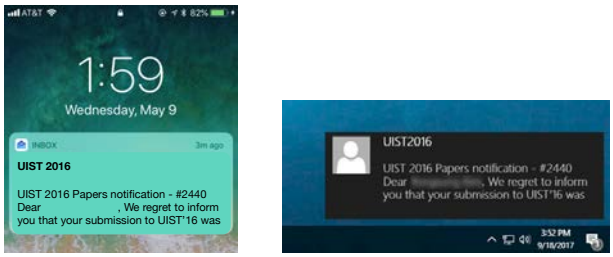

Figure 1: An example of an email notification on an iPhone (a) and on a computer with Windows 10 (b). The notification reveals the email's sender, subject, and first sentence from the message body. When in the presence of others (e.g, during meetings), users may be uncomfortable receiving notifications and revealing these data to onlookers.

- **RQ3:** To what degree can a machine-learned system anticipate information disclosure risks? If such predictions are possible, what features are important?

To answer RQ1 and RQ2, we conducted two studies in an enterprise environment grounded in the scenario of a person receiving an email notification on their notification-capable devices while attending a meeting. We focus on emails because they are the primary source of notifications in this environment: 86% of professionals cite email as their primary means of communication, and an average 112.5 billion business emails were exchanged per day in 2015 [14]. Moreover, email often carries notifications for other services (Twitter, Facebook, Slack), suggesting that our findings are likely to provide insights about notifications generated by other communication platforms.

We first conducted an exploratory retrospective online survey (N=131) that asked respondents about hypothetical situations involving recent emails and meetings. From this survey we gained an understanding about the existence and prevalence of the accidental information disclosure problem, and we learned about people's preferences and concerns.

Findings from the retrospective survey guided design decisions for the second study, which provides a deeper, data-centric investigation into information disclosure risks in enterprise settings. This study employed a custom-built labeling tool, to collect labels and preferences for email-meeting pairs. The labeling tool integrated directly with participants' email and calendaring accounts (N=169), allowing the tool to systematically identify emails that were actually received during meetings, focusing labeling on non-hypothetical cases. For each email-meeting pair, the tool automatically extracts features summarizing high-level characteristics of the user, the content of the email message, and the properties of the meeting; and, it does so in a manner that maintains participant anonymity.

Finally, to answer RQ3, we leverage the data collected by the aforementioned contextual labeling tool to explore feature sets and machine learning algorithms to predict information disclosure risks. Here we explore: (a) features that are associated with users (e.g. job title); (b) features that describe a particular email message (e.g. number of recipients in an email); and (c) features that describe a meeting instance (e.g., whether or not a manager is present).

The rest of the paper is structured as follows: We review related work, then discuss the findings of the exploratory retrospective survey. We describe the second study, which involved the deployment of a custom contextual-labeling tool, then describe relevant findings. Finally, we explore machine learning algorithms to predict people's comfort levels, and we present implications for the design of future social-context aware notification systems.

2 RELATED WORK

2.1 Productivity Cost in Notifications

Previous works in notifications mainly focused on the negative impact of interruptions on productivity, and seek to identify low-cost interruptible moments to send notifications. Studies show that the cognitive load of current tasks [6, 20], task transitions [11, 16], physical activities, user interactions on devices [27], and other context such as time and location [29] can be used to identify interruptible moments for notifications. In office settings, for example, Fogarty et al. [13] show that sensor-based statistical models can be used to predict one's interruptibility by leveraging features such as: phone use, ambient noise (e.g., to detect conversations), mouse and keyboard usage. Likewise, Horvitz et al. [18] use computer activity, calendar information, audio and video signals, and location data to predict users' availability. Notification policies then use inferred levels of availability and interruptibility to determine the ideal time to deliver notifications. Research has also recognized that there can be costs associated with delaying notifications, suggesting that such policies should consider both the cost and benefits of delays [17, 19].

Our work is distinguished in that we study the privacy costs associated with notifications, as opposed to productivity costs. As such, the scenarios we consider are privacy-sensitive, and this has implications for our methodology. We have taken careful steps to respect respondents' privacy in our studies.

2.2 Privacy Cost in Notifications

2.2.1 Privacy Attitudes and Behaviors. A first step in understanding the potential privacy cost of ill-timed notifications is to understand people's general attitudes towards privacy. Pioneering work in this space includes the Westin Privacy Segmentation Index [39], that categorizes people into three groups: privacy fundamentalist, marginally concerned, and pragmatist. *Privacy fundamentalists* are those who are very concerned about their privacy and very reluctant to share any of their information. *Marginally concerned* are generally willing to share details or data about themselves. *Privacy pragmatists* are people who are somewhat concerned about their privacy, but are willing to compromise some privacy for convenience.

Numerous follow-up studies have adopted the Westin Index [1–3, 28], but have reported that people's preferences are nuanced and context sensitive, with complex interactions between the types of disclosures and the audiences who bear witness. For example, Ackerman et al. show that people are generally comfortable sharing their favorite TV shows, favorite snacks, and even email addresses with websites, but are much less comfortable when there is a chance that the website could share the information with others in an identifiable way, or if the information were instead provided by a child under their care [1]. Likewise, Olson et al. show that, even among one's trusted inner circles, one's willingness to disclose information varies greatly depending on the nature of the information being shared [28]. For example, respondents were often uncomfortable disclosing work-related documents with family members, or health information (e.g., pregnancy status) with co-workers.

Adding to this complex motif, past work reports that privacy attitudes are not always correlated with behaviors [2, 26, 33]. For example, participants' behavior in an online shopping scenario was different from their self-reported privacy preferences [33], and one's privacy attitude was a poor predictor of whether participants would share location information [5]. Like privacy attitudes, privacy behaviors are context-specific [5, 12, 40] and multi-dimensional [23].

In this paper we recognize the potential for these complex context-dependent attitudes and behaviors. We designed both of our studies to collect a multitude of signals that characterize how information, audiences, and contexts interact with one another to create situations in which people are uncomfortable (or comfortable) receiving

notifications. Additionally, we designed our second study such that it grounds data collection on specific historical instances rather than asking people about general or hypothetical scenarios and attitudes.

2.2.2 Difference in Disclosures and Privacy Management Strategies. In addition to understanding privacy attitudes in a broader context, it is also important to understand how notifications may differ from the scenarios explored in past work. Here, prior work has mainly examined intentional sharing of information with websites or social networking services (SNSs) [2–4, 36, 37]. Granted that when people disclose their information to these services they don't have perfect knowledge of the consequences, with few exceptions, they have agency in deciding which information to disclose. As such, people often perform an informal risk-benefit analysis before taking actions that may have privacy implications [7, 8, 25, 40]. People also enact preventive strategies, including self-censoring, managing access control groups, and taking actions to conceal their identity [24, 37].

Agency and control is not available in cases where people receive push notifications. Instead, the notification scenario bears resemblance to the scenario in which people are tagged in photos shared to SNSs without consent [24] or posts being unintentionally shared on SNSs as a consequence of *if-this-then-that (IFTTT)* [34]. Here, users can often take corrective actions by either untagging the photos or deleting the contents before more people see the posts. With push notifications, disclosures are instantaneous, and it is unclear what corrective actions can be taken after the event.

A similar situation arises with the accidental disclosure of web browsing history [15]. Through a survey of 155 people, Hawkey et al. found that, as before, comfort level is related to one's level of control (e.g., control over the mouse and keyboard). Moreover, people's comfort is higher when disclosures are to spouses or close friends, and lower with colleagues.

Most closely related to our work is on examining the privacy costs of receiving notifications on a smart TV when watching in a social setting [38]. From a survey of 167 participants, Weber et al. assessed people's comfort levels with different notification variants, and found that the comfort level is higher when the notification reveals less information (e.g. notification indicators). Our work is inspired by these findings, but both extends them to an enterprise setting, and considers a richer set of contexts (e.g. meeting type or location, social structure of people in the room, etc.).

2.2.3 Limitations and Trade-offs in Existing Notification Strategies. Finally, we note that existing mobile devices and applications provide some minimal options for managing notifications. Typically, such options are binary (e.g. turning on and off notifications, enabling notifications for "important" emails in Gmail, and enabling notifications to show previews). Recognizing the privacy risks of notifications, some applications (e.g., WhatsApp) and mobile devices (e.g., iPhone X) have disabled notification previews by default, preferring instead to provide generic indicators (e.g., "You have a new message.") These solutions are context independent, and employ a one-size fits all strategy. Users must accept the trade-offs between minimizing privacy risks (e.g., suppressing notifications) and maintaining timely access to information. In contrast, our work takes into consideration both user contexts and notification contents.

As more and more internet-connected devices and services become capable of displaying information via notifications, there is a need to better understand people's preferences and concerns about notification-induced information disclosures. There is also a need to develop designs and strategies that can adapt both to a notification's content and the user's context.

3 STUDY #1: EXPLORATORY RETROSPECTIVE SURVEY

As a first step, we describe the results of an exploratory retrospective survey which was designed to gain our initial understanding of the following: (1) How often notifications pose an information disclosure risk? (2) How do features of the notifications, meetings and individuals contribute to the perceived risk? As noted in the introduction, the methods employed here allow a broad investigation covering numerous contexts (e.g., personal vs. work, email topics and themes, etc.)

3.1 Procedure

The survey began by collecting basic demographic information including education, job role, age, gender, notification-capable device use, average number of meetings in a day. It then asked participants to answer questions about a notification scenario, which was evolved slowly over several sections of the questionnaire, as follows:

(1) Respondents were first asked to consider their most recent meeting. Respondents answered questions about their role in the meeting, their relation to each of the meeting's attendees, and the meeting's time and location, and the types of notification-capable devices that were present (including Desktop PC, Laptop, Smartphone, Smartwatch, and Smart speaker).
(2) The survey then asked respondents to open their primary work email inbox, consider their 10 most recent emails (excluding the survey invitation), and imagine a scenario in which they received notifications for those emails during the aforementioned meeting. Respondents were asked about the age of the 10^{th} email.[1] Furthermore, we asked participants to imagine that their notification-capable devices' screens were visible to meeting attendees, and answer how many email notifications (out of the ten emails) they would have been uncomfortable sharing with the people in the room. We refer to this scenario as a *hypothetical information disclosure event*, or *HIDE*.
(3) The questions above were then repeated for the 10 most recent emails in respondents' personal email inboxes.
(4) Respondents were then asked to select one email (could be from either work or personal email inbox), if applicable, that they would have been most uncomfortable receiving in the scenario outlined above. We refer to this email as the *HIDE email*. Respondents were asked to rate their comfort level in

[1]We decided to only rely on a respondent's 10 most recent emails to (a) convey a simple and consistent sampling criteria in the retrospective survey, and (b) minimize response and counting errors by allowing respondents to observe their emails within a single window pane (the decision made after pilot testing). To partially compensate for this limitation, we additionally asked the age of 10^{th} email, which enables us to calculate the incoming email rate.

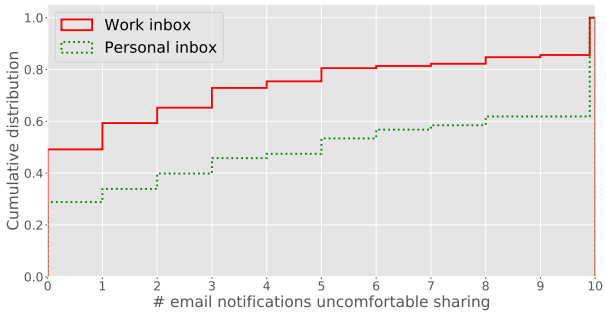

Figure 2: Cumulative distribution of the number of work (red, solid) and personal (green, dotted) emails that people felt uncomfortable sharing with meeting attendees.

sharing the HIDE email notification with the people in the room with a 5-point Likert scale (1: Very uncomfortable, 5: Very comfortable). Respondents then were asked to describe general features of the HIDE email, including their relation to its sender, the number of recipients, the type of the inbox (work or personal), the type of content contained therein, and to explain, in broad terms, why receiving notifications for this email would be uncomfortable.

The survey was deployed by emailing a random sample of 800 employees within a large IT corporation. There were 21 email delivery failures, for various technical reasons, resulting in 779 individuals successfully receiving the invitation. We describe our findings next.

3.2 Results

3.2.1 Participants. We received 118 completed, and 13 partially completed responses (response rate = 17%, completion rate = 90%). Of the 131 total respondents, 85 were male (65%), 44 were female (34%), 2 preferred not to answer. Ages were distributed as follows: 18 – 24 years old (5%), 25 – 34 (24%), 35 – 44 (31%), 45 – 54 (27%), 55 – 64 (8%), ≥ 65 (2%), and 2% declined to answer.

Participants reported occupying a diverse set of job roles including: program managers (28%), software developers (19%), marketing and sales people (8%), and IT support staff (8%). The remaining 49 individuals (37%) worked in diverse roles such as administrative assistants, data scientists, designers, attorneys or other roles in the legal department, and human resources.

3.2.2 Prevalence of the information disclosure risk. One key finding from the retrospective survey, and a partial answer to our first research question, is that the majority of respondents (53.4%) reported that *at least one* of their ten most recent work emails would have resulted in an uncomfortable disclosure of information had the email arrived during their most recent meeting. This increases significantly to 73.3% when respondents were asked to consider the ten most recent emails delivered to their personal accounts (two tailed difference of proportions test, $p << 0.001$, $Z = 3.33$). While these findings demonstrate the potential for risk, we cannot be sure how many emails were actually received during the meetings. We address this limitation in the second study.

3.2.3 Three groups of respondents. Figure 2 extends the above analysis by presenting the cumulative distribution for work emails (red) and for personal emails (green) that participants indicated they would be uncomfortable receiving in their most recent meeting. There are two notable features of these distributions: first, there is a sharp rise at $x = 10$ emails, with 17% of respondents noting they would be uncomfortable receiving *any* work email notification in the presence of others. This increases to 40% for personal emails. We also note that the y-intercepts of the two curves are rather high: 47% of respondents reported that *none* of their ten most recent work emails were sensitive. This decreases to 25% for personal emails. The remaining 36% and 35% of respondents were more selective, and reported that *some* of their work and personal emails were sensitive, respectively.

On the surface, these three groups bear some resemblance to Westin's three categories, but we are sensitive to the fact that privacy concerns are complex and multidimensional. The responses we collected may be dependant on user characteristics (e.g. personal preferences, the nature of their occupation), contents in the notifications, and the contexts and their relationship with the people in the meeting. For example, one participant explained that she was uncomfortable sharing the information in notifications due to the nature of her occupation:

> "*I deal with a lot of privileged and confidential information on an hourly, daily basis. I am not able to share the information and it should not be visible to others.*"–P122

We could also see that some of the respondents are less concerned about the email notifications divulging information because they personally are less concerned about the contents of notifications being shared with the other people in the room. As P81 reported:

> "*...But I'm generally not embarrassed by who and what I am. Plus, humor is a good way to diffuse why I get the spam I get.*"

Also, worth noting that the floor and ceiling effects we observe may simply reflect limitations in our ability to sample the most/least sensitive contexts, contents, and emails for some users. Our second study will use more sophisticated sampling method to address such limitations.

To sum up, the distribution of responses indicate the three distinct groups of respondents. While some of the open-ended survey responses – like the ones above – highlight the relationship between respondents' occupation, personality and demographics [32] on notification preferences, some indicate that their preferences depend on the context. To understand this relationship, in the next sections, we extend the analysis by examining the content disclosed by notifications, and the people attending the meeting.

3.2.4 Notification fields and their content. Given prior research [28], we suspect that one's comfort level depends both on the types of information disclosed by notifications, and on the audience witnessing the disclosure. Addressing the former, participants were asked to select one email that they would have been uncomfortable sharing in their most recent meeting from among their 10 most recent emails. As noted earlier, we refer to this as a hypothetical information disclosure event (HIDE). Participants were asked to answer questions about their HIDE emails, and to describe, in their

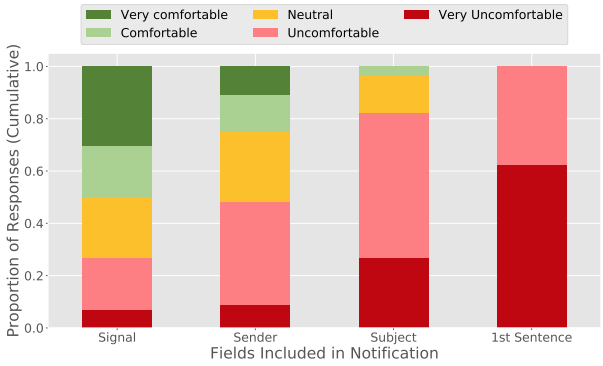

Figure 3: Distribution of respondent comfort levels for sharing different fields included in typical email notifications for HIDE emails.

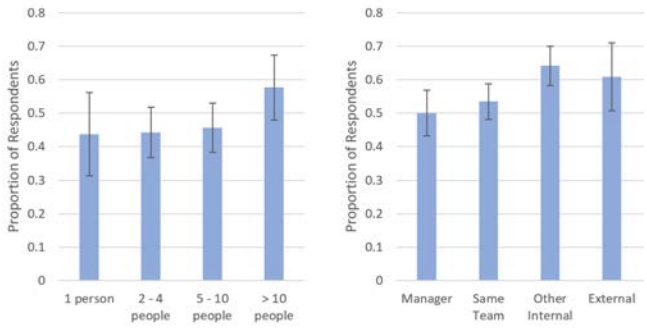

Figure 4: Proportion of respondents reporting HIDE emails, partitioned by the number of people attending the meeting (left) and the attendees' relationships to the respondent (right). Error bars show standard error; none of the pairwise differences are statistically significant at the $\alpha = 0.05$ level.

own words, the types of information that rendered a notification sensitive. We limit the remaining discussion to the 62 respondents (47%) who both identified a HIDE email, and who fully completed this portion of the survey questionnaire. We describe the general properties of HIDE emails, then analyze open-ended responses.

In most cases (72.6%), respondents elected to describe HIDE emails that were delivered to their work email inboxes – perhaps reflecting that the survey invitation was sent during business hours. Among these emails, most were sent by work colleagues (75.6%), including: direct superiors (15.6%), team members (28.9%), and other members of the organization (28.9%). Conversely, external senders included: clients or customers (8.9%), family and friends (4.4%), and one instance each from a doctor, and from an insurance company. Conversely, when HIDE emails were delivered to personal inboxes, most were from friends and family (76.5%), but also included messages from: doctors, banking institutions and external recruiters.

In the majority of cases (62.9%) respondents were the only recipient of their HIDE emails – though there were 11 cases (12.9%) where the email was sent to 5 or more people (via the to: or cc: lines). This finding agrees with the intuition that emails sent only to one person are, perhaps, more likely to contain private information. We explore this hypothesis further in the second part of this paper.

As noted above, we asked participants to describe, in broad terms, what types of information rendered these emails sensitive. Open-ended responses were analyzed, and themes identified, following open coding practices [22]. Among the top themes were: unspecified personal life details (14 instances), unspecified confidential work documents (11 instances), details of ongoing projects (10 instances), health information (7 instances), personal successes or failures (7 instances), financial communications (4 instances), and messages that mention people attending the meeting (3 instances). These themes largely overlap those identified by Olson et al. in [28].

As email notifications can reveal numerous email fields (Figure 1) including: sender, subject, and the first sentence of the email body, we asked participants to rate how comfortable would they have been if the people in the room saw the different email fields. Each field-type reveals a different class of information, and, to varying degrees, poses an information disclosure risk. For example, the sender field reveals that a respondent is in correspondence with a particular individual, while the subject reveals the topic of discussion. Correspondingly, among HIDE emails 25% of survey respondents were comfortable with email notifications that revealed the sender's identity, while only 3.6% were comfortable with notifications that reveal the email subject. This difference is highly statistically significant ($p = 0.001$, $Z = 3.20$). Figure 3 provides further details, breaking down respondent comfort levels by field-type.

3.2.5 Audience features. We explored whether meeting properties (e.g., location, attendance, etc.) impacted the proportion of respondents who identified a HIDE email among their 10 most recent messages. Though this analysis revealed no statistically significant results, we present our findings to: (1) characterize the meetings our respondents attend, (2) offer points of comparison with the results from our second study, and (3) identify weak trends that may yet become features in machine-learned models.

The majority of respondents reported that their most recent meeting occurred in a conference room (52.7%), though people also reported hosting meetings in their own offices (22.9%), attending meetings in someone else's office (15.3%), and attending meetings in other common spaces such as a lounge or atrium (8.4%). Among respondents whose meetings occurred in conference rooms, 50.7% were able to identify an email they would have been uncomfortable receiving in that context. Likewise, among respondents meeting in offices, 46.6% were able to identify such an email. These differences are not statistically significant ($p = 0.61$, $Z = 0.509$).

When asked how many people attended the respondent's most recent meeting, the mode response was "5 – 10 other people" (35.1%). Other response categories included: "2-4 other people" (32.8%), "10 or more people" (14.5%), and "1:1 meetings" (12.2%). Again, we examine the proportion of respondents who were able to identify an email they would have been uncomfortable receiving in each of these contexts. This proportion monotonically increases with the size of the meeting (Figure 4, left), but the pairwise differences are not significant.

Finally, we report that meetings were attended by team members (65.6%), direct superiors (41.2%), other members of the respondent's organization (51.1%), as well as people external to the organization (17.6%). In each case, we examine the proportion of respondents who were able to identify an email they would have been uncomfortable

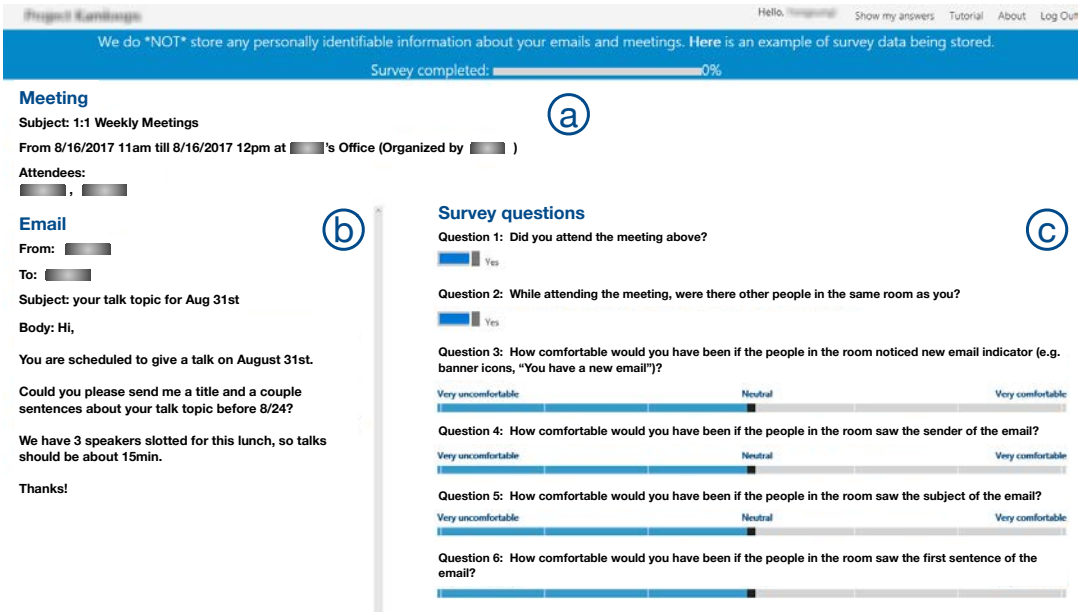

Figure 5: Interface for survey questions about email-meeting pairs. (a) Meeting pane that shows a randomly chosen meeting, time and location of the meeting, attendees, and subject of the meeting; (b) Email pane that shows a randomly chosen email that was received during the meeting, the sender, recipients, subject, and body of the email; (c) survey questions about their comfort level in sharing different fields of the email, type of the email, preferences for different devices and disclosure level.

receiving in the meeting. Figure 4 (right) shows that the proportion increases as the meeting's attendee list grows beyond one's own team. Though this agrees with intuition, the differences are not statistically significant. We revisit this observation later (§4).

In summary, results from the exploratory retrospective survey provide a key set of initial insights about the prevalence of the information disclosure risks posed by notifications, and about how email topics and fields may contribute to this risk. Moreover, we found that respondents could be clustered into three distinct groups based on the proportion of emails they received that would result in uncomfortable notifications.

While the survey was designed to ground responses in respondents' actual emails and meetings, it is limited in two important ways. First, to convey a simple and consistent sampling criteria and to minimize response or counting errors, the survey asked respondents to comment only on a single meeting, and on their single most-sensitive email. Second, it asked respondents to consider *hypothetical* situations in which they receive the most-sensitive email during the most recent meeting. Together, these survey design choices limit our ability to measure actual incidence rates, and to model the overall distribution of risk. To address these limitations, we developed and deployed a custom-built contextual labeling tool, which we describe in the next section.

4 STUDY #2: CONTEXTUAL LABELING STUDY

Based on the insights we gained from the exploratory retrospective study, we developed and deployed a tool (Figure 5) to extract various features and collect labelled data for learning a context-dependent predictive model of disclosure risk. The tool allows participants to: view emails that they received during meetings, view the details of those meetings, and rate their comfort-levels in receiving the corresponding email notification in that context. We described the procedure, apparatus, and results below.

4.1 Procedure and Apparatus

The contextual-labeling study was deployed within the same large IT company as the initial retrospective survey. Participants shared a common computing environment. In particular, they stored their emails and calendars in a common email and calendar web service. This homogeneous environment greatly simplified the administration of the study, and the implementation of the tool.

4.1.1 Procedure. Participants were recruited by emailing a random sample of 4000 employees, distinct from the 800 who were contacted for the retrospective survey. The invitation email described the study's purpose and procedure, and provided sufficient information to validate the authenticity of the invitation (e.g., links to internal systems and pages documenting the experiment, and the results of both an internal review process, and IRB review). Crucially, the invitation also included a link to the web application that hosted the labeling tool.

Upon navigating to the web application, participants were first shown the purpose of the study (i.e. characterizing people's preferences about information disclosed by desktop and mobile notifications that arrive when the intended recipient is in the presence of others). Then, participants were asked to authenticate to the tool using their corporate credentials, and to grant the tool time-limited access to their corporate email and calendaring accounts. Once

participants were authenticated, they were presented with a brief tutorial of the labeling tool, and its three regions:

- The top region (Figure 5a) displayed a recent meeting, randomly selected from a day. Visible fields included: meeting subject, time, location, organizer, and a list of attendees.
- The left region (Figure 5b) displayed a randomly selected email that arrived during the meeting. Visible fields included: the sender, recipient list (the 'to:' and 'cc:' lines), subject, and email body.
- The right region (Figure 5c) contained a short survey, where participants could answer questions about the email-meeting pair. Questions asked about participants' comfort levels in having notifications disclose various fields of the email to the people attending the meeting with a 7-point Likert Scale (1: Very uncomfortable, 7: Very comfortable).[2]

To collect data across a wide range of email-meeting pairs, the tool samples one email-meeting pair per day, moving backward in history one day at a time until 10 pairs are labeled. In each day, a meeting was randomly selected and then an email that was received during the meeting was randomly selected as well. If participants indicated that they did not attend a scheduled meeting, or that the meeting was conducted via teleconference, the tool selected another email-meeting pair for labeling.

Upon inputting labels for 10 email-meeting pairs, participants were presented with a debriefing page, and an optional invitation to take part in a raffle for one of three $50 Amazon.com gift cards. This sweepstakes was conducted in appreciation for their participation.

In addition to collecting user-provided labels and preferences, the labeling tool collected high-level features of the emails and meetings (Table 1). Importantly, the study was conducted completely anonymously: users were assigned random session ID, the participation sweepstakes was conducted on a separate unconnected system, and the features were chosen to be non-personally identifiable. We provide more details about these features in the next section.

4.2 Feature Extraction

Table 1 presents a list of features automatically collected by the labeling tool. Features are broadly categorized into three groups. User features are those that are associated with the participant, but not with a particular email-meeting pair. For example, this class includes the average number of emails a person received during meetings in the past 7 days, their depth in the organization chart, and their job title. To preserve anonymity, we used k-anonymization ($k = 50$) at the organizational level for full job titles, and separately, for job-title bigrams. Email features are those that describe a particular email message. Examples of these features include the number of recipients, Linguistic Inquiry and Word Count (LIWC, [35]) feature vectors, mentions of people, locations, and organizations, and whether the email is machine-generated. For LIWC categories, we tokenized the body, categorized each token into the pre-defined psychological and linguistic categories in LIWC, then computed the percentage of tokens in each category relative to the email body as a whole. We used the Stanford named entity recognizer [10] to detect mentions of people, places and organizations. To check whether or not an email is autogenerated, we used a simple heuristic to check whether or not an email contains 'Unsubscribe.' Meeting features describe the meeting instance, and include details such as the number of attendees, and whether a person's manager is in attendance. Organizational relationships were computed by cross referencing the attendee information from the calendar and the company's organizational chart as follows: for each attendee, we checked whether or not the attendee was the person's manager, direct report, above or below the org chart. Finally, we include one hybrid feature which counts the number of meeting attendees mentioned in the email.

[2]Since our exploratory survey results exhibited ceiling and floor effects, we extended the scale to 7 points to allow for more nuanced responses.

	Feature	Description
User	jobTitle	k-anonymized job title
	orgDepth	depth in the organizational chart
	numEmails	number of emails received in the past week
	numMeetings	number of meetings scheduled in the past week
	avgEmlPerMtg	average number of emails received in meetings
	numMtgWithEml	number of meetings interrupted by emails
Email	numRecipients	number of recipients in the email
	numDistList	number of distribution lists as the recipient
	numThreads	number of threads in the email
	isAutogenerated	is autogenerated email
	numPplMentioned	number of attendees mentioned in the email
	numAttachment	number of attachments
	attachment[type]	type of attachment in the email
	isSenderInternal	is the sender internal to the organization
	numSubjectWords	number of words in the email subject
	numBodyWords	number of words in the email body
	entity[type]	mentions of people, locations and organizations
	LIWC[cat]	feature vector over email body
Meeting	location	meeting location
	numAttendees	number of people attending the meeting
	isManagerPresent	is the person's manager present
	numDirectReports	number of direct reports present
	numOrgAbove	number of attendees above in the org chart
	numOrgBelow	number of attendees below in the org chart
	numExternal	number of attendees external to organization
	numSubjectWords	number of words in the meeting subject
	numBodyWords	number of words in the meeting body
	LIWC[cat]	feature vector over meeting body

Table 1: A list of user, email and meeting features that the labeling tool automatically computed for each email-meeting pair labeled by participants.

4.3 Results

We sought to replicate the analyses we conducted in the exploratory retrospective survey, when possible. As we will show, the consistency of their results helps bolster our confidence in their validity and reliability. Now, we discuss our main findings of this study.

4.3.1 Participants. In total, we received 1,040 meeting-email pairs labeled by 169 participants. Similar to the retrospective survey, job roles were diverse. The largest two categories included software developers (21.3%) and program managers (13.6%). An additional 52 individuals (30.8%) occupied various roles including: marketing managers, attorneys, sales specialists, business planners, etc. Finally, the job roles of 58 participants (34.3%) were filtered by k-anonymization.

	10 Uncomfort	Mixed	10 Comfort
Labeling Study	23%	36%	41%
Study1 (work)	17%	36%	47%
Study1 (personal)	40%	35%	25%

Table 2: Distribution of three groups of respondents in both the retrospective and contextual-labeling study. "10 Uncomfort" indicates respondents who labelled all 10 emails as uncomfortable, "10 Comfort" indicates all 10 emails as comfortable, and "Mixed" indicates a mixture of both comfortable and uncomfortable emails.

In addition to collecting job demographics, the labeling tool collected general measurements of the participants' calendars and email inboxes. For performance reasons, these coarse measurements are constrained to examining users' 300 most recent emails, together with the last 7 days of their calendar. 75.15% of participants' inboxes contained fewer than 300 emails received during this 7-day window (average: 103.7), allowing a full measurement of email-meeting co-occurrences during the week. These participants' 7-day calendars contained an average of 13.84 meetings (SD: 9.04). On average participants received emails during 7.35 (53%) of these meetings (SD: 6.10). In other words, slightly more than half of all meetings were interrupted by email.

A similar analysis can be performed for the remaining 24.85% who received more than 300 emails. Here, the results cover a variable time frame that is necessarily shorter than a week. For these participants, their most recent 300 inbox emails co-occurred with an average of 8.74 meetings (SD: 6.14). These participants' 7-days calendars contained an average of 18.83 meetings (SD: 11.66), suggesting that *at least* 46% of their meetings are interrupted by email.

The remaining analysis considers specific email-meeting pairs that are sampled from participant's calendars and inboxes. Unlike the above-mentioned aggregate measures, the sampling procedure is not constrained by the 7-day, 300-email, limit.

4.3.2 Prevalence of the information disclosure risk. As detailed in the procedure section, participants were asked to answer questions about 10 email-meeting pairs. To generate these pairs, we randomly sampled a meeting, then randomly sampled an email received during the meeting. Mirroring the analysis of the retrospective survey, 90 out of 169 people (53.3%) had at least one email whose notification they rated as uncomfortable sharing (i.e., they selected a comfort rating of <= 4 on the 7-point Likert scale for sharing the sender, subject and first sentence of the email). This proportion is nearly identical to that which was found in the retrospective survey for emails delivered to work inboxes (53.4%, Figure 2).

4.3.3 Three groups of respondents. Earlier, when we analyzed the results of the retrospective survey, we observed that respondents fell into three groups based on their responses to a hypothetical scenario in which they received notifications of their 10 most-recent emails while attending their most recent meeting. In this labeling study, participants were asked to label 10 emails known to have actually arrived during 10 distinct meetings. This allows a more ecologically valid analysis of this phenomenon. For comparison purposes we transform the 7-point Likert scale to a binary scale. Here scores > 4 (neutral) affirm that the user is comfortable with the notification. Results are presented in Table 2, together with the distribution reported in our retrospective survey. The results show that 23% of the respondents were uncomfortable sharing any of 10 emails in the respective meetings ("10 Uncomfort") , while 41% of the respondents were comfortable sharing all of the 10 emails ("10 Comfort") , and 36% of them were uncomfortable sharing some emails ("Mixed") . Notably, the distribution of users is roughly consistent across both the retrospective survey and the labeling tool (for work inboxes). This suggests that, although the retrospective survey involved a hypothetical situation, its findings closely match those of real-world scenarios. The distribution of the groups also resembles the classical trichotomy of the Westin Index; but, again, we are sensitive to the fact that these preferences can be highly nuanced and context-sensitive. To that end, we explore contextual factors below, as well as later in the section 5.

4.3.4 Email and meeting properties. When reporting the results of the retrospective survey, we examined various properties of emails and meetings that might indicate, or themselves constitute, an information disclosure risk. We now reexamine those criteria.

Number of email recipients: In the retrospective survey, we found that the number of people in an email's recipient list may influence users' comfort levels. Specifically, we observed that the majority of HIDE emails (62.9%) had only a single recipient. We can report a similar statistic for data collected via the labeling tool but must first filter the data such that they are directly comparable: In the retrospective survey, users were asked to discuss the most sensitive email from among those they would be uncomfortable sharing in a meeting. When we apply the same criteria to label-tool data, we find that 46.8% of emails have only a single recipient.

The labeled data also allows for a more deliberate examination of this phenomenon. This is because it contains examples of both sensitive and non-sensitive email-meeting pairs. Over all 1040 pairs, 406 (39%) emails were delivered to a single recipient (i.e., contains no other recipients in either the 'to:' or 'cc:' fields). For 131 (32.3%) of these emails, participants indicated that they would be uncomfortable with meeting attendees seeing the resultant email notifications. This number falls to 23.2% for emails delivered to multiple individuals. This difference is statistically significant ($Z = 3.228$, $p = 0.001$), suggesting that, when multiple people are in an email thread, the likelihood of the email containing sensitive information may be lower.

Number of external meeting attendees: Results from the earlier retrospective survey also suggested that meeting attendance might influence how comfortable people are with sharing their email notifications.[3] Specially, the presence of people outside of one's team or organization *might* increase levels of discomfort. Again, the labeled-data allows for a more ecologically valid and sensitive analysis: Of the 1040 email-meeting pairs, 298 (27.8%) were attended by people from outside of the organization.[4] Participants

[3]Results from the retrospective survey were not statistically significant, but suggested a possible trend worth further investigation (Figure 4).

[4]External to the organization via the *numExternal* feature. Note, the organization chart used in the labeling tool was not sufficiently fine-grained to determine if a fellow employee was a member of a different team.

Classifier	AUC	Pr	Re	F1
Boosted tree ensemble	0.85	0.71	0.63	0.67
kNN	0.59	0.39	0.23	0.29
SVM	0.58	0.78	0.03	0.06

Table 3: Results of the classifiers that predict if a respondent would be uncomfortable revealing a given email notification in a particular meeting context (i.e., an email-meeting pair).

Table 4: Top 20 most informative features for the boosted tree ensemble classifier. The number in the parentheses indicates the information gain, normalized such that the most informative feature scores a 1.0. The prefixes 'U', 'E', and 'M', denote user, email, and meeting features, respectively.

reported that in 95 cases (32.3%), they would be uncomfortable sharing the email notification with meeting attendees. This proportion falls to 24.4% for meetings in which all attendees are fellow employees of the same organization. This difference is statistically significant ($Z = 2.78$, $p = 0.005$), suggesting that meeting attendance may indeed influence comfort levels about email notifications.

Together, these findings reinforce and extend our answers to the first two research questions: people are often interrupted by emails when in meetings, in a sizable minority of cases people are uncomfortable sharing the resultant email notifications with the people in the room (RQ1). These levels of discomfort may depend on individual characteristics, as well as on features of the meetings and emails (RQ2). This, in turn, hints at the possibility of using machine learning to predict when email notifications pose an information disclosure risk. We examine this in the next section, and, in doing so, answer our final research question (RQ3).

5 PREDICTING COMFORT LEVEL

To further explore the problem space, we developed binary classifiers that, given an email-meeting pair, decide if the delivery of an email notification would result in an uncomfortable situation. In constructing these classifiers, we both: (1) gain a deeper understanding of how combinations of user, email and meeting features may contribute to one's concerns about email notifications, and (2) explore modeling decisions and requirements that can lead to context-dependent predictions accurate enough to be used to manage users' notifications in real-world settings.

5.1 Prediction Results

For training and evaluation we use the 1040 labeled examples collected in the second study, above. Training and evaluation is done using 10-fold cross-validation, stratified the data such that, for each user, 7 labeled data points are included in the training set, and 3 labeled data points are included in the test split, and optimized to maximize the area under the receiver operating characteristic curve (AUC). We train boosted tree ensemble, SVM with linear kernel, and k-nearest neighbor (k=3) classifiers.

Detailed results are presented in Table 3. There are a few points to note. Our best performing classifier, the boosted tree ensemble, achieved an AUC of 0.85 which is well above chance. However, with our best performing model achieving a precision of 0.71, and a recall of 0.62, the classifiers are likely to be less useful in high-risk applications. Nevertheless, our explorations reveal that generic features provide some information about the information disclosure risks of an email-meeting pair.

For example, we looked at the 20 most informative features with our best performing classifier, the boosted tree ensemble (Table 4). In addition to the user features that might be indicative of potential exposure (the number of emails a user receives in a week, the average emails per meeting, the number of meetings), and email features that are related to email contents and length, we found features related to meeting context. Notably, the fourth most informative feature was one that counted how many meeting attendees were above the recipient in the organizational chart. Again, we also found that people were more uncomfortable sharing emails when the meeting description contains strong negative or positive emotion words categorized by LIWC [35].

To this end, we have answered our research questions. In the next section, we offer design implications, then conclude with a brief discussion of limitations and future work.

6 DESIGN IMPLICATIONS

In this section, we discuss some of the implications for designing contextually-relevant notification systems and policies.

Personalization matters. Both our exploratory retrospective survey and the contextual labeling study revealed three general and distinct groups of respondents. If a user can be quickly characterized as *Always Comfortable* or as *Always Uncomfortable*, then the notifications policies are rather straightforward: unconditionally allow all notifications for the unconcerned, and turn off notifications for those *Always Uncomfortable* unless the system is certain the user is alone. However, there exists a much richer strategy space for the *Mixed Comfortable* group, where various notification actions can be designed by hiding certain fields of messages, or delivering notifications only to certain devices.

Even simple context is helpful. As discussed above, for some people an effective notification policy might need only know if a person is alone, and examining a user's calendar may serve as an acceptable approximation. More sophisticated policies might consider whether an email was delivered to multiple people, or whether a meeting will be attended by people from outside the organization. These possibilities make clear that interesting notification policies can be developed from simple, easy-to-compute, signals.

Better sensing is likely to help. Both the retrospective survey and the contextual-labeling study included questions that could not be automatically answered based on calendar appointments and emails alone. For example, we asked participants if they attended meetings, and whether meetings were conducted via teleconference. With richer sensing capabilities, it is possible that these features could be reasoned about automatically.

Choose your notification fields wisely. Finally, our studies revealed that some notification fields are less sensitive than others. However, these preferences weren't universal, and varied even within a single user's responses. For example, an email's sender field may pose little risk in some cases (e.g., an email from a known collaborator), but pose significant risk in others (e.g., an email from a medical specialist). Systems should leverage these preferences, but also be expressive enough to allow exceptions. Systems should also scale their services, opting for more conservative notification strategies when there is uncertainty in predicting comfort level.

7 ETHICAL SAFEGUARDS FOR OUR STUDIES

In our studies, we sought to ensure participant anonymity and to avoid collecting any personally identifiable information. To make participation anonymous, we assigned participants random session identifiers in the labeling tool study, and hosted participation sweepstakes on a separate unconnected system. To preserve anonymity in feature extraction, for example, we used k-anonymization ($k = 50$) for full job titles and job-title bigrams. To avoid collecting personally identifiable information, we asked participants to describe their emails in broad terms in open-ended questions and cautioned participants not to include any personally identifiable information. Further in the labeling tool study, we chose email and meeting features that were not personally identifiable. For example, instead of collecting exact words that an email contained, we only collected LIWC feature vectors of the email. Finally, due to the sensitive nature of the topic we investigate, we also allowed participants to see the data being collected, and allowed them to delete their responses should they change their mind during or after the study.

8 DISCUSSION AND LIMITATIONS

In this paper, we characterized information disclosure risks that arise when people receive notifications in the presence of others. Specifically, we focused on emails that arrive during meetings. We employed multiple lines of evidence, including a large retrospective survey, and data collected in a second study via a purpose-built labeling tool. We report similar findings in both datasets, and are encouraged by this consistency.

Nevertheless, we caution readers against overgeneralizing our findings. Both the survey and labeling tool were deployed within a single large U.S.-based information technology company. Though respondents occupied a wide variety of job roles, it remains to be demonstrated that our findings generalize to other companies, company cultures, and industries. For example, it seems likely that people working in financial, legal, and medical industries may be more sensitive to information disclosure risks. It is also possible that preferences and concerns may vary by country and culture. Thankfully the *features* we described in this paper are very general, and are likely to be available in other companies and industry settings. As such, we expect replication efforts to be rather straightforward.

We would also like to extend our analysis to personal emails and contexts (e.g., social gatherings, etc). The retrospective survey revealed that people perceive a higher risk when personal emails arrive during work meetings. One wonders: Is the same true for social gatherings? How might work notifications be perceived in non-work contexts? We believe this line of investigation will be fruitful future research.

Likewise, our studies focused exclusively on email notifications. This choice was deliberate and practical; as noted in the introduction, email is often a carrier for other types of notifications (e.g., social networks). In the future, we hope to explore the privacy risks of other notification types, including: instant messages, calendar appointments, reminders, and other information proactively displayed by virtual assistants. Studying these notifications requires deeper technical integration with devices and platforms. Our studies were also exclusively performed from the perspective of the notification recipient. We recognize that the senders of emails are also subject to disclosure risks. When such risks are present, message originators can take some limited preventive actions to mitigate risks (e.g., by using the email subject to indicate that an email is sensitive, or by adding blank lines to the beginning of a message).

One goal of this paper is to assess the basic feasibility of machine learned classifiers, and in doing so, to identify features that help predict notification comfort levels. Our top classifier achieved an AUC of 0.85, and its strongest features capture aspects of notifications that were deemed important in our survey. Moving forward, we hope to improve accuracy, and this likely requires the collection of more data—our sample of 1040 labeled email-meeting pairs is rather small for state-of-the-art classifiers, and this data scarcity is confounded by the fact that the labels are likely correlated; the 1040 labeled pairs represent only 169 individuals. With more data, we hope to improve prediction accuracy enough to implement real-time notification policies for virtual assistants.

Finally, we recognize that there are costs to delaying notifications and hiding notification fields [17, 19]. Our studies did not measure these costs, and cannot directly experiment with formal notification policies. Nevertheless, we feel our analysis has showcased the need and opportunity to develop such policies, and has provided hints about which features and properties are likely to be informative.

9 CONCLUSION

In this paper, we report results from a retrospective survey and a larger contextual labeling study. Our research necessitated that we ask users to discuss sensitive scenarios. Specifically, we asked user to describe sensitive emails, and to discuss why they would feel uncomfortable receiving notifications for those messages when in the presence of others. To this end, we designed our studies to carefully respect participant privacy, and we believe these considerations were instrumental in allowing us to recruit a combined total of 300 individuals. From these individuals, we learned:

- (RQ1) Email notifications indeed pose an information disclosure risk.
- (RQ2) The real or perceived severity of these risks depend both on user characteristics (e.g. the nature of occupation)

and attributes of the meeting or email (e.g., the number of recipients or attendees).
- (RQ3) Machine-learned models can learn attributes, patterns and signals associated with risky email-meeting pairs. Here, user-level features are more informative than generic meeting or email-level features.

Taken together, our findings present a rich picture of notifications, as viewed through the lens of privacy. We hope that our findings will inform the design of future notification systems.

ABSTRACT

Recent studies show that an overwhelming majority of emails are machine-generated and sent by businesses to consumers. Many large email services are interested in extracting structured data from such emails to enable intelligent assistants. This allows experiences like being able to answer questions such as "What is the address of my hotel in New York?" or "When does my flight leave?". A high-quality email classifier is a critical piece in such a system. In this paper, we argue that the rich formatting used in business-to-consumer emails contains valuable information that can be used to learn better representations. Most existing methods focus only on textual content and ignore the rich HTML structure of emails. We introduce *RiSER* (Richly Structured Email Representation) – an approach for incorporating both the structure and content of emails. RiSER projects the email into a vector representation by jointly encoding the HTML structure and the words in the email. We then use this representation to train a classifier. To our knowledge, this is the first description of a neural technique for combining formatting information along with the content to learn improved representations for richly formatted emails. Experimenting with a large corpus of emails received by users of Gmail, we show that RiSER outperforms strong attention-based LSTM baselines. We expect that these benefits will extend to other corpora with richly formatted documents. We also demonstrate with examples where leveraging HTML structure leads to better predictions.

KEYWORDS

Email Representation; HTML Structure Encoding; Email Classification

1 INTRODUCTION

Classifying documents into two or more target classes is a core problem in many web applications, and has received attention from several research communities. Identifying the sentiment in text documents [43], detecting spam in email [12] and the web [36], and fake news detection [42] are well-known applications. Even enterprise applications like legal discovery [40] make use of the core abstraction of document classification.

Most existing approaches focus on short plain-text documents like tweets, reviews, and posts in online discussion forums. However, several interesting applications are on corpora where the documents are longer, and often have rich HTML markup structure. Such corpora have not received as much research attention, but are important for many applications. For instance, web pages have rich HTML structure; classifying them [39] is useful for several applications like focused crawling, faceted search, and even as a signal for web page search ranking.

Email is another area that contains longer documents with rich HTML markup structure. Recent studies [31] have shown that most email is richly formatted and machine-generated rather than plain-text sent by humans. Several interesting applications beyond spam-detection rely on learning good classifiers over email. This includes foldering [19], automatic prioritization [15], and even information extraction [2, 14, 41]. In particular, these studies show that learning a high-precision classifier over richly formatted emails is a key ingredient to extracting structured data from email that is then used to power several intelligent experiences [14, 41].

In this paper, we tackle the problem of learning a good representation (embedding) for structured documents like richly formatted emails. We focus on evaluating these embeddings for the task of classifying an email into one of k target classes. Recent literature has shown that for relatively short documents, a recurrent neural network with an attention mechanism [48] is a very strong baseline for learning good representations. With richly formatted documents, most existing techniques ignore the formatting information except

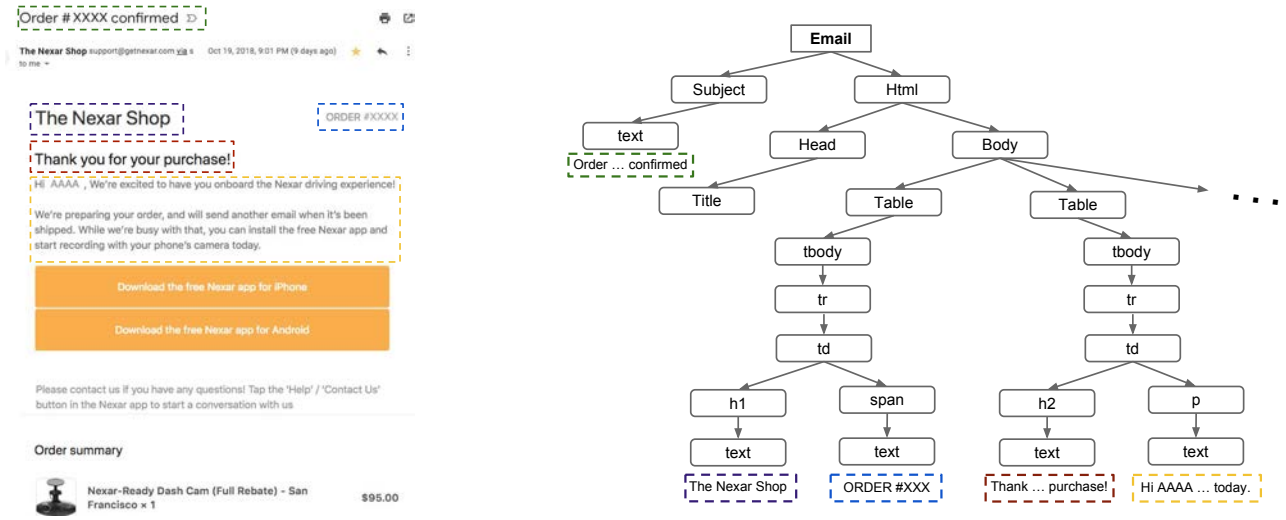

Figure 1: An example *purchase* email (left) and a simplified DOM tree (right) representing a portion of the email. For clarity, we trim long trivial HTML sequences such as nested *div* tags. Note that we extend the DOM tree beyond the email message body to include a branch representing the subject.

for assuming that documents are hierarchically organized [48] into sentences and paragraphs. We illustrate in Section 2 that the rich structure of HTML-formatted email can be a valuable signal for the relative importance of various pieces of information in the document. We introduce a neural architecture called RiSER (Richly Structured Email Representation) to take advantage of the structure of the email in addition to the content. RiSER projects the input email into a vector representation by jointly encoding the HTML structure of the email along with the terms in the email. It consists of a 2-level LSTM to first construct a structural encoding and combines this with an encoding of the terms for which there is a second LSTM layer. This provides a simple way to encode the formatting and layout information as opposed to manually engineering structural and visual features.

Experiments on real data from Gmail corpus show that the structure does indeed contain useful information and that RiSER is able to exploit this information to outperform a strong baseline that only considers textual information. While we focus on emails, the techniques introduced in RiSER are generic and can be used for any document corpus containing richly formatted information such as HTML web pages and PDF documents.

We make the following key contributions in this paper:

- We identify that structural information in richly formatted HTML emails is a valuable signal that is ignored by existing classification approaches focused on textual content.
- We propose a 2-level neural architecture called RiSER that jointly learns to encode both the structure and the content of the email by examining the sequence of HTML tags that each text term is associated with.
- We demonstrate through experiments on two classification tasks on data from Gmail that RiSER learns enhanced email representations.

The rest of this paper is organized as follows: Section 2 provides more detailed background on the information available in the structure and markup, explains how we represent the input document, and lays out the problem definition for applications like information extraction. Section 3 introduces our two-level neural architecture that jointly encodes the HTML markup and the textual content of documents to learn a good representation. Section 4 reports on the performance of this architecture on two real-world classification tasks using data from Gmail. We compare the performance of this architecture with several baselines including ones that try to leverage manual feature-engineering to represent aspects of this information. The experimental results show that the models with the proposed architecture significantly increase recall at high precision compared to previous baselines by up to 8.6%. Section 5 summarizes areas of related work from the data mining, NLP, and ML research communities. Finally, Section 6 concludes the paper with a summary and potential directions for additional research.

2 EMAIL STRUCTURE

We focus on business-to-consumer (B2C) emails, the vast majority of which are machine-generated instantiations of predefined templates, accounting for up to 90% of all email traffic on the internet [30].

Figure 1 (*left*) depicts an example email from the author's inbox that contains a purchase confirmation. Unlike personal emails sent by humans, B2C emails like these often have rich HTML structure. This structure introduces a complex hierarchy which can be represented by a Document Object Model (DOM) tree [27], such as the one illustrated in Figure 1 (*right*). Each node in this tree represents an HTML tag in the message body, and its children consist of the HTML tags nested within it. The text of the message resides at the leaf nodes. Note that we have extended this DOM tree beyond the

standard model to also include the subject of the email as a child node of the email root. A typical commercial email like the example in Figure 1 may contain around 2,000 leaf nodes. In fact, we have observed some messages, albeit few, that have as many as 10,000 leaf nodes and a depth of up to 200.

The use of rich HTML structure draws the attention of the human eye to different parts of the email. We find that the categorically similar emails often share similar structure. For example, bill reminder emails will format a "pay now" link close to the middle of the email, while hotel confirmation emails often contain tables of check-in and check-out information. This manifests as tables, headers, footers, highlighted and emboldened text in the markup. The key hypothesis we test in this paper is whether the markup in such richly formatted emails offers additional signal over just the textual content.

The remainder of this section describes how we convert this tree representation into a sequence of features that are suitable as input for the classification models described in the following section. The sequence consists of three types of features: *textual features*, *annotation features*, and *structural features*.

The textual features consist of a sequence of the first 200 terms (including punctuation) extracted from the DOM tree (including the subject branch) via in-order traversal. Limiting ourselves to 200 terms allows us to fully represent most emails without the risk of allowing very long emails to derail model training.

The annotation features indicate whether a particular text span contains an annotation. Several examples such as *Date*, *Price*, and *Time* are listed in Table 1. A term may correspond to one or more annotations. These annotations are extracted through a variety of methods including dictionary lookups and regular expression matching. Libraries of these annotators were developed over several years to support more traditional rule-based information extraction tasks. An entity detection library, for example, is also available as a Google Cloud API [18]. Readers can refer to Sheng et al. [41] for more detailed discussion on these annotators. In this work, we provide a way to incorporate the signals from these annotations.

Annotation Types	
Address	Location
Alphabet-Number	Price
Confirmation Number	Telephone Number
Date	Time
Establishment	Tracking Number

Table 1: Annotation features.

Finally, we represent the structure of the document using XPaths [7]. An XPath is the sequence of nodes (HTML tags) extending from the root of the DOM tree to a leaf node. For example, the XPath of the term "ORDER" in the example email in Figure 1 is */html/body/table/tbody/tr/td/span/text*. All the terms in a paragraph (in a *p* node), for instance, might share the same sequence of HTML tags for their XPath feature.

We considered several alternative approaches to represent document structure. For example, one can identify the XPath patterns for text in key HTML tags like headers, tables, lists and then use these to mark each term. This approach is labor-intensive and more importantly ad-hoc and may not take into account patterns than an engineer has not visually inspected and considered important. For our problem, we are interested in an approach that can be applied to all the emails from various domains with different structural patterns without having to manually engineer structural features. Another possible representation is to use a visual blocks structure using external parsers [11]. Visual blocks are tree structures based on the visual layout of the page. Such an approach would depend on an external parser to produce features that can then be represented as part of the input example. We chose to use the XPath since it is simple, and provides a detailed representation of the markup. This allows us to directly test the hypothesis of whether the information in the markup is valuable for learning a better representation. We expect that using visual features from a sub-system that understands document layout could be interesting future work.

A complete set of features representing a single email document thus consists of a stream of up to 200 terms, the set of annotations that each term is a part of, and the XPath that each term resides at. Figure 2 denotes the features corresponding to three terms – "Shop", "ORDER" and "#XXXX" from the email in Figure 1. The terms "Shop" and "ORDER" do not contain any annotation, but "#XXXX" has two annotations: *Confirmation Number* and *Alphabet-Number*. The bottom row contains the XPath in the DOM tree at which each of these terms appear.

We describe the architecture that combines these three features in Section 3 below, and explore the utility of different combinations of these features in Section 4.

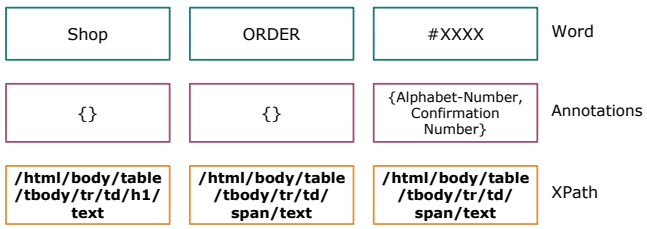

Figure 2: Feature sets of three terms "Shop", "ORDER" and "#XXXX" from the top of the email in Figure 1.

3 MODEL ARCHITECTURE

In this section, we present our email representation framework – RiSER. The proposed model consists of two main components: an XPath encoder and a word encoder. At a high level, the XPath encoder models an email's DOM structure by encoding the tags along the XPath to a leaf node using an LSTM layer [21] while the word encoder combines word embeddings with the corresponding XPath encodings and additional features to learn an enhanced representation of the email. The enhanced email representation is then used as a feature for email classification. Figure 3 shows an overview of the model architecture. We describe the details of the framework and its components in the following sections.

3.1 XPath Encoder

Recall from Section 2 that an XPath is a sequence of HTML tags from root to leaf of an email's DOM tree. The proposed XPath encoder

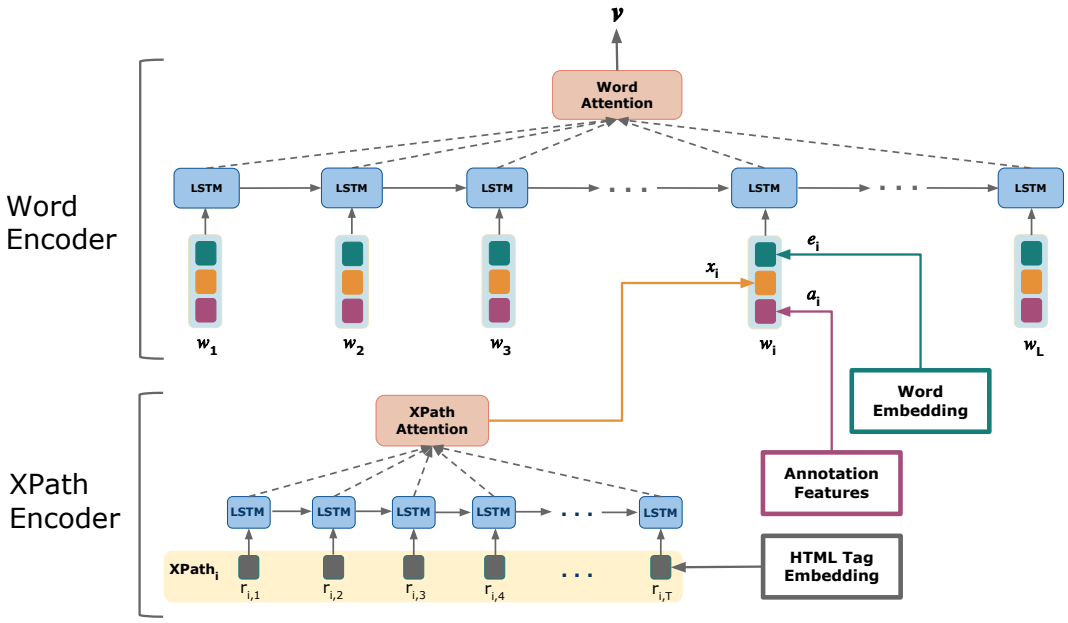

Figure 3: Overview of the RiSER architecture. The XPath Encoder iteratively encodes the tags in the XPath for each term in the email's DOM tree. Later, each XPath encoding (x_i) is combined with the corresponding word embedding (e_i) and annotation features (a_i) of the term to form a word representation (w_i). The Word Encoder then processes these word representations ($\{w_1, w_2, \cdots, w_L\}$) to learn an enhanced email representation (v). *(best viewed in color)*

in Figure 3 summarizes this sequence with a vector of fixed length. In this work, we use an LSTM encoder with an additional attention mechanism [48] to represent the sequential elements (HTML tags), however, one is free to choose any standard sequence encoder to model the sequential input. More precisely, let the $XPath_i$ be a sequence of HTML tags with embeddings $[r_{i1}, \cdots, r_{iT}]$. In practice, we randomly initialize these embeddings and update them during training. We pass these embeddings through an LSTM layer to produce output vectors:

$$h_{it} = \overrightarrow{LSTM}(r_{it}), t \in [1, T] \tag{1}$$

Typical practices for extracting a final output representation from an LSTM layer include selecting the final output or averaging across all outputs. However, we observe that XPath sequences can be very long and highly repetitive. Furthermore, not all HTML tags may contribute equally to the email structure. For instance, HTML tags such as `strong`, `em` or `big` can be more informative than other much more common tags, such as `div`. Hence, we apply an attention mechanism [48] over the outputs of the LSTM layer in order to (1) extract such informative tags from long sequences and reward their contributions to the XPath representation, and (2) simultaneously reduce the impact of highly repetitive tags.

The final XPath encoding vector is computed as follows. First, we feed the LSTM output h_{it} through a fully connected layer with trainable weight matrix W_r and bias vector b_r, as well as a *tanh* activation function to produce the hidden vector u_{it}:

$$u_{it} = \tanh(W_r h_{it} + b_r) \tag{2}$$

Next we calculate an importance weight α_{it} for each HTML tag r_{it} in the sequence as a normalized similarity score between the hidden vector u_{it} and a trainable structure vector u_r:

$$\alpha_{it} = \frac{\exp(u_{it}^T u_r)}{\sum_i \exp(u_{it}^T u_r)} \tag{3}$$

Finally, we compute the *XPath encoding* vector x_i as a weighted sum of all the LSTM outputs:

$$x_i = \sum_t \alpha_{it} h_{it} \tag{4}$$

The proposed XPath encoder has the following two desirable properties. First, as we show in Section 4.5, the XPath encoding vectors capture information that is highly valuable for an email classifier. Second, the XPath encoder captures the relative hierarchy of an email's structure, i.e. two XPath sequences will have similar embeddings in the vector space if they correspond to closer leaf nodes in the DOM tree since they share long common subsequences. In the next section, we explain how the XPath encoder interacts with the word encoder.

3.2 Word Encoder

The word encoder is responsible for learning a rich representation of the email which not only summarizes the email's content but also encodes its HTML structure. In order to accomplish this goal, we go

beyond the word-embeddings-based representations and capture additional features with structural information from the email. We create our rich word representation vector w_i by leveraging the following three components:

- *Word embeddings.* We construct our vocabulary with the most frequent 20,000 words in our data. Each word in the vocabulary is mapped to a word embedding vector through an embedding look-up matrix. Out-of-vocabulary (OOV) words are mapped to an *unknown* vector. In this work, we randomly initialize the word embeddings and jointly train them with the model. One can also use pre-trained word embeddings such as Word2Vec [35], Glove [38], or fastText [9].
- *XPath encodings.* The corresponding XPath of each word is passed through the XPath encoder to produce an XPath encoding. These XPath encodings implicitly capture the position of the word in the DOM tree. Since XPath sequences can be very long, we only keep the first T tags of the sequence and omit the rest. Note that T is a hyper-parameter in our framework.
- *Annotation vectors.* We represent the annotations a word corresponds to as a 10-D binary vector. Each dimension (0/1) indicates whether a word is annotated by a particular markup shown in Table 1. These features turn out to be very helpful, as we will show in Section 4.4.

To form improved word representations, the word embeddings, XPath encodings, and annotation vectors are concatenated for each term and fed into a fully connected layer with *tanh* non-linearity. Formally, given an email with L words, we represent each word in the sequence as:

$$w_i = \tanh(W_s[e_i, x_i, a_i]), i \in [1, L] \tag{5}$$

where $e_i \in \mathbb{R}^k$ is the word embedding vector, $x_i \in \mathbb{R}^l$ is the corresponding XPath encoding calculated in Equation (4), and a_i is the 10-dimensional binary vector representing the annotations mentioned in Section 2. $W_s \in \mathbb{R}^{m*m}$ is a trainable weight matrix, where $m = k + l + 10$.

With $[w_1, w_2, \cdots, w_L]$ we can now compute an email representation vector by using another LSTM layer to encode the sequence and apply an additional attention mechanism [48] over that layer:

$$h_i = \overrightarrow{LSTM}(w_i), i \in [1, L] \tag{6}$$

$$u_i = \tanh(W_w h_i + b_w) \tag{7}$$

$$\alpha_i = \frac{\exp(u_i^T u_w)}{\sum_i \exp(u_i^T u_w)} \tag{8}$$

$$v = \sum_i \alpha_i h_i \tag{9}$$

where v is the email representation vector that summarizes both the email structure and semantics.

3.3 Email Classification

We use the email representation computed above as a feature in email classification. More specifically, we use a linear layer to convert the email representation vector to a real-valued vector of size $|C|$, where C is the set of classes to predict. A final softmax layer is applied to obtain the normalized probabilities over the labels:

$$p = \text{softmax}(W_c v + b_c) \tag{10}$$

The training objective of our framework is cross-entropy loss:

$$loss = -\sum_{d \in D} \sum_{c \in C} p_c^g(d) \cdot log(p_c(d)) \tag{11}$$

where D is the set of training emails, C is the collection of email classes, $p_c(d)$ is the probability of predicting email d as class c, and $p_c^g(d)$ is a binary value indicating whether c is the correct label. The entire model is trained through back-propagation with respect to all parameters. Training details are further explained in Section 4.3.

4 EXPERIMENTS

This section presents the results from several experiments on data from a large Gmail corpus to illustrate the effectiveness of the RiSER architecture. We focus on two binary classification tasks for this purpose. The first task is one of detecting if an email contains a bill. This model is used by the email service to determine if it wants to proactively remind the user when a bill is due. The second task is one of detecting if an email contains a hotel reservation confirmation. This model is also used to support intelligent applications such as travel planning. We refer to these two as the *Bill* and *Hotel* tasks. We pick these two tasks for illustrative purposes. The overall system that these classifiers are a part of includes several other classifiers (and extractors) for flights, calendar appointments, shipping confirmations, etc.

The experiments are designed to compare the performance of different RiSER variants (introduced in Section 4.2) against a strong baseline and to understand the incremental advantage of incorporating the annotations and XPath embeddings. Before describing the experimental setting, we first describe how the datasets are constructed including the source for the labels and sampling techniques used to deal with biases.

4.1 Dataset

The training and testing datasets are constructed by sampling from the Gmail corpus. During the course of this work, user privacy was protected through strict data access controls and data preprocessing to avoid training on sensitive data. Nobody involved with this project had access to visually inspect any of the data. Only terms matching the dictionary of top 20,000 terms are used, while the rest are replaced by an *unknown* identifier. Any text spans that contain potentially private data (such as addresses, dates, and phone numbers) are denoted by the corresponding annotation feature, and the underlying terms are replaced by the *unknown* identifier.

4.1.1 Labels. Ground truth labels for this dataset are derived from three sources: Microdata [20], manually defined parsers, and rule-based extractors. Microdata is a standard that enables senders to explicitly label and mark up their outgoing emails with structured information. For example, when sending a confirmation email to a customer, hotels can include markup to indicate that their emails are reservation confirmations, and even specify details such as confirmation numbers, addresses, check-in and check-out out dates and times, etc. While Microdata markup is precise, it is not widely

adopted by all email senders, so the volume of annotations tends to be low.

Manually defined parsers are designed to extract category-specific fields from emails in lieu of Microdata. These are created on a per-sender basis and hand-crafted based on several instances of emails donated by users for this very purpose. For the purposes of email classification, we use the presence of a successful extraction from an email as a positive label for the category.

Note that we prioritize construction of parsers for high volume senders, since (a) parser construction is laborious, thus focusing on larger senders yields more labeled samples, and (b) the donated corpus is relatively small and thus contains a limited number of samples from low volume senders. Manually defined parsers tend to be highly precise but brittle, since small changes to the emails can often break the parsers, requiring human involvement and new donated emails to fix them.

Rule-based extractors consist of a manually engineered set of traditional information extraction techniques, such as dictionary lookups and regular expressions, that operate across senders. These are also constructed by leveraging the donated email corpus for both development and validation. These tend to have higher recall than the approaches above, but often at the cost of lower precision. Similar to the manually defined parsers, we use the presence of a successful extraction of an email as a positive label for the email.

4.1.2 Sampling. Despite drawing labeled examples from the three sources of ground truth mentioned above, the vast majority of emails remain unlabeled, and even among those that are labeled, the distribution is skewed towards higher volume senders. Thus, training classifiers using a uniformly random sample of data often leads to overfitting and poor generalization to smaller senders.

Domain-based sampling attenuates this issue by limiting the number of samples observed from high volume senders and boosting those from smaller senders, however this method can be too coarse for larger senders that have their own internal skew—e.g. the majority of amazon.com email might be classified as *purchase orders*, while a small fraction are *account memberships* or *bill reminders*.

We find a balance between these two methods by stratifying emails by the templates from which they are instantiated. This ensures that an even number of emails are represented from the *purchase order*, *account membership*, and *bill reminder* templates, along with emails from much smaller senders.

These templates are inferred through a one-time template generation process that clusters similarly structured emails into groups that are likely to have been instantiated from a single template. These techniques range from clustering on the sender and subject of an email [3] to clustering on the structure of the email body [2, 4]. In this work, we use structural clustering techniques based on a locality sensitive hash of the email body similar to the technique described in [41].

We split the data into train and test sets with a ratio of 9:1 while ensuring that samples belonging to the same sender domain appear in only one of these sets to prevent the effects of memorization. For the training data, we downsample the negative examples to yield a positive-to-negative ratio of about 1:100. We keep the original ratio in the test set. To put this into perspective, the resulting training sets have approximately *150M* total samples for the Bill task and *31M* samples for the Hotel task.

4.2 Experiment Configuration

We train and evaluate four variants of the RiSER architecture, each incorporating a different combination of the textual, annotation, and structural features described in Section 3.2.

- **RiSER-W** uses the Word Encoder only and represents words using the *word embeddings* component only. That is, in Equation 5, the word representation w_i is represented by the word embedding e_i only.
- **RiSER-WA** uses the Word Encoder and represents words with the *word embeddings* and *annotation features*.
- **RiSER-WX** uses both the Word Encoder and the Xpath Encoder and represents words with the *word embeddings* and *XPath encodings*.
- **RiSER-WXA** uses both the Word Encoder and the XPath Encoder and represents words with the *word embeddings*, *XPath encodings*, and *annotation features*. This variant is the one displayed in Figure 3.

The RiSER-W variant is simply an LSTM-based recurrent model with an attention mechanism, as it only includes word embeddings in its input layer. Recent studies in the literature have shown that attention-based LSTM models [29, 48] are excellent for modeling text documents and achieve state-of-the-art performance in document classification tasks by outperforming linear models, SVMs, and feed-forward neural networks. Therefore we consider RiSER-W as a baseline model to compare against the remaining RiSER variants.

Note that one can employ more complex neural architectures than just the RiSER-W architecture to improve email classification performance. However the focus of this work is to demonstrate the advantages of exploiting the rich formatting structure of emails through our proposed XPath Encoder and overall architecture. Moreover, we aim to demonstrate that textual content can be better utilized when combined with structural information for learning email representations.

We compare the performance of the RiSER-WA, RiSER-WX and RiSER-WXA variants against the baseline RiSER-W model to determine whether structural information and annotation features can improve the learned representations. We test this hypothesis by classifying emails into two semantic categories, *Bills* and *Hotels*. While we could have posed this as a multi-class classification problem, practical convenience of improving one model without affecting any other models motivated us to pose these as separate *binary classification* tasks. The general idea of leveraging structure to learn a better representation holds for multi-class, multi-label, or even regression tasks.

