Given as input a feature vector $\mathbf{v}$, the classifier outputs the following probabilities: $p(unrelated)$, $p(agree|related)$, $p(disagree|related)$, and $p(discuss|related)$. However, these last 3 probabilities are not comparable with the first one. To make them comparable we derive

Algorithm 1: Parameter update process based on the mini-batch gradient descent algorithm.

input : Sample mini-batch $\{\mathbf{v}_i, \mathbf{r}_i, \mathbf{s}_i\}_{i=1}^n$, mini-batch size n, hyperparameters α, β, and μ
output: θ_u, θ_r, θ_s, θ_d

begin
  Initialize θ_u, θ_r, θ_s, θ_d;
  repeat
    /* forward propagation */
    $l^r, l^s \leftarrow 0$;
    for *i from* 1 *to n* **do**
      $\mathbf{u}_i \leftarrow f(\mathbf{v}_i;\theta_u)$;
      $\hat{\mathbf{r}}_i \leftarrow g(\mathbf{u}_i;\theta_r)$;
      $l_i^r \leftarrow \mathrm{KL}(\mathbf{r}_i \| \hat{\mathbf{r}}_i)$;
      $l^r \leftarrow l^r + l_i^r$;
      if $\mathbf{r}_i \cdot (1,0) = 1$ **then**
        /* classify related */
        $\hat{\mathbf{s}}_i \leftarrow h(\hat{\mathbf{r}}_i \cdot (1,0);\theta_s)$;
        $l_i^s \leftarrow \mathrm{KL}(\mathbf{s}_i \| \hat{\mathbf{s}}_i)$;
      else
        /* unrelated */
        $l_i^s = 0$;
      $l^s \leftarrow l^s + l_i^s$;
    $d = \mathrm{MMD}(\{\mathbf{u}_i, \mathbf{r}_i\}_{i=1}^n;\theta_d)$;
    /* backward propagation */
    $\theta_s \leftarrow \theta_s - \mu \cdot \alpha \cdot \frac{\partial l^s}{\partial \theta_s}$;
    $\theta_r \leftarrow \theta_r - \mu \cdot (\frac{\partial l^r}{\partial \theta_r} + \alpha \cdot \frac{\partial l^s}{\partial \theta_r})$;
    $\theta_d \leftarrow \theta_d + \mu \cdot \beta \cdot \frac{\partial d}{\partial \theta_d}$;
    $\theta_u \leftarrow \theta_u - \mu \cdot (\frac{\partial l^r}{\partial \theta_u} + \alpha \cdot \frac{\partial l^s}{\partial \theta_u} - \beta \cdot \frac{\partial d}{\partial \theta_u})$;
  until θ_u, θ_r, θ_s, θ_d *converge*;

$p(agree)$, $p(disagree)$ and $p(discuss)$. By observing that the class agree is assumed as related, thus $p(agree, related) = p(agree)$, we derive that:

$$\begin{aligned} p(agree) &= p(agree, related) \\ &= p(agree|related) \times p(related) \\ &= p(agree|related) \times (1 - p(unrelated)). \end{aligned} \tag{14}$$

Similarly, for the other two classes we derive that:

$$\begin{aligned} p(disagree) &= p(disagree|related) \times (1 - p(unrelated)), \\ p(discuss) &= p(discuss|related) \times (1 - p(unrelated)). \end{aligned} \tag{15}$$

Thereby, the model actual output $\hat{\mathbf{y}}$ is:

$$\hat{\mathbf{y}} = (p(agree), p(disagree), p(discuss), p(unrelated)), \tag{16}$$

where the class with the highest probability corresponds to the predicted stance.

5 EXPERIMENTAL SETUP

We start this section by presenting the datasets and evaluation measures relevant to the stance detection task. Then, we describe the features used by our model and the model parameterization. Finally, we present the baselines. The software used to run the experiments of this paper is available on the website of the first author.

5.1 Datasets

Experiments are conducted on two publicly available datasets: the *Emergent* dataset[1] [14] and the *FNC-1* dataset[2]. In these two datasets, a claim consists of a news article headline and an evidence of a news article content. These datasets are split into train and test subsets; see Table 1 for statistics about the splits.

The FNC-1 dataset consist of 75,385 instances. Each instance in the dataset is a pair claim-evidence labeled as one of the four stances: agree, disagree, discuss and unrelated. The ratio of training data over testing data in the FNC-1 dataset is ∼2:1. Every class accounts for a similar percentage in the train and test subsets. The unrelated stances are the majority (over 70%) in both subsets, while the disagree stances are less than 3%. The agree and discuss stances are less than 20% and 10%.

The Emergent dataset is similar to the FNC-1 dataset, however it contains only agree, disagree and discuss stances. Hence, it needs to be augmented with unrelated stances. Similarly to how the FNC-1 dataset unrelated stances have been labeled, we manually labeled unrelated stances by pairing a claim with an unrelated evidence, i.e., paired with another claim. Moreover, to make the class distributions less imbalanced, we make the ratio of related stances and unrelated ones ∼1:1. The augmented Emergent dataset contains 4,071 training labels and 1,024 testing labels with a ratio of ∼4:1. Class distributions between train and test subsets are similar.

Compared to the FNC-1 dataset, the class distributions of the augmented Emergent dataset is more balanced. The percentage of unrelated stances is about 50%, whereas the percentages of agree and disagree stances are about 24% and 8%. Both datasets have similar percentages of the discuss stances.

5.2 Evaluation Measure

In line with the FNC-1 challenge, the evaluation is based on a weighted two-level scoring system based on the *accuracy* measure. This evaluation measure, called *relative score*, evaluates a model by splitting the stance detection task into two sub-tasks, related/unrelated and agree/disagree/discuss classification sub-tasks. To the former sub-task is given a 25% weight. This is done because this sub-task is considered to be easier than the latter sub-task to which is given a 75% weight.

We report the evaluation measures: relative score, accuracy, and accuracy on a per class basis.

5.3 Feature Extraction

To represent claims and evidences we use a bag-of-words approach. For each claim and evidence we generate a TF-IDF vector, and for each pair claim-evidence we compute their cosine similarity. We also include the FNC-1 official features into the input feature vector.

The final set of features include:

- TF-IDF vectors of claims;
- TF-IDF vectors of evidences;
- Cosine similarity (CosSim) between the claim vector and the evidence;
- Ratio of word overlap (WordLap) between the claim and the evidence;
- An Indicator whether a claim has refuting words (RefWord);
- The polarity (Pol) of the claim and the evidence;
- The number of overlapping n-grams (NGrams) for $n \in \{2, 3, 4, 5, 6\}$ between the claim and the evidence.

For the TF-IDF vectors, we only use the top 2,000 most frequent terms except stop-words. All of these features are concatenated to form the input feature vector $\mathbf{v}$.

5.4 Experimental Setting

The following hyperparameters have been set via a five-cross validation on the train subsets:

- The dimension k of hidden representations is set to 100;
- The dimension j of the MMD is set to 10;
- The activation function used in the hidden layers is set to ReLu;
- The parameters α are set to 1.5 and 1.3 for the Emergent and FNC-1 datasets.
- The parameter β is set to 0.001;

We include a L2 regularization term [29] for the MLP weight parameters in the final loss function to mitigate overfitting. Dropout is also used to mitigate overfitting with rate set to 0.6. We train in mini-batches of size 64 over the entire train subset. Note that the gradient steps in Algorithm 1 can easily be alternated with a more powerful optimizer such as the Adam optimizer [20]. Early stopping is applied when the classification loss on the validation subset does not get smaller for three continuous iterations. The whole model is implemented with TensorFlow.

5.5 Baselines

We compare our model against the methods mentioned in Section 2. These methods are detailed in the following. Among them we distinguish between methods that use the same features as ours and methods that learn their representations. We start with the latter type, we call these *representation learning-based baselines*:

Bidirectional LSTM (BiLSTM). Augenstein et al. [4] build a neural network architecture based on bidirectional LSTM on a Tweeter dataset. A LSTM encodes the claim, and another LSTM encodes the evidence with the encoded claim set as initial states. The 100-d GloVe word embedding is used as input [30];

Attentive CNN (AtCNN). Bajaj [6] builds an attention-augmented CNN. The claim and the evidence are input to a convolutional neural network to obtain hidden representations, and the attention mechanism is employed to locate the most influential words or phases on the final results;

	unrelated	500	48.83	18,349	72.20
		1,024		25,413	

Memory Network (MN). Mohtarami et al. [26] develop an end-to-end memory network for stance detection. The network operates at the paragraph level and integrates convolutional and recurrent neural networks, as well as a similarity matrix as part of the overall architecture;

Ranbking Model (RM). Zhang et al. [48] build a ranking method to tackle the stance detection and achieve empirical performance improvements. A ranking loss function is proposed to replace Softmax and maximize the representation difference between four classes of stance.