4.3 Hyper-parameters and Training

For all four variants, we perform grid search over the word embedding dimension ({50, 100, 200}), the word encoder LSTM output (hidden state) dimension ({64, 128, 256}), the initial learning rate ({0.01, 0.001, 0.0001}), the batch size ({50, 100, 200}), the word encoder dropout rate ({0, 0.25, 0.5}), and the optimizer type (AdaGrad [16] and Adam [24]). For the Adam optimizer, we use the default settings suggested by the authors ($\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$).

For the RiSER-WX and RiSER-WXA models we also search over the following additional hyper-parameters: the HTML tag embedding dimension ({25, 50, 100}), the XPath encoder LSTM output dimension ({16, 32, 64}), the XPath encoder dropout rate ({0, 0.25, 0.5}), and the maximum XPath length ({20, 30, 40}).

We use the norm clipping trick with a *threshold* of 5.0 in all four models to avoid the exploding gradient problem.

For each model, we use the Vizier [17] platform to select the best combination of hyper-parameters based on AUC-PR after a maximum of 1M training steps. The selected hyper-parameters for each model are shown in Table 2. We later continue training the selected models until they converge and report their highest numbers on the test data in the next section.

BILL				
Hyper-parameter	RiSER-W	RiSER-WA	RiSER-WX	RiSER-WXA
batch size	200	200	200	200
learning rate	0.001	0.0001	0.0001	0.001

4.4 Results and Discussion

Classifier performance is often measured using area under the receiver operating characteristic curve (AUC-ROC). However, when dealing in datasets with high class skew—which is often the case for email—the area under the precision-recall curve (AUC-PR) provides a much fairer representation of model performance. In practice, even the AUC-PR metric is inadequate given that applications for email generally require extremely high precision. For example, misclassifying an important email as spam is an incredibly bad user experience.

Thus, we evaluate our models based on their *recall at a fixed level of high precision*. By requiring that all models reach a prespecified precision threshold, we minimize bad user experiences. Fixing the precision then allows us to evaluate different models by the extent of their coverage at that level of precision. That being said, we also report the AUC-PR metric for clarity. The experimental results on both datasets are summarized in Table 3.

BILL				
Model	R@P=0.85	R@P=0.90	R@P=0.95	AUC-PR
RiSER-W	76.4	71.5	57.4	85.4
RiSER-WA	76.8	73.0	63.1	85.9
RiSER-WX	76.6	73.5	64.1	86.2
RiSER-WXA	78.0	73.7	66.0	85.6

HOTEL				
Model	R@P=0.85	R@P=0.90	R@P=0.95	AUC-PR
RiSER-W	95.9	95.0	92.4	97.1
RiSER-WA	97.3	95.7	93.2	98.0
RiSER-WX	96.3	95.5	93.5	97.2
RiSER-WXA	97.4	96.3	92.9	97.7

Table 3: Recall at a fixed level of precision and AUC-PR performance metrics for four RiSER variants trained for the Bill and Hotel classification tasks.

4.4.1 **Recall-at-fixed-precision (R@P).** Results show that our RiSER-WXA variant overall gives the best performance across both datasets. The improvement in performance depends on the data type. For more complex dataset, such as Bill, the RiSER-WXA variant outperforms the baseline model (RiSER-W) by 2.2% on R@P(0.9), and by 8.6% on R@P(0.95) metrics. Note that recall tends to decrease drastically for the baseline model as the precision threshold increases, while RiSER-WXA demonstrates more robust performance. This leads to a larger gap between both models' recall at higher precision thresholds. On the other hand, improvements in the Hotel task are smaller compared to the Bill task, leading to 1.3% on R@P(0.9), and by 0.5% on R@P(0.95) metrics. We also report the experimental results of RiSER-WA and RiSER-WX variants in order to better evaluate the effects of each component.

Effect of annotation features. Our experiments show that using crafted annotation features on top of word embeddings provides important performance gains over the baseline. With respect to the R@P(0.95) metric, the RiSER-WA variant outperforms the RiSER-W variant by 5.7% on the Bill task, and 0.8% on the Hotel task. Similarly, the gap between recall is smaller (1.5% and 0.7%) as we decrease the precision threshold.

We believe the reason behind the performance boost that comes with the annotation features is that they allow us to recover meanings in words that cannot be captured with the defined vocabulary. To be more specific, emails include dates, numbers, addresses such that most of these terms are anonymized due to privacy constraints and are embedded with the *unknown* vector. Thus, including the annotation features allows our framework to capture these additional signals, which intuitively improves the model's ability to correctly classify an email. As a toy example, an email without a date is most likely not a hotel reservation.

Effect of email structure. Combining XPath encodings with word embeddings leads to an improvement of 6.7% in the Bill task, and 1.1% in the Hotel task with respect to the R@P(0.95) metric. More importantly, by comparing the performance of RiSER-W and RiSER-WX, we verify that incorporating the *HTML structure* into the learning process leads to *improved email representations*. In

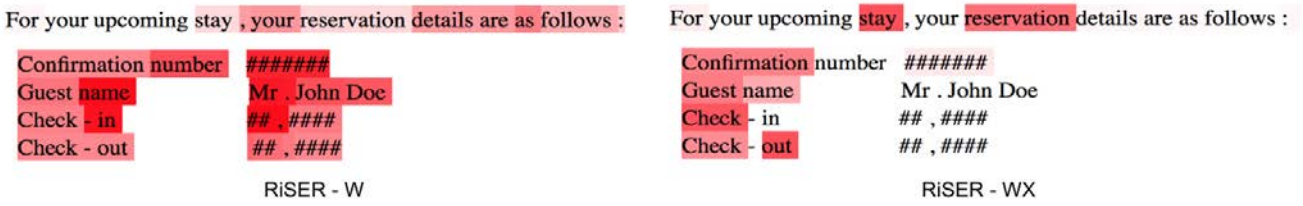

Figure 4: Word attention weights on an example donated Hotel email using the RiSER-W and RiSER-WX variants. Brighter red highlighting indicates a higher attention weight for the corresponding term relative to the other terms in the email.

Section 4.5, we illustrate this with some example emails in which the inclusion of HTML structure results in better classification.

While improvements of the order of 5% to 10% may seem small, they represent a significant reduction in "bad experiences" for users of Gmail. Consider, for example, a service that extracts structured data from these emails to remind people when their bills are due or answers questions about their hotel reservations. The improved models directly translate to improved recall for both these assistive experiences.

4.4.2 **AUC-PR.** The AUC-PR metric generally improves for RiSER-WA, RiSER-WX and RiSER-WXA variants compared to the baseline variant on both classification tasks. However, the improvements are not always in line with the improvements to the recall-at-fixed-precision metric. Surprisingly, unlike the R@P metric, the RiSER-WXA variant does not have the highest AUC-PR for either task. For the Bill task, the RiSER-WX variant performs the best (86.2%), while for the Hotel task, the RiSER-WA variant has the highest AUC-PR (98.0%).

4.5 Qualitative Analysis

In order to get an intuition into how RiSER utilizes the HTML structure of an email, we visualize and compare the attention weights of two architecture variants: one that excludes the XPath encodings and one that includes the XPath encodings. Here, we use the RiSER-W and RiSER-WX variants trained for the Hotel classification task. We illustrate the resulting attention weights of the two models applied to a single donated email example in Figure 4. Note that we obfuscate key information for privacy reasons.

In comparing the term attention weights of the RiSER-W and RiSER-WX models, we find that the latter is much better at attending to terms that are semantically relevant to the hotel reservation class. For example, terms such as `'stay'`, `'reservation'`, `'confirmation'`, and `'guest'` are attended to while the RiSER-W model attends to nearly all words. In fact, it attends more to those that are less semantically relevant in this example.

To get an intuition as to why structural information helps these models attend differently to these terms, we inspect the attention weights of the XPath tags in addition to the term attention weights. We visualize these weights for a donated email example in Figure 5. Red highlighting indicates term attention weights while yellow highlighting indicates the XPath's HTML tag attention weights.

Our first observation is that the use of structure helps the model understand the boundaries of different parts of the email. In this particular example the model attends to terms that belong to the subject more than the remainder of the text stream. Note that the word attention weights drop suddenly at the boundary of the subject and the beginning of the message body. We observed this pattern across many donated examples.

Our second observation is that the model also attends more to HTML tags that are often used to highlight important text. In this example, the model pays particular attention to meaningful tags such as `strong` (which indicates if a word is bold-ed), `h1`/`h2`/`h3` (which indicate headers), and `ul` and `li` (which indicate list items). These types of markup are generally used to draw the user's attention to specific text in a rendered email, often containing important information. Similarly, note that the `center` tag, which aligns all inner HTML to the center of the display, is also highly attended to.

In summary, from inspecting the attention weights of the RiSER architecture with and without XPath encodings, we observe that including structural information improves attention at the term

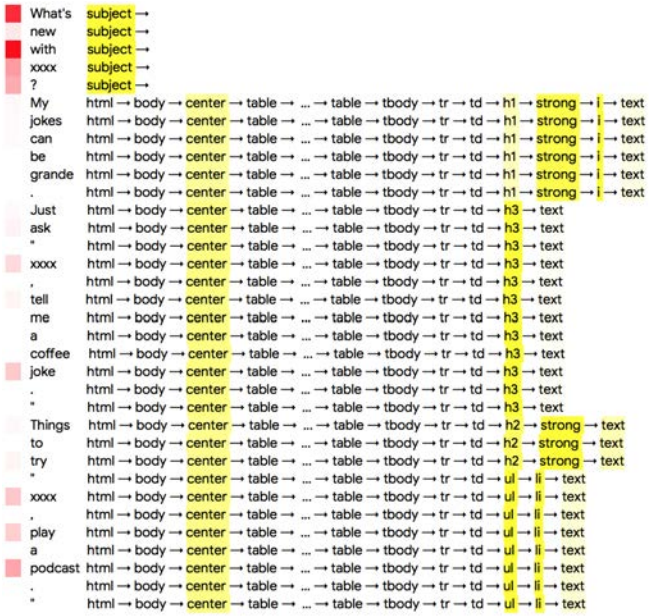

Figure 5: Term and XPath attention weights. Red highlighting indicates the term attention weights. Yellow highlighting indicates the XPath's HTML tag attention weights (row normalized). Brighter colors indicate higher attention weights.

level by helping the model learn about boundaries in documents (e.g. subject vs. message body), as well as learn to focus on parts that the original sender intended to draw the user's attention to (e.g. `strong`, `center`, etc.).

5 RELATED WORK

Our work builds on contributions from several research areas including natural language processing, data mining, web mining, and deep learning. Here we discuss related work in two main categories: text representation and email representation.

There is a rich history of work in text representation [33, 47] for various tasks like sentiment classification [37] (e.g. positive or negative reviews) and genre detection (e.g. sports, news, entertainment, etc.). More recently, the availability of large amounts of text data has led to unsupervised approaches for learning a good distributed representation for words. Techniques like Word2Vec [34] and Glove [38] have produced pre-trained embeddings for words that can be combined with more complex neural approaches.

The success of these approaches are later combined with the power of recurrent neural networks (RNNs) which led others to learn distributed representations of a larger piece of text like sentences [26], paragraphs [28], and documents [25]. Several variants of RNNs like convolutional-gated RNN [45], tree-LSTM [44] and Quasi-RNN [10] are proposed as alternative architectures. Apart from recurrent neural networks, methods employing convolutional networks [23, 49] have also produced compelling results for text classification tasks.

Recently, authors in [48] have argued that the hierarchical structure of documents helps to learn better representations. Acknowledging that the importance of words or sentences may vary depending on the context, they use an attention mechanism [5] while hierarchically encoding words into sentences and sentences into documents. In addition to the hierarchical structure, discourse structure [32] in the text, which represents the linguistic organization of a text as a tree, has also been studied in recent document representation work [8, 22, 29].

Each of these lines of research are based solely on the textual content assuming that the documents are plain-text. In this paper, we focus on machine-generated emails which have a rich HTML structure. In addition to leveraging the textual context, we encode the structural markup to learn a better representation. Note that in our work, the term "structure" corresponds to a formatting structure of an email, rather than the linguistic structure mentioned above. Combining our framework with the aforementioned architectures is possible and makes for promising future work.

Learning good email representations has been an area of interest for multiple research groups [2, 14, 41]. In addition to information extraction, email classifiers are useful for other applications like automatic foldering [6, 19], spam classification [13], and message priority ranking [1].

Lastly, systems like Fonduer [46] tackle richly formatted documents for the task of Knowledge Base Construction (KBC). Fonduer shows that augmenting textual features with structural and visual features produced by a library that parses the HTML markup and providing it to a strong baseline like a bi-directional LSTM with attention can indeed provide a significant improvement over just using the text features. Our results agree with the findings in Fonduer – formatting information does indeed help us learn a better representation for an email. In contrast to the approach of engineering a set of structural features (examples from Fonduer include HTML tag of the term, HTML tag of the parent, tabular features like row number, column number, n-grams from all the cells in the same row) our approach simply relies on learning an encoding using the sequence of HTML tags that appear in the path from the root to the node containing the term. Our results show that this is a powerful approach when combined with well-known building blocks like LSTMs and an attention mechanism. While we do not implement the nearly 40 structural, tabular, and visual features implemented in Fonduer, an interesting piece of future work is to study if XPath encodings as learned by our model can be as effective as the sophisticated features manually engineered in Fonduer.

6 CONCLUSION

In this paper, we study the problem of learning representations for richly structured emails. Considering the fact that most of today's emails are machine generated, we argue the rich formatting used in these emails contains highly valuable information that can be used to learn better representations. To address this gap in the literature, we proposed a novel framework called RiSER. Our framework combines three components from the email in order to learn an enhanced email representation: 1) textual content, 2) HTML structure, 3) manual annotation features. We show the effectiveness of our approach by evaluating the individual components as well as the full framework on email classification task across two datasets from a large email service. The experimental results and visualizations further indicate that our framework is learning an improved representation for emails and is capable of capturing valuable information buried in the email's HTML structure.

We are exploring multiple avenues of future research. We expect that leveraging structure will be valuable for other challenging tasks like information extraction from emails and web pages. We are considering ways to extend the RiSER framework to other types of documents with rich structure. For instance, PDFs and scanned images contain many informative layout and structural signals. However such documents do not contain XPath-style markup. We are exploring alternative ways to represent the layout and formatting information from such documents.

Reputation Deflation Through Dynamic Expertise Assessment in Online Labor Markets

Marios kokkodis
Boston College
kokkodis@bc.edu

ABSTRACT

Current reputation systems in online labor markets (e.g., Freelancer, PeoplePerHour) experience three major shortcomings: (1) reputation inflation (i.e., reputation scores are inflated to "above average" values) (2) reputation attribution (i.e., attribution of reputation scores to individual skills is unfeasible) and (3) reputation staticity (i.e., reputation scores are uniformly averaged over time). These shortcomings render online reputation systems uninformative, and sometimes even misleading. This work proposes a data-driven approach that deflates reputation scores by solving the problems of reputation attribution and saticity. The deflating process starts with projecting any random set of skills to a set of competency dimensions. For each competency dimension, a Hidden Markov Model estimates a contractor's current (but latent) competency-specific expertise. Aggregation of competency-specific estimates provides expertise predictions for any given set of required skills. Empirical analysis on 61,330 completed tasks from a major online labor market shows that the resulting estimates are deflated and they better predict contractor performance. These results suggest a series of implications for online (labor) markets and their users.

1 INTRODUCTION

Online labor markets such as Peopleperhour and Freelancer connect buyers with contractors around the globe to accomplish a diverse set of tasks. These tasks span multiple categories, including web development, graphic design, accounting and sales and marketing. On par with other online platforms, online labor markets have experienced an accelerated growth in the past decade [43]. A typical transaction in these markets starts with a buyer posting a job description. Contractors who are looking for opportunities submit their job applications to relevant jobs. The buyer then chooses to hire one (or more) contractor(s) from the pool of applicants. Once hired, the contractors complete the task and receive the prearranged compensations.

To identify the best candidate for each opening, buyers assess a series of observed and latent characteristics of the available contractors. Observed characteristics include the contractors' skills, work histories, and certifications. Latent characteristics include the contractors' true knowledge and abilities. The existence of latent characteristics, the heterogeneity that appears in the observed ones [26], and the interactions between the two create an uncertain environment of information asymmetry [4].

To reduce information asymmetry and help buyers make better-informed hiring decisions, online labor markets have developed reputation systems. Contractors get rated for the tasks they complete, and these ratings become part of their online resumes. Buyers then consider the contractors' past performance as a signal for future performance. In theory, such reputation mechanisms should inform and facilitate buyers' choices. In practice however, current reputation systems experience three major shortcomings:

- Reputation inflation: In online labor markets, raters feel pressure to rate "above average" [14]. At the same time, contractors who receive low ratings are unable to get hired. As a result, they leave the market and look for alternatives, or rejoin with different credentials [20]. These two synergic forces result in a highly inflated rating distribution [14, 19].
- Reputation attribution: Current reputation systems in online labor markets provide a uni-dimensional accumulated reputation score for each contractor [41]. Because these markets support heterogeneous distributions of skills and qualifications [26], accurate attribution of accumulated reputation scores to individual skills is unfeasible. For instance, consider a contractor who completes a task that requires `java`, `SQL` and `python` and receives a feedback score 9/10. Does this score capture the contractor's performance on `java`, on `SQL`, on `python`, or on any combinations of those skills?
- Reputation staticity: Over time, contractors evolve, as they gain expertise on skills that they repeatedly use. Current reputation systems however uniformly average received ratings to provide an aggregate score, thereby assuming that the latent expertise of a contractor does not change over time [27].

The end result of these shortcomings is that current reputation scores are often uninformative and sometimes even misleading.

This work proposes a data-driven framework that directly solves reputation attribution and reputation staticity, and, indirectly, deflates the reputation distribution. The framework first incorporates

word embeddings to project skills into a set of competency dimensions. For each one of these competency dimensions a Hidden Markov Model (HMM) uses observed signals to dynamically estimate a contractor's competency-specific level of expertise. These estimates are a solution to reputation attribution, as they map expertise to specific skillsets. Because the HMMs allow contractors to dynamically evolve to various expertise states, they provide *current* estimates of expertise (solution to reputation staticity). Aggregation of competency-specific expertise estimates provides expertise predictions for any given set of required skills (HMM-W2V reputation).

In theory, compared to current reputation scores in online labor markets, HMM-W2V reputation should be closer to the true expertise of contractors on a given set of skills. Since these markets attract millions of contractors of various abilities, HMM-W2V reputation is likely to form a deflated, Paretian distribution [38]. Empirical evaluation of the HMM framework on 61,330 completed tasks from a major online labor market shows that, compared to current reputation scores, HMM-W2V reputation is (1) deflated, and (2) a better predictor of contractor performance on a any given set of skills.

This work is the first to propose a data-driven solution that dynamically estimates contractors' expertise in online labor markets. Competency-specific estimates provide deflated scores for the dynamic expertise of contractors on any given set of skills. These estimates can improve an online labor market's transaction efficacy through better and more relevant candidate recommendations [30]. Better-informed buyers are likely to make more successful hiring decisions (through accurate opening-specific expertise estimates) and as a result continue using the platform. At the same time, the market can better understand the demand and supply of experienced contractors in every competency dimension, and create any necessary interventions. Finally, the proposed framework generalizes beyond online labor markets, and it is directly applicable to other markets that suffer from reputation inflation, such as Amazon, Yelp, and TripAdvisor.

2 RESEARCH CONTEXT

Digital markets signal the quality of their services (or products) through online reputation systems. The strong economic impact of these systems on product selection and quality assessment has been repeatedly verified in multiple contexts [1, 3, 12, 13, 23, 29, 44]. Next, we discuss the importance of reputation signals in the context of an online labor market.

2.1 Reputation in online labor markets

Buyers place a very significant weight on contractors' reputation when making hiring decisions [45], and they are willing to trade-off reputation and price to accept higher bids posted by more reputable contractors [36]. This trade-off is also observed on the contractor side, where the contractor's past performance has a significant impact on future wages [7]. Reputation can be a significant predictor of success for fixed-price contracts [32], and it can substantially improve contractors' subsequent employment outcomes [39]. Furthermore, reputation can capture latent qualities of a contractor that transfer across multiple task categories that require a diverse set of skills [27]. Overall, these works show that reputation drives both hiring decisions and subsequent task outcomes.

Table 1: Data summary

	Obs.	Min	Mean	Median	Max	StD
Hourly wage	61,330	3	13.6	11.1	219	10.6
Skills per user	671,340	1	9.6	9	61	5.9
Skills per opening	61,330	1	2.4	2	21	1.7
Applications	671,340					
Hires	61,330					
Openings	61,330					
Skills ($\mathbb{R}$)	215					
Unique skillsets	17,449					

Contractors come from 182 countries. The dataset spans 4 years.

2.2 Reputation inflation

Response bias, i.e., who chooses to rate a service, drives the overall rating of a service more so than the actual service characteristics [35]. One type of response bias is acquisition bias, which recognizes that buyers typically choose services that they expect to like [18]. This predisposition of buyers introduces a bias in the sample of users who are able to rate a service, which partially explains the observation that overall ratings tend to be positively inflated on most digital platforms [19].

Reputation inflation is present in online labor markets as well [14]. Even state-of-the art bilateral feedback systems [8] suffer from inflation [14]. However, acquisition bias might not be the only driving force of this inflation. One reason for this is "Customer death" [20]: users that receive low feedback scores leave the marketplace since they cannot get hired, and they either create new accounts and rejoin, or join alternative marketplaces to use. An alternative explanation is that raters likely feel pressure to assign good ratings due to inefficiencies of current reputation systems [14]. The proposed dynamic framework in this work tackles these inefficiencies from a design science perspective: it uses information from multiple observed signals in an online labor market to create a deflated, informative reputation.

2.3 Reputation as a signal of expertise

In theory, reputation systems resolve information asymmetries by providing an accurate estimate of the service (or product) quality [12]. In the context of online labor markets, service quality is bound to the expertise of a contractor on a given set of skills. Hence, ideally, reputation scores in online labor markets should signal a contractor's level of expertise. In practice however, due to reputation inflation reputation attribution and reputation staticity, current reputation scores fail to accurate assess a contractor's expertise.

The focal framework of this study relies on accurate skillset-specific expertise assessment. Expertise is latent, and its assessment is a very hard task due to lack of observable signals [26]. Item Response Theory [16] is the classic test-based approach for assessing

expertise on a given set of skills. Other approaches use observational data to identify experts (in online communities) through analyses of networks [21, 40, 46] and static user profiles [6].

In the context of an online labor market there are multiple observed signals that draw a more complete picture of a contractor's expertise. Such signals include the total number of completed jobs and the contractor's premium (hourly compensation). Furthermore, through observing contractors over multiple years, online labor markets become aware of dynamic changes in user profiles (e.g., new skill acquisitions, wage fluctuations, etc.). The proposed framework incorporates these observed signals to estimate the up-to-date expertise of a contractor on any given set of skills.

3 REPUTATION INFLATION IN AN ONLINE LABOR MARKET

The focal data forms a snapshot of 671,340 job applications that led to 61,330 completed tasks by 17,510 contractors from a major online labor market, `GigWork` (pseudonym). `GigWork` supports a diverse set of tasks, including software and web development, writing and translation, sales and marketing, data science, etc. The dataset spans four years, and it considers only contractors who have completed two or more tasks. For these contractors the dataset includes complete information, including any new skill acquisition, and the complete set of their job applications.

Table 1 summarizes the dataset. Overall, the contractor profiles and job openings span across 215 skills. The contractors come from 182 different countries, and they complete tasks for which they earn between $3 and $219 per hour.

On `GigWork`, buyers rate contractors after the completion of a task with a score $Y \in \{0, 1/9, 2/9, \ldots, 9/9\}$. The platform supports a state of the art reputation system: The buyer and the contractor each gets two weeks to leave their feedback score – however this is a double blind process: neither party learns its own rating before leaving a rating for the other party. Figure 1 shows the resulting accumulated feedback distribution on `GigWork`. The mean of this distribution is 0.96 and the median 0.98. Simply put, most of the contractors appear to have an almost perfect reputation. Hence, it is fair to say that `GigWork` suffers from reputation inflation.

At the same time, the heterogeneity in terms of skills and qualifications on the platform in combination with the fact that feedback scores are assigned uniformly (reputation attribution) adds to the noise of the inflated distribution. Figure 2 shows that skills accumulate vastly different feedback scores: from `translation`, with median 1 and mean 0.91, to `twitter-marketing` with median 7/9 and mean 0.74. This variation suggests that there is a need for skill-specific reputation.

4 PROBLEM FORMULATION AND METHODOLOGY

Independent contractors in an online labor market are on the lookout for suitable opportunities. When they find good matches, contractors submit job applications and (some of them) eventually get hired. Once hired, they complete the assigned tasks and receive a pre-arranged compensation along with the respective performance feedback scores. Due to inefficiencies of current reputation systems,

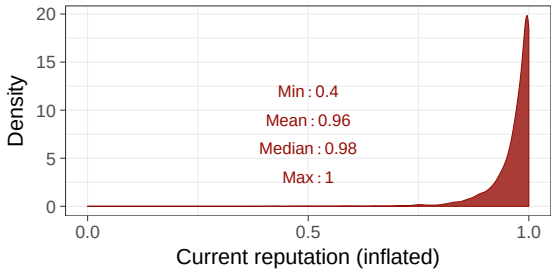

Figure 1: Reputation inflation on `GigWork`. Accumulated contractor feedback scores are skewed to the right. The mean is 0.96 and the median 0.98.

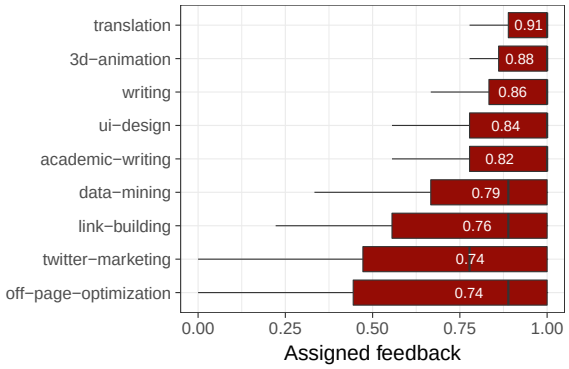

Figure 2: Boxplots of assigned feedback scores for a subset of skills. Each boxplot includes the mean feedback score for the respective skill.

performance feedback scores are inflated (Figure 1), and have high variability across different skills (Figure 2).

Problem definition: *Given a contractor's history on the market, our goal is to estimate a score that captures the current, deflated and true contractor's expertise on any given set of skills.*

The proposed framework (`HMM-W2V-framework`) consists of three components. The first component focuses on decomposing skills into competency dimensions that allows the framework to generalize and accommodate any arbitrary number of skills. The second component presents a dynamic model that combines multiple signals to estimate a contractor's current, competency-specific expertise. The final component aggregates competency-specific predictions to get a current estimate of the contractor's expertise on any arbitrary set of skills. Figure 3 draws the interconnections of these three components, which we describe in detail next.

4.1 Component A: Skills decomposition

Buyers can request contractors with any arbitrary combination of skills. This creates a space of tens of thousands of available combinations of unique skillsets (Table 1). Theoretically, we could directly estimate the expertise of a contractor on any observed

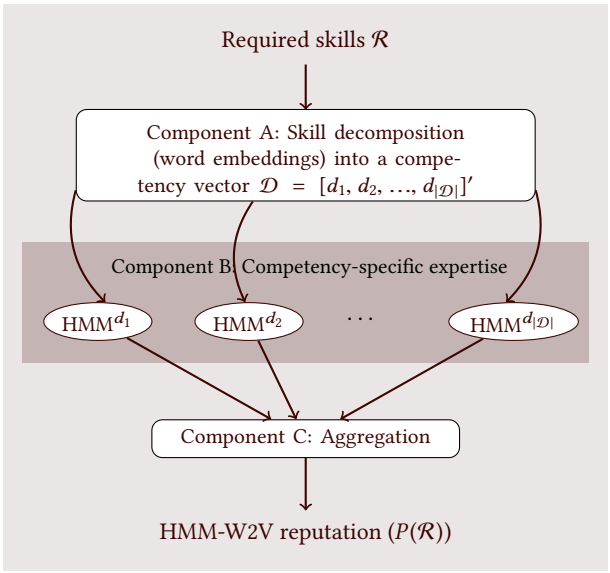

Figure 3: The three components of the `HMM-W2V-framework`. Component A maps any set of skills to competency dimensions through word embeddings. Component B provides dynamic models (HMM) that make competency-specific and up-to-date expertise estimates. Component C aggregates these estimates to provide a skillset-specific expertise assessment.

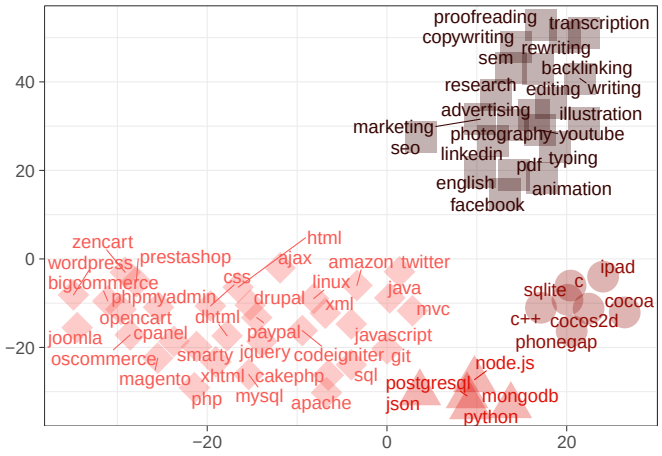

Figure 4: Visualization of mapped skills through W2V in a reduced, two dimensional space through stochastic neighbor embedding [17]. Contextually similar skills appear close to each other (e.g., `c++, c, sqlite`), while contextually dissimilar skills appear far away from each other (e.g., `mongodb` vs. `proofreading`).

skillset. There are three major drawbacks of this approach: first, independent of the size of the data analyzed, considering only skillset-specific observations will result in very sparse training datasets. Second, expertise is transferable [25, 27] and many skillsets are highly correlated. Third, an entrance of new skills would require retraining of the complete framework from scratch.

To overcome these shortcomings we use a distributed representation of words model (word embeddings–W2V) [2, 33] that projects individual skills into a set of competency dimensions. W2V embed words from a vocabulary into a lower dimensional space (i.e., competency dimensions), in which semantically similar words appear close to each other, while semantically dissimilar words appear far away from each other [33]. In the context of an online labor market, a "skill" maps to a "word," and a "skillset" to a "document." Based on this representation, W2V projects contextually similar skills close to each other in the $|\mathcal{D}|$-dimensional space of competencies. (The actual number of competency dimensions $|\mathcal{D}|$ is an input parameter.)

Figure 4 shows how a randomly selected subset of skills maps into a reduced two-dimensional space. The plot reveals hidden contextual similarities between skills; For instance it shows that buyers who request `c++` usually also request `sqlite`, while buyers who request `python` usually also request `mongodb`. The plot hence indicates that `python` is contextually closer to `mongodb` than `sqlite`.

The `HMM-W2V-framework` maps any observed skillset $\mathcal{R}$ into a $|\mathcal{D}|$-dimensional vector space of competencies (Figure 3). To do so, it aggregates competency-specific scores of each skill in a given skillset. Specifically, a skillset $\mathcal{R} = \{R_1, R_2, \ldots, R_{|\mathcal{R}|}\}$, $R_k \in \mathbb{R}$ maps to an aggregated representation as follows:

$$w^d_{\mathcal{R}} = \sum_{R \in \mathcal{R}} \text{W2V}^d(R), \quad \forall d \in \mathcal{D}\,, \tag{1}$$

where $w^d_{\mathcal{R}}$ is the d–competency score of skillset $\mathcal{R}$, and $\text{W2V}^d(R)$ is the W2V score for skill R in dimension d. (Alternatively, we could use a distributed memory model (document embeddings, D2V) [31]. In practice, W2V outperformed D2V in this context.)

4.2 Component B: Competency-specific expertise

At any given time (t), each participating contractor has a level of expertise in each available competency dimension $d \in \mathcal{D}$. This expertise is latent (unobserved). However, for each completed task with required skills $\mathcal{R}$ we observe a feedback score (Y_t) that the contractor receives, which maps into competency-specific scores $Y^d_t = w^d_{\mathcal{R}} Y_t, \forall d \in \mathcal{D}$. These scores ($Y^d_t$) form up-to-date proxies of the contractor's expertise in each competency dimension $d \in \mathcal{D}$.

In addition to latent, a contractor's expertise dynamically evolves with time. Contractors gain (or lose) expertise in any competency dimension through learning new skills, improving their knowledge in others, or by completely abandoning skills that the market deems obsolete. The `HMM-W2V-framework` formulates this evolution through a structured Hidden Markov Model (HMM [15, 28]). At any point in time t, contractors operate from a latent, competency-specific state, which determines their propensity to perform with score Y^d_t. Depending on these performance scores on completed tasks, contractors stochastically transition to new latent states. The framework assumes a set of $\mathcal{S}^d$ latent states that describe K^d different levels of expertise for each competency d, $\mathcal{S}^d$ =

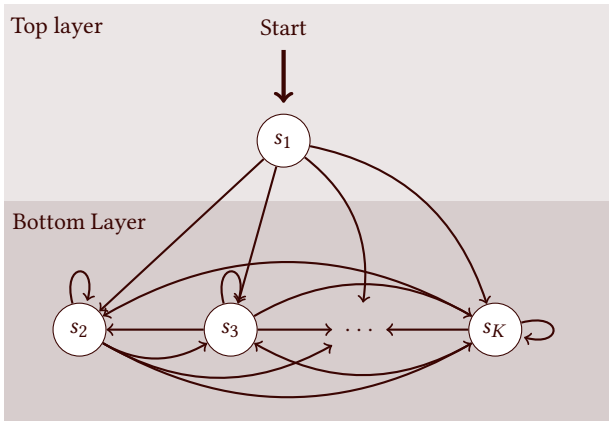

Figure 5: Two-layered structure of each competency-specific HMM. The top layer includes an initial state s_1, which clusters all contractors when they first join the platform. Once contractors start completing tasks, they emit observations and transition to an appropriate state in the bottom layer.

$\{s_1, s_2, \ldots, s_{K^d}\}$. The rest of the paper assumes that the unit of time (t) is a new completed task.

HMM structure: Every new contractor who joins the platform has a certain level of expertise across the competency dimensions $d \in \mathcal{D}$. As the contractor completes new tasks on the platform, we observe signals of the contractor's latent expertise. To capture this behavior, the `HMM-W2V-framework` imposes a two-layer structure: In the first layer, it assume only an initial latent state s_1, where all new contractors land. This state makes an average initial estimate of a contractor's competency-specific expertise. (Alternatively, contractors could land stochastically to one of the second layer states. This would add noise to the estimates, and as a result it could potentially hurt the performance of the framework.) Once the contractors complete their first job and emit an observation (i.e., $Y_1^d, \quad \forall d \in \mathcal{D}$), they stochastically transition to one of the $K^d - 1$ states of the second layer. Figure 5 presents the structure with the two layers and derives the possible transitions from each state.

To define an HMM for a given competency dimension d, we need (1) a vector of initial state probabilities $\boldsymbol{\pi}^d$, (2) a transition matrix T^d that stores the transition probabilities between states, and (3) an emission matrix E^d that describes the state-specific probability distributions for observations Y_t^d. Since every new contractor lands in state s_1, the initial probability vector of the HMM is the following:

$$\boldsymbol{\pi}^d = [1, 0, 0, ..., 0]' \ . \tag{2}$$

A contractor's history provides multiple observable signals that drive transitions to new expertise states (e.g., received feedback scores in previous tasks, total wages received, hiring rates, number of completed tasks). Such historical attributes define a vector $\boldsymbol{Z}_t^d$, which directly affects the transition probability matrix T^d. Formally, we define the transition probability of a given contractor for a given dimension to move from state s_k to state s_l at time t as follows:

$$\lambda^{d,s_k s_l}_{\boldsymbol{\gamma}_{kl}^d \boldsymbol{Z}_{t-1}^d} = \Pr(S_t^d = s_l | S_{t-1}^d = s_k; \boldsymbol{\gamma}_{kl}^d, \boldsymbol{Z}_{t-1}^d) = \text{softmax}(\boldsymbol{\gamma}_{kl}^d \boldsymbol{Z}_{t-1}^d) \ . \tag{3}$$

In the previous Equation, $\boldsymbol{\gamma}_{kl}^d$ is the vector of coefficients of state s_k that define the weights of $\boldsymbol{Z}_{t-1}^d$ in estimating the transition probability to state s_l.

Because of the HMM structure (Figure 5), the transition matrix is not completely filled with elements of Equation 3. Specifically, at time t, the transition matrix has the following form:

$$T^d(\boldsymbol{\Gamma}^d, \boldsymbol{Z}_{t-1}^d) = \begin{bmatrix} 0 & \lambda^{d,s_1 s_2}_{\boldsymbol{\gamma}_{12}^d \boldsymbol{Z}_{t-1}^d} & \cdots & \lambda^{s_1 s_{K^d}}_{\boldsymbol{\gamma}_{1K^d}^d \boldsymbol{Z}_{t-1}} \\ 0 & \lambda^{d,s_2 s_2}_{\boldsymbol{\gamma}_{22}^d \boldsymbol{Z}_{t-1}^d} & \cdots & \lambda^{d,s_2 s_{K^d}}_{\boldsymbol{\gamma}_{2K^d}^d \boldsymbol{Z}_{t-1}^d} \\ \vdots & \vdots & \vdots & \vdots \\ 0 & \lambda^{d,s_{K^d} s_2}_{\boldsymbol{\gamma}_{K^2}^d \boldsymbol{Z}_{t-1}^d} & \vdots & \lambda^{s_{K^d} s_{K^d}}_{\boldsymbol{\gamma}_{K^d K^d}^d \boldsymbol{Z}_{t-1}^d} \end{bmatrix} , \tag{4}$$

where $\boldsymbol{\Gamma}^d = [\boldsymbol{\gamma}_{11}^d, \boldsymbol{\gamma}_{12}^d, \ldots, \boldsymbol{\gamma}_{K^d K^d}^d]'$.

Similarly, current, opening-specific observed characteristics (e.g., bidding price or whether or not a contractor has been invited to apply) drive the observed emissions of the HMM (matrix E^d). These characteristics form a vector $\boldsymbol{X}_t^d$ which affects the elements of the emission matrix. Formally, the conditional probability of observing Y_t^d given the current state of the contractor S_t^d is:

$$\Pr(Y_t^d | S_t^d = s_k; \boldsymbol{\theta}_k^d, \boldsymbol{X}_t^d) = f^d(\boldsymbol{\theta}_k^d \boldsymbol{X}_t^d) \ , \tag{5}$$

where $f^d(.)$ is a continuous probability distribution (e.g., Gaussian), and $\boldsymbol{\theta}_k^d$ is the parameter vector of the continuous distribution for state k and competency d. The vector of complete parameter vectors $\boldsymbol{\Theta}^d$ (for all states $s_k \in \mathcal{S}^d$) is as follows:

$$\boldsymbol{\Theta}^d = [\boldsymbol{\theta}_1^d, \boldsymbol{\theta}_2^d, ..., \boldsymbol{\theta}_{K^d}^d]' . \tag{6}$$

HMM identification: Given the structure of the HMM the focus turns on estimating the parameter vectors $\boldsymbol{\Theta}^d, \boldsymbol{\Gamma}^d$. To do so, we maximize the conditional probability of the set of observations given the HMM. (For simplicity, in the following analysis we drop the superscript d. However, keep in mind that this estimation process happens independently for each dimension $d \in \mathcal{D}$.)

Let us assume that we have the following sequence of M observations for a given contractor i:

$$\boldsymbol{Y}_i = Y_{i1}, Y_{i2}, \ldots, Y_{iM} \ . \tag{7}$$

These observations correspond to a sequence of input vectors:

$$\boldsymbol{X}_{1:M} = \boldsymbol{X}_1, \boldsymbol{X}_2, \ldots, \boldsymbol{X}_M \ . \tag{8}$$

Furthermore, let us assume that $\boldsymbol{Y}_i$ is the result of a sequence of latent states, $\boldsymbol{S}_i$:

$$\boldsymbol{S}_i = S_{i1}, S_{i2}, \ldots, S_{iM} \ , \tag{9}$$

where $S_{im} \in \mathcal{S}$. This sequence of states is affected by the sequence of historic vectors $\boldsymbol{Z}_{1:M-1}$:

$$\boldsymbol{Z}_{1:M-1} = \boldsymbol{Z}_1, \boldsymbol{Z}_2, \ldots, \boldsymbol{Z}_{M-1} \ . \tag{10}$$

Figure 6 shows these sequences along with their interactions. Based on the structure of the graph, we get the conditional likelihood of observing sequence $\boldsymbol{Y}_i$:

$$\Pr(\boldsymbol{Y}_i | \boldsymbol{S}_i; \boldsymbol{\Theta}, \boldsymbol{X}_{1:M}) = \prod_{t=1}^{M} \Pr(Y_{it} | S_{it}; \boldsymbol{\Theta}, \boldsymbol{X}_t) \ , \tag{11}$$

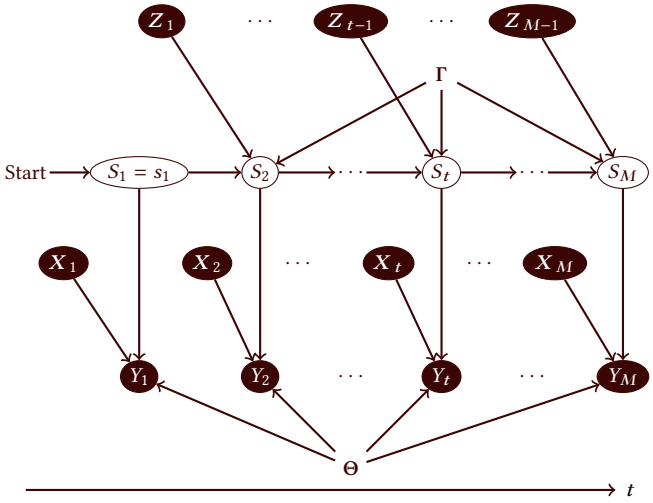

Figure 6: Temporal evolution of the HMM. The structure of the latent state sequence S_i, the observed sequence of outcomes Y_i, the parameter vectors Θ, Γ, and the sequences of input vectors $X_{1:M}, Z_{1:M-1}$ for a given contractor i. For better readability we have dropped the contractor subscript i and the competency superscript d. As with traditional probabilistic graphical models, latent states are in clear ellipses, and observed features in shaded ones.

where Equation 5 estimates the right hand side. From Figure 6, the conditional probability of observing the sequence S_i is:

$$\Pr(S_i|\Gamma, Z_{1:M-1}) = \boldsymbol{\pi}(S_1) \prod_{t=2}^{M} \Pr(S_{it}|S_{it-1}; \Gamma, Z_{t-1}) \ , \tag{12}$$

where $\boldsymbol{\pi}(S_1)$ is the the prior probability of being at state S_1. Equation 3 estimates these transition probabilities. Since the structure of the HMM (Figure 5) imposes that every new contractor lands in state s_1 ($\boldsymbol{\pi}(S_1 = s_1) = 1$), the previous equation becomes:

$$\Pr(S_i|\Gamma, Z_{1:M-1}) = \prod_{t=2}^{M} \Pr(S_{it}|S_{it-1}; \Gamma, Z_{t-1}) \ . \tag{13}$$

Based on this analysis and the graph in Figure 6, the likelihood of this sequence of observations for contractor i is as follows:

$$\begin{aligned} l(Y_i; \Theta, \Gamma) &= \Pr(Y_i|\Theta, \Gamma, X_{1:M}, Z_{1:M-1}) \\ &= \sum_{\forall S_i} \Pr(Y_i, S_i|\Theta, \Gamma, X_{1:M}, Z_{1:M-1}) \\ &\overset{\text{Figure 6}}{=} \sum_{\forall S_i} \Pr(Y_i|S_i; \Theta, X_{1:M}) \Pr(S_i|\Gamma, Z_{1:M-1}) \\ &= Pr(Y_{i1}|S_{i1}; \Theta, X_1) \\ &\times \sum_{\forall S_i} \prod_{t=2}^{M} \Pr(Y_{it}|S_{it}; \Theta, X_t) \\ &\times \Pr(S_{it}|S_{it-1}; \Gamma, Z_{t-1}), \end{aligned} \tag{14}$$

where we used the structure of the HMM to decompose the joint probability of $\Pr(Y_i, S_i|\Theta, \Gamma, X_{1:M}, Z_{1:M-1})$. Then, the complete likelihood for a dataset with N contractors is:

$$L(\Theta, \Gamma) = \prod_{i=1}^{N} l(Y_i; \Theta, \Gamma) \ . \tag{15}$$

Maximization of this likelihood estimates the parameters Θ, Γ. We do this numerically through the limited memory Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm [9]. (In practice we minimize the negative log-likelihood.)

Table 2: Descriptive statistics for the attributes in vectors X, Z, and the outcome variable Y_{it}.

		Mean	Median	StD	Min	Max
	Observed outcome (Y_{it})	0.86	1	0.22	0	1
Vector Z_t	Current reputation (FB_{it})	0.96	0.98	0.05	0.4	1
	Total money earned ($)	202	44	883	3	56,433
	Completed jobs	3.14	2	2.17	2	39
	Hiring rate	0.20	0.09	0.26	0.002	1
Vector X_t	Invited	0.3	0	0.46	0	1
	Hourly bid ($)	11.93	8.89	12.31	3	400
	Buyer's reputation	0.93	1	0.13	0	1
	Rehires	0.02	0	0.1	0	1

4.3 Component C: Aggregation

This process happens independently for each competency dimension $d \in \mathcal{D}$. As a result, for a given contractor i, each HMM estimates a current (t) competency-specific expertise (p_{it}^d). To predict the expertise of a contractor for a given opening with a set of required skills $\mathcal{R}$ the `HMM-W2V-framework` aggregates the available competency-specific estimates. Let us define a vector with all the competency-specific weights for the opening at hand (Equation 1),

$$\boldsymbol{w}_{\mathcal{R}} = [w_{\mathcal{R}}^1, w_{\mathcal{R}}^2, ..., w_{\mathcal{R}}^{|\mathcal{D}|}]' \ , \tag{16}$$

and a vector with the competency-specific expertise estimates,

$$\boldsymbol{p}_{it} = [p_{it}^1, p_{it}^2, ..., p_{it}^{|\mathcal{D}|}]' \ . \tag{17}$$

The aggregated expertise for skillset $\mathcal{R}$ is then the inner product of the two:

$$P_{it}(\mathcal{R}) = \langle \boldsymbol{w}_{\mathcal{R}} \cdot \boldsymbol{p}_{it} \rangle \ . \tag{18}$$

5 IMPLEMENTATION DETAILS AND RESULTS

Next, we discuss the implementation details and the performance of the `HMM-W2V-framework`.

5.1 Features

Figure 6 shows how vectors $\mathbf{Z}_t$ and $\mathbf{X}_t$ affect the transitions and the emissions of the HMM respectively. What variables compose these two vectors?

Transition probabilities to new states are driven by the framework's current expertise estimate of any given contractor. Even

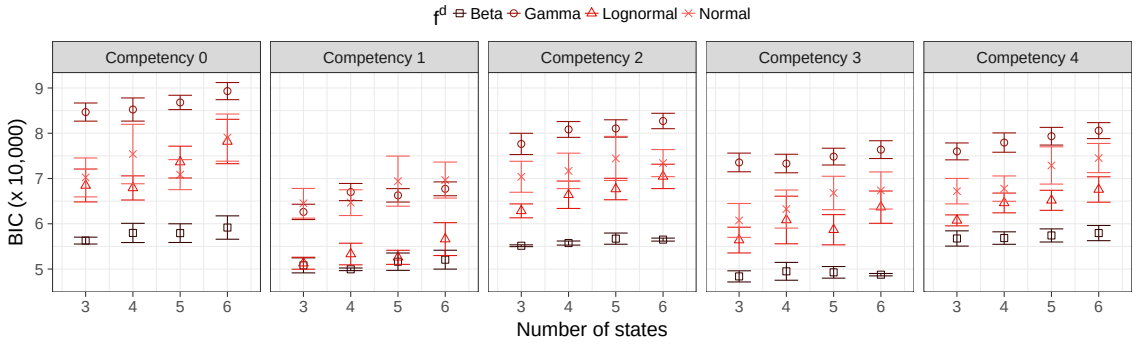

Figure 7: Number of states selection and choice of function f^d, for the five competency dimensions $d \in \mathcal{D}$. Error bars represent 95% confidence intervals.

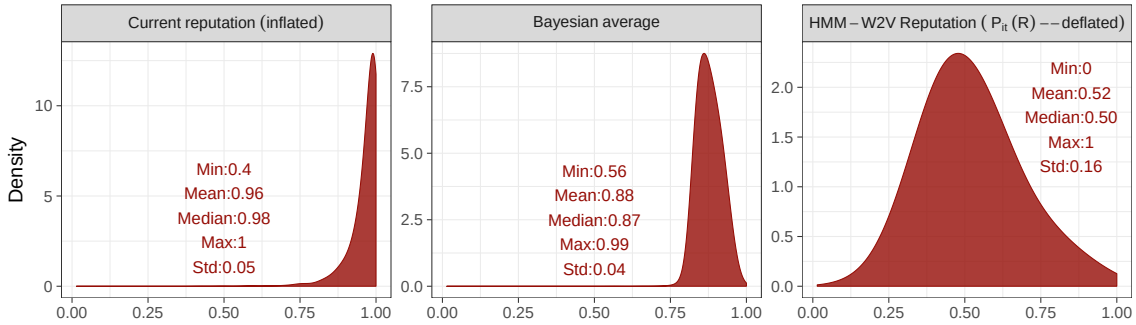

Figure 8: Reputation deflation: Distributions of the inflated current reputation (left), Bayesian average (middle), and HMM-W2V reputation (right).

Table 3: Regression analysis of the `HMM-W2V-framework` and the two baselines.

DV: Observed rating	(A1)	(A2)	(A3)	(A4)	(A5)	(A6)	(A7)	(A8)
Current reputation	-0.004	-0.097***					-0.017*	-0.108***

						(0.08)		(0.08)
R^2	0.000	0.001	0.000	0.000	0.010	0.010	0.010	0.012

Robust standard errors in parentheses. The constant term is estimated but omitted from the table. ($^{***}p-$value < 0.001, $^{**}p-$value < 0.01, $^{*}p-$value < 0.05).

though actual expertise is latent, online labor markets provide observed signals that are correlated with expertise. Such signals form vector $\mathbf{Z}_t$, and include the accumulated feedback score, the total amount of received wages, the hiring rate of the contractor, and the total number of completed jobs. For each competency $d \in \mathcal{D}$, the `HMM-W2V-framework` customizes these signals by weighing them with $w^d_{\mathcal{R}}$. (Note that these signals are estimated at time $t-1$, i.e., at the completion of task $t-1$.)

Similarly, emission probabilities are affected by other, opening-specific characteristics that are not directly related to the latent expertise of the worker (feature vector $\mathbf{X}_t$). Such characteristics are whether or not the contractor has been invited to apply to the specific opening, the bidding price of the contractor, the number of times that a contractor has previously worked with the buyer at hand, and the focal employer's reputation.

Table 2 shows the descriptive statistics of the variables that form vectors $\boldsymbol{X}_t, \boldsymbol{Z}_t$, as well as the outcome variable Y_t.

5.2 Modeling choices and parameter estimation

For the purposes of this study, we pick the number of competency dimensions to be $|\mathcal{D}| = 5$. (In practice, engineers can experiment with various competency dimensions – however, to keep the analysis focused, we only present results for $|\mathcal{D}| = 5$.) We split the dataset into training (66%) and test sets (34%) based on contractors (i.e., the sequence of outcomes of each contractor can only be in either the test or the training set, but not in both). We use the training set to estimate the parameters of the framework and to choose appropriate functions. We then use the test set to evaluate the performance of the framework.

Function f^d (Equation 5) and the number of states (K^d) for each competency are fundamental choices for the implementation of the framework. To make the best possible choices, we estimate the configurations that yield the smallest Bayesian information criterion (BIC) scores in the training set [37]. In particular, the framework considers the following continuous probability distributions for modeling function f^d:

$$f^d \in \{\text{ Gaussian, Gamma, Beta, LogNormal}\}\ \forall d \in \mathcal{D}\ , \qquad (19)$$

and the following set of number of states:

$$K^d \in \{2, 3, ..., 6\}, \forall d \in \mathcal{D}\ . \qquad (20)$$

For each combination in $\{K^d \times f^d\}$, we estimate the the set of parameters $\boldsymbol{\Theta}^d, \boldsymbol{\Gamma}^d$ that maximize the likelihood of Equation 15. Because the optimization process depends on the initialization of $\boldsymbol{\Theta}^d, \boldsymbol{\Gamma}^d$, it is prone to stuck in local maxima. To increase the likelihood of reaching a potential global maximum, we conduct a search of 1,000 random initializations for each combination in $\{K^d \times f^d\}$. Finally, for each competency dimension $d \in \mathcal{D}$ we pick the configuration that yields the lowest BIC score.

Figure 7 shows the BIC scores for a series of configurations, for each one of the five competencies we consider. In terms of the emission function f^d, Beta seems to perform statistically significantly better than the other three choices, for competencies 0,2,3,4. In competency 1, Beta performs on par with the Lognormal distribution. In terms of number of states selection, none of the available choices is statistically significantly better than the rest (given f^d =Beta). The configurations that yielded the minimum BIC scores are:

- Competency-0: $K^0 = 6$ states, f^0 =Beta emissions.
- Competency-1: $K^1 = 3$ states, f^1 =Beta emissions.
- Competency-2: $K^2 = 4$ states, f^2 =Beta emissions.
- Competency-3: $K^3 = 6$ states, f^3 =Beta emissions.
- Competency-4: $K^4 = 4$ states, f^4 =Beta emissions.

After estimating the parameters and choosing the states k^d and functions f^d, the `HMM-W2V-framework` is ready to estimate the latent expertise of the contractors in the test set.

5.3 Results

Because contractors' levels of expertise are latent, the evaluation of the `HMM-W2V-framework` is not straightforward. Recall that the main goal of this study is to estimate scores that (1) are not inflated (like the current reputation scores), and (2) they capture the up-to-date expertise of contractors on any arbitrary set of skills. Testing whether the `HMM-W2V-framework` deflates reputation is straightforward through estimating and plotting the resulting distribution of $P_{it}(\mathcal{R})$. To evaluate whether the information of HMM-W2V reputation is more accurate than current reputation, we use as ground truth the observed outcomes of each task in the test set.

Baselines: Two baseline algorithms form a benchmark for the HMM-W2V reputation. The first one, is the current accumulated feedback score of `GigWork`. The second baseline is a Bayesian average of current reputation, which is frequently used for ranking items with star ratings [10, 34]. The Bayesian average for contractor i at time τ is as follows:

$$\text{Bayesian average:} BA_{i\tau} = \frac{h_{\text{tasks}} h_{\text{fb}} + \sum_{t=1}^{\tau-1} Y_{it}}{h_{\text{tasks}} + (\tau - 1)}\ , \qquad (21)$$

where h_{tasks} and h_{fb} are priors for the number of completed tasks per contractor and the contractor outcomes respectively. We set these priors to the mean values of the training set.

Reputation deflation: Figure 8 compares the distributions of the two baselines and the HMM-W2V reputation. Visually, the two baseline distributions are shifted to the right, while the focal HMM-W2V reputation distribution is almost centered at 0.5. While the two baselines take values in [0.4,1] (current reputation) and [0.56.0.99] (Bayesian average), HMM-W2V reputation deflates these scores to [0,1]. The mean of current reputation is 0.96, while Bayesian average brings this mean down to 0.88. However, the mean of HMM-W2V reputation is down to 0.52. Finally, while the two baselines have low variation (Standard deviation around 0.05), the deflated distribution clearly ranks contractors in the available space, with a standard deviation (0.16) 3.2 times higher than the baselines.

HMM-W2V reputation accuracy: The deflated distribution would have had very little value if the deflated HMM-W2V reputation was not a better (than the baselines) representation of the latent contractor expertise. Four metrics test this:

- Regression analysis: Does HMM-W2V reputation better explain the observed outcomes Y_{it} than the two baselines?
- Predictive analysis: Does HMM-W2V reputation better predict the observed outcomes Y_{it} than the two baselines?

Table 4: Predictive performance of the `HMM-W2V-framework` compared to the two baselines.

	Predictive analysis		Ranking correlations		Mutual Information
	MAE	MSE	Kendall τ	Spearman's rank	
Current reputation	0.17 ± 0.007	0.061 ± 0.001	0.07^{***}	0.05^{***}	0.006
Bayesian average	0.18 ± 0.007	0.061 ± 0.001	0.01^{**}	0.01^{**}	0.006
HMM-W2V reputation	0.14 ± 0.003	0.057 ± 0.001	0.12^{***}	0.09^{***}	0.016
Improvement over baselines	16%-17%	7%	71%-1100%	80% - 800%	166%

(95% Confidence intervals for MAE and MSE. $^{***}p-$value < 0.001, $^{**}p-$value < 0.01.)

- Ranking correlation: Does HMM-W2V reputation rank contractors better than the two baselines?
- Mutual information: Does HMM-W2V reputation and the observed outcomes Y_{it} yield higher mutual information than the two baselines?

For the regression analysis we estimate the following specification:

$$Y_{it} = c_1 + \boldsymbol{c_2}\text{poly}(P_{it}(\mathcal{R}), 2) + \boldsymbol{c_3}\text{poly}(FB_{it}, 2) + \boldsymbol{c_4}\text{poly}(BA_{it}, 2)\ , \quad (22)$$

where poly(x,2) estimates the first and second order of variable x. Table 3 shows the results. These models use the complete test set to estimate the necessary parameters. Columns (A1,A2) show models that consider only current reputation scores (FB_{it}). Columns (A3,A4) show models that consider only Bayesian average scores (BA_{it}). Columns (A5,A6) show models that consider only HMM-W2V reputation scores ($P_{it}(\mathcal{R})$). The comparison shows that HMM-W2V reputation has higher explanatory power than the two baselines, as it yields more than 10 times greater R^2, while coefficients $\boldsymbol{c_2}$ are consistently statistically significant ($p < 0.001$). Models (A7,A8) show how the six variables behave when we estimate the complete specification of Equation 22. Again, the coefficients of HMM-W2V reputation remain large and statistically significant ($p < 0.001$).

Models A2, A4 and A6 in Table 3 test the predictive performance of the three reputation scores. Table 4 shows the 10-fold cross validation Mean Absolute Error (MAE) and Mean Squared Error (MSE) for the three models. The last row shows the percentage improvement of the HMM-W2V reputation over the two baselines. For both metrics HMM-W2V reputation outperforms the two baselines, showing an improvement (decrease in errors) between 7% and 17%.

A correct expertise assessment should rank contractors according to their likelihood of performing good in any given opening with required skills $\mathcal{R}$. Two ranking correlation coefficients (Kendall τ [22], Spearman's rank [42]) test the ordinal associations between expertise estimates and observed outcomes. Table 4 shows the clear superiority of HMM-W2V reputation over the two baselines.

Finally, mutual information measures the dependence between two variables [11]. Observed outcomes should be dependent to an accurate expertise estimate. Table 4 shows that observed outcomes are 166% more dependent to HMM-W2V reputation compared to the two baselines.

Overall, the empirical analysis in this section shows a clear superiority of the HMM-W2V reputation over the two baselines, both in terms of deflating reputation scores and estimating the latent contractor expertise (accuracy). This promising performance of the `HMM-W2V-framework` suggests important implications for online (labor) markets and their users. We discuss these next.

6 IMPLICATIONS

Deflated reputation scores help (1) contractors to differentiate, (2) buyers to make better-informed and faster (reduced search cost [5]) decisions, and (3) the market to build more accurate recommendation algorithms but also to better understand the supply distributions across latent competencies. When contractors can be accurately differentiated, the quality of the supply side of the market naturally increases. High-quality contractors are more likely to keep participating, when low-quality contractors could potentially give space to newcomers. When buyers make better-informed (and faster) decisions that lead to better outcomes become more likely to keep participating in the market. At the same time, markets can improve the performance of their recommendation algorithms by using HMM-W2V reputation as an additional feature. Better recommendations imply higher income and higher transaction efficacy [24, 30]. Finally, through studying the resulting HMM-W2V reputation, markets can get a better picture of the distribution of skills and abilities, and intervene where they think appropriate (e.g., through targeted advertising on skills that there is a deficit).

Besides the direct implications to online labor markets, the `HMM-W2V-framework` can be adjusted and implemented in any online market that has similar rating distributions for products or services. Amazon for instance could deploy the proposed framework to deflate product ratings. In this scenario, the dimensions could be latent product characteristics, and the required skills could be the preferences of the buyer across these latent product characteristics. Similarly, reputation platforms such as Yelp and TripAdvisor could use this framework, as they could decompose venue features to latent dimensions and ask for user preferences across these dimensions.

In conclusion, we presented a framework that deflates reputation in online labor markets through solving reputation attribution and reputation staticity. Analysis of real hiring decisions from an online labor market showed a clean superiority of the proposed framework over current reputation and a Bayesian average baseline.

ABSTRACT

Question answering promises a means of efficiently searching web-based content repositories such as Wikipedia. However, the systems of this type most prevalent today merely conduct their learning once in an offline training phase while, afterwards, all parameters remain static. Thus, the possibility of improvement over time is precluded. As a consequence of this shortcoming, question answering is not currently taking advantage of the wealth of feedback mechanisms that have become prominent on the web (e. g., buttons for liking, voting, or sharing).

This is the first work that introduces a question-answering system for (web-based) content repositories with an on-line mechanism for user feedback. Our efforts have resulted in QApedia – a framework for on-line improvement based on shallow user feedback. In detail, we develop a simple feedback mechanism that allows users to express whether a question was answered satisfactorily or whether a different answer is needed. Even for this simple mechanism, the implementation represents a daunting undertaking due to the complex, multi-staged operations that underlie state-of-the-art systems for neural questions answering. Another challenge with regard to web-based use is that feedback is limited (and possibly even noisy), as the true labels remain unknown. We thus address these challenges through a novel combination of neural question answering and a dynamic process based on distant supervision, asynchronous updates, and an automatic validation of feedback credibility in order to mine high-quality training samples from the web for the purpose of achieving continuous improvement over time.

Our QApedia framework is the first question-answering system that continuously refines its capabilities by improving its now dynamic content repository and thus the underlying answer extraction. QApedia not only achieves state-of-the-art results over several benchmarking datasets, but we further show that it successfully manages to learn from shallow user feedback, even when the feedback is noisy or adversarial. Altogether, our extensive experimental evaluation, with more than 2,500 hours of computational experiments, demonstrates that a feedback mechanism as simple as a binary vote (which is widespread on the web) can considerably improve performance when combined with an efficient framework for continuous learning.

1 INTRODUCTION

Question-answering (QA) systems promise an efficient way to search content repositories, as both questions and answers are presented in natural language [38]. Use cases can include the vast majority of freely-available materials that have been developed on the web. Hence, question answering has been developed for traditional knowledge bases and knowledge graphs [e. g., 1, 2, 14, 41, 45] but also for unstructured open-domain content such as Wikipedia [3, 8, 11] and social media [7], as well as various domain-specific applications including Stack Overflow [4].

Content-based question answering widely assumes that answer extraction mechanisms are static; see the systems in [8, 11] as illustrative examples. This is in contrast to QA for knowledge bases, where a key objective involves building up the knowledge base itself [12, 16], as well as continuously updating the underlying decision rules for answering [2]. However, in the context of QA for linguistic content, such dynamic mechanisms are, to the best of our knowledge, non-existent.

This paper suggests a framework for content-based QA in order to bolster QA systems with dynamic capabilities: our framework aids continuous learning on the basis of a simple mechanism for user feedback. In fact, user feedback plays a prominent role in web-based systems, as a large proportion of websites now offer tools for social interaction. Examples include buttons for liking or sharing content (e. g., as on Instagram), as well as voting with an array of categorical emotions (e. g., as on Facebook) [25]. There have been previous attempts to utilize user interactions in classical information retrieval [5, 27] or knowledge bases [1], and yet there is a dearth of content-based QA systems that leverage user interactions.

Extending content-based QA with user feedback promises several benefits. When interacting with a QA system, the correct answer is unknown to a user, and yet it is fairly easy to judge whether

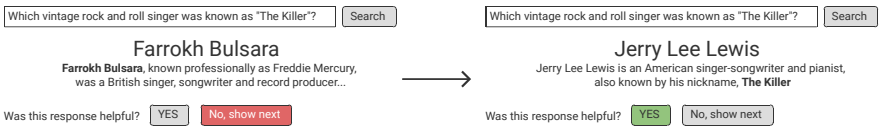

Figure 1: Illustrative sketch of shallow user feedback in question-answering for natural language. A simple credibility check is often sufficient in order to judge whether an answer makes sense in the given context.

an answer makes sense in the given context (see Fig. 1). In addition, shallow feedback in the form of a binary vote can be collected at low cost. It is especially low-cost in comparison to reverting to a human annotator in order to retrieve the correct label. Finally, the prevalence of feedback mechanisms on the web ensures that such user interactions have become widely intuitive.

Contributions: This work proposes QApedia: a neural question-answering framework for encyclopedic content that continuously improves on the basis of on-line user feedback. To the best of our knowledge, QApedia represents the first content-based QA system that improves over time. Our feedback framework advances the status quo of static QA systems while being specifically tailored to web-based settings:

(1) **Feedback for dynamic knowledge.** Content on the web is subject to considerable time variability and, hence, a QA system must adapt to this dynamic nature. To facilitate this, we develop an effective feedback mechanism so that the abilities of the QA system can successfully continue to improve over time. Our framework directly incorporates user feedback in an end-to-end loop: collected feedback is fed back into the system in an on-line fashion. As a key challenge during implementation, we must overcome the problem of catastrophic forgetting that is known in neural networks and thus also neural QA. For this reason, we develop a tailored form of distant supervision with asynchronous updates.

(2) **Shallow feedback.** We only require shallow user feedback in the form of a simple up or down vote, which is nowadays common on the web. We specifically refrain from asking users to report the exact answers, as users might not know these answers or else be reluctant to report them; instead, it is sufficient for our framework to receive a simple credibility check. Receiving only limited feedback – and not necessarily the correct solution – requires a specialized adaptation of distant supervision to our setting.

(3) **Noisy and adversarial feedback.** User feedback in web-based settings is often noisy or even adversarial. Our framework must therefore be designed so that, despite errors in user feedback, it maintains its performance (or even continues to improve) and is thus especially robust. This is achieved by incorporating a validation procedure, based on knowledge mining, during which the credibility of user feedback is checked.

Our findings demonstrate that our QApedia framework successfully manages to learn from on-line feedback. It not only adapts to the feedback provided in the on-line setting, but it also maintains the abilities it has acquired through previous training, thus overcoming the issue of catastrophic forgetting. Our results yield a considerable improvement: the user feedback ensures that the performance over time no longer remains static but, even when evaluating the QA system with question-answer pairs from a different domain, the number of correct answers continues to increase over time on the order of 10–20 percentage points. For instance, in one dataset, fewer than 60,000 user interactions with shallow feedback were sufficient to double the percentage of exact answers. These performance improvements are even maintained in the case of noisy and adversarial feedback. Furthermore, catastrophic forgetting in a naïve QA system decreases the ratio of exact answers by 5 percentage points, whereas our QApedia framework largely maintains the original performance.

2 RELATED WORK

Question Answering: Question answering can be divided into two main paradigms, namely systems that operate in relation to structured knowledge and those that rely upon (primarily unstructured) textual content (or both, as in [15]).

QA systems for structured knowledge [e. g., 1, 2, 14, 41, 45] derive answers from knowledge bases, ontologies, or knowledge graphs. Structured knowledge bases augment web search and sometimes even serve as substitutes; see, for instance, Wikidata or Google Knowledge Graph. Explicit structures entail the benefit of simplifying the process of answer extraction, yet they are incomplete and limited to rigid (and often pre-defined) schemata and, therefore, lack the same flexibility as running text.

QA systems for content in natural language [e. g., 9, 11, 16, 31, 42] overcome some of the drawbacks of raw knowledge bases, as they extract answers directly from an underlying corpus of unstructured text documents. Hence, they find widespread application in mining web-based content such as Wikipedia or other online encyclopedias [3, 8, 11]. The content-based approach greatly contributes to overall flexibility, especially when such systems leverage the growing body of knowledge in web-based content repositories. Hence, QA systems for (web-based) content repositories constitute the focus of this work. Yet prior systems for question answering for content repositories have been designed as static systems: all decision rules are determined once and are static thereafter, thus curbing any form of continuous improvement.

Neural Question Answering for Content: Content-based QA systems commonly proceed through multiple phases [24]: they first select a subset of documents (or paragraphs) that are considered relevant and then extract the final answer. Answer extraction has traditionally been based on linguistic rules or pattern matching [13, 20, 31, 37], whereas deep neural networks [11, 17, 35, 42] have evolved only recently as the state-of-the-art. This is later reflected by our implementation, in which we combine several of the recent advances from neural question answering, such as attention [40, 43] and adaptive retrieval [23], in order to obtain a reference system that represents the status quo.

Learning from User Feedback: Improving (i. e., learning) from user feedback is a well-studied problem in, for instance, information retrieval and web-based search [5, 27]. Applications in these disciplines include user feedback that is leveraged in order to improve conversational agents [36], assess the relevance of answers in search queries for knowledge graphs [39], or identify incorrect queries to databases [18]. While [34] makes use of shallow binary feedback for machine translation, it does not account for noisy or adversarial feedback.

Closest to our research is the seminal work by Abujabal et al. [1] that distinguishes the relevance of a set of potential answers based on user feedback in the context of question answering for a structured knowledge base. Yet the latter work addresses a different objective and, in contrast to our research, thus entails marked differences. First, the aforementioned feedback mechanism from [1] is tailored to knowledge bases, while we contribute to the specific methodological foundation of content-based question answering. Second, the authors' work integrates user feedback into ontology-based representations, while we extract answers from natural language based on deep neural networks. Third, the methodology in [1] utilizes user feedback at strategic intervention points (i. e., when decision rules are unknown), whereas we develop a framework in which on-line feedback is directly integrated end-to-end. That is, user feedback is collected continuously across potentially all user interactions and then directly incorporated at the most effective point of the QA system such that the overall performance of the QA task improves. Furthermore, our work presents – to the best of our knowledge – the first attempt in the field of question answering that adapts to the particular characteristics of user feedback on the web, namely the possibility of errors and even malicious feedback; therefore, we evaluate our proposed framework with user feedback that is noisy or even adversarial.

Never-Ending Learning: In never-ending learning [10, 30], models continue to learn new tasks and/or improve upon existing tasks over time, even after their initial estimation. Never-ending learning represents an especially challenging undertaking in combination with neural networks, as neural networks are inherently prone to so-called catastrophic forgetting [22]. Catastrophic forgetting describes the phenomenon whereby models forget what they have learned earlier; i. e., while learning new tasks, the performance on tasks that have already been trained decreases dramatically.

In prior literature, applications of never-ending learning to question answering are scarce. To the best of our knowledge, there is only one such approach, the NEQA system [1]. This system is designed to address the specific needs of knowledge bases and is thus not applicable to content-based QA as in our research. More precisely, the NEQA system accumulates new rules on the basis of which it extract answers from a knowledge base. In contrast, we pursue a different objective as we develop a data-driven approach for updating the deep neural network that is nowadays common in content-based QA: both training data and model parameters are treated as dynamic components. For this purpose, we need to derive a specific framework involving distant supervision combined with asynchronous updating.

Distant Supervision: Distant supervision (i. e., enriching weakly labeled data with labels that are potentially noisy) has been previously used for neural question answering, but for purposes other than aiding never-ending learning. Previous use cases include, for example, locating correct answers in text passages [28] or for data augmentation [11, 19]. In this work, we contribute two-fold: (1) in contrast to prior works, we apply distant supervision to on-line feedback mechanisms for question answering in relation to content repositories. (2) We suggest a nascent setting in which on-line user feedback can be subject to errors, thus necessitating a novel feedback loop whereby user feedback is validated against the current content repository as a prerequisite for performing distant supervision.

3 QApedia: CONTINUOUS IMPROVEMENT FROM USER FEEDBACK

The architecture of our proposed QApedia framework (see Fig. 2) consists of three modules: a *content base* stores the knowledge for answering questions. Examples include, e. g., Wikipedia or other content repositories in natural language. This module also manages the datasets that are used for learning the question-answering capabilities. The *question-answering module* provides the actual system that takes a question as input and then suggests an answer. Its implementation adheres to the state-of-the-art of neural QA as detailed in Section 4. The module for *continuous improvement* represents our core contribution and ensures that dynamic learning takes place. It thus receives feedback through user interactions and, on this basis, updates the content base and, subsequently, the neural network inside the question-answering module.

3.1 Feedback Mechanism through User Interactions

3.1.1 Motivation Behind Shallow User Feedback. The QApedia framework achieves its dynamic learning based on user interactions that are simple in nature: a user is merely asked to assess the overall fit of an answer in the given context and should then respond with a simple up- or down-vote. This binary feedback system was specifically chosen as it promises inherent benefits. First, shallow user feedback can be collected at low cost. Accordingly, it does not require expert users or rigorous fact-checking through which the correct answer is determined. Instead, we strive for a simple integration whereby the context of an answer is assessed, and we thus expect that user feedback might include a small portion of erroneous assessments. Similar feedback mechanisms have become prevalent in web-based use cases [33, 34], e. g., when users are asked to classify whether a translation was helpful. Hence, users should be familiar with this arrangement, which ensures straightforward use.

Our design, based on shallow feedback, also comes with limitations: if the QA system comes up with the wrong answer, it will likely receive a negative vote. However, it does not necessarily obtain the correct answer, which can be used as a label. This poses challenges – beyond those that accompany web-based use – that we must carefully address in our design.

Another challenge arises from the web-based nature of the user inputs: there is no guarantee that user feedback is correct. Some users might be better at judging the suitability of an answer in a given context than others. Some users might, however, just click a random feedback option or even test the system's capability by intentionally responding with an erroneous answer. Hence, the

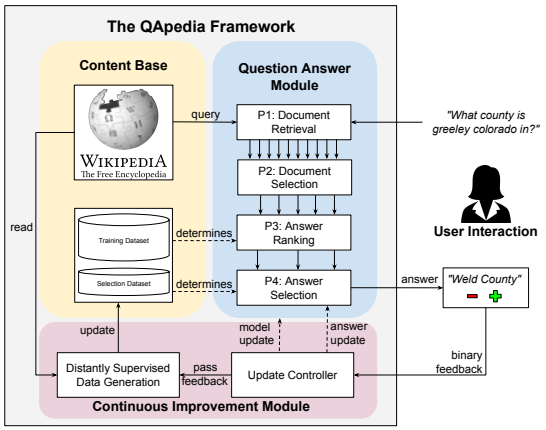

Figure 2: Architecture of our QApedia framework.

system must adapt to noisy (i. e., partially random) and adversarial (i. e., explicitly wrong) feedback.

3.1.2 Feedback Collection. The QA system takes a question q as input and then returns a triplet $\langle q, a, p \rangle$, where a refers to the answer and p to the surrounding paragraph that can be used for assessing the fit (see the example presentation in Fig. 1). Let ψ denote the (optional) feedback, i. e., an up-vote or a down-vote. Depending on the feedback, the system proceeds as follows:

- *Positive feedback* is directly passed to the module for continuous improvement. The module first performs a credibility check to validate the answer a with an up-vote against the content base. It then generates a new data sample $\langle q, a, p \rangle$ (or, more precisely, $\langle q, a, p^* \rangle$ with an improved p^* through distant supervision as described in Section 3.3) and, based on this, updates the datasets in the content base. The updated training sets are then used at regular intervals for re-estimating the neural network inside the QA module.
- *Negative feedback* triggers a process in which the current answer is rephrased and an alternative answer a' is displayed to the user. For this purpose, the QA module is queried in order to generate the next-best but different answer. We achieve this by choosing the next answer in the ranked list and ensuring that it is not a duplicate of the original answer. Eliminating duplicates is necessary, since the candidate answers during answer ranking are often identical. Users can repeatedly provide negative feedback, where ρ denotes the maximum frequency that we use in our experimental evaluation, whereas such a limit would not be enforced in practice.

The user feedback is directly fed into the content base through distant supervision and thus follows a human-in-the-loop process.

3.2 Content Base

Our QApedia framework performs question answering for content repositories. As part of our experiments, we later adhere to earlier research [3, 8, 11] and utilize Wikipedia as a widespread baseline. Without loss of generality, our framework can also be used in relation to all other knowledge bases that contain unstructured materials in (English) natural language.

Our model estimation further relies upon two datasets with labeled questions, answers, and paragraphs. These datasets are time-dependent and thus dynamic in order to enable continuous learning. Then, the training dataset $\mathcal{D}^t_{\text{train}}$ at time t is needed for estimating the parameters inside the question-answering module. A second dataset $\mathcal{D}^t_{\text{selection}}$ at time t is used for model selection. Both datasets contain triplets $\langle q, a, p \rangle$ with a question q, an answer a, and the corresponding paragraph p (i. e., in which the answer a is located).

It is important to point out that the dynamic, time-dependent nature of our datasets $\mathcal{D}^t_{\text{train}}$ and $\mathcal{D}^t_{\text{selection}}$ is integral for incorporating user feedback at runtime. This allows us to include user feedback in the form of new data samples. Finally, this time dependency is in stark contrast to prior literature on content-based QA [e. g., 11, 42], which builds upon corpora that are static. In such examples, the QA models are trained once during an off-line phase, whereas we implement the datasets for training and model selection as dynamic components updated through on-line feedback.

3.3 Continuous Improvement Module

The continuous improvement module is responsible for three tasks. First, user feedback is not directly fed into the content base but subject to a customized process with *distant supervision*. This entails an internal credibility check of the user feedback against the content base in order to deal with feedback that is noisy or adversarial. Second, the credibility check produces aggregated evidence with high-quality data samples that is eventually integrated into the content base. Third, the actual updates of the QA module can be triggered at arbitrary time intervals, for which we draw upon *asynchronous model updates*. As part of this, all trainable parameters inside the QA module are re-estimated based on the current state of the content base.

Prior work on distant supervision in question answering [11, 19] assumes that the provided answer to a question is always correct, whereas a web-based setting does not allow for this assumption and we thus adapt to incorrect feedback via credibility validation.

3.3.1 Credibility Validation. QApedia improves under noisy and adversarial feedback thanks to a careful design: we do not directly integrate triples $\langle q, a, p \rangle$ with a positive up-vote into the training data but instead rely upon a novel validation procedure with distant supervision, which filters erroneous or malicious feedback. As a credibility check, we mine so-called evidence $\mathcal{E} = \{p_1, \ldots, p_n\}$ from the content base that supports the user feedback. Only if this evidence surpasses a certain threshold do we treat the user feedback as credible.

Evidence is mined as follows. We utilize the QA system – more precisely, the mechanisms for document retrieval and document selection – in order to retrieve text passages $\mathcal{E}$ from the content base that are likely to contain the answer to question q. The resulting evidence $\mathcal{E}$ is further processed by a set of filtering rules, so that we obtain only a subset $\mathcal{E}_{\text{filtered}} \subseteq \mathcal{E}$. Without difficulty, we can reject all passages that fail to contain the assumed answer a; i. e., $a \notin p$. These passages do not provide any strong evidence for a being an answer of q. Furthermore, we filter passages that are very short, since we noticed that these commonly contain summarizing statements or headlines but are rarely extensive enough to contain

Algorithm 1: Updating procedure for continuous improvement of QA systems from shallow user feedback.

Input: User feedback ψ for question-answer-paragraph triple $\langle q, a, p \rangle$, where $\psi \in \{0, \uparrow, \downarrow\}$ denotes either an up-vote, down-vote, or no vote

$\mathcal{E}_{\text{filtered}} \leftarrow \emptyset$
if $\psi = \downarrow$ **then**
  Trigger answer selection to refine the displayed answer
else if $\psi = \uparrow$ **then**
  Initialize evidence $\mathcal{E} \leftarrow$ document_selection(q) by querying for q
  for $p \in \mathcal{E}$ **do**
    if $a \in p$ **and** $len(p) > min_len$ **and** $NE(q) \subseteq NE(p)$ **then**
      Score the evidence $s \leftarrow score(p, q, a)$ based on a sliding window
      if $s \geq 2$ **then**
        $\mathcal{E}_{\text{filtered}} \leftarrow \mathcal{E}_{\text{filtered}} \cup \{\langle q, s \rangle\}$;
      end
    end
  end
  if $|\mathcal{E}_{\text{filtered}}| >$ threshold τ **then**
    Determine best paragraph $p^* \leftarrow \max \mathcal{E}_{\text{filtered}}$ in the evidence (with the score from document retrieval as a tie breaker)
    Determine randomly which corpus $c \leftarrow corp(q, a)$ to update
    if $c =$ train **then**
      $\mathcal{D}^{t+1}_{\text{train}} = \mathcal{D}^{t}_{\text{train}} \cup \{\langle q, a, p^* \rangle\}$;
    else
      $\mathcal{D}^{t+1}_{\text{selection}} = \mathcal{D}^{t}_{\text{selection}} \cup \{\langle q, a, p^* \rangle\}$;
    end
  end
end

the answer. Accordingly, we check that the paragraph length $len(p)$ exceeds a minimum length (here we use min_len = 25). Following [11, 19], we further filter paragraphs that do not contain all of the named entities that were found in the question.[1] Let $NE(p)$ refer to the named entities – we then ensure that $NE(q) \subseteq NE(p)$. Finally, we score the quality of each of the remaining passages by counting the bi-gram overlap between the question and a 15-word window around the found answer in the passage. We reject all passages where the score is below a threshold. In our experiments, we follow [11] and enforce at least two overlaps of bi-grams. All remaining passages $\mathcal{E}_{\text{filtered}}$ are considered as strong evidence for the correctness of the feedback.

The decision of whether or not an item of feedback is credible is made based on the number of remaining text passages, i. e., $|\mathcal{E}_{\text{filtered}}| \geq \tau$. The hyperparameter τ controls the trade-off between a fast improvement (i. e., more samples will be generated) on the one hand, and a more restrictive filtering of noise on the other hand (i. e., more feedback will be rejected). We demonstrate the effects of rigorous filtering in our experiments on noisy and adversarial users.

3.3.2 Data Generation via Distant Supervision. If the user feedback is found to be credible, we do not add $\langle q, a, p \rangle$ directly into our content base; instead, we generate a new data sample $\langle q, a, p^* \rangle$ with replaced paragraph p^* from the evidence. The aim behind this is to find a high-quality paragraph p^* which contains more information than the original paragraph p that received the up-vote. To achieve this, we make direct use of the aforementioned credibility validation and the evidence set $\mathcal{E}_{\text{filtered}}$ accumulated in that phase. In detail, we use the highest scoring text passage $p^* \in \max_p \mathcal{E}_{\text{filtered}}$, i. e., we take the paragraph with the highest bi-gram overlap. If there are multiple passages with the same overlap, we use the retrieval score as a tiebreaker. This results in a new data sample $\langle q, a, p^* \rangle$, which is added to the dataset either for training or model selection, i. e.,

$$\mathcal{D}^{t+1}_{\text{train}} \leftarrow \mathcal{D}^{t}_{\text{train}} \cup \{\langle q, a, p^* \rangle\} \quad \text{or} \tag{1}$$

$$\mathcal{D}^{t+1}_{\text{selection}} \leftarrow \mathcal{D}^{t}_{\text{selection}} \cup \{\langle q, a, p^* \rangle\}. \tag{2}$$

The choice is made randomly, while maintaining the original ratio of the splits between training and model selection set (i. e., 90 % vs. 10 %). Furthermore, we assert that no question is in both datasets at the same time and that every dataset contains no duplicate question-answer pairs.

3.3.3 Asynchronous Model Updates. At desired time steps t, the continuous improvement module invokes an asynchronous model update. Here the idea is to use the current training sets from the content base, i. e., $\mathcal{D}^{t}_{\text{train}}$ and $\mathcal{D}^{t}_{\text{selection}}$ at time t in order to re-estimate the neural QA system. We use the above training data $\mathcal{D}^{t}_{\text{train}}$ with mini-batch gradient descent for 45 epochs. After each epoch, we evaluate the performance on the selection dataset $\mathcal{D}^{t}_{\text{selection}}$. Finally, we select the model with the highest-scoring performance on the selection dataset and use it to replace our current model.

The combination of distant supervision and data-driven learning of model parameters proves to be very robust against noisy or even adversarial feedback, as it provides two lines of defense. The first line of defense is our method for generating new data samples, since it filters most of the noise before it can enter the system. The second line of defense is the update mechanism itself. Its data-driven nature tolerates a small fraction of noise by definition, since noisy gradients are averaged out as long as the corpus contains enough correct samples. This is in strong contrast to a rule-based system, where even one wrong rule is guaranteed to generate wrong answers.

4 THE QUESTION-ANSWERING MODULE

The question-answering module within our framework for learning from on-line feedback provides the functional core that is responsible for extracting the displayed answers from the web-based content repository. Its structure is designed such that it combines recent advances in the field of neural question answering that are regarded as state-of-the-art in order to yield a reference implementation. Specifically, it builds upon attention mechanisms [40, 43], adaptive retrieval [23], and neural answer extraction at paragraph level [11, 42], concepts that have been proposed only recently. Consistent with the literature, the question-answering module operates along four phases (see Fig. 2), which we summarize briefly in the following: In **(P1) Document Retrieval**, all documents from the content repository are scored based on their relevance to the question. In **(P2) Document Selection**, after ranking all documents by their relevance, only a small subset of documents is selected, while all others are discarded. In **(P3) Answer Ranking**, a deep neural network is used to suggest the locations of candidate answers. In **(P4) Answer Selection**, finally, the probabilities are used in order to determine the best answer over all paragraphs and documents. The resulting answer is also the one that is presented to the user or leveraged for additional computations inside the proposed framework for continuous improvement from on-line feedback.

[1] We used the Stanford CoreNLP toolkit: https://nlp.stanford.edu/software/

4.1 P1: Document Retrieval

During information retrieval, all documents in the content repository are ranked based on their relevance to the input question q. Our actual implementation is analogous to the neural question answering from [11], which is widely used as a baseline. In detail, the approach from [11] represents each question q and all documents as vectors with hashed bigram counts [44] that are weighted by tf-idf. Then a dot product between the vectors of the question and each document is computed in order to obtain the relevance scores. This process is further accelerated by constructing all vectors using an inverted index in order to allow for fast retrieval.

4.2 P2: Document Selection

During document selection, the content repository is filtered for N documents that entail the highest relevance scores. It is often suboptimal to select only a single document (i. e., $N = 1$) since the recall can improve by choosing a larger subset (i. e., $N > 1$). However a larger subset also increases the proportion of noise and thus the possibility of eventually selecting a wrong answer. As a remedy, we follow the adaptive approach in [23], where the actual size n is determined based on a trainable classifier. Such an adaptive document selection is known to be especially suited to settings in which the size of the content repository is variable [23]. This adaptive selection represents an important element in our continuous learning framework, in which the dataset for training is intentionally designed to be dynamic and thus grows over time.

4.3 P3: Answer Ranking

The selected documents are further split into paragraphs and, in order to obtain greater accuracy in practice, all subsequent steps are performed at paragraph-level, as suggested by [11]. The objective is then to determine the probability of a candidate answer based on the following deep neural network. For this purpose, we compute the probability distributions over all start and end positions. These are given by p^s and p^e, respectively.

The architecture consists of an embedding layer, separate encoding layers for both the question and paragraphs, as well as a subsequent prediction layer. The network architecture adapts a simplified version of the document reader that was used in [11]; however, it is extended by additional encoding layers similar to [42] in order to yield a good predictive power while maintaining a reasonable runtime.

Input: The neural network for answer extraction receives input in the form of a paragraph $p = \langle p_1, \ldots, p_l \rangle$ of length l and a question $q = \langle q_1, \ldots, q_k \rangle$ of length k, where $p_1, \ldots, p_l$ and $q_1, \ldots, q_k$ denote the tokens therein.

Embedding Layer: The embedding layer maps each token onto a vector representation.[2] A question q is then given by an $n \times k$ matrix $\boldsymbol{Q} = [\boldsymbol{q}_1, \ldots, \boldsymbol{q}_k]$, where n is the embedding dimension and $\boldsymbol{q}_i$ (in bold) denotes the embedding vector that corresponds to the original token q_i, for $i = 1, \ldots, k$. Analogously, we translate the paragraph p into an $n \times l$ matrix $\boldsymbol{P} = [\boldsymbol{p}_1, \ldots, \boldsymbol{p}_l]$. Following [11, 26], we further compute a paragraph-aligned representation of the question $\boldsymbol{U} = [\boldsymbol{u}_1, \ldots, \boldsymbol{u}_l]$ using question-to-query attention $\boldsymbol{u}_i = \sum_{j=1}^{k} \alpha_{i,j}\, \boldsymbol{q}_j$ with

$$\alpha_{i,j} = \frac{\exp\left(f(\boldsymbol{p}_i)^T\, f(\boldsymbol{q}_j)\right)}{\sum_{j'=1}^{k} \exp\left(f(\boldsymbol{p}_i)^T\, f(\boldsymbol{q}_{j'})\right)} \quad \text{for } i = 1, \ldots, l, \tag{3}$$

where $f(\cdot)$ refers to a fully-connected neural network layer that we implemented with ReLU activation.

Encoding Layer for Paragraphs: A multi-layered bidirectional long short-term memory (BiLSTM) is used in order to encode the previous embeddings. That is, we apply BiLSTMs to both the paragraph and the paragraph-aligned representations in order to concatenate their hidden states along the sequence of tokens, i. e.,

$$\boldsymbol{H}^P = \text{BiLSTM}_1(\boldsymbol{P}) \quad \text{and} \quad \boldsymbol{H}^U = \text{BiLSTM}_2(\boldsymbol{U}), \tag{4}$$

where $\boldsymbol{H}^P$ and $\boldsymbol{H}^U$ are matrices of size $2mh$-by-l with h being the hidden size of the LSTM and m the number of bi-directional layers (hence the 2). Notably, these are separate models – namely, BiLSTM_1 and BiLSTM_2 – which do not share any parameters. Both are finally combined into a joint encoding $\boldsymbol{G}$ of the paragraph by stacking the hidden states, their element-wise interactions [42], and exact match features [11]. More specifically, this is accomplished with the help of an additional multi-layer BiLSTM given by

$$\boldsymbol{G} = \text{BiLSTM}_3\left(\left[\boldsymbol{H}^P; \boldsymbol{H}^U; \boldsymbol{H}^P \odot \boldsymbol{H}^U; \boldsymbol{z}\right]\right), \tag{5}$$

where $\boldsymbol{G}$ is again a $2mh \times l$ matrix, $\odot$ refers to the element-wise multiplication and exact match features are represented by an l-dimensional binary vector $\boldsymbol{z} = [z_1, \ldots, z_l]$ with $z_i = 1_{[p_i \in q]}$. In other words, z_i equals one if the i-th token of a paragraph is included in the question.

Encoding Layer for Questions: Questions are encoded by feeding their embeddings into a multilayer BiLSTM network, yielding a matrix of size $2mh$-by-k that is given by

$$\boldsymbol{H}^Q = \text{BiLSTM}_4(\boldsymbol{Q}). \tag{6}$$

In order to obtain a representation $\boldsymbol{r}$ of questions that is independent of their length, we use so-called self-attention [43] which sums over all k tokens via

$$\boldsymbol{r} = \sum_{i=1}^{k} \beta_i\, \boldsymbol{h}_i^Q \quad \text{with} \quad \beta_i = \frac{\exp(\boldsymbol{w}^T\, \boldsymbol{q}_i)}{\sum_{i'=1}^{k} \exp(\boldsymbol{w}^T\, \boldsymbol{q}_{i'})}, \tag{7}$$

where $\boldsymbol{w}$ is a trainable parameter and $\boldsymbol{h}_i^Q$ is the i-th column vector of $\boldsymbol{H}^Q$.

Prediction Layer: Following [11], we obtain scores proportional ($\propto$) to the probabilities for which each token represents the start and the end position of a candidate answer. This is computed via

$$\boldsymbol{p}^s \propto \exp(\boldsymbol{G}^T \boldsymbol{W}_s \boldsymbol{r}) \quad \text{and} \quad \boldsymbol{p}^e \propto \exp(\boldsymbol{G}^T \boldsymbol{W}_e \boldsymbol{r}), \tag{8}$$

respectively, such that $\boldsymbol{W}_s$ and $\boldsymbol{W}_e$ denote weight matrices of size $2mh$-by-$2mh$ that can be trained. For any subspan a of a paragraph p that ranges from token a_s to a_e, we can now determine the probability of answering a question: this probability is proportional to the dot product between $p^s_{a_s}$ and $p^e_{a_e}$. Notably, we refrain from normalizing these scores in order to ensure comparability across paragraphs and even documents.

[2] We utilized pre-trained, case-sensitive Glove embeddings, the so-called common crawl from http://nlp.stanford.edu/data/glove.840B.300d.zip.

4.4 P4: Answer Selection

The phase for answer selection aims at determining the best answer out of all candidates, i. e., $\max_a \mathbb{P}(a \mid q, p)$. Hence, one simply optimizes over the joint probabilities of start and end positions that are given by $\boldsymbol{p}^s$ and $\boldsymbol{p}^e$, respectively. Consistent with [11], an additional constraint is enforced in order to ensure that the end token comes after the start token, as well as guaranteeing that the final answer has a maximum length (here: 15 tokens, as suggested in [11]). This yields the following optimization problem

$$\max_{a_s, a_e} \left(p^s_{a_s}\right)^T p^e_{a_e} \quad \text{s. t.} \quad a_s \leq a_e \leq a_s + 15, \tag{9}$$

which selects the final answer that is displayed to the user.

In the case of negative feedback, the answer selection module is triggered to refine the answer by selecting the next best scoring answer that is different from the down-voted answer shown before.

5 EXPERIMENTAL SETUP

5.1 Content Repository

Our QA system draws upon the English-language Wikipedia[3] as the central source of knowledge in order to answer questions. The English-language Wikipedia currently consists of more than five million documents containing more than eight million words and, therefore, provides an excellent basis for question answering that spans various disciplines and topics. Wikipedia is freely available and has an active community that keeps it up-to-date. By following a content-based paradigm for QA, we directly query Wikipedia articles and extract answers from these. We also use Wikipedia when validating the credibility of user feedback, a process in which we aggregate evidence in a distantly-supervised fashion that should validate the correctness of the feedback.

5.2 Question-Answer Corpora

We use two different question-answer corpora during our experiments in order to highlight the dynamic nature (i. e., dependent on time step t): one to initialize our system (at $t = 0$) and one to simulate user feedback after deployment (for $t > 0$); see Fig. 3. This split into two different phases represents an experimental setup that is especially challenging since both corpora stem from separate domains, each with a question-answer style that is distinctly different. Hence, it allows us to benchmark both the ability of continuous learning in relation to new question-answer pairs and its robustness against forgetting when samples stem from the initial domain.

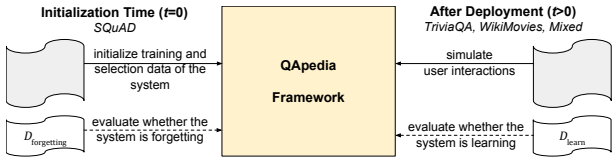

Figure 3: Overview of different corpora used to initialize our QApedia framework, as well as to simulate users.

[3]We used the preprocessed dump from https://github.com/facebookresearch/DrQA.

During *initialization time* ($t = 0$), we use the Stanford Question Answering Corpora (SQuAD) [32] to initialize the training data $\mathcal{D}^{t=0}_{\text{train}}$ and the selection data $\mathcal{D}^{t=0}_{\text{selection}}$ within the framework, and to estimate the model parameters. SQuAD includes more than 100,000 question-answer-paragraph samples with paragraphs exclusively extracted from Wikipedia. We keep a hold-out fraction of about 10,000 SQuAD samples, which we call $\mathcal{D}_{\text{forgetting}}$, in order to re-evaluate the performance over time and test whether our system is prone to catastrophic forgetting. Our hypothesis is that a system that is initialized on SQuAD and robust against catastrophic forgetting does not decrease in its initial performance on the SQuAD corpus (e. g., $\mathcal{D}_{\text{forgetting}}$).

After *deployment* ($t > 1$), we simulate user interactions on another corpus with a substantially different question-answer style. To show the robustness of our results, we run three independent experiments using the TriviaQA [19] corpus, the WikiMovies [29] corpus, and a third corpus that combines questions from TriviaQA (25 %) and WikiMovies (50 %) with the WebQuestions [6] corpus (25 %). In all three experiments, these corpora are split into a simulation part $\mathcal{D}^{t>0}_{\text{sim}}$ which provides the samples that represent our simulated users and a hold-out part $\mathcal{D}_{\text{learn}}$ in order to evaluate the extent to which continuous learning is achieved. Our hypothesis is: a system with our continuous improvement module increases its initial performance on $\mathcal{D}_{\text{learn}}$ due to learning and, at the same time, its performance remains robust against forgetting when evaluated on $\mathcal{D}_{\text{forgetting}}$.

5.3 Simulation of User Interactions

User interactions are simulated based on the following routine:

Initialization: use the SQuAD corpus to initialize the training data $\mathcal{D}^{t=0}_{\text{train}}$ and selection data $\mathcal{D}^{t=0}_{\text{selection}}$

Deployment: repeat for time steps $t = 1, \ldots$

- **(a) Simulation:** simulate $N_\phi = 10,000$ user interactions with up- and down-votes based on the corpus $\mathcal{D}^t_{\text{sim}}$ that is used after deployment
- **(b) Distant supervision:** validate the credibility of the user feedback and, if necessary, generate new data samples from the user feedback
- **(c) Dataset update:** merge training and selection data from the previous time step $t - 1$ and the new data samples into $\mathcal{D}^t_{\text{train}}$ and $\mathcal{D}^t_{\text{selection}}$
- **(d) Model update:** re-estimate the parameters inside the neural QA based on $\mathcal{D}^t_{\text{train}}$ and $\mathcal{D}^t_{\text{selection}}$ at time t
- **(e) Learning effect:** evaluate the new QA model on $\mathcal{D}_{\text{learn}}$
- **(f) Robustness against forgetting:** evaluate the new QA model on a hold-out fraction $\mathcal{D}_{\text{forgetting}}$ of the SQuAD corpus

The above procedure allows us to study the overall effect of continuous learning on $\mathcal{D}_{\text{learn}}$, as well as the robustness against forgetting on the SQuAD dataset $\mathcal{D}_{\text{forgetting}}$. We again point out that all evaluations in the following are conducted on hold-out data that has been used neither for training, simulating users nor model selection.

5.4 Clairvoyant, Noisy, and Adversarial Feedback

We study QApedia under different types of user responses:

(1) Clairvoyant users always provide feedback that is accurate. Hence, these users respond to a correct answer from the QA system with an up-vote and, conversely, with a down-vote if it is wrong. These users underlie our initial experiments in order to confirm continuous learning, while subsequent experiments control for the possibility of errors in the user feedback.
(2) Noisy feedback tests the system when a certain portion of user responses deviate from the ground-truth. Here we assume that a certain share of users (i. e., experts) respond with the correct answer, while others provide random feedback with probability ε.
(3) Adversarial feedback refers to feedback that is intentionally incorrect; i. e., up-votes if an answer is wrong and down-votes if an answer is correct. Here we again assume users that follow the ground truth and others that respond adversarially with probability ε.

For noisy and adversarial users, the total proportion of incorrect up-votes is not only determined by ε, but also by the performance of the system itself. For instance, if a system answers 20 % of the questions correctly and 10 % of the users vote randomly whereas 90 % provide correct feedback, then approximately one out three up-votes will be noisy. In our experiments, we chose a system-specific initialization of $\varepsilon = 0.05$, so that 18 % of the initial up-votes are noisy when averaged over all users. Due to its probabilistic nature, this number can vary across individual batches of user simulation and reach, e. g., up to 30 % in some of them.

Users are allowed to provide negative feedback repeatedly. Let ρ refer to the maximum frequency with which negative feedback is provided. In our experiments, we set $\rho = 1$ in order to yield a challenging setup and later experiment with $\rho = 3$ as part of a sensitivity analysis.

5.5 Implementation Details

As part of the answer ranking (P3), we train deep neural networks using mini-batch gradient descent over the content repository, i. e., the question-answer-paragraph triples, with a batch size of 32. We implemented a loss function $\mathcal{L}$ following [11]. Let a^* refer to the ground-truth answer, which spans from a_s^* to a_e^*. Given predictions $\boldsymbol{p}^s$ and $\boldsymbol{p}^e$ from the neural network, we then minimize the negative log-likelihood

$$\mathcal{L} = -\log \frac{\exp(p^s_{a^*_s})}{\sum_{j=1}^{l} \exp(p^s_j)} - \log \frac{\exp(p^e_{a^*_e})}{\sum_{j=1}^{l} \exp(p^e_j)}. \tag{10}$$

For this purpose, we utilize the AdaMax optimizer [21] with gradient clipping set to 10. All LSTM layers entail 128 hidden units and are trained with a recurrent dropout of 0.4. For all encoding layers, we use three BiLSTM layers, e. g., $m = 2$.

6 RESULTS

We conducted more than 2,500 hours of experiments and report results over more than 1.5 million simulated user interactions with 150 model re-estimations. We divide the results into three sections. First, we illustrate the learning process given shallow user feedback. Second, we check the robustness of our approach against forgetting. Third, we simulate noisy and adversarial users and evaluate whether our system still manages to improve under these challenging conditions.

6.1 Performance Improvements from Shallow User Feedback

The objective behind our first set of experiments is to determine the overall performance improvements from shallow user feedback. For this reason, we study the influence of user feedback when users always provide the correct response and, hence, consider results in the absence of noise or errors. This type of user interactions enables us to obtain an upper bound to the performance.

Fig. 4 reports our key results. In detail, we measure the fraction of correctly answered questions, e. g., where the predicted answer matches exactly to one of the ground truth answers. Per design, a traditional QA system fails to incorporate user feedback and is thus limited to a static performance. By contrast, our plots consistently derive considerable performance improvements from user feedback. Furthermore, we compare QApedia to a baseline without distant supervision in which we append samples with positive feedback directly into the training set.

- **WikiMovies:** Prior to the inclusion of user feedback, the systems obtain 13.3 % exact matches, which is identical to the performance of a static QA system. Our learning framework successfully manages to improve the performance over time. Distant supervision with shallow feedback increases the share of exact matches up to 35.5 % – an increase of 22.2 percentage points. On the other hand, the exact matches from the baseline without distant supervision amount to 30.9 %, which is inferior to QApedia by 4.6 percentage points. As determined later, the difference between this baseline and the performance of our system is attributable to the quality improvement of samples during the distantly supervised data generation process.
- **TriviaQA:** Distant supervision with $\rho = 3$ yields the best performance overall. Choosing $\rho = 1$ at first resembles the baseline without distant supervision in terms of performance but, after sufficient user interactions, outperforms it.
- **Combined dataset:** The combined dataset shows similar results. The performance differences are small, and yet the QApedia with $\rho = 3$ is still ranked first.

Evidently, continuous learning can be efficiently achieved through shallow user feedback using only a fraction of the original dataset. Choosing a larger τ yields much richer information, and yet both variants show little difference in performance, suggesting that simple feedback is already sufficient.

6.2 Robustness Against Forgetting in Neural QA

Our neural QA system could theoretically – as is the case for all other neural networks – be prone to catastrophic forgetting and we thus evaluate whether this issue is attenuated by our design. Fig. 5 compares the performance across user interactions: we measure the robustness of how well a QA system can answer questions regarding the initialization corpus (i. e., its hold-out part $\mathcal{D}_{\text{forgetting}}$) over time

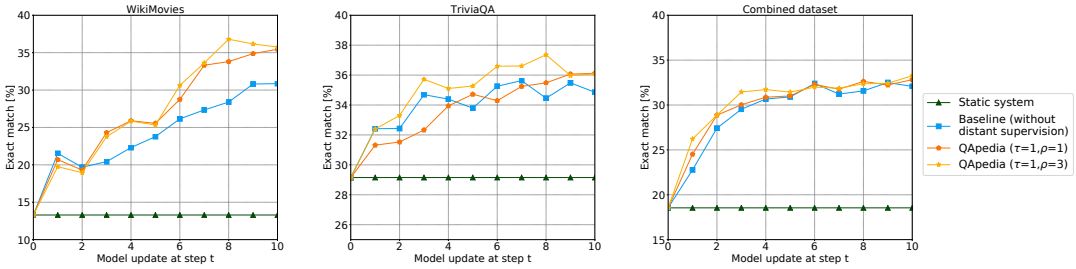

Figure 4: In a clairvoyant setting where correct feedback is provided, our QApedia achieves considerable performance improvements of up to 20 percentage points in terms of exact matches. The primary baseline represents the static QA system (i. e., horizontal line). For comparison, a trivial update framework without distant supervision is also reported.

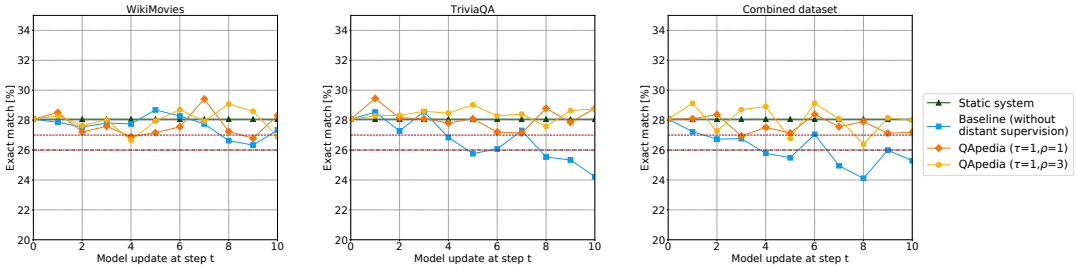

Figure 5: In a clairvoyant setting where only correct feedback is provided, our QApedia is considerably less prone to forgetting than alternative baselines. For better readability, a threshold is plotted at a 2-percentage-point decrease in performance in order to aid comparisons.

as user feedback is included. Small fluctuations are natural due to the data-driven learning method.

- **WikiMovies:** All system configurations reveal fairly similar patterns. Overall, our QApedia framework performs best with distant supervision and $\rho = 3$ repeated answers. This configuration not only shows continuous improvements for the feedback dataset, but only once attains a performance decrease of more than 1 % relative to the initial system and, moreover, reveals a gradual upward trend. The baseline without distant supervision performs less stably in this setting but, contrary to the next two datasets, does not show forgetting.
- **TriviaQA:** The performance of the baseline without distant supervision declines dramatically: the system's performance drops from 28.1 % exact matches down to only 24.2 %. In contrast, distant supervision again obtains a fairly stable performance.
- **Combined dataset:** The findings point in the expected directions, and yet we see that the mixed original of question-answer pairs in this dataset presents a challenging undertaking and results in considerable volatility. Again, the baseline without supervision hints at structural patterns of forgetting, as it regularly falls short by 2 % or more. Both distantly supervised approaches behave similarly and never undercut the 2 % mark.

Overall, our approach of distant supervision, and especially utilizing a larger value of ρ (i. e., 3 as opposed to 1), can reduce the risk of forgetting. Since the user feedback was simulated correctly (without noise), we credit this for the improved data generation via distant supervision. To obtain a better understanding, we quantitatively analyzed 200 question-answer-paragraph triplets generated from positive feedback by QApedia and the baseline without distant supervision. In the clairvoyant setting, all answers are correct, and yet we still see a distinct difference in the quality of the paragraphs. We found that, for QApedia, only about 4 % of data samples were uninformative (i. e., although the answer is correct contained within the paragraph, the paragraph alone is not sufficient to answer the question). For the baseline without distant supervision, the fraction of uninformative samples was considerably higher and amounted to 13 %.

6.3 Performance Under Noisy User Feedback

Being robust to user feedback with noise is a key requirement for use cases on the web. This experiment thus studies the effect of noise on the overall performance with noisy users as described in Section 5.4. We fix ρ to 1, and vary τ between 1 and 2. As described above, τ controls how rigorously we filter feedback during the credibility validation.

We report the experiment based on the WikiMovies dataset in Fig. 6. The total improvement declines only slightly as a result of the presence of noisy users: while it was up to 22.2 percentage points in the previous experiment based on feedback that was always correct, we now still achieve an increase in exact matches by 20.6 percentage points ($\tau = 2$) and 18.1 percentage points ($\tau = 1$). More importantly, the baseline (where positive feedback is directly added to the training set) sees an improvement of merely 9.8 percentage points, which is less than half of the performance gain from our QApedia framework. We further see that the QApedia

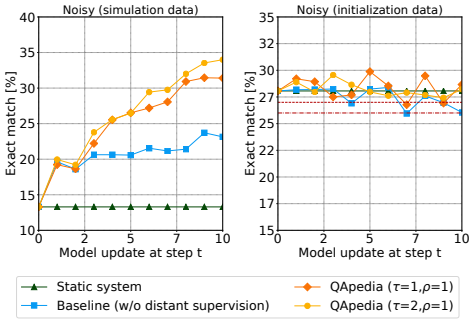

Figure 6: The proposed QApedia framework addresses a web-based use case where user feedback can be subject to noise, but remains fairly robust. Reported is the WikiMovies dataset.

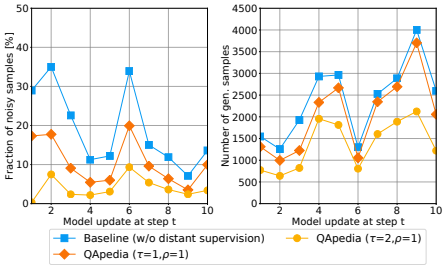

Figure 7: Our QApedia framework with automated credibility check for answers is considerably more robust than the baseline without distant supervision: our approach for the WikiMovies dataset removes more samples that received incorrect feedback (left) and thus results in fewer such samples that are added to the training set (right). This behavior is reinforced when choosing a stricter credibility check (e. g., $\tau = 2$).

framework, especially with stricter filtering, is also less prone to forgetting as compared to the baseline.

We now provide descriptive analysis concerning the update mechanism. We report (see Fig. 7 left) the relative frequency of incorrect samples that are added to the training data $\mathcal{D}_{\text{train}}$. Here we find that the baseline without distant supervision generates new training samples of which, on average, 19,2 % are wrong. Distant supervision decreases this share significantly. It plummets to 10.5 % for distant supervision with $\tau = 1$ and to 3.5 % for $\tau = 2$. Fig. 7 (right) reports the number of total samples that are generated (correct and incorrect). Here a higher τ decreases the number of samples added to the training set, but also results in fewer samples with incorrect feedback.

6.4 Robustness to Adversarial User Feedback

We repeat the previous experiments with users among whom an average of 20 % of the feedback is adversarial, i. e., users up-vote wrong answers and down-vote correct answers. The performance is depicted in Fig. 8 and resembles the previous findings under noise. The ratio of exact matches in our proposed approach increases by

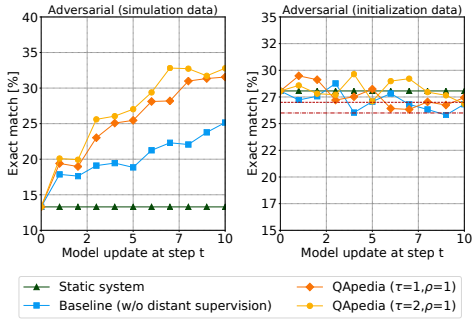

Figure 8: The proposed QApedia framework addresses a web-based use case where user feedback can be subject to adversarial inputs, but remains fairly robust.

19.4 percentage points, which is significantly larger than for the baseline without distant supervision (i. e., 11.8-percentage-point gain). Adversarial feedback leads to a larger variation in performance of the initialization task, where QApedia (in contrast to the baseline) again registers a better mean value. This is an interesting observation, since individual re-estimation steps can entail feedback of which 30 % is wrong. Altogether, these findings concerning adversarial feedback highlight the robustness of QApedia, especially with more rigorous credibility validation ($\tau = 2$).

7 DISCUSSION

This work presents QApedia: the first question-answering system for encyclopedic content repositories that gradually improves over time by harnessing shallow user feedback. A careful design was necessary in order to obtain state-of-the-art performance and, moreover, tailor the framework to the specific requirements of on-line feedback mechanisms on the web. We identified the following levers as especially pertinent. First, continuous learning from feedback can bolster the performance considerably; e. g., the proportion of exact matches can rise by up to 20 percentage points. We could have theoretically built our system such that it asks users to provide the correct labels as feedback (i. e., active crowd sourcing); however, we specifically decided upon shallow binary feedback, since, from a user perspective, this is considerably less costly. Second, our results establish that the problem of catastrophic forgetting can be effectively solved. Here it is important that all parts can efficiently deal with training sets that are dynamic in size and over time. For this reason, we utilize document retrieval, which adapts to the corpus size, and implement a novel distant supervision based on asynchronous updates. Third, we present a demanding setup with extensive adversarial feedback, and yet it does not necessarily diminish performance. Rather, our framework yields improvements of up to 30 %. This highlights the relevance of a simple credibility check.

ABSTRACT

We study the strategic implications that arise from adding one extra option to the miners participating in the bitcoin protocol. We propose that when adding a block, miners also have the ability to pay forward an amount to be collected by the first miner who successfully extends their branch, giving them the power to influence the incentives for mining. We formulate a stochastic game for the study of such incentives and show that with this added option, smaller miners can guarantee that the best response of even substantially more powerful miners is to follow the expected behavior intended by the protocol designer.

1 INTRODUCTION

Bitcoin, currently the most-widely used cryptocurrency, was introduced in a 2009 white paper [12] by the mysterious Satoshi Nakamoto as a form of decentralized, distributed, peer-to-peer digital currency. The backbone of the bitcoin protocol is the *blockchain*, a distributed ledger that (ideally) takes the form of a chain where bitcoin *transactions* are stored into *blocks*. Blocks are created by special nodes of the bitcoin network called miners that: (*i*) collect and validate the set of transactions to be included in a block and (*ii*) solve a crypto-puzzle (the so-called *proof of work*) that cryptographically links the newly created (*mined*) block to the tail of the existing blockchain. The main purpose of the blockchain is to solve the problem of *distributed consensus*, where the consensus to be obtained is on the history (and relative order) of the bitcoin transactions.

Since mining new blocks is a computationally intensive (and expensive) task, miners need a reward scheme to keep mining blocks. Bitcoin has two main reward schemes for miners: (*i*) *transaction fees*, that are left by bitcoin users on a voluntary basis (and hence vary in frequency and size) and *coinbase* (or block) rewards, which are constituted by a fixed set amount (currently 12.5Ƀ) of newly minted bitcoins. Coinbase rewards are the only way by which bitcoins can ever be created, and the protocol specifies that (to avoid inflation) coinbase rewards be decreasing over time, until the limit of 21 million bitcoins are created: at that point the only incentive scheme left for miners will be transaction fees. Currently, most of the rewards for mining a block are coinbase.

In a distributed setting populated by selfish miners, however, the blockchain will hardly be a chain at all, but rather a *tree*. For instance, network delays may lead miners to add newly mined blocks to different blocks that they believed to be the tail of the chain. For this reason, newly mined blocks are not part of the consensus until sufficient time has passed since their creation (i.e., d levels of other blocks are added to the blockchain – currently $d = 100$), and block rewards become available to miners only then. Worse still, even though the bitcoin protocol prescribes that miners should mine from the last known block in the chain (the so-called Frontier strategy), self-interested miners may try to create a *fork* by intentionally adding a sequence of blocks (a *branch*) constituting a parallel history of the transactions, in an attempt to reap more block rewards or to double-spend bitcoins (once per each branch of the fork).

It should be clear from now that the bitcoin protocol is rife with game-theoretic issues. Nakamoto [12] analyzed in a simple model, providing rough estimates showing that if a large majority of miners follow Frontier, then their chain will be the longest and contain the agreed upon history.

Since Nakamoto's paper, there has been significant work about the strategies of miners, mainly under the assumption that the reward per block is fixed (see for example [5, 8, 16]). In particular, these *mining games* have been systematically evaluated through the lens of game-theory by Kiayias et al. [8]. They considered mining games in which miners can influence the blockchain in two ways: by strategically choosing to mine at different branches in an attempt to overtake the longest branch and by withholding their mined blocks and releasing them at the right time, wasting

everyone else's computational power. In [8, 16], it was shown by both formal proofs and simulations that the Nakamoto protocol is stable when no miner has computation power more than 0.33 of the total. Furthermore, it was also shown that when the miners do not withhold blocks, the protocol is stable if no miner has computation power more than 0.42.

This raises the issue of *fairness* and *compliance* in the bitcoin protocol. By deviating from the protocol and mining strategically, large miners could affect the network in two ways. By increasing their own rewards disproportionately to their computational power they limit the mining rewards claimed by smaller miners, which is unfair. Also, their constant forking in an attempt to add more blocks upsets the protocol and can cause delays, as well as negate transactions that have been already processed.

In this work, we propose a slight modification to the protocol whereby miners can entice other miners to mine at their block by adding a *pay-forward* amount. This pay-forward amount is collected by the miner of the next block, thus providing incentives to other miners to try to extend the tree from this particular branch. When we extend the available strategies for the miners by adding the ability to pay-forward, we reclaim some stability by ensuring that the attacking (computationally powerful) miner is incentivized to follow the protocol, even if he still reaps more than his fair share of rewards.

The main technical contribution is the study of mining games in which the strategies are extended by pay-forward. We show that with this extension, the stability of the protocol increases significantly: the computational power needed by a dishonest miner to disrupt the blockchain is substantially higher. This shows an interesting trade-off for small miners: on one hand they lose the pay-forward amount but on the other hand, they provide the right incentives to large miners to play Frontier and thus secure that their block will end up in the longest chain.

1.1 Our Results

We consider two types of *stochastic games*, whose states are rooted trees. The game is played in discrete time-steps. At the beginning of each time-step, every miner chooses a block and tries to mine from it. Each player i has probability p_i to mine a new block, proportional to his computational power. In the end, the new block may be added to the blockchain or kept hidden and released later. After many rounds of playing, the utility of each player is the fraction of bitcoins he owns (from block and pay-forward rewards) over the total value that has been mined in the longest chain.

Let p be the computational power of the strongest player, called Miner 1. If p is large enough, his best response, given that everyone else is playing Frontier, may be a different strategy. We find thresholds on p and w, the pay forward amount of every other player, to guarantee that mining at the end of the longest chain is a best response for Miner 1. As in [8], we consider two variants. In the immediate release case, any mined block has to be added to the blockchain immediately for other players to use. In this case, without pay forward rewards, it was proven in [8] that Frontier is a best response for Miner 1 for $p < h$, where $0.361 \leq h \leq 0.455$. Experimentally, they also showed that there is always a deviating strategy for $h \approx 0.42$. In the strategic release case, the newly mined blocks are public knowledge, but can only be used by other players when their creators decide to *release them.* As before, it was shown in [8] that there is a threshold $\hat{h} \geq 0.308$ (experimentally shown to be approximately 0.33 [8, 16]) such that $p < \hat{h}$ leads to Frontier as a best response for Miner 1.

We improve these thresholds to $h = 0.5$ and $\hat{h} \geq 0.344$ by showing that there exists some w (as a function of p) that guarantees Miner 1's best response is to play Frontier when all remaining miners play Frontier and pay forward w. In addition, we experimentally show that for $h \leq 0.44$ that outcome is also a pure Nash equilibrium for the immediate release case, while for the strategic release case we find that $\hat{h} \approx 0.38$. We also devise a linear program to calculate the minimum value of w for any given p.

1.2 Related Work

Bitcoin, originally introduced by Nakamoto in [12] and followed by several cryptocurrencies, such as Litecoin, Ethereum and Ripple, initiated the research on blockchains. Nakamoto's original paper analyses double spending attacks while Rosenfeld provides a more detailed analysis [15]. Bonneau et al. [2] and Tschorsch and Scheuermann [20] provided extensive surveys of the research and challenges in cryptocurrencies.

Kroll et al. [10] was one the first papers to consider the economics of Bitcoin mining, assuming that participants behave according to their incentives. Eyal and Sirer [7] showed that the security of bitcoin is not guaranteed by a majority of honest miners as was previously assumed. They gave a specific mining strategy and argued that a pool of miners, with at least a 1/3 of the total processing power, can get extra profit regardless of the block propagation characteristics of the network. With sufficiently favorable block propagation, this threshold of processing power falls to 0. Extending this, Sapirshtein et al. [16] provided systematic analysis of the space of selfish mining strategies based on computational results.

A similar approach was taken by Kiayias et al. [8] who provided a framework for studying the strategic considerations made by Bitcoin miners. They formulated two abstract stochastic games and proved rigorous bounds on the threshold of computational power below which the honest strategy is a Nash Equilibrium. Carlsten et al. [3] extended the previous approaches by investigating mining games when the reward for miners varies and comes mainly from transaction fees. They observed that the random block arrival times lead to high variance in rewards and they considered strategies that lead to instability. They showed via simulation that an equilibrium exists, but it has the counter intuitive and undesirable effect of a growing backlog of unprocessed transactions.

Several other studies examine possible attacks on the protocol and suggest adaptations to ensure its security. Rosenfeld [14] and Courtois and Bahack [4] discuss pool mining attacks. Eyal [5] introduces an attack in which mining pools infiltrate one another resulting in a pool game. Lewenberg et al. [11] also provide a game theoretic analysis of pool mining. Babaioff et al. [1] consider Sybil attacks on the network and propose a reward scheme to prevent miners from hiding transactions in competition with other miners.

There is also considerable work on the performance and scalability of blockchain inspired networks. Sompolinsky and Zohar's

[18] Greedy-Heaviest-Observed-Sub-Tree rule is an alternative consensus mechanism. Eyal [6] proposes Bitcoin-NG which increases the throughput of Bitcoin. Poon and Dryja's Lightning Network [13] scales via off-chain transactions and hashed commitments. Sompolinsky and Zohar's PHANTOM [19] achieves near unlimited transaction throughput. SPECTRE [17], by Sompolinsky et al, fully orders the transactions in blocks using recursive elections and can used in combination with PHANTOM. Kiayias et al. developed Ouroboros[9], a proof of stake network with provable security, utilising a secure multi-party coin flipping protocol.

2 MODEL AND NOTATION

The model contains subtleties in the abstractions that at first glance might be overlooked by readers who are too familiar with the bitcoin protocol. We do our best to point out any of those instances, but be especially vigilant when reading about the way payoffs are calculated.

The bitcoin mining game with pay forward is an abstraction of the actual protocol, simplified in a way that can only accentuate its game theoretic issues (i.e. negative results hold a fortiori for the actual protocol) while being open to rigorous analysis. The parameters of the game are:

(1) the number n of miners (or players).
(2) the probabilities $p_1, \ldots, p_n$, representing the *hash power* of each miner, which is the probability that they solve the crypto-puzzle. They are proportional to the computational power of each miner and such that: $p_i \geq 0$ for each i and $\sum_{i=1}^{n} p_i = 1$.
(3) the depth d after which mined blocks are 'paid', i.e. their coinbase becomes usable by the respective miner. Without loss of generality we mostly consider $d = \infty$ which gives the attacker extra power.

We assume that each block has a *fixed reward*, which by appropriate scaling is equal to 1. This is reasonable, as the large majority of rewards come from the fixed coinbase rewards. The fluctuating transaction fees (while not insignificant) are still comparatively small.

During the execution of the protocol, miners add their blocks to the blockchain one at a time[1]. Their goal is to maximize the fraction of their blocks on the longest branch of the blockchain, as the longest branch represents the consensus and all other branches are pruned and the computational power spent for their creation is wasted. This does not mean that all the miners try to extend the longest branch at every time step, because some times they might benefit by either adding a block to a shorter branch or withholding it for later.

Definition 2.1. A public state is a rooted tree. Every node is labelled by one of the players and the amount of money he pays-forward. The nodes represent mined blocks and the label indicates the player who mined the block. The pay-forward amount is collected by the next miner in the longest branch. Every level of the tree has at most one node labelled i because there is no reason for a player to mine twice the same level.

A private state of player i is similar to the public state except it may contain more nodes called private nodes and labelled by i. The public tree is a subtree of the private tree and has the same root.

The incomplete information case (where the p_i's or private states are unknown) is significantly more complicated. In this work we only consider the full information case where even the private states are common knowledge (but only become part of the public state when their respective miners add them). We consider two variants:

Immediate-release model Every mined block is added to the public tree immediately.

Strategic-release model Mined blocks can be withheld: every miner is aware of their existence, but they can only mine from them once they are added to the public tree.

The second model has no counterpart in practice, but it serves as an intermediate step between the full and incomplete information models and allows us to study issues around strategic release of blocks. If a strategy is not dominant in this model it cannot be dominant in the incomplete information setting.

Definition 2.2 (Strategy). The strategy of miner i can be fully characterized by three functions $\mu_i, r_i, \mathrm{PF}_i$:

- the mining function μ_i selects a block of the public state to mine from
- the release function r_i which is the rooted tree he releases to the public. It is a subtree of his private state that contains the public state.
- the pay-forward function PF_i which is the amount of money to be left for the next miner.

Both functions depend on the public and private states of every player.

The original suggested strategy in [12] is Frontier.

Definition 2.3 (Frontier). A miner follows strategy Frontier if he releases mined blocks immediately, always mines at the deepest node in the blockchain and pays forward 0 B.

In the following, we refer to Frontier(w) as the strategy that mines and releases like Frontier but always pays forward w.

The game is played in *phases*. At each phase exactly one miner will mine a block. Then he will choose if he wants to release it, which may trigger a cascade of releases from other players. Eventually, once no one else wants to release anything the public knowledge is updated and the next phase begins. Even if no one releases a block, miners know when the phase ends since everything is public knowledge.

To incentivise miners to mine new blocks, payments are necessary. When a block is added, it is unclear if it is going to remain on the longest branch permanently. To remedy this, blocks are paid for only after their branch is increased by d blocks, after which time it is safe to assume it will stay in the longest branch. Blocks are paid through coinbase, transaction fees and pay-forward. Currently, coinbase rewards (which can be claimed at $d = 100$) far outweigh

[1] Due to the decentralized nature of bitcoin, it is possible for more than one miners to mine a block simultaneously. This event does occur by chance, but it is very rare and it is not something a miner can plan for. For this reason, we assume that exactly one block is mined at every step, but most of our analysis could be easily extended to the case in which each miner succeeds with probability p_i independently.

transaction fees. However, by design Bitcoin will eventually do away with coinbase rewards to limit inflation, at which point only transaction fees will remain, leading to potential instability [3]. We only consider coinbase rewards in this work. For game theoretic analysis we rigorously define payments:

Definition 2.4 (Payments). For some nodes of the tree, the miners who discovered them will get a payment (coinbase rewards are normalized to 1). The payments comply with the following rules:

- the blocks that receive a payment must form a path from the root. This immediately adds the restriction that at every level of the tree exactly one node receives payment.
- among the blocks of a single level that satisfy the above condition, the first one which succeeds in having a descendant d generations later receives payment.

Since only one block per level is paid for and they form the longest branch, the utility of a miner in the long run is defined as the fraction of pay-forward and coinbase rewards he obtained minus the pay-forward he paid in that branch, over it's length.

When a block is paid for, strategic miners will ignore any branch that starts at an earlier node. This limits the shape of the public state to a long path (the *trunk*) with ignored *stale* branches dangling from it. Only at the end of the trunk we may find multiple active branches, competing to reach length d and render the others stale. We will also consider the case where $d = \infty$. Here there is the possibility that two competing branches will go on forever, but since one of them will have less computational power, a case of gamblers ruin makes this impossible.

3 IMMEDIATE RELEASE

In this section we show that if Frontier(w) (for some value of w) is followed by all miners but one, the remaining miner's best response is Frontier, provided his hash power is $p < 0.5$. Since only one miner might deviate, we can view this situation as Miner 1 being the potentially deviant large miner with hash power $p < 0.5$ and Miner 2 all small miners combined into one, which we call the honest miners, since they follow the same strategy.

In essence, every honest player mines at the deepest node and always pays forward w. This amount propagates across the small miners forming Miner 2 but Miner 1 can claim it for himself, leading to an interesting stochastic game where Miner 1 is incentivise to mine the longest chain, since the rewards don't accumulate.

The blockchain itself is a rooted tree, but after pruning abandoned branches we are left with one long, undisputed, main path followed by two branches of length a and b, mined by Miner 1 and Miner 2 respectively. Therefore, the possible states of the game have the form (a, b, c), where $a \leq b + 1$ since Miner 2 always mines the longest branch (except briefly, right when Miner 1's branch overtakes the longest) and c is either 0 or 1, to indicate whether the *last block before the fork* contained a pay forward reward.

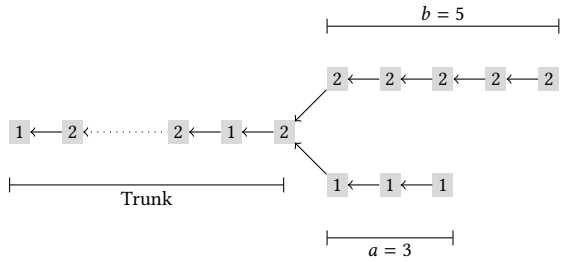

Figure 1: A typical state tree. The trunk represents the blocks whose rewards have already been collected. The current state $(3, 5, 1)$ of the game is represented by the blocks mined by Miner 1 and Miner 2 and $c = 1$ because Miner 2 controls the block before the fork.

The set of states (a, b, c) can be partitioned as follows:

(1) **Winning states**: the set W of states where Miner 2 capitulates and starts mining from the tip of Miner 1's branch. This happens exactly when $a = b+1$, therefore $W = \{(b+1, b, c) \mid b \geq 0 \text{ and } c \in \{0, 1\}\}$. After Miner 1 overtakes, the new state of the game is $(0, 0, 0)$ since they both mine at the same point.
(2) **Capitulation states**: the set C of states where Miner 1 capitulates, abandons his branch and mines from a block of Miner 2's branch, thus moving the game to state $(0, s, 1)$ for some s s.t. $0 \leq s < b$. We say that Miner 1 capitulates *at* (a, b, c) and *to* $(0, s, 1)$. Clearly, after capitulating there would be a pay forward reward available.
(3) **Mining states**: the set M of states where Miner 1 and Miner 2 mine their respective branches.

Miner 1 can capitulate to any state $(0, s, 1)$ and will always choose the one that maximizes his payoff. Since he is rational, when capitulating from state (a, b, c) he would only go to states $(0, s, 1)$ with $s < b$, otherwise he would be undercutting his own tentative branch. The strategy Frontier has $M = \{(0, 0, 0), (0, 0, 1)\}$, $C = \{(0, 1, 0), (0, 1, 1)\}$ and always capitulates to $(0, 0, 1)$.

Let $g_k(a, b, c)$ denote the optimal expected gain of Miner 1 starting from state (a, b, c) when the longest chain is extended by k levels. Knowing Miner 1 will never pay-forward, we can recursively define:

$$g_k(a,b,c) = \begin{cases} g_{k-1}(0,0,0) + a + w \cdot c & \text{if } a = b+1 \\ \max \begin{cases} \max_{s=0,\ldots,b-1} g_k(0,s,1) \\ p g_k(a+1,b,c) + (1-p) g_{k-1}(a,b+1,c) \end{cases} & \end{cases}. \tag{1}$$

The first line represents Miner 2 capitulating to Miner 1's chain. The second line containing the max has two cases. In the first case, Miner 1 capitulates to the optimal point within Miner 2's chain. In the second, they both mine and extend their chains with probability p and $(1-p)$ respectively. Notice that the first term is $pg_k(a+1, b, c)$ and not $pg_{k-1}(a+1, b, c)$. Since $a < b + 1$, if Miner 1 adds a block the deepest level of the blockchain does not change, thus k remains the same.

Clearly, Miner 1 eventually will add some block to the chain and the game will restart at state $(0, 0, 0)$. Therefore, we expect that

the initial state (a, b, c) has no effect asymptotically. We define the expected gain per level $g^\star$ as:

$$g^\star = \lim_{k\to\infty} \frac{g_k(a, b, c)}{k}. \tag{2}$$

We can decompose $g^\star$ into two separate quantities:

$$g^\star = q_M + q_{\text{PF}} \cdot w, \tag{3}$$

where q_M is the expected fraction of blocks he mined and q_{PF} the expected fraction of blocks mined and containing pay forward rewards.

Lemma 3.1. *If Miner 1 follows Frontier, we have $q_M = p$ and $q_{PF} = p(1-p)$.*

Proof. If Miner 1 is honest then the probability that he mined any arbitrary block is p. That block also contains pay forward rewards if the one that immediately preceded it was mined by Miner 2, which occurs with probability $p(1-p)$. □

We are ready to state the main theorem of this section.

Theorem 3.2. *For every $p < 0.5$, there exists $w \geq 0$ large enough so that if every miner but one follows Frontier(w), the best response of the remaining miner with hash power p is Frontier.*

Proof. We will show that q_{PF} attained by Frontier is at least as large as that of any optimal strategy, and in particular it is larger for $0 < p < 0.5$. □

Lemma 3.3. *If Frontier is not the optimal strategy and $0 < p < 0.5$, we have that $p(1-p) > q_{PF}$. For $p = 0$ or $p = 0.5$ we have equality.*

Proof. Assuming Frontier is not an optimal strategy, we consider different cases, depending on the actions of the optimal strategy starting from state $(0, 1, c)$. □

Clearly, we have that $g_k(0, 1, 1) \geq g_k(0, 1, 0)$ for all k. To see this, consider what happens if we apply exactly the same sequence of actions starting from $(0, 1, 0)$ and from $(0, 1, 1)$. As the only difference between the two states is the initial pay forward amount, if we start from $(0, 1, 1)$ the reward will be the higher (in expectation) by some fraction of w. Therefore, if the optimal strategy capitulates at $(0, 1, 1)$ it must also capitulate at $(0, 1, 0)$. This is exemplified in Figure 2, where blocks with a red outline represent those mined by the optimal strategy, and red arrows show how the action of the optimal strategy in one case implies the same action in the other.

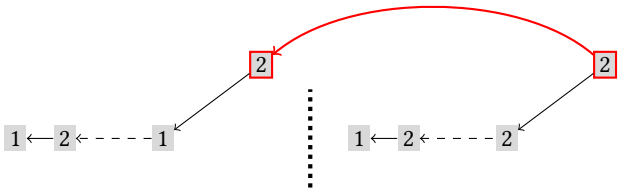

Figure 2: Mining like Frontier

But in this case, the optimal strategy capitulates at exactly the same states as Frontier, as shown in Figure 2. Since the blockchain starts empty, at $(0, 0, 0)$ this strategy would behave exactly the same as Frontier and would therefore not be optimal.

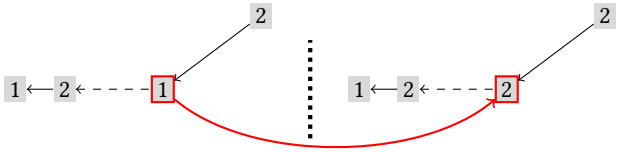

Figure 3: Case 1

In Case 1 (shown in Figure 3), we assume that the optimal strategy mines at $(0, 1, 0)$. As before, since $(0, 1, 1)$ is a more beneficial state it would mine from there as well. We can therefore assume that the optimal strategy always capitulates to states $(0, s, 1)$ with $s \geq 1$. Blocks are permanently added to the blockchain only after a capitulation. Given that, in order to compute q_{PF} for Miner 1, we construct the Markov chain shown in Figure 4, with states $(0, 0, 0)$ and $(0, s, 1)$ indicating that Miner 2 or Miner 1 capitulated respectively. Each transition is labelled with a pair where the first element is the transition probability, whereas the second element is the minimum number of blocks added to the chain when the transition occurs.

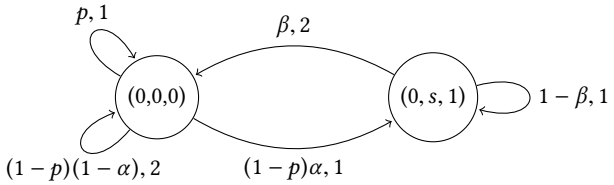

Figure 4: Case 1 Markov chain

Starting from $(0, 0, 0)$, with probability p Miner 1 adds a block and the game restarts. With probability $1 - p$ we move to state $(0, 1, 0)$ and the optimal strategy has probability α of losing the race and capitulating to some state $(0, s, 1)$. From there, the optimal strategy has probability β of winning and returning to $(0, 0, 0)$.

As q_{PF} is an asymptotic quantity, we are interested in the fraction of pay forward rewards per block mined at the stationary distribution. Let π be the stationary probability of state $(0, s, 1)$. Then:

$$\pi = \frac{\alpha - \alpha \cdot p}{\alpha - \alpha \cdot p + \beta} \tag{4}$$

In the actual game, multiple blocks are potentially mined in each edge transition, and only the first block might claim a pay forward reward. On every transition at least one block is permanently added, *except from* $(0, s, 1)$ *to* $(0, 0, 0)$ *and* $(0, 0, 0)$ *to itself through transition* $(1-p)(1-\alpha)$. In these cases at least two blocks are added, since Miner 1 must mine at least two blocks to be ahead of Miner 2. From $(0, s, 1)$ to $(0, 0, 0)$ is the only transition where Miner 1 wins a block containing pay forward. Dividing the blocks with pay-forward over the total amount mined at the stationary distribution:

$$q_{\text{PF}} \leq \frac{\pi\beta}{(1-\pi)(2(1-\alpha)(1-p) + \alpha(1-p) + p) + \pi(2\beta + 1 - \beta)} \tag{5}$$

We now need to set the parameters α and β optimally to maximize the upper bound on q_{PF}. We take the derivative of the upper bound of q_{PF} with respect to α and β to get:

$$\frac{dq_{\text{PF}}}{d\alpha} = \frac{\beta^2(2-p)(1-p)}{(\alpha(p-1)+\beta(p-2))^2} \geq 0 \tag{6}$$

and

$$\frac{dq_{\text{PF}}}{d\beta} = \frac{\alpha^2(1-p)^2}{(\alpha(p-1)+\beta(p-2))^2} \geq 0. \tag{7}$$

From [8, Lemma 1], we know that the probability that Miner 1 reaches a winning state starting from (a, b) is at most $(p/(1-p))^{(b-a+1)}$. Therefore, the optimal strategy must have

$$\alpha \leq 1 \text{ and } \beta \leq \left(\frac{p}{1-p}\right)^{s+1} \leq \left(\frac{p}{1-p}\right)^2 \tag{8}$$

Since q_{PF} is an increasing function of α, β, the upper bound is obtained by setting them to their highest possible value, leading to:

$$q_{\text{PF}} \leq \frac{(1-p)p^2}{1-(1-p)p(3-2p)}. \tag{9}$$

Compared to the honest outcome $p(1-p)$, we have:

$$p(1-p) - \frac{(1-p)p^2}{1-(1-p)p(3-2p)} = \frac{(1-p)p(1-2p)}{1-(1-p)p(3-2p)} \geq 0, \tag{10}$$

with equality obtained only for $p = 0$ and $p = 0.5$. We also plot this result at the end of the proof.

In the last case, the optimal strategy capitulates at $(0, 1, 0)$ but mines at $(0, 1, 1)$.

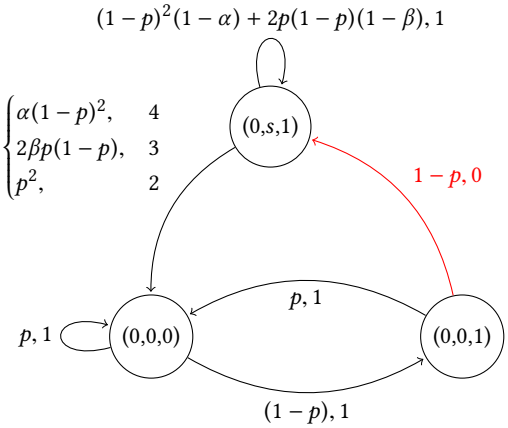

Figure 5: Case 2 Markov chain

The Markov chain in this case (Figure 5) is trickier. As before each state represents a capitulation: $(0, 0, 0)$ for Miner 2 and $(0, 0, 1)$, $(0, s, 1)$ with $s \geq 1$ for Miner 1. However, the transition indicated with the red arrow is *not* a capitulation: it is merely a move to a state that Miner 1 could also capitulate *to*. To more accurately model the transitions of state $(0, s, 1)$, we consider multiple moves ahead. Specifically, three outcomes could happen before the optimal strategy considers capitulating. With probability p^2, Miner 1 could add two blocks and move to $(0, 0, 0)$. Miner 2 could also add two blocks and move to $(0, s + 2, 1)$, with probability $(1-p)^2$. Then, Miner 1 wins with probability α. Finally, Miner 1 and Miner 2 could both add one block leading to $(1, s + 1, 1)$ with probability $2p(1-p)$. From there, Miner 1 wins with probability β.

Carefully adjusting for the more complicated transitions, the same analysis as before holds. For both cases, we plot the difference $p(1-p) - q_{\text{PF}}$ in Figure 6.

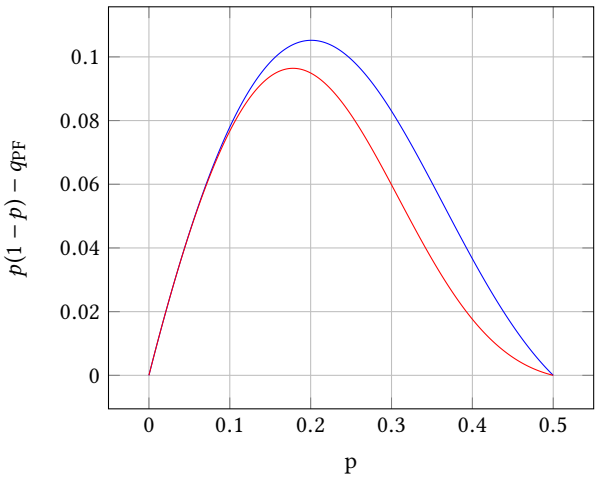

Figure 6: Advantage of Frontier in collecting q_{PF} for Case 1 (blue) and Case 2 (red)

Therefore, by (3) and Lemma 3.1 we have that

$$g^\star = q_M + q_{\text{PF}} \cdot w \leq p + (1-p) \cdot w \Rightarrow w \geq \frac{q_M - p}{(1-p) - q_{PF}}$$

and since $(1-p) > q_{PF}$ for $0 < p < 0.5$ there must be some value of w large enough to make Frontier the best response. Unfortunately, this result is not enough to calculate w. Giving crude upper bounds on q_M or q_{PF} independently is not too hard, we can use [8, Lemma 1] from example. However, because the trade-off between the two is hard to establish and the actual blockchain does not use $d = \infty$, it is more useful to develop an algorithm that finds the minimum w required for a specific d, to any degree of accuracy.

3.1 Calculating the optimal w for finite d

In reality, the values of w needed are not too large. We could attempt to find the minimum w necessary by computing $g_k(0, 0, 0)/k$ for large values of k and comparing with $p + p(1-p)w$, but a naive implementation would take $O(k^3)$ time. To simplify this search we can define a potential as in [8]

$$\phi(a, b, c) = \lim_{k\to\infty} g_k(a, b, c) - k \cdot g^\star, \tag{11}$$

that captures the advantage of Miner 1 at different states. This quantity is bounded, because irrespective of the initial state (a, b, c) the game repeats: in particular, when Miner 1 gets ahead of Miner 2 they both restart at state $(0, 0, 0)$. Therefore, the gain per k asymptotically converges to $g^\star$ and ϕ is well defined. Following recurrence (1), we have:

$$\phi(a,b,c) = \begin{cases} \phi(0,0,0) + a + c \cdot w - g^\star & \text{if } a = b+1 \\ \max \begin{cases} \max_{s=0,\ldots,b-1} \phi(0,s,1) \\ p \cdot \phi(a+1,b,c) \\ \quad +(1-p) \cdot (\phi(a,b+1,c) - g^\star) \end{cases} & \end{cases}, \quad (12)$$

where we set $\phi(0,0,0) = 0$. Finding a ϕ that satisfies these constraints is even harder. However, if we truncate the game at depth d, it becomes more feasible through linear programming. Notice that (12) (which holds for $d = \infty$) does not explicitly define the value of $\phi(a,b,c)$: the recursion is unbounded. By truncating the game at d we limit the available states to $a, b \le d$. Specifically, Miner 1 *has* to capitulate when $b = d$.