We now review the second type of baselines: those methods that use the same features as our method, we call these *feature engineering-based baselines*:

Official Baseline (OB). This is the FNC-1 official baseline that uses one gradient boosting decision trees model for four-way classification;

Logistic Regression (LR). Bourgonje et al. [10] use n-gram matching and a rule-based procedure to decide relatedness, and three-way logistic regression to distinguish among the related classes;

Gradient Boosted Decision Trees (GBDT). Wang et al. [43] develop two GBDT models, one to determine the relatedness of an evidence to a claim, and another to distinguish among the related classes;

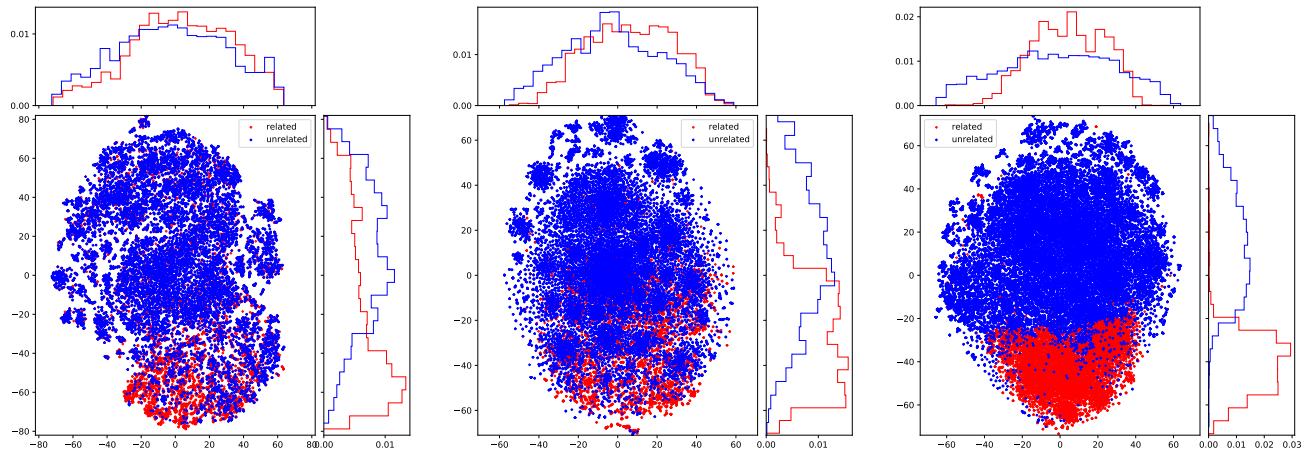
Multi-Layer Perception (MLP). This model [33] achieved the third best performance in FNC-1. It extracts TF-IDF and cosine similarity between claims and evidences as input features, and uses a MLP as the four-class classifier.

6 RESULTS AND DISCUSSION

In this section, we start by analyzing the dependency assumption. Then, we compare and contrast our model against the baselines. Next, we provide a sensitivity analysis of the hyperparameters. We conclude with an impact analysis of the features used by the model.

6.1 Dependency Assumption

In Figure 2 we show the effect of the 3 dependency assumptions by visualizing the learned representations using a t-SNE projection [24]. We observe that when the classifiers are assumed independent, i.e., the classification is performed in cascade — no error is propagated from the second layer to the first during training — then the learned representation well separates the unrelated class from the unrelated ones. When the classifiers are assumed dependent, i.e., the two classifiers are trained together — the error is left free to propagate from the second layer to the first — then the learned representation is not very well separated. However, when the dependence assumption of the two classifiers is learned via the MMD regularization, i.e., the two classifiers are trained together with the error propagation controlled by the regularizer, then the learned representation is again well separated like in the first case. Well-separated representations suggest a greater discriminative power of the model — the unrelated and related classes are almost linearly separable.



The last three rows of Tables 2 and 3 show the performance of our model on the two test subsets for each one of the three assumptions: independent, dependent, and learned. Looking at the accuracy of the unrelated class, we observe that the accuracy is greater when the learned representations are well-separated, as in the independent and learned cases. Furthermore, looking at all the other scores, we observe that the learned assumption outperforms both the independent and dependent assumptions in all other cases, demonstrating that learning together both, relatedness and stance of the evidences towards claims, is beneficial to the stance detection task.

6.2 Overall Performance

In Tables 2 and 3 we compare our model against the state-of-the-art models. Our model achieves the best stance detection performance for the relative score on both datasets. The model achieves 89.30% on the augmented Emergent test subset and 88.15% on the FNC-1 test subset.

By comparing with four-way classification baselines (OB, MLP, BiLSTM, AtCNN, MN and RM) we demonstrate the advantage of separating the relatedness detection from the stance detection. We observe that these classifiers perform poorly on the disagree class, which is caused by the large percentage difference between the minority disagree class and the majority unrelated class. Further, the more imbalanced the evaluation dataset becomes, the worse performance the four-way classifiers achieve on the minority disagree class.

By comparing with baselines that separate the relatedness detection from the stance detection (LR and GBDT) we demonstrate the

Learned	**82.52**	**69.05**	84.30	**97.00**	**89.30**

superiority of a single end-to-end model. LR and GBDT are better on the disagree class, although their overall performance is worse than our model.

In Figure 3 we show the confusion matrix of our model. Here we observe the detection performance on a per class basis. For the related/unrelated classification, we correctly classify 97.00% and 99.53% unrelated instances on the augmented Emergent and the FNC-1 test subsets. We can see that there is some misclassification between the agree and unrelated classes, and between the discuss and unrelated classes. The misclassification of the disagree class accounts for the largest error of the unrelated instances.

Our model achieves an accuracy of 69.05% and 72.35% for the disagree class on the Emergent and the FNC-1 test subsets. The classification accuracy is largely improved compared to the state-of-the-art. Some misclassification error exists between agree and disagree. However, our model can distinguish between the discuss and the disagree with few errors. While the number of discuss cases is the largest and the number of disagree instances is the smallest, our model does not mistake disagree instances as discuss ones, i.e., the model has learned the core representation difference between these two classes. Due to ambiguous expressions, misclassification between agree and discuss is the cause of most errors between these classes, which leads to a slightly worse accuracy for the discuss class on the Emergent (84.30%) and FNC-1 (77.49%) test subsets.

Two reasons account for the improved empirical performance observed on our model. On the one hand, the mitigation of the

Table 3: Performance comparison of our model against the State-of-the-Art models on the FNC-1 dataset.

Model	Accuracy (%)				Relative Score (%)
	agree	disagree	discuss	unrelated	
Feature Engineering-Based Baselines

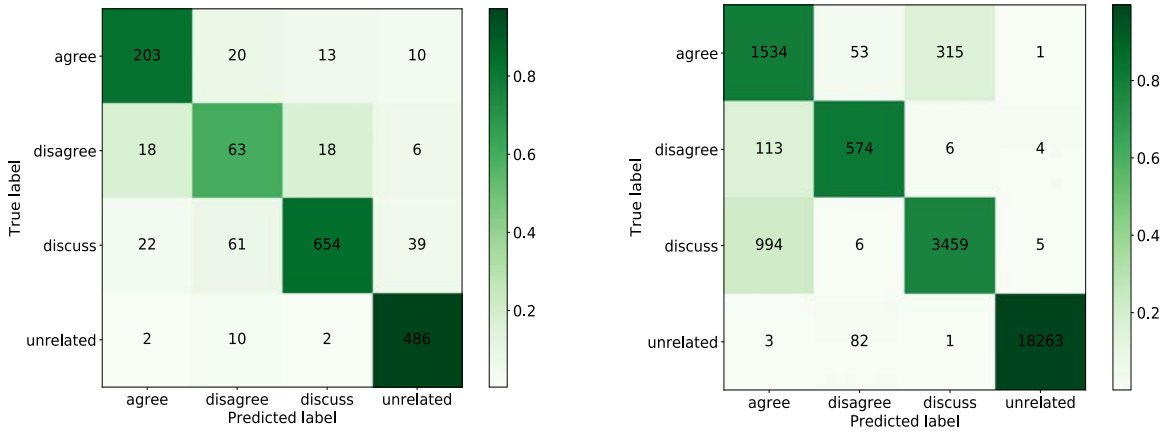

Figure 3: The confusion matrices of our model for the augmented Emergent (on the left) and FNC-1 (on the right) datasets.

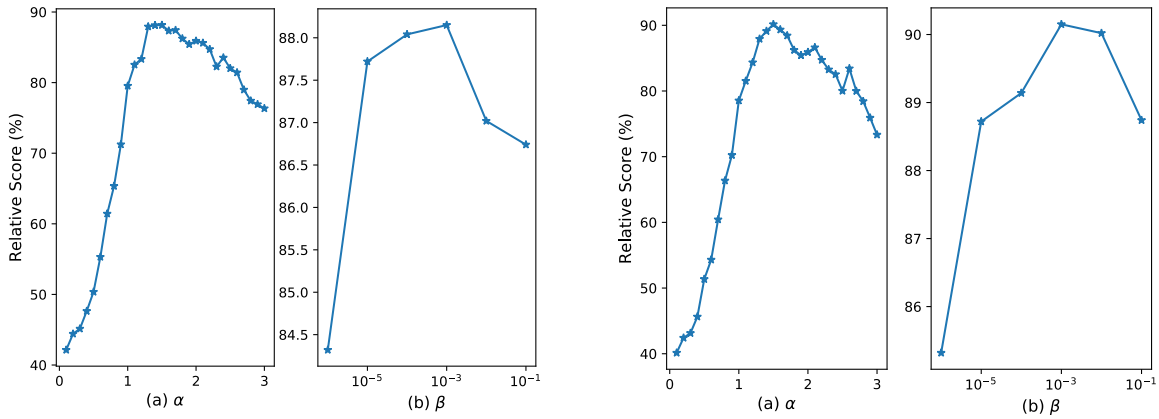
class imbalance problem. Contrary to the four-way classifiers that directly compare the disagree and unrelated instances, the hierarchical model avoids the direct comparison of this minority disagree class (which is less than 2% in the FNC-1 dataset) with the majority unrelated one (which is more than 70% in the FNC-1 dataset). On the other hand, the MMD term that maximizes the discrepancy between the unrelated class and the aggregated related classes. Since the agree, disagree and discuss belong to the same class, the related class, the MMD regularization promotes the emergence of features that are useful to separate the class pairs: agree with unrelated, disagree with unrelated, and discuss with unrelated.



6.3 Hyperparameters Sensitivity

In this subsection we discuss the sensitivity to the hyperparameters of our model. The most influential hyperparameters for the proposed model are α and β. The former controls the relative importance of classification layers. The latter leverages the regularization.

In Figures 4(a) and 4(b) we show how the performance of the model changes when varying α and β for the augmented Emergent and FNC-1 test subsets. α is searched between 0.1 and 3.0 with steps of 0.1, and β is searched in $\{0, 0.1, 0.01, 0.001, 0.0001, 0.00001\}$. For α, we observe that the performance of the model improves quickly as α increases and peaks at 1.5 and 1.3 for the FNC-1 and augmented Emergent datasets, then the performance experiences a slight decrease when α is increased. We hypothesize that the optimal α is related to the class balance between the unrelated class and the related ones. The more unbalanced the dataset is towards the unrelated class, larger is the optimal α. For β, we observe that the performance is the highest when β is set to 0.001. This happens for both augmented Emergent and FNC-1 test subsets. These optimal values of α and β observed on the test subsets are equal to the one found when training the model.