The exact value of d has a small effect on the game. In particular, Miner 1 has more options as d increases, since he does not have to capitulate early. Therefore, the minimum w needed for compliance is a slightly increasing function of d. The effect of this is quite muted however; the probability of having two branches with length greater than d, without Miner 1 winning or capitulating, decreases exponentially in d. In this section we select $d = 8$, as it is large enough to show the trend, but not too large to render the LP computationally infeasible.

Relaxing the two maxes by inequalities, we get the following LP:

$$\begin{aligned} &\text{minimize} \quad g + \tfrac{1}{D} \sum_{a=0}^{d} \sum_{b=0}^{d} \sum_{c=0}^{1} \phi(a,b,c) \\ &\text{subject to} \\ &\quad \phi(b+1,b,c) \ge \phi(0,0,0) + b + 1 + c \cdot w - g \\ &\qquad \text{for } b < d, c \le 1 \\ &\quad \phi(a,b,c) \ge \phi(0,s,1) \\ &\qquad \text{for } a \le b < d, s < b, c \le 1 \\ &\quad \phi(a,b,c) \ge p \cdot \phi(a+1,b,c) + (1-p)(\phi(a,b+1,c) - g) \\ &\qquad \text{for } a \le b < d, c \le 1 \end{aligned},$$

where $\phi(a,b,c) \ge 0$ and $D \gg d^2$ is a normalizing factor to keep the sum of states insignificant compared to g. The constraints are straightforward enough, but the objective is a minimization, which might appear odd at first. The second term of the sum is only there to ensure that feasible solutions only contain potential functions ϕ that tightly satisfy (12). Since many states could be unreachable (for example, if w is high enough so that Miner 1 plays Frontier, the only mining states would be $(0,0,0)$ and $(0,0,1)$), their exact value does not affect g and we need this 'extra' term to keep them in check, just to bias the LP towards certain feasible solutions. We minimize g to use the following lemma:

Lemma 3.4. *For any g, ϕ pair satisfying (12) we have:*

$$g_k(a,b,c) \le \phi(a,b,c) + k \cdot g.$$

Proof. We use induction on k. Clearly, for $k = 0$ we have $g_0(a,b,c) = 0 \le \phi(a,b,c)$. For fixed k we do strong induction on b and backwards induction on a. Starting with $b = 0$, we begin the induction on $a = b + 1$:

$$\begin{aligned} g_k(1,0,c) &= g_{k-1}(0,0,0) + 1 + c \cdot w \\ &\le \phi(0,0,0) + (k-1)g + 1 + c \cdot w \\ &= \phi(0,0,0) + 1 + c \cdot w - g + k \cdot g \\ &= \phi(1,0,c) + k \cdot g \end{aligned}$$

and

$$\begin{aligned} g_k(0,0,c) &= p \cdot g_k(1,0,c) + (1-p) g_{k-1}(0,1,c) \\ &\le p(\phi(1,0,c) + k \cdot g) + (1-p)(\phi(0,1,c) + (k-1)g) \\ &= p \cdot \phi(1,0,c) + (1-p)(\phi(0,1,c) - g) + k \cdot g \\ &= \phi(0,0,c) + k \cdot g. \end{aligned}$$

For $b > 0$ the proof works the same, starting from $g_k(b+1,b,c)$ as the base case for a. For $a < b + 1$:

$$\begin{aligned} g_k(a,b,c) &= \max \begin{cases} \max_{s=0,\ldots,b-1} g_k(0,s,1) \\ p g_k(a+1,b,c) + (1-p) g_{k-1}(a,b+1,c) \end{cases} \\ &\le \max \begin{cases} \max_{s=0,\ldots,b-1} \phi(0,s,1) + kg \\ p \cdot (\phi(a+1,b,c) + kg) \\ \quad +(1-p)(\phi(a,b+1,c) + (k-1)g) \end{cases} \\ &= k \cdot g + \max \begin{cases} \max_{s=0,\ldots,b-1} \phi(0,s,1) \\ p \cdot \phi(a+1,b,c) \\ \quad +(1-p)(\phi(a,b+1,c) - g) \end{cases} \\ &= \phi(a,b,c) + kg, \end{aligned}$$

where strong induction was used for the capitulation case. □

Using this lemma, we can find the minimum value of w that leads to Frontier being a best response for different values of p by using binary search on w, checking that the ϕ produced from the LP satisfies (12) and that $g = p + p(1-p)w$. By the definition of $g^\star$:

$$g^\star = \lim_{k\to\infty} \frac{g_k(a,b,c)}{k} \le \lim_{k\to\infty} \frac{\phi(a,b,c) + k \cdot g}{k} = p + p(1-p)w,$$

For $d = 8$, we obtain the graph in fig. 7.

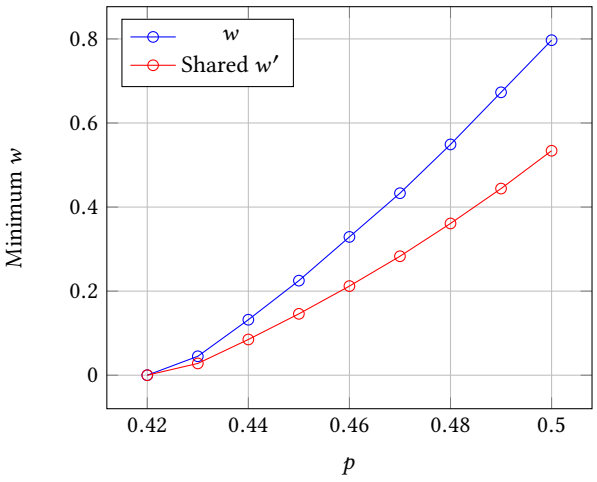

Figure 7: Minimum w for the immediate release case.

It is not a mistake that $w < 1$ for $p = 0.5$. The reason is that d is finite. For $d = \infty$, the strategic miner with $p \geq 0.5$ never has a reason to capitulate, no matter w: the probability that his branch eventually overtakes the honest one is always quite high. However, the probability that he will win the race *within d steps* is much smaller, leading to this result.

If not all honest miners are required to pay forward exactly w, they can share the costs. In particular, one strategy which also makes Miner 1 comply with the protocol is for the first honest miner after Miner 1 to pay forward w' and every other honest miner to pay forward $2w'$, until Miner 1 adds a block and claims the reward for himself, where the process restarts. As we can see from the Figure 7, although the total amount paid forward is larger (as $2w' \geq w$), the maximum contribution of any honest miner is $w' \leq w$. We can verify compliance is indeed a best response for Miner 1 by using a slightly modified LP.

3.2 Pure Nash Equilibria for small miners

So far, we have only considered the best responses of Miner 1, given a society of honest, identical miners and identified the minimum value w needed to ensure his compliance. The natural question is to consider if this also a best response from the other miners. Clearly, when treated as a group this is not their best response. If they do not pay forward any amount, Miner 1 would have an average gain of $g' \geq p$, by mining strategically. By paying forward enough, they need to *increase* his gain to $g^\star \geq g'$, as he can always employ strategic mining while they also pay forward. Therefore, it is more costly for Miner 2 to pay forward w and ensure compliance than to pay forward nothing and allow strategic mining.

We will argue however that under certain conditions paying forward can be a pure Nash equilibrium, if Miner 2 consists of many *small* miners that are treated individually. A miner is considered *small* if his chance of mining a block is negligible. Of course at every step some small miner will mine a block with probability $1 - p$. To see why paying forward is an equilibrium, consider the options of a small miner at the *exact* moment when he mines a block: he can either pay forward and guarantee it is included in the chain or keep everything for himself, but risk getting undercut by Miner 1. Being a small miner, his payoff from mining another block in the future is insignificant compared to the current reward at stake. Formally, the following strategy, called StrictFrontier(w), is part of a PNE:

Definition 3.5 (StrictFrontier). Every miner (except Miner 1) pays forward w and mines at the end of the longest chain that contains blocks with pay forward values either w or 0

Miner 1's strategy is to mine at the frontier without paying forward, as before. Note, that paying forward some value other than w or 0 *cannot* be a best response, since that block will be ignored by the honest miners, who have the majority of the computational power[2]

Theorem 3.6. *For $d = 8$ and any $p \leq 0.44$, there exists w such that Miner 1 playing Frontier and every other small miner playing StrictFrontier(w) is a pure Nash equilibrium.*

[2]The reason StrictFrontier accepts pay forward of 0 is just to incentivize Miner 1 to cooperate. Without it, every block would have the same pay forward, negating any effects this may have and reducing to the classic bitcoin protocol.

Proof sketch. From the perspective of the small miner, he has two opportunities *not* to pay forward: after another small miner or after Miner 1. We can modify the LP from Section 3.1 to contain both these deviations by the small miner. Examining the tightness of the constraints, we can identify the mining states of Miner 1. Specifically, for $p \leq 0.44$, we observe that in both cases, after the small miner adds his block without paying forward, Miner 1 immediately forks the chain behind the small miner and starts mining in parallel. In particular, states $(0, 1, c)$, $(1, 1, c)$, $(1, 2, c)$ and $(2, 2, c)$ become mining states and $(0, 3, c)$, $(1, 3, c)$, $(2, 3, c)$ capitulation states, for $c \in \{0, 1\}$. Essentially he mines while one step behind and capitulates if the honest miners add 2 more blocks. Overall, he overtakes the honest branch with probability at least $p^2 + (1 - p)p^3$.

Therefore, the expected payoff of the small miner is at most $(1 + w)(1 - p^2 - (1 - p)p^3)$, compared to at least $1 - w$ which would have been his payoff had he paid forward w (since in this case he would always keep his mined block). Plugging in the p, w pairs found in Figure 7 we verify that StrictFrontier(w) is indeed a best response. □

It would be very interesting to see if there exists a strategy profile that is a PNE where Miner 1 plays Frontier for $0.45 < p < 0.5$. The analysis seems quite challenging and would likely require different techniques to analyze the emerging stochastic game. Ideally, every small miner comprising Miner 1 would use the same w, but it could be the case that better bounds could be obtained if the pay forward amount use depends on the pay forward received from the previous block.

4 STRATEGIC RELEASE

Similarly to the immediate release case, we identify the maximum hash power p such that if all miners but one follow Frontier(w), the remaining miner's best response is Frontier if his hash power is less than p. As before, it is enough to consider a two player game where Miner 1 is the deviant miner with hash power $p < 0.5$ and Miner 2 represents all small miners, as they follow the same strategy.

The blockchain retains its structure: it still contains a long trunk of blocks followed by two branches, corresponding to the released blocks of Miner 1 and Miner 2. Since Miner 1 could also have more unreleased blocks in his branch the state is now a quadruple (a_r, a, b, c) where a is the number of blocks in Miner 1's branch, of which a_r have been released, and b is the number of blocks in Miner 2's branch. Also, contrary to the immediate release case we can have $a > b + 1$.

Since Miner 2 follows the Frontier(w) strategy, he will capitulate if $a_r \geq b + 1$ and continue mining his branch for $a_r < b + 1$. Therefore, without loss of generality we can assume that at state (a_r, a, b, c) if $a < b + 1$ then $a_r = a$ and if $a \geq b + 1$ then $a_r = b$, otherwise Miner 2 would immediately capitulate and the game would continue at state $(0, a - a_r, 0, 0)$. Therefore, we can encode the states of the mining game with strategic release by the triplet (a, b, c), where $a_r = \min(a, b)$.

As before, we need to recursively define the gain of Miner 1 after the longest branch is extended by k levels. When $a < b + 1$, the actions of Miner 1 are exactly the same as in the immediate release case: he can either capitulate to $(0, s, 1)$ or mine. However,

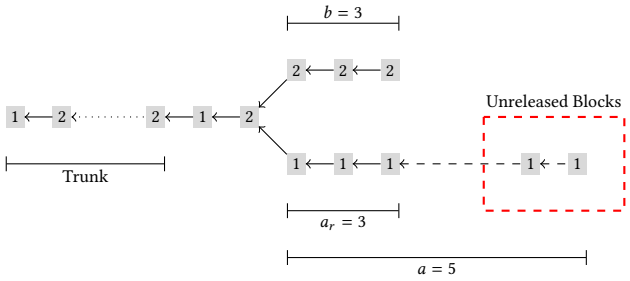

Figure 8: This tree represents state $(3, 5, 3, 1)$. Miner 1 has already mined 5 blocks ahead of the fork, but has only released 3 of them. Miner 2 knows this because the game is complete information. However, he cannot mine there until Miner 1 releases his blocks. Miner 1 can strategically release blocks right when Miner 2's branch is about to become the main one, thus wasting Miner 1's computational power.

for $a \geq b+1$ he can release one more block to force Miner 2 to capitulate and continue at state $(a-b-1, 0, 0)$.

$$\hat{g}_k(a,b,c) = \max \begin{cases} k+b+c\cdot w & \text{if } a \geq k+b \\ \max \begin{cases} \max_{s=0,\ldots,b-1} \hat{g}_k(0,s,1) \\ p\hat{g}_k(a+1,b,c) \\ \quad +(1-p)\hat{g}_{k-1}(a,b+1,c) \\ \hat{g}_{k-1}(a-b-1,0,0) \\ \quad +b+1+c\cdot w \end{cases} \end{cases} \tag{13}$$

where the last term applies for $a \geq b+1$. Equivalently, we can define $g_k(a,0,c) = -\infty$ for all k and $a < 0$. The first term is necessary, as without it the recurrence is ill-defined and Miner 1 can keep mining forever. Once he reached the horizon k he can safely release all his blocks. We define the expected gain per level $\hat{g}^\star$ and potential $\hat{\phi}$ as we did in (2) for the immediate release. Note that the case where $a = k+b$ does not appear, since ϕ is the asymptotic advantage as $k \to \infty$ and a, b are bounded.

$$\hat{\phi}(a,b,c) = \max \begin{cases} \max_{s=0,\ldots,b-1} \hat{\phi}(0,s,1) \\ p\hat{\phi}(a+1,b,c) + (1-p)(\hat{\phi}(a,b+1,c) - \hat{g}^\star) \\ \hat{\phi}(a-b-1,0,0) + b + 1 + c\cdot w - \hat{g}^\star \end{cases}. \tag{14}$$

Releasing blocks only causes Miner 2 to capitulate if $a \geq b+1$, so we set $\phi(a,0,c) = -\infty$ for $a < 0$. Before moving on, we need a useful inequality of the *immediate release* potential ϕ, to use for bounding the advantage of some states relative to others.

Lemma 4.1. *For nonnegative integers a, b and $\ell \in \{0,1\}$ we have that:*

$$\phi(a+\ell, b+\ell, 1) \leq \phi(a,b,0) + (\ell+w)\cdot\left(\frac{p}{1-p}\right)^{b-a+1}. \tag{15}$$

Proof. We first need to establish that for $c \in \{0,1\}$

$$g_k(a+\ell, b+\ell, c) \leq g_k(a,b,c) + \ell\cdot\left(\frac{p}{1-p}\right)^{b-a+1} \tag{16}$$

and

$$g_k(a+\ell, b+\ell, 1) \leq g_k(a,b,0) + (\ell+w)\cdot\left(\frac{p}{1-p}\right)^{b-a+1}. \tag{17}$$

Suppose that from state (a,b) Miner 1 follows the same strategy as state $(a+\ell, b+\ell)$. This is possible, as winning or capitulating depends only on the difference $b-a$. Let $\bar{g}_k(a,b,c)$ be the gain from playing this suboptimal strategy and $\bar{r}(a,b)$ the probability of winning from state (a,b). Clearly, we have:

$$g_k(a,b,c) \geq \bar{g}_k(a,b,c) = g_k(a+\ell, b+\ell, c) - \ell\cdot\bar{r}(a,b). \tag{18}$$

Given that $\bar{r}(a,b) \leq (p/(1-p))^{b-a+1}$ from [8, Lemma 1] we get the first inequality.

For the second, let $r(a,b)$ be the probability of winning from (a,b) with the optimal strategy. As before:

$$g_k(a,b,1) = g_k(a,b,0) + w\cdot r(a,b) \leq g_k(a,b,0) + w\cdot\left(\frac{p}{1-p}\right)^{b-a+1}, \tag{19}$$

which we substitute in (16).

To complete the proof, we take limits in (16) and use the definition of ϕ. □

In [8] it was shown that for $p \leq 0.361$ Frontier is a best response, therefore (for $w=0$) there exists a ϕ such that for $g^\star = p$ (12) is satisfied, meaning that honest mining maximizes the fraction of blocks added by Miner 1. By Lemma 3.3, increasing w can only strengthen this result, therefore for $p \leq 0.361$ and any $w \leq 1$ there exists ϕ that satisfies (12) for $g^\star = p + p(1-p)w$. Using this, we extend the potential to states (a,b,c) with $a > b+1$:

$$\bar{\phi}(a,b,c) = \begin{cases} \phi(a,b,c) & \text{if } a \leq b+1 \\ a\lambda + b\mu + \kappa + c\cdot w & \text{otherwise} \end{cases}, \tag{20}$$

where $\lambda = \frac{(p-1)^2(1-pw)}{1-2p}$, $\mu = \frac{p(p-(p-1)^2 w)}{2p-1}$ and $\kappa = \frac{(p-1)p(pw-1)}{2p-1}$. The constants have been selected so that $\bar{\phi}(a,b,c) = p\bar{\phi}(a+1,b,c) + (1-p)(\bar{\phi}(a,b+1,c) - \hat{g}^\star)$ and $\bar{\phi}(b+1,b,c) = b+1+c\cdot w - \hat{g}^\star = \phi(b+1,b,c)$, for $\hat{g}^\star = p + p(1-p)w$ which is the honest gain. Doing this, we can use known results about ϕ for smaller states while having a tight enough closed form of $\hat{\phi}$ on states which are unlikely to be reached.

Following the notation of [8] we define $\bar{\phi}_M$ for when Miner 1 continues to mine, $\bar{\phi}_R$ when Miner 1 releases some blocks and $\bar{\phi}_C$ when he capitulates.

$$\begin{aligned} \bar{\phi}_M(a,b,c) &= p\cdot\bar{\phi}(a+1,b,c) + (1-p)(\bar{\phi}(a,b+1,c) - \hat{g}^\star) \\ \bar{\phi}_R(a,b,c) &= \bar{\phi}(a-b-1,0,0) + b + 1 + c\cdot w - \hat{g}^\star \\ \bar{\phi}_C(a,b,c) &= \max_{s=0,\ldots,b-1} \bar{\phi}(0,s,1). \end{aligned}$$

Theorem 4.2. *For every $p < 0.344$, there exists $w \geq 0$ large enough so that if every miner but one follows Frontier(w), the best response of the remaining miner with hash power p is Frontier.*

Proof. We need to show that $\bar{\phi}$ is a valid potential and satisfies (14) for $\hat{g}^\star = p + p(1-p)w$, or equivalently:

$$\bar{\phi}(a,b,c) = \max\{\bar{\phi}_M(a,b,c), \bar{\phi}_R(a,b,c), \bar{\phi}_C(a,b,c)\}$$

□

Lemma 4.3. *The potential $\bar{\phi}$ and $\hat{g}^\star = p + p(1-p)w$ satisfy recurrence (14) for $p \leq 0.344$ (root of the polynomial $-p^4 + 3p^3 - 7p^2 + 5p - 1$) and some $w < 1$.*

Claim 1. *For states* (a, b, c) *with* $a < b + 1$*:*

$$\bar{\phi}(a, b, c) = \phi(a, b, c) = \max\{\bar{\phi}_M(a, b, c), \bar{\phi}_R(a, b, c), \bar{\phi}_C(a, b, c)\}.$$

In this case $\bar{\phi}_R(a, b, c) = -\infty$ and therefore $\bar{\phi}(a, b, c) = \phi(a, b, c)$ which satisfies (12) and (14) by definition, as releasing is only possible for $a \geq b + 1$.

Claim 2. *For states* (a, b, c) *with* $a > b + 1$*:*

$$\bar{\phi}(a, b, c) = \bar{\phi}_M(a, b, c) = \max\{\bar{\phi}_M(a, b, c), \bar{\phi}_R(a, b, c), \bar{\phi}_C(a, b, c)\}.$$

By definition, $\bar{\phi}(a, b, c) = \bar{\phi}_M(a, b, c)$. We have:

$$\bar{\phi}(a, b, c) - \bar{\phi}_R(a, b, c) = \frac{b(2 - 4p) + (1 - p)(2 - 3p)(1 - pw)}{1 - 2p} > 0.$$

Since $p \leq 0.344$ we know that $\phi(a, b, c)$ corresponds to the potential of the honest mining strategy, in the immediate release case. Therefore:

$$\begin{aligned}\bar{\phi}_C(a, b, c) &= \max_{s=0,\ldots,b-1} \bar{\phi}(0, s, 1) \\ &= \max_{s=0,\ldots,b-1} \phi(0, s, 1) = \phi(0, 0, 1) \leq w \cdot \frac{p}{1 - p}\end{aligned}$$

as $(0, 0, 1)$ and $(0, 0, 0)$ are the only mining states and by using Lemma 4.1for the last inequality. Also:

$$\begin{aligned}\bar{\phi}_R(a, b, c) &= \bar{\phi}(a - b - 1, 0, 0) + b + 1 + c \cdot w - \hat{g}^\star \\ &\geq 1 - p(1 - p)w \\ &\geq w \cdot \frac{p}{1 - p} \\ &\geq \bar{\phi}_C(a, b, c),\end{aligned}$$

for $p < 0.344$.

Claim 3. *For states* $(b + 1, b, c)$*:*

$$\begin{aligned}\bar{\phi}(b + 1, b, c) &= \bar{\phi}_R(b + 1, b, c) \\ &= \max\{\bar{\phi}_M(b + 1, b, c), \bar{\phi}_M(b + 1, b, c), \bar{\phi}_C(b + 1, b, c)\}.\end{aligned}$$

Exactly as before, we have $\bar{\phi}_R(b + 1, b, c) = b + 1 + c \cdot w - \hat{g}^\star \geq \bar{\phi}_C(b + 1, b, c)$. For $\bar{\phi}_M(b + 1, b, c)$:

$$\begin{aligned}\bar{\phi}_M(b + 1, b, c) &= p\bar{\phi}(b + 2, b, c) + (1 - p)\left(\bar{\phi}(b + 1, b + 1, c) - g\right) \\ &\leq p((b + 2)\lambda + b\mu + \kappa + c \cdot w) \\ &\quad + (1 - p)\left((b + 1 + c \cdot w)\frac{p}{1 - p} - g\right),\end{aligned}$$

by the definition of $\bar{\phi}$ and Lemma 4.1. Then:

$$\begin{aligned}&\bar{\phi}_R(a, b, c) - \bar{\phi}_M(a, b, c) \geq \\ &\quad b(1 - 2p)^2 + (p - 1)\left(p^3 w - p^2(w + 1) + p(2c \cdot w + 5) - c \cdot w\right) \\ &\quad + 1.\end{aligned}$$

Since $b \geq 0$ we only need:

$$(p - 1)\left(p^3 w - p^2(w + 1) + p(2c \cdot w + 5) - c \cdot w\right) + 1 \geq 0.$$

Setting $w = 1$, it holds for $p \leq 0.344$ for $c = 0$ and $p \leq 0.442$ for $c = 1$. For smaller values of p it is not necessary to set w to it's highest value.

Now, we can use the equivalent of Lemma 3.4(whose proof has very minor differences) for the strategic release case to get that:

$$\begin{aligned}\hat{g}^\star = \lim_{k\to\infty} \frac{\hat{g}_k(a, b, c)}{k} &\leq \lim_{k\to\infty} \frac{\bar{\phi}(a, b, c) + k \cdot (p + p(1 - p)w)}{k} \\ &= p + p(1 - p)w.\end{aligned}$$

This shows that his gain is at most what he would get by playing Frontier, hence a best response.

Through a procedure similar to Section 3.1, adjusting the LP for this case, we obtain the following graph for $d = 8$ for the minimum value of w required.

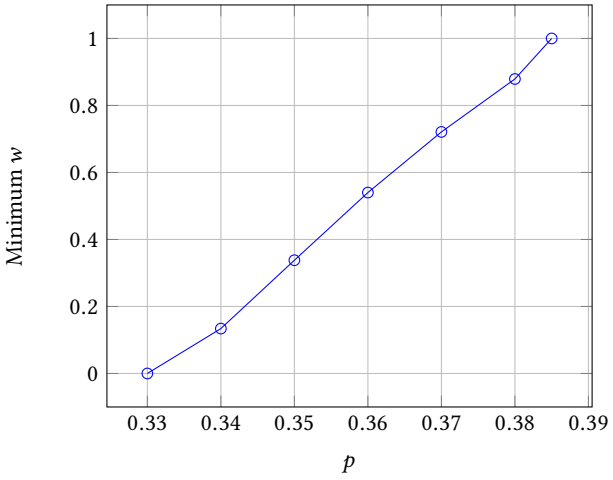

Figure 9: Minimum values of w for the strategic release case.

Contrary to Figure 7, for $p = 0.385$ we have $w \approx 1$. As $d \to \infty$, we reach $w = 1$ for $p \approx 0.38$.

ABSTRACT

Given posts on 'abortion' and posts on 'religion' from a political forum, how can we find topics that are discriminative and those in common? In general, (1) how can we *compare and contrast* two or more different ('labeled') document collections? Moreover, (2) how can we *visualize* the data (in 2-d or 3-d) to best reflect the similarities and differences between the collections?

We introduce (to the best of our knowledge) the first *contrastive and visual* topic model, called ContraVis, that jointly addresses both problems: (1) contrastive topic modeling, and (2) contrastive visualization. That is, ContraVis learns not only latent topics but also embeddings for the documents, topics and labels for visualization. ContraVis exhibits three key properties by design. It is (*i*) **Contrastive:** It enables comparative analysis of different document corpora by extracting latent discriminative and common topics across labeled documents; (*ii*) **Visually-expressive:** Different from numerous existing models, it also produces a visualization for all of the documents, labels, and the extracted topics, where proximity in the coordinate space is reflective of proximity in semantic space; (*iii*) **Unified:** It extracts topics and visual coordinates *simultaneously* under a joint model.

Through extensive experiments on real-world datasets, we show ContraVis 's potential for providing visual contrastive analysis of multiple document collections. We show *both qualitatively and quantitatively* that ContraVis significantly outperforms both unsupervised and supervised state-of-the-art topic models in contrastive power, semantic coherence and visual effectiveness.

CCS CONCEPTS

• **Computing methodologies** → **Topic modeling**; • **Mathematics of computing** → *Dimensionality reduction.*

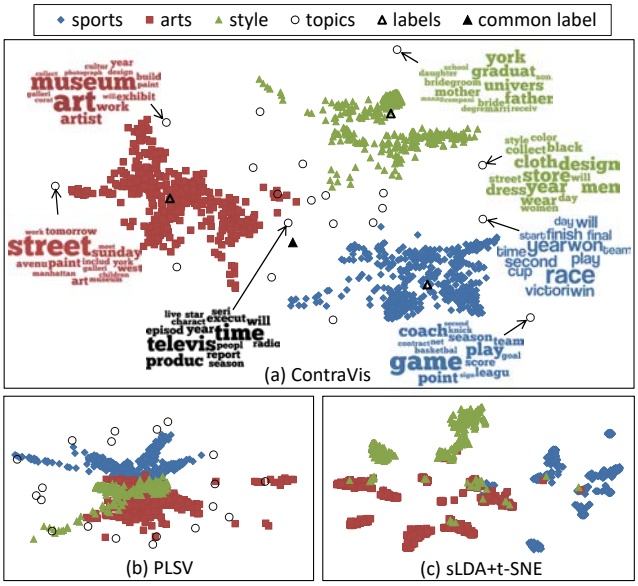

Figure 1: (best in color) Contrastive analysis of `sports`, `arts`, `style` documents from NYTnews (K=20 topics); (top) ContraVis (supervised joint method) not only finds latent discriminative topics but also gives visual embedding of documents and topics. Two discriminative topics per label shown in wordclouds (w/ respective colors) + one common topic (black); (bottom) *PLSV* (unsupervised joint method) gives visual embedding of documents and topics. However, the topics are not as discriminative, indicated by a mixing of labels. *sLDA*+tSNE (supervised topic modeling followed by embedding, document-only) has a mixing of labels and gives no means to visually explore topics. (See details in §5)

1 INTRODUCTION

Topic modeling is widely used for identifying latent themes (=topics) in a large collection (or corpus) of documents. Topics are simply groups of words that best represent the information in the corpus. As such, they aid in sense-making by characterizing the corpus at a high level, and can also be used for several downstream tasks like indexing, search and classification.

Vast majority of topic models are designed to extract topics from a *single* corpus. In many cases, on the other hand, one is interested in comparing and contrasting documents from *multiple* corpora. These corpora could be from different time periods, e.g. science articles 1960-80 vs. 1980-2000; spatial locations, e.g. news articles from 'Asia' vs. 'USA' vs. 'Europe'; or different sub-populations, e.g. essays on neuroscience vs. psychology.

Our Goal. In this work, we focus on the latter area, broadly known as comparative text mining [28]. Specifically, we address the *cross-collection modeling and visualization* problems, motivated by the following questions. How can we find hidden topics from *two or more* document collections? What are the *common and discriminative* topics among these collections? Further, how can we *visualize* the documents and topics to easily explore, compare and contrast the collections? In this paper, we refer to the task of finding common and discriminative topics as contrastive topic modeling as these topics help to contrast document collections. In addition, the visualization produced by embedding document collections and their contrastive topics is referred to as contrastive visualization. Ideally, a contrastive visualization can help users to easily spot the discriminative and common topics. In this work, we are interested in scatterplot visualization where documents and topics are embedded in a 2-d or 3-d visualization space. §6 provides a brief review of other visualization forms for visual comparison.

Previous Approaches. Topic models like *LDA* [2] and its variants can be used to find hidden topics from document collections. However, since these models are unsupervised, the extracted topics may not be discriminative. For contrastive topic modeling, we can leverage the labels of the document collections to employ supervised topic models [9, 16, 20, 21, 30]. Although the learned topics may be discriminative, these models are not designed for visualization. One can perform a post-hoc embedding using dimensionality reduction methods such as t-SNE [14] for visualization. This two-phase approach, however, has two different objective functions (one for topic modeling and one for visualization) that are optimized separately, which may result in poor visualization. Recently, new models that follow a joint approach have been developed; tying together the two steps using a single objective function [7, 10–12]. This type of unified approach is pioneered by *PLSV* [7], which jointly models topics and visualization by locating documents and topics in the same visualization space. However, *PLSV* is unsupervised and therefore the extracted topics and visualization may not be discriminative for contrastive analysis. We compare to these previous approaches through extensive experiments in §4 and §5.

Our Model. We introduce a supervised joint technique called ContraVis that addresses both contrastive topic modeling and contrastive visualization. It *simultaneously* learns (a) latent topics among multiple corpora for sensemaking and (b) 2-d or 3-d embeddings for documents, identified topics, and labels (where each corpus is represented with a unique label) for visual analysis. The topics capture both the common themes across the corpora as well as discriminative themes specific to each corpus/label. Moreover, the embeddings in the visual coordinate system reflect the semantic proximities between (*i*) the documents and topics and (*ii*) the topics and labels. To the best of our knowledge, ContraVis is the *first supervised joint technique for simultaneous contrastive topic modeling and visual embedding*.

Example. To demonstrate ContraVis's novel aspects, we show Figure 1 on an example real-world dataset from NYTnews (see Section 4.1) where we contrast three labeled corpora: `sports`, `arts` and `style`. In (b) and (c), we use unsupervised and supervised topic models, *PLSV* [7] and *sLDA* [16] respectively, to extract topics and topic probability distributions of the labeled documents. For *sLDA*, we also perform a post-hoc embedding of the documents to 2-d based on their topic representations using t-SNE [14]. In contrast, we show the output of our ContraVis in (a). Besides extracting topics, ContraVis readily produces a visual embedding (i.e., no post-hoc embedding is necessary). Moreover, it embeds not only the documents but also the labels (triangles) and the topics (circles). This provides a *holistic* view of the data. In (a), one can see the top few representative words or wordclouds per topic, like other models. What is more: (1) one can also see how documents relate to different topics and visually infer each document's probability distribution over topics, and (2) how topics relate to different labels (=corpora) which facilitates identifying the common and discriminative ones.

To summarize, our model exhibits the following key properties, which constitute the main contributions of our work.

- **Contrastive power:** We propose a new topic model called ContraVis for the comparative analysis of multiple document corpora. It quantifies its identified topics in terms of their relevance to different corpora, revealing common and discriminative ones.
- **Visual-expressiveness:** ContraVis produces embeddings, to visualize (all of) documents, labels, and topics in 2- or 3-d. Proximity in embedding space is reflective of proximity in semantic space, which helps easily infer (*i*) most dominant topics per document and (*ii*) most relevant/discriminative topics per label.
- **Unified nature:** ContraVis estimates the topics and the embedding coordinates simultaneously within a single, joint model. Thus, it is a more holistic model for comparative text analysis than existing models that require post-hoc embeddings.

We evaluate the semantic, contrastive, and visualization quality of ContraVis both qualitatively and quantitatively on diverse real-world datasets. We show the superiority of ContraVis and its potential as a method for visual contrastive analysis of multiple document collections, from diverse domains and from different sub-populations, space, or time.

Reproducibility: We share the source code for ContraVis and all of our public-domain datasets at https://github.com/tuanlvm/ContraVis.

2 PROBLEM DEFINITIONS

In this problem we aim to build a model to compare and contrast documents across different corpora, e.g. three collections of posts respectively on 'gun control', 'taxes', and 'military'. Documents belonging to a specific corpus can be labeled by its name. As such, the input is a collection of single-label documents $\mathcal{D} = \{(d_1, s_1), \ldots, (d_N, s_N)\}$, where $s_n \in \mathcal{L}$ is the label of document d_n and $\mathcal{L}$ is the set of unique labels from a finite domain. For output, our model seeks to produce a comparison that is interpretable; by inferring common topics and discriminative ones for each label. In addition, for an effective exploratory and contrastive analysis, we propose to use an visualization where documents, topics and labels are embedded in the same space such that the visual proximities between them reflect their semantic similarities and differences. Given these objectives, we give our problems formally.

Table 1: Notation used in text.

	Notation	Description
Input Corpus	$\mathcal{D}$	document corpus
	N	number of documents, $\|\mathcal{D}\| = N$
	$\mathcal{V}$	vocabulary, $\|\mathcal{V}\| = W$
	d_n	a specific document
	M_n	number of words in document d_n
	$\mathcal{L}$	set of unique labels, $\|\mathcal{L}\| = L$
	s_n	single label of document d_n
	c	common label, which is applied to all documents
	Λ_n	$\Lambda_n := \{s_n, c\}$
Topics	K	total number of topics
	z	a specific latent topic
	β_z	word distribution of topic z
	$\boldsymbol{\beta}$	collection of β_z's for all topics
Visualization	d	visualization dimension (2 or 3)
	x_n	latent coordinate of doc. d_n in visualization space
	ϕ_z	latent coordinate of topic z in visualization space
	μ_l	latent coordinate of label l in visualization space
	$\boldsymbol{\chi}$	collection of x_n's for all documents
	$\boldsymbol{\Phi}$	collection of ϕ_z's for all topics
	$\boldsymbol{\mu}$	collection of μ_l for all labels

Given *a collection of single-label documents $\mathcal{D}$ containing words from a finite vocabulary $\mathcal{V}$ and labels from set $\mathcal{L}$, number of topics K, and visualization dimension d;*

Problem 1 (Contrastive Topic Modeling). **Find**
(i) K latent topics, and word probability distributions of topics,
(ii) topic distributions of documents, and
(iii) topic and word distributions of labels.

Problem 2 (Contrastive Document Visualization). **Find** *d-dimensional visualization coordinates for (i) N documents, (ii) K topics, and (iii) L labels,*

such that *the spatial proximities between documents, topics, and labels are reflective of (or proportional to) the topic-document and topic-label probability distributions above.*

In our formulation, we introduce a new label c as a common label, which is applied to all documents. Hereafter, we denote $\mathcal{L} := \{\mathcal{L}, c\}$ and $\Lambda_n := \{s_n, c\}$ as the set of labels for each d_n. We use label c to capture the common topics among documents. Note that we infer K latent topics overall and find the probability distribution of these topics over different labels. This provides a "soft assignment" of topics to labels, from which we can deduce the relevance of each topic to each label, as well as mutual and common topics across labels. This reduces the parameter complexity of our model; as compared to finding K_l mutual topics per label $l \in \mathcal{L}$ and K_c common topics, which would require $L + 1$ hyperparameters to choose, we only set K (details in §3.2.2).

3 PROPOSED CONTRAVIS MODEL

We introduce ContraVis, a new, visually-expressive contrastive topic model that jointly addresses Problem 1 and Problem 2. Specifically, ContraVis introduces an innovative generative process that ties together the probability distributions with the visualization coordinates, as we describe next.

3.1 Generative Process

Besides inferring topic-word and document-topic probability distributions, our additional objective is to learn latent visualization coordinates x_n of each document d_n and ϕ_z for each topic. In addition, each label l is also assumed to have a latent coordinate μ_l in the same visualization space. Let $\boldsymbol{\mu} = \{\mu_l\}_1^L$. The label distribution of d_n is expressed by its Euclidean distances to labels as follows:

$$\mathrm{P}(l|x_n, \boldsymbol{\mu}) = \frac{\exp(-\frac{1}{2}||x_n - \mu_l||^2)}{\sum_{l'=1}^{L} \exp(-\frac{1}{2}||x_n - \mu_{l'}||^2)} \quad (1)$$

According to Eq. (1), $\mathrm{P}(l|x_n, \boldsymbol{\mu})$ is high when x_n is close to μ_l. Since we observe the label s_n of document d_n, d_n should be placed close to μ_{s_n} in the visualization space so that $\mathrm{P}(s_n|x_n, \boldsymbol{\mu})$ is high. Note that each document also has a probability $\mathrm{P}(c|x_n, \boldsymbol{\mu})$ of belonging to the common label c. By introducing the common label, we can model the overlap among labels while still aiming to separate them for extracting discriminative topics.

For each document, we introduce a label-dependent topic distribution $\mathrm{P}(z|l, x_n, \boldsymbol{\Phi})$, which is determined by:

$$\mathrm{P}(z|l, x_n, \boldsymbol{\Phi}) = \frac{\exp(-\frac{1}{2}||\mu_l - \phi_z||^2)\exp(-\frac{1}{2}||x_n - \phi_z||^2)}{\sum_{z'=1}^{K} \exp(-\frac{1}{2}||\mu_l - \phi_{z'}||^2)\exp(-\frac{1}{2}||x_n - \phi_{z'}||^2)} \quad (2)$$

We can see that for a label l, x_n has high $\mathrm{P}(z|l, x_n, \boldsymbol{\Phi})$ when it is close to topic ϕ_z and ϕ_z is close to label μ_l. Therefore, as x_n is to be placed close to its observed label s_n, topics that best describe d_n and are discriminative for s_n are also to be placed close to s_n.

The steps of the generative process of ContraVis are as follows:

(1) For each label $l \in \mathcal{L}$ (including common label c):
  (a) Draw l's coordinate: $\mu_l \sim \mathrm{Normal}(0, \sigma_0^{-1} I)$
(2) For each topic $z = 1, \ldots, K$:
  (a) Draw z's word distribution: $\beta_z \sim \mathrm{Dirichlet}(\lambda)$
  (b) Draw z's coordinate: $\phi_z \sim \mathrm{Normal}(0, \varphi^{-1} I)$
(3) For each document d_n, where $n = 1, \ldots, N$:
  (a) Draw d_n's coordinate: $x_n \sim \mathrm{Normal}(\mu_{s_n}, \gamma^{-1} I)$
  (b) For each word $w_{nm} \in d_n$:
    (i) Draw a label: $l \sim \mathrm{Multi}(\{\mathrm{P}(l|x_n, \boldsymbol{\mu})\}_{l=1}^{L})$
    (ii) Draw a topic: $z \sim \mathrm{Multi}(\{\mathrm{P}(z|l, x_n, \boldsymbol{\Phi})\}_{z=1}^{K})$
    (iii) Draw a word: $w_{nm} \sim \mathrm{Multi}(\beta_z)$
  (c) Set Λ_n = unique labels of w_{nm}

Above, I is the $d \times d$ identity matrix. σ_0, φ, and γ are hyperparameters that control the variance of the Normal distributions. Similar to LDA [2], ContraVis associates each topic with a word probability distribution β_z where $\mathrm{P}(\beta_z) = \frac{\Gamma\left((\lambda+1)W\right)}{\Gamma(\lambda+1)^W} \prod_{w=1}^{W} \beta_{zw}^{\lambda}$ and λ is the Dirichlet prior. Coordinates of topics and labels are drawn from spherical Normal distributions with mean at zero. For each document, we assume that its coordinate is drawn from Normal distributions with mean at μ_{s_n}. Note that this does not ensure that its generated label will be s_n. For each word w_{nm} in document d_n, first we draw a label l and draw a topic z from $\mathrm{P}(z|l, x_n, \boldsymbol{\Phi})$, w_{nm} is then drawn from multinomial β_z. Finally, labels of d_n are unique labels of d_n's words. Figure 2 illustrates the corresponding graphical model for the generative process of our model.

3.2 ContraVis Inference

The parameters of ContraVis include the word distributions of topics $\boldsymbol{\beta} = \{\beta_z\}_{z=1}^{K}$, document coordinates $\boldsymbol{\chi} = \{x_n\}_{n=1}^{N}$, topic coordinates $\boldsymbol{\Phi} = \{\phi_z\}_{z=1}^{K}$, and label coordinates $\boldsymbol{\mu} = \{\mu_l\}_{l=1}^{L}$ (including common label c). Let $\Omega = \langle \boldsymbol{\beta}, \boldsymbol{\chi}, \boldsymbol{\Phi}, \boldsymbol{\mu} \rangle$. In addition to the model

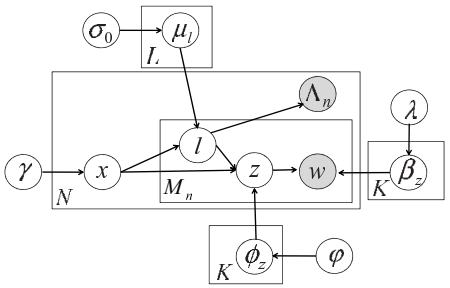

Figure 2: Graphical model representation of ContraVis's generative process (See §3.1).

parameters, the label and topic assignment of words in the documents are unobserved latent variables (See (3bi) and (3bii) of the generative process in §3.1). Therefore, we use the EM algorithm to infer Ω from $\mathcal{D}$ based on maximum a posteriori estimation. Data likelihood can be written as follows (hyperparameters omitted for simplicity).

$$\begin{aligned}\mathrm{P}(\mathcal{D}|\Omega) &= \sum_{\mathcal{L}_\mathcal{W}}\sum_{\mathcal{Z}_\mathcal{W}} \mathrm{P}(\mathcal{D},\, \mathcal{L}_\mathcal{W},\, \mathcal{Z}_\mathcal{W}|\Omega) = \prod_{n=1}^{N} \mathrm{P}(\Lambda_n)\mathrm{P}(d_n|x_n,\, \boldsymbol{\mu},\, \boldsymbol{\Phi},\, \boldsymbol{\beta}) \\ &= \prod_{n=1}^{N}\Big[\mathrm{P}(\Lambda_n)\prod_{m=1}^{M_n}\sum_{l=1}^{L}\sum_{z=1}^{K}\Big[\mathrm{P}(l|x_n,\, \boldsymbol{\mu})\mathrm{P}(z|l,\, x_n,\, \boldsymbol{\Phi})\mathrm{P}(w_{nm}|\beta_z)\Big]\Big]\end{aligned} \tag{3}$$

where $\mathcal{L}_\mathcal{W}, \mathcal{Z}_\mathcal{W}$ are respectively label assignments and topic assignments to all the words $\mathcal{W}$ in $\mathcal{D}$, and

$$\mathrm{P}(\Lambda_n) = \prod_{m=1}^{M_n}\sum_{l\in\Lambda_n}\mathrm{P}(l|x_n,\, \boldsymbol{\mu}) \tag{4}$$

The EM algorithm seeks to find the MLE of the marginal likelihood by iteratively applying E and M steps that we outline below.

E step: The conditional expectation of the data loglikelihood with priors under the current estimate of the parameters $\hat{\Omega}$ is

$$\begin{aligned}C(\Omega|\hat{\Omega}) &= \mathrm{E}_{(\mathcal{L}_\mathcal{W},\mathcal{Z}_\mathcal{W}|\mathcal{D},\hat{\Omega})}[\log \mathrm{P}(\mathcal{D},\, \mathcal{L}_\mathcal{W},\, \mathcal{Z}_\mathcal{W}|\Omega)] \\ &= \sum_{n=1}^{N}\sum_{m=1}^{M_n} log \sum_{l\in\Lambda_n}\mathrm{P}(l|x_n,\, \boldsymbol{\mu}) \\ &+ \sum_{n=1}^{N}\sum_{m=1}^{M_n}\sum_{l=1}^{L}\sum_{z=1}^{K}\mathrm{P}(l,\, z|n,\, m,\, \hat{\Omega})\log\Big[\mathrm{P}(l|x_n,\, \boldsymbol{\mu})\mathrm{P}(z|l,\, x_n,\, \boldsymbol{\Phi})\mathrm{P}(w_{nm}|\beta_z)\Big] \\ &+ \sum_{n=1}^{N}\log\mathrm{P}(x_n) + \sum_{z=1}^{K}\log\mathrm{P}(\phi_z) + \sum_{z=1}^{K}\log\mathrm{P}(\beta_z) + \sum_{l=1}^{L}\log\mathrm{P}(\mu_l)\end{aligned} \tag{5}$$

where

$$\mathrm{P}(x_n) = \Big(\frac{\gamma}{2\pi}\Big)^{\frac{D}{2}}\exp\Big(-\frac{\gamma}{2}\parallel x_n - \mu_{s_n}\parallel^2\Big), \tag{6}$$

$$\mathrm{P}(\phi_z) = \Big(\frac{\varphi}{2\pi}\Big)^{\frac{D}{2}}\exp\Big(-\frac{\varphi}{2}\parallel \phi_z\parallel^2\Big), \tag{7}$$

$$\mathrm{P}(\mu_l) = \Big(\frac{\sigma_0}{2\pi}\Big)^{\frac{D}{2}}\exp\Big(-\frac{\sigma_0}{2}\parallel \mu_l\parallel^2\Big). \tag{8}$$

We set hyper-parameters $\varphi = 0.1N$ as used in *PLSV* [7], $\gamma = L^2$ and $\sigma_0 = 0.1N$ which work well in practice. The conditional distribution of label l and topic z given the m'th word in the n'th document under current estimate of the parameters is given as

$$\mathrm{P}(l,\, z|n,\, m,\, \hat{\Omega}) = \frac{\mathrm{P}(l|\hat{x}_n)\mathrm{P}(z|l,\, x_n,\, \hat{\boldsymbol{\Phi}})\mathrm{P}(w_{nm}|\hat{\beta}_z)}{\sum_{l'=1}^{L}\sum_{z'=1}^{K}\mathrm{P}(l'|\hat{x}_n)\mathrm{P}(z'|l',\, x_n,\, \hat{\boldsymbol{\Phi}})\mathrm{P}(w_{nm}|\hat{\beta}_{z'})}. \tag{9}$$

M step: We update the entries of each β_z as follows:

$$\hat{\beta}_{zw} = \frac{\sum_{n=1}^{N}\sum_{m=1}^{M_n}\mathbb{1}(w_{nm}=w)\mathrm{P}(z|n,\, m,\, \hat{\Omega}) + \lambda}{\sum_{w'=1}^{W}\sum_{n=1}^{N}\sum_{m=1}^{M_n}\mathbb{1}(w_{nm}=w')\mathrm{P}(z|n,\, m,\, \hat{\Omega}) + \lambda W} \tag{10}$$

where $\mathbb{1}(X) = 1$ if X is true and 0 otherwise. As for the other parameters, x_n, ϕ_z, μ_l's, we do not have closed form solutions. We update them using the quasi-Newton method L-BFGS [17] with the following gradients of $C(\Omega|\hat{\Omega})$ w.r.t x_n, ϕ_z, μ_l.

$$\begin{aligned}\frac{\partial C(\Omega|\hat{\Omega},\, g)}{\partial \phi_z} &= \sum_{n=1}^{N}\sum_{m=1}^{M_n}\sum_{l=1}^{L}\Big(\mathrm{P}(l|n,\, m,\, \hat{\Omega})\mathrm{P}(z|l,\, x_n,\, \boldsymbol{\Phi}) - \mathrm{P}(l,\, z|n,\, m,\, \hat{\Omega})\Big)(2\phi_z - \mu_l - x_n) \\ &\quad - \varphi\phi_z\end{aligned} \tag{11}$$

$$\begin{aligned}\frac{\partial C(\Omega|\hat{\Omega},\, g)}{\partial x_n} &= M_n\Big(\sum_{l=1}^{L}(x_n-\mu_l)\mathrm{P}(l|x_n,\, \boldsymbol{\mu}) - \sum_{l=1}^{\Lambda_n}(x_n-\mu_l)\frac{\mathrm{P}(l|x_n,\, \boldsymbol{\mu})}{\sum_{l=1}^{\Lambda_n}\mathrm{P}(l|x_n,\, \boldsymbol{\mu})}\Big) \\ &\quad - \gamma(x_n - \mu_{s_n}) + \sum_{m=1}^{M_n}\sum_{l=1}^{L}\Big(\mathrm{P}(l|x_n,\, \boldsymbol{\mu}) - \mathrm{P}(l|n,\, m,\, \hat{\Omega})\Big)(x_n-\mu_l) \\ &\quad + \sum_{m=1}^{M_n}\sum_{l=1}^{L}\sum_{z=1}^{Z}\Big(\mathrm{P}(l|n,\, m,\, \hat{\Omega})\mathrm{P}(z|x_n,\, l,\, \boldsymbol{\Phi}) - \mathrm{P}(l,\, z|n,\, m,\, \hat{\Psi})\Big)(x_n-\phi_z)\end{aligned} \tag{12}$$

$$\begin{aligned}\frac{\partial C(\Omega|\hat{\Omega},\, g)}{\partial \mu_l} &= -\sigma_0\mu_l + \sum_{n=1,\, l=s_n}^{N}\gamma(x_n-\mu_{s_n}) - \sum_{n=1,\, l\notin\Lambda_n}^{N}M_n\mathrm{P}(l|x_n,\, \boldsymbol{\mu})(x_n-\mu_l) \\ &\quad + \sum_{n=1,\, l\in\Lambda_n}^{N}M_n\Big(\frac{\mathrm{P}(l|x_n,\, \boldsymbol{\mu})}{\sum_{l'=1}^{\Lambda_n}\mathrm{P}(l'|x_n,\, \boldsymbol{\mu})} - \mathrm{P}(l|x_n,\, \boldsymbol{\mu})\Big)(x_n-\mu_l) \\ &\quad + \sum_{n=1}^{N}\sum_{m=1}^{M_n}\Big(\mathrm{P}(l|n,\, m,\, \hat{\Omega}) - \mathrm{P}(l|x_n,\, \boldsymbol{\mu})\Big)(x_n-\mu_l) \\ &\quad + \sum_{n=1}^{N}\sum_{m=1}^{M_n}\sum_{z=1}^{Z}\Big(\mathrm{P}(l|n,\, m,\, \hat{\Omega})\mathrm{P}(z|x_n,\, l,\, \boldsymbol{\Phi}) - \mathrm{P}(l,\, z|n,\, m,\, \hat{\Omega})\Big)(\mu_l-\phi_z)\end{aligned} \tag{13}$$

Our estimated model parameters, $\Omega = \langle\boldsymbol{\beta}, \boldsymbol{\chi}, \boldsymbol{\Phi}, \boldsymbol{\mu}\rangle$, respectively capture topic word distributions (Problem 1 *(i)*) as well as document, topic, and label coordinates (Problem 2). Using Ω we can also compute the topic probability distribution of a document d_n (Problem 1 *(ii)*) and topic and word distributions of a label l (Problem 1 *(iii)*), respectively as follows.

$$\mathrm{P}(z|d_n,\, \Omega) = \sum_{l=1}^{L}\mathrm{P}(l|x_n)\mathrm{P}(z|l,\, x_n,\, \boldsymbol{\Phi}) \tag{14}$$

$$\mathrm{P}(z|l,\, \Omega) = \frac{\sum_{n=1}^{N}\mathrm{P}(d_n)\mathrm{P}(l|x_n)\mathrm{P}(z|l,\, x_n,\, \boldsymbol{\Phi})}{\sum_{n=1}^{N}\mathrm{P}(d_n)\mathrm{P}(l|x_n)} \tag{15}$$

$$\mathrm{P}(w|l,\, \Omega) = \frac{\sum_{n=1}^{N}\sum_{z=1}^{K}\mathrm{P}(d_n)\mathrm{P}(l|x_n)\mathrm{P}(z|l,\, x_n,\, \boldsymbol{\Phi})\mathrm{P}(w|\beta_z)}{\sum_{n=1}^{N}\mathrm{P}(d_n)\mathrm{P}(l|x_n)},\ \mathrm{P}(d_n) = \frac{1}{N}$$

3.2.1 Quantifying Common and Discriminative Topics.

Based on $p(z|l)$ as in Eq. (15), we define $cmn_score = p(z|c)$ and $disc_score = \frac{p(z|l)}{max_{l'\neq l}p(z|l')}$ to identify common and discriminative topics, respectively. Visually, common topics are those close to the common label and discriminative topics of a label are those near to that label but far from the other labels in the embedding space.

3.2.2 Choosing K.

In practice, setting K is challenging for the contrastive task for guessing the total number of relevant topics across corpora is nontrivial. Topic models are typically evaluated by either measuring performance on some external task, such as document classification, or by estimating the probability of unseen

held-out documents. On average, a better model produces a higher probability of held-out documents.

In our case, we aim to find K that gives rise to a model that explains (or represents) the original data $\mathcal{D}$ the best. To this end, we fix topic word distributions as well as the topic and label coordinates, and pick K (among a set of alternatives) that maximizes the following marginal likelihood of the input documents.

$$\mathrm{P}(\mathcal{D}|\boldsymbol{\mu}, \Phi, \boldsymbol{\beta}) = \prod_{n=1}^{N} \int_{x_n} \mathrm{P}(\Lambda_n)\, \mathrm{P}(d_n|x_n, \boldsymbol{\mu}, \Phi, \boldsymbol{\beta})\, \mathrm{P}(x_n) dx_n \,, \quad (16)$$

where $\mathrm{P}(d_n|x_n, \boldsymbol{\mu}, \Phi, \boldsymbol{\beta})$ is as given in Eq. (3). Here we treat input documents as though they are unseen and integrate out the unknown variables (their coordinates) to compute their likelihood.

The integral in Eq. (16) is not tractable, as such, we use importance sampling [27] to estimate the marginal likelihood, where we sample S (=500) samples of x_n from $P(x_n)$. The marginal likelihood is then approximated as:

$$\mathrm{P}(\mathcal{D}|\boldsymbol{\mu}, \Phi, \boldsymbol{\beta}) \simeq \prod_{n=1}^{N} \Big[\frac{1}{S} \sum_{s} \mathrm{P}(\Lambda_n)\, \mathrm{P}(d_n|x_n^{(s)}, \boldsymbol{\mu}, \Phi, \boldsymbol{\beta}) \Big] \,. \quad (17)$$

3.2.3 **Computational Complexity.** In ContraVis inference algorithm, E-step is performed in $O(NLKW)$ where we evaluate Eq. (9) for all words of each document. For M-step, the most expensive task is to perform the L-BFGS algorithm. As we know, for each iteration, L-BFGS has a computational cost of $O(qp)$ plus the cost to evaluate $C(\Omega|\hat{\Omega})$ in Eq. (5) and its gradients [17]. Here, q is the number of steps stored in the memory and $p = (N + L + K)d$ is the number of variables. The evaluations of $C(\Omega|\hat{\Omega})$ and its gradients can be performed in $O(NLKW)$. Since modest values of q are often between 3 and 20 [17] and the number of iterations in L-BFGS is often small, M-step can be performed at a cost of $O(NLKW)$. Therefore, ContraVis inference has an overall computational cost of $O(NLKW)$ per iteration, which is linear in the number of documents, labels, topics and vocabulary size.

4 QUANTITATIVE EVALUATION

We evaluate ContraVis both quantitatively (in this section) and qualitatively (in §5, through many case studies). Before detailing our experiment results, we describe the datasets we used for evaluation, which come from three different domains: news articles, political posts, and employee peer reviews.

4.1 Dataset Description

NYTnews consists of all the news articles published at the New York Times from January 1987 to June 2007.[1] Articles are labeled by online sections where they are published to. We omit articles published in more than one online section and select the following $L = 9$ categories: `sports`, `business`, `arts`, `style`, `travel`, `technology`, `real-estate`, `magazine`, and `health`. We also use time information to contrast articles, like `technology` news from 1990's vs. 2000's.

PolForum contains posts from a political forum, which is organized into various threads of subject areas for discussion.[2] Posts are labeled by the thread under which they appear. In total there are $L = 8$ different threads; in order of frequency: `abortion`, `religion`, `taxes`, `economy`, `military`, `gun-control`, `environment`, and `race`.

PeerReview contains peer-reviews among employees of a ride-sharing company (proprietary dataset). We group all the reviews each employee received into a document and label documents by their department. The company has $L = 4$ major departments: `operations`, `engineering`, `people-analytics`, and `finance`.

Table 2: Dataset statistics. Descriptions given in §4.1.

	#labels L	#documents N	# words W
NYTnews	9	515252	8666
PolForum	8	18732	6774
PeerReview	4	5336	4032

Table 2 shows the size of each dataset after preprocessing. In our experiments, for each dataset, we sample 250 documents from each label uniformly at random and construct 10 such collections with different samples. We report results averaged across 10 collections.

In this section, we evaluate ContraVis on three different *quantitative* tasks, and compare it to existing topic models rigorously. The tasks capture both semantic and visualization quality of the competing methods. We present quantitative performance on all datasets; NYTnews with 9, PolForum with 8, and PeerReview with 4 labels.

Before detailing our empirical results, we describe the baseline methods that we compared to.

4.2 Comparison Methods

Table 3 lists comparative methods and their properties. We compare ContraVis to both unsupervised and supervised topic models. ContraVis makes use of document labels for topic modeling and visualization, as such it is in the supervised category.

(1) (Supervised) *sLDA*[3][16] (s for supervised)
(2) (Supervised) *DiscLDA*[4] [9] (Disc for discriminative)
(3) (Unsupervised): *LDA*[5] [2]

The above baselines do not produce an explicit visual embedding of the documents (nor of the topics or labels), unlike ContraVis. For our quantitative tasks that evaluate visualization quality, we pipeline these methods with dimensionality reduction. Specifically, we obtain the documents' topic representation and use t-SNE [14] to embed them into 2-d. (See for e.g., Fig. 8b)

(4) (Unsupervised & Joint (Topics+Vis)): *PLSV*[6] [7]
(5) (Supervised & Joint (Topics+Vis)): ContraVis [this paper].

Table 3: Comparison of methods by properties.

Properties vs. Methods	*LDA*	*sLDA*, *DiscLDA*	*PLSV*	ContraVis
Contrastive (Supervised)		✔		✔
Visually-expressive			✔	✔
Unified/Jointly modeled			✔	✔

4.3 Task 1: Discrimination in 2-d

With this work, we set out to not only perform topic modeling but also visualization that enables contrastive analysis—which sets our work apart. As such, the first quantitative task involves contrastive

[1] Publicly available at https://catalog.ldc.upenn.edu/ldc2008t19
[2] Publicly available at https://github.com/tuanlvm/ContraVis/tree/master/data
[3] We use author implementation at https://github.com/blei-lab/class-slda. This is a variant of *sLDA* with a categorical response [5].
[4] We obtained the implementation from the author Prof. Simon Lacoste-Julien. In our experiments, we use *DiscLDA* with fixed transformation matrix T.

[6] We use the implementation at https://github.com/tuanlvm/SEMAFORE

power in the visualization space. Intuitively, a good contrastive visualization should well separate the documents with common topics from those belonging to discriminative topics. Moreover, it should be easy for users to spot these documents in the visualization. With this intuition, we design two subtasks for evaluation, named *Common* and *Discriminative*, described as follows.

Setup: To setup, we identify the top three most frequent labels from each dataset, which we refer to as C, B, and A (without loss of generality). For the *Common* task, we sample 250 documents each from label A and B, and 100 from C. We split C documents in half and mix with those from A and B. We consider 300 documents (250 A + 50 C) as class 1 and the other 300 (250 B + 50 C) as class 2. We then apply the methods to compare class 1 and class 2. The goal is to identify the documents with common topics among the two classes, i.e. the hidden label C ones which are considered as ground truth for the *Common* task.

For the *Discriminative* task, we sample 500 documents from C, and 50 each from A and B. We consider 300 documents (250 C + 50 A) as class 1 and the other 300 (250 C + 50 B) as class 2. We then apply the methods to compare class 1 and class 2. This time the goal is to identify the documents with discriminative topics among the two classes, i.e. the hidden label A and B ones which are considered as ground truth for the *Discriminative* task.

We quantify the ranking performance of the methods. Concretely, we rank the documents by their distance to the common label c (in 2-d) for our ContraVis (in increasing order for *Common*, and decreasing order for *Discriminative*). Since the baseline methods do not have such a c, we first find the mean coordinate of all documents from each class and take the mean of these means to designate as the common label's coordinate. We repeat the experiments for 10 randomly selected samples per dataset, and report average precision and recall on each subtask. Basically, a good contrastive visualization will have a better ranking performance because it separates well the documents with common topics from the ones with discriminative topics.

Results: Figure 3 shows the precision versus recall curves for all methods on each dataset for the *Common* task, and Figure 4 the respective plots for the *Discriminative* task. We see that ContraVis produces a better ranking for both tasks and outperforms the competing methods.

More concretely, Table 4 and Table 5 provide the mean average precision (area under PR curves) respectively for both tasks. We find that ContraVis is significantly better than the baselines in many cases according to the paired Wilcoxon signed rank test. An example illustration on NYTnews is given in Figure 5 comparing ContraVis with *sLDA* for these two subtasks. These results show the contrastive power of ContraVis in the visualization space. In addition, the ContraVis's ranking performance indicates that users can easily spot the similarities or differences among document collections by simply observing the distances between documents and the common label c, which enables visual contrastive analysis. Many case studies will be presented in §5 to show the potential of ContraVis for contrasting and comparing document collections.

4.4 Task 2: Word-to-Label Relevances

We find that the ContraVis's contrastive power in visualization space (§4.3) does not come at the expense of discriminative power and semantic coherence. To show this, we measure semantic discrimination quality, particularly, how well ContraVis can identify the most relevant words to a label (or class) as compared to the baseline methods. For instance, humans would frequently use words like 'life' and 'baby' when talking about `abortion`, and the words 'god' and 'faith' for `religion` (See Figure 10).

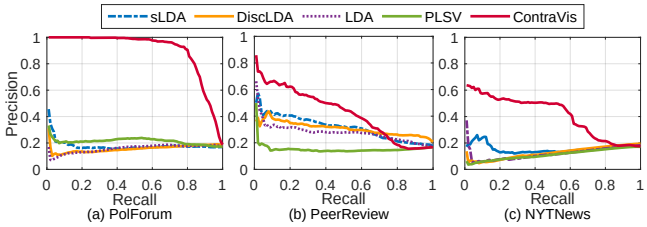

Figure 3: Precision-Recall curves (avg'ed over 10 samples) for task *Common*.

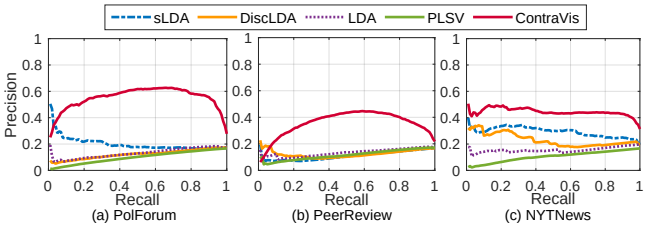

Figure 4: Precision-Recall curves (avg'ed over 10 samples) for task *Discriminative*.

Table 4: Mean Average Precision (MAP) (avg'ed across 10 samples) ± stan.dev. on task *Common*. ▲ (p<0.001) and △ (p<0.005) are cases where ContraVis is significantly better than the baseline w.r.t. the paired Wilcoxon signed rank test.

Ground truth: There is no existing repository of word-to-subject-matter relevances that we could directly use as ground truth. Therefore, we use 3 different means to create a ranked list of words by relevance to each label.

1) tf-idf: We rank the words that appear in documents of a certain label by their total tf-idf values. As such, this ranking is obtained based on in-corpus information.

2) Google 5-gram frequencies: We take a large collection of 5-grams generated by Google Inc. from around 1 trillion word tokens of text from public Web pages.[7] For each label l (e.g. `religion`), we count the number of times the word pair (w, l) co-occurs across the 5-grams, and sort the words (w's) by their frequency.

[7] https://catalog.ldc.upenn.edu/ldc2006t13

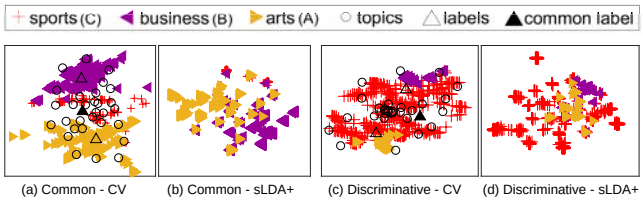

Figure 5: (best in color) Visualization of documents from NYTnews (K=30); *Common* task: (a) ContraVis (CV) places docs with common topics (sports) near the common label, (b) *sLDA+*: it is not as easy to spot common docs; *Discriminative* task: (c) CV places docs with discr. topics (business, arts) far from the common label as well as one another, (d) *sLDA+*: it is not easy to spot these docs. + is short for +t-SNE.

3) Yahoo 5-gram frequencies: We obtain a 3rd ranking of words by label relevance based on Yahoo 5-grams[8], in the same fashion as the above.

Setup: We quantify the word-to-label relevances of models by computing $p(w|l)$, which is given in Eq. (3.2) for ContraVis. For unsupervised models, *LDA* and *PLSV*, we compute $p(w|l) = \sum_z p(w|z)p(z|l)$, where $p(w|z)$ is readily output by the model and $p(z|l) = \frac{\sum_{d_n:s_n=l} p(z|d_n)}{\sum_{z=1}^{K}\sum_{d_n:s_n=l} p(z'|d_n)}$. For *sLDA* and *DiscLDA*, $p(w|l) \propto \sum_{n=1}^{N}\sum_{z=1}^{K} p(w|z)p(z|d_n)p(l|d_n)p(d_n)$ with $p(d_n) = \frac{1}{N}$, where $p(l|d_n)$ for *sLDA* is computed using softmax [5], and is approximated for *DiscLDA* using bridge sampling [9].

We measure the quality of the top t words in a given model's ranking, based on the Normalized Discounted Cumulative Gain: $NDCG = \frac{DCG@t}{IDCG@t}$. $DCG@t = \sum_{i=1}^{t} \frac{rel_i}{\log_2(i+1)}$ (the higher, the better), where rel_i is the "true" relevance of top ith word. We obtain rel_i from the ground truth using corresponding word's respective score used for ranking (i.e., frequencies or tf-idf). $IDCG@t$ is the "ideal" DCG, that of the top t words of the ground truth itself.

Note that Yahoo and Google rankings contain many out-of-corpus words since they are based on external corpora, where we expect all methods to obtain lower $NDCG$ relative to the tf-idf ground truth with the ranked list of in-corpus words.

Results: Figure 6 shows $NDCG@t$ performance of the methods for $t \in \{10, 20, \ldots, 100\}$ on each dataset based on the tf-idf in-corpus ground truth. ContraVis consistently ranks among the top across all t thresholds, closely followed by *sLDA*. To quantify the differences more concretely, we perform the paired Wilcoxon signed rank test across 10 samples and all labels of each dataset, as presented in Table 6 for all three ground truth. As one can see, ContraVis significantly outperforms the competing methods in many cases. On NYTnews there is no significant difference between ContraVis and *sLDA*, but, ContraVis is significantly superior to *sLDA* on the other two datasets across all ground truth.

Pairwise significance tests according to the paired Wilcoxon signed rank test reveal the (total or partial) orderings in Table 7. We find that ContraVis is significantly superior to all methods in many cases and ties with *sLDA* and *LDA* in some cases. We wrap up with Table 8 that provides qualitative evidence to the quality of $p(w|l)$ rankings by ContraVis. It ranks words like 'white' and 'black' at top for l : `race` from PolForum, 'candidate' and 'recruit' for l : `people-analytics` from PeerReview, and 'building' and 'house' for l : `real-estate` from NYTnews, among others, which all agree with human intuition.

4.5 Task 3: Classification in 2-d

Since learning contrastive visualization is supervised, we can expect that the labels should be well separated in the visualization space. However, we find it is still valuable to show what is the extent that ContraVis separates the labels compared to the baselines. To investigate this, we perform k Nearest Neighbors (kNN) classification with visualization coordinates as inputs, i.e., each document will be assigned to the dominant label among its k nearest neighbors in

Table 8: Top 5 most relevant/discriminative words for a selection of three labels from each dataset w.r.t. $p(w|l)$ by ContraVis closely agree with human understanding.

Dataset	Label	Top 5 Words
PolForum	abortion	abort, human, life, peopl, person
	taxes	tax, govern, incom, pay, will
	race	black, white, peopl, race, racist
PeerReview	operations	help, citi, idea, busi, peopl
	engineering	help, project, engin, issu, good
	people-analytics	candid, help, recruit, hire, manag
NYTnews	sports	game, team, play, season, year
	business	compani, year, percent, will, market
	real-estate	build, hous, year, number, apart

the visualization space. The accuracy is the fraction of documents with predicted label matching the truth. We report the accuracy on each dataset, averaged across 10 collections. Intuitively, higher accuracy means that labels are more separated in the visualization space.

Results: Figure 7 shows kNN accuracy of all methods on each dataset, for varying (left) number of topics K and (right) number of nearest neighbors k and an example illustration on NYTnews is given in Figure 8 comparing ContraVis with *DiscLDA* (the second best performing baseline on this task). We note the near-perfect accuracy that ContraVis achieves across all datasets and settings which may imply that ContraVis aggressively separate the labels to learn discriminative topics and thus the learned topic model may be too overfitted. However, as discussed in §6, ContraVis focuses on comparing document collections, which aims to learn a discriminative topic model that best explains the similarities and differences among these document collections. Its focus is not on prediction tasks such as classification or regression. Therefore, overfitting may not be a big issue to ContraVis, but conversely, in some cases it may be a good trait (e.g., when we try to extract the differences between two very similar labels).

5 QUALITATIVE EVALUATION

In this section, we evaluate ContraVis qualitatively through many case studies where we apply our method to contrast and compare 2 or 3 document collections. These case studies represent common application scenarios. Our case studies are designed to answer two questions: (1) How well does ContraVis capture the underlying discriminative and common topics? Do these topics agree with human intuition? and (2) How good are the visualizations that ContraVis produces?

5.1 NYTnews

We perform our first case study on NYTnews using three labels (`sports`, `arts`, `style`). As shown in Figure 1(a), ContraVis well-separates the collections and the learned topics are also discriminative. For `sports`, we see topics about basketball and racing game. Topics exclusive to `arts` include 'museum', 'art', 'exhibit' and 'street', 'art', 'paint'. For `style`, we see a topic on fashion ('cloth', 'design', 'women') and another one about lifestyle ('graduate', 'university', 'father'). Figures 1(b) and 1(c) show the visualizations by *PLSV* and *sLDA*+t-SNE which are not as comprehensive and documents are not as well separated.