6.4 Feature Analysis

In this subsection we evaluate and discuss the importance of each feature towards the final prediction. To examine the influence of each feature on the final performance, we do a leave-one feature set-out approach and record the classification accuracy on the stance

(a) Emergent (b) FNC-1

Figure 4: Sensitivity of the trained model when varying the parameters α and β on the test subset of the augmented Emergent (on the left) and FNC-1 (on the right) datasets.

Table 4: Performance of our model with different feature sets on the FNC-1 dataset. "/" denotes no feature set is removed.

Removed Feature Set	Accuracy (%)			
	agree	disagree	discuss	unrelated
CosSim	71.53	85.08	78.76	69.37

RefWord	74.43	64.37	77.03	97.49
Pol	60.49	67.93	80.92	98.79
NGrams	74.27	75.73	87.82	84.52
/	80.61	82.35	77.49	99.53

detection task. The following analysis is only based on the FNC-1 dataset. Similar results are observed on the augmented Emergent dataset.

In Table 4 we show the results of this analysis. We observe that removing the CosSim feature leads to a large decrease in accuracy for the unrelated class. Similarly, the use of WordLap has a positive effect for the agree class, and it also contributes to the unrelated class. The RefWord and Pol features help for the classes agree and disagree, while removing the NGram feature leads to an increase on the discuss class, i.e., the NGram feature causes confusion between the discuss and the other classes.

7 CONCLUSION

In this paper, we studied the problem of stance detection: the classification of the stance of an evidence towards a claim into one of the four classes: agree, disagree, discuss and unrelated.

We proposed a hierarchical representation of the stance classes, where the classes agree, disagree and discuss are combined together into a class referred as the related class. The main idea here is to divide a concept into sub-concepts that are organized in a hierarchical structure, and design constraints between sub-concepts in order to make the model parameter optimization more sensible. The primary advantage of this hierarchical representation is that it is useful to overcome the class imbalance problem.

This hierarchical representation has inspired the proposed two-layer neural network to tackle the stance detection task. The first layer performs a related-unrelated classification, while the second layer performs a more fine-grained classification among the related classes. Furthermore, we have empirically demonstrated that (1) it is advantageous to learn these two classification tasks together, and (2) the dependency between these two layers can be learned through a MMD regularization term, which measures the representation discrepancy between the two layers. Experiments on two publicly available datasets have shown that our model is able to outperform the state-of-the-art stance detection methods.

As future work we consider the enriching of the proposed model as follows. First, integrating a credibility evaluation of information sources as features. Second, improving the explainability of the model by showing which words or phrases are the most influential in predicting the stance via attention mechanisms.

ABSTRACT

Social media platforms are a plethora of misinformation and its potential negative influence on the public is a growing concern. This concern has drawn the attention of the research community on developing mechanisms to detect misinformation. The task of misinformation detection consists of classifying whether a claim is *True* or *False*. Most research concentrates on developing machine learning models, such as neural networks, that outputs a single value in order to predict the veracity of a claim. One of the major problem faced by these models is the inability of representing the uncertainty of the prediction, which is due incomplete or finite available information about the claim being examined. We address this problem by proposing a Bayesian deep learning model. The Bayesian model outputs a distribution used to represent both the prediction and its uncertainty. In addition to the claim content, we also encode auxiliary information given by people's replies to the claim. First, the model encodes a claim to be verified, and generate a *prior belief* distribution from which we sample a latent variable. Second, the model encodes all the people's replies to the claim in a temporal order through a Long Short Term Memory network in order to summarize their content. This summary is then used to update the prior belief generating the *posterior belief*. Moreover, in order to train this model, we develop a Stochastic Gradient Variational Bayes algorithm to approximate the analytically intractable posterior distribution. Experiments conducted on two public datasets demonstrate that our model outperforms the state-of-the-art detection models.

1 INTRODUCTION

Although the digital news consumption has increased in the last decade, the increasing amount of misinformation and fake news has not certainly proven its quality. Different from traditional media where news are published by reputable organizations, online news on social media platforms such as Facebook and Twitter are shared by individuals and/or organizations without a careful checking or with malicious intents. In Figure 1 we show a false claim posted on Twitter about an alleged shooting in Ottawa. While some users showed surprise and asked for further clarifications in their replies, other users believed the claim and re-tweeted it as if it was true. This misinformation, when done on a large scale can influence the public by depicting a false picture of reality. Hence, detecting misinformation effectively has become one of the biggest challenges faced by social media platforms [17, 27].

A valuable attempt at rectifying this epidemic of false claims has been tackled by some news websites, such as: Snopes[1], Polifact[2], and Emergent[3], which have employed professional journalists to manually check and verify every potential false news. However, such manual approach is very expensive and way too slow to be able to check all the daily generated claims appearing on the web. Thus, making automatic tools is in great need to speed up this verification process.

In this paper, we tackle the automatic misinformation detection task, which consists in classifying whether a claim is *True* or *False*. Most existing models employ feature engineering or deep learning to extract features from claims' content and auxiliary information such as people's replies. However, these models generate deterministic mappings to capture the difference between true or false claims. A major limitation of these models is their inability to represent uncertainty caused by incomplete or finite available data about the claim being examined.

[1] https://www.snopes.com/
[2] https://www.politifact.com/
[3] http://www.emergent.info/

Figure 1: An example of a false claim and people's replies to it. From the replies, 231 users chose to trust the claim and re-tweeted it as if it was true, while only 4 users asked for further clarifications.

We address this problem by proposing a Bayesian deep learning model, which incorporates stochastic factors to capture complex relationships between the latent distribution and the observed variables. The proposed model makes use of the claim content and replies content. First, to represent the claim content we employ a neural model to extract textual features from claims. To deal with the ambiguity of the language used in claims and obtain salient credibility information, the model generates a latent distribution based on the extracted linguistic features. Since no auxiliary information has been used so far, we interpret this latent distribution as a *prior belief* of the claim being true. Second, to extract auxiliary information from people's replies content, we rank all the replies of the claim in temporal order, and summarize them using a Long Short Term Memory neural network (LSTM). Finally, after updating the *prior belief* with the aid of the LSTM output, the model computes the veracity prediction and its uncertainty. This updated prior belief distribution is interpreted as the *posterior belief*.

In order to train the proposed Bayesian deep learning model, due to the analytical intractability of the posterior distribution, we develop a Stochastic Gradient Variational Bayes (SGVB) algorithm. A tractable Evidence Lower BOund (ELBO) objective function of our model is derived to approximate the intractable distribution. The model is optimized along the direction of maximizing the ELBO objective function.

Our model inherit two advantages: first of all, the model incorporates a latent distribution, which enables to represent uncertainty and promote robustness; second, the Bayesian model formulates all of its prior knowledge about a claim being examined in the form of a prior, which can be updated by more added auxiliary information generating more accurate detection results. To sum up, the proposed model advances state-of-the-art methods in four aspects:

(1) An effective representation of uncertainty due to incomplete/finite available data;
(2) A temporal order-based approach to extract auxiliary information from people's replies;
(3) A SGVB algorithm to infer latent distributions;
(4) A systematic experimentation of our model on two real-world datasets.

The remainder of the paper is organized as follows: § 2 summarizes the related work; § 3 defines the misinformation detection task; § 4 details the proposed Bayesian deep learning model; § 5 derives the Stochastic Gradient Variational Bayes optimization algorithm; § 6 describes the used datasets and experimental setup; § 7 is devoted to experimental results, and; § 8 concludes the paper.

2 RELATED WORK

Misinformation has been existing for centuries in different forms of media, such as printed newspaper and television. Recently, online social media platforms are also suffering from the same issues. Recent work on misinformation detection have tried to understand the differences between true and false claims in various aspects: claim content, information source, multimedia such as affiliated images and videos, and other users' engagement.

2.1 Textual Content

The text of a claim can provide linguistic features to help predict its veracity. Since misinformation and false claims are created for financial or political purposes rather than to report an objective event, they often contain opinionated or inflammatory language [6]. In order to reveal linguistic differences between true and false claims, lexical and syntactic features at character, word, sentence and document level have been exploited [1, 11, 33, 36]. Wawer et al. [43] compute psycholinguistic features using a bag-of-words paradigm. Rashkin et al. [34] compare the language of true claims with that of satire, hoaxes, and propaganda to find linguistic characteristics of untrustworthy text. Kakol et al. [21] construct a content credibility corpus and examine a list of language factors that might affect web content credibility based on which a predictive model is developed. Bountouridis et al. [3] compare heterogeneous articles of the same story and reveal that pieces of information cross-referenced are more likely to be credible. Derczynski et al. [9] extract features from claim tweets including bag-of-words, presence of URLs, and presence of hashtags. A Support Vector Machine (SVM) is then used to distinguish between true and false claims. Guacho et al. [14] leverages a tensor decomposition to derive concise claim embeddings that capture contextual information from each claim; and uses these embeddings to create a claim-by-claim graph on which the labels propagate. Textual content has been empirically proven to be a strong indicator of claim veracity, and thus can be used as a prior probability.

2.2 Source Credibility Analysis

The credibility analysis of the sources of a claim is an important auxiliary information. As misinformation is usually published by unbelievable individuals or automatic bots, credibility plays a crucial role in message communication [18, 32]. Accurate and timely discrimination of such accounts inhibits the proliferation of misinformation at an early stage. Tseng and Fogg [40] identify two components of source credibility, namely trustworthiness and expertise. Trustworthiness is generally taken to mean truthful, unbiased and well intentioned. Expertise instead is understood as knowledgeable, experienced and competent. Thus, features that can reveal the trustworthiness and expertise of information sources are strong indicators of source credibility. With the aid of information source Thomson et al. [39] examine the credibility of tweets related to the Fukushima Daiichi nuclear disaster in Japan. They found that tweets from highly credible institutions and individuals are mostly correct. Useful account features can be derived from the account demographics, such as integrity of personal information, the number of followers and followees [5]. Besides, aggregating a group of account features are indicative, since spreaders of true and false claims might come from different communities [44], such as the percentage of verified user accounts [28] and the average number of followers [26]. However, account demographics can easily be altered to decrease the similarity between credible and incredible sources.