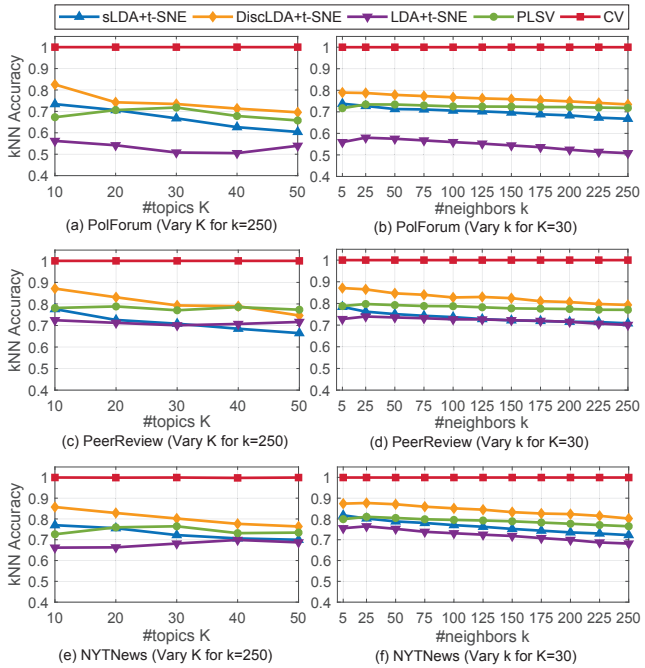

Figure 7: kNN classification accuracy in 2-d (avg'ed across 10 random samples per dataset) on (from top to bottom) PolForum, PeerReview, and NYTnews. ContraVis (denoted as CV) consistently and significantly outperforms competition in all settings.

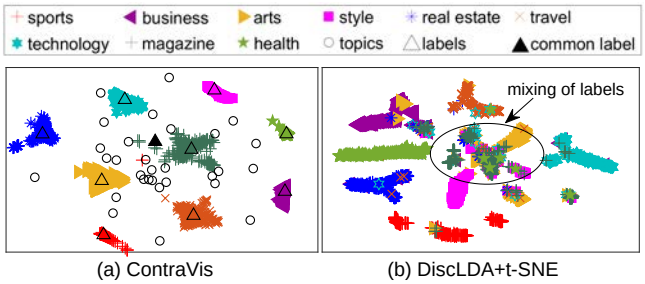

Figure 8: (best in color) 2-d visualization of documents from NYTnews ($K = 30$); (left) ContraVis embedding well-separates documents with different labels, in contrast (right) *DiscLDA*+tSNE embedding is not as pure.

The next study compares documents across time. Specifically, we apply ContraVis to contrast `technology` articles in NYTnews from 1990's vs. 2000's. As shown in Figure 9, in 1990's, tech-news talked about 'website', 'travel', 'find', 'book', etc. Notice that WWW was invented in 1989, after which computers started being used for finding information, booking travel, etc. In contrast, in 2000's news started to involve 'video', 'game', and 'xbox', that is around the period when Xbox was introduced in 2001. In both time periods, tech-news discuss about 'system', 'machine', 'power', and 'technology'. The number of articles also reflects the development of technology. We have only 79 articles on `technology` in 1990-1997, with a lot more in 2000 and onward.

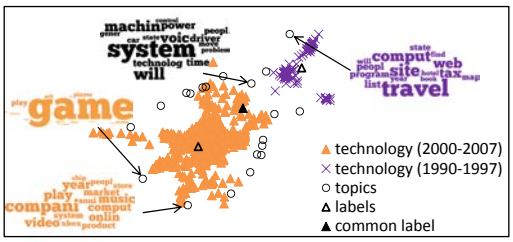

Figure 9: (best in color) Comparing `technology` articles from different time periods in NYTnews using ContraVis (K=20).

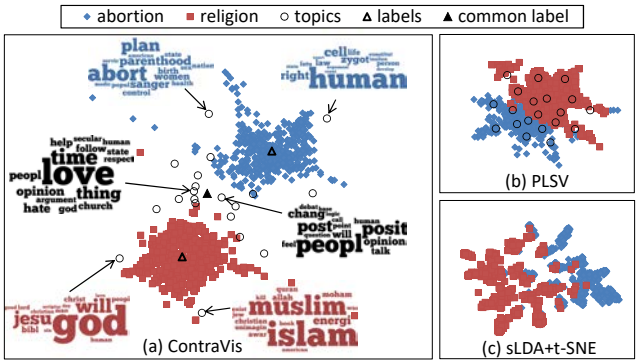

Figure 10: (best in color) Contrastive visualization of `abortion` and `religion` posts from PolForum (K=20); (left) ContraVis embedding well-separates the collections and two most discriminative topics per label and two common topics shown are intuitive, while (right) *PLSV* and *sLDA*+tSNE embeddings are not on par.

5.2 PolForum

Next, we apply ContraVis to see what topics are discussed in different threads of PolForum. Figure 10 shows a contrastive visualization of `abortion` vs. `religion` posts. *PLSV* and *sLDA*+t-SNE embeddings in Figure 10(b) and 10(c) do not provide a well visual comparison of the two threads. ContraVis embedding in Figure 10(a), by contrast, shows separated clusters. Also shown are two most discriminative topics for each thread as well as two common topics. Abortion topics are intuitive; with words like 'abort', 'plan', 'parenthood' and 'human', 'cell', 'zygote'. Under `religion`, people talk about Christianity and Islam, respectively involving words 'god', 'jesus', 'bible' and 'islam', 'muslim', 'allah'. They share common topics around 'peopl', 'opinion', 'position', etc.

Figure 11 shows another use case, comparing posts from `taxes`, `military` and `gun-control` threads. We see that a common topic has frequently used words such as 'govern', 'right', 'rule' and 'power'. Also shown are one discriminative topic for each thread, which are right on subject and coherent. For example, topic exclusive to `gun-control` has representative words 'gun', 'furious', 'law', 'firearm' and 'atf'. ATF is a United States law enforcement agency for regulating use of firearms. In the embedding, `taxes` and `gun-control` posts are close to each other which suggests that they may be more related to each other than they are to `military`.

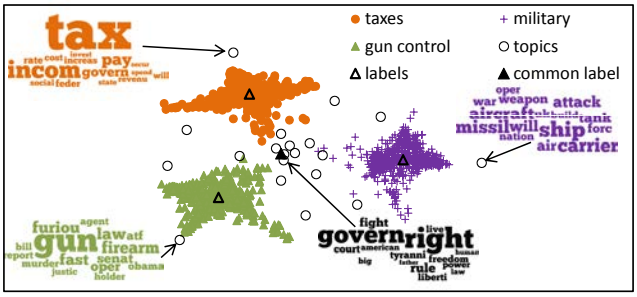

Figure 11: (best in color) Comparing posts on `gun-control`, `taxes`, & `military` from PolForum using ContraVis (K=20).

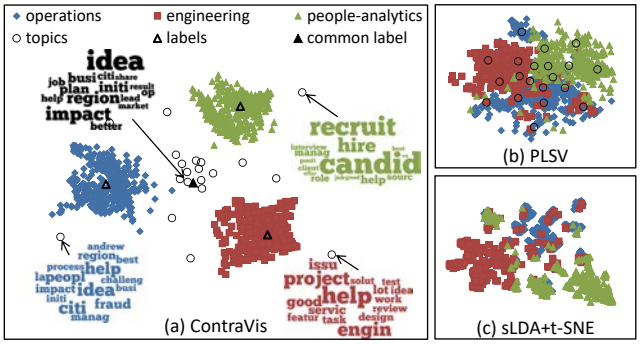

Figure 12: (best in color) Contrastive visualization of reviews for employees from different departments in PeerReview (K=20); (left) In ContraVis embedding, departments are well-separated and disc. topics reflect the role of each department; (right) *PLSV* and *sLDA*+tSNE embeddings mix the labels. *sLDA*+tSNE embedding is doc-only (no topics).

5.3 PeerReview

Finally, we present a case study where we compare reviews of employees from different departments in PeerReview. Since documents are reviews, we expect to see very frequent words like 'help(ful)', 'good' and 'idea' in the topics. In spite of that, ContraVis still can detect discriminative topics which are closely related to the role of each department. For example, from ContraVis embedding in Figure 12(a), one can tell that `people-analytics` department is responsible for recruiting, `engineering` deals with project design and testing, and `operations` is responsible for managing business in different regions. These insights cannot be gained from the embeddings by *PLSV* and *sLDA*+t-SNE in Figure 12(b) and 12(c).

Through several case studies from different domains above, we have shown that ContraVis finds meaningful topics that agree with human understanding. In addition, it provides an intuitive visualization that helps quickly identify common and discriminative topics as well as their relationship to documents and labels. Overall, ContraVis shows promise for exploratory and comparative text analysis, and is superior to existing topic models like *PLSV* (unsupervised joint method) and *sLDA* which necessitates post-hoc embedding with subpar results.

6 RELATED WORK

Unsupervised Topic Modeling and Visualization: There are various unsupervised topic models [2, 6, 22]. *LDA* [2] is arguably the most popular one that represents each document as a mixture of topics and each topic as a probability distribution over words. For visualization, one needs to pipeline these with dimensionality reduction methods such as t-SNE [14], LargeVis [26]. Recently, methods that jointly model topics and visualization using a single generative model have been developed. This line of research is pioneered by *PLSV* [7] and is further developed by later works that incorporate the neighborhood graph [12], use document network/hyperlinks information [10], or model documents' spherical representation [11]. Similar to ContraVis, these methods assume that all documents and topics are represented as points in the same visualization space. The main differences between ContraVis and these methods are: (1) ContraVis is a supervised method where labels are used to extract the discriminative topics and produce contrastive visualization; (2) ContraVis assumes that each document has a label distribution and labels are also located as points in the visualization space. The distances from documents to labels encode the label distributions; (3) ContraVis introduces label-dependent topic distributions for each document. Basically, a document tends to pick topics belonging to its label for generating its words; (4) ContraVis explicitly models common topics by introducing the common label which is shared across documents. By modeling label distributions and label-dependent topic distributions, ContraVis can effectively extract discriminative and common topics. We extensively compare to *LDA*+t-SNE and *PLSV*. Other joint methods [10–12] are not directly comparable to ContraVis, as they use additional input such as neighborhood information or the document network. We can extend ContraVis to incorporate such information if available.

Supervised Topic Modeling and Visualization: Several supervised topic models have been proposed such as *sLDA* [16], *DiscLDA* [9] for single-label documents and *LabeledLDA* [20], *PLDA* [21] for multi-label and partially labeled documents respectively. Recently, *MedLDA* integrates the max-margin principle into supervised topic models by optimizing the goodness of fit of the learned topic model and its prediction accuracy on a max-margin classifier [29]. These models use document side information such as categories or review rating scores to steer the model learning towards extracting more discriminative topics for prediction tasks such as classification or regression. Unlike these supervised topic models, ContraVis focuses on the task of comparing document collections whose objective is to extracting common and discriminative topics for exploring both the similarities and the differences among these collections. Its focus is not on document classification tasks. Moreover, ContraVis also jointly produces a contrastive visualization, which enable visual comparison of document collections. For supervised topic models mentioned above, one needs to pipeline these methods with a post-hoc embedding using a dimensionality reduction technique (like t-SNE [14]), which is not effective for visually contrasting document collections as we demonstrated in our experiments. Among these models, *sLDA* and *DiscLDA* are more closely related to our work as they are for single-label documents and in principle we can extend ContraVis to integrate the max-margin mechanism as in *MedLDA*. In our experiments, we extensively compared to two state-of-the-art supervised topic models for single-label documents, *sLDA*+t-SNE and *DiscLDA*+t-SNE.

Comparative Text Mining: There have been works that directly model common and discriminative topics for comparative text mining. CCMix [28] introduces a probabilistic mixture model to identify k common themes across all collections and k collection-specific themes for each collection. ccLDA [19] improves over CCMix [28] by introducing an LDA-based analog, which automatically learns the probability of using the common vs. collection-specific word distributions while generating documents. While ccLDA maintains common and collection-specific word probability vectors for each topic, differential topic models [4] propose to use a hierarchy of topics across collections. Recently, there are works that propose using spectral methods [30] and nonnegative matrix factorization [8] for comparative text mining. However, they mainly focus on scenarios involving two collections while our method can handle multiple corpora. Moreover, although these methods can infer common and discriminative topics across collections, they do not provide any means for visual comparison, unlike ContraVis.

Visualization for Comparison: ContraVis uses scatterplot visualization to display the relationship between documents, topics, and labels. There exist work that propose other visualization forms for making comparisons. For example, DiTop-View, in which topics are represented as glyphs on a 2D plane, is used for comparing document collections [18]. Buddy plots, on the other hand, represent each document as a row and other documents are encoded as circular glyphs along the row for comparison of topic models [1]. TextDNA [25] use configurable colorfields to visualize word usage patterns across different text collections. Other work focus on comparing two or more documents using word clouds [3, 13]. Compared to these visualization forms, scatterplot by ContraVis provides an effective way to get an overview of multiple corpora as it explicitly shows the relationship between documents, topics and labels. A challenge with scatterplots is that they are susceptible to overdraw (overlapping glyphs); for very large document corpora one could employ several tackling strategies [15].

We note that work on summarizing and extracting phrases for contrasting opinions in text documents [23, 24] are different in focus, without specific emphasis on topic modeling or visual analysis.

7 CONCLUSION

We propose ContraVis[9], a new supervised topic model for contrasting and visualizing multiple document collections. Our model jointly learns common and discriminative topics as well as embeddings of documents, topics, and labels for visualization. Due to its joint nature of contrastive topic modeling and visualization, the learned topics and their relationships to documents and labels are reflected faithfully in the visualization, which facilitates exploring and comparing the collections. To the best of our knowledge, ContraVis is the first to jointly address the contrastive topic modeling and visualization problems. We conduct comprehensive experiments on real-life datasets and the results show that our method significantly outperforms the existing techniques in terms of contrastive power as well as visual and semantic coherence.

Classifying Extremely Short Texts by Exploiting Semantic Centroids in Word Mover's Distance Space

ABSTRACT

Automatically classifying extremely short texts, such as social media posts and web page titles, plays an important role in a wide range of content analysis applications. However, traditional classifiers based on bag-of-words (BoW) representations often fail in this task. The underlying reason is that the document similarity can not be accurately measured under BoW representations due to the extreme sparseness of short texts. This results in significant difficulty to capture the generality of short texts. To address this problem, we use a better regularized word mover's distance (RWMD), which can measure distances among short texts at the semantic level. We then propose a RWMD-based centroid classifier for short texts, named RWMD-CC. Basically, RWMD-CC computes a representative semantic centroid for each category under the RWMD measure, and predicts test documents by finding the closest semantic centroid. The testing is much more efficient than the prior art of K nearest neighbor classifier based on WMD. Experimental results indicate that our RWMD-CC can achieve very competitive classification performance on extremely short texts.

1 INTRODUCTION

The amount of extremely short texts available online, such as social media posts and web page titles, has exploded. Automatic classification of extremely short texts is significant for a wide range of content analysis applications, e.g., user interest profiling [41] and query suggestion [31] etc. However, it is acknowledged as a very challenging task [17, 19, 32] due to the sparseness of extremely short texts, where a single short text, e.g., Twitter posts, often contains even less than 10 words.

Table 1: Examples of document similarity. All values are computed after a removal of the stopwords. *BoW*: the cosine of the BoW representation. *WMD*: the normalized inverse of WMD using a pre-trained *Glove* word embeddings.

Document	*BoW*	*WMD*

The relentless pursuit of perfection makes things better. *The constant striving for perfection improves the situation.*	0.13	0.92

The major difficulty in extremely short text classification is that there are much less informative word co-occurrences among short texts under the bag-of-words (BoW) representations, therefore the existing algorithms are mainly based on feature expansion [8, 12, 18, 20, 21, 25, 29, 32, 35, 38–40]. The representative works include: the method of [29] uses search engines to obtain auxiliary contexts, and applies traditional classifiers to those expanded short texts; the work in [25] expands document features by hidden topics learnt from a big reference Wikipedia corpus, where the latent Dirichlet allocation (LDA) [3] topic model is used as a hidden topic excavator. Although these feature expansion methods empirically improve the classification performance, they are heavily domain-dependent. For example, the hidden topics learnt from reference corpora may be inconsistent with the current dataset, making the concatenation features less discriminative.

In some sense, we can analyze the difficulty of extremely short text classification with BoW representations from a just different perspective of document similarity misalignment. Because the short texts are extremely sparse, i.e., containing very few words, even semantically close text pairs may merely share any same word by no means, resulting in inaccurate similarity measure under their BoW representations (Examples are shown in Table 1). In this situation, it is intractable to find the generality of short texts from the same category and the difference of ones from different categories, raising up significant difficulty to build the decision plane of classifiers. Fortunately, recently a word mover's distance (WMD) [15] has been developed, which measures the optimal transport from

the embedded words of one document to those of another one, a special case of earth mover's distance (EMD) [26]. The WMD can effectively measure semantic distances among documents using word embeddings [16, 23], therefore it must be a good choice to short texts, instead of distances, as well as similarities, of BoW. Reviewing examples in Table 1, the WMD can effectively measure short text distances even when they share no any same word.

Driven by the success in WMD, we aim at developing short text classifiers using it. A straightforward previous classifier with WMD is the K nearest neighbour (KNN) with a prefetch and prune scheme [15]. It has shown very competitive classification performance, however, the KNN classifier based on WMD is much testing-inefficient especially for big corpora, where for prediction of a test sample one must compute its WMDs with all training samples. Motivated by this, we would like to train a representative semantic centroid for each category, and predict a test sample by comparing the WMDs between it and these semantic centroids, so as to reduce the testing complexity to the category number. We propose a novel **R**egularized **W**ord **M**over's **D**istance **C**entroid **C**lassifier (**RWMD-CC**), of which the objective is built on hypothesis margin with WMD. In RWMD-CC, a problem is that the objective with WMD must be intractable to compute, because the WMD itself is a optimal transport problem. To solve this, we borrow the idea from regularized WMD [6] for efficient optimization, i.e., computing the gradient of the objective. Experimental results indicate that our RWMD-CC outperforms the state-of-the-art baseline classifiers of short texts.

The major contributions of this paper are outlined as follows:

- We develop a both effective and efficient RWMD-CC method for short text classification.
- We build a loss function using hypothesis margin that is based on the structural risk minimization principle, and borrow the idea from regularized WMD for efficient optimization.
- Empirical results indicate that our RWMD-CC outperforms the state-of-the-arts, and is much more efficient on testing than the existing WMD-based methods.

2 PRELIMINARIES

Formally, the word mover's distance (WMD) [15] is a special case of the earth mover's distance (EMD) [26, 27], also named Wasserstein distance [4]. Therefore, we first introduce the EMD, and then show the WMD in detail.

2.1 Optimal Transport and Earth Mover's Distance

The earth mover's distance is the special case of optimal transport distance. Essentially, the optimal transport distance [34] is a measure of the distance between two probability measures over a finite set $\mathcal{V}$ of size $|\mathcal{V}| = V$, i.e., p_1 and p_2. Given a cost function $c : \mathcal{V} \times \mathcal{V} \to \mathcal{R}$, the optimal transport distance measures the optimal (i.e., cheapest) way to transport the mass in probability measure p_1 to match that in p_2:

$$W_c\left(p_1, p_2\right) = \inf_{\gamma \in \Pi(p_1, p_2)} \int_{\mathcal{V}\times\mathcal{V}} c\left(v_1, v_2\right) \gamma\left(dv_1, dv_2\right), \qquad (1)$$

where $\Pi(p_1, p_2)$ denotes the set of joint probability measures on $\mathcal{V} \times \mathcal{V}$ with p_1 and p_2 as marginals. When the cost function c is a metric or the p-th power with $p \geq 1$ of one over $\mathcal{V}$, Eq.1 is called the earth mover's distance, also Wasserstein distance.

In terms of the discrete measures, both marginals are in the simplex, i.e., $p_1,\ p_2 \in \Delta^{\mathcal{V}} = \{\mathbf{x} \in \mathcal{R}_+^V \mid \mathbf{x}^\intercal \mathbf{1} = 1\}$, where $\mathbf{1}$ is the all-one vector. The EMD thus can be written as follows:

$$W_c\left(p_1, p_2\right) = \inf_{\gamma \in \Pi(p_1, p_2)} \langle \gamma, C \rangle \qquad \gamma \mathbf{1} = p_1,\ \gamma^\intercal \mathbf{1} = p_2, \qquad (2)$$

where $\langle \cdot, \cdot \rangle$ stands for the Frobenius dot-product, $C \in \mathcal{R}^{V \times V}$ is the distance matrix computed by cost function c, also a metric. The time complexity of calculating the EMD between two V-dimensional discrete distributions scales at least in $O(V^3 \log(V))$ [24].

2.2 Word Mover's Distance

The WMD can be seemed as a special case of the discrete EMD, used for measuring distances among documents. Given a document d, we can represent it as a normalized V-dimensional term frequency vector:

$$tf_d = \left(\frac{tf_{d1}}{\sum_{v=1}^V tf_{dv}}, \frac{tf_{d2}}{\sum_{v=1}^V tf_{dv}}, \cdots, \frac{tf_{dV}}{\sum_{v=1}^V tf_{dv}} \right), \qquad (3)$$

where tf_{dv} is the term frequency of word v in document d, and V is the number of unique words.

One can consider that the above normalized term frequency vector as a discrete multinomial distribution over words, also a simplex. In this case, given two documents d_i and d_j, we can use the EMD to measure the distance between them, leading to the WMD, i.e., $W_c\left(tf_{d_i}, tf_{d_j}\right)$.

Here, the cost function is the distance or similarity of the corresponding word embeddings of words occurring in the documents, and also a metric over word embeddings. By using word embeddings, the WMD can take semantic information of words into consideration. In this sense, the WMD actually measures the optimal transport from one document to any other at the semantic level.

Regularized WMD. The authors of [6] formulated a smoothed version of EMD by introducing an entropic regularization term to the objective of EMD. This makes the objective strictly convex, so as to efficiently be solved by Sinkhorn-Knopp algorithm [30]. Following this, we can obtain a regularized WMD (RWMD), a.k.a. dual-Sinkhorn divergence [6], formulated by:

$$W_c^\lambda\left(tf_{d_i}, tf_{d_j}\right) = \left\langle \gamma_\lambda^*, C \right\rangle, \qquad (4)$$

where

$$\gamma_\lambda^* = \underset{\gamma \in \Pi(tf_{d_i}, tf_{d_j})}{\arg\min} \langle \gamma, C \rangle - \frac{1}{\lambda} H(\gamma),\ \gamma \mathbf{1} = tf_{d_i},\ \gamma^\intercal \mathbf{1} = tf_{d_j}, \qquad (5)$$

where $H(\cdot)$ denotes the entropy, and $\lambda > 0$ is a regularization parameter. With λ larger, the closer the regularized WMD is to the original EMD. Cuturi [6] shows that with Sinkhorn-Knopp algorithm [30] the regularized WMD can be solved in $O(V^2)$ time, which is significantly lower than computing the original EMD that costs at least in $O(V^3 \log(V))$ [24].

3 RWMD-BASED CENTROID CLASSIFIER

In this section, we describe the proposed RWMD-CC method for short texts.

3.1 Formulation

For clarity, we first give a formulation of the text classification task.

We use $x_d \in \Delta^{\mathcal{V}}$ and $y_d \in \mathcal{Y} = \{1, 2, \cdots, L\}$ to respectively denote the normalized term frequency vector and the label of short text d, where $\mathcal{V}$ is the set of unique words with size V and L is the number of labels. Then, a training dataset of D short texts is described by $S = \{x_d, y_d\}_{d=1}^{d=D}$. Our goal is to learn a classifier from S for predicting future short texts, i.e., learning a prediction function $f(x|\theta) \rightarrow y$ with parameter θ.

3.2 RWMD-CC

We begin with the centroid-based classification methodology. The mechanism is that given L category centroids $\{\theta_l \in \Delta^{\mathcal{V}}\}_{l=1}^{l=L}$, we predict any future short text x' by finding its closest category centroid.

The goal now is to learn these L category centroids from the training dataset S. Inspired by the prior art [33] and based on the structural risk minimization principle, we design a loss function of RWMD-CC using hypothesis margin, which involves both training errors (> 0) and inverse training margins (< 0). With a squared Frobenius norm regularizer, the loss function with repsect to θ is defined to be:

$$\begin{aligned}\mathcal{L}(\theta) = &\frac{1}{D}\left\{\sum_{d=1}^{D}\left|W_c^{\lambda}\left(g(x_d), g(\theta_R)\right) - W_c^{\lambda}\left(g(x_d), g(\theta_M)\right)\right|_{-}\right. \\ &\left. + \sum_{d=1}^{D}\eta\left|W_c^{\lambda}\left(g(x_d), g(\theta_R)\right) - W_c^{\lambda}\left(g(x_d), g(\theta_M)\right)\right|_{+}\right\} \\ &+ \frac{\lambda'}{2}\|\theta\|_F^2,\end{aligned} \tag{6}$$

where $|z|_{-} = min\{z, 0\}$, $|z|_{+} = max\{z, 0\}$; θ_R and θ_M denote the nearest category centroids to x_d under the RWMD measure with same and different label, respectively; $\eta \geq 1$ is a constant parameter to balance the training errors and inverse training margins in the loss function; $\|\cdot\|_F^2$ is the squared Frobenius norm, and $\lambda' \in [0, 1]$ is a regularization parameter. Here, we introduce $g(\cdot)$ with the constant importance vector $\mathbf{w}$:

$$g(x) = \frac{\mathbf{w} \circ x}{\mathbf{w}^{\intercal} x},$$

where $\circ$ represents the Hadamard product, to reflect the importance of words for distinguishing the categories in different classification tasks and datasets.

With the category centroids $\hat{\theta}$ obtained by optimizing $\mathcal{L}(\theta)$, for any future short text x', the prediction function of RWMD-CC is defined by:

$$y = \underset{l=1,\cdots,L}{\arg\min}\, W_c^{\lambda}\left(g(x'), g(\hat{\theta}_l)\right). \tag{7}$$

Besides, to obtain normalized centroids and avoid constrained conditions, we use the softmax transformation $\mathfrak{s}(\mu)$ for centroids θ with auxiliary parameters μ:

$$\theta = \mathfrak{s}(\mu), \qquad \theta_{lv} = \frac{\exp(\mu_{lv})}{\sum_{i=1}^{V}\exp(\mu_{li})}. \tag{8}$$

Combining Eq.6 and Eq.8, we reach the following final loss function with respect to the auxiliary parameters μ:

$$\mathfrak{L}(\mu) = \mathcal{L}\Big(\mathfrak{s}(\mu)\Big). \tag{9}$$

3.3 Optimization

We use gradient descent to minimize the loss function $\mathfrak{L}(\mu)$. In the following, we first show the optimization process, and then provide the implementation details.

3.3.1 The Optimization Algorithm of RWMD-CC. In gradient descent, given the gradient $\nabla\mathfrak{L}(\mu)$ and the learning rate φ, the parameters μ are updated by $\mu \leftarrow \mu - \varphi\nabla\mathfrak{L}(\mu)$. In the following, we mainly describe the computation of the gradient $\nabla\mathfrak{L}(\mu)$ and then outline the full algorithm.

The gradient $\nabla\mathfrak{L}(\mu)$. After some simple derivations, we show the gradient $\nabla\mathfrak{L}(\mu)$ as follows:

$$\begin{aligned}\nabla\mathfrak{L}(\mu) &= \frac{\partial\mathcal{L}\Big(\mathfrak{s}(\mu)\Big)}{\partial\mathfrak{s}(\mu)} \times \frac{\partial\mathfrak{s}(\mu)}{\partial\mu} \\ &= \theta \circ \frac{\partial\mathcal{L}(\theta)}{\partial\theta} - \theta\left(\theta^{\intercal}\frac{\partial\mathcal{L}(\theta)}{\partial\theta}\mathbf{I}_L\right),\end{aligned} \tag{10}$$

where $\mathbf{I}_L$ is the identity matrix with dimension L. The calculation of $\nabla\mathfrak{L}(\mu)$ only depends on $\frac{\partial\mathcal{L}(\theta)}{\partial\theta}$ that is given below.

[Computation of $\frac{\partial\mathcal{L}(\theta)}{\partial\theta}$]

For convenience, we re-write $\mathcal{L}(\theta)$ in Eq.6 as

$$\mathcal{L}(\theta) = \frac{1}{D}\left(\sum_{d=1}^{D}\delta\Big(h(x_d, \theta)\Big)h(x_d, \theta)\right) + \frac{\lambda'}{2}\|\theta\|_F^2, \tag{11}$$

where

$$\delta(z) = \begin{cases}\eta & \text{if } z \geq 0, \\ 1 & \text{if } z < 0;\end{cases}$$

$$h(x_d, \theta) = W_c^{\lambda}\left(g(x_d), g(\theta_R)\right) - W_c^{\lambda}\left(g(x_d), g(\theta_M)\right).$$

Consequently, the gradient of $\mathcal{L}(\theta)$ with respect to each category centroid θ_l can be computed by:

$$\frac{\partial\mathcal{L}(\theta)}{\partial\theta_l} = \frac{1}{D}\left(\sum_{d=1}^{D}\delta\Big(h(x_d, \theta)\Big)\frac{\partial h(x_d, \theta)}{\partial\theta_l}\right) + \lambda'\theta_l, \tag{12}$$

where

$$\frac{\partial h(x_d, \theta)}{\partial\theta_l} = \begin{cases}\frac{\partial W_c^{\lambda}\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)} \times \frac{\partial g(\theta_l)}{\partial\theta_l} & \text{if } \theta_R = \theta_l \\ -\left(\frac{\partial W_c^{\lambda}\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)} \times \frac{\partial g(\theta_l)}{\partial\theta_l}\right) & \text{if } \theta_M = \theta_l,\end{cases} \tag{13}$$

and

$$\frac{\partial g(\theta_l)}{\partial\theta_l} = \frac{\text{diag}(\mathbf{w}) - g(x)\mathbf{w}^{\intercal}}{\mathbf{w}^{\intercal}x}.$$

The computation of $\frac{\partial\mathcal{L}(\theta)}{\partial\theta_l}$ requires $\frac{\partial W_c^{\lambda}\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)}$, which, unfortunately, is intractably solved from the regularized WMD in Eq.4 directly. Inspired by the recent works on fast earth mover's distance computation [6, 7, 10], we change the regularized WMD

$W_c^\lambda\left(g(x_d), g(\theta_l)\right)$ to its dual problem and compute the gradient $\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)}$ by solving the dual problem with well-known Sinkhorn-Knopp algorithm which is also used in [6, 7, 43]. We now show the details.

[Computation of $\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)}$]

We first give the dual problem of the regularized WMD $W_c^\lambda\left(g(x_d), g(\theta_l)\right)$. Following [7], the Lagrange duality of regularized WMD $W_c^\lambda\left(g(x_d), g(\theta_l)\right)$ with dual variables $\alpha, \beta \in \mathcal{R}^V$ is given by:

$$^dW_c^\lambda\left(g(x_d), g(\theta_l)\right) = \sup_{(\alpha,\beta)} \Bigg(\alpha^\intercal g(x_d) + \beta^\intercal g(\theta_l) - \sum_{i,j} \frac{e^{-\lambda\left(C(i,j)-\alpha_i-\beta_j\right)}}{\lambda} \Bigg). \tag{14}$$

From [2], we know that the dual optimal β^* of Eq.14 is, in fact, the gradient $\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)}$ that we need:

$$\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)} = \beta^*. \tag{15}$$

Then, below we give the details of how to compute the dual optimal β^*. Following Proposition 2 of [7], when given $\mathbf{K} = e^{-\lambda C}$ which is the element-wise exponential of $-\lambda C$, there exists a pair of vectors $(\mathbf{u}, \mathbf{v}) \in \mathcal{R}^V \times \mathcal{R}^V$ such that the optimal solutions of regularized WMD, i.e., γ_λ^* of Eq.4 in Section 2.2 and its dual in Eq.14, i.e., β^*, are respectively given by

$$\gamma_\lambda^* = \mathrm{diag}(\mathbf{u})\mathbf{K}\mathrm{diag}(\mathbf{v}),\ \beta^* = -\frac{\log(\mathbf{v})}{\lambda} + \frac{\log(\mathbf{v})^\intercal \mathbf{1}}{\lambda V}\mathbf{1}. \tag{16}$$

where the term $\frac{\log(\mathbf{v})^\intercal \mathbf{1}}{\lambda V}\mathbf{1}$ is used to normalize β^* [7]. Besides, based on the Sinkhorn's theorem [30], the pair $(\mathbf{u}, \mathbf{v})$ can be recovered as a fixed point of the Sinkhorn map $(\mathbf{u}, \mathbf{v}) \leftarrow (g(x_d) \oslash \mathbf{K}\mathbf{v}, g(\theta_l) \oslash \mathbf{K}^\intercal \mathbf{u})$, where $\oslash$ represents the element-wise division. This fixed point iteration can also be written as a single update:

$$\mathbf{v} \leftarrow g(\theta_l) \oslash \left(\mathbf{K}^\intercal \left(g(x_d) \oslash \mathbf{K}\mathbf{v}\right)\right).$$

Hence, with vector $\mathbf{v}$, the gradient $\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)}$ can be computed by combining Eq.15 and Eq.16:

$$\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)} = \beta^* = -\frac{\log(\mathbf{v})}{\lambda} + \frac{\log(\mathbf{v})^\intercal \mathbf{1}}{\lambda V}\mathbf{1}. \tag{17}$$

In summary, we outline the detailed computation procedure of the gradient of the regularized WMD in *Algorithm 1*.

In regularized WMD, λ is the entropic regularization parameter as mentioned in Section 2.2. In our experiments, we use $\lambda = 10$ following [13].

Full algorithm. In summary, we outline the optimization procedure of RWMD-CC in *Algorithm 2*.

3.3.2 Implementation Details.

Algorithm 1 Gradient of the regularized WMD

Input: $g(x_d)$, $g(\theta_l)$, matrix $\mathbf{K}$, regularization parameter $\lambda > 0$;
Output: $\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)}$.

Initialize $\mathbf{v} = \mathbf{1}$;
while $\mathbf{v}$ has not converged **do**
  $\mathbf{v} \leftarrow g(\theta_l) \oslash \left(\mathbf{K}^\intercal \left(g(x_d) \oslash \mathbf{K}\mathbf{v}\right)\right)$;
end while
$\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)} \leftarrow -\frac{\log(\mathbf{v})}{\lambda} + \frac{\log(\mathbf{v})^\intercal \mathbf{1}}{\lambda V}\mathbf{1}$;

Algorithm 2 Optimization for RWMD-CC

Input: Distance matrix C, training dataset $S = \{x_d, y_d\}_{d=1}^{d=D}$, importance vector $\mathbf{w}$, regularization parameters λ, $\lambda' > 0$, and learning rate φ;
Output: $\mu = \{\mu_l\}_{l=1}^{l=L}$.

Initialize θ;
Calculate μ by the inverse of Eq.8 with θ;
Calculate $g(x_d)$ for $d = 1, \ldots, D$;
for $t = 1$ **to** N_{iter} **do**
  Calculate θ using Eq.8 with μ;
  Calculate $g(\theta_l)$ for $l = 1, \ldots, L$;
  for $d = 1$ **to** D **do**
    for $l = 1$ **to** L **do**
      Calculate $\frac{\partial W_c^\lambda\left(g(x_d), g(\theta_l)\right)}{\partial g(\theta_l)}$ using *Algorithm 1*;
      Calculate $\frac{\partial h(x_d, \theta)}{\partial \theta_l}$ using Eq.13;
    end for
  end for
  Calculate $\frac{\partial \mathcal{L}(\theta)}{\partial \theta_l}$ using Eq.12 for $l = 1, \ldots, L$;
  Calculate $\nabla\mathfrak{Q}(\mu)$ using Eq.10;
  $\mu \leftarrow \mu - \varphi\nabla\mathfrak{Q}(\mu)$;
end for

Initialization of category centroids θ. In RWMD-CC, we use *Class-Feature-Centroid* (CFC) [11] centroids as the initialization values of category centroids θ. In CFC centroids, the unnormalized mass of word v in category l is given by

$$\theta_{lv} = b^{\frac{DF_v^l}{D_l}} \bullet \log(\frac{L}{CF_v}), \tag{18}$$

where DF_v^l is word v's document frequency in category l; D_l is the number of documents in category l; CF_v is the number of categories containing word v; and b is a constant larger than one. Here, we set b to $e - 1.0$ (≈ 1.718) following [11].

Setting of importance vector $\mathbf{w}$. The constant importance vector $\mathbf{w}$ in RWMD-CC is set by using *balanced distributional concentration* (bdc) [37]. In bdc, the weight $\mathbf{w}_v$ of word v is given by:

$$\mathbf{w}_v = 1 + \frac{\sum_{l=1}^L \frac{p(v|l)}{\sum_{l=1}^L p(v|l)} \log\left(\frac{p(v|l)}{\sum_{l=1}^L p(v|l)}\right)}{\log(L)},$$

where $p(v|l) = \frac{TF_v^l}{TF^l}$ is the proportion of word v in its relevant category l, and TF_v^l, TF^l denote the frequency of word v in category l and the frequency sum of all words in category l, respectively.

3.4 Stochastic Optimization

The computation of the gradient $\frac{\partial \mathcal{L}(\theta)}{\partial \theta}$ needs to pass all training documents per-iteration and may be expensive for big datasets. To address this, we propose a stochastic optimization version of RWMD-CC, namely ***RWMD-CC***$_s$.

In RWMD-CC$_s$, we approximate noisy gradient of each category centroid θ_l by using a randomly selected subset S' per-iteration, instead of the whole training set S:

$$\frac{\partial \mathcal{L}(\theta)}{\partial \theta_l} \approx \frac{1}{D_{mini}} \left(\sum\nolimits_{\{x_d, y_d\} \in S'} \delta\Big(h(x_d, \theta)\Big) \frac{\partial h(x_d, \theta)}{\partial \theta_l} \right) + \lambda' \theta_l, \tag{19}$$

where $D_{mini} = |S'|$ is the mini-batch size. Since the size of S' is greatly less than that of S, i.e., $|S'| = D_{mini} \ll |S| = D$, the computation of gradients in RWMD-CC$_s$ is more effective than that in RWMD-CC, and we use RWMD-CC$_s$ in our experiments.

With the gradient $\frac{\partial \mathcal{L}(\theta)}{\partial \theta}$ approximated by Eq.19, $\nabla \mathfrak{L}(\mu)$ is calculated by Eq.10. In RWMD-CC$_s$, rather than using constant learning rate, we use *Adam* algorithm [14], which computes adaptive learning rate for each parameter, to update μ with the gradient $\nabla \mathfrak{L}(\mu)$.

3.5 Time Complexity

We now discuss the time complexity of RWMD-CC and RWMD-CC$_s$ for both training and testing phases, respectively. For clarity, we revisit some notations: L the number of category centroids, D the number of training documents, D_{mini} the mini-batch size in RWMD-CC$_s$, V the number of unique words; and introduce a new notation D_{avg} the average length of documents.

Training. For simplicity, we only discuss the per-iteration time complexity. In detail, the main time consuming part is the calculation of the gradient of the RWMD (step 9 in Algorithm 2). In our algorithms, we obtain the gradient of the RWMD between a document and a category centroid via the Sinkhorn-Knopp algorithm [6, 10], whose time complexity is $O(D_{avg}V)$. For RWMD-CC, we need to repeat this process between every document of training dataset and every category centroid, i.e., Eq.12, hence require DL times. Consequently, the per-iteration takes $O(DLD_{avg}V)$ time. Since one document in short texts only contains few words, e.g., $D_{avg} = 3.2$ in *Trec* dataset, each iteration of the training phase can be done in minutes. For RWMD-CC$_s$, we use the subset of training dataset with size D_{mini} to approximate the gradient of the objective, i.e., Eq.19, thus the time complexity of per-iteration is $O(D_{mini}LD_{avg}V)$, and per-iteration can be done in seconds.

Testing. When predicting a test document, both our RWMD-CC and RWMD-CC$_s$ only compute the RWMDs between the test document and all category centroids following the prediction function Eq.7. Hence the testing time complexity of our algorithms is linear with respect to L. However, for predicting a test document, WMD-based KNN classifiers, such as WMD+KNN, have to compare the WMDs between this test document and all documents of training datasets, so the testing time complexity of WMD-based KNN classifiers is a linear function of D. Obviously, our RWMD-CC and RWMD-CC$_s$ are much more efficient than WMD-based KNN classifiers. Actually, we can consider the centroid as a representative pseudo-document for each category. In this sense, the centroid classifier is a special case of K nearest neighbour (KNN) classifier with these pseudo-documents where $K = 1$.

We will further demonstrate the real run-time of training and testing phases in the experiment.

3.6 Generalization Error of RWMD-CC

Given a set of i.i.d. samples $S = \{x_d, y_d\}_{d=1}^{d=D}$, let $\hat{\theta}$ be the empirical risk minimizer

$$\hat{\theta} = \arg\min_{\theta \in \Theta} \Big\{ \hat{\mathbb{E}}_S \Big[\delta\Big(h(x, \theta)\Big) h(x, \theta) \Big] = \frac{1}{D} \left(\sum\nolimits_{d=1}^{D} \delta\Big(h(x_d, \theta)\Big) h(x_d, \theta) \right) \Big\}. \tag{20}$$

Further suppose $\Theta = \mathfrak{s} \circ (\Theta^o \times \cdots \times \Theta^o)$ is the composition of the softmax transformation $\mathfrak{s}$ and a L-valued function space with a base hypothesis space Θ^o of functions mapping into $\mathcal{R}^V$. The softmax transformation $\mathfrak{s}$ guarantees that θ_l lies in the simplex $\Delta^{\mathcal{V}}$.

Theorem 3.1. *For any $\tau > 0$, with probability at least $1 - \tau$, it holds that*

$$\mathbb{E}\Big[\delta\Big(h(x, \hat{\theta})\Big) h(x, \hat{\theta})\Big] \le \inf_{\theta \in \Theta} \mathbb{E}\Big[\delta\Big(h(x, \theta)\Big) h(x, \theta)\Big] + \eta\left(256V\sqrt{L^3}\|C\|_\infty \Re_D(\Theta^o) + 64\sqrt{L^3}\frac{\log V}{\lambda} + \|C\|_\infty \sqrt{\frac{2\log(1/\tau)}{D}}\right) + \|C\|_\infty \sqrt{\frac{2\log(1/\tau)}{D}} \tag{21}$$

with the constant $\|C\|_\infty = \max_{ij} C_{ij}$. $\Re_D(\Theta^o)$ is the Rademacher complexity [1] measuring the complexity of the hypothesis space Θ^o.

Remark. From Theorem 3.1, there is a constant error, which is introduced by regularized WMD, in risk bound. We can see that the constant error will vanish as $\lambda \to \infty$, which also coincides with the risk bound for the EMD with the standard convergence rate $O(1/\sqrt{D})$. However, as shown in [6], with λ larger, computing regularized WMD costs more time in same dimension. These mean that the value of λ reflects the trade-off between computation speed and approximation accuracy to some degree. Here, we set $\lambda = 10$ following [13].

4 RELATED WORK

In this section, we review some most related works on short text classification and classification using WMD.

4.1 Short Text Classification

Previous works on short text classification are mainly based on feature expansion. They can be roughly divided into two classes. One is to extract auxiliary context information using search engines [8, 29, 32]. Traditional classification algorithms are then applied to such expanded short texts, which are deemed as long pseudo-documents. An limitation is that such algorithms must require high quality search results. The other is to expand document features by

employing external knowledgebases such as Wikipedia and WordNet [12, 21, 25, 35]. For example, [25] uses hidden topics of LDA learnt from Wikipedia to enrich document-level features. These algorithms perform well, however, they may be problematic when the pre-trained topics and concepts are inconsistent with the current dataset for certain applications.

Recently, some deep learning-based classifiers have been proposed [9, 36, 42]. To our knowledge, an early representative work is the character to sentence convolutional neural network (CharSCNN) [9]. As suggested by the name, the CharSCNN is based on CNN, and it exploits from character- to sentence-level information to perform short text classification. Other deep learning classifiers are also based on the CNN architecture, and the pre-trained word embeddings are used as the input.

Additionally, many researchers have developed generic short text topic models, e.g., biterm topic model (BTM) [5] and word network topic model [44]. They learn topic representations of short texts and then use a traditional algorithm, e.g., SVMs, as a downstream classifier. Such methodology empirically performed well on classification evaluations of short texts.

4.2 Classification Using WMD

Since the WMD is a measure of document distance, a most straightforward classification method is WMD+*K*NN [15]. A recent work [13] incorporates the supervision (i.e., labels) into a WMD learning procedure, leading to supervised WMD (S-WMD). Empirically, S-WMD+*K*NN performed better than WMD+*K*NN. In contrast to those methods, our RWMD-CC computes a representative centroid for each category. Roughly, RWMD-CC can reduce the number of calculating WMDs from D to L when predicting each test document.

5 EXPERIMENTS

In this section, we empirically compare our RWMD-CC against the existing baseline algorithms of short texts.

In early experiments, we have evaluated the performance of RWMD-CC and RWMD-CC$_s$ (the stochastic optimization version of RWMD-CC) on all the datasets, and found that the performance gap between RWMD-CC and RWMD-CC$_s$ is very small. That is, the stochastic optimization does not affect the performance of RWMD-CC. Hence we only show RWMD-CC$_s$ in the experiments.

5.1 Experimental Settings

Datasets. We choose three datasets of short texts, including *Trec*[1], *biomedical*[2] and *StackOverFlow*[2]. For all datasets, we remove the standard stopwords, words with term frequency less than 5, and empty documents. The statistics of datasets are shown in Table 2. Besides, we employ pre-trained *GloVe*[3] word embeddings and randomly set embeddings of the words that are not included in the vocabulary of pre-trained word embeddings. We use the cosine distance, i.e., $1 - cos(w_i, w_j)$, which is used to measure the distance between any word embeddings pair $\{w_i, w_j\}$, as the cost function c in the regularized WMD to compute the distance matrix C.

[3]https://nlp.stanford.edu/projects/glove/. The 100-dimensional vectors trained on Wikipedia 2014 and Gigaword 5 are used.

Table 2: Statistics of datasets. *#doc*: the number of documents. *#word*: the number of unique words. D_{avg}: the average document length. *#label*: the number of categories. *Rate*: the word cover rate of GloVe word embeddings.

Dataset	*#doc*	*#word*	D_{avg}	*#label*	*Rate* (%)
Trec	5,864	1,058	3.2	6	99.3
biomedical	19,970	4,472	7.3	20	94.7
StackOverFlow	19,768	2,651	3.9	20	78.7

Baseline algorithms. We choose four existing algorithms for comparison. Details are given as below.

- **TFIDF + *K*NN**: We use tf-idfs as the representations of short texts, and then perform *K*NN as a downstream classifier with counting the similarities between short texts by cosine measure.
- **BTM + SVMs**: We first learn the topic representations of short texts using BTM [5], and then perform SVMs[4] as a downstream classifier.
- **WMD + *K*NN**: This is the first use of WMD for classification in its original paper [15]. The code is available on the net[5].
- **S-WMD + *K*NN**: S-WMD [13] is a supervised extension of WMD, and also uses stochastic optimization. The code is available on the net[6].

For the *K*NN-based methods, the neighborhood number K is tested from $\{1, \ldots, 19\}$. For BTM+SVMs, WMD+*K*NN and S-WMD+*K*NN, we use default parameter settings in their papers and codes, except the mini-batch size of S-WMD+*K*NN, which is set to 256.

Evaluation metrics. The comparison is based on two popular classification metrics, i.e., macro-averaging F1 and micro-averaging F1. The macro-averaging F1 (Macro-F1) and micro-averaging F1 (Micro-F1) are the two different types of average of F1 score and used to measure the classification performance for the whole corpus. The F1 score is a combined form of precision (π) and recall (ρ):

$$\pi_l = \frac{TP_l}{TP_l + FP_l}, \quad \rho_l = \frac{TP_l}{TP_l + FN_l}, \quad F1_l(\pi_l, \rho_l) = \frac{2\pi_l\rho_l}{\pi_l + \rho_l},$$

where TP_l (True Positives) is the number of documents assigned correctly to category l; FP_l (False Positives) is the number of documents that do not belong to category l but are assigned incorrectly to it by classifier; FN_l (False Negatives) is the number of documents that belong to category l but are assigned incorrectly to other ones by classifier. Specifically, Micro-F1 and Macro-F1 are the F1 score of the whole dataset and the average F1 score of all categories, respectively.

Parameter settings. For RWMD-CC$_s$, in our experiments, its parameters are empirically set as follows: $\lambda = 10$, $b = e - 1.0$, $\eta = 60.0$, $\lambda' = 0.001$, $D_{mini} = 256$ and $N_{iter} = 50$. All the experiments are carried on a Linux server with Intel Xeon 3.10 GHz CPU and 16G memory.

	StackOverFlow	0.6616 ± 0.0079‡	0.6095 ± 0.0044‡	0.7899 ± 0.0111‡	0.7842 ± 0.0130‡	**0.8460 ± 0.0057**

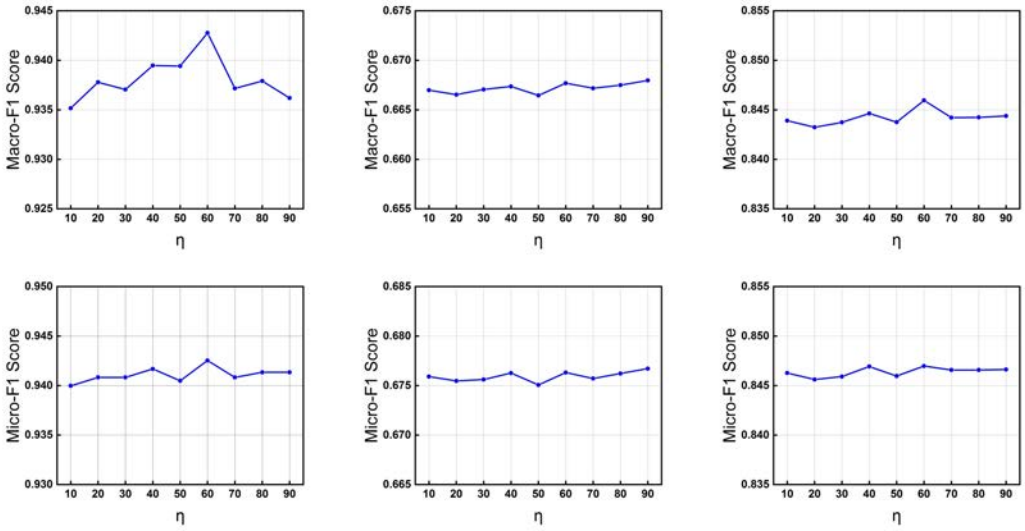

Figure 1: Classification performance by varying η on *Trec* (left), *biomedical* (middle) and *StackOverFlow* (right).

5.2 Performance Comparison

For all methods, we perform a 5-fold cross validation and report the average scores. The classification results over all datasets are shown in Table 3. Overall, our RWMD-CC$_s$ performs better than the baselines in most cases. Some observations are made as follows:

Comparing RWMD-CC$_s$ against baselines: First, RWMD-CC$_s$ consistently outperforms BoW-based methods on Micro-F1 and Macro-F1 scores, especially the scores of RWMD-CC$_s$ are even about 0.18 higher than those of TFIDF+*K*NN on *StackOverFlow*. Second, RWMD-CC$_s$ performs better than other WMD-based methods on *biomedical* and *StackOverFlow*, e.g., about 0.06 higher than S-WMD+*K*NN on *StackOverFlow*. RWMD-CC$_s$ only has a small decrease compared with S-WMD+*K*NN on *Trec*. The possible reason is the category-imbalanced nature of *Trec*, in which the number of documents of each category is {1300, 1309, 95, 1288, 1005, 867}, and thus some documents of other categories may be misclassified into the category, which contains fewer documents, for centroid-based classifiers.

Comparing WMD-based methods against BoW-based methods: WMD-based methods (including WMD+*K*NN, S-WMD+*K*NN and RWMD-CC$_s$) significantly dominate BoW-based methods (including TFIDF+*K*NN and BTM+SVMs) on two evaluation metrics on all three datasets. For example, the Micro-F1 scores of WMD+*K*NN beat TFIDF+*K*NN by 0.11, 0.05 and 0.13 on *Trec*, *biomedical*, and *StackOverFlow*, respectively. It means that for short text classification the WMD-based classifiers are much better than the classifiers based on BoW representations. The result is expected since the WMD can effectively measure semantic distances among documents with word embeddings and hence reduce the document similarity misalignment, especially for short texts. This is also an evidence of that the WMD is a better distance measure than the distances or similarities based on BoW.

Observation about word embeddings: The classification performance of RWMD-CC$_s$ is insensitive to the word embeddings. For instance, on *StackOverFlow* the performance of RWMD-CC$_s$ is still very competitive even the cover rate of pre-trained GloVe word

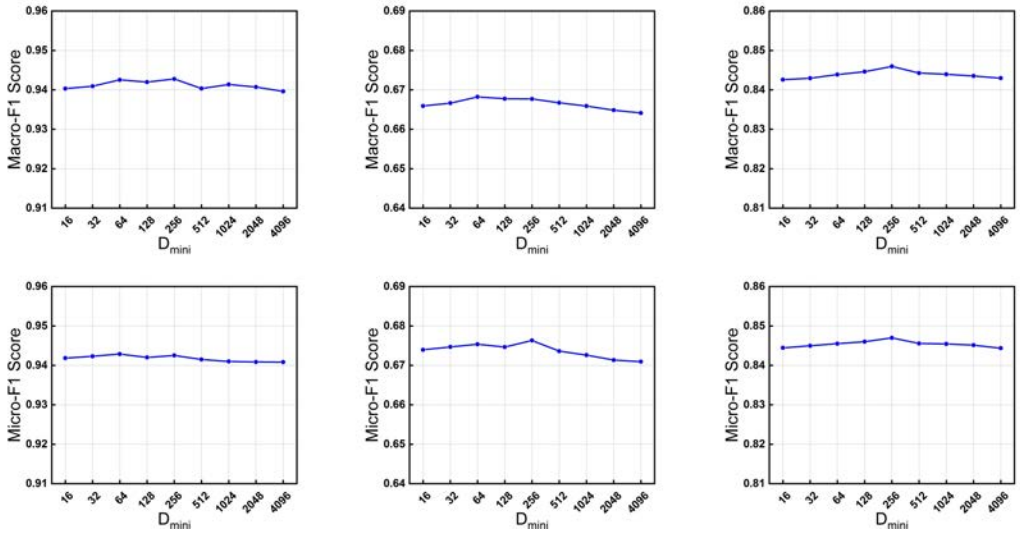

Figure 2: Classification performance by varying D_{mini} on *Trec* (left), *biomedical* (middle) and *StackOverFlow* (right).

Table 4: Time cost of WMD+*K*NN, S-WMD+*K*NN and RWMD-CC$_s$ on *Trec* (top section), *biomedical* (middle section) and *StackOverFlow* (bottom section). Init. Time: time cost during initializing parameters. Iter. Time: per-iteration time in the training phase. Test Time: time cost of predicting all test documents. h: hours, m: minutes, s: seconds.

Method	Init. Time	Iter. Time	Test Time
WMD+*K*NN	–	–	8m 49s
S-WMD+*K*NN	21m 57s	2s	8m 17s
RWMD-CC$_s$	–	1s	18s
WMD+*K*NN	–	–	1h 46m
S-WMD+*K*NN	4h 34m	3s	1h 35m
RWMD-CC$_s$	–	3s	5m 38s
WMD+*K*NN	–	–	3h 4m
S-WMD+*K*NN	4h 52m	4s	2h 44m
RWMD-CC$_s$	–	2s	3m 40s

embeddings is only 78.7%. Therefore, we argue that RWMD-CC$_s$ is practical even big collections of word embeddings lack.

5.3 Efficiency Comparison

We compare the running time of the three WMD-based methods, including RWMD-CC$_s$, WMD+*K*NN and S-WMD+*K*NN.

We compare these algorithms in initializing time, per-iteration training time and testing time. To be fair, we use the following settings: (a) for all datasets, we randomly select 20% from full dataset as the test set and remain 80% as the training set; (b) for all methods, we set the entropic regularization parameter λ of regularized WMD to 10; (c) specifically for RWMD-CC$_s$ and S-WMD+*K*NN, we set the mini-batch size to 256 in their training phases. All experiments are carried with **single thread** on a Linux server with Intel Xeon 3.10 GHz CPU and 16G memory. Table 4 shows the running time results averaged on 100 runs. Some observations are made as follows:

Comparison of testing time: RWMD-CC$_s$ is significantly faster than WMD+*K*NN and S-WMD+*K*NN when predicting test documents, e.g., WMD+*K*NN and S-WMD+*K*NN cost about 3 hours on *StackOverFlow* dataset, as comparison, RWMD-CC$_s$ merely 4 minutes. This is consistent with the time complexity analysis mentioned in the section 3.5. That is because when predicting a test document, RWMD-CC$_s$ only calculates the WMDs between this test document and the category centroids, WMD+*K*NN and S-WMD+*K*NN, in contrast, have to compute the WMDs between it and all documents of training datasets. We thus argue that RWMD-CC$_s$ is a more practical choice, especially for real world applications, where fast response is required.

Comparison of training time: Thanks to stochastic optimization, both the training phases of RWMD-CC$_s$ and S-WMD+*K*NN spend very little time. Therefore, the training of RWMD-CC$_s$ is also efficient for big corpora.

Comparison of initializing time: S-WMD+*K*NN takes huge time during initializing parameters, e.g., about 5 hours on *StackOverFlow* dataset, in contrast, our RWMD-CC$_s$ spends no time for initialization. This again demonstrates RWMD-CC$_s$ is more practical.

5.4 Evaluation of Parameters

In this subsection, we empirically evaluate two crucial parameters of RWMD-CC$_s$, including the trade-off parameter η and mini-batch size D_{mini}.

We first evaluate the impact of different η values over the set $\{10, 20, \cdots, 90\}$. The results are shown in Figure 1. Roughly, both Macro-F1 and Micro-F1 scores of RWMD-CC$_s$ have a small change in all settings with the η value varying from 10 to 90. That is to say,

RWMD-CC$_s$ is insensitive to η, making it more robust in real world applications. Besides, the best scores are achieved at $\eta = 60$ in most cases. We thus fix $\eta = 60$ in our experiments, and suggest choosing the value of η from 50 to 70 for short texts in practice.

Then, we examine the classification performance of different D_{mini} values over the set $\{16, 32, \cdots, 4096\}$. As the results shown in Figure 2, we argue that RWMD-CC$_s$ is insensitive to the mini-batch size D_{mini}. Furthermore, the best performance is achieved when $D_{mini} = 256$. Thus, in the experiments, we use $D_{mini} = 256$ as the default setting of RWMD-CC$_s$, which is also the suggested value in practice.

6 CONCLUSION

In this paper, we propose a RWMD-CC method for extremely short text classification. Our RWMD-CC is based on the popular document distance, e.g., WMD, which measures the distance at the semantic level. We learn a representative semantic centroid for each category, and predict any text sample depending on the WMDs between this sample and all semantic centroids. To achieve this, we build a loss function with hypothesis margin that is based on the structural risk minimization principle. For fast optimization, we follow the spirit of the regularized WMD and stochastic optimization. Experimental results indicate that our RWMD-CC outperforms the state-of-the-art baseline methods, and more importantly it is much more efficient than the existing WMD-based KNN methods during prediction.

A STATISTICS LEARNING BOUNDS

We establish the proof of Theorem 3.1 in this section. For simpler notation, given a sequence $S = \{x_d, y_d\}_{d=1}^{d=D}$ of i.i.d. training samples, we denote the empirical risk $\hat{R}_S$ and expected risk R as

$$\hat{R}_S(\theta) = \hat{\mathbb{E}}_S\Big[\delta\Big(h(x,\theta)\Big)h(x,\theta)\Big] = \frac{1}{D}\Big(\sum\nolimits_{d=1}^{D}\delta\Big(h(x_d,\theta)\Big)h(x_d,\theta)\Big),$$
$$R(\theta) = \mathbb{E}\Big[\delta\Big(h(x,\theta)\Big)h(x,\theta)\Big]. \tag{22}$$

where

$$\delta(z) = \begin{cases}\eta & \text{if } z \geq 0,\\ 1 & \text{if } z < 0;\end{cases} \qquad h(x_d,\theta) = W_c^{\lambda}\Big(x_d,\theta_R\Big) - W_c^{\lambda}\Big(x_d,\theta_M\Big),$$

θ_R and θ_M denote the nearest category centroids to x_d under RWMD measure with same label and different label, respectively.

Lemma A.1 (Lemma B.1 of [10]). *Let $\hat{\theta}$, $\theta^* \in \Theta$ be the minimizer of the empirical risk $\hat{R}_S$ and expected risk R, respectively. Then*

$$R(\hat{\theta}) \leq R(\theta^*) + 2\sup_{\theta\in\Theta}|R(\theta) - \hat{R}_S(\theta)|.$$

To bound the risk for $\hat{\theta}$, we need to establish a uniform concentration bound for the loss function $\mathcal{L}(\theta)$ in Eq.11. Therefore, we define a loss function space induced by the hypothesis space Θ as

$$\mathcal{H} = \Big\{\mathfrak{h} : x \mapsto \delta\Big(h(x,\theta)\Big)h(x,\theta) : \theta \in \Theta\Big\}. \tag{23}$$

The uniform concentration bound depends on the "complexity" of $\mathcal{H}$, which is measured by the empirical *Rademacher complexity* defined below.

Definition A.2 (Rademacher Complexity [1]). Let $\mathcal{F}$ be a family of mapping from $\mathcal{Z}$ to $\mathcal{R}$, and $S = (z_1, \ldots, z_D)$ a fixed sample from $\mathcal{Z}$. The empirical Rademacher complexity of $\mathcal{F}$ with respect to S is defined as

$$\hat{\mathfrak{R}}_S(\mathcal{F}) = \mathbb{E}_\sigma\Big[\sup_{f\in\mathcal{F}}\frac{1}{D}\sum_{d=1}^{D}\sigma_d f(z_d)\Big], \tag{24}$$

where $\sigma = (\sigma_1, \ldots, \sigma_d, \ldots, \sigma_D)$, with σ_d's independent uniform random variables taking values in $\{+1, -1\}$. σ_d's are called the Rademacher random variables. The Rademacher complexity is defined by taking expectation with respect to the samples S,

$$\mathfrak{R}_D(\mathcal{F}) = \mathbb{E}_S\Big[\hat{\mathfrak{R}}_S(\mathcal{F})\Big].$$

Theorem A.3. *Let $\mathcal{H} = \Big\{\mathfrak{h} : x \mapsto \delta\Big(h(x,\theta)\Big)h(x,\theta) : \theta \in \Theta\Big\}$. For any $\tau > 0$, with probability at least $1 - \tau$, the following holds for all $\mathfrak{h} \in \mathcal{H}$,*

$$\mathbb{E}[\mathfrak{h}] - \hat{\mathbb{E}}_S[\mathfrak{h}] \leq 2\mathfrak{R}_D(\mathcal{H}) + (\eta+1)\|C\|_\infty\sqrt{\frac{\log(1/\tau)}{2D}}, \tag{25}$$

where $\mathfrak{R}_D(\mathcal{H})$ is Rademacher complexity of the loss function space $\mathcal{H}$ associated to Θ, and $\|C\|_\infty = \max_{ij} C_{ij}$.

Following the definition of $\mathcal{H}$, $\mathbb{E}[\mathfrak{h}] = R(\theta)$ and $\hat{\mathbb{E}}_S[\mathfrak{h}] = \hat{R}_S(\theta)$. Hence, a uniform control for the deviation of the empirical risk from the expected risk is given by the Theorem A.3.

Theorem A.4 (McDiarmid's Inequality). *Let $S = \{X_1, \ldots, X_D\}$ be i.i.d. random variables with size D from $\mathcal{X}$. Assume there exists $C > 0$ such that $f : \mathcal{X}^D \to \mathcal{R}$ satisfies the following stability condition*

$$|f(x_1, \ldots, x_d, \ldots, x_D) - f(x_1, \ldots, x'_d, \ldots, x_D)| \leq C \tag{26}$$

for all $d = 1, \ldots, D$ and any $x_1, \ldots, x_D, x'_d \in \mathcal{X}$. Then for any $\varepsilon > 0$, denoting $f(X_1, \ldots, X_D)$ by $f(S)$, it holds that

$$\mathbb{P}(f(S) - \mathbb{E}[f(S)] \geq \varepsilon) \leq \exp\Big(-\frac{2\varepsilon^2}{DC^2}\Big). \tag{27}$$

Lemma A.5. *Let the constant $\|C\|_\infty = \max_{ij} C_{ij}$ is the maximum in the distance matrix C, then $0 \leq W_c^{\lambda}(\cdot,\cdot) \leq \|C\|_\infty$.*

Proof. For any x and θ_l, let γ_λ^* be the relaxed transport plan that solves (5), then

$$W_c^{\lambda}(x,\theta_l) = \Big\langle\gamma_\lambda^*, C\Big\rangle \leq \|C\|_\infty\sum_{v_1,v_2}\gamma_{v_1,v_2} = \|C\|_\infty.$$

□

Lemma A.6. *Let the constant $\|C\|_\infty = \max_{ij} C_{ij}$ is the maximum in the distance matrix C, then $-\|C\|_\infty \leq h(x,\theta) \leq \|C\|_\infty$, $-\|C\|_\infty \leq \delta\Big(h(x,\theta)\Big)h(x,\theta) \leq \eta\|C\|_\infty$.*

Lemma A.6 can be easily proved following the definitions of $\delta(z)$ and $h(x,\theta)$ with Lemma A.5.

Proof of Theorem A.3. Inspired by the proof of Theorem B.3 of [10], the Theorem A.3 can be easily proved by using Lemma A.6 and Theorem A.4. The details can be found in the proof of Theorem B.3 of [10]. □

Now, we establish the Rademacher complexity $\mathfrak{R}_D(\mathcal{H})$. For each instance (x_d, y_d) from S, we denote the category centroids θ_l with the same label y_d as θ_l^+ and the ones with a different label than y_d as θ_l^-, then $\theta_R \in \{\theta_l^+\}$ and $\theta_M \in \{\theta_l^-\}$. Thus, we can re-write the function $h(x,\theta) = W_c^\lambda(x,\theta_R) - W_c^\lambda(x,\theta_M)$ as

$$h(x,\theta) = \left(\min_{\theta_l^+}\left\{W_c^\lambda(x,\theta_l^+)\right\} - \min_{\theta_l^-}\left\{W_c^\lambda(x,\theta_l^-)\right\}\right). \tag{28}$$

Then, we define a function $\mathfrak{m} : [-\|C\|_\infty, \|C\|_\infty] \to \mathcal{R}$ and a real function space $\mathcal{F}$ as follows:

$$\mathfrak{m} : z \mapsto z\delta(z), \tag{29}$$

$$\mathcal{F} = \left\{\mathfrak{f} : (x,\vartheta) \mapsto W_c^\lambda(x,\vartheta)\right\}. \tag{30}$$

Theorem A.7. *Let the function $\mathfrak{m}$ and the function space $\mathcal{F}$ be defined as above. For the loss function space $\mathcal{H}$, it holds that*

$$\mathfrak{R}_D(\mathcal{H}) \le 16\eta\sqrt{L^3}\mathfrak{R}_D(\mathcal{F}). \tag{31}$$

Theorem A.8 (Rademacher Vector Contraction Inequality [22]). *Let $\mathcal{F}$ be a class of real functions, and $\mathcal{H} \subset \mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_K$ be a K-valued function class. If $\mathfrak{t} : \mathcal{R}^K \mapsto \mathcal{R}$ is a L_m-Lipschitz continuous function and $\mathfrak{t}(\mathbf{0}) = 0$, then*

$$\hat{\mathfrak{R}}_S(\mathfrak{t} \circ \mathcal{H}) \le \sqrt{2}L_m \sum_{k=1}^{K} \hat{\mathfrak{R}}_S(\mathcal{F}_k). \tag{32}$$

Proof of Theorem A.7. With the function $\mathfrak{m}$, the loss function space $\mathcal{H} = \left\{\mathfrak{h} : x \mapsto \delta\Big(h(x,\theta)\Big)h(x,\theta) : \theta \in \Theta\right\}$ can be written as $\mathcal{H} = \mathfrak{m} \circ \mathcal{G}$, where $\mathcal{G} = \left\{\mathfrak{g} : x \mapsto h(x,\theta) : \theta \in \Theta\right\}$ is a function space.

Now, we first show the function $\mathfrak{m}$ is Lipschitz continuous with constant η, then give $\mathfrak{R}_D(\mathcal{G})$, which is the Rademacher complexity of $\mathcal{G}$.

With the definition of function $\mathfrak{m}$ and $\delta, \eta \ge 1$, it holds that

$$|\mathfrak{m}(z_1) - \mathfrak{m}(z_2)| = \left\{\begin{array}{ll} |\eta z_1 - \eta z_2| = \eta|z_1 - z_2| & \text{if } z_1, z_2 \ge 0 \\ |\eta z_1 - z_2| = \eta z_1 + (-z_2) & \text{if } z_1 \ge 0, z_2 < 0 \\ |z_1 - \eta z_2| = (-z_1) + \eta z_2 & \text{if } z_1 < 0, z_2 \ge 0 \\ |z_1 - z_2| & \text{if } z_1, z_2 < 0 \end{array}\right\} \le \eta|z_1 - z_2|.$$

Thus, $\mathfrak{m}$ is Lipschitz with constant η and $\mathfrak{m}(0) = 0$.

As next step, we establish the Rademacher complexity $\mathfrak{R}_D(\mathcal{G})$. Following Eq.28, the functions $\mathfrak{g}$ contained in $\mathcal{G}$ can be expressed as the sum of two terms of identical form, one multiplied by -1, such as

$$x \mapsto \min_{\theta_l}\left\{W_c^\lambda(x,\theta_l)\right\}, \tag{33}$$

where the minimum is taken over at most L terms, L denotes the number of category centroids. Let $\mathcal{M}$ be the function space, in which the form of functions is Eq.33. Note that $\mathfrak{R}_D(\sum_{k=1}^K \mathcal{F}_k) \le \sum_{k=1}^K \mathfrak{R}_D(\mathcal{F}_k)$ holds for all real function classes $\mathcal{F}_k$ by Theorem 12 of [1] due to the triangle inequality. Further, following Theorem 12 of [1] multiplying a function space by -1 does not change its Rademacher complexity. Therefore, we can upper bound $\mathfrak{R}_D(\mathcal{G})$ by twice the complexity of the function space $\mathcal{M}$:

$$\mathfrak{R}_D(\mathcal{G}) \le 2\mathfrak{R}_D(\mathcal{M}). \tag{34}$$

Following [28], the function that calculates the minimum of L values as follows,

$$(z_1, \ldots, z_L) \mapsto \min\{z_1, \ldots, z_L\},$$

is Lipschitz continuous with constant $\sqrt{8L}$. We apply Theorem A.8 to the $\sqrt{8L}$-Lipschitz continuous function min and the function space

$$\underbrace{\mathcal{F} \times \cdots \times \mathcal{F}}_{L \text{ copies}}.$$

It holds

$$\hat{\mathfrak{R}}_S(\mathcal{M}) \le \sqrt{2}\sqrt{8L}\sum_{l=1}^{L}\hat{\mathfrak{R}}_S(\mathcal{F}) = 4\sqrt{L^3}\hat{\mathfrak{R}}_S(\mathcal{F}). \tag{35}$$

Then, following Theorem 12 of [1] and combining Eq.34 with Eq.35, we have

$$\mathfrak{R}_D(\mathcal{H}) = \mathfrak{R}_D(\mathfrak{m} \circ \mathcal{G}) \le 2\eta\mathfrak{R}_D(\mathcal{G}) \le 16\eta\sqrt{L^3}\mathfrak{R}_D(\mathcal{F}).$$

□

Before establishing $\mathfrak{R}_D(\mathcal{F})$, we provide some useful properties of regularized WMD.

Lemma A.9 (Lemma 2 of [43]). *For two discrete measures $p_1,\ p_2 \in \Delta^{\mathcal{V}}$, the regularized WMD $W_c^\lambda(p_1,p_2)$ and the EMD $W_c(p_1,p_2)$ satisfy the following relationship,*

$$W_c(p_1,p_2) \le W_c^\lambda(p_1,p_2) \le W_c(p_1,p_2) + \frac{2}{\lambda}\log V,$$

where $V = |\mathcal{V}|$.