2.3 Multimedia Features

Multimedia features have been shown to be an important manipulator for propaganda based on misinformation [4]. As we have characterized, online misinformation exploits the individual vulnerabilities of people and thus often relies on sensational or even fake images to provoke anger or other emotional response of consumers. Visual-based features are extracted from images and videos to capture the different characteristics of misinformation. Faking images are identified based on various user-level and tweet-level hand-crafted features [15]. Recently, various visual and statistical features have been extracted for news verification [20]. Yang et al. [45] develop a convolutional neural network to extract text and visual features simultaneously. Visual features include clarity score, coherence score, diversity score, and clustering score. Statistical features include count, image ratio, multi-image ratio, hot image ratio, long image ratio, etc. This approach suffers from the problem that some misinformation on social media does not contain multimedia content.

2.4 Social Engagement

The news spreading process over time on social media involves user-driven engagement. Auxiliary information can also be derived from such engagement to improve the claim veracity detection. Ma et al. [29] propose to learn discriminative features by following non-sequential propagation structure of tweets. A top-down and a bottom-up recursive neural networks are proposed to predict claim veracity. Glenski et al. [12] seek to better understand how users react to trusted and deceptive news sources across two popular, and very different, social media platforms. Significant differences have been observed in the speed and the type of reactions between trusted and deceptive news sources on Twitter, but far smaller differences on Reddit. People react to a piece of claim by expressing their stances or emotions in social media posts. Stances can be categorized as supportive, opposing, and neutral, which can be used to infer claim veracity [19, 46, 47]. Kochkina et al. [25] propose a neural multi-task model that leverages the relationship between veracity detection and stance detection in a joint learning setup. Another common post feature is the topic distribution that indicates the central point of relevant affairs, which is derived by topic models [2]. Post features are expanded in two ways: via aggregation with relevant posts for a specific affair, and via temporal evolution of post features. The first way relies on the "wisdom of crowds" to locate potential misinformation [5], while the second way captures the periodic fluctuations of shock cycles [26] or temporal pattern of user activities, such as the number of engaged users and time intervals between engagements [37]. Yet, semantic coherence and temporal changes between users' replies are not fully explored by existing methods.

3 PROBLEM STATEMENT

The task of misinformation detection is to predict the news' veracity of claims, given their content and their people's replies.

Let $C = \{\boldsymbol{c}_1, \boldsymbol{c}_2, \ldots, \boldsymbol{c}_N\}$ be a set of N claims. The claim $\boldsymbol{c}_i$ is commented by a set of M user replies $\mathcal{D}_i = \{\boldsymbol{d}_{i,1}, \boldsymbol{d}_{i,2}, \ldots, \boldsymbol{d}_{i,M}\}$. We use y_i to denote the binary veracity label of the claim $\boldsymbol{c}_i$, which could be either $y_i = 1$ for true or $y_i = 0$ for false. The tuple of a claim and people's replies, i.e., $\{\boldsymbol{c}_i, \mathcal{D}_i\}$, forms a data instance to predict the claim veracity y_i. For the sake of clarity, in the following, we will omit the subscripts i when describing a single instance: $\{\boldsymbol{c}, \mathcal{D}, y\}$.

4 BAYESIAN DEEP LEARNING

In this section, we present our proposed Bayesian deep learning model that effectively integrates claim and people's replies. We will first introduce how to encode claim content with deep learning and generate a latent distribution that is interpreted as a prior belief of claim veracity. We then describe the temporal-ordered approach to encode people's replies, which captures semantic variation along the time line. Finally, we correct the prior belief with the aid of people's replies, the result of which process is interpreted as the posterior belief of claim veracity. Figure 2 describes the proposed model.

4.1 Encoding a Claim

As content are strong indicators of claim veracity [42], we apply deep learning to extract linguistic features from the claim $\boldsymbol{c}$. To avoid the ambiguity of claims and obtain salient credibility information, we generate a latent distribution based on the extracted linguistic features. The output of this claim encoder is the prior belief of the veracity of the claim.

Let each claim $\boldsymbol{c}$ be a sequence of discrete words or tokens, i.e., $\boldsymbol{c} = [\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_l]$, where $\boldsymbol{w}_l \in \mathbb{R}^d$ is a d-dimensional word embedding vector. Based on the sequence of word embeddings, textual features are extracted via a Bidirectional Long Short Term Memory (BiLSTM) neural network [13]. The BiLSTM captures long and short semantic dependencies both from previous time steps and future time steps via forward and backward states.The BiLSTM

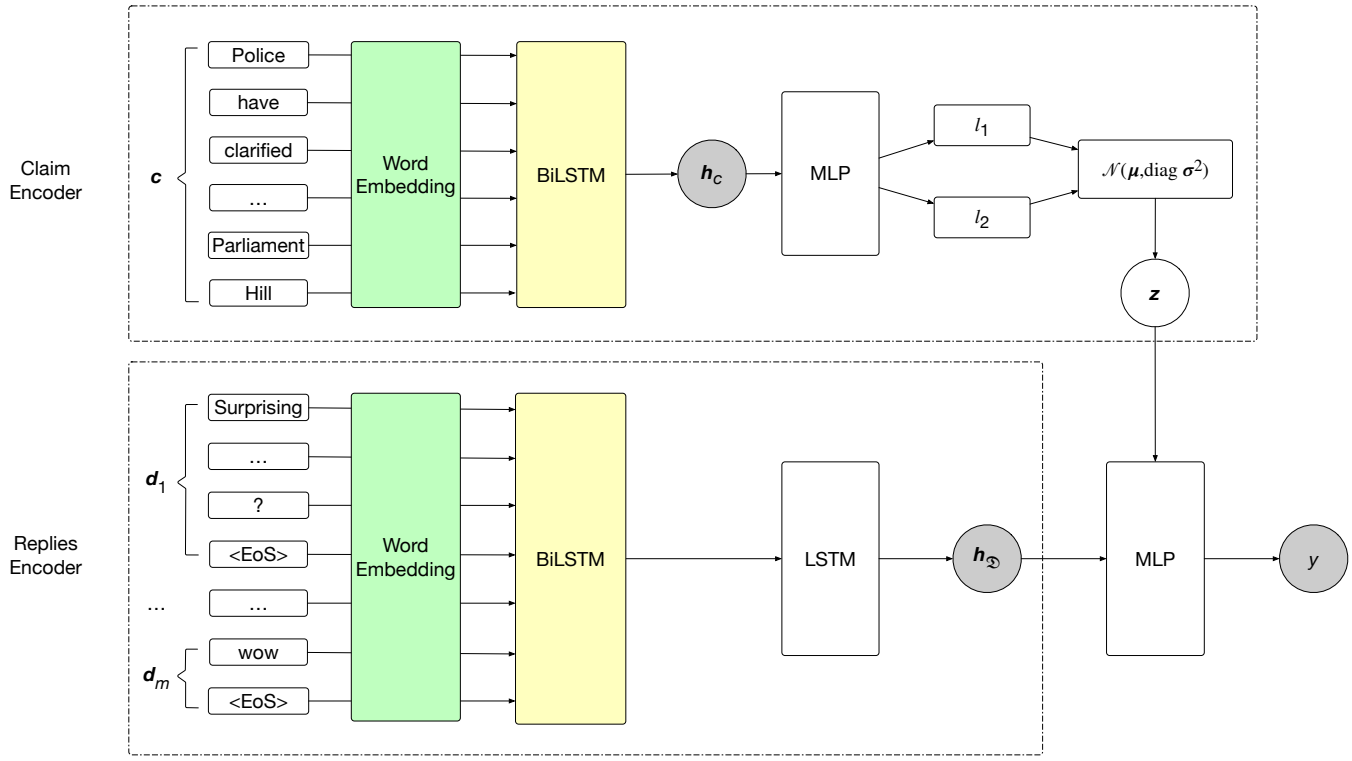

Figure 2: Framework of the Bayesian deep learning model. The framework consists of two parts, the claim encoder (§ 4.1) and the replies encoder (§ 4.2), the concatenation of which determines the *posterior belief* of claim veracity. Blocks and nodes represent computation modules and variables. Grey nodes are observed variables while blank nodes are latent variables (similarly with Figure 3). Note that blocks of the same color denote the same module.

takes as input $\boldsymbol{c}$, converts the sequence of word embeddings into a dense representation, and outputs the concatenation of two hidden states capturing past and future information:

$$\boldsymbol{h}_c = \text{BiLSTM}(\boldsymbol{c}), \tag{1}$$

where $\boldsymbol{h}_c$ denote the concatenated hidden states.

To avoid the ambiguity of claims, instead of a deterministic non-linear transformation, we generate a latent distribution, from which we sample a latent stochastic variable $\boldsymbol{z}$. To embed linguistic information into the latent variable, we set the latent variable to be conditional on $\boldsymbol{h}_c$:

$$\boldsymbol{z} \sim p_\theta(\boldsymbol{z}|\boldsymbol{h}_c), \tag{2}$$

where p is a latent distribution and θ denotes the non-linear transformation of $\boldsymbol{h}_c$ to generate the parameters of p. This non-linear transformation is essential to capture higher level representations of $\boldsymbol{h}_c$; we implement this non-linear transformation via a Multi-Layer Perceptron (MLP).

We assume that the latent variable $\boldsymbol{z}$ is continuous and follows a multivariate Gaussian distribution. The variable $\boldsymbol{z}$ is parameterized as follows:

$$p_\theta(\boldsymbol{z}|\boldsymbol{h}_c) = \mathcal{N}(\boldsymbol{z}|\boldsymbol{\mu}_\theta, \text{diag}(\boldsymbol{\sigma}_\theta^2)), \tag{3}$$

where $\boldsymbol{\mu}_\theta$ and $\text{diag}(\boldsymbol{\sigma}_\theta^2)$ are the mean and the covariance matrix of the multivariate Gaussian distribution. Since the variable $\boldsymbol{z}$ is conditional on the the claim hidden states $\boldsymbol{h}_c$, we derive these two parameters of the Gaussian distribution from $\boldsymbol{h}_c$ through a deep neural network:

$$\boldsymbol{\pi}_\theta = f_\theta(\boldsymbol{h}_c), \tag{4}$$

$$\boldsymbol{\mu}_\theta = l_1(\boldsymbol{\pi}_\theta) \quad \ln(\boldsymbol{\sigma}_\theta) = l_2(\boldsymbol{\pi}_\theta), \tag{5}$$

where f_θ denotes a MLP, l_1 and l_2 denote two Linear Transformations (LT). Since LT can generate negative values, to produce σ_θ we exponentiate the result of l_2.