Then, we define a function space $\mathcal{F}_{EMD}$ corresponding to the family of the EMD as follows:

$$\mathcal{F}_{EMD} = \left\{\mathfrak{f}_{EMD} : (x,\vartheta) \mapsto W_c(x,\vartheta)\right\}.$$

From Theorem 4 of [43], the Rademacher complexities of $\mathcal{F}$ and $\mathcal{F}_{EMD}$ satisfy

$$\mathfrak{R}_D(\mathcal{F}) \le \mathfrak{R}_D(\mathcal{F}_{EMD}) + \frac{\log V}{\lambda}. \tag{36}$$

In the following, we relate the Rademacher complexity of $\mathcal{F}_{EMD}$ with the hypothesis space Θ^o by using the similar processing method in [10] and give the proof of Theorem 3.1.

Proof of Theorem 3.1. Consider a function space $\mathcal{F}_{EMD}$ with a softmax transformation $\mathfrak{s}$

$$\mathcal{F}_{EMD} = \left\{f_{EMD} : (x,\mu) \mapsto W_c(\mathfrak{s}(x),\mathfrak{s}(\mu))\right\},$$

From Proposition B.10 of [10], we know that the $\mathcal{R}^V \times \mathcal{R}^V \mapsto \mathcal{R}$ map $\iota : (z,z') \mapsto W_c(\mathfrak{s}(z),\mathfrak{s}(z'))$ is a $2\sqrt{2}\|C\|_\infty$-Lipschitz continuous function and $\iota(\mathbf{0},\mathbf{0}) = 0$. We apply Theorem A.8 to the $2\sqrt{2}\|C\|_\infty$-Lipschitz continuous function ι, and it holds

$$\hat{\mathfrak{R}}_S(\mathcal{F}_{EMD}) \le \sqrt{2}\cdot 2\sqrt{2}\|C\|_\infty V\hat{\mathfrak{R}}_S(\Theta^o). \tag{37}$$

The conclusion of Theorem 3.1 follows by combining Eq.37 with Eq.36, Theorem A.7, Theorem A.3 and Lemma A.1. □

ABSTRACT

Domain ontology is widely used to index literature for the convenience of literature retrieval. Due to the high cost of manual curation of key aspects from the scientific literature, automated methods are crucially required to assist the process of semantic indexing. However, it is a challenging task due to the huge amount of terms and complex hierarchical relations involved in a domain ontology. In this paper, in order to lessen the curse of dimensionality and enhance the training efficiency, we propose an approach named *Deep Level-wise Extreme Multi-label Learning and Classification (Deep Level-wise XMLC)*, to facilitate the semantic indexing of literatures. Specifically, Deep Level-wise XMLC is composed of two sequential modules. The first module, deep level-wise multi-label learning, decomposes the terms of a domain ontology into multiple levels and builds a special convolutional neural network for each level with category-dependent dynamic max pooling and macro F-measure based weights tuning. The second module, hierarchical pointer generation model merges the level-wise outputs into a final summarized semantic indexing. We demonstrate the effectiveness of Deep Level-wise XMLC by comparing it with several state-of-the-art methods on automatic labeling of MeSH, on literature from PubMed MEDLINE and automatic labeling of AmazonCat13K.

1 INTRODUCTION

With the explosively growing amount of scientific literature, semantic indexing methods with high efficiency are required to build retrieval systems. Even with effective techniques, the semantic indexing process still involves manual curation of key aspects from scientific literature. In order to summarize the main topics of articles, domain experts are usually invited to manually index articles with keywords that are selected from the domain ontology.

In the medical field, MEDLINE [3, 19, 27] is perhaps the world largest biomedical literature database, and Medical Subject Headings (MeSH) is the domain ontology for indexing articles in MEDLINE. It has greatly improved the experience of medical literature search by mapping queries to MeSH headings. For example, the query *teen drug use* is mapped to the MeSH headings *Adolescent* and *Substance–Related Disorders*. Currently, most of the mapping rules as well as the final indexing of medical literature from MEDLINE are manually generated by domain experts. It is expensive and time-consuming for the human-labeling process of semantic indexing. Automated methods are therefore crucially desired.

The task of automated curation, however, faces significant challenges. First of all, an article is often labeled with multiple keywords or concepts. In addition, the domain ontology involves hundreds of thousands or even millions of labels. Those labels are typically organized in hierarchical structures that are represented in the form of a forest. It is a non-trivial task to simultaneously deal with massive labels, data samples and complex hierarchical structures.

In this paper, we consider the task of automated semantic indexing as an extreme multi-label learning and classification (XMLC) problem. Different from the traditional multi-class [15, 16, 34], XMLC allows for the co-existence of millions of labels for each data sample. Recently, several approaches are proposed to deal with XMLC, including FASTXML [29], LOMTrees [9], SLEEC [4], robust Bloom filters [10], label partitioning [33], fast label embeddings [25] and several deep learning methods, Hierarchical multi-label classification using local neural networks [7], DXML [20] and XML-CNN [37]. To a good extent, those methods have achieved good progress in handling XMLC. However, the curse of dimensionality (for which we refer to the huge label space) and the high demand of hand-crafted feature engineering are two major barriers for further improving the effectiveness and efficiency.

In order to address these two issues, we propose a novel framework named *Deep Level-wise Extreme Multi-label Learning and Classification (Deep Level-wise XMLC)* to deal with the problem of large scale semantic indexing. Deep Level-wise XMLC consists of two sequential modules. The first module is a level-wise multi-label classification model. It addresses the curse of dimensionality effectively by decomposing massive labels (in a higher dimensional space) into multiple levels (in a lower dimensional space). For each level, a convolutional neural network is constructed with two novel designs: One design is a category-based dynamic max pooling strategy aiming at capturing both label co-occurrences and categorical

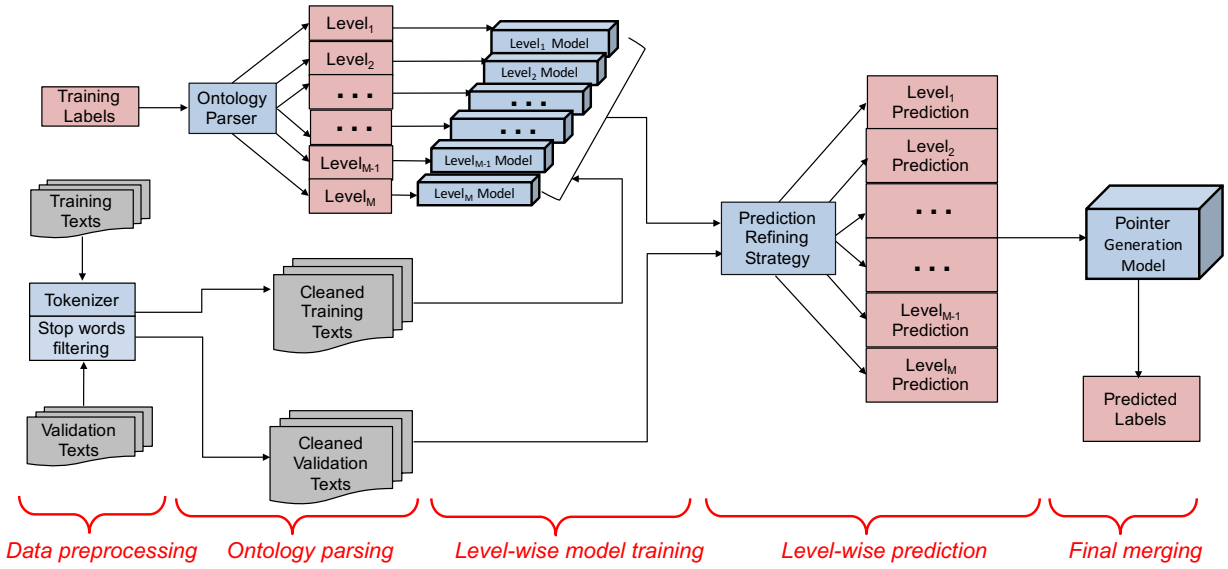

Figure 1: System architecture of the proposed framework. From left to right, there are five steps or blocks. In the data preprocessing stage, as usual, tokenization and filtering are made to obtain clean texts. Training and validation data are randomly selected according some proportions. Different from usual NLP tasks, an extra step of ontology parsing on the training labels is needed so that labels will be split into multiple levels based on their ontological hierarchies. In the third stage, the neural model described in the methodology section is employed to train level-wise models. Then, in the testing stage, testing data is fed into the trained level-wise models for label predictions or tagging after the testing data is preprocessed in a similar fashion. In the last stage, a final merging is made with a pointer generation model so that some less related labels are sifted out.

relations among labels. It helps connect the level-wise classification models tightly. The other design is a prediction refining strategy based on macro F-measure optimization, which enables the module to automatically select the labels in an incremental manner. The second module of Deep Level-wise XMLC is a hierarchical pointer generation model that merges predicted labels for each level into final summarized semantic indexing by the way of copying and generation mechanism [31]. As a whole, Deep Level-wise XMLC avoids the high cost of human interferences by learning semantic indexing without any feature engineering. We show the entire system architecture in Figure 1.

In summary, our major contributions are summarized as follows:

- We propose *Deep Level-wise XMLC* to learn large scale semantic indexing. It divides labels into multiple levels to lessen the curse of dimensionality while improving the training efficiency.
- We introduce a new strategy with category-dependent dynamic max pooling to capture both co-occurrences and categorical relations among labels.
- We explore a prediction refining technique derived from macro F-measure optimization to intelligently select the best labels in an online fashion.
- We develop a hierarchical pointer generation model to merge the level-wise outputs into the final summarized semantic indexing.
- We demonstrate the effectiveness of Deep Level-wise XMLC by comparing it with several state-of-the-art methods on automatic labeling of MeSH from MEDLINE, as well as AmazonCat13K [1], which is the XMLC dataset with similar nature as MeSH.

[1]https://manikvarma.github.io

2 METHODOLOGY

There are two primary challenges in XMLC. Firstly, the number of labels in one dataset can be more than 10,000 or even as large as one million. Secondly, one data sample can be indexed with multiple labels, the number typically ranging from one to several dozens.

In this paper, we propose Deep Level-wise XMLC to handle these two challenges by decomposing labels of each data sample into multiple levels. Five steps are involved in Deep Level-wise XMLC as shown in Figure 1. Firstly, the input raw texts for training and validations are processed with NLP preprocessors. Words are tokenized and stop words are filtered out. Secondly, the training labels are parsed into level-wise labels with ontology parsers. Thirdly, level-wise models are trained with Deep Level-wise XMLC. Fourthly, level-wise prediction is made on the datasets with refining strategies. Finally, a point generation model is trained to merge level-wise models into a unified label set.

The following subsections will focus on 1) our deep level-wise multi-label learning framework and 2) the pointer generation model to merge labels of all levels into one unified label set.

2.1 Deep level-wise multi-label learning

Formally, the problem can be defined as follows. Given a set of input pairs $\cup_{i=1}^{N}\{\mathbf{x}_i, \mathbf{y}_i\}$, Deep Level-wise XMLC decomposes them into M levels and trains M neural models on the training data. The whole label set is denoted as $\mathcal{L}$ and $|\mathcal{L}|$ refers to the total number of labels in $\mathcal{L}$. Each $\mathbf{y}_i$ is a multi-hot vector with length $|\mathcal{L}|$. Each model at level m predicts the most probable K labels, $\{\hat{y}_1^m, ..\hat{y}_j^m, ..., \hat{y}_K^m\}$ on each data sample. K is determined with a refining strategy. In the

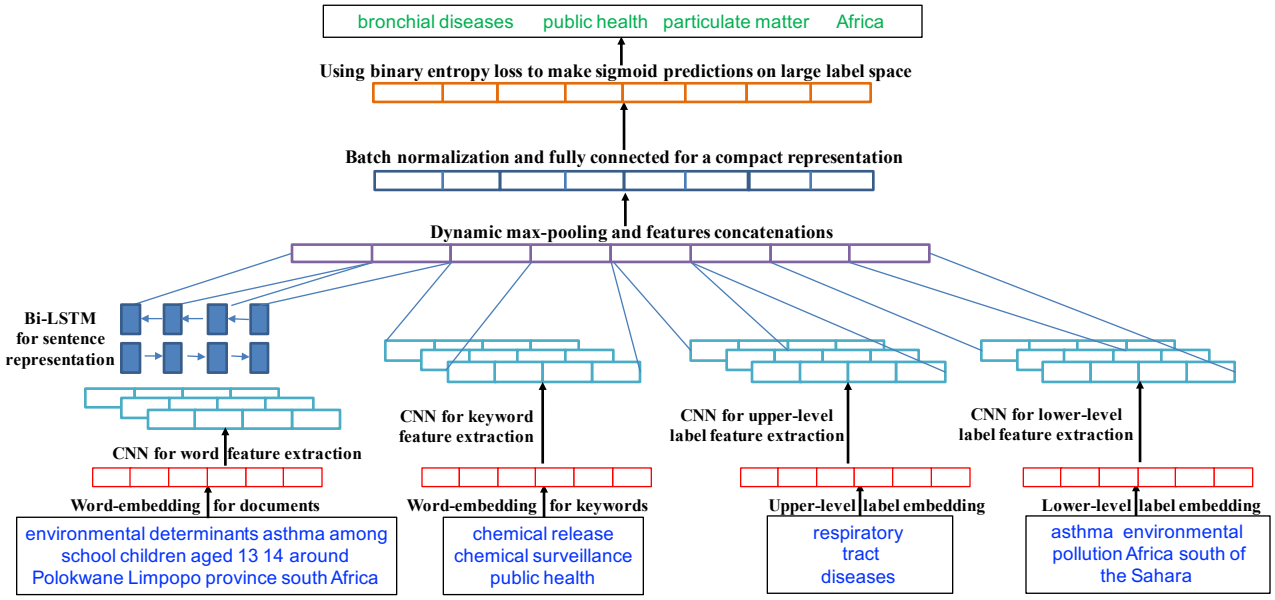

Figure 2: Neural structure of the proposed deep multi Label learning framework. As shown in this figure, the inputs involve four parts: word embedding for documents, word embedding for key words, upper-level and lower level embedding. Embeddings are pretrained with documents, keywords and labels for each document of the training data. Note that label embeddings are made with the same source, namely, the corresponding ontology. After the embedding representations are obtained, all of them are fed into CNN for feature extractions. In order to keep the order for documents, Bi-LSTM is employed for sentence representation. Then, dynamic max-pooling and batch normalization follow those feature extractions. Finally, binary entropy loss is computed to make sigmoid predictions on each label. We can also view this network structure as a multi-task learning.

end, a pointer generation model is trained to merge the predicted $\{\hat{\mathbf{y}}_i^1, ..., \hat{\mathbf{y}}_i^m, ..., \hat{\mathbf{y}}_i^M\}$ of M levels for each data sample $\mathbf{x}_i$ into one unified label set $\mathbf{y}_i$.

2.1.1 Feature embedding construction. We construct models in a level-wise manner. A neural model is built at each level with four parallel inputs as shown in Figure 2. The four inputs include documents, keywords and level-related information. They provide diverse information for the construction of more discriminative features. We employ CNNs to learn a rich number of feature representations. Document and keyword embedding are learned through CNN directly. The other two embeddings, upper-level and lower-level label embeddings, are learned from the embedding of prediction results from upper and lower levels. Specifically, two steps are involved. Firstly, similar to word embedding for input texts and keywords, we employ Gensim to train label embeddings from the annotated MeSH. Secondly, in both training and testing, predicted labels for some documents at some levels will be utilized as input features for their upper level or lower level. The two embeddings can not only help capture level-wise dependencies, but also deal with label imbalance issues in XMLC [4, 37]. In this way, both label co-occurrences and the knowledge from their upper and lower levels can help enhance the representation learning of rare labels.

For example, in MeSH, *Lymphangioma* is a rare label and it can not be easily represented by itself. With the information of its upper level MeSH, *Lymphatic Vessel Tumors* and lower level MeSH *Lymphangioma*, *Cystic Lymphangioma* can be better represented in the embedding space.

After the four embeddings are learned, they are concatenated and delivered into the max-pooling layer.

Due to the order information, raw tokens/words cannot be directly concatenated to the embeddings of keywords, upper and lower level labels. Hence, we construct a Bi-LSTM for raw tokens/words over their CNN features to keep the language order information [14] before concatenation.

2.1.2 The objective function of the learning framework. After the embedding concatenation, a dynamic max pooling layer, a binary cross-entropy loss over sigmoid output and a hidden bottleneck layer are employed. The loss function L of the binary cross-entropy objective is formulated as

$$L = \tag{1}$$

$$\underset{f}{\text{argmin}} -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{|\mathcal{L}|} y_{ij}\log(\sigma(f_j(\mathbf{x}_i)) + (1-y_{ij})\log(1-\sigma(f_j(\mathbf{x}_i))),$$

where $\sigma(f_j(\mathbf{x}_i)) = \frac{1}{1+e^{-f_j(\mathbf{x}_i)}}$ and $f_j(\mathbf{x}_i)$ denote the output layer function. In addition, $f_j(\mathbf{x}_i) = \mathbf{w}_o g_h(\mathbf{w}_h[P(\mathbf{c}_1), ..., P(\mathbf{c}_\iota))])$. Here $\mathbf{w}_h \in R^{h\times(\iota p)}$ and $\mathbf{w}_o \in R^{|\mathcal{L}|\times h}$ are weight matrices associated with the bottleneck layer and output layer, g_h is the element-wise activation functions, e.g., *sigmoid* or *tanh* applied to the bottleneck layer and ιp is the product of ι and p at the dynamic max pooling layer. ι refers to the number of features fed into pooling layers and

p refers to pooling numbers. Both are determined by the number of features in $\mathbf{x_i}$. In addition, $\mathbf{c}_i$ is the vector of convolutional features after the pooling operation $P(.)$ from lower layers.

2.1.3 Categorical-oriented dynamic max pooling. In traditional CNN models for text classification, a max-over-time [11] scheme is often adopted, as intuitively the maximum element of a feature map should take the most important information, i.e., $P(\mathbf{c}) = \max\{\mathbf{c}\}$. This approach, however, exhibits a severe drawback. Using only one value to represent the whole feature map may miss information when the input document includes multiple topics. For multiple-label learning tasks, multiple pooling can capture richer information [20]. In this work, we dynamically perform pooling as $P(\mathbf{c}) = [\max\{\mathbf{c}_{(1:\frac{l}{p})}\}, ..., \max\{\mathbf{c}_{(l-\frac{l}{p}+1:l)}\}] \in R^p$, where $\mathbf{c}_{(1:\frac{l}{p})}$ refers to the sub-vector of $\mathbf{c}$ starting from index 1 to $\frac{l}{p}$. Previous work used a fixed p. If p is set too large, redundant features may be included. If it is set too small, relevant features may be missing.

In our work, level-wise related information, i.e., categorical information of labels is incorporated into the neural structures to help select p dynamically. Specifically, we tune p with the distribution of the label levels. For example, in MeSH, all terms are divided into 16 categories, like *Anatomy*, *Organisms*, *Diseases* and etc. Each category involves diverse subcategories and each label involves different distributions. Based on the distribution, we assign different weights to determine the p. The larger the weight of the category is, the larger the p is. The weight of the category or the label is initialized from the training data.

2.1.4 Refining predictions with macro F-measure maximization. With embeddings and dynamic max pooling, the network can make level-wise predictions as shown in Figure 1. At each level, we select the top-K predicted labels for each data sample. However, a fixed K may yield high recall but low precision. In this work, we refine the predictions with a more flexible weight adjustment strategy.

We apply the online F-measure optimization (OFO) [6, 13] for the weight adjustment. With OFO, a dynamic balance of precision and recall can be achieved. Formally, the OFO algorithm optimizes the binary F-measure through threshold tuning in an online fashion.

$$F_{ij}^t = \frac{2\sum_{l=1}^{i} y_{lj}^t \hat{y}_{lj}^t}{\sum_{l=1}^{i} y_{lj}^t + \sum_{l=1}^{i} \hat{y}_{li}^t} = \frac{2\alpha_{ij}^t}{\beta_{ij}^t}, \tag{2}$$

with $\alpha_{ij}^t = \sum_{l=1}^{i} y_{lj}^t \hat{y}_{lj}^t$ and $\beta_{ij}^t = \sum_{l=1}^{i} y_{lj}^t + \sum_{l=1}^{i} \hat{y}_{li}^t$. Here y_{lj}^t is the j-th label of the l-th data sample. F_{ij}^t is the accumulated F-score from the first to the i-th data sample on label y_j at iteration t.

Due to the incremental property, the threshold of OFO is updated by two rules. At the same iteration, the threshold λ_{ij}^t is updated as $\lambda_{ij}^t = \alpha_{(i-1)j}^t / \beta_{(i-1)j}^t$. At different iterations, it is updated as $\lambda_{ij}^t = \alpha_{Nj}^{(t-1)} / \beta_{Nj}^{(t-1)}$. Given the i-th data sample, OFO refines predicted labels as $\hat{y}_{ij}^t = \left[\hat{\eta}(\mathbf{x}_{ij}^t) > \lambda_{ij}^t\right]$, where $\hat{\eta}(\mathbf{x}_{ij}^t)$ refers to the prediction probability of $\mathbf{x}_i$ on label y_j at iteration t. The optimal F-measure $\hat{F}(\lambda)$ is twice the value of the optimal threshold $\hat{\lambda}$ as $\hat{F}(\lambda) = 2\hat{\lambda}$. Since our refining mechanism is dynamic, level-wise and incremental, the optimal threshold $\hat{\lambda}$ will not be fixed until the end of training. It will be saved as a parameter for testing.

2.2 Pointer generation model for final merging

After we have level-wise outputs, we need to merge those outputs into one unified label set. However, we cannot simply combine them together because a simple concatenation will lead to a much larger number of labels than the gold standard labels. In this paper, we propose a filtering method to remove some level-wise labels to make sure that the final distributions of predicted labels are consistent with the gold standard ones. Inspired by the text summarization [23, 31], we treat each level-wise predication as one sentence and the gold standard as a summarized output. We take into consideration the hierarchical relations of labels among levels during decoding, encoding and attention states [23, 31].

2.2.1 Hierarchical pointer generation model. Inspired by [31], we design our hierarchical pointer generation model by allowing both copying labels from the level-wise predictions and generating labels from the whole label set.

The model is composed of five parts as in Figure 3. The first part, i.e., the input, is about the level-wise predictions from level 1 to level M. In the second part, the input is encoded to M sequences of hidden states. Each encoded hidden state reflects the inner relations of the predicted labels at a certain level. We represent the *encoder hidden state* as $\mathbf{e}^\tau = \mathbf{v}^T \tanh(\mathbf{w}_h \gamma^\tau + \mathbf{w}_s \mathbf{s}^\tau + b_{attn})$. Here $\mathbf{s}^\tau$ and γ^τ are the predicted *label sequence vector* and the *context vector* surrounding the predicted labels, respectively. The terms $\mathbf{v}$, $\mathbf{w}_h$, $\mathbf{w}_s$ and b_{attn} are weight parameters. The *context vector* is about the co-occurrences of labels.

In the third part, *attention generators* are derived from the *encoder hidden state* to generate an attention distribution $\mathbf{a}^\tau$ and a context vector γ^τ at time step τ. $\mathbf{a}^\tau$ is calculated as $\mathbf{a}^\tau = softmax(\mathbf{e}^\tau)$. The attention distribution is a probability distribution over the predicted level-wise labels. It is used to produce γ^τ as a hierarchical weighted sum of the *encoder hidden states*: $\gamma^\tau = \sum_q \mathbf{w}_q \mathbf{a}_q^\tau \gamma_q$.

In Figure 3, each attention generator is named as a coverage vector, which shows how much focus is given to labels of each level. As is known, summarizations may lead to repetitions. Hence, the same label may be generated more than once as well. The well-designed coverage vector plays the role of judging whether the label is a duplicate or not. If not a duplicate, the label with a high attention has more chance of being decoded as one right label. If a duplicate, the mechanism at 2.2.3 will filter the label out.

In the fourth part, i.e., the *decoder hidden states*, the generation probability $p_{gen} \in [0, 1]$ for time step τ is calculated from the context vector γ_τ, the encoder state $\mathbf{s}_\tau$ and the decoder input $\mathbf{y}^\tau$ as:

$$p_{gen} = \sigma(\mathbf{w}_h \gamma^\tau + \mathbf{w}_s \mathbf{s}^\tau + \mathbf{w}_y \mathbf{y}^\tau + b_{ptr}), \tag{3}$$

where $\mathbf{w}_h$, $\mathbf{w}_s$, $\mathbf{w}_y$ and b_{ptr} are weight parameters. Here p_{gen} is used as a soft switch to choose between *generating* a label from the whole label set by *sampling* from the label distribution, $p_{\mathcal{L}}$ (see how $p_{\mathcal{L}}$ is calculated in 2.2.2) or *copying* a label from the input sequences by sampling from the attention distribution $\mathbf{a}^\tau$.

With the above four parts, the proposed hierarchical pointer generation model can be trained to generate the final summarized semantic indexing. In the fifth part, we learn the probability of generating the final labels. Given a training pair $(\cup_{m=1}^{M} \mathbf{y}^m, \mathbf{y})$, we compute the conditional probability $p(\cup_{m=1}^{M} \mathbf{y} | y, \theta)$ to estimate the

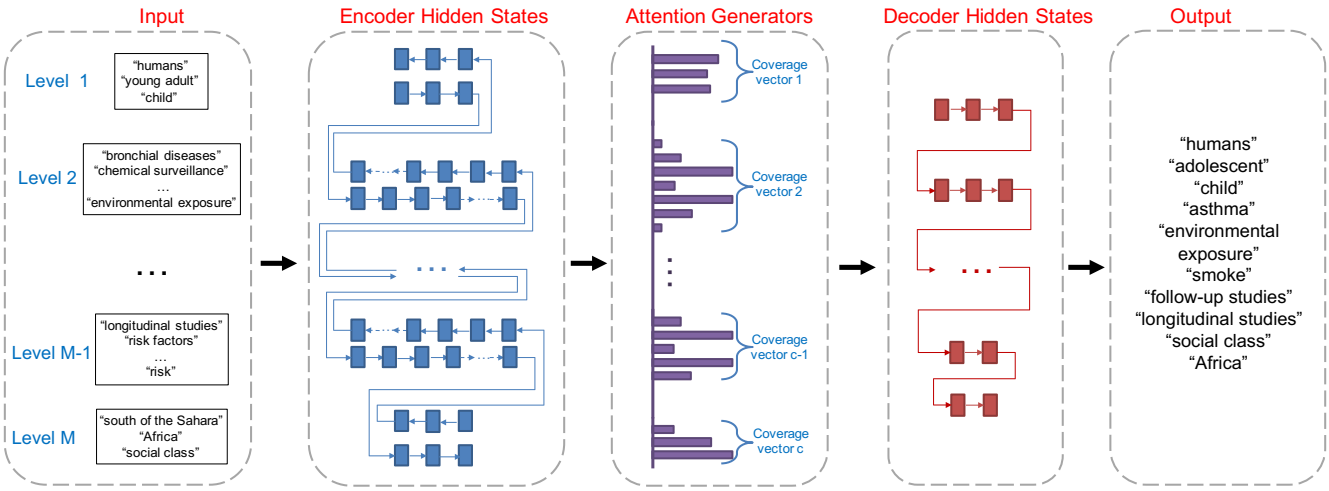

Figure 3: Pointer generation model for final merging. This step follows the level-wise neural structure learning. Five components can be seen from left to right. The input is the predicted level-wise labels. They are organized as sequences level by level. Then, they are encoded into hidden states. Based on coverage vectors described in the methodology, attentions are generated. Then, decoder is working to generate outputs with reduced sizes.

labels of the terms of the probability chain rule as

$$p(\mathbf{y}|\cup_{m=1}^{M}\mathbf{y}^m;\theta)=\prod_{\delta=1}^{|\mathcal{L}|}p_\theta(y_\delta|y_1,...,y_{\delta-1};\theta), \tag{4}$$

where $\mathbf{y}=\{\mathbf{y}_1,...,\mathbf{y}_{|\mathcal{L}|}\}$ is a sequence of $|\mathcal{L}|$ vectors. The parameters of the model are learned by maximizing the conditional probabilities for the training set as $\theta=\underset{\theta}{\text{argmax}}\sum_{\mathbf{y},\cup_{m=1}^{M}}\log p(\mathbf{y}|\cup_{m=1}^{M}\mathbf{y}^m;\theta)$, where the sum is over training examples.

2.2.2 Sequence-to-sequence probability calculation. The above procedure finally will produce the label vocabulary distribution $p_{\mathcal{L}}$:

$$p_{\mathcal{L}}=softmax(\mathbf{v}'(\mathbf{v}[s_t,h_{*t}]+b)+b'), \tag{5}$$

where $\mathbf{v}$, $\mathbf{v}'$, b and b' are learnable parameters. For a specific label, we can obtain from $p(y_{ij})=p_{\mathcal{L}}(y_{ij})$. The loss function is the negative log likelihood of the target label $\hat{y}_{ij}$. The following example illustrates the procedure of probability calculations for one label given other labels.

Suppose we have a label set $\{Nutritional\ and\ Metabolic\ Diseases\}$. The hierarchical relations are shown in Figure 4. The left words in the figure are acronyms for the labels. For example, $Wolfram\ Syndrome$ is shortened with their initial letters as ws.

Given $context=\{nmd,md,dm,dmt1\}$, we follow the hierarchical relations among those labels to calculate $p(\mathbf{e}_{ws}|context)$ as

$$p(\mathbf{e}_{ws}|context)=(1-\sigma(b_{ptr}+\mathbf{e}_{nmd}^T\mathbf{h}_{nmd})\sigma(b_{ptr}+\mathbf{e}_{md}^T\mathbf{h}_{md})$$
$$\sigma(b_{ptr}+\mathbf{e}_{dm}^T\mathbf{h}_{dm})\sigma(b_{ptr}+\mathbf{e}_{dmt1}^T\mathbf{h}_{dm1})). \tag{6}$$

2.2.3 Mechanism to avoid duplications. A problem for pointer generation model or sequence-to-sequence model is that it may copy terms from input multiple times [24, 30]. In our task, we do not need any repetitive terms since each label should be unique. Previous works [31, 32] adapts a coverage mechanism to avoid repetition. Namely, if labels have been seen in the output, the probability of generating them will become low. We take similar approaches by combining a coverage mechanism into the whole pointer generation model. Specifically,

$$\varkappa^m=\sum_{\mathbf{y}^m=0}^{|\varkappa|}\varkappa^{\mathbf{y}^m}, \tag{7}$$

where, $\varkappa$ refers to a coverage vector, $\mathbf{y}^m$ refers to m-th level.

Our coverage vectors are composed of a set of vectors for all levels. For each coverage vector, $\varkappa^{\mathbf{y}^m}$ is an unnormalized distribution over the level-wise inputs that represents the degree of coverage that those labels have received from the attention mechanism so far. Since we order labels with levels, there should be no repetitions at different sections of levels, this mechanism aims at removing all duplicate labels found in different sections and also avoid duplicates within the same level. $w_\varkappa\varkappa^{\mathbf{y}^m}$ is added to the attention mechanism and a $covloss_{\mathbf{y}^m}$ is also added to the total loss function of the pointer generation model as the penalty for any duplications.

3 EXPERIMENTAL RESULTS

In this section, we evaluate the effectiveness of our Deep Level-wise XMLC with MEDLINE dataset labeled with MeSH and AmazonCat13K. As described in Section 1, MEDLINE is the largest biomedical literature database in the world and Medical Subject Headings (MeSH) is the domain ontology for tagging articles in MEDLINE. The other dataset we use, AmazonCat13K, is one of benchmark datasets for developing extreme classification algorithms. It involves 13330 labels, with all labels hierarchically organized, similar to MeSH. The dataset scale, the expert labeling and the hierarchical nature provide a perfect testbed for our proposed framework.

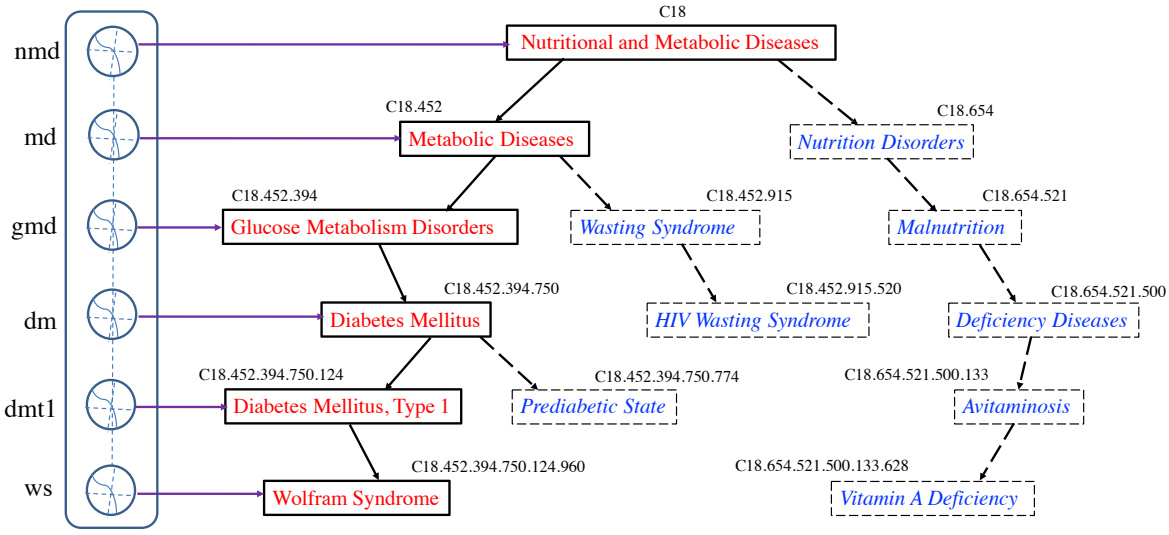

Figure 4: Example of sequence-to-sequence probability calculation. The calculation of the example is described in section 2.2.2. A little bit clarification may be necessary is on those short forms. On the left, for space saving and for better illustration of the process, Sigmoid symbols are drawn there with those short forms, which are the initial letters of the mesh terms.

3.1 Data setting and preprocessing

The total number of MeSH labels in MEDLINE is 26,000, among which 60% appear more than 1000 times. We remove those MeSH labels occurring less than 10 times in the experiment. The MEDLINE has 26 million articles with abstracts. 90% of these articles have about 20 MeSH labels. 4 to 16 MeSH labels are assigned to 82% of articles. In MeSH, 3.5 million abstracts have both MeSH labels and keywords. The ontology of MeSH labels can be decomposed into 7 levels, where the lowest level (the 7th level) includes the most specific MeSH labels while the highest level (the 1st level) has the most general and abstract MeSH labels. For articles with only MeSH labels of the lowest level, we expand them by the following method. Starting from labels at the lowest level, we find out all labels of their upper levels. We construct 7 datasets for the proposed Deep Level-wise XMLC framework.

Meanwhile, 102,167 abstracts with MeSH labels from all the 7 levels are put aside for testing. The statistics of the dataset at each level is shown in Table 1. It can be observed that the middle levels have the largest number of labels while the highest level has only 83 labels and the lowest level has 2445 labels. Similar trend can been found for data volumes. Two million articles have labels from level 2, 3 and 4 while less than one million articles have labels from level 1, 6 and 7.

For AmazonCat13K, we cannot directly use their preprocessed dataset since Deep Level-wise XMLC requires text data. Meanwhile, we need divide the data based on their level-wise categories. It is found that all labels can be decomposed into 9 levels. Somewhat differently, if a document from AmazonCat13K has lower labels, it must have higher labels while a document from MeSH is not necessarily so. Therefore, it is straightforward to find a common set for testing for AmazonCat13K (simply use documents with lower categories). In order to keep a reasonable pool of testing data, we ignore documents which have levels higher than 6 (only 9990, 385 and 31 documents for level 7,8, and 9, respectively).

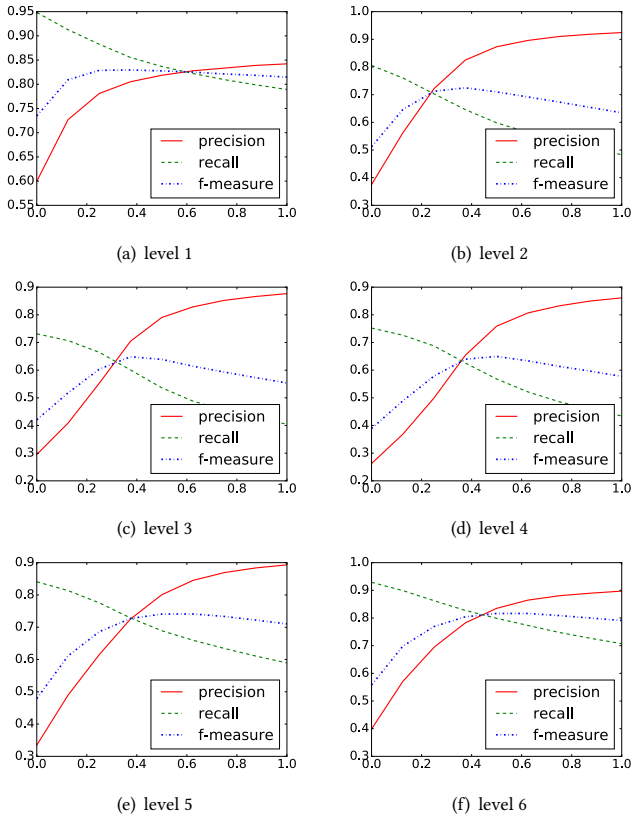

Table 1: The statistics of the datasets. For each level, there are different data volumes. Papers in Medline, do not necessarily imply that they can be tagged higher level MeSH terms even if they are tagged with lower level MeSH terms.

Levels	Data Volumes		The number of labels	
	MeSH	AmazonCat13K	MeSH	AmazonCat13K
Level 1	969,233	858,795	83	44
Level 2	2,444,854	812,249	1,382	362
Level 3	2,405,321	549,326	4,484	2,281
Level 4	2,182,885	427,378	6,568	6,181
Level 5	1,522,195	178,042	5,750	5,372
Level 6	906,873	71,041	3,895	1,998
Level 7	402,794	9,990	2,445	441

In the experiments, for the MEDLINE articles and keywords, at each level, we first train an individual neural network according to the first component of Deep Level-wise XMLC. The trained model is employed to make predictions on the testing data for each level. Then the predicted level-wise labels as well as the gold standard labels from the training data are utilized by the pointer generation model for the final merging. Likewise, we train level-wise model for AmazonCat14K except that the latter do not have keywords.

3.2 Evaluation metrics

In extreme multi-label classification datasets, even though there are usually huge label spaces, only limited number of relevant labels for each document. This means that it is important to present a short ranked list of relevant labels for each test document. The

(a) level 1 (b) level 2

(c) level 3 (d) level 4

(e) level 5 (f) level 6

Figure 5: Macro precision, recall and F-measure obtained by OFO with Deep Level-wise XMLC for the first six levels.

evaluation thus focuses on the quality of such ranked lists with emphasis on the relevance of the top portion of each list. In our work, however, we use two evaluation metrics for the purpose of comparisons with the two sources of datasets. The medical community prefers to use precision, recall and F-score while those from the general domains prefer precision at K (P@K) and the Normalized Discounted Cummulated Gains (NDCG@K or G@K for short).

Specifically, given a predicted label list $\mathbf{y}_1^m = \{y_1, y_2, ..., y_K\}$ with top K items at level m, precision, recall and F-score are defined as follows,

$$MiP = \frac{\sum_{i=1}^{N} c(K, i, y_1^K)}{\sum_{i=1}^{N} K_i}, \qquad MaP = \frac{1}{N}\sum_{i=1}^{N} \frac{c(K, i, y_1^K)}{K_i}, \tag{8}$$

$$MiR = \frac{\sum_{i=1}^{N} c(K, i, y_1^K)}{\sum_{i=1}^{N} AK_i}, \qquad MaR = \frac{1}{N}\sum_{i=1}^{N} \frac{c(K, i, y_1^K)}{AK_i}, \tag{9}$$

$$MiF = \frac{2 * MiP * MiR}{MiP + MiR}, \qquad MaF = \frac{2 * MaP * MaR}{MaP + MaR}, \tag{10}$$

where N is the number of data samples and $c(K, i, y_1^K)$ is the number of correct labels among the top K ranked labels; AK_i is the total number of the gold standard labels for article i; The difference between micro measures and macro measures lies in the calculation of the predicted probabilities. For micro measures, the probability calculation is not done until all correct predictions are added together, while for macro measures, the probability calculation will be done for each article and in the end, an average is used as the macro scores. We report both measures in order to see how accurate the model is for a single article and for an entire dataset.

In contrast, the definition of P@K and NDCG@K is,

$$P@k = \frac{1}{k}\sum_{l \in r_k(\hat{\mathbf{y}})} y_l \tag{11}$$

$$DCG@k = \sum_{l \in r_k(\hat{\mathbf{y}})} \frac{y_l}{log(l+1)} \tag{12}$$

$$NDCG@k = \frac{DCG@k}{\sum_{l=1}^{min(k, \|\vec{y}\|)} \frac{y_l}{log(l+1)}} \tag{13}$$

where $\vec{y} \in \{0, 1\}^L$ is denoted as the vector of true labels of a document and $\hat{\vec{y}} \in R^L$ as the system-predicted score vector for the same document. We use $k = 1, 3, 5$, following the convention of P@K and NDCG@K.

3.3 Parameter settings

For the neural network of Deep Level-wise XMLC, we use the rectified linear units. The filtering windows are set to 3, 4, 5. The dropout rate is set to 0.5 and the L2 constraint is set to 3. The mini-batch size is set to 256. The embedding dimensions vary for different features. For Mesh, word embedding for medical words involves 500,000 unique tokens, keyword embedding involves over 100,000 phrases and label embedding 26,000 MeSH terms. Gensim is employed to train the embedding with 300 as the dimension. For AmazonCat13K, pretrained GoogleNews-vectors-negative300.bin is utilized with 3 million tokens and 300 as the dimension. The values for other hyperparameters are chosen via a grid search on a smaller validation set from the training data.

3.4 Performance with online F-measure optimization

As discussed in Section 2.1.4, the online macro F-measure optimization (OFO) is integrated into the proposed framework. In order to show the effectiveness of OFO, we report the macro precision, recall and F-score for the first 6 levels in Figure 5 for MeSH. Due to space limit, we do not show the result of the 7th level and that of AmazonCat13K in this paper. Similar performances can be obtained for them. We can observe that OFO helps achieve a balance between macro precision and recall. It is further observed that the optimal F-score is different at different levels. If we always select the top K ($k = 10$ in our experiment) for the level-wise prediction, we cannot obtain the best F-score though the recall at each level can be as high as around 80%. The precision can be as low as or less than 20%. The reason is that after we divide MeSH labels of each article into 7 levels, most of articles have only 2 to 5 labels at each level. This means that even if all of labels are within the top 10, the precision is only from 20% to 50% although the recall can be 100%. In this case, the F-scores are not high either. The OFO greatly removes less relevant labels so that the number of labels in the final prediction set of each level ranges from 2 to 5 as well. Meanwhile, most of

Table 2: The level-wise performance for micro measures with Top K and OFO. This table aims at showing the incremental improvements on the micro measures when the new features added stepwise for each level. Meanwhile, for each level, results for TopK without optimization and with optimization as OFO are shown there as well.

the correct predictions are still kept in the prediction set. Evidently, this tuning strategy greatly boosts the performance.

3.5 Level-wise Performance

As discussed in Section 2, our framework decomposes the task of XMLC into level-wise model constructions. Therefore, in this section, we report level-wise prediction results in order to see the intermediate developments and improvements of the whole model.

As is shown in Figure 2, the level-wise neural models learn label embeddings from the MEDLINE collections, keywords and the predicted labels from the upper or lower levels. Here we report the performance of the level-wise neural models with different embeddings. We further show the effectiveness of OFO by comparing with the level-wise neural models by fixing the top K labels for each level. We test on different K from 1 to 10 and find that the best performance is achieved when K is 5.

Table 2 reports the micro performance for the level-wise model with OFO and top K fixing strategies. Here K is set to 5 for the best results. We also show the performance for the macro measurement in Table 3. We can see that OFO always perform better than the strategy of fixing top K, no matter on the micro or the macro measurements.

Table 2 and Table 3 also report the level-wise prediction with three different embeddings for MeSH. Although the evaluation for AmazonCat13K dataset is not based on F-scores, we also report micro measures for AmazonCat13K to show the advantages of OFO. After all, the result of P@K and NDCG@K for it is computed on the filtered output with OFO. From this result, we can see an evident incremental trend for all seven levels. Namely, with keywords and predicted MeSH terms of upper and lower levels added, the prediction sees quick improvements accordingly. It is not hard to see that in general, macro results are better than micro results. Among

them, the third level and the fourth level of MeSH while the fourth and the fifth level of AmazonCat13K yield worse results than others while level 1 obtain much better results for both datasets. This is understandable considering the larger number of labels for third and the fourth (4,484 and 6,568 for MeSH while 6,181 and 5,372 for AmazonCat13K respectively).

3.6 Performance of final merging

The proposed Deep Level-wise XMLC will merge the level-wise predictions into one unified label set with a pointer generation model. In this section, we further compare with five state-of-the-art approaches to demonstrate the effectiveness of the pointer generation model, including MTIDEF [12], MeSH Now [22], MeSHLabeler, MeSHRanker [21] and Deep Mesh [28] for MeSH results. All these existing systems make heavy use of feature engineering. In contrast, Deep Level-wise XMLC uses limited external resources. For AmazonCat13K, we report results of XML-CNN, the state of the art systems on this benchmark dataset.

Let us start from MeSH labeling. After we achieve the level-wise results, the hierarchical pointer generation model is trained with predicted results from all levels as the input and the gold standard labels as the output. For model training, the inputs can be organized with each label as an independent unit or with labels of the same level as one unit (known as *sentence* in the summarization community). Hence, two pointer generation models are trained, with the former known as Deep Level-wise XMLC$_{label}$ and with the latter as Deep Level-wise XMLC$_{level}$. For comparison, we also report results which adds results of all levels together and then filter less relevant labels by their prediction probabilities and by the label distributions in the gold standard (Deep Level-wise XMLC$_{sampling}$).

Table 4: Performance of Deep Level-wise XMLC for MeSH dataset. From the bold numbers, we can see that the best performances come from Deep Level-wise XMLC. It is obvious to see that level based and dynamic pooling obtain better performance than label based and dynamic pooling.

Methods	MaP	MaR	MaF
No Level-wise XMLC			
MTIDEF	49.39	51.40	50.37
BC_D2V-TFIDF	47.41	46.33	46.86
MeSHRanker	53.64	54.13	53.89
MeSHLabeler	54.50	51.72	50.54
DeepMesh	53.80	55.05	54.42
MeSH Now	51.28	53.72	52.47
Deep Level-wise XMLC without pointer generation network			
Sampling	49.56	51.21	50.37
Max pooling	51.56	65.52	57.70
Deep Level-wise XMLC with pointer generation network			
Dynamic pooling & label-based	**61.20**	57.21	59.14
Dynamic pooling & level-based	53.22	**70.65**	**60.77**

As shown in Table 4, both Deep Level-wise XMLC$_{label}$ and Deep Level-wise XMLC$_{level}$ outperform other systems much on macro measures in precisions, recalls as well as F-scores. Due to the page limit, we do not report the micro measures, which have similar trends.

By involving embeddings from MEDLINE collections and keywords, Deep Level-wise XMLC$_{label}$ and Deep Level-wise XMLC$_{level}$ achieve much better performances than all other existing cutting edge frameworks. To our interest, it seems that different organizations of the inputs will lead to different performances in precision and recall although F scores are quite similar. Deep Level-wise XMLC$_{label}$ achieves better precision while Deep Level-wise XMLC$_{level}$ better recall. This seems to indicate that our hierarchical pointer generation model takes into considerations the correlations between labels within the unit. Therefore, Deep Level-wise XMLC$_{level}$, which has longer input unit, obtains better recall. Yet, it also includes more false positives, thus reducing its precision. In contrast, Deep Level-wise XMLC$_{label}$ wins in precision probably it considers more smaller units and then misses more true positives.

Meanwhile, we can see that Deep Level-wise XMLC$_{sampling}$ obtains much poorer results than most of existing systems. This shows that the hierarchical pointer generation model plays essential roles in reaching the optimal performances in the end. Besides, we also report results of Deep Level-wise XMLC$_{level}$ with max pooling. By default, all of our systems work with dynamic max pooling. Evidently, the result shows that dynamic max pooling gains advantages over the usual max pooling strategies.

Table 5: Performance of Deep Level-wise XMLC for AmazonCat13K. We use the version with pointer generation network and dynamic pooling & level-based. As stated in 3.1, in order to extend our methodology from medical field to more general ones, we test our model on AmazonCat13K as well. For those who use AmazonCat13K, they prefer reporting precision@K and NDCG@K. We also list the performance of XML-CNN for AmazonCat13K for comparisons.

	P@1	P@3	P@5	G@1	G@3	G@5
XML-CNN	95.06	79.86	63.91	95.06	89.48	87.06
Deep Level-wise XMLC	96.52	83.72	67.89	97.48	92.32	87.52

For AmazonCat13K, the result is given in Table 5. We also copy the state of the art results from XML-CNN from their work [20] in Table 5. We can see higher results from our work. Due to the differences of the testing data, we cannot tell which work is better from those results (our testing dataset are extracted from the raw text data with labels of each level for better evaluations). Their work is tested on the standard test dataset prepared by data collectors. Yet, it at least shows that our model can achieve results as comparable to the best model.

4 RELATED WORK

4.1 Tree-based methods

Due to the huge number of labels, the prediction of XMLC may involve high cost in both time and space. Tree-based methods make efforts to reduce both training and testing cost. For example, the label partitioning by sub-linear ranking (LPSR) method attempts to reduce the prediction time by learning a hierarchy over a base

classifier [17, 18, 33]. Argrawal et al., 2013 [1] proposes a method as the multi-label random forest (MLRF), which seeks to learn an ensemble of randomized trees instead of relying on the learning of a base classifier. FastXML [29] is proposed to learn a hierarchy not over the label space but over the feature space. It defines the set of labels active in a region to be the union of the labels of all training points present in that region. At each node of the hierarchy, an NDCG-based objective is optimized. Namely, at each node, a hyperplane is induced and it splits the set of documents in the current node into two subsets. Predictions are made by returning the ranked list of the most frequently occurring labels in all the leaf nodes. Recently, Mu et al [26] develops multi-label classifications for social streams based on ensemble random forests. It integrates a base learner and a label-based learner to learn hierarchical labels. However, these approaches suffer from high cost of training due to the dimensionality of both label space and feature space.

4.2 Embedding methods

Embedding methods attempt to overcome the intractability issue brought by the huge number of labels by projecting label vectors onto a low dimensional space and thus reducing the number of labels. The assumption is that the label matrix is low-rank. Due to its strong theoretical foundations and the ability to handle label correlations, embedding methods have proved to be the most popular approach for tackling XMLC problems [2, 5, 8, 10]. In particular, the recently proposed embedding method SLEEC [4] greatly increases the accuracy after they incorporates the non-linear neighborhood constraints in the low-dimensional embedding space for training and use a simple k-nearest neighbor (k-NN) clustering in the embedding space for testing. In our approach, we take steps further by exploring level-wise label embedding to improve the predictions of our neural structure.

4.3 Max-margin method

Max-margin method is also employed to handle multi-label classification. Yen et al [36] proposes a model named as PD-Sparse. Essentially, a linear classifier is learned for each label with $L1$ and $L2$ norm penalty on the weight matrix associated with this label. This results in a sparse solution in both the primal and dual spaces. Their fully-Corrective Block-Coordinate Frank-Wolfe training algorithm achieves sub-linear training time w.r.t the number of primal and dual variables while getting better performance than 1-vs-all SVM and logistic regression on multi-label classification, with significantly reduced training time and model size. However, same as 1-vs-all SVM, the method is algorithmically not scalable to extreme multi-label learning.

4.4 Deep learning based method

Deep learning based method has also been used for multi-label learning [20, 37]. Zhang et al. [37] incorporate label space embedding into feature embedding. Specifically, they construct an adjacency matrix for labels A and derive the label graph matrix with the equation $M = (A + A^2)/2$. Then, for each nonzero entry in the matrix, a tuple composed of the index p, q and M_{pq} is fed to a label embedding network to train a compound network together with the word-embedding. In the prediction stage, k-NN search is performed in the low-dimensional feature representation to find similar samples from training datasets. The average of the k-NN's labels is set as final label prediction. [20] proposes to take multi-label co-occurrence patterns into the nueral network objective to improve the classification performance. They also propose to employ dynamic max pooling to capture rich information from different regions of the document and an additional hidden bottleneck layer to reduce model size. Moreover, a binary cross-entropy loss over sigmoid output is tailored to XMLC. However, these methods are not applicable for data with complex hierarchical labels like ours since the decomposition of label hierarchies reduce the label space greatly. In addition, Yan et al [35] proposes Boltzmann CNNs-based hybrid learning network to handle biomedical literature classification. Their work is enriched with data sequence embeddings. This design is not good for huge label space. Their experiments only focus on classes fewer than 2,000 MeSH labels. The work mostly close to ours is hierarchical multi-label classification network (HMCN) proposed by [7]. Their HMCN is claimed to be capable of simultaneously optimizing local and global loss functions for discovering local hierarchical class-relationships and global information from the entire class hierarchy while penalizing hierarchical violations. But their work has higher computational complexity due to the utilization of fully feed-forward layers. Even if they simplify their network with an LSTM-like model with shared weights, it still has high computation burden. It seems that is why they only report works on datasets of at most about 4000 labels.

5 CONCLUSION

In this work, we propose deep learning based level-wise framework to handle extreme multi-label learning and classification, named as Deep Level-wise XMLC. The innovation of Deep Level-wise XMLC includes a few points. Firstly, we develop a split model training mechanism, with which, labels are divided into multiple levels so that the curse of dimensionality and training cost are both lessened to a large degree. Secondly, category-dependent dynamic max pooling and weights adjustments with macro F-measure are integrated into the neural architecture so that the final predictions fit more to the distributions of the levels and their hierarchical relations. Thirdly, we successfully design a hierarchical pointer generation model to merge level-wise outputs into one unified label prediction.

The results show that Deep Level-wise XMLC achieves the state-of-the-art results by utilizing MEDLINE collections, keywords and predicted labels from upper and lower levels are utilized. The results for AmazonCat13K also show that Deep Level-wise XMLC is generic enough to handle diverse datasets.

In this work, it is not hard to see that Deep Level-wise XMLC can be conveniently transferred to tasks, like large scale semantic indexing for constructing more efficient and accurate information retrieval engines and reducing expensive manual expert efforts as shown in this work.

In future work, more experiments will be done on diverse datasets. Besides, model improvements can be made on designing more robust loss functions as well as adding more layers for handling feature refinements or weight adjustments and meanwhile improving running efficiency.

ABSTRACT

The problem of selecting a group of vertices under certain constraints that maximize their joint centrality arises in many practical scenarios. In this paper, we extend the notion of current flow closeness centrality (CFCC) to a set of vertices in a graph, and investigate the problem of selecting a subset S to maximizes its CFCC $C(S)$, with the cardinality constraint $|S| = k$. We show the NP-hardness of the problem, but propose two greedy algorithms to minimize the reciprocal of $C(S)$. We prove the approximation ratios by showing the monotonicity and supermodularity. A proposed deterministic greedy algorithm has an approximation factor $(1 - \frac{k}{k-1} \cdot \frac{1}{e})$ and cubic running time. To compare with, a proposed randomized algorithm gives $(1 - \frac{k}{k-1} \cdot \frac{1}{e} - \epsilon)$-approximation in nearly-linear time, for any $\epsilon > 0$. Extensive experiments on model and real networks demonstrate the effectiveness and efficiency of the proposed algorithms, with the randomized algorithm being applied to massive networks with more than a million vertices.

1 INTRODUCTION

A fundamental problem in network science and graph mining is to identify crucial vertices [35, 38]. It is an important tool in network analysis and found numerous applications in various areas [44]. The first step of finding central vertices is to define suitable indices measuring relative importance of vertices. Over the past decades, many centrality measures were introduced to characterize and analyze the roles of vertices in networks [5, 8, 9, 53]. Among them, a popular one is closeness centrality [3, 4]: the closeness of a vertex is the reciprocal of the sum of shortest path distances between it and all other vertices. However, this metric considers only the shortest paths, and more importantly, neglects contributions from other paths. Therefore it can produce some odd effects, or even counterintuitive results [7]. To avoid this shortcoming, Brandes and Fleischer presented current flow closeness centrality [11] based on electrical networks [19] , which takes into account contributions from all paths between vertices. Current flow based closeness has been shown to better discriminate vertices than its traditional counterparts [7].

While most previous works focus on measures and algorithms for the importance of individual vertices in networks [38], the problem of determining a group of k most important vertices arises frequently in data mining and graph applications. For example, in social networks, retailers may want to choose k vertices as promoters of product, such that the number of the potentially influenced customers is maximized [31]. Another example is P2P networks, where one wants to place resources on a fixed number of k peers so they are easily accessed by others [25]. In order to measure the importance of a group of vertices, Everett and Borgatti [21] extended the idea of individual centrality to group centrality, and introduced the concepts of group centrality, for example, group closeness. Recently, some algorithms have been developed to compute or estimate group closeness [6, 13, 56]. However, similar to the case of individual vertices, these notions of group centrality also disregard contributions from paths that are not shortest.

In this paper, we extend current flow closeness of individual vertices [7] by proposing current flow closeness centrality (CFCC) for group of vertices. In a graph with n vertices and m edges, the CFCC $C(S)$ of a vertex group $S \subset V$ is equal to the ratio of n to the sum of effective resistances between S and all vertices u in $V \setminus S$. We then consider the optimization problem: how can we find a group

S^* of k vertices so as to maximize $C(S^*)$. We solve this problem by considering an equivalent problem of minimizing the reciprocal of $C(S^*)$. We show that the problem is NP-hard in Section 4, but also prove that the problem is an instance of supermodular set function optimization with cardinality constraint in Section 5. The latter allows us to devise greedy algorithms to solve this problem, leading to two greedy algorithms with provable approximation guarantees:

(1) A deterministic algorithm with a $(1-\frac{k}{k-1}\cdot\frac{1}{e})$ approximation factor and $O(n^3)$ running time (Section 6);
(2) A randomized algorithm with a $(1-\frac{k}{k-1}\cdot\frac{1}{e}-\epsilon)$-approximation factor and $\widetilde{O}(km\epsilon^{-2})$ running time[1] for any small $\epsilon > 0$ (Section 7).

A key ingredient of our second algorithm is nearly linear time solvers for Laplacians and symmetric, diagonally dominant, M-matrices (SDDM) [16, 48], which has been used in various optimization problems on graphs [17, 30, 41].

We perform extensive experiments on some networks to evaluate our algorithm, and some of their results are in Section 8. These results show that both algorithms are effective. Moreover, the second algorithm is efficient and is scalable to large networks with more than a million vertices.

1.1 Related Works

There exist various measures for centrality of a group of vertices, based on graph structure or dynamic processes, such as betweenness [18, 22, 39, 55], absorbing random-walk centrality [37, 40, 57], and grounding centrality [14, 46]. Since the criterion for importance of a vertex group is application dependent [24], many previous works focus on selecting (or deleting) a group of k vertices (for some given k) in order to optimize related quantities. These quantities are often measures of vertex group importance motivated by the applications, including minimizing the leading eigenvalue of adjacency matrix for vertex immunization [12, 51], minimizing the mean steady-state variance for first-order leader-follower noisy consensus dynamics [15, 45], maximizing average distance for identifying structural hole spanners [47, 54], and others.

Previous works on closeness centrality and related algorithms are most directly related to our focus on the group closeness centrality in this paper. The closeness centrality for an individual vertex was proposed [3] and formalized [4] by Bavelas. For a given vertex, its closeness centrality is defined as the reciprocal of the sum of shortest path distances of the vertex to all the other vertices. Everett and Borgatti [21] extended the individual closeness centrality to group closeness centrality, which measures how close a vertex group is to all other vertices. For a graph with n vertices and m edges, exactly computing the closeness centrality of a group of vertices involves calculating all-pairwise shortest path length, the time complexity of the state-of-the-art algorithm [28] for which is $O(nm + n^2 \log n)$. To reduce the computation complexity, various approximation algorithms were developed. A greedy $O(n^3)$ algorithm with approximation ratio $\left(1-\frac{k}{k-1}\cdot\frac{1}{e}\right)$ was devised [13], and a sampling algorithm that scales better to large networks, but without approximation guarantee was also proposed in the same paper. Very recently, new techniques [6] have been developed to speed up the greedy algorithm in [13] while preserving its theoretical guarantees.

Conventional closeness centrality is based on the shortest paths, omitting the contributions from other paths. In order to overcome this drawback, Brandes and Fleischer introduced current flow closeness centrality for an individual vertex [11], which essentially considers all paths between vertices, but still gives large weight to short paths. Our investigation can be viewed as combining this line of current based centrality measures with the study of selecting groups of k vertices.

[1]We use the $\widetilde{O}(\cdot)$ notation to hide the poly log factors.

2 PRELIMINARIES

In this section, we briefly introduce some useful notations and tools for the convenience of description of our problem and algorithms.

2.1 Notations

We use normal lowercase letters like a, b, c to denote scalars in $\mathbb{R}$, normal uppercase letters like A, B, C to denote sets, bold lowercase letters like $\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}$ to denote vectors, and bold uppercase letters like $\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{C}$ to denote matrices. We write $\boldsymbol{a}_{[i]}$ to denote the i^{th} entry of vector $\boldsymbol{a}$ and $\boldsymbol{A}_{[i,j]}$ to denote entry (i, j) of matrix $\boldsymbol{A}$. We also write $\boldsymbol{A}_{[i,:]}$ to denote the i^{th} row of $\boldsymbol{A}$ and $\boldsymbol{A}_{[:,j]}$ to denote the j^{th} column of $\boldsymbol{A}$.

We write sets in matrix subscripts to denote submatrices. For example, $\boldsymbol{A}_{[I,J]}$ denotes the submatrix of $\boldsymbol{A}$ with row indices in I and column indices in J. To simplify notation, we also write $\boldsymbol{A}_{-i}$ to denote the submatrix of $\boldsymbol{A}$ obtained by removing the i^{th} row and i^{th} column of $\boldsymbol{A}$. For example, for an $n \times n$ matrix $\boldsymbol{A}$, $\boldsymbol{A}_{-n}$ denotes the submatrix $\boldsymbol{A}_{[1:n-1,1:n-1]}$.

Note that the precedence of matrix subscripts is the lowest. Thus, $\boldsymbol{A}_{-n}^{-1}$ denotes the inverse of $\boldsymbol{A}_{-n}$ instead of a submatrix of $\boldsymbol{A}^{-1}$.

For two matrices $\boldsymbol{A}$ and $\boldsymbol{B}$, we write $\boldsymbol{A} \preceq \boldsymbol{B}$ to denote that $\boldsymbol{B} - \boldsymbol{A}$ is positive semidefinite, i.e., $\boldsymbol{x}^T\boldsymbol{A}\boldsymbol{x} \le \boldsymbol{x}^T\boldsymbol{B}\boldsymbol{x}$ holds for every real vector $\boldsymbol{x}$.

We use $\boldsymbol{e}_i$ to denote the i^{th} standard basis vector of appropriate dimension, and $\mathbf{1}_S$ to denote the indicator vector of S.

2.2 Graphs, Laplacians, and Effective Resistances

We write $G = (V, E, w)$ to denote a positively weighted undirected graph with n vertices, m edges, and edge weight function $w : E \to \mathbb{R}^+$. The Laplacian matrix $\boldsymbol{L}$ of G is defined as $\boldsymbol{L}_{[u,v]} = -w(u, v)$ if $u \sim v$, $\boldsymbol{L}_{[u,v]} = \deg(u)$ if $u = v$, and $\boldsymbol{L}_{[u,v]} = 0$ otherwise, where $\deg(u) \stackrel{\text{def}}{=} \sum_{u\sim v} w(u, v)$ is the weighted degree of u and $u \sim v$ means $(u, v) \in E$. Let $w_{\max}$ and $w_{\min}$ denote, respectively, the maximum weight and minimum weight among all edges. If we orient each edge of G arbitrarily, we can also write it's Laplacian as $\boldsymbol{L} = \boldsymbol{B}^T\boldsymbol{W}\boldsymbol{B}$, where $\boldsymbol{B}_{m\times n}$ is the signed edge-vertex incidence matrix defined by $\boldsymbol{B}_{[e,u]} = 1$ if u is e's head, $\boldsymbol{B}_{[e,u]} = -1$ if u is e's tail, and $\boldsymbol{B}_{[e,u]} = 0$ otherwise, and $\boldsymbol{W}_{m\times m}$ is a diagonal matrix with $\boldsymbol{W}_{[e,e]} = w(e)$. It is not hard to show that quadratic forms of $\boldsymbol{L}$ can be written as $\boldsymbol{x}^T\boldsymbol{L}\boldsymbol{x} = \sum_{u\sim v} w(u, v)\left(\boldsymbol{x}_{[u]} - \boldsymbol{x}_{[v]}\right)^2$, which immediately implies that $\boldsymbol{L}$ is positive semidefinite, and $\boldsymbol{L}$ only has one zero eigenvalue if G is a connected graph.

The following fact shows that submatrices of Laplacians are always positive definite and inverse-positive.

Fact 2.1. *Let $\boldsymbol{L}$ be the Laplacian of a connected graph and let $\boldsymbol{X}$ be a nonnegative, diagonal matrix with at least one nonzero entry. Then, $\boldsymbol{L}+\boldsymbol{X}$ is positive definite, and every entry of $(\boldsymbol{L}+\boldsymbol{X})^{-1}$ is positive.*

Let $0 = \lambda_1 < \lambda_2 \leq \ldots \leq \lambda_n$ be eigenvalues of $\boldsymbol{L}$ of a connected graph G, and $\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_n$ be the corresponding orthonormal eigenvectors. Then we can decompose $\boldsymbol{L}$ as $\boldsymbol{L} = \sum_{i=2}^{n} \lambda_i \boldsymbol{v}_i \boldsymbol{v}_i^T$ and define its pseudoinverse as $\boldsymbol{L}^{\dagger} = \sum_{i=2}^{n} \frac{1}{\lambda_i} \boldsymbol{v}_i \boldsymbol{v}_i^T$.

It is not hard to verify that if $\boldsymbol{L}$ and $\boldsymbol{H}$ are Laplacians of connected graphs supported on the same vertex set, then $\boldsymbol{L} \preceq \boldsymbol{H}$ implies $\boldsymbol{H}^{\dagger} \preceq \boldsymbol{L}^{\dagger}$.

The pseudoinverse of Laplacian matrix can be used to define effective resistance between any pair of vertices [32].

Definition 2.2. For a connected graph $G = (V, E, w)$ with Laplacian matrix $\boldsymbol{L}$, the effective resistance between vertices u and v is defined as $R_{\text{eff}}(u, v) = (\boldsymbol{e}_u - \boldsymbol{e}_v)^T \boldsymbol{L}^{\dagger} (\boldsymbol{e}_u - \boldsymbol{e}_v)$.

The effective resistance between two vertices can also be expressed in term of the diagonal elements of the inverse for submatrices of $\boldsymbol{L}$.

Fact 2.3 ([27]). $R_{\text{eff}}(u, v) = \left(\boldsymbol{L}_{-u}^{-1}\right)_{[v,v]} = \left(\boldsymbol{L}_{-v}^{-1}\right)_{[u,u]}$.

2.3 Current Flow Closeness Centrality

The current flow closeness centrality was proposed in [11]. It is based on the assumption that information spreads efficiently like an electrical current.

To define current flow closeness, we treat the graph G as a resistor network via replacing every edge e by a resistor with resistance $r_e = 1/w(e)$. Let $v_{st}(u)$ denote the voltage of u when a unit current enters the network at s and leaves it at t.

Definition 2.4. The current flow closeness $C(u)$ of a vertex u is defined as $C(u) = n/\sum_{v \in V} (v_{uv}(u) - v_{uv}(v))$.

It has been proved [11] that the current flow closeness of vertex u equals the ratio of n to the sum of effective resistances between u and other vertices.

Fact 2.5. $C(u) = n/\sum_{v \in V} R_{\text{eff}}(u, v)$.

Actually, current flow closeness centrality is equivalent to information centrality [50].

2.4 Supermodular Functions

We now give the definitions for monotone and supermodular set functions. For simplicity, we write $S + u$ to denote $S \cup \{u\}$ and $S - u$ to denote $S \setminus \{u\}$.

Definition 2.6 (Monotonicity)**.** A set function $f : 2^V \to \mathbb{R}$ is monotone if $f(S) \geq f(T)$ holds for all $S \subseteq T$.

Definition 2.7 (Supermodularity)**.** A set function $f : 2^V \to \mathbb{R}$ is supermodular if $f(S) - f(S + u) \geq f(T) - f(T + u)$ holds for all $S \subseteq T \subseteq V$ and $u \in V$.

3 CURRENT FLOW CLOSENESS OF A GROUP OF VERTICES

We follow the idea of [11] to define current flow closeness centrality (CFCC) of a group of vertices.

To define current flow closeness centrality for a vertex set $S \subseteq V$, we treat the graph G as a resistor network in which all vertices in S are grounded. Thus, vertices in S always have voltage 0. For a vertex $u \notin S$, let $v_{uS}(v)$ be the voltage of v when a unit current enters the network at u and leaves it at S (i.e. the ground). Then, we define the current flow closeness of S as follows.

Definition 3.1. Let $G = (V, E, w)$ be a connected weighted graph. The current flow closeness centrality $C(S)$ of a vertex group $S \subseteq V$ is defined as $C(S) = n/\sum_{u \in V} (v_{uS}(u) - v_{uS}(S)) = n/\sum_{u \in V} v_{uS}(u)$.

Note that there are different variants of the definition of CFCC for a vertex group. For example, we can use$(n - |S|) / (\sum_{u \in V} v_{uS}(u))$ as the measure of CFCC for a vertex set S. Definition 3.1 adopts the standard form as the classic closeness centrality [13].

We next show that $C(S)$ is in fact equal to the ratio of n to a sum of effective resistances as in Fact 2.5.

Let $u \in V$ be a fixed vertex. Suppose there is a unit current enters the network at u and leaves it at S. Let $\boldsymbol{v} \in \mathbb{R}^n$ be a vector of voltages at vertices. By Kirchhoff's Current Law and Ohm's Law, we have $\boldsymbol{L}\boldsymbol{v} = \boldsymbol{e}_u - \boldsymbol{i}_S$, where $\boldsymbol{i}_S$ denotes the amount of current flowing out of S. Since vertices in S all have voltage 0, we can restrict this equation to vertices in $V - S$ as $\boldsymbol{L}_{[V-S, V-S]} \boldsymbol{v}_{[V-S]} = \boldsymbol{e}_u$, which leads to $\boldsymbol{v}_{[V-S]} = \boldsymbol{L}_{[V-S, V-S]}^{-1} \boldsymbol{e}_u$. This gives the expression of voltage at u as $v_{uS}(u) = \boldsymbol{e}_u^T \boldsymbol{v} = \boldsymbol{e}_u^T \boldsymbol{L}_{-S}^{-1} \boldsymbol{e}_u$. Now we can write the CFCC of S as

$$C(S) = \frac{n}{\sum_{u \in V} v_{uS}(u)} = \frac{n}{\sum_{u \in V - S} \boldsymbol{e}_u^T \boldsymbol{L}_{-S}^{-1} \boldsymbol{e}_u} = \frac{n}{\text{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right)}.$$

Note that the diagonal entry $\left(\boldsymbol{L}_{-S}^{-1}\right)_{[u,u]}$ of $\left(\boldsymbol{L}_{-S}^{-1}\right)$ is exactly the effective resistance $R_{\text{eff}}(u, S)$ between vertex u and vertex set S [15], with $R_{\text{eff}}(u, S) = 0$ for any $u \in S$. Then we have the following relation governing $C(S)$ and $R_{\text{eff}}(u, S)$.

Fact 3.2. $C(S) = n/\text{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right) = n/\sum_{u \in V} R_{\text{eff}}(u, S)$.