In order to make μ_θ and σ_θ differentiable and backpropagate the loss through the latent distribution (p), the following reparameterization trick is used:

$$\boldsymbol{z} = \boldsymbol{\epsilon} \cdot \boldsymbol{\sigma}_\theta + \boldsymbol{\mu}_\theta \quad \text{where } \boldsymbol{\epsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}), \tag{6}$$

where $\mathbf{0}$ is a vector of zeros and $\mathbf{I}$ is the identity matrix. By making use of the latent variable ($\boldsymbol{z}$), our model is able to capture complex noisy patterns in the data.

4.2 Encoding People's Replies

We now present the people's replies encoder to obtain auxiliary information. This auxiliary information is claim-specific and is used to generate the posterior belief by correcting the prior belief of the claim veracity.

Replies on social media platforms are listed along the time line as shown in Figure 1, where the earliest reply appears at the top of the list. Truth about an event can be gradually manifest as more

evidence emerges, thus we assume that the latest replies tend to be more reliable and more important than the earlier replies. Based on this assumption, we design a two-layer recurrent neural network to encode replies: the first-layer applies a BiLSTM to summarize the semantic information of each reply and the second-layer applies a LSTM to capture the temporal semantic variation of the replies.

Given a claim $\boldsymbol{c}$ commented by a list of replies $\mathfrak{D} = \{\boldsymbol{d}_1, \ldots \ldots, \boldsymbol{d}_m, \ldots, \boldsymbol{d}_M\}$, these replies are ranked based on their temporal order. The content of a $\boldsymbol{d}_m$ consists of a sequence of words $\boldsymbol{d} = [\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k]$. To project the claim and replies into the same semantic space, we use the same pre-trained word embeddings for both claims and replies. Hence, $\boldsymbol{w}_k \in \mathbb{R}^d$ is a d-dimensional vector such as the word embedding vector used to encoding the claim. For the sake of semantic coherence, we also employ the same BiLSTM to encode both the claim and its replies. Take the reply $\boldsymbol{d}_m \in \mathfrak{D}$ for example, the concatenation of hidden states from forward and backward directions is denoted as:

$$\boldsymbol{h}_{d_m} = \text{BiLSTM}(\boldsymbol{d}_m), \tag{7}$$

where $\boldsymbol{h}_{d_m}$ is the summary of the reply $\boldsymbol{d}_m$.

In order to capture the semantic information of all replies, we sequentially input the concatenated hidden states of each reply into a LSTM. We use the LSTM rather than a BiLSTM because the former gives high weights to recent input, which matches our assumption on the relative importance of the latest reply. Specifically, the LSTM takes the hidden states of each reply as input in a sequential way:

$$\boldsymbol{h}_{\mathfrak{D}} = \text{LSTM}(\boldsymbol{h}_d^M), \tag{8}$$

where $\boldsymbol{h}_d^M = \{\boldsymbol{h}_{d_1}, \ldots, \boldsymbol{h}_{d_m}, \ldots, \boldsymbol{h}_{d_M}\}$.

The last hidden state $\boldsymbol{h}_{\mathfrak{D}}$ contains both the linguistic information of each reply and the semantic changes between replies along the time line. This $\boldsymbol{h}_{\mathfrak{D}}$ is then used to generate the posterior belief by correcting the prior belief of the claim veracity.

4.3 Veracity Modeling

In § 4.1, we developed a prior belief of the claim veracity. In this section we show how to correct this prior belief by including its replies.

The posterior belief is generated by combining the claim and reply information via a MLP. The strong non-linearity of MLPs make them suitable to find complex relationships between the claim and its replies. Specifically, the MLP input is the latent claim variable $\boldsymbol{z}$ concatenated to the hidden state of replies $\boldsymbol{h}_{\mathfrak{D}}$:

$$y = \text{MLP}(\boldsymbol{z}, \boldsymbol{h}_{\mathfrak{D}}). \tag{9}$$

This is the final prediction of our Bayesian deep learning model for misinformation detection.

5 OPTIMIZATION

The stochastic variables of our model are non-linear and non-conjugate [41]. Hence, the posterior distribution cannot be derived analytically. To approximate the posterior distribution, we construct an inference model parameterized by ϕ to approximate the intractable true posterior $p_\theta(\boldsymbol{z}|\boldsymbol{h}_c)$; then we derive an objective function to measure how well $p_\theta(\boldsymbol{z}|\boldsymbol{h}_c)$ is approximated; finally we exploit the Stochastic Gradient Variational Bayes (SGVB) method [24, 35] to learn the inference model parameters ϕ together with the generative model parameters θ. Figure 3 shows the graphical representation of the generative model and the inference model.

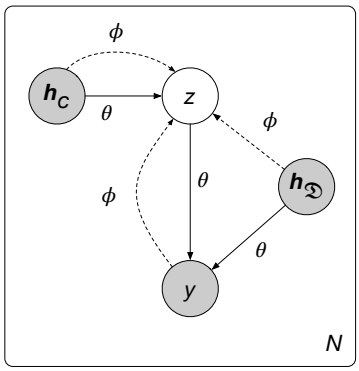

Figure 3: The directed graphical model. Grey nodes represent observed variables while blank nodes represent latent variables. Solid lines denote the generative model $p_\theta(z|\boldsymbol{h}_c)p(y|z, \boldsymbol{h}_{\mathfrak{D}})$, dashed lines denote the variational approximation $q_\phi(z|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$ to the intractable posterior $p_\theta(z|\boldsymbol{h}_c)$. The variational parameters are learned together with the generative model parameters.

5.1 Inference Model

Following the neural variational inference approach [24], we construct an inference model (as in Fig. 3) parameterized by ϕ to compute an approximated posterior distribution, called variational distribution. Given the observed variables, we define a variational distribution $q_\phi(\boldsymbol{z}|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$ to approximate the true posterior distribution $p_\theta(\boldsymbol{z}|\boldsymbol{h}_c)$. Like for the Variational Auto Encoder (VAE) [24], similarly to Eq. 3 for $p_\theta(\boldsymbol{z}|\boldsymbol{h}_c)$, the variational distribution is chosen to be a multivariate Gaussian distribution:

$$q_\phi(\boldsymbol{z}|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}) = \mathcal{N}(\boldsymbol{z}|\boldsymbol{\mu}_\phi, \text{diag}(\boldsymbol{\sigma}_\phi^2)), \tag{10}$$

where $\boldsymbol{\mu}_\phi$ and $\text{diag}(\boldsymbol{\sigma}_\phi^2)$ are the mean and the covariance matrix of the multivariate Gaussian distribution. We use a deep neural network to derive these two parameters from the observed variables:

$$\boldsymbol{\pi}_\phi = f_\phi(y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}), \tag{11}$$

$$\boldsymbol{\mu}_\phi = l_3(\boldsymbol{\pi}_\phi), \quad \ln(\boldsymbol{\sigma}_\phi) = l_4(\boldsymbol{\pi}_\phi), \tag{12}$$

where f_ϕ denotes a MLP, and l_3 and l_4 denote two LTs. Note that in the inference model to compute $\boldsymbol{\mu}$ and $\log \boldsymbol{\sigma}$ we use $y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}$ and not only $\boldsymbol{h}_c$ as in the generative model.

5.2 Objective Function

In the following we derive the objective function of our Bayesian deep learning model following the variational principle. To maximize the log-likelihood $\ln(p(y|\boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}))$, we derive an Evidence Lower Bound (ELBO) objective function, which ensures a correct approximation of the true posterior. To simplify the notation of the derivation of the objective function we make the following substitutions: $p_\theta(y) = p_\theta(y|\boldsymbol{z}, \boldsymbol{h}_{\mathfrak{D}})$, $p_\theta(\boldsymbol{z}) = p_\theta(\boldsymbol{z}|\boldsymbol{h}_c)$, $q_\phi(\boldsymbol{z}) =$

    $\mathcal{L}(\theta, \phi|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}) \leftarrow$ compute the loss for the full dataset according to Eq. 15;
    $\theta \leftarrow \theta - \eta \cdot \nabla_\theta \mathcal{L}(\theta, \phi|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$;
    $\phi \leftarrow \phi - \eta \cdot \nabla_\phi \mathcal{L}(\theta, \phi|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$;
  until θ, ϕ *converge*;
  return θ, ϕ;

$q_\phi(z|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$. The objective function is derived as follows:

$$\begin{aligned}\ln\left(p(y|\boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})\right) &= \ln\left(\int p_\theta(y)p_\theta(z)dz\right)\\ &\geq \int q_\phi(z)\ln\left(\frac{p_\theta(z)}{q_\phi(z)}p_\theta(y)\right)dz\\ &= \mathbb{E}_{q_\phi(z)}[\ln\left(p_\theta(y)\right)] - D_{KL}[q_\phi(z)\|p_\theta(z)]\\ &= \mathcal{L}(\theta, \phi|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}),\end{aligned} \tag{13}$$

where $\mathcal{L}(\theta, \phi|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$ is the ELBO objective function. The second line of the derivation is possible by using the Jensen's inequality [16]. Since the ELBO objective function is a lower bound of the log-likelihood $\ln(p(y|\boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}))$, its maximization maximizes the log-likelihood.

5.3 Gradient Estimation

Large-scale inference needs minibatch optimization. Thus, we derive a minibatch-based SGVB estimator to differentiate and optimize the ELBO objective function ($\mathcal{L}(\theta, \phi|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$) with respect to both the inference parameters (ϕ) and the generative parameters (θ).

Through Monte Carlo estimation we compute the expectation part of the ELBO objective function. Let the minibatch size to be B and, for each claim $\boldsymbol{c}_i$ with $i \in [1, B]$, S a sample drawn from the variational posterior distribution $\tilde{z} \sim q_\phi$. Given a subset of claims, we can construct an estimator of ELBO objective function for the full dataset based on mini-batches as follows:

$$\begin{aligned}\mathcal{L}(\theta, \phi|y_i, \boldsymbol{h}_{c_i}, \boldsymbol{h}_{\mathfrak{D}_i}) =& \frac{1}{S}\sum_{s=1}^{S}\left[\log p_\theta(y_i|\tilde{z}^{(s)}, \boldsymbol{h}_{\mathfrak{D}_i})\right]\\ &- D_{KL}[q_\phi(z)\|p_\theta(z)],\end{aligned} \tag{14}$$

$$\mathcal{L}(\theta, \phi|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}}) \approx \frac{N}{B}\sum_{i=1}^{B}\mathcal{L}(\theta, \phi|y_i, \boldsymbol{h}_{c_i}, \boldsymbol{h}_{\mathfrak{D}_i}), \tag{15}$$

where $\mathcal{L}(\theta, \phi|y_i, \boldsymbol{h}_{c_i}, \boldsymbol{h}_{\mathfrak{D}_i})$ denote the estimates based on the i claim and N is the total number of claims. Algorithm 1 shows the minibatch gradient descent optimization process for both the generative (θ) and inference (ϕ) parameters. Note that the gradient steps in Algorithm 1 can easily be alternated with a more powerful optimizer such as the Adam algorithm [23].

Although both $q_\phi(z|y, \boldsymbol{h}_c, \boldsymbol{h}_{\mathfrak{D}})$ and $p_\theta(z|\boldsymbol{h}_c)$ are modeled as parameterized Gaussian distributions. The former is an approximation of the latter that only functions during learning. The latter, instead, is the learned distribution from which samples are generated in order to classify claim veracity.

5.4 Prediction

After training, we compute the posterior distribution $p_\theta(z|\boldsymbol{h}_c)$ through the generative network. The actual prediction of a claim veracity is given by taking the expectation of S samples:

$$\overline{y} = \frac{1}{S}\sum_{s=1}^{S}\text{MLP}(z^s, \boldsymbol{h}_{\mathfrak{D}}), \tag{16}$$

where z^s denote the samples drawn from the true posterior distribution $p_\theta(z|\boldsymbol{h}_c)$.

6 EXPERIMENT SETUP

In this section we start by introducing 4 research questions. We then present the methodology used to answer them. The software used to run the experiments in this paper is available on the website of the first author.

6.1 Research Questions

We seek to answer the following four research questions, which will be guide the remainder of the paper:

RQ1 Does our model outperform the state-of-the-art misinformation detection baselines?
RQ2 Does the incorporation of the latent distribution outperforms a deterministic counterpart?
RQ3 Does the auxiliary information from people's replies produce a more accurate *posterior belief* of claim veracity?
RQ4 Is the temporal order better than random when encoding replies?
RQ5 Is it beneficial to incorporate a latent variable to encode replies?
RQ6 How does the dimension of the latent variable z affect the model's performance?

6.2 Datasets

In order to compare the performance of our proposed model against the baselines, we experimented with two real-world benchmark datasets, the *RumourEval* [9] and the *Pheme* [48] datasets. Both datasets contain Twitter conversation threads about news (like the example shown in Figure 1). A conversation thread consists of a tweet making a true or false claim, and branches of people's replies expressing their opinion about it. A summary of the datasets statistics is available in Table 1.

The RumourEval dataset has been developed for the SemEval-2017 Task 8 competition. This dataset consists of 325 source tweets

Table 1: Statistics of the datasets.

Subset	Veracity	RumourEval		Pheme	
		#Claims	#Replies	#Claims	#Replies
Training	True	83	1,949	861	24,438
	False	70	1,504	625	17,676
	Total	153	3,453	1,468	42,114
Validation	True	10	101	95	1,154
	False	12	141	115	1,611
	Total	22	242	210	2,765
Testing	True	9	412	198	3077
	False	12	437	219	3,265
	Total	21	849	417	6,342

and 5,568 user reply tweets. The veracity of each tweet can be true (45%), false (23%) or unverified (32%). Since we aim to only distinguish true and false claims, we filter out the unverified tweets. We divide the filtered dataset into a training subset, a validation subset and a testing subset. The training subset contains 153 claims with 3,453 replies, the validation subset contains 22 claims with to 242 replies, and the test subset contains 21 claims with 849 replies.

The *Pheme* dataset is constructed to help understand how users treat online rumour before and after the news is detected to be true or false. Like the *RumourEval* dataset, we divide the *Pheme* dataset into a training subset, a validation subset and a testing subset. Specifically, 70% of the claims are randomly selected as training instances, 10% as validation instances and the rest as testing instances. Users' replies are divided according to the claims.

6.3 Evaluation Measures

The misinformation detection task is a binary classification task. Such tasks are commonly evaluated by the following evaluation measures: Accuracy, F_1, Precision, and Recall.

Accuracy is a common evaluation measure for classification tasks. However, it is less reliable when datasets suffer from class imbalance. The evaluation measures Precision, Recall and F_1 complement Accuracy because not suffering from this problem.

6.4 Hyperparameters Setting

The activation function of the three LSTMs is tanh. The activation function of the MLPs is *ReLu*.

The hyperparameters tuned on the validation subset are:

- the dimension of the hidden layer of all three LSTMs is 30;
- the dimension of the latent variables is 10;
- the minibatch size is 32;
- the number of samples used in Monte Carlo estimates is 20.

State-of-the-art techniques have been employed to optimize the objective function: Dropout [38] is applied to improve neural networks training, L2-norm regularization is imposed on the weights of the neural networks, Adam optimizer [23] is exploited for fast convergence, and stepwise exponential learning rate decay is adopted to anneal the variations of convergence.

6.5 Baselines

We test our Bayesian deep learning model against six state-of-the-art models. In order to have a fair comparison, only those models using the claim content and users' replies have been selected.

Support Vector Machine (SVM). This model evaluates the performance of manually extracted features. The extracted features from claim content include: bag-of-words representation, presence of URLs, presence of hashtags, proportion of supporting and denying response [9]. These features are then input to a linear Support Vector Machine classifier. This classifier achieves the highest misinformation detection performance in the SemEval-2017 Task 8[4];

Convolutional Neural Networks (CNN). This model evaluates the performance of CNNs on the veracity detection task. Apart from the sequential approach such as BiLSTM, the convolutional model is another powerful neural architecture for natural language understanding [7, 8, 10, 22, 45]. CNN takes as input pre-trained word embeddings generated with Word2Vec [30] trained on the Google News dataset. To capture features similar to n-grams, we apply different convolutional window sizes. A max poling layer is applied to compress the output information of the convolutional layers [7];

Tensor Embeddings (TE). This model leverages tensor decomposition to derive concise claim embeddings, which are used to create a claim-by-claim graph on which labels propagate [14];

Evidence-Aware Deep Learning (DeClarE). This model retrieves evidences from replies using claims as a queries [31]. Then both claims and retrieved replies are input into a deep neural network with attention mechanism. Claim veracity is then computed by aggregating over the prediction generated by every claim-retrieved reply pair;

Multitask Learning (Multitask). This model leverages the relationship between two tasks of the veracity detection pipeline [25], stance detection and veracity prediction tasks. The model is trained on both jointly. We apply the hard parameter sharing mechanism, where different tasks share the same hidden LSTM layers. Task-specific layers takes the shared hidden information and generate per-task predictions;

Tree-structured RNN (TRNN). This model learns discriminative features from replies content by following their non-sequential propagation structure. Among the proposed two structures, we select the top-down structure for tweet representation learning because marginally better than the bottom-up structure [29].

7 RESULTS AND DISCUSSION

This section answers the research questions proposed in § 6.

7.1 Performance Comparison (RQ1)

Table 2 summarizes the classification performance of the baselines and our Bayesian deep learning framework on the RumourEval and Pheme datasets. We can observe that: (1) In terms of *Accuracy*

[4] http://alt.qcri.org/semeval2017/task8/

Table 2: Performance comparison of the proposed Bayesian deep learning framework against the baselines.

Dataset	Measure	SVM	CNN	TE	DeClarE	Multitask	TRNN	Ours
RumourEval	Accuracy (%)	71.42	61.90	66.67	66.67	66.67	76.19	**80.95**
	Precision (%)	66.67	54.54	60.00	58.33	57.14	70.00	**77.78**
	Recall (%)	66.67	66.67	66.67	77.78	**88.89**	77.78	77.78
	F_1 (%)	66.67	59.88	63.15	66.67	69.57	73.68	**77.78**
Pheme	Accuracy (%)	72.18	59.23	65.22	67.87	74.94	78.65	**80.33**
	Precision (%)	**78.80**	56.14	63.05	64.68	68.77	77.11	78.29
	Recall (%)	75.75	64.64	64.64	71.21	**87.87**	78.28	79.29
	F_1 (%)	72.10	60.09	63.83	67.89	77.15	77.69	**78.78**

and F_1, most deep learning-based models, such as ours, TRNN and Multitask, outperform the feature engineering-based models, i.e., SVM. This demonstrates that deep neural networks indeed help to learn better hidden representation of claims and replies. (2) Methods exploring relationships between a claim and its replies, such as ours, TRNN and Multitask, achieve better performance than claim content-based methods like TE and CNN. This demonstrates the significance of utilizing people's replies in the misinformation detection task. (3) Our model achieves state-of-the-art performance on both measures and both datasets demonstrating the effectiveness of our model in the misinformation detection task. This is true despite, our system is not the best for precision and recall alone. This because precision and recall alone do not offer a clear picture about the performance of a model since one measure can be increased at the expense of the other and *vice versa*.

Specifically, our model achieves the highest accuracy (80.95%), precision (77.78%) and F_1 (77.78%) on the RumourEval test subset, and the highest Accuracy (80.33%) and F_1 (78.78%) on the Pheme test subset. The TRNN is the strongest baseline achieving the second highest accuracy and F_1 on both RumourEval (76.19% and 73.68%) and Pheme (78.65% and 77.69%) test subsets.