Being able to define CFCC of a vertex set raises the problem of maximizing current flow closeness subject to a cardinality constraint, which we state below.

Problem 1 (Current Flow Closeness Maximization, CFCM). *Given a connected graph $G = (V, E, w)$ with n vertices, m edges, and edge weight function $w : E \to \mathbb{R}^+$ and an integer $1 \leq k \leq n$, find a vertex group $S^* \in V$ such that the CFCC $C(S^*)$ is maximized, that is* $S^* \in \underset{S \subseteq V, |S|=k}{\arg\max} \; C(S)$.

4 HARDNESS OF CURRENT FLOW CLOSENESS MAXIMIZATION

In this section, we prove that Problem 1 is NP-hard. We will give a reduction from vertex cover on 3-regular graphs (graphs whose vertices all have degree 3), which is an NP-complete problem [23]. The decision version of this problem is stated below.

Problem 2 (Vertex Cover on 3-regular graphs, VC3). *Given a connected 3-regular graph $G = (V, E)$ and an integer k, decide whether or not there is a vertex set $S \subset V$ such that $|S| \leq k$ and S is a vertex cover of G (i.e. every edge in E is incident with at least one vertex in S).*

We then give the decision version of Problem 1.

Problem 3 (Current Flow Closeness Maximization, Decision Version, CFCMD). *Given a connected graph $G = (V, E, w)$, an integer k, and a real number $r \in \mathbb{R}$, decide whether or not there is a vertex set $S \subset V$ such that $|S| \leq k$ and $C(S) \geq r$.*

To give the reduction, we will need the following lemma.

Lemma 4.1. *Let $G = (V, E, w)$ be a connected 3-regular graph with all edge weights being 1 (i.e. $w(e) = 1$ for all $e \in E$). Let $S \subset V$ be a nonempty vertex set, and $k = |S|$. Then, $C(S) \leq 3n/(n-k)$ and the equality holds if and only if S is a vertex cover of G.*

Proof. We first show that if S is a vertex cover of G then $C(S) = 3n/(n-k)$. When S is a vertex cover, $V \setminus S$ is an independent set. Thus, $\boldsymbol{L}_{-S}$ is a diagonal matrix with all diagonal entries being 3. So we have

$$C(S) = n/\mathrm{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right) = n/\mathrm{Tr}\left((\mathrm{diag}(3,\ldots,3))^{-1}\right) = 3n/(n-k).$$

We then show that if S is not a vertex cover of G then $C(S) < 3n/(n-k)$. When S is not a vertex cover, $V \setminus S$ is not an independent set. Thus, $\boldsymbol{L}_{-S}$ is a block diagonal matrix, with each block corresponding to a connected component of $G[V \setminus S]$, the induced graph of G on $V \setminus S$. Let $T \subseteq V \setminus S$ be a connected component of $G[V \setminus S]$ such that $|T| > 1$. Then, the block of $\boldsymbol{L}_{-S}$ corresponding to T is $\boldsymbol{L}_{[T,T]}$. For a vertex $u \in T$, let the u^{th} column of $\boldsymbol{L}_{[T,T]}$ be $\begin{pmatrix} 3 \\ -\boldsymbol{a} \end{pmatrix}$. Then, we can write $\boldsymbol{L}_{[T,T]}$ into block form as

$$\boldsymbol{L}_{[T,T]} = \begin{pmatrix} 3 & -\boldsymbol{a}^T \\ -\boldsymbol{a} & \boldsymbol{A} \end{pmatrix},$$

where $\boldsymbol{A} \stackrel{\text{def}}{=} \boldsymbol{L}_{[T-u,T-u]}$. By blockwise matrix inversion we have

$$\left(\boldsymbol{L}_{[T,T]}^{-1}\right)_{[u,u]} = 1/\left(3 - \boldsymbol{a}^T\boldsymbol{A}^{-1}\boldsymbol{a}\right).$$

Since $\boldsymbol{L}_{[T,T]}^{-1}$ is positive definite, we have $1/(3 - \boldsymbol{a}^T\boldsymbol{A}^{-1}\boldsymbol{a}) > 0$ and hence $\boldsymbol{a}^T\boldsymbol{A}^{-1}\boldsymbol{a} < 3$. Since T is a connected component, $\boldsymbol{a}$ is not a zero vector, which coupled with the fact that $\boldsymbol{A}^{-1}$ is positive definite gives $\boldsymbol{a}^T\boldsymbol{A}^{-1}\boldsymbol{a} > 0$. Thus, $1/(3 - \boldsymbol{a}^T\boldsymbol{A}^{-1}\boldsymbol{a}) > 1/3$. Since this holds for all $u \in T$, we have $\mathrm{Tr}\left(\boldsymbol{L}_{[T,T]}^{-1}\right) > |T|/3$. Also, since T can be any connected component of $G[V \setminus S]$ with at least two vertices, and a block of an isolate vertex in $G[V \setminus S]$ contributes a 1/3 to $\mathrm{Tr}\left((\boldsymbol{L}_{-S})^{-1}\right)$, we have for any S which is not a vertex cover of G

$$\mathrm{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right) > |V \setminus S|/3 = (n-k)/3,$$

which implies $C(S) = n/\mathrm{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right) < 3n/(n-k)$. This completes the proof. □

The following theorem then follows by Lemma 4.1.

Theorem 4.2. *Maximizing current flow closeness subject to a cardinality constraint is NP-hard.*

Proof. We give a polynomial reduction

$$p : \{(G = (V, E), k)\} \to \{(G = (V, E, w), k, r)\}$$

from instances of VC3 to instances of CFCMD. For a connected 3-regular graph $G = (V, E)$ with n vertices, we construct a weighted graph $G' = (V, E, w_1)$ with the same vertex set and edge set and an edge weight function $w_1 : E \to \{1\}$ mapping all edges to weight 1. Then, we construct a reduction p as

$$p\left((G = (V, E), k)\right) = \left(G' = (V, E, w_1), k, 3n/(n-k)\right).$$

By Lemma 4.1, p is a polynomial reduction from VC3 to CFCMD, which implies that CFCM is NP-hard. □

5 SUPERMODULARITY OF THE RECIPROCAL OF CURRENT FLOW GROUP CLOSENESS

In this section, we prove that the reciprocal of current flow group closeness, i.e., $\mathrm{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right)/n$, is a monotone supermodular function. Our proof uses the following lemma, which shows that $\boldsymbol{L}_{-S}^{-1}$ is entrywise supermodular.

Lemma 5.1. *Let $u, v \in V$ be an arbitrary pair of vertices. Then, the entry $\left(\boldsymbol{L}_{-S}^{-1}\right)_{[u,v]}$ is a monotone supermodular function. Namely, for vertices $u, v \neq w$ and nonempty vertex sets $S \subseteq T \subseteq V$ such that $u, v, w \notin T$,*

$$\left(\boldsymbol{L}_{-S}^{-1}\right)_{[u,v]} \geq \left(\boldsymbol{L}_{-T}^{-1}\right)_{[u,v]}$$

and

$$\left(\boldsymbol{L}_{-S}^{-1}\right)_{[u,v]} - \left(\boldsymbol{L}_{-(S+w)}^{-1}\right)_{[u,v]} \geq \left(\boldsymbol{L}_{-T}^{-1}\right)_{[u,v]} - \left(\boldsymbol{L}_{-(T+w)}^{-1}\right)_{[u,v]}.$$

To prove Lemma 5.1, we first define a linear relaxation $\boldsymbol{H} : [0,1]^n \to \mathbb{R}^{n\times n}$ of $\boldsymbol{L}_{-S}$ as

$$\left(\boldsymbol{H}(\boldsymbol{x})\right)_{[u,v]} = \begin{cases} \boldsymbol{L}_{[u,u]} & \text{if } u = v, \\ \left(1 - \boldsymbol{x}_{[u]}\right) \cdot \left(1 - \boldsymbol{x}_{[v]}\right) \cdot \boldsymbol{L}_{[u,v]} & \text{if } u \neq v. \end{cases} \tag{1}$$

Remark 5.2. We remark the intuition behind this relaxation $\boldsymbol{H}(\boldsymbol{x})$. Let $\boldsymbol{x}_{[=1]}$ denote the indices of entries of $\boldsymbol{x}$ equal to one, and let $\boldsymbol{x}_{[<1]}$ denote the indices of entries of $\boldsymbol{x}$ less than one. Then, by the definition in (1), we can write $\boldsymbol{H}(\boldsymbol{x})$ into a block diagonal matrix as

$$\boldsymbol{H}(\boldsymbol{x}) = \begin{pmatrix} \left(\boldsymbol{H}(\boldsymbol{x})\right)_{[\boldsymbol{x}_{[=1]},\boldsymbol{x}_{[=1]}]} & \boldsymbol{0} \\ \boldsymbol{0} & \left(\boldsymbol{H}(\boldsymbol{x})\right)_{[\boldsymbol{x}_{[<1]},\boldsymbol{x}_{[<1]}]} \end{pmatrix},$$

where $\left(\boldsymbol{H}(\boldsymbol{x})\right)_{[\boldsymbol{x}_{[=1]},\boldsymbol{x}_{[=1]}]}$ is itself a diagonal matrix. This means that if $\boldsymbol{x} = \boldsymbol{1}_S$ for some nonempty vertex set $S \subseteq V$, the following statement holds:

$$\left(\boldsymbol{H}^{-1}(\boldsymbol{1}_S)\right)_{-S} = \boldsymbol{L}_{-S}^{-1}.$$

The condition that every entry of $\boldsymbol{x}$ is in $[0,1]$ coupled with Fact 2.1 also implies that all submatrices of $\boldsymbol{H}(\boldsymbol{x})$ are positive definite and inverse-positive.

Now for vertices $u, v \neq w$ and nonempty vertex set $S \subseteq V$ such that $u, v, w \notin S$, we can write the marginal gain of a vertex w as

$$\left(\boldsymbol{L}_{-S}^{-1} - \boldsymbol{L}_{-(S+w)}^{-1}\right)_{[u,v]} = \left(\boldsymbol{H}^{-1}(\boldsymbol{1}_S) - \boldsymbol{H}^{-1}(\boldsymbol{1}_{S+w})\right)_{[u,v]}. \tag{2}$$

We can further write the matrix on the rhs of (2) as an integral by

$$\begin{aligned}
&\boldsymbol{H}^{-1}(\mathbf{1}_S) - \boldsymbol{H}^{-1}(\mathbf{1}_{S+w}) = -\left.\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\right|_0^1 \\
&= -\int_0^1 \frac{\mathrm{d}\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)}{\mathrm{d}t}\mathrm{d}t \\
&= \int_0^1 \boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\frac{\mathrm{d}\boldsymbol{H}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)}{\mathrm{d}t}\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\mathrm{d}t \\
&= \int_0^1 \boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\left(-t\boldsymbol{H}(\mathbf{1}_V - \boldsymbol{e}_w)\right)\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\mathrm{d}t, \quad (3)
\end{aligned}$$

where the second equality follows by the identity

$$\frac{\mathrm{d}\boldsymbol{A}^{-1}}{\mathrm{d}x} = -\boldsymbol{A}^{-1}\frac{\mathrm{d}\boldsymbol{A}}{\mathrm{d}x}\boldsymbol{A}^{-1}$$

for any invertible matrix $\boldsymbol{A}$. To prove Lemma 5.1, we will also need the following lemma, which shows the entrywise monoticity of $\boldsymbol{H}^{-1}(\boldsymbol{x})$.

Lemma 5.3. *For $0 \le t \le 1$, the following statement holds for any vertices $u, v \ne w$ and nonempty vertex sets $S \subseteq T \subseteq V$ such that $u, v, w \notin T$:*

$$\left(\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\right)_{[u,v]} \ge \left(\boldsymbol{H}^{-1}(\mathbf{1}_T + t\cdot\boldsymbol{e}_w)\right)_{[u,v]}.$$

Proof. For simplicity, we let $\boldsymbol{S} \stackrel{\text{def}}{=} \boldsymbol{H}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)$ and $\boldsymbol{T} \stackrel{\text{def}}{=} \boldsymbol{H}(\mathbf{1}_T + t\cdot\boldsymbol{e}_w)$. We also write $P \stackrel{\text{def}}{=} V\setminus T$, $Q \stackrel{\text{def}}{=} V\setminus S$, and $F \stackrel{\text{def}}{=} T\setminus S$. Due to the block diagonal structures of $\boldsymbol{S}$ and $\boldsymbol{T}$, we have

$$\left(\boldsymbol{S}^{-1}\right)_{[u,v]} = \left(\boldsymbol{S}^{-1}_{[Q,Q]}\right)_{[u,v]} \quad (4)$$

and

$$\left(\boldsymbol{T}^{-1}\right)_{[u,v]} = \left(\boldsymbol{T}^{-1}_{[P,P]}\right)_{[u,v]}. \quad (5)$$

Since $\boldsymbol{S}$ and $\boldsymbol{T}$ agree on entries with indices in P, we can write the submatrix $\boldsymbol{S}_{[Q,Q]}$ of $\boldsymbol{S}$ in block form as

$$\boldsymbol{S}_{[Q,Q]} = \begin{pmatrix} \boldsymbol{T}_{[P,P]} & \boldsymbol{S}_{[P,F]} \\ \boldsymbol{S}_{[F,P]} & \boldsymbol{S}_{[F,F]} \end{pmatrix}.$$

By blockwise matrix inversion, we have

$$\begin{aligned}
&\left(\boldsymbol{S}^{-1}_{[Q,Q]}\right)_{[P,P]} \\
=&\boldsymbol{T}^{-1}_{[P,P]} + \boldsymbol{T}^{-1}_{[P,P]}\boldsymbol{S}_{[P,F]}\left(\boldsymbol{S}^{-1}_{[Q,Q]}\right)_{[F,F]}\boldsymbol{S}_{[F,P]}\boldsymbol{T}^{-1}_{[P,P]} \\
=&\boldsymbol{T}^{-1}_{[P,P]} + \boldsymbol{T}^{-1}_{[P,P]}\left(-\boldsymbol{S}_{[P,F]}\right)\left(\boldsymbol{S}^{-1}_{[Q,Q]}\right)_{[F,F]}\left(-\boldsymbol{S}_{[F,P]}\right)\boldsymbol{T}^{-1}_{[P,P]},
\end{aligned}$$

where the second equality follows by negating both $\boldsymbol{S}_{[P,F]}$ and $\boldsymbol{S}_{[F,P]}$. By definition the matrix $-\boldsymbol{S}_{[P,F]}$ is entrywise nonnegative. By Fact 2.1, every entry of $\boldsymbol{S}^{-1}_{[Q,Q]}$ and $\boldsymbol{T}^{-1}_{[P,P]}$ is also nonnegative. Thus, the matrix

$$\boldsymbol{T}^{-1}_{[P,P]}\left(-\boldsymbol{S}_{[P,F]}\right)\left(\boldsymbol{S}^{-1}_{[Q,Q]}\right)_{[F,F]}\left(-\boldsymbol{S}_{[F,P]}\right)\boldsymbol{T}^{-1}_{[P,P]}$$

is entrywise nonnegative, which coupled with (4) and (5), implies $\left(\boldsymbol{S}^{-1}\right)_{[u,v]} \ge \left(\boldsymbol{T}^{-1}\right)_{[u,v]}$. □

We are now ready to prove Lemma 5.1.

Proof of Lemma 5.1. By definition the matrix $-t\boldsymbol{H}(\mathbf{1}_V - \boldsymbol{e}_w)$ is entrywise nonnegative when $t \ge 0$. By Fact 2.1, the matrix $\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)$ is also entrywise nonnegative when $0 \le t \le 1$. Thus, the derivative in (3) is entrywise nonnegative, which implies the the monotonicity of $\left(\boldsymbol{L}^{-1}_{-S}\right)_{[u,v]}$ for any pair of vertices $u, v \in V$.

We then prove the supermodularity, i.e.,

$$\left(\boldsymbol{L}^{-1}_{-S} - \boldsymbol{L}^{-1}_{-(S+w)}\right)_{[u,v]} \ge \left(\boldsymbol{L}^{-1}_{-T} - \boldsymbol{L}^{-1}_{-(T+w)}\right)_{[u,v]} \quad (6)$$

for any $S \subseteq T \subseteq V$ and $u, v \notin T$. Lemma 5.3, coupled with the fact that $\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)$ and $-t\boldsymbol{H}(\mathbf{1}_V - \boldsymbol{e}_w)$ are both entrywise nonnegative, gives the entrywise monotonicity of the derivative in (3) as

$$\begin{aligned}
&\left(\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\left(-t\boldsymbol{H}(\mathbf{1}_V - \boldsymbol{e}_w)\right)\boldsymbol{H}^{-1}(\mathbf{1}_S + t\cdot\boldsymbol{e}_w)\right)_{[u,v]} \\
\ge&\left(\boldsymbol{H}^{-1}(\mathbf{1}_T + t\cdot\boldsymbol{e}_w)\left(-t\boldsymbol{H}(\mathbf{1}_V - \boldsymbol{e}_w)\right)\boldsymbol{H}^{-1}(\mathbf{1}_T + t\cdot\boldsymbol{e}_w)\right)_{[u,v]}.
\end{aligned}$$

Integrating both sides of the above inequality with respect to t on the interval $[0, 1]$ gives (6). □

The following theorem then directly follows by Lemma 5.1.

Theorem 5.4. *The reciprocal of current flow group centrality, i.e., $\mathrm{Tr}\left(\boldsymbol{L}^{-1}_{-S}\right)/n$, is a monotone supermodular function.*

We note that [15] has previously proved that $\mathrm{Tr}\left(\boldsymbol{L}^{-1}_{-S}\right)$ is monotone and supermodular by using the connection between effective resistance and commute time for random walks. However, our proof is fully algebraic. Moreover, we present a more general result that $\boldsymbol{L}^{-1}_{-S}$ is entrywise supermodular.

By Theorem 5.4, one can obtain a $(1 - \frac{k}{k-1}\cdot\frac{1}{e})$-approximation to the optimum $\mathrm{Tr}\left(\boldsymbol{L}^{-1}_{-S^*}\right)$ by a simple greedy algorithm, by picking the vertex with the maximum marginal gain each time [42]. However, since computing $\mathrm{Tr}\left(\boldsymbol{L}^{-1}_{-S}\right)$ involves matrix inversions, a naive implementation of this greedy algorithm will take $O(kn^4)$ time, assuming that one matrix inversion runs in $O(n^3)$ time. We will show in the next section how to implement this greedy algorithm in $O(n^3)$ time using blockwise matrix inversion.

6 A DETERMINISTIC GREEDY ALGORITHM

We now consider how to accelerate the naive greedy algorithm. Suppose that after the i^{th} step, the algorithm has selected a set S_i containing i vertices. We next compute the marginal gain $\mathrm{Tr}\left(\boldsymbol{L}^{-1}_{-S_i}\right) - \mathrm{Tr}\left(\boldsymbol{L}^{-1}_{-(S_i+u)}\right)$ of each vertex $u \notin S_i$.

For a vertex $u \notin S_i$, let $\begin{pmatrix} d_u \\ -\boldsymbol{a}\end{pmatrix}$ denote the u^{th} column of the submatrix $\boldsymbol{L}_{-S_i}$. Then we write $\boldsymbol{L}_{-S_i}$ in block form as $\boldsymbol{L}_{-S_i} = \begin{pmatrix} d_u & -\boldsymbol{a}^T \\ -\boldsymbol{a} & \boldsymbol{A}\end{pmatrix}$, where $\boldsymbol{A} \stackrel{\text{def}}{=} \boldsymbol{L}_{-(S_i+u)}$. By blockwise matrix inversion, we have

$$\boldsymbol{L}^{-1}_{-S_i} = \begin{pmatrix} \frac{1}{s} & \frac{1}{s}\boldsymbol{a}^T\boldsymbol{A}^{-1} \\ \frac{1}{s}\boldsymbol{A}^{-1}\boldsymbol{a} & \boldsymbol{A}^{-1} + \frac{1}{s}\boldsymbol{A}^{-1}\boldsymbol{a}\boldsymbol{a}^T\boldsymbol{A}^{-1}\end{pmatrix}, \quad (7)$$

where $s = d_u - \boldsymbol{a}^T \boldsymbol{A}^{-1} \boldsymbol{a}$. Then the marginal gain of u can be further expressed as

$$\begin{aligned}
&\operatorname{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-(S_i+u)}^{-1}\right) \\
=&\left(\boldsymbol{L}_{-S_i}^{-1}\right)_{[u,u]} + \sum_{v \in V \setminus (S_i+u)} \left(\left(\boldsymbol{L}_{-S_i}^{-1}\right)_{[v,v]} - \left(\boldsymbol{L}_{-(S_i+u)}^{-1}\right)_{[v,v]}\right) \\
=&\frac{1}{s} + \frac{1}{s}\operatorname{Tr}\left(\boldsymbol{A}^{-1}\boldsymbol{a}\boldsymbol{a}^T\boldsymbol{A}^{-1}\right) = \frac{1}{s} + \frac{1}{s}\boldsymbol{a}^T\boldsymbol{A}^{-1}\boldsymbol{A}^{-1}\boldsymbol{a} \\
=&\left(\boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-2} \boldsymbol{e}_u\right) / \left(\boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-1} \boldsymbol{e}_u\right),
\end{aligned}$$

where the second equality and the fourth equality follow by (7), while the third equality follows by the cyclicity of trace.

By (7), we can also update the inverse $\boldsymbol{L}_{-S_i}^{-1}$ upon a vertex u by

$$\boldsymbol{L}_{-(S_i+u)}^{-1} = \left(\boldsymbol{L}_{-S_i}^{-1} - \left(\boldsymbol{L}_{-S_i}^{-1} \boldsymbol{e}_u \boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-1}\right) / \left(\boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-1} \boldsymbol{e}_u\right)\right)_{-u}.$$

At the first step, we need to pick a vertex u_1 with minimum $\sum_{v \in V} R_{\text{eff}}(u_1, v)$, which can be done by computing $\sum_{v \in V} R_{\text{eff}}(u, v)$ for all $u \in V$ using the relation [10]

$$\sum\nolimits_{v \in V} R_{\text{eff}}(u, v) = n\left(\boldsymbol{L}^{\dagger}\right)_{[u,u]} + \operatorname{Tr}\left(\boldsymbol{L}^{\dagger}\right).$$

We give the $O(n^3 + kn^2)$-time algorithm as follows.

$S_k = \textsc{ExactGreedy}\,(G, \boldsymbol{L}, k)$

(1) Compute $\boldsymbol{L}^{\dagger}$ by inverting $\boldsymbol{L}$ in $O(n^3)$ time.
(2) $S_1 \leftarrow \{u_1\}$ where $u_1 = \arg\min_{u \in V} n\left(\boldsymbol{L}^{\dagger}\right)_{[u,u]} + \operatorname{Tr}\left(\boldsymbol{L}^{\dagger}\right)$.
(3) Compute $\boldsymbol{L}_{-S_1}^{-1}$ in $O(n^3)$ time.
(4) Repeat the following steps for $i = 1, \ldots, k-1$:
  (a) $u_{i+1} \leftarrow \arg\max_{u \in (V \setminus S_i)} \frac{\boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-2} \boldsymbol{e}_u}{\boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-1} \boldsymbol{e}_u}$, $S_{i+1} \leftarrow S_i + u_{i+1}$
  (b) Compute $\boldsymbol{L}_{S_{i+1}}^{-1}$ in $O(n^2)$ time by

$$\boldsymbol{L}_{-(S_i+u_{i+1})}^{-1} = \left(\boldsymbol{L}_{-S_i}^{-1} - \frac{\boldsymbol{L}_{-S_i}^{-1} \boldsymbol{e}_{u_{i+1}} \boldsymbol{e}_{u_{i+1}}^T \boldsymbol{L}_{-S_i}^{-1}}{\boldsymbol{e}_{u_{i+1}}^T \boldsymbol{L}_{-S_i}^{-1} \boldsymbol{e}_{u_{i+1}}}\right)_{-u_{i+1}}.$$

(5) Return S_k.

The performance of ExactGreedy is characterized in the following theorem.

Theorem 6.1. *The algorithm $S_k = \textsc{ExactGreedy}(G, \boldsymbol{L}, k)$ takes an undirected positive weighted graph $G = (V, E, w)$ with associated Laplacian $\boldsymbol{L}$ and an integer $2 \le k \le n$, and returns a vertex set $S_k \subseteq V$ with $|S_k| = k$. The algorithm runs in time $O(n^3)$. The vertex set S_k satisfies*

$$\operatorname{Tr}\left(\boldsymbol{L}_{-u^*}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S_k}^{-1}\right) \ge \left(1 - \frac{k}{k-1} \cdot \frac{1}{e}\right)\left(\operatorname{Tr}\left(\boldsymbol{L}_{-u^*}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right)$$

where

$$S^* \overset{\text{def}}{=} \arg\min_{|S| \le k} \operatorname{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right), \quad u^* \overset{\text{def}}{=} \arg\min_{u \in V} \sum_{v \in V} R_{\text{eff}}(u, v).$$

Proof. The running time is easy to verify. We only need to prove the approximation ratio.

By supermodularity, for any $i \ge 1$

$$\operatorname{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S_{i+1}}^{-1}\right) \ge \frac{1}{k}\left(\operatorname{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S*}^{-1}\right)\right),$$

which implies

$$\operatorname{Tr}\left(\boldsymbol{L}_{-S_{i+1}}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right) \le \left(1 - \frac{1}{k}\right)\left(\operatorname{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right).$$

Then, we have

$$\begin{aligned}
&\operatorname{Tr}\left(\boldsymbol{L}_{-S_k}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right) \\
\le&\left(1 - \frac{1}{k}\right)^{k-1}\left(\operatorname{Tr}\left(\boldsymbol{L}_{-S_1}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right) \\
\le&\frac{k}{k-1} \cdot \frac{1}{e}\left(\operatorname{Tr}\left(\boldsymbol{L}_{-S_1}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right),
\end{aligned}$$

which coupled with $\operatorname{Tr}\left(\boldsymbol{L}_{-S_1}^{-1}\right) = \operatorname{Tr}\left(\boldsymbol{L}_{-u^*}^{-1}\right)$ finishes the proof. □

7 A RANDOMIZED GREEDY ALGORITHM

The deterministic greedy algorithm ExactGreedy has a time complexity $O(n^3)$, which is still not acceptable for large networks. In this section, we provide an efficient randomized algorithm, which achieves a $(1 - \frac{k}{k-1} \cdot \frac{1}{e} - \epsilon)$ approximation factor in time $\widetilde{O}(km\epsilon^{-2})$.

To further accelerate algorithm ExactGreedy we need to compute the marginal gains

$$\operatorname{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \operatorname{Tr}\left(\boldsymbol{L}_{-(S_i+u)}^{-1}\right) = \frac{\boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-2} \boldsymbol{e}_u}{\boldsymbol{e}_u^T \boldsymbol{L}_{-S_i}^{-1} \boldsymbol{e}_u} \tag{8}$$

for all $u \in V$ and a vertex set $S_i \subseteq V$ more quickly. We also need a faster way to compute

$$\sum\nolimits_{v \in V} R_{\text{eff}}(u, v) = n\left(\boldsymbol{L}^{\dagger}\right)_{[u,u]} + \operatorname{Tr}\left(\boldsymbol{L}^{\dagger}\right) \tag{9}$$

for all $u \in V$ at the 1st step. We will show how to solve both problems in nearly linear time using Johnson-Lindenstrauss Lemma and Fast SDDM Solvers. Our routines are motivated by the effective resistance estimation routine in [33, 49].

Lemma 7.1 (Johnson-Lindenstrauss Lemma [29]). *Let $\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_n \in \mathbb{R}^d$ be fixed vectors and $0 < \epsilon < 1$ be a real number. Let q be a positive integer such that*

$$q \ge 4(\epsilon^2/2 - \epsilon^3/3)^{-1} \ln n$$

and $\boldsymbol{Q}_{q \times d}$ be a random matrix obtained by first choosing each of its entries from Gaussian distribution $N(0, 1)$ independently and then normalizing each of its columns to a length of 1. With high probability, the following statement holds for any $1 \le i, j \le n$:

$$(1 - \epsilon)\left\|\boldsymbol{v}_i - \boldsymbol{v}_j\right\|^2 \le \left\|\boldsymbol{Q}\boldsymbol{v}_i - \boldsymbol{Q}\boldsymbol{v}_j\right\|^2 \le (1 + \epsilon)\left\|\boldsymbol{v}_i - \boldsymbol{v}_j\right\|^2.$$

Lemma 7.2 (Fast SDDM Solvers [16, 48]). *There is a routine $\boldsymbol{x} = \textsc{Solve}(\boldsymbol{S}, \boldsymbol{b}, \epsilon)$ which takes a Laplacian or an SDDM matrix $\boldsymbol{S}_{n \times n}$ with m nonzero entries, a vector $\boldsymbol{b} \in \mathbb{R}^n$, and an error parameter $\delta > 0$, and returns a vector $\boldsymbol{x} \in \mathbb{R}^n$ such that*

$$\left\|\boldsymbol{x} - \boldsymbol{S}^{-1}\boldsymbol{b}\right\|_{\boldsymbol{S}} \le \delta\left\|\boldsymbol{S}^{-1}\boldsymbol{b}\right\|_{\boldsymbol{S}}$$

holds with high probability, where $\|\boldsymbol{x}\|_{\boldsymbol{S}} \overset{\text{def}}{=} \sqrt{\boldsymbol{x}^T \boldsymbol{S}\boldsymbol{x}}$, and $\boldsymbol{S}^{-1}$ denotes the pseudoinverse of $\boldsymbol{S}$ when $\boldsymbol{S}$ is a Laplacian. The routine runs in expected time $\widetilde{O}(m \log(1/\delta))$.

7.1 Approximation of (9)

To approximate (9) we need to approximate all diagonal entries of $\boldsymbol{L}^\dagger$, i.e., $\boldsymbol{e}_u^T\boldsymbol{L}^\dagger\boldsymbol{e}_u$ for all $u \in V$. We first write $\boldsymbol{e}_u^T\boldsymbol{L}^\dagger\boldsymbol{e}_u$ in an Euclidean norm as

$$\begin{aligned}\boldsymbol{e}_u^T\boldsymbol{L}^\dagger\boldsymbol{e}_u &= \boldsymbol{e}_u^T\boldsymbol{L}^\dagger\boldsymbol{L}\boldsymbol{L}^\dagger\boldsymbol{e}_u = \boldsymbol{e}_u^T\boldsymbol{L}^\dagger\boldsymbol{B}^T\boldsymbol{W}\boldsymbol{B}\boldsymbol{L}^\dagger\boldsymbol{e}_u\\ &= \boldsymbol{e}_u^T\boldsymbol{L}^\dagger\boldsymbol{B}^T\boldsymbol{W}^{1/2}\boldsymbol{W}^{1/2}\boldsymbol{B}\boldsymbol{L}^\dagger\boldsymbol{e}_u = \left\|\boldsymbol{W}^{1/2}\boldsymbol{B}\boldsymbol{L}^\dagger\boldsymbol{e}_u\right\|^2.\end{aligned}$$

Then we use Johnson-Lindenstrauss Lemma to reduce the dimensions. Let $\boldsymbol{Q}_{q\times m}$ be a random Gaussian matrix where $q = \left\lceil 4(\epsilon^2/2-\epsilon^3/3)^{-1}\ln n\right\rceil$. By Lemma 7.1,

$$\left\|\boldsymbol{W}^{1/2}\boldsymbol{B}\boldsymbol{L}^\dagger\boldsymbol{e}_u\right\|^2 \approx_{1+\epsilon} \left\|\boldsymbol{Q}\boldsymbol{W}^{1/2}\boldsymbol{B}\boldsymbol{L}^\dagger\boldsymbol{e}_u\right\|^2$$

holds for all $u \in V$ with high probability. Here we can use sparse matrix multiplication to compute $\boldsymbol{Q}\boldsymbol{W}^{1/2}\boldsymbol{B}$, and Fast SDDM solvers to compute $\boldsymbol{Q}\boldsymbol{W}^{1/2}\boldsymbol{B}\boldsymbol{L}^\dagger$.

We give the routine for approximating (9) as follows.

$\{r_u\}_{u\in V} = \textsc{ERSumsEst}\,(G, \boldsymbol{L}, \epsilon)$

(1) Set $\delta = \frac{\epsilon}{9n^2}\left(\frac{(1-\epsilon/3)w_{\min}}{(1+\epsilon/3)w_{\max}}\right)^{1/2}$.
(2) Generate a random Gaussian matrix $\boldsymbol{Q}_{q\times m}$ where $q = \left\lceil 4((\epsilon/3)^2/2-(\epsilon/3)^3/3)^{-1}\ln n\right\rceil$.
(3) Compute $\left(\boldsymbol{Q}\boldsymbol{W}^{1/2}\boldsymbol{B}\right)_{q\times n}$ by sparse matrix multiplication in $O(qm)$ time.
(4) Compute an approximation $\widetilde{\boldsymbol{Z}}_{q\times n}$ to $\boldsymbol{Z}_{q\times n} \stackrel{\text{def}}{=} \boldsymbol{Q}\boldsymbol{W}^{1/2}\boldsymbol{B}\boldsymbol{L}^\dagger$ by
$$\widetilde{\boldsymbol{Z}}_{[i,:]} \leftarrow \textsc{Solve}(\boldsymbol{L}, \left(\boldsymbol{Q}\boldsymbol{W}^{1/2}\boldsymbol{B}\right)_{[i,:]}^T, \delta)^T$$
where $1 \le i \le q$.
(5) $r_u \leftarrow \left\|\widetilde{\boldsymbol{Z}}\right\|_F^2 + n\left\|\widetilde{\boldsymbol{Z}}\boldsymbol{e}_u\right\|^2$ for all $u \in V$ and return $\{r_u\}_{u\in V}$.

The performance of ERSumsEst is characterized in the following lemma.

Lemma 7.3. *The routine ERSumsEst runs in time $\widetilde{O}(m)$. For $0 < \epsilon \le 1/2$, the $\{r_u\}_{u\in V}$ returned by ERSumsEst satisfies*

$$(1-\epsilon)\sum_{v\in V} R_{\text{eff}}(u,v) \le r_u \le (1+\epsilon)\sum_{v\in V} R_{\text{eff}}(u,v)$$

with high probability.

7.2 Approximation of (8)

We first approximate the numerator of (8), which can be recast in an euclidian norm as $\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-2}\boldsymbol{e}_u = \left\|\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|^2$. We then once again use Johnson-Lindenstrauss Lemma to reduce the dimensions. Let $\boldsymbol{P}_{p\times n}$ be a random Gaussian matrix where $p = \left\lceil 4(\epsilon^2/2-\epsilon^3/3)^{-1}\ln n\right\rceil$. By Lemma 7.1, we have that for all $u \in V$,

$$(1-\epsilon)\left\|\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|^2 \le \left\|\boldsymbol{P}\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|^2 \le (1+\epsilon)\left\|\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|^2,$$

where $\boldsymbol{P}\boldsymbol{L}_{-S_i}^{-1}$ can be computed using Fast SDDM Solvers.

We continue to approximate the denominator of (8). Since $\boldsymbol{L}_{-S_i}$ is an SDDM matrix, we can express it in terms of the sum of a Laplacian and a nonnegative diagonal matrix as $\boldsymbol{L}_{-S_i} = \boldsymbol{B}'^T\boldsymbol{W}'\boldsymbol{B}' + \boldsymbol{X}$. Then we can write

$$\begin{aligned}&\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u = \boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{L}_{-S_i}\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\\ =&\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-1}\left(\boldsymbol{B}'^T\boldsymbol{W}'\boldsymbol{B}' + \boldsymbol{X}\right)\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\\ =&\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{B}'^T\boldsymbol{W}'\boldsymbol{B}'\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u + \boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{X}\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\\ =&\left\|\boldsymbol{W}'^{1/2}\boldsymbol{B}'\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|^2 + \left\|\boldsymbol{X}^{1/2}\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|^2. \qquad (10)\end{aligned}$$

Let $\boldsymbol{Q}_{q\times m}$ and $\boldsymbol{R}_{r\times n}$ be random Gaussian matrices where

$$q = r = \left\lceil 4(\epsilon^2/2-\epsilon^3/3)^{-1}\ln n\right\rceil.$$

By Lemma 7.1, we have for all $u \in V$

$$(10) \approx_{1+\epsilon} \left\|\boldsymbol{Q}\boldsymbol{W}'^{1/2}\boldsymbol{B}'\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|_2^2 + \left\|\boldsymbol{R}\boldsymbol{X}^{1/2}\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u\right\|_2^2.$$

Here $\boldsymbol{Q}\boldsymbol{W}'^{1/2}\boldsymbol{B}'\boldsymbol{L}_{-S_i}^{-1}$ and $\boldsymbol{R}\boldsymbol{X}^{1/2}\boldsymbol{L}_{-S_i}^{-1}$ can be computed using Fast SDDM Solvers.

We give the routine for approximating (8) as follows.

$\{g_u\}_{u\in V} = \textsc{GainsEst}\,(G, \boldsymbol{L}, S_i, \epsilon)$

(1) Set $\delta_1 = \frac{w_{\min}\epsilon}{27w_{\max}n^4}\left(\frac{(1-\epsilon/9)}{(1+\epsilon/9)n}\right)^{1/2}$ and $\delta_2 = \delta_3 = \frac{1}{4n^4w_{\max}}\left(\frac{\epsilon w_{\min}^{3/2}}{9n}\right)^{1/2}$.
(2) Generate random Gaussian matrices $\boldsymbol{P}_{p\times n}, \boldsymbol{Q}_{q\times m}, \boldsymbol{R}_{r\times n}$ where
$$p, q, r = \left\lceil 4((\epsilon/9)^2/2-(\epsilon/9)^3/3)^{-1}\ln n\right\rceil.$$
(3) Let $\boldsymbol{X} = \text{Diag}\left(\boldsymbol{L}_{-S_i}\boldsymbol{1}\right)$ and denote $\boldsymbol{L}_{-S_i} - \boldsymbol{X}$ by $\boldsymbol{B}'^T\boldsymbol{W}'\boldsymbol{B}'$.
(4) Compute $\boldsymbol{Q}\boldsymbol{W}'^{1/2}\boldsymbol{B}'$ and $\boldsymbol{R}\boldsymbol{X}^{1/2}$ by sparse matrix multiplication in $O(pm)$ time.
(5) Compute approximations $\widetilde{\boldsymbol{Z}}^{(1)}$ to $\boldsymbol{Z}^{(1)} \stackrel{\text{def}}{=} \boldsymbol{P}\boldsymbol{L}_{-S_i}^{-1}$, $\widetilde{\boldsymbol{Z}}^{(2)}$ to $\boldsymbol{Z}^{(2)} \stackrel{\text{def}}{=} \boldsymbol{Q}\boldsymbol{W}'^{1/2}\boldsymbol{B}'\boldsymbol{L}_{-S_i}^{-1}$, and $\widetilde{\boldsymbol{Z}}^{(3)}$ to $\boldsymbol{Z}^{(3)} \stackrel{\text{def}}{=} \boldsymbol{R}\boldsymbol{X}^{1/2}\boldsymbol{L}_{-S_i}^{-1}$ by
(a) $\widetilde{\boldsymbol{Z}}^{(1)}_{[i,:]} \leftarrow \textsc{Solve}(\boldsymbol{L}_{-S_i}, \boldsymbol{P}^T_{[i,:]}, \delta_1)^T$,
(b) $\widetilde{\boldsymbol{Z}}^{(2)}_{[i,:]} \leftarrow \textsc{Solve}(\boldsymbol{L}_{-S_i}, \left(\boldsymbol{Q}\boldsymbol{W}'^{1/2}\boldsymbol{B}'\right)^T_{[i,:]}, \delta_2)^T$, and
(c) $\widetilde{\boldsymbol{Z}}^{(3)}_{[i,:]} \leftarrow \textsc{Solve}(\boldsymbol{L}_{-S_i}, \left(\boldsymbol{R}\boldsymbol{X}^{1/2}\right)^T_{[i,:]}, \delta_3)^T$.
(6) $g_u \leftarrow \frac{\left\|\widetilde{\boldsymbol{Z}}^{(1)}\boldsymbol{e}_u\right\|^2}{\left\|\widetilde{\boldsymbol{Z}}^{(2)}\boldsymbol{e}_u\right\|^2 + \left\|\widetilde{\boldsymbol{Z}}^{(3)}\boldsymbol{e}_u\right\|^2}$ for all $u \in V$ and return $\{g_u\}_{u\in V}$.

Lemma 7.4. *The routine GainsEst runs in time $\widetilde{O}(m)$. For $0 \le \epsilon \le 1/2$, the $\{g_u\}_{u\in V}$ returned by GainsEst satisfies*

$$(1-\epsilon)\frac{\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-2}\boldsymbol{e}_u}{\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u} \le g_u \le (1+\epsilon)\frac{\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-2}\boldsymbol{e}_u}{\boldsymbol{e}_u^T\boldsymbol{L}_{-S_i}^{-1}\boldsymbol{e}_u}$$

with high probability.

We now give the $\widetilde{O}(mk)$-time greedy algorithm as follows.

S_k = ApproxGreedy $(G, \boldsymbol{L}, k, \epsilon)$

(1) $\{r_u\}_{u\in V} \leftarrow$ ERSumsEst $(G, \boldsymbol{L}, \epsilon/3)$
(2) $S_1 \leftarrow \{u_1\}$ where $u_1 = \arg\min_{u\in V} r_u$.
(3) Repeat the following steps for $i = 1, \ldots, k-1$:
  (a) $\{g_u\}_{u\in V} \leftarrow$ GainsEst $(G, \boldsymbol{L}, S_i, \epsilon/2)$
  (b) $S_{i+1} \leftarrow S_i + u_{i+1}$ where
$$u_{i+1} = \arg\max_{u\in(V\setminus S_i)} g_u.$$
(4) Return S_k.

The performance of ApproxGreedy is characterized in the following theorem.

Theorem 7.5. *The algorithm $S_k =$ ApproxGreedy$(G, \boldsymbol{L}, k, \epsilon)$ takes an undirected positively weighted graph $G = (V, E, w)$ with associated Laplacian $\boldsymbol{L}$, an integer $2 \le k \le n$, and an error parameter $0 < \epsilon \le 1/2$, and returns a vertex set $S_k \subseteq V$ with $|S_k| = k$. The algorithm runs in time $\widetilde{O}(km)$. With high probability, the vertex set S_k satisfies*

$$(1+\epsilon)\mathrm{Tr}\left(\boldsymbol{L}_{-u^*}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S_k}^{-1}\right) \ge \left(1 - \frac{k}{k-1}\cdot\frac{1}{e} - \epsilon\right)\left((1+\epsilon)\mathrm{Tr}\left(\boldsymbol{L}_{-u^*}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right),$$

where

$$S^* \stackrel{\text{def}}{=} \arg\min_{|S|\le k} \mathrm{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right), \quad u^* \stackrel{\text{def}}{=} \arg\min_{u\in V} \sum_{v\in V} R_{\text{eff}}(u, v).$$

Proof. The running time is easy to verify. It follows by the running times in Lemma 7.3 and 7.4.

We now prove the approximation ratio. The main difference between ApproxGreedy and ExactGreedy is that at each step, ExactGreedy picks a vertex with maximum marginal gain, while ApproxGreedy picks a vertex with at least $\frac{1-\epsilon/2}{1+\epsilon/2} \ge 1-\epsilon$ times maximum marginal gain. By supermodularity we have for any $i \ge 1$

$$\mathrm{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S_{i+1}}^{-1}\right) \ge \frac{1-\epsilon}{k}\left(\mathrm{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S*}^{-1}\right)\right),$$

which implies

$$\mathrm{Tr}\left(\boldsymbol{L}_{-S_{i+1}}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right) \le \left(1 - \frac{1-\epsilon}{k}\right)\left(\mathrm{Tr}\left(\boldsymbol{L}_{-S_i}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right).$$

Then, we have

$$\begin{aligned}
&\mathrm{Tr}\left(\boldsymbol{L}_{-S_k}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right) \\
&\le \left(1 - \frac{1-\epsilon}{k}\right)^{k-1}\left(\mathrm{Tr}\left(\boldsymbol{L}_{-S_1}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right) \\
&\le \frac{k}{k-1}\cdot\frac{1}{e^{(1-\epsilon)}}\left(\mathrm{Tr}\left(\boldsymbol{L}_{-S_1}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right) \\
&\le \frac{k}{k-1}\cdot\left(\frac{1}{e} + \epsilon\right)\left(\mathrm{Tr}\left(\boldsymbol{L}_{-S_1}^{-1}\right) - \mathrm{Tr}\left(\boldsymbol{L}_{-S^*}^{-1}\right)\right).
\end{aligned}$$

By Lemma 7.3, we obtain

$$\mathrm{Tr}\left(\boldsymbol{L}_{-S_1}^{-1}\right) \le \frac{1+\epsilon/3}{1-\epsilon/3}\mathrm{Tr}\left(\boldsymbol{L}_{-u^*}^{-1}\right) \le (1+\epsilon)\,\mathrm{Tr}\left(\boldsymbol{L}_{-u^*}^{-1}\right),$$

which plus the above inequality finishes the proof. □

8 EXPERIMENTS

In this section, we study the performance of our algorithms by conducting experiments on some classic network models and real-world networks taken from KONECT [34] and SNAP [36]. We run our experiments on the largest components of these networks. Related information of these networks is shown in Table 1, where networks are shown in increasing order of their numbers of vertices.

Table 1: Information of datasets. For a network with n vertices and m edges, we use n' and m' to denote the number of vertices and edges in its largest connected component, respectively.

We implement our algorithms in Julia to facilitate interactions with the SDDM solver contained in the Laplacian.jl package[2]. All of our experiments were run on a Linux box with 4.2 GHz Intel i7-7700 CPU and 32G memory, using a single thread.

8.1 Accuracy of routine GainsEst

We first show the accuracy of routine GainsEst. We use quantity JLfactor to denote $q/\ln n$ in GainsEst. We run GainsEst with different JLfactors on network arXiv High Energy Physics - Theory collaboration network (ca-HepTh). And we set $S_i = \{u^*\}$ where

$$u^* \stackrel{\text{def}}{=} \arg\min_{u\in V} \sum\nolimits_{v\in V} R_{\text{eff}}(u, v).$$

[2]https://github.com/danspielman/Laplacians.jl

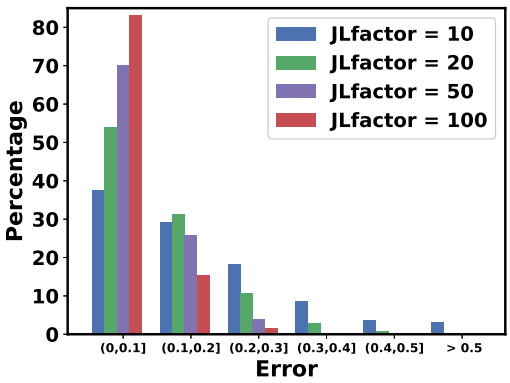

Figure 1: Error distribution for routine GainsEst with different JLfactors on network ca-HepTh.

For each JLfactor, we compute the relative error of gain of each vertex $u \neq u^*$, given by

$$\frac{\left|g_u - \left(\boldsymbol{e}_u^T \boldsymbol{L}_{-u^*}^{-2} \boldsymbol{e}_u\right) / \left(\boldsymbol{e}_u^T \boldsymbol{L}_{-u^*}^{-1} \boldsymbol{e}_u\right)\right|}{\left(\boldsymbol{e}_u^T \boldsymbol{L}_{-u^*}^{-2} \boldsymbol{e}_u\right) / \left(\boldsymbol{e}_u^T \boldsymbol{L}_{-u^*}^{-1} \boldsymbol{e}_u\right)}.$$

We then draw the distribution of relative errors with different JLfactors in a histogram. The results are shown in Figure 1. We observe that the errors become small when JLfactor gets larger. Moreover, almost all errors are in the range $(0, 0.5]$ when JLfactor ≥ 20.

We set JLfactor $= 20$ in all other experiments. We will show that this is sufficient for our greedy algorithm to obtain good solutions empirically.

8.2 Effectiveness of Greedy Algorithms

We show the effectiveness of our algorithms by comparing the results of our algorithms with the optimum solutions on four small model networks (Barabási-Albert (BA) [2], Watts-Strogatz (WS) [52], Erdös-Rényi (ER) [20], and a regular ring lattice [52]) and four small realistic networks (Dolphins, Contiguous USA, Zachary karate club, and Windsurfers). We are able to compute the optimum solutions on these networks because of their small sizes.

For each $k = 1, 2, \ldots, 6$, we first find the set of k vertices with the optimum current flow closeness by brute-force search. We then compute the current flow closeness of the vertex sets returned by ExactGreedy and ApproxGreedy. Also, we compute the solutions returned by the random scheme, which chose k vertices uniformly at random. The results are shown in Figure 2 and 3. We observe that the current flow closenesses of the solutions returned by our two greedy algorithms and the optimum solution are almost the same. This means that the approximation ratios of our greedy algorithms are significantly better than their theoretical guarantees. Moreover, the solutions returned by our greedy algorithms are much better than those returned by the random scheme.

We then demonstrate the effectiveness of our algorithms further by comparing it to the random scheme, as well as two other schemes, Top-degree and Top-cent, on six larger networks. Here the Top-degree scheme chooses k vertices with highest degrees, while the Top-cent scheme chooses k vertices with highest current flow closeness centrality according to Definition 2.4. A comparison of results for these five algorithms is shown in Figure 4. We observe

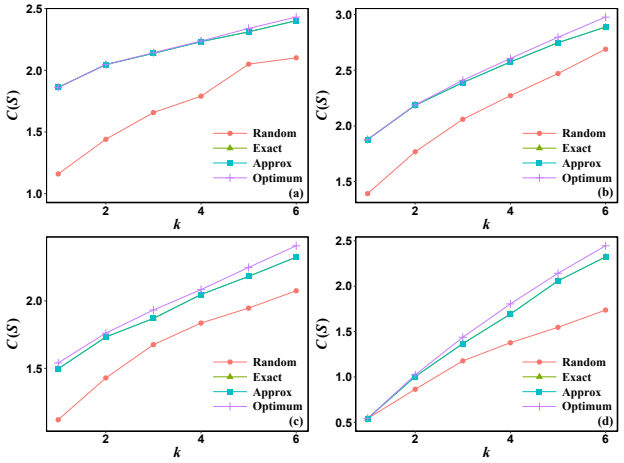

Figure 2: Current flow closeness of vertex sets returned by ExactGreedy, ApproxGreedy, random and optimum strategies on four models: BA (a), WS (b), ER (c), and a regular ring lattice (d).

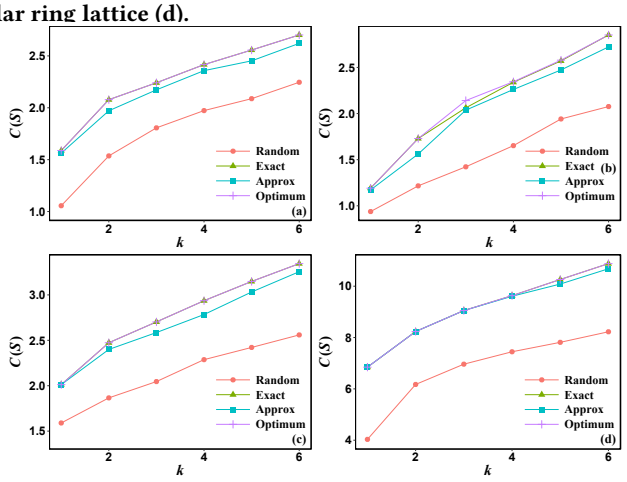

Figure 3: Current flow closeness of vertex sets returned by ExactGreedy, ApproxGreedy, random and optimum strategies on four networks: Dolphins (a), Contiguous USA (b), Zachary karate club (c), and Windsurfers (d).

that our two greedy algorithms obtain similar approximation ratios, and both outperform the other three schemes (random, Top-degree, and Top-cent).

8.3 Efficiency of Greedy Algorithms

We now show that algorithm ApproxGreedy runs much faster than ExactGreedy, especially on large-scale networks. We run our two greedy algorithms on a larger set of real-world networks. For each network, we use both greedy algorithms to choose $k = 10$ vertices, and then compare their running times as well as the solutions they returned. For networks with more than 30000 vertices, we compute the current flow closeness of the vertex set returned by ApproxGreedy by combining Fast Laplacian solvers and Hutchinson's trace estimation [1, 26]. We list the results in Table 2. We observe that the ratio of the running time of ExactGreedy to

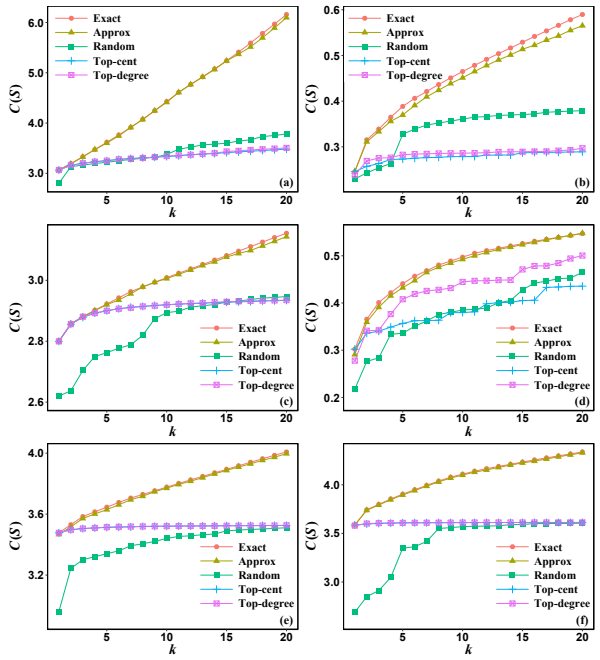

Figure 4: Current flow closeness of vertex sets returned versus the number k of vertices chosen for the five algorithms on David Copperfield (a), Euroroad (b), U. Rovira i Virgili (c), US power grid (d), Hamsterster full (e), and Reactome (f).

Table 2: The average running times and results of ExactGreedy (Exact) and ApproxGreedy (Approx) algorithms on a larger set of real-world networks, as well as the ratios of running times of ExactGreedy to those of ApproxGreedy, and ratios of current-flow closenesses achieved by ApproxGreedy to those achieved by ExactGreedy.

Network	Time (seconds)			Current flow closeness

that of ApproxGreedy increases rapidly when the network size becomes larger, while the vertex sets they returned have approximately the same current flow closeness. Moreover, ApproxGreedy is able to solve current flow closeness maximization for networks with more than 10^6 vertices in a few hours, whereas ExactGreedy fails because of its high time and space complexity.

9 CONCLUSIONS

In this paper, we extended the notion of current flow closeness centrality (CFCC) to a group of vertices. For a vertex group S in an n-vertex graph with m edges, its CFCC $C(S)$ equals the ratio of n to the sum of effective resistances between S and all other vertices. We then considered the problem of finding the set S^* of k vertices with an aim to maximize $C(S^*)$, and solved it by considering an equivalent problem of minimizing $\mathrm{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right)/n$. We showed that the problem is NP-hard, and proved that the objective function is monotone and supermodular. We devised two approximation algorithms for minimizing $\mathrm{Tr}\left(\boldsymbol{L}_{-S}^{-1}\right)/n$ by iteratively selected k vertices in a greedy way. The first one achieves a $(1-\frac{k}{k-1}\cdot\frac{1}{e})$ approximation ratio in time $O(n^3)$; while the second one obtains a $(1-\frac{k}{k-1}\cdot\frac{1}{e}-\epsilon)$ approximation factor in time $\widetilde{O}(mk\epsilon^{-2})$. We conducted extensive experiments on model and realistic networks, the results of which show that both algorithms can often give almost optimal solutions. In particular, our second algorithm is able to scale to huge networks, and quickly gives good approximate solutions in networks with more than 10^6 vertices. In future works, we plan to introduce and study the betweenness group centrality based on current flow [43], which takes into account all possible paths.

ABSTRACT

Node classification and graph classification are two graph learning problems that predict the class label of a node and the class label of a graph respectively. A node of a graph usually represents a real-world entity, e.g., a user in a social network, or a protein in a protein-protein interaction network. In this work, we consider a more challenging but practically useful setting, in which a node itself is a graph instance. This leads to a hierarchical graph perspective which arises in many domains such as social network, biological network and document collection. For example, in a social network, a group of people with shared interests forms a user group, whereas a number of user groups are interconnected via interactions or common members. We study the node classification problem in the hierarchical graph where a "node" is a graph instance, e.g., a user group in the above example. As labels are usually limited in real-world data, we design two novel semi-supervised solutions named SEmi-supervised grAph cLassification via Cautious/Active Iteration (or SEAL-C/AI in short). SEAL-C/AI adopt an iterative framework that takes turns to build or update two classifiers, one working at the graph instance level and the other at the hierarchical graph level. To simplify the representation of the hierarchical graph, we propose a novel supervised, self-attentive graph embedding method called SAGE, which embeds graph instances of arbitrary size into fixed-length vectors. Through experiments on synthetic data and Tencent QQ group data, we demonstrate that SEAL-C/AI not only outperform competing methods by a significant margin in terms of accuracy/Macro-F1, but also generate meaningful interpretations of the learned representations.

1 INTRODUCTION

Graph has been widely used to model real-world entities and the relationship among them. Two graph learning problems have received a lot of attention recently, i.e., node classification and graph classification. Node classification is to predict the class label of nodes in a graph, for which many studies in the literature make use of the connections between nodes to boost the classification performance. For example, [25] enhances the recommendation precision in LinkedIn by taking advantage of the interaction network, and [27] improves the performance of document classification by exploiting the citation network. Graph classification, on the other hand, is to predict the class label of graphs, for which various graph kernels [3, 9, 29, 30] and deep learning approaches [22, 23] have been designed. In this work, we consider a more challenging but practically useful setting, in which a node itself is a graph instance. This leads to *a hierarchical graph in which a set of graph instances are interconnected via edges.* This is a very expressive data representation, as it considers the relationship between graph instances, rather than treating them independently. The hierarchical graph model applies to many real-world data, for example, a social network can be modeled as a hierarchical graph, in which a user group is represented by a graph instance and treated as a node in the

hierarchical graph, and then

predicted class probabilities of all graph instances. To enforce a consistency between the two classifiers, we define a disagreement loss to measure the degree of divergence between the predictions by them and aim to minimize the disagreement loss.

Another challenge is that the amount of available class labels is usually very small in real-world data, which limits the classification performance. To address this challenge, we take a semi-supervised learning approach to solving the graph classification problem. We design an iterative algorithm framework which takes turns to build or update classifiers IC and HC. We start with the limited labeled training set and build IC, which produces the embedding vectors of graph instances. HC takes the embedding vectors as input and produces predictions. We cautiously select a subset of predicted labels by HC with high confidence to enlarge the training set. The enlarged training set is then fed into IC in the next iteration to update its parameters in the hope of generating more accurate embedding vectors and predictions. HC further takes the new embedding vectors for model update and class prediction. This is our proposed solution, called SEmi-supervised grAph cLassification via Cautious Iteration (SEAL-CI), to the graph classification problem.

We also extend this iterative algorithm to the active learning framework, in which we iteratively select the most informative instances for manual annotation, and then update the classifiers with the newly labeled instances in a similar process as described above. This method is called SEAL-AI in short.

Our contributions are summarized as follows.

- We study semi-supervised graph classification from a hierarchical graph perspective, which, to the best of our knowledge, has not been studied before. Our proposed solutions SEAL-C/AI achieve superior classification performance to the state-of-the-other graph kernel and deep learning methods, even when given very few labeled training instances.
- We design a novel supervised, self-attentive graph embedding method called SAGE to embed graphs of arbitrary size into fixed-length vectors, which are used as a common form of input for classification. The embedding approach not only simplifies the representation of a hierarchical graph greatly, but also provides meaningful interpretations of the underlying data in two forms: 1) embedding vectors of graph instances, and 2) node importance in a graph instance learned through a self-attentive mechanism that differentiates their contribution in classifying a graph instance.
- We evaluate SEAL-C/AI on both synthetic graphs and Tencent QQ group data. From the social networking platform Tencent QQ, we select 37,836 QQ groups with 18,422,331 unique anonymized users and classify them as "game" or "non-game" groups. SEAL-C/AI achieve a Macro-F1 score of 70.8% and 73.2% respectively with only 2.6% labeled instances. They both outperform other competing methods by a large margin.

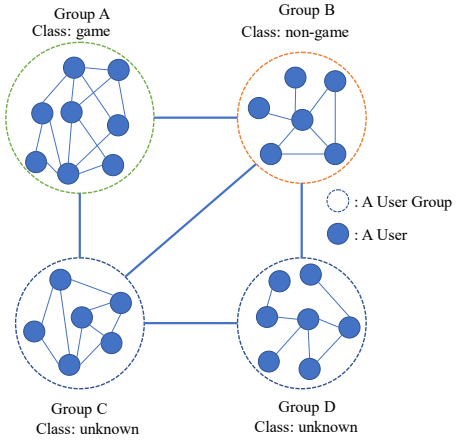

Figure 1: A hierarchical graph with four graph instances A, B, C, D, each of which corresponds to a user group in a social network.

The remainder of this paper is organized as follows. Section 2 gives the problem definition and Section 3 describes the design of SEAL-C/AI. We report the experimental results in Section 4 and discuss related work in Section 5. Finally, Section 6 concludes the paper.

2 PROBLEM DEFINITION

We denote a set of objects as $O = \{o_1, o_2, \ldots, o_N\}$ which represent real-world entities. We use ϕ attributes to describe properties of objects, e.g., age, gender, and other information of people.

We use a *graph instance* to model the relationship between objects in O, which is denoted as $g = (V, A, X)$, $V \subseteq O$ is the node set and $|V| = n$, A is an $n \times n$ adjacency matrix representing the connectivity in g, and $X \in \mathbb{R}^{n \times \phi}$ is a matrix recording the attribute values of all nodes in g.

A set of graph instances G can be interconnected, and the connectivity between the graph instances is represented by an adjacency matrix Θ. The graph instances and their connections are modeled as a *hierarchical graph*.

A graph instance $g \in G$ is a *labeled graph* if it has a class label, represented by a vector $y \in \{0, 1\}^c$, where c is the number of classes. A graph instance is *unlabeled* if its class label is unknown. Then G can be divided into two subsets: labeled graphs G_l and

unlabeled graphs G_u, where $G = G_l \cup G_u$, $|G_l| = L$ and $|G_u| = U$. In this paper, we study the problem of ***graph classification***, which determines the class label of the unlabeled graph instances in G_u from the available class labels in G_l and the hierarchical graph topological structure. As the amount of available class labels is usually very limited in real-world data, we take a semi-supervised learning approach to solving this problem.

Figure 1 depicts a hierarchical graph in the context of a social network. A, B, C, D denote four user groups. Group A has the class label of "game", B has the label of "non-game", while the class labels of C and D are unknown. These four groups are connected via some kind of relationships, e.g., interactions or common members. The internal structure of each user group shows the connections between individual users. From this hierarchical graph, we want to determine the class labels of groups C and D.

3 METHODOLOGY

3.1 Problem Formulation

In our problem setting, we have two kinds of information: graph instances and connections between the graph instances, which provide us with two perspectives to tackle the graph classification problem. Accordingly, we build two classifiers: a classifier IC constructed for graph instances and a classifier HC constructed for the hierarchical graph, both of which make predictions for unlabeled graph instances in G_u.

For both classifiers, one goal is to minimize the supervised loss, which measures the distance between the predicted class probabilities and the true labels. Another goal is to minimize a disagreement loss, which measures the distance between the predicted class probabilities by IC and HC. The purpose of this disagreement loss is to enforce a ***consistency*** between the two classifiers.

Formally, we formulate the graph classification problem as an optimization problem:

$$\min \zeta(G_l) + \xi(G_u), \tag{1}$$

where $\zeta(G_l)$ is the supervised loss for the labeled graph instances, and $\xi(G_u)$ is the disagreement loss for the unlabeled graph instances.

Specifically, $\zeta(G_l)$ includes two parts:

$$\zeta(G_l) = \sum_{g_i \in G_l} (\mathcal{L}(y_i, \psi_i) + \mathcal{L}(y_i, \gamma_i)), \tag{2}$$

where ψ_i is a vector of predicted class probabilities by IC, and γ_i is a vector of predicted class probabilities by HC. $\mathcal{L}(\cdot, \cdot)$ is the cross-entropy loss function.

The disagreement loss $\xi(\cdot)$ is defined as:

$$\xi(G_u) = \sum_{g_i \in G_u} D_{KL}(\gamma_i || \psi_i), \tag{3}$$

where $D_{KL}(\cdot||\cdot)$ is the Kullback-Leibler divergence, $D_{KL}(P||Q) = \sum_j P_j \log\left(\frac{P_j}{Q_j}\right)$. In the following subsections, we describe our design of classifiers IC and HC, and our approach to minimizing the supervised loss and the disagreement loss.

3.2 Design of Classifiers

Classifier IC takes a graph instance as input. As different graph instances have different numbers of nodes, IC is expected to handle graph instances of arbitrary size. Classifier HC takes the hierarchical graph as input, in which individual graph instances are the "nodes". This is a much too complicated input for a classifier. To deal with the above challenges, we propose to embed a graph instance $g_i \in G$ into a fixed-length vector e_i via IC first. Then HC can take as input the embedding vectors of graph instances and the adjacency matrix Θ. In particular, IC takes as input the adjacency matrix A_i and attribute matrix X_i of an arbitrary-sized graph instance g_i, and outputs an embedding vector e_i and a vector of predicted class probabilities ψ_i, i.e., $(e_i, \psi_i) = \text{IC}(A_i, X_i)$. HC takes the embedding vectors $E = \{e_i\}_{i=1}^{L+U}$ and Θ, and outputs the predicted class probabilities $\Gamma = \{\gamma_i\}_{i=1}^{L+U}$, i.e., $\Gamma = \text{HC}(E, \Theta)$. In the following, we illustrate the design of IC which performs discriminative graph embedding, and then the design of HC which performs graph-based classification.

3.2.1 Discriminative graph embedding. Our graph embedding task is to produce a fixed-length discriminative embedding vector of a graph instance. In the literature, graph representation techniques have recently shifted from hand-crafted kernel methods [33] to neural network based end-to-end methods, which achieve better performance in graph-structured learning tasks. In this vein, we adopt neural network methods for the graph embedding task, for which, however, we identify three challenges:

- *Size invariance*: How to design the neural network structure to flexibly take an arbitrary-sized graph instance and produce a fixed-length embedding vector?
- *Permutation invariance*: How to derive the representation regardless of the permutation of nodes?
- *Node importance*: How to encode the importance of different nodes into a unified embedding vector?

In particular, the third challenge is *node importance*, i.e., different nodes in a graph instance have different degrees of importance. For example, in a "game" group the "core" members should be more important than the "border" members in contributing to the derived embedding vector. We need to design a mechanism to learn the node importance and then encode it in the embedding vector properly.

To this end, we propose a self-attentive graph embedding method, called SAGE, which can take a variable-sized graph instance, and combine each node to produce a fixed-length vector according to their importance within the graph. In SAGE, we first utilize a multi-layer GCN [16] to smooth each node's features over the graph's topology. Then we use a self-attentive mechanism to learn the node importance and then transform a variable number of smoothed nodes into a fixed-length embedding vector, as proposed in [18]. Finally, the embedding vector is cascaded with a fully connected layer and a softmax function, in which the label information can be leveraged to discriminatively transform the embedding vector e into ψ. Figure 2 depicts the overall framework of SAGE.

Formally, we are given the adjacency matrix $A \in \mathbb{R}^{n \times n}$ and the attribute matrix $X \in \mathbb{R}^{n \times \phi}$ of a graph instance g as input. In the preprocessing step, the adjacency matrix A is normalized:

$$\hat{A} = \tilde{D}^{-\frac{1}{2}}(A + I_n)\tilde{D}^{-\frac{1}{2}}, \tag{4}$$

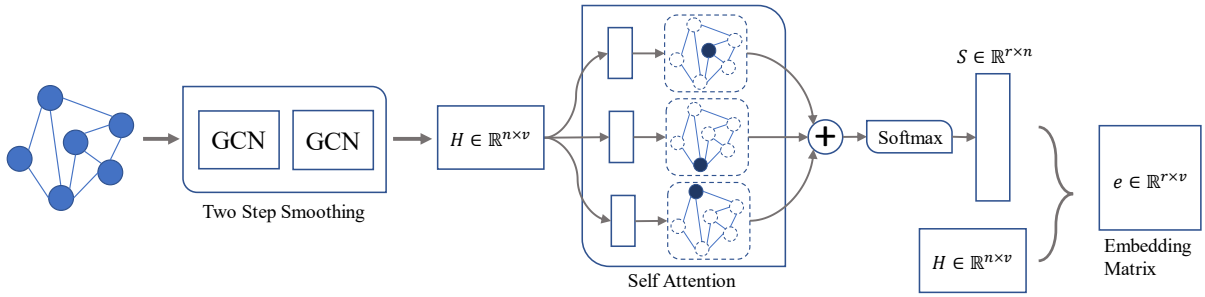

Figure 2: The supervised self-attentive graph embedding method SAGE.

where I_n is the identity matrix and $\tilde{D}_{ii} = \sum_m (A + I_n)_{im}$. Then we apply a two-layer GCN network:

$$H = \hat{A}\,\mathrm{ReLU}(\hat{A}XW^0)W^1. \tag{5}$$

Here $W^0 \in \mathbb{R}^{\phi \times h}$ and $W^1 \in \mathbb{R}^{h \times v}$ are two weight matrices. GCN can be considered as a Laplacian smoothing operator for node features over graph structures, as pointed out in [17]. Then we get a set of representation $H \in \mathbb{R}^{n \times v}$ for nodes in g. Note that the representation H does not provide node importance, and it is size variant, i.e., its size is still determined by the number of nodes n. So next we utilize the self-attentive mechanism to learn node importance and encode it into a unified graph representation, which is size invariant:

$$S = \mathrm{softmax}\Big(W_{s2}\tanh(W_{s1}H^T)\Big), \tag{6}$$

where $W_{s1} \in \mathbb{R}^{d \times v}$ and $W_{s2} \in \mathbb{R}^{r \times d}$ are two weight matrices. The function of W_{s1} is to linearly transform the node representation from a v-dimensional space to a d-dimensional space, then nonlinearity is introduced by tying with the function tanh. W_{s2} is used as r views of inferring the importance of each node within the graph. It acts like inviting r experts to give their opinions about the importance of each node independently. Then softmax is applied to derive a standardized importance of each node within the graph, which means in each view the summation of all the node importance is 1.

After that, we compute the final graph representation $e \in \mathbb{R}^{r \times v}$ by multiplying $S \in \mathbb{R}^{r \times n}$ with $H \in \mathbb{R}^{n \times v}$:

$$e = SH. \tag{7}$$

e is size invariant since it does not depend on the number of nodes n any more. It is also permutation invariant since the importance of each node is learned regardless of the node sequence, and only determined by the task labels.

One potential risk in SAGE is that r views of node importance may be similar. To diversify their views of node importance, a penalization term is imposed:

$$P = \left\| SS^T - I_r \right\|_F^2. \tag{8}$$

Here $\left\| \cdot \right\|_F$ represents the Frobenius norm of a matrix. We train the classifier in a supervised way with the task at hand, in the hope of minimizing both the penalization and the cross-entropy loss.

To summarize, we use SAGE to construct the instance-level classifier IC. It produces not only the estimated class probability vector ψ, but also a graph embedding e, which is the input for classifier HC described in the next subsection.

3.2.2 Graph-based classification. Given the graph embedding $E = \{e_i\}_{i=1}^{L+U}$ and the adjacency matrix $\Theta \in \mathbb{R}^{(L+U)\times(L+U)}$, our next task is to infer the parameters of classifier HC and derive the predicted probabilities $\Gamma = \{\gamma_i\}_{i=1}^{L+U}$. This problem falls into the setting of traditional graph-based learning where E can be treated as the set of node features. Recently neural network based approaches such as [16, 34] have demonstrated their superiority to traditional methods such as ICA [27]. In this context we make use of GCN [16] again for the consideration of efficiency and effectiveness. In the following, we consider a two-layer GCN and apply preprocessing by $\hat{\Theta} = \tilde{D_\Theta}^{-\frac{1}{2}}(\Theta + I_{L+U})\tilde{D_\Theta}^{-\frac{1}{2}}$. Then the model becomes:

$$\Gamma = HC(E, \Theta) = \mathrm{softmax}\Big(\hat{\Theta}\,\mathrm{ReLU}(\hat{\Theta}EW_\Theta^0)W_\Theta^1\Big), \tag{9}$$

where $W_\Theta^0 \in \mathbb{R}^{(rv)\times M}$ is an input-to-hidden weight matrix with M feature maps and $W_\Theta^1 \in \mathbb{R}^{M \times c}$ is a hidden-to-output weight matrix. The softmax function is applied row-wise and we get Γ. With Γ and Ψ we can compute the supervised loss in problem (2) and the disagreement loss in problem (3).