7.2 Ablation of the Latent Distribution (RQ2)

In this subsection, we evaluate the impact of using a latent distribution into the claim encoder on the misinformation detection task. To evaluate the impact of the latent distribution p, we ablate p in our model and compare its classification performance against the full model. Specifically, the ablation is done by taking the output of the BiLSTM hidden states, i.e., $\boldsymbol{h}_c$ and give this as input to the output MLP. The rest of the model remains unchanged. Since no latent distribution is involved, the ablated model is optimized in accordance with the conventional Softmax loss minimization.

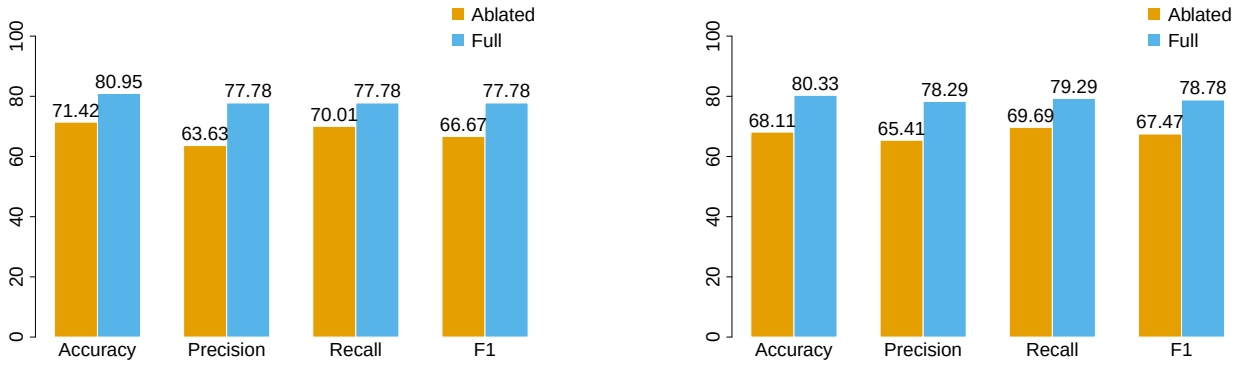
In Figure 4(a) and 4(b) we show the classification performance of the ablated model against the full model on the *RumourEval* and *Pheme* test subsets. We observe that the full model outperforms the ablated one by at least 7.77% on every evaluation measure. This demonstrates the better representation quality achieved by the use of the latent distribution.

7.3 Ablation of People's Replies (RQ3)

We now evaluate the contribution people's replies in the misinformation detection task. In order to examine its contribution we compare our full model with and without replies. Specifically, we ablate the input coming from the replies to the final MLP, which now is used only to perform a non-linear transformation of the latent variable $\boldsymbol{z}$.

In Figure 5(a) and 5(b) we show the classification performance of the ablated model against the full model on the RumourEval and the Pheme test subsets. Here, we observe that the auxiliary information extracted from people's replies has a large impact to the final performance our model. In fact, every evaluation measure is increased by at least 10.11%.

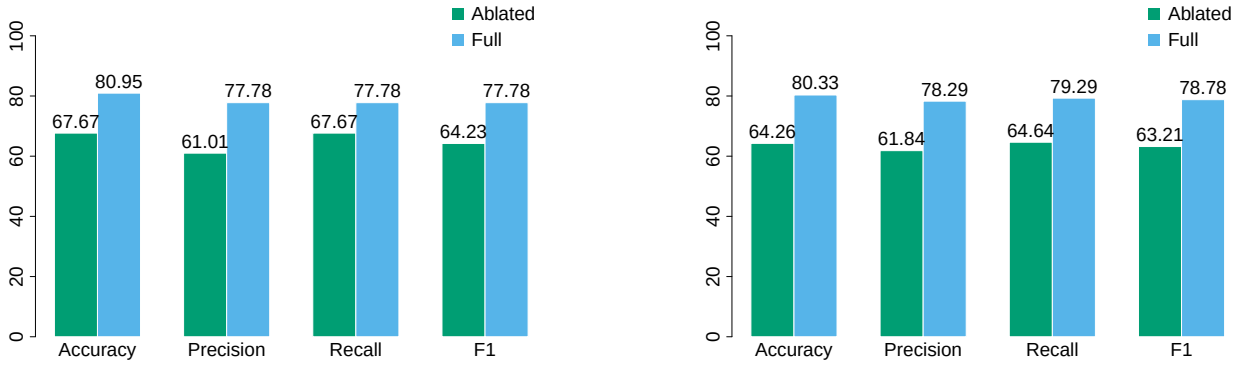
7.4 Random vs. Temporal Ordered Replies (RQ4)



The proposed model rank people's replies based on the temporal order. In this subsection, we analyze the contribution of ranking the replies according to their temporal order. We compare this against a random order.Specifically, we randomize the $\boldsymbol{h}_d^M$ before it is input to the LSTM.

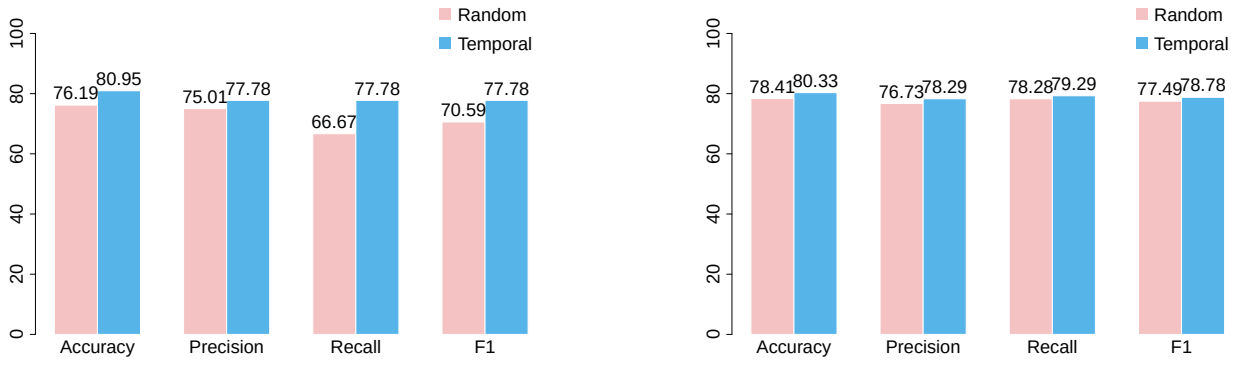
In Figure 6(a) and 6(b) we show the performance comparison of these two orders. We observe that the temporal ordered replies achieve better performance than the random ordered. Besides, the random ordered model is still worse TRNN yet better than Multitask. This is probably because TRNN takes the temporal structure of replies into the model while Multitask fail to involve temporal information.

7.5 A Latent Distribution for Replies (RQ5)



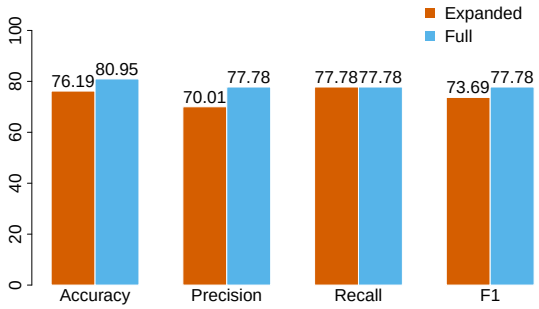
Considering the improved performance brought by the latent distribution for claims, in this subsection we answer whether it would be beneficial to incorporate a latent distribution also for replies. In order to answer this research question, we expand our model by adding a new latent distribution in the reply encoder. Similarly to what done for the claim encoder, the new latent distribution is designed as a multidimensional Gaussian distribution with mean and covariance matrix derived from the LSTM output $\boldsymbol{h}_{\mathcal{D}}$ (as in Eq. 3, 4 and 5). A new latent variable is sampled similarly as in Eq 6 and input to the MLP to predicting veracity of the claim being examined.

In Figure 8(a) and 8(b) we show the model performance comparison. We observe that the new latent distribution does not have an effect on the performance on the model for all the evaluation measures and dataset test subsets. Based on this analysis, we conclude that the incorporation of the additional latent distribution for replies does not provide any additional improvement in performance.



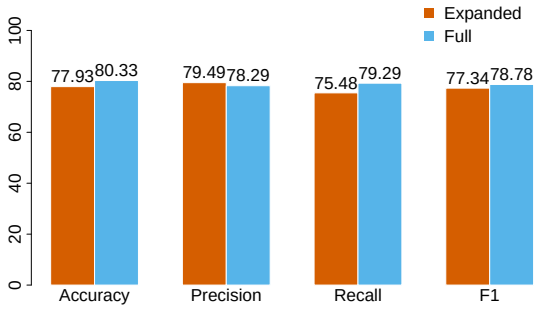
(a) RumourEval (b) Pheme

Figure 4: The impact of the latent distribution p on the model performance. In both figures we show the performance change on all the evaluation measures of the model with (Full) or without (Ablated) p. Figure (a) shows it for the RumourEval test subset and Figure (b) shows it for the Pheme test subset.



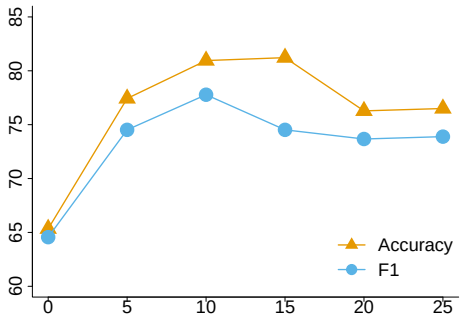
(a) RumourEval (b) Pheme

Figure 5: The impact of people's replies on the model performance. In both figures we show the performance change on all the evaluation measures of the model with (Full) or without (Ablated) replies information. Figure (a) shows it for the RumourEval test subset Figure (b) shows it for the Pheme test subset.

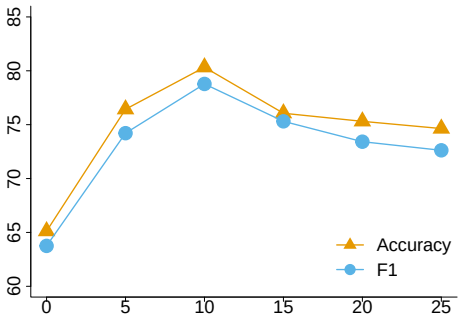


(a) RumourEval (b) Pheme

Figure 6: The effect of the temporal order of the reply encoder on model performance. In both figures we show the performance change on all the evaluation measures of the model with random and temporal ordered people's replies. Figure (a) shows it for the RumourEval test subset and Figure (b) shows it for the Pheme test subset.