3.3 The Proposed SEAL-CI Model

In this subsection, we present our method to minimize the objective function (1). In real-world scenarios, the number of labeled graph instances L can be quite small compared to the number of unlabeled instances U. In this context, neural network based classifiers such as IC may suffer from the problem of overfitting. To mitigate this, we have both the disagreement loss (3) and the supervised loss (2) included in the objective function (1). The disagreement loss can be regarded as a regularization to prevent overfitting.

Problem (1) is a mixed combinatorial and continuous optimization problem. The supervised loss (2) includes two parts, $\mathcal{L}(y_i, \psi_i)$ and $\mathcal{L}(y_i, \gamma_i)$, i.e., the supervised loss of IC and HC. $\mathcal{L}(y_i, \gamma_i)$ depends on classifier IC to provide accurate graph embedding. All these issues make the problem highly non-convex. As such, we use the idea of iterative algorithm to alternate minimizing the supervised loss of IC and HC, and minimizing the disagreement loss by trusting a subset of predictions by HC in the next iteration of graph embedding by IC.

To be more specific, we combine the graph embedding algorithm in Section 3.2.1 and graph-based classification algorithm in Section 3.2.2 into one iterative algorithm. We build IC to produce graph embedding E^t for all graph instances in iteration t, and then feed E^t into HC to get the predicted probabilities Γ^t. We then make use of Γ^t to update the parameters of IC and generate E^{t+1}, which is

Algorithm 1: SEAL-CI

Input: A, X, Θ.
Output: Ψ^t, Γ^t.

1 Initial: $G_{tmp} = \emptyset, G_l^0 = G_l, t = 0$;
2 **while** $t\lambda \leq U$ **do**
3 $\quad \mathcal{W}^{t+1} \leftarrow \arg\min \zeta(G_l^t|\mathcal{W}^t)$;
4 $\quad \Psi^{t+1}, E^{t+1} \leftarrow \mathsf{IC}(A, X|\mathcal{W}^{t+1})$;
5 $\quad \Gamma^{t+1} \leftarrow \mathsf{HC}(E^{t+1}, \Theta|\mathcal{W}^{t+1})$;
6 $\quad G_{tmp} \leftarrow h(t\lambda, \Gamma_{G_u}^{t+1})$;
7 $\quad G_l^{t+1} \leftarrow G_l \cup G_{tmp}$;
8 $\quad G_{tmp} = \emptyset$;
9 Return Ψ^t, Γ^t;

then used as the input of HC in iteration $t+1$. Figure 3 depicts the overall framework of this iterative process. Although this method may not reach the global optimum, similar setting [20, 27] has been proven to be effective.

3.3.1 How to utilize Γ^t? To update the graph embedding vectors, a naive approach is feeding the whole set of Γ^t for the parameter update in IC, which is the idea of the original ICA [27]. However, not all Γ^t are correct in their predictions. The false predictions may lead the update of embedding neural network to the wrong direction. To this end, we make use of the idea of [20], a variant of the original ICA, and cautiously exploit a subset of Γ^t to update the parameters of IC in each iteration. Specifically, in iteration t, we choose the $t\lambda$ most confident predicted labels while ignoring the less confident predicted labels. This operation continues until all the unlabeled samples have been utilized. To further improve the efficiency, the parameters of IC are not re-trained but fine-tuned based on the parameters obtained in the previous iteration. This algorithm is called SEmi-supervised grAph cLassification via Cautious Iteration (SEAL-CI) and is presented in Algorithm 1. Note here $\mathcal{W}$ is the set of all the parameters of IC and HC. In line 6, the training set for IC has been enlarged by $t\lambda$ instances and it is done by "committing" these instances' labels from their maximum probability. In other words, the newly enrolled training instances are found by:

$$h(\lambda, \Gamma) = \text{top}(\max_{\gamma \in \Gamma} \gamma, \lambda). \tag{10}$$

Here function $\text{top}(\cdot, \lambda)$ is used to select the top λ instances and function $\max \gamma$ is used to select the maximum value in the probability vector γ.

3.4 The Proposed SEAL-AI Model

Our proposed model is easy to extend to the active learning scenario. In case further annotation is available, we can perform active learning and ask for annotations with a budget of B. Denote the set of graph instances being annotated as G_B, then the objective function in the active learning setting is re-written as:

$$\begin{aligned} &\min f(G|B, \mathcal{W}) \\ &\text{s.t.} \quad |G_B| \leq B, \end{aligned} \tag{11}$$

where $f(G|B, \mathcal{W}) = \zeta(G_l \cup G_B|\mathcal{W}) + \xi(G_u \setminus G_B|\mathcal{W})$. This is still a mixed combinatorial and continuous optimization problem. It is very hard to infer the model parameters and the active learning set G_B simultaneously. By definition, the active learning set G_B is intractable unless the model parameters are completely inferred. To solve this chicken-and-egg problem, we decompose the objective function into two sub-steps: parameter optimization and candidate generation. Then we optimize $f(G|B, \mathcal{W})$ iteratively. This algorithm is called SEmi-supervised grAph cLassification via Active Iteration (SEAL-AI) and is shown in Algorithm 2.

Algorithm 2: SEAL-AI

Input: A, X, Θ.
Output: Ψ^t, Γ^t.

1 Initial: $G_{tmp} = \emptyset, G_B^0 = \emptyset, G_l^0 = G_l, G_u^0 = G_u, t = 0$;
2 **while** $|G_B^t| \leq B$ **do**
3 $\quad \mathcal{W}^{t+1} \leftarrow \arg\min \zeta(G_l^t|\mathcal{W}^t)$;
4 $\quad \Psi^{t+1}, E^{t+1} \leftarrow \mathsf{IC}(A, X|\mathcal{W}^{t+1})$;
5 $\quad \Gamma^{t+1} \leftarrow \mathsf{HC}(E^{t+1}, \Theta|\mathcal{W}^{t+1})$;
6 $\quad G_{tmp} \leftarrow \arg\min_{|G_{tmp}|=k} \xi(G_u^t \setminus G_{tmp}|\mathcal{W}^{t+1})$;
7 $\quad G_B^{t+1} \leftarrow G_B^t \cup G_{tmp}$;
8 $\quad G_l^{t+1} \leftarrow G_l^t \cup G_{tmp}$;
9 $\quad G_u^{t+1} \leftarrow G_u^t \setminus G_{tmp}$;
10 $\quad G_{tmp} = \emptyset$;
11 Return Ψ^t, Γ^t;

At the beginning of this iterative process, we optimize the supervised loss $\zeta(G_l|\mathcal{W})$ based on current labeled graphs in G_l (line 3 in Algorithm 2). In active learning, the choice of candidate generator is a key component. We exploit the idea of ALFNET [1] and choose the candidate graph instances G_{tmp} by maximizing the decrease of the current disagreement loss based on the new parameter obtained in the first step (line 6 in Algorithm 2). At last we label G_{tmp} and update G_B, G_l and G_u respectively (line 7-9 in Algorithm 2).

It is worth noting that from the hard example mining perspective, the disagreement score is an excellent criterion for the active learning setting. Specifically, we choose the candidates by first calculating the distribution divergence of (γ_i, ψ_i) from $\Gamma_u = \{\gamma_i\}_{i=1}^U$ and $\Psi_u = \{\psi_i\}_{i=1}^U$:

$$z(\psi_i, \gamma_i) = D_{KL}(\gamma_i||\psi_i). \tag{12}$$

Then we choose k instances with the largest KL divergence. Intuitively, the KL divergence between ψ_i and γ_i can be viewed as the conflict of two supervised models. A large KL divergence indicates that one of the models gives wrong predictions. To this end, the instances with a large KL divergence are more informative to help the algorithm converge more quickly.

3.5 Complexity Analysis

We analyze the computational complexity of our proposed methods. Here we only focus on Algorithm 1, since Algorithm 2 is almost the same except the step of selecting candidate graph instances to the training set. In Algorithm 1, the intensive parts in each iteration contain the updates of IC and HC as well as the selection of candidate instances. We discuss each part in details below.

Regarding IC, the core is to compute the activation matrix H in Eq. (5) where the matrix-vector multiplications are up to $O(E_1\phi)$

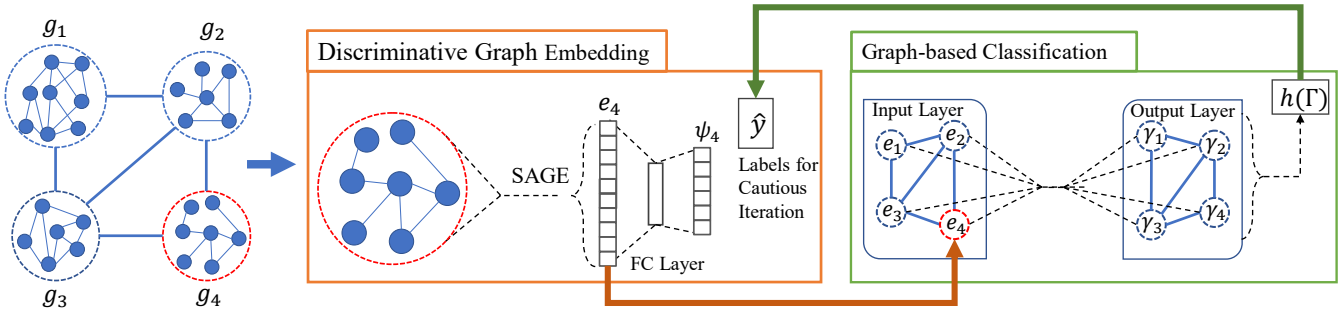

Figure 3: Schematic diagram of the learning framework SEAL-CI. There are two subroutines: discriminative graph embedding (in the orange box) and graph-based classification (in the green box).

flops for one input graph instance; here E_1 denotes the number of edges in the graph instance and ϕ is the input feature dimension. Thus, it leads to the complexity of $O(E_1(L+U)\phi)$ by going through all $L+U$ graph instances.

Next, the computation by HC in Eq. (9) requires $O(E_2 rv)$ flops in total, where E_2 denotes the number of links between graph instances. Then in candidate selection, performing comparisons between all unlabeled graph instances has a complexity of $O(L+U)$ given the outputs of two classifiers IC and HC.

Overall, the complexity of our method is $O(E_1(L+U)\phi + E_2 rv)$ which scales linearly in terms of the number of edges in each graph instance (i.e., E_1), the number of links between graph instances (i.e., E_2) and the number of graph instances (i.e., $(L+U)$). Thus, our method is computationally comparable to the GCN-based method [16], and more efficient than PSCN [23] that is quasi-linear with respect to the numbers of nodes and edges.

4 EXPERIMENTS

We first validate the effectiveness of our graph embedding algorithm SAGE on two data sets: PROTEINS and D&D. Then we evaluate our SEAL-C/AI methods on both synthetic and Tencent QQ group data sets.

4.1 Performance of SAGE

We use two benchmark data sets, PROTEINS and D&D, to evaluate the classification accuracy of SAGE, and compare it with the state-of-the-art graph kernels and deep learning approaches. PROTEINS [4] is a graph data set where nodes are secondary structure elements and edges represent that two nodes are neighbors in the amino-acid sequence or in 3D space. D&D [7] is a set of structures of enzymes and non-enzymes proteins, where nodes are amino acids, and edges represent spatial closeness between nodes. Table 1 lists the statistics of these two data sets.

4.1.1 Baselines and Metrics. The baselines include four graph kernels and two deep learning approaches:

- the shortest-path kernel (SP) [3],
- the random walk kernel (RW) [9],
- the graphlet count kernel (GK) [30],
- the Weisfeiler-Lehman subtree kernel (WL) [29],
- PATCHY-SAN (PSCN) [23], and
- graph2vec [22].

Table 1: Statistics of PROTEINS and D&D

	PROTEINS	D&D
Max number of nodes	620	5748
Avg number of nodes	39.06	284.32
Number of graphs	1113	1178

Table 2: Accuracy of different classifiers

Approach	PROTEINS	D&D
SP	75.07±0.54%	-
RW	74.22±0.42%	-
GK	71.67±0.55%	78.45±0.26%
WL	72.92±0.56%	77.95±0.70%
PSCN	75.89±2.76%	77.12±2.41%
graph2vec	73.30±2.05%	-
SAGE	**77.26**±2.28%	**80.88**±2.33%

We follow the experimental setting as described in [23], and perform 10-fold cross validation. In each partition, the experiments are repeated for 10 times. The average accuracy and the standard deviation are reported. We list results of the graph kernels and the best reported results of PSCN according to [23].

For SAGE, we use the same network architecture on both data sets. The first GCN layer has 128 output channels, and the second GCN has 8 output channels. We set $d = 64$, $r = 16$, and the penalization term coefficient to be 0.15. The dense layer has 256 rectified linear units with a dropout rate of 0.5. We use minibatch based Adam [15] to minimize the cross-entropy loss and use He-normal [11] as the initializer for GCN. For both data sets, the only hyperparameter we optimized is the number of epochs.

4.1.2 Results. Table 2 lists the experimental results. As we can see, SAGE outperforms all the graph kernel methods and the two deep learning methods by 1.27% – 5.59% in accuracy. This shows that our graph embedding method SAGE is superior.

Table 3: Statistics of generated graph instances

Type	Number	Nodes	Edges	Density
Watts-Strogatz	351	173	347	2.3%
Tree	217	127	120	1.5%
Erdős-Rényi	418	174	3045	20%
Barbell	818	169	2379	16.3%
Bipartite	426	144	1102	10.6%
Barabási-Albert	298	173	509	3.4%
Path	180	175	170	1.1%

The node and edge numbers and density are the average for each type of graph.

4.2 SEAL-C/AI on Synthetic Data

We evaluate the performance of SEAL-C/AI on synthetic data. We first give a description of the synthetic generator, then visualize the learned embeddings and analyze the self-attentive mechanism on the generated data. Finally we compare our methods with baselines in terms of classification accuracy.

4.2.1 Synthetic Data Generation. The benchmark data set Cora [19] contains 2708 papers which are connected by the "citation" relationship. We borrow the topological structure of Cora to provide the skeleton (i.e., edges) of our synthetic hierarchical graph. Then we generate a set of graph instances, which serve as the nodes of this hierarchical graph. Since there are 7 classes in Cora, we adopt 7 different graph generation algorithms, that is, Watts-Strogatz [32], Tree graph, Erdős-Rényi [8], Barbell [13], Bipartite graph, Barabási-Albert graph [2] and Path graph, to generate 7 different types of graph instances, and connect them in the hierarchical graph.

Specifically, to generate a graph instance g, we randomly sample a number from $[100, 200]$ as its size n. Then we generate its structure and assign the class label according to the graph generation algorithm. In this step, the parameter p in Watts-Strogatz, Erdős-Rényi, Bipartite graph and Barabási-Albert graph is randomly sampled from $[0.1, 0.5]$, the branching factor for Tree graph is randomly sampled from $[1, 3]$. At last, to make this problem more challenging, we randomly remove 1% to 20% edges in the generated graph g. The statistics of the generated graph instances are listed in Table 3.

4.2.2 Visualization. To have a better understanding of the synthesized graph instances, we split all 2708 graph instances into two parts. 1708 instances are used for training and the remaining 1000 instances are used for testing. We apply SAGE on the training set and derive the embeddings of the 1000 testing instances. We then project these learned embeddings into a two-dimensional space by t-SNE [31], as depicted in Figure 4. Each color in Figure 4 represents a graph type. As we can see from this two-dimensional space, the geometric distance between the graph instances can reflect their graph similarity properly.

We then examine the self-attentive mechanism of SAGE. We calculate the average attention weight across r views and normalize the resulting attention weights to sum up to 1. From the testing instances, we select three examples: a Tree graph, an Erdős-Rényi graph and a Barbell graph, for which SAGE has a high confidence (> 0.9) in predicting their class label. The three examples are depicted in Figure 5, where a bigger node implies a larger average attention weight, and a darker color implies a larger node degree. On the left is a Tree graph, in which most of the important nodes learned by SAGE are leaf nodes. This is reasonable since leaves are discriminative features to distinguish Tree graph from the other 6 types of graphs. In the center is an Erdős-Rényi graph. We cluster these nodes into 5 groups by hierarchical clustering [14], and see that SAGE tends to highlight those nodes with large degrees within each cluster. On the right is a Barbell graph, in which SAGE pays attention to two kinds of nodes. The first kind is those nodes that connect a dense graph and a path, and the second kind is the nodes that are on the path.

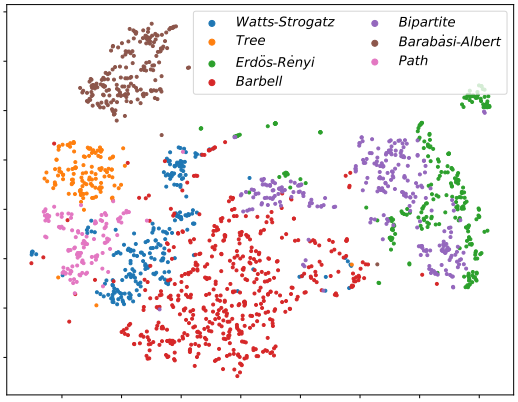

Figure 4: Two-dimensional visualization of graph embeddings generated from the synthesized graph instances using SAGE. The nodes are colored according to their graph types.

4.2.3 Baselines and Metrics. We use 6 approaches as our baselines:

- GK-SVM/GCN [30], which calculates the graphlet count kernel (GK) matrix, then GK-SVM feeds the kernel matrix into SVM [12] whereas GK-GCN feeds the kernel vector of each graph instance to GCN.
- WL-SVM/GCN [29], which is similar as above but using the Weisfeiler-Lehman subtree kernel (WL).
- graph2vec-GCN [22], which embeds the graph instances by graph2vec and then feeds the embeddings to GCN.
- cautious-SAGE-Cheby, which is similar to SEAL-CI except that we replace GCN with Cheby-GCN [6].
- active-SAGE-Cheby, which is similar to SEAL-AI except that we replace GCN with Cheby-GCN [6].
- SAGE, which ignores the connections between graph instances and treats them independently.

We use 300 graph instances as the training set for all methods except SEAL-AI and active-SAGE-Cheby, for which only 140 graphs are used as labeled graph instances at hand and then $B = 160$ is set for active learning. We use 1000 graph instances as the testing set. We run each method 5 times and report its average accuracy. The number of epochs for graph2vec is 1000 and the learning rate is 0.3. To avoid overfitting of SAGE on this small data set, we use a relatively small number of neurons. The first GCN layer has 32 output channels and the second GCN layer has 4 output channels.

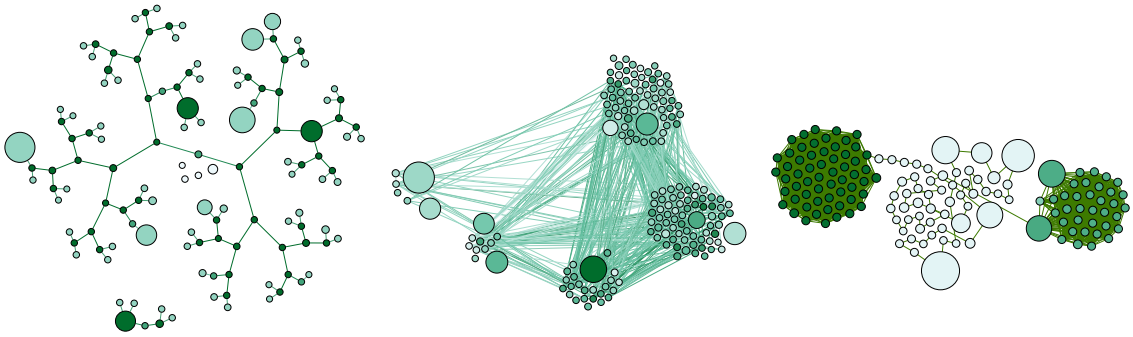

Figure 5: Attention of graph embeddings on 3 different types of graphs (left: Tree graph; middle: Erdős-Rényi graph; right: Barbell graph). A bigger node indicates a larger importance, and a darker color implies a larger node degree.

We set $d = 32$ and $r = 10$. The dense layer has 48 units with a dropout rate of 0.3. We set $M = 16$ in HC.

4.2.4 Results. Table 4 shows the experimental results for semi-supervised graph classification. Among all approaches, SEAL-C/AI achieve the best performance. In the following, we analyze the performance of all methods categorized into 4 groups.

Group *1: Both GK-SVM and WL-SVM outperform their GCN-based counterparts, indicating that SVM is more effective than GCN with the computed kernel matrix. All the embedding-based methods perform better than these two kernel methods, which proves that embedding vectors are effective representations for graph instances and are suitable input for graph neural networks.

Group *2: graph2vec-GCN achieves 85.2% accuracy, which is comparable to that of SAGE, but lower than that of SEAL-C/AI. One possible explanation is that graph2vec is an unsupervised embedding method, which fails to generate discriminative embeddings for classification. Another possibility is that there is no iteration in this method, and the 300 training instances do not include very informative ones. These limitations of graph2vec are also motivations for us to design the supervised embedding method SAGE and the iterative framework in SEAL-CI.

Group *3: cautious-SAGE-Cheby outperforms SAGE by only 0.8%, which is not remarkable considering that it exploits many more training instances. The accuracy of active-SAGE-Cheby is 3.3% lower than that of SEAL-AI, which means that Cheby-GCN is inferior to GCN.

Group *4: Both SEAL-CI and SEAL-AI outperform SAGE significantly, which proves the effectiveness of our hierarchical graph based perspective and the iterative algorithm for graph classification. SEAL-AI outperforms SEAL-CI only slightly, by 1.2%. This shows, although SEAL-CI can make use of more training samples, it is still influenced by the misclassified cases of GCN.

4.2.5 Influence of the number of labeled training instances. We examine how the number of labeled training instances affects the performance of our methods. We train SAGE and SEAL-CI with a label size of $\{140, 180, 220, 260, 300\}$. We train SEAL-AI with 140 labeled instances and then set the budget B for active learning at $\{0, 40, 80, 120, 160\}$. Thus the three methods have the same number of labeled training instances. We set $\lambda = 40$ in SEAL-CI and $k = 10$ in SEAL-AI. We run all methods 5 times, and plot their average accuracy in Figure 6. As we can see from Figure 6, when the number of labeled training instances is 140, SEAL-CI performs best since it can utilize more training samples. As the number of labeled training instances increases, the performance of SEAL-AI improves dramatically. SEAL-AI catches up with SEAL-CI at 260 labeled training instances and outperforms SEAL-CI at 300 labeled training instances. It validates that SEAL-AI can make use of the iterations to find informative and accurate training samples. Meanwhile SEAL-CI trusts the prediction of GCN conditionally on its confidence, which may bring some noise to the learning process. SEAL-C/AI outperform SAGE in all cases, which makes sense because SEAL-C/AI make good use of the hierarchical graph setting and consider the connections between the graph instances for classification.

Table 4: Comparison of different methods on the synthetic data set for semi-supervised graph classification

	Algorithm	Accuracy
*1	**GK-SVM/GCN**	77.8%/73.4%
	WL-SVM/GCN	83.4%/75.5%
*2	**graph2vec-GCN**	85.2%
*3	**cautious-SAGE-Cheby**	86.5%
	active-SAGE-Cheby	89.1%
*4	**SAGE**	85.7%
	SEAL-CI	91.2%
	SEAL-AI	**92.4**%

4.3 SEAL-C/AI on Tencent QQ Group

In this section, we evaluate SEAL-C/AI on Tencent QQ group data. We describe the characteristics of this data set and then present the experimental results. Finally, we have some open discussions on how to construct a hierarchical graph from real-world data.

4.3.1 Data Description. Tencent QQ is a social networking platform in China with nearly 800 million monthly active users[1]. There

[1]https://www.tencent.com/en-us/articles/17000391523362601.pdf

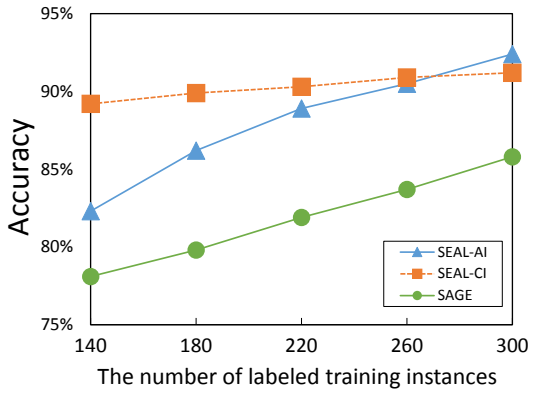

Figure 6: Accuracy with different number of labeled training instances on synthetic data for semi-supervised graph classification.

Table 5: Statistics of collected Tencent QQ groups

Class label	Number	Nodes	Edges	Density
game	1,773	147	395	5.48%
non-game	36,063	365	1586	3.28%

The node and edge numbers and density are the average for each type of QQ group.

are around 100 million active online QQ groups. In this experiment, we select 37,836 QQ groups with 18,422,331 unique anonymized users. For each user, we extract seven personal features:

- number of days ever since the registration day;
- most frequently active area code in the past 90 days;
- number of friends;
- number of active days in the past 30 days;
- number of logging in the past 30 days;
- number of messages sent in the past 30 days;
- number of messages sent within QQ groups in the past 30 days.

We have 298,837,578 friend relationships among these users. 1,773 groups are labeled as "game" and the remaining groups are labeled as "non-game".

We construct the hierarchical graph from this Tencent QQ group data as follows. A user is treated as an object, and a QQ group as a graph instance. The users in one group are connected by their friendship. The attribute matrix X is filled with the attribute values of the users. The statistics of the graph instances are listed in Table 5. We build the hierarchical graph from the graph instances via common members across groups. That is, if groups A and B have more than one common member, we connect them.

4.3.2 Baselines and Metrics. We use the same set of baselines as in Section 4.2.3. 1000 graph instances are used as labeled training instances for all methods except SEAL-AI and active-SAGE-Cheby, for which only 500 are used as labeled training instances at hand and then B is set to 500 for active learning. We use 10,000 instances for testing for all methods. We run each method 3 times and report its average accuracy. The hyperparameters of SAGE are the same as the settings in Section 4.1.1. Since the class distribution is quite imbalanced in this data set, we report the Macro-F1 instead of accuracy.

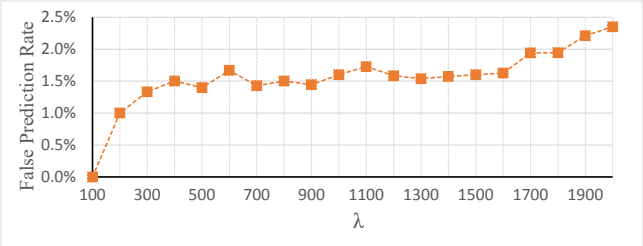

Figure 7: The false prediction rate of GCN with λ in SEAL-CI.

Table 6: Comparison of different methods on Tencent QQ group data for semi-supervised graph classification

	Algorithm	Macro-F1
*1	**GK-SVM**	48.8%
	WL-SVM	47.8%
*2	**graph2vec-GCN**	48.1%
*3	**cautious-SAGE-Cheby**	64.3%
	active-SAGE-Cheby	66.7%
*4	**SAGE**	54.7%
	SEAL-CI	70.8%
	SEAL-AI	**73.2%**

4.3.3 Results. Table 6 shows the experimental results. SEAL-C/AI outperform GK, WL and grah2vec by at least 12% in Macro-F1. Within our framework, GCN is better than Cheby-GCN for about 6%. SEAL-AI outperforms SEAL-CI by 2.4%. Next we provide the reason why SEAL-AI outperforms SEAL-CI on this data set. Figure 7 shows the false prediction rate (i.e., the percentage of misclassified instances) within the λ most confident predictions of GCN. As we can see, the false prediction rate increases as λ increases and it reaches 2.4% when $\lambda = 2000$. In the framework of SEAL-CI, as the iteration goes on, we shall bring in more noise to the parameter update of SAGE, while all the training samples in SEAL-AI are informative and correct. This explains why SEAL-AI outperforms SEAL-CI on this Tencent QQ group data.

4.3.4 Visualization. We provide visualization of a "game" group and its neighborhood in Figure 8. The left part is the ego network of the center "game" group. In the one-hop neighborhood of this "game" group, there are 10 "game" groups and 19 "non-game" groups. "Game" groups are densely interconnected with a density of 34.5%, whereas "non-game" groups are sparsely connected with a density of 8.8%. The much higher density among "game" groups validates that common membership is an effective way to relate them in a hierarchical graph for classification. The right part depicts the internal structure of the ego "game" group with 22 users. A bigger node indicates a larger importance, and a darker green color implies a larger node degree. These 22 members are loosely connected and there are no triangles. This makes sense because in reality online "game" groups are not acquaintance networks. Regarding

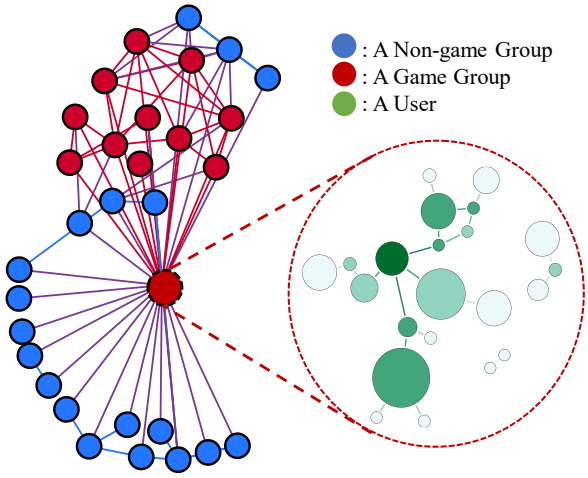

Figure 8: The ego network of a "game" group. The left side is the ego network, in which "game" groups are in red and "non-game" groups are in blue. The right side is the internal structure of the ego "game" group, in which a bigger node indicates a larger importance, and a darker color implies a larger node degree.

the learned node importance, node 1 has the highest importance as it is the second active member and has a large degree in this group. Node 16 is also important since it has the highest degree in this group. The "border" member 5 has a big attention weight since it has the largest number of days ever since the registration day and is quite active in this group.

4.3.5 Discussion. How to construct a hierarchical graph from raw data is an open question. In the above experiment, we connect two QQ groups if they have more than one common member (i.e., > 1). When we change the threshold, it directly affects the edge density in the hierarchical graph, and may influence the classification performance. For example, if we connect two QQ groups when they have one common member or more (i.e., ≥ 1), the edge density is 2.8% compared with 0.27% in the first setting. A proper setting of this threshold is data dependent, and can be determined through a validation set.

5 RELATED WORK

This work is related to semi-supervised classification of networked data, variable-sized graph embedding and active learning.

Most work on semi-supervised learning for networked data aims to utilize the network structure to boost the learning performance. The assumption is that network context can provide additional information that is not covered by node attributes. Ever since the pioneer work of Sen et al. [27], Iterative Classification Algorithm (ICA) has become a paradigm for networked data with limited annotations. In ICA, for each node a local classifier takes the estimated labels of its neighborhood and its own features as input, and outputs a new estimated label. The iteration continues until adjacent estimations stabilize. In ALFNET [1], the authors first cluster the network nodes into several groups, and design a content-only classifier CO and a collective classifier CC. Based on the disagreement score of CO and CC in each iteration, a candidate instance set is generated from different clusters and labeled. Then both CO and CC are re-trained using the labeled set until convergence. One main difference between ICA and ALFNET is that ICA does not require human intervention while ALFNET needs human annotation in case labels of the candidate set are not available.

Recent work has focused on using deep learning neural networks to further improve the performance. [34] leverages both network context and node features by jointly training node embedding to predict the class label and the context of the network. Later Kipf and Welling [16] simplify the loss design by only considering the supervised loss while network context is exploited by the GCN operator. Our problem setting is different from all of the above, as the node is no longer a fixed-size feature vector but a variable-size graph. It can be regarded as a generalization of the previous setting, and cannot be handled by existing solutions effectively.

Representation learning on graphs has been proposed to transform instances in topological space into fixed-size vectors in Euclidean space in which geometric distance reflects their structural similarity. There are two trends on this topic, one of which is a shift from node embedding [10, 24] to whole graph embedding. [33] uses CBOW and skip-gram model [21], previously proven to be successful in natural language processing, to learn a new graph kernel. Meanwhile, some other methods focus on generating graph embeddings by integrating node embeddings. [23] proposes a spatial-based graph CNN operator and then concatenates these obtained node representations by imposing a problem-specific node ordering. [6] defines a "graph coarsening" operation by first clustering the node representations and then applying a max-pooling operation. However, all these methods need some preprocessing steps such as node ordering or clustering, which is not a necessity from a data-driven perspective. Another trend is a shift from unsupervised embedding [21] to supervised embedding [5, 18], which provides better performance for downstream classification tasks. In this sense, our embedding method SAGE performs whole graph embedding in a supervised way.

Active learning has been integrated in many collective classification methods [1, 28] to find the most informative samples to be labeled. However, research that generalizes active learning with deep semi-supervised learning is still lacking. The closest work is [35] in which the authors utilize active learning to incrementally fine-tune a CNN network for image classification. Our solution SEAL-AI is different in the sense that the informative samples selected by active learning are used to update the parameters of the graph embedding network, whose output is then fed into HC in an iterative framework.

6 CONCLUSION

In this paper, we study semi-supervised graph classification from a hierarchical graph perspective. The hierarchical graph is a much too complicated input for classification, thus we first design a supervised, self-attentive graph embedding method SAGE to embed graph instances into fixed-length vectors, which are a common input form for classification. We build two classifiers IC and HC at the

graph instance level and the hierarchical graph level respectively to fully exploit the available information. Our semi-supervised solutions SEAL-C/AI adopt an iterative framework to update IC and HC alternately with an enlarged training set. Experimental results on synthetic graphs and Tencent QQ group data show that SEAL-C/AI outperform other competitors by a significant margin in accuracy/Macro-F1, and they also generate meaningful interpretations of the learned representations for graph instances.

ABSTRACT

A fundamental question in any peer-to-peer ridesharing system is how to, both effectively and efficiently, dispatch user's ride requests to the right driver in real time. Traditional rule-based solutions usually work on a simplified problem setting, which requires a sophisticated hand-crafted weight design for either centralized authority control or decentralized multi-agent scheduling systems. Although recent approaches have used reinforcement learning to provide centralized combinatorial optimization algorithms with informative weight values, their single-agent setting can hardly model the complex interactions between drivers and orders. In this paper, we address the order dispatching problem using multi-agent reinforcement learning (MARL), which follows the distributed nature of the peer-to-peer ridesharing problem and possesses the ability to capture the stochastic demand-supply dynamics in large-scale ridesharing scenarios. Being more reliable than centralized approaches, our proposed MARL solutions could also support fully distributed execution through recent advances in the Internet of Vehicles (IoV) and the Vehicle-to-Network (V2N). Furthermore, we adopt the mean field approximation to simplify the local interactions by taking an average action among neighborhoods. The mean field approximation is capable of globally capturing dynamic demand-supply variations by propagating many local interactions between agents and the environment. Our extensive experiments have shown the significant improvements of MARL order dispatching algorithms over several strong baselines on the accumulated driver income (ADI), and order response rate measures. Besides, the simulated experiments with real data have also justified that our solution can alleviate the supply-demand gap during the rush hours, thus possessing the capability of reducing traffic congestion.

1 INTRODUCTION

Real-time ridesharing refers to the task of helping to arrange one-time shared rides on very short notice [4, 10]. Such technique, embedded in popular platforms including Uber, Lyft, and DiDi Chuxing, has greatly transformed the way people travel nowadays. By exploiting the data of individual trajectories in both space and time dimensions, it offers more efficiency on traffic management, and the traffic congestion can be further alleviated as well [18].

One of the critical problems in large-scale real-time ridesharing systems is how to dispatch orders, i.e., to assign orders to a set of active drivers on a real-time basis. Since the quality of order dispatching will directly affect the utility of transportation capacity, the amount of service income, and the level of customer satisfaction, therefore, solving the problem of order dispatching is the key to any successful ride-sharing platform. In this paper, our goal is to develop an intelligent decision system to maximize the accumulated driver income (ADI), i.e., the value of all the orders served in a single day, with the ability to scale up to a large number of drivers and robust to potential hardware or connectivity failures. The challenge of order dispatching is to find an optimal trade-off between the short-term and long-term rewards. When the number of available orders is larger than that of active drivers within the order broadcasting area (shown as the grey shadow area in the center of Fig. 1b), the problem turns into finding an optimal order choice for each driver. Taking an order with a higher price will contribute to the immediate income; however, it might also harm the ADI in the long run if this order takes the driver to a sparsely populated area. As illustrated in Fig. 1a, considering the two orders starting from the same area but to two different destinations, a neighboring central business district (CBD) and a distant suburb. A driver taking the latter one may have a higher one-off order price due to the longer travel distance, but the subsequent suburban area with little demand could also prevent the driver from further sustaining income. Dispatching too many such orders will, therefore, reduce the number of orders taken and harm the long-term ADI. The problem becomes more serious

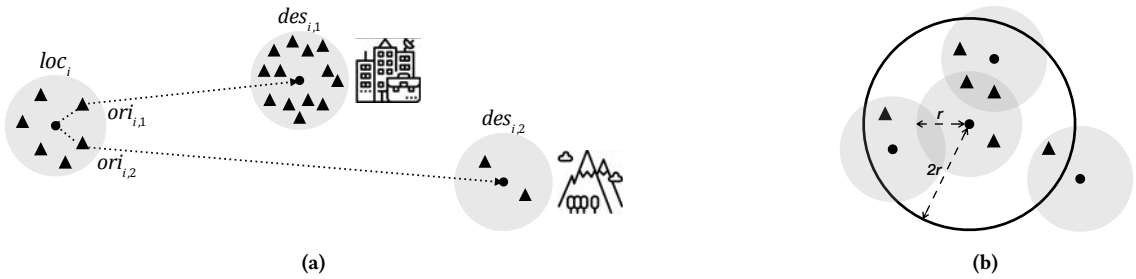

Figure 1: The order dispatching problem. (a) Two order choices (black triangle, departing from $ori_{i,1}$ and $ori_{i,2}$ respectively) within a driver i's (black dot, located at loc_i) order receiving area (grey shadow), where one ends at a neighboring CBD (located at $des_{i,1}$) with high demand, and the other ends at a distant suburb (located at $des_{i,2}$) with low demand. Both orders have the same pick-up distance for driver i. (b) Details within a neighborhood, where the radius of the order receiving area and the neighborhood (black circle) are r and $2r$ respectively.

particularly during the peak hours when the situation in places with the imbalance between vehicle supply and order demand gets worse. As such, an intelligent order dispatching system should be designed to not only assign orders with high prices to the drivers, but also to anticipate the future demand-supply gap and distribute the imbalance among different destinations. In the meantime, the pick-up distance should also be minimized, as the drivers will not get paid during the pick-up process; on the other hand, long waiting time will affect the customer experience.

One direction to tackle the order dispatching challenge has been to apply hand-crafted features to either centralized dispatching authorities (e.g., the combinatorial optimization algorithm [28, 45]) or distributed multi-agent scheduling systems [3, 40], in which a group of autonomous agents that share a common environment interact with each other. However, the system performance relies highly on the specially designed weighting scheme. For centralized approaches, another critical issue is the potential "single point of failure" [23], i.e., the failure of the centralized authority control will fail the whole system. Although the multi-agent formulation provides a distributed perspective by allowing each driver to choose their order preference independently, existing solutions require rounds of direct communications between agents during execution [30], thus being limited to a local area with a few agents.

Recent attempts have been made to formulate this problem with centralized authority control and model-free reinforcement learning (RL) [33], which learns a policy by interacting with a complex environment. However, existing approaches [41] formulate the order dispatching problem with the single-agent setting, which is unable to model the complex interactions between drivers and orders, thus being oversimplifications of the stochastic demand-supply dynamics in large-scale ridesharing scenarios. Also, executing an order dispatching system in a centralized manner still suffers from the reliability issue mentioned above that is generally inherent to the centralized architecture.

Staying different from these approaches, in this work we model the order dispatching problem with multi-agent reinforcement learning (MARL) [7], where agents share a centralized judge (the critic) to rate their decisions (actions) and update their strategies (policies). The centralized critic is no longer needed during the execution period as agents can follow their learned policies independently, making the order dispatching system more robust to potential hardware or connectivity failures. With the recent development of the Internet of Things (IoT) [5, 11, 44] and the Internet of Vehicles (IoV) [22, 42], the fully distributed execution could be practically deployed by distributing the centralized trained policy to each vehicle through the Vehicle-to-Network (V2N) [1]. By allowing each driver to learn by maximizing its cumulative reward through time, the reinforcement learning based approach relieves us from designing a sophisticated weighting scheme for the matching algorithms. Also, the multi-agent setting follows the distributed nature of the peer-to-peer ridesharing problem, providing the dispatching system with the ability to capture the stochastic demand-supply dynamics in large-scale ridesharing scenarios. Meanwhile, such fully distributed executions also enable us to scale up to much larger scenarios with many more agents, i.e., a scalable real-time order dispatching system for ridesharing services with millions of drivers.

Nonetheless, the major challenge in applying MARL to order dispatching lies in the changing dynamics of two components: the size of the action set and the size of the population. As illustrated in Fig. 1b, the action set for each agent is defined as a set of neighboring active orders within a given radius r from each active driver (shown as the shadow area around each black dot). As the active orders will be taken and new orders keep arriving, the size and content of this set will constantly change over time. The action set will also change when the agent moves to another location and arrives in a new neighborhood. On the other hand, drivers can also switch between online and offline in the real-world scenario, the population size for the order dispatching task is therefore also changing over time.

In this paper, we address the two problems of variable action sets and population size by extending the actor-critic policy gradient methods. Our methods tackle the order dispatching problem within the framework of centralized training with decentralized execution. The critic is provided with the information from other agents to incorporate the peer information, while each actor behaves independently with local information only. Our major contributions are listed as follows:

- We propose the MARL-based *independent order dispatching* (IOD) algorithm to solve the issue of changing action set, where we use the vectorized features of each order as the

network input to generate a set of ranking values to choose an order.
- We propose the *cooperative order dispatching* (COD) algorithm, an extension of IOD to resolve the variable population size, where we adopt the mean field approximation to transform the interactions between agents to the pairwise interaction between an agent and the average response from a sub-population in the neighborhood.
- We provide the convergence proof of mean field reinforcement learning algorithms with function approximations to justify our algorithm in theory.

Experiments on the large-scale simulator show that compared with variant multi-agent learning benchmarks, the mean field multi-agent reinforcement learning algorithm gives the best performance towards the accumulated driver income, the order response rate, and the average pick-up distance. Besides the state of the art performance, our solution also enjoys the advantage of distributed execution, which has lower latency and is easily adaptable to be deployed in the real world application.

2 METHOD

In this section, we first illustrate our definition of order dispatching as a Markov game, and discuss two challenges when applying MARL to this game. We then propose a MARL approach with the independent Q-learning, namely the independent order dispatching algorithm (IOD), to solve this game. By extending IOD with mean field approximations, which capture dynamic demand-supply variations by propagating many local interactions between agents and the environment, we finally propose the cooperative order dispatching algorithm (COD).

2.1 Order Dispatching as a Markov Game

2.1.1 Game Settings. We model the order dispatching task by a Partially Observable Markov Decision Process (POMDP) [20] in a fully cooperative setting, defined by a tuple $\Gamma = \langle \mathcal{S}, \mathcal{P}, \mathcal{A}, \mathcal{R}, \mathcal{O}, N, \gamma \rangle$, where $\mathcal{S}, \mathcal{P}, \mathcal{A}, \mathcal{R}, \mathcal{O}, N, \gamma$ are the sets of states, transition probability functions, sets of joint actions, reward functions, sets of private observations, number of agents, and a discount factor respectively. Given two sets $\mathcal{X}$ and $\mathcal{Y}$, we use $\mathcal{X} \times \mathcal{Y}$ to denote the Cartesian product of $\mathcal{X}$ and $\mathcal{Y}$, i.e., $\mathcal{X} \times \mathcal{Y} = \{(x, y) | x \in \mathcal{X}, y \in \mathcal{Y}\}$. The definitions are given as follows:

- N: N homogeneous agents identified by $i \in \mathcal{I} \equiv \{1, ..., N\}$ are defined as the active drivers in the environment. As the drivers can switch between online and offline via a random process, the number of agents N could change over time.
- $\mathcal{S}, \mathcal{O}$: At each time step t, agent i draws private observations $o_i^t \in \mathcal{O}$ correlated with the true environment state $s^t \in \mathcal{S}$ according to the observation function $\mathcal{S} \times \mathcal{I} \to \mathcal{O}$. The initial state of the environment is determined by a distribution $p_1(s^1) : \mathcal{S} \to [0, 1]$. A typical environmental state s includes the order and driver distribution, the global timestamp, and other environment dynamics (traffic congestion, weather conditions, etc.). In this work, we define the observation for each agent i with three components: agent i's location loc_i, the timestamp t, and an on-trip flag to show if agent i is available to take new orders.
- $\mathcal{P}, \mathcal{A}$: In the order dispatching task, each driver can only take active orders within its neighborhood (inside a given radius, as illustrated in Fig. 1b). Hence, agent i's action set $\mathcal{A}_i$ is defined as its own active order pool based on the observation o_i. Each action candidate $a_{i,m} \in \mathcal{A}_i$ is parameterized by the normalized vector representation of corresponding order's origin $ori_{i,m}$ and destination $des_{i,m}$, i.e., $a_{i,m} \equiv [ori_{i,m}, des_{i,m}]$. At time step t, each agent takes an action $a_i^t \in \mathcal{A}_i$, forming a set of joint driver-order pair $\mathbf{a}^t = \mathcal{A}_1 \times ... \times \mathcal{A}_N$, which induces a transition in the environment according to the state transition function

$$\mathcal{P}(s^{t+1} | s^t, \mathbf{a}^t) : \mathcal{S} \times \mathcal{A}_1 \times ... \times \mathcal{A}_N \to \mathcal{S}. \tag{1}$$

  For simplicity, we assume no order cancellations and changes during the trip, i.e., a_i^t keeps unchanged if agent i is on its way to the destination.
- $\mathcal{R}$: Each agent i obtains rewards r_i^t by a reward function

$$\mathcal{R}_i(s^t, \mathbf{a}^t) : \mathcal{S} \times \mathcal{A}_1 \times ... \times \mathcal{A}_N \to \mathbb{R}. \tag{2}$$

  As described in Section 1, we want to maximize the total income by considering both the charge of each order and the potential opportunity of the destination. The reward is then defined as the combination of driver i's own income ${}^0r$ from its order choice and the order destination potential ${}^1r$, which is determined by all agents' behaviors in the environment. Considering the credit-assignment problem [2] arises in MARL with many agents, i.e., the contribution of an agent's behavior is drowned by the noise of all the other agents' impact on the reward function, we set each driver's own income instead of the total income of all drivers as the reward. To encourage cooperation between agents and avoid agents' being selfish and greedy, we use the order destination's demand-supply gap as a constraint ${}^1r$ on the behavior of agents. Precisely, we compare the demand-supply status between the order origin and destination, and encourage the driver to choose the order destination with a larger demand-supply gap. The order destination potential (DP) is defined as

$$DP = \#DD - \#DS, \tag{3}$$

  where #DD and #DS is the demand and the supply of the destination respectively. We consider the DP only if the number of orders are larger than that of drivers at the origin. If the order destination has more drivers than orders, we penalize this order with the demand-supply gap at the destination, and vice versa.

  To provide better customer experience, we also add the pick-up distance ${}^2r$ as a regularizer. The ratio of the DP and the pick-up distance to order price are defined as ${}^1\alpha$ and ${}^2\alpha$ respectively, i.e., $r_i^t = {}^0r_i^t + {}^1\alpha^1 r_i^t + {}^2\alpha^2 r_i^t$. We typically choose the regularization ratio to scale different reward terms into approximately the same range, although in practice a grid-search could be used to get better performance. The effectiveness of our reward function setting is empirically verified in Section 3.1.3.
- γ: Each agent i aims to maximize its total discounted reward

$$G_i^t = \sum_{k=t}^{\infty} \gamma^{k-t} r_i^k \tag{4}$$

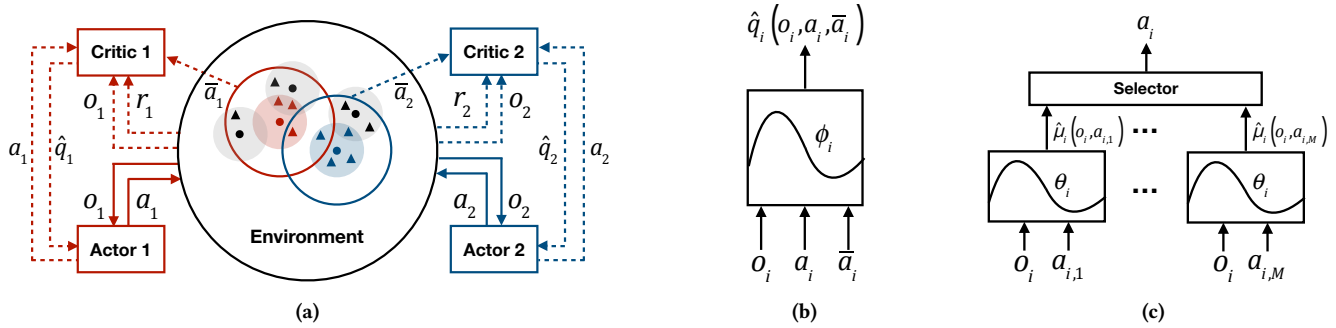

Figure 2: Overview of our COD approach. (a) The information flow between RL agents and the environment (shown with two agents). The centralized authority is only needed during the training stage (dashed arrows) to gather the average response $\bar{a}$; agents could behave independently during the execution stage (solid arrows), thus being robust to the "single point of failure". (b) and (c) Architectures of the critic and the actor.

from time step t onwards, where $\gamma \in [0, 1]$ is the discount factor.

We denote joint quantities over agents in bold, and joint quantities over agents other than a given agent i with the subscript $-i$, e.g., $\boldsymbol{a} \equiv (\boldsymbol{a}^t_{-i}, a^t_i)$. To stabilize the training process, we maintain an experience replay buffer $\mathcal{D}$ containing tuples $(\boldsymbol{o}^t, \boldsymbol{a}^t, \boldsymbol{r}^t, \boldsymbol{o}^{t+1})$ as described in [26].

2.1.2 Dynamic of the Action Set Elements. In the order dispatching problem, an action is defined as an active order within a given radius from the agent. Hence, the content and size of the active order pool for each driver are changing with both the location and time, i.e., the action set for an agent in the order dispatching MDP is changing throughout the training and execution process. This aspect of order dispatching refrains us from using the Q-table to log the Q-value because of the potentially infinite size of the action set. On the other hand, a typical policy network for stochastic actions makes use of a softmax output layer to produce a set of probabilities of choosing each action among a fixed set of action candidates, thus is unable to fit into the order dispatching problem.

2.1.3 Dynamic of the Population Size. To overcome the non-stationarity of the multi-agent environment, Lowe et al. [21] uses Q-Learning to approximate the discounted reward G^t_i, and rewrites the gradient of the expected return for agent i following a deterministic policy μ_i (parameterized by θ_i) as

$$\nabla_{\theta_i} J(\theta_i) = \mathbb{E}_{\boldsymbol{o},\boldsymbol{a}\sim\mathcal{D}}[\nabla_{\theta_i}\mu_i(a_i|o_i)\nabla_{a_i}Q_i(o_i,\boldsymbol{a})]. \tag{5}$$

Here $Q_i(o_i, \boldsymbol{a})$ is a centralized action-value function that takes as input the observation o_i of agent i and the joint actions $\boldsymbol{a}$ of all agents, and outputs the Q-value for agent i. However, as off-line drivers cannot participate in the order dispatching procedure, the number of agents N in the environment is changing over time. Also, in a typical order dispatching task, which involves thousands of agents, the high dynamics of interactions between a large number of agents is intractable. Thus, a naive concatenation of all other agents' actions cannot form a valid input for the value network and is not applicable to the order dispatching task.

2.2 Independent Order Dispatching

To solve the order dispatching MDP, we first propose the independent order dispatching algorithm (IOD), a straightforward MARL approach with the independent Q-learning. We provide each learner with the actor-critic model, which is a popular form of policy gradient (PG) method. For each agent i, PG works by directly adjusting the parameters θ_i of the policy μ_i to maximize the objective $J(\theta_i) = \mathbb{E}_{\boldsymbol{o},\boldsymbol{a}\sim\mathcal{D}}\left[G^t_i\right]$ by taking steps in the direction of $\nabla_{\theta_i} J(\theta_i)$. In MARL, independent actor-critic uses the action-value function $Q_i(o_i, a_i)$ to approximate the discounted reward G^t_i by Q-Learning [39]. Here we use temporal-difference learning [32] to approximate the true $Q_i(o_i, a_i)$, leading to a variety of actor-critic algorithms with $Q_i(o_i, a_i)$ called as the critic and μ_i called as the actor.

To solve the problem of variable action sets, we use a policy network with both observation and action embeddings as the input, derived from the in-action approximation methods (shown in Fig. 2b). As illustrated in Fig. 2c, we use a deterministic policy μ_{θ_i} (denoted by $\mu_{\theta_i} : \mathcal{O} \times \mathcal{A} \to \mathbb{R}^*$, abbreviated as μ_i) to generate ranking values of each observation-action pair $(o_i, a_{i,m})$ for each of the M_i candidates within agent i's action set $\mathcal{A}_i$. To choose an action a_i, these values are then fed into a Boltzmann softmax selector

$$\pi_i(a_{i,j}|o_i) = \frac{\exp(\beta\mu_i(o_i, a_{i,j}))}{\sum_{m=0}^{M_i}\exp(\beta\mu_i(o_i, a_{i,m}))}, \quad \text{for } j = 1, \ldots, M_i \tag{6}$$

where β is the inverse temperature to control the exploration rate. Note that a typical policy network with out-action approximation is equivalent to this approach, where we can use an M_i-dimension one-hot vector as the embedding to feed into the policy network. The main difference between these approaches is the execution efficiency, as we need exactly M_i forward passes in a single execution step. Meanwhile, using order features naturally provide us with an informative form of embeddings. As each order is parameterized by the concatenation of the normalized vector representation of its origin $ori_{i,m}$ and destination $des_{i,m}$, i.e., $a_{i,m} \equiv [ori_{i,m}, des_{i,m}]$. Similar orders will be close to each other in the vector space and produce similar outputs from the policy network, which improves the generalization ability of the algorithm.

Algorithm 1 Cooperative Order Dispatching (COD)

Initialize Q_{ϕ_i}, $Q^-_{\phi_i}$, μ_{θ_i}, and $\mu^-_{\theta_i}$ for all $i \in \{1, \dots, N\}$
while training not finished **do**
  For each agent i, sample action a_i using the Boltzmann softmax selector $\pi_i(a_i|o_i)$ from Eq. (6)
  Take the joint action $\boldsymbol{a} = [a_1, \dots, a_N]$ and observe the reward $\boldsymbol{r} = [r_1, \dots, r_N]$ and the next observations $\boldsymbol{o'}$
  Compute the new mean action $\bar{\boldsymbol{a}} = [\bar{a}_1, \dots, \bar{a}_N]$
  Store $\langle \boldsymbol{o}, \boldsymbol{a}, \boldsymbol{r}, \boldsymbol{o'}, \bar{\boldsymbol{a}} \rangle$ in replay buffer $\mathcal{D}$
  for $i = 1$ to N **do**
    Sample K experiences $\langle \boldsymbol{o}, \boldsymbol{a}, \boldsymbol{r}, \boldsymbol{o'}, \bar{\boldsymbol{a}} \rangle$ from $\mathcal{D}$
    Update the critic by minimizing the loss from Eq. (9)
    Update the actor using the policy gradient as Eq. (11)
  end for
  Update the parameters of the target networks for each agent i with updating rates τ_ϕ and τ_θ:

$$\phi^-_i \leftarrow \tau_\phi \phi_i + (1 - \tau_\phi)\phi^-_i$$
$$\theta^-_i \leftarrow \tau_\theta \theta_i + (1 - \tau_\theta)\theta^-_i$$

end while

In IOD, each critic takes input the observation embedding o_i by combining agent i's location and the timestamp t. The action embedding is built with the vector representation of the order destination and the distance between the driver location and the order origin. The critic is a DQN [26] using neural network function approximations to learn the action-value function Q_ϕ (parameterized by ϕ, abbreviated as Q_i for each agent i) by minimizing the loss

$$\mathcal{L}(\phi_i) = \mathbb{E}_{\boldsymbol{o}, \boldsymbol{a}, \boldsymbol{r}, \boldsymbol{o'}}[(y - Q_i(o_i, a_i))^2], \quad y = r_i + \gamma\, Q^-_i(o'_i, \mu^-_i(o'_i, a'_i)), \tag{7}$$

where Q^-_i is the target network for the action-value function, and μ^-_i is the target network for the deterministic policy. These earlier snapshots of parameters are periodically updated with the most recent network weights and help increase learning stability by decorrelating predicted and target Q-values and deterministic policy values.

Following Silver et al. [31], the gradient of the expected return for agent i following a deterministic policy μ_i is

$$\nabla_{\theta_i} J(\theta_i) = \mathbb{E}_{\boldsymbol{o}, \boldsymbol{a} \sim \mathcal{D}}[\nabla_{\theta_i} \mu_i(o_i, a_i) \nabla_{a_i} Q_i(o_i, a_i)]. \tag{8}$$

Here $Q_i(o_i, a_i)$ is an action-value function that takes as input the observation o_i and action a_i, and outputs the Q-value for agent i.

2.3 Cooperative Order Dispatching with Mean Field Approximation

To fully condition on other agents' policy in the environment with variable population size, we propose to integrate our IOD algorithm with mean field approximations, following the Mean Field Reinforcement Learning (MFRL) [43]. MFRL addresses the scalability issue in the multi-agent reinforcement learning with a large number of agents, where the interactions are approximated pairwise by the interaction between an agent and the average response $\bar{a}$ from a sub-population in the neighborhood. As this pairwise approximation shadows the exact size of interacting counterparts, the use of mean field approximation can help us model other agents' policies directly in the environment with variable population sizes.

In the order dispatching task, agents are interacting with each other by choosing order destinations with a high demand to optimize the demand-supply gap. As illustrated in Fig. 1b, the range of the neighborhood is then defined as twice the length of the order receiving radius, because agents within this area have intersections between their action sets and interact with each other. The average response $\bar{a}_i$ is therefore defined as the number of drivers arriving at the same neighborhood as agent i, divided by the number of available orders for agent i. For example, when agent i finishes the order and arrives at the neighborhood in Fig. 1b (the central agent), the average response $\bar{a}_i$ is 2/3, as there are two agents within the neighborhood area and three available orders.

The introduction of mean field approximations enables agents to learn with the awareness of interacting counterparts, thus helping to improve the training stability and robustness of agents after training for the order dispatching task. Note that the average response $\bar{a}$ only serves for the model update; thus the centralized authority is only needed during the training stage. During the execution stage, agents could behave in a fully distributed manner, thus being robust to the "single point of failure".

We propose the cooperative order dispatching algorithm (COD) as illustrated in Fig. 2a, and present the pseudo code for COD in Algorithm 1. Each critic is trained by minimizing the loss

$$\mathcal{L}(\phi_i) = \mathbb{E}_{\boldsymbol{o}, \boldsymbol{a}, \boldsymbol{r}, \boldsymbol{o'}}[(r_i + \gamma\, v^{\mathsf{MF}}_{i^-}(o'_i) - Q_i(o_i, (\bar{a}_i, a_i)))^2], \tag{9}$$

where $v^{\mathsf{MF}}_{i^-}(o'_i)$ is the mean field value function for the target network Q^-_i and μ^-_i (shown as the Boltzmann selector π^-_i from Eq. 6)

$$v^{\mathsf{MF}}_{i^-}(o'_i) = \sum\nolimits_{a'_i} \pi^-_i(a'_i|o'_i) \mathbb{E}_{\bar{a}'_i(\boldsymbol{a}'_{-i}) \sim \boldsymbol{\pi}^-_{-i}}[Q^-_i(o'_i, (\bar{a}'_i, a'_i))], \tag{10}$$

and $\bar{a}_i$ is the average response within agent i's neighborhood. The actor of COD learns the optimal policy by using the policy gradient:

$$\nabla_{\theta_i} J(\theta_i) = \mathbb{E}_{\boldsymbol{o}, \boldsymbol{a} \sim \mathcal{D}}[\nabla_{\theta_i} \mu_i(o_i, a_i) \nabla_{a_i} Q_i(o_i, (\bar{a}_i, a_i))]. \tag{11}$$

In the current decision process, active agents sharing duplicated order receiving areas (e.g., the central and upper agent in Fig. 1b) might select the same order following their own strategy. Such collisions could lead to invalid order assignment and force both drivers and customers to wait for a certain period, which equals to the time interval between each dispatching iteration. Observe that the time interval of decision-making also influences the performance of dispatching; a too long interval will affect the passenger experience, while a too short interval without enough order candidates is not conducive to the decision making. To solve this problem, our approach works in a fully distributed manner with asynchronous dispatching strategy, allowing agents have different decision time interval for individual states, i.e., agents assigned with invalid orders could immediately re-choose a new order from updated candidates pool.

To theoretically support the efficacy of our proposed COD algorithm, we provide the convergence proof of MFRL with function approximations as shown below.

2.4 Convergence of Mean Field Reinforcement Learning with Function Approximations

Inspired by the previous proof of MFRL convergence in a tabular Q-function setting [43], we further develop the proof towards the converge when the Q-function is represented by other function approximators. In addition to the Markov Game setting in Section 2.1.1, let $\mathcal{Q} = \{\boldsymbol{Q}_\phi\}$ be a family of real-valued functions defined on $\mathcal{S} \times \mathcal{A} \times \bar{\mathcal{A}}$, where $\bar{\mathcal{A}}$ is the action space for the mean actions computed from the neighbors. For simplicity, we assume the environment is a fully observable MDP Γ, i.e., each agent $i \in \mathcal{I} \equiv \{1, ..., N\}$ can observe the global state s instead of the local observation o_i.

Assuming that the function class is linearly parameterized, for each agent i, the Q-function can be expressed as the linear span of a fixed set of P linearly independent functions $\omega_i^p : \mathcal{S} \times \mathcal{A} \times \bar{\mathcal{A}} \to \mathbb{R}$. Given the parameter vector $\phi_i \in \mathbb{R}^P$, the function Q_{ϕ_i} (abbreviated as Q_i) is thus defined as

$$Q_i(s, (\bar{a}_i, a_i)) = \sum_{p=1}^{P} \omega_i^p(s, (\bar{a}_i, a_i))\phi_i(p) = \omega_i(s, (\bar{a}_i, a_i))^\top \phi_i. \quad (12)$$

In the function approximation setting, we apply the update rules:

$$\phi_i' = \phi_i + \alpha\Delta\nabla_{\phi_i} Q_i(s, (\bar{a}_i, a_i)) = \phi_i + \alpha\Delta\omega_i(s, (\bar{a}_i, a_i)), \quad (13)$$

where Δ is the temporal difference:

$$\begin{aligned}\Delta &= r_i + \gamma\, v_i^{\mathsf{MF}}(s') - Q_i(s, (\bar{a}_i, a_i)) \\ &= r_i + \gamma\, \mathbb{E}_{\boldsymbol{a}\sim\boldsymbol{\pi}^{\mathsf{MF}}}[Q_i(s', (\bar{a}_i, a_i))] - Q_i(s, (\bar{a}_i, a_i)). \end{aligned} \quad (14)$$

Our goal is to derive the parameter vector $\boldsymbol{\phi} = \{\phi_i\}$ such that $\boldsymbol{\omega}^\top\boldsymbol{\phi}$ approximates the (local) Nash Q-values. Under the main assumptions and the lemma as introduced below, Yang et al. [43] proved that the policy $\boldsymbol{\pi}$ is $\frac{K}{2T}$ Lipschitz continuous with respect to ϕ, where $T = 1/\beta$ and $K \geq 0$ is the upper bound of the observed reward.

Assumption 1. *Each state-action pair is visited infinitely often, and the reward is bounded by some constant K.*

Assumption 2. *Agent's policy is Greedy in the Limit with Infinite Exploration (GLIE). In the case with the Boltzmann policy, the policy becomes greedy* w.r.t. *the Q-function in the limit as the temperature decays asymptotically to zero.*

Assumption 3. *For each stage game $[Q_t^1(s), ..., Q_t^N(s)]$ at time t and in state s in training, for all t, s, $j \in \{1, \ldots, N\}$, the Nash equilibrium $\boldsymbol{\pi}_* = [\pi_*^1, \ldots, \pi_*^N]$ is recognized either as 1) the* global optimum *or 2) a* saddle point *expressed as:*

1. $\mathbb{E}_{\boldsymbol{\pi}_*}[Q_t^j(s)] \geq \mathbb{E}_{\boldsymbol{\pi}}[Q_t^j(s)],\ \forall\boldsymbol{\pi} \in \Omega\Big(\prod_k \mathcal{A}^k\Big)$;
2. $\mathbb{E}_{\boldsymbol{\pi}_*}[Q_t^j(s)] \geq \mathbb{E}_{\pi^j}\mathbb{E}_{\boldsymbol{\pi}_*^{-j}}[Q_t^j(s)],\ \forall\pi^j \in \Omega\big(\mathcal{A}^j\big)$ *and* $\mathbb{E}_{\boldsymbol{\pi}_*}[Q_t^j(s)] \leq \mathbb{E}_{\pi_*^j}\mathbb{E}_{\boldsymbol{\pi}^{-j}}[Q_t^j(s)],\ \forall\boldsymbol{\pi}^{-j} \in \Omega\Big(\prod_{k\neq j} \mathcal{A}^k\Big)$.

Lemma 2.1. *The random process $\{\Delta_t\}$ defined in $\mathbb{R}$ as*

$$\Delta_{t+1}(x) = (1 - \alpha_t(x))\Delta_t(x) + \alpha_t(x)F_t(x)$$

converges to zero with probability 1 (w.p.1) *when*

1. $0 \leq \alpha_t(x) \leq 1$, $\sum_t \alpha_t(x) = \infty$, $\sum_t \alpha_t^2(x) < \infty$;
2. $x \in \mathcal{X}$, *the set of possible states, and* $|\mathcal{X}| < \infty$;
3. $\|\mathbb{E}[F_t(x)|\mathcal{F}_t]\|_W \leq \gamma\|\Delta_t\|_W + c_t$, *where* $\gamma \in [0, 1)$ *and* c_t *converges to zero* w.p.1;
4. $\mathbf{var}[F_t(x)|\mathcal{F}_t] \leq K(1 + \|\Delta_t\|_W^2)$ *with constant* $K > 0$.

Here $\mathcal{F}_t$ denotes the filtration of an increasing sequence of σ-fields including the history of processes; $\alpha_t, \Delta_t, F_t \in \mathcal{F}_t$ and $\|\cdot\|_W$ is a weighted maximum norm [6].

Proof. See Theorem 1 in Jaakkola et al. [13] and Corollary 5 in Szepesvári and Littman [35] for detailed derivation. We include it here to stay self-contained. □

In contrast to the previous work Yang et al. [43], we establish convergence of Eq. (13) by adopting an ordinary differentiable equation (ODE) with a globally asymptotically stable equilibrium point where the trajectories closely follow, following the framework of the convergence proof of single-agent Q-learning with function approximation [25].

Theorem 2.2. *Given the MDP Γ, $\{\boldsymbol{\omega}_p, p = 1, ..., P\}$, and the learning policy $\boldsymbol{\pi}$ that is $\frac{K}{2T}$ Lipschitz continuous with respect to ϕ, if the Assumptions 1, 2 & 3, and Lemma 2.1's first and second conditions are met, then there exists C_0 such that the algorithm in Eq.* (13) *converges w.p.1 if $\frac{K}{2T} < C_0$.*

Proof. We first re-write the Eq. (13) as on ODE:

$$\begin{aligned}\frac{d\boldsymbol{\phi}}{dt} &= \mathbb{E}_{\boldsymbol{\phi}}\left[\boldsymbol{\omega}_s^\top\left(\boldsymbol{r}(s, \boldsymbol{a}, s') + \gamma\boldsymbol{\omega}_{s'}^\top\boldsymbol{\phi} - \boldsymbol{\omega}_s^\top\boldsymbol{\phi}\right)\right] \\ &= \mathbb{E}_{\boldsymbol{\phi}}\left[\boldsymbol{\omega}_s^\top(\gamma\boldsymbol{\omega}_{s'}^\top - \boldsymbol{\omega}_s^\top)\right]\boldsymbol{\phi} + \mathbb{E}_{\boldsymbol{\phi}}\left[\boldsymbol{\omega}_s^\top(\boldsymbol{r}(s, \boldsymbol{a}, s'))\right] \\ &= \boldsymbol{A}_\phi\boldsymbol{\phi} + \boldsymbol{b}_\phi \end{aligned} \quad (15)$$

Notice that we use a vector for considering the updating rule for the Q-function of each agent. We can easily know that necessity condition of the equilibrium is $\boldsymbol{\phi}^* = \boldsymbol{A}_{\phi^*}^{-1}\boldsymbol{b}_{\phi^*}$. The existence of the such equilibrium has been restricted in the scenario that meets Assumption 3. Yang et al. [43] proved that under the Assumption 3, the existing equilibrium, either in the form of a global equilibrium or in the form of a saddle-point equilibrium, is unique.

Let $\tilde{\boldsymbol{\phi}} = \boldsymbol{\phi}^t - \boldsymbol{\phi}^*$, we have:

$$\begin{aligned}\frac{d}{dt}||\tilde{\boldsymbol{\phi}}||_2 &= 2\boldsymbol{\phi}\cdot\frac{d\boldsymbol{\phi}}{dt} - 2\boldsymbol{\phi}^*\cdot\frac{d\boldsymbol{\phi}}{dt} \\ &= 2\tilde{\boldsymbol{\phi}}^\top(\boldsymbol{A}_\phi\boldsymbol{\phi} + \boldsymbol{b}_\phi - \boldsymbol{A}_{\phi^*}\boldsymbol{\phi}^* - \boldsymbol{b}_{\phi^*}) \\ &= 2\tilde{\boldsymbol{\phi}}^\top(\boldsymbol{A}_{\phi^*}\boldsymbol{\phi} - \boldsymbol{A}_{\phi^*}\boldsymbol{\phi} + \boldsymbol{A}_\phi\boldsymbol{\phi} + \boldsymbol{b}_\phi - \boldsymbol{A}_{\phi^*}\boldsymbol{\phi}^* - \boldsymbol{b}_{\phi^*}) \\ &= 2\tilde{\boldsymbol{\phi}}^\top\boldsymbol{A}_{\phi^*}\tilde{\boldsymbol{\phi}} + 2\tilde{\boldsymbol{\phi}}^\top(\boldsymbol{A}_\phi - \boldsymbol{A}_{\phi^*})\boldsymbol{\phi} + 2\tilde{\boldsymbol{\phi}}^\top(\boldsymbol{b}_\phi - \boldsymbol{b}_{\phi^*}) \\ &\leq 2\tilde{\boldsymbol{\phi}}^\top\left(\boldsymbol{A}_{\phi^*} + \sup_{\boldsymbol{\phi}}||\boldsymbol{A}_\phi - \boldsymbol{A}_{\phi^*}||_2 + \sup_{\boldsymbol{\phi}}\frac{||\boldsymbol{b}_\phi - \boldsymbol{b}_\phi^*||_2}{||\boldsymbol{\phi} - \boldsymbol{\phi}^*||_2}\right)\tilde{\boldsymbol{\phi}}. \end{aligned} \quad (16)$$