(a) RumourEval



(b) Pheme

Figure 7: The effect of an additional latent distribution for people's replies on the model performance. In both figures we show the performance change on all the evaluation measures of the model with (Expanded) and without (Full) an additional latent variable for the people's replies. Figure (a) shows it for the RumourEval test subset and Figure (b) shows it for the Pheme test subset.

(a) RumourEval

(b) Pheme

Figure 8: The effect of the latent variable dimension on model performance. In both figures we show how the accuracy and F_1 scores change when varying the dimension of z. Figure (a) shows it for the RumourEval test subset and Figure (b) shows it for the Pheme test subset.

7.6 Sensitivity Analysis (RQ6)

In this subsection we evaluate the effect of the dimension of the latent variable z. To do this after setting a dimension for z we optimize the rest of the hyperparameters on the validation subset.

In Figure 8(a) and 8(b) we show the effect on performance of the dimension of z on both datasets. We observe that the results are similar for both evaluation measures, accuracy and F_1. Varying the dimension from 1 to 5 the model brings a larger performance improvement than when varying it from 5 to 25. When the dimension is 15 the model obtains the highest accuracy, 81.22%, on the RumourEval test subset while when the dimension is 10 the model obtains the highest F_1, 78.78%, on the RumourEval test subset and highest accuracy, 80.33% and F_1, 78.78%, on the Pheme test subset. These results also show that the increase in model capacity may not necessarily lead to an improvement in performance. The reason could be found on the limited size of the datasets, which might cause overfitting when the model is too complex.

8 CONCLUSIONS

In this paper, we study the problem of misinformation detection on social media platforms. One major problem faced by existing machine learning methods is the inability to represent uncertainty due to incomplete or finite available information. We address the problem by proposing a Bayesian deep learning model. When encoding claim content, we incorporate a latent distribution accounting for uncertainty and randomness caused by noisy patterns in the finite dataset. This latent distribution provides a prior belief of claim veracity. We also encode auxiliary information from people's replies in a temporal order through an LSTM. Such auxiliary information is then used to update the prior belief generating a posterior belief. In order to optimize the Bayes model, we derive a minibatch-based gradient estimation algorithm. Systematic experimentation has demonstrated the superiority of our approach against the state-of-the-art approaches in the misinformation detection task.

Despite encouraging experimental results, online misinformation detection is still a challenging problem with many open questions. In this paper, auxiliary information comes from people's replies alone, we argue that the proposed model can be enriched by utilizing other auxiliary information, such as source credibility. Also, the reply stances are a strong veracity indicator for a claim, since false claims are usually controversial and accompanied by opposite stances. We let for future work, the combination of features extract from credibility analysis and reply stances.

ABSTRACT

Network alignment, which aims to find the node correspondence across multiple networks, is a fundamental task in many areas, ranging from social network analysis to adversarial activity detection. The state-of-the-art in the data mining community often view the node correspondence as a probabilistic cross-network node similarity, and thus inevitably introduce an $\Omega(n^2)$ lower bound on the computational complexity. Moreover, they might ignore the rich patterns (e.g., clusters) accompanying the real networks. In this paper, we propose a multilevel network alignment algorithm (Moana) which consists of three key steps. It first efficiently *coarsens* the input networks into their structured representations, and then *aligns* the coarsest representations of the input networks, followed by the *interpolations* to obtain the alignment at multiple levels including the node level at the finest granularity. The proposed *coarsen-align-interpolate* method bears two key advantages. First, it overcomes the $\Omega(n^2)$ lower bound, achieving a *linear* complexity. Second, it helps reveal the alignment between rich patterns of the input networks at multiple levels (e.g., node, clusters, super-clusters, etc.). Extensive experimental evaluations demonstrate the efficacy of the proposed algorithm on both the node-level alignment and the alignment among rich patterns (e.g., clusters) at different granularities.

1 INTRODUCTION

Networks are often *multi-sourced* (i.e., variety) and *large-scale* (i.e., volume), such as the financial networks built from the massive size of transactions in different institutes, the social networks with a substantial number of users on various platforms and so on. Whether or not subtle patterns associated with different networks (e.g., a complex fraud schema) can be distilled, profoundly depends on the successful integration of the multi-sourced network data. Network alignment that aims to uncover the node correspondence across different networks has drawn a lot of attention in many applications, including social network analysis [37], bioinformatics [10], adversarial activity detection [31], etc. For instance, financial criminals (e.g., money launderers [38, 39]) often camouflage themselves by frequently conducting less suspicious activities in different financial transaction networks, making it hard to detect them if we only focus on a single network. By finding the correspondence among the suspects across different networks, network alignment could help unveil such complex fraud transaction patterns.

Generally speaking, network alignment can be categorized into *local* alignment and *global* alignment. Among others, local network alignment essentially intends to find the similar motifs across different networks [3]. Such local alignment methods might be too restrictive to find the node correspondence, or to align the larger complex structures across different networks. On the other hand, a prevalent choice for global alignment in the data mining community is the soft alignment that views the node correspondence as a probabilistic cross-network node similarity (e.g., *IsoRank* [27], *FINAL* [35]). However, it suffers from the following drawbacks. First, the soft alignment inevitably introduces an $\Omega(n^2)$ lower bound on the computational complexity due to the dense alignment matrix, where n is the number of nodes. Second, most soft alignment methods (e.g., *BigAlign* [16]) assume one network is a noisy permutation of the other and perform the alignment at a single node level. Consequently, these approaches might ignore the rich patterns accompanying networks, e.g., clusters, etc.

Some recent efforts attempt to go beyond this assumption and perform the alignment at two levels [2, 20]. In addition to the node-level alignment, these methods aim to find the alignment at the coarser level, for instance, among clusters. Compared to the node-level alignment, these methods not only break the $\Omega(n^2)$ floor of the computational complexity by viewing the node-level alignment as the interpolation of the cluster-level alignment, but also reveal the more complicated alignment across the input networks (e.g., which cluster in network $\mathcal{G}_1$ links to which cluster in network $\mathcal{G}_2$).

Nonetheless, these two-level alignment methods still bear some fundamental limitations. First (*problem setting*), the existing methods are restricted to only two levels, and therefore might overlook some richer patterns in the underlying networks, e.g., the hierarchical *cluster-within-clusters* structure [25]. Second (*alignment accuracy*), it is not clear how the coarser-level alignment would impact the accuracy of the finer-level alignment. This is crucial especially if we want to perform the multilevel alignment, as the error at one level could be propagated or even diverged through different levels. Third (*computational efficiency*), most of the existing

two-level approaches, with the only exception of [36], still requires a *sub-quadratic* computational complexity, e.g., [2].

In this paper, we aim to systematically address the above limitations and the main contributions are summarized as follows:

- **Problem Definition.** To our best knowledge, we are the first to address the multilevel network alignment problem.
- **Algorithm and Analysis.** We propose a multilevel network alignment algorithm (MOANA), which scales *linearly* w.r.t. the size of the input networks. In theory, we prove a condition on the perfect interpolation, which in principle allows us to perform the alignment at an arbitrary number of levels, without any interpolation error. In practice, we drive an error bound of alignment due to the coarsening step.
- **Experiments.** We perform extensive experiments, which demonstrate that (1) the proposed algorithm achieves a close node-level alignment accuracy to its single-level counterpart *FINAL* [35] with an up to 10× speedup, in the meanwhile outperforming all the other existing node-level alignment algorithms. Note that the proposed MOANA can be considered as an approximation of *FINAL* at the finest node level; (2) it scales *linearly* w.r.t. the size of the networks; and (3) it also reveals the alignment among the more complicated cluster structures at different granularities.

2 PROBLEM DEFINITION

Table 1 summarizes the main symbols and notations used throughout the paper. We use the bold uppercase letters to denote matrices (e.g., $\mathbf{A}$), bold lowercase letters for vectors (e.g., $\mathbf{s}$) and letters not in bold for scalars (e.g., α). We use $\mathbf{A}(i,j)$ to denote the entry at the intersection of the i-th row and j-th column of the matrix $\mathbf{A}$. We denote the transpose of a matrix by a superscript T (e.g., $\mathbf{A}^T$ as the transpose of $\mathbf{A}$). We use the subscripts to index the matrices at different levels. For example, $\mathbf{A}_1$ represents the symmetrically normalized matrix of the adjacency matrix $\bar{\mathbf{A}}_1$ of network $\mathcal{G}_1$ at the first level (i.e., $\mathbf{A}_1 = \mathbf{D}_1^{-\frac{1}{2}}\bar{\mathbf{A}}_1\mathbf{D}_1^{-\frac{1}{2}}$ where $\mathbf{D}_1$ is the diagonal degree matrix of $\bar{\mathbf{A}}_1$), and $\mathbf{A}_l$ is the corresponding coarsened adjacency matrix at the l-th level ($l \geq 2$). The identity matrix of size $n \times n$ is denoted by $\mathbf{I}_n$. Throughout this paper, we simplify $\mathbf{I}_n$ to $\mathbf{I}$ if the size is clear from the context. Without loss of generality, we assume that $\mathcal{G}_1$ and $\mathcal{G}_2$ share a comparable size, i.e., $O(n_1) = O(n_2) = O(n)$ and $O(m_1) = O(m_2) = O(m)$, to simplify the complexity analysis.

2.1 Multilevel Network Alignment Problem

Many large real-world networks often have the complex hierarchical *cluster-within-clusters* structures. For example, given the input network $\mathcal{G}_1$ in Figure 1 (a), nodes $\{1,3\}$ can be viewed as a two-node cluster and similarly nodes $\{2,12\}$ form another two-node cluster (in Figure 1 (b)). These two clusters are represented by node-1 and node-2 respectively at the second level, which further construct an even coarser two-node cluster (in Figure 1 (c)). This coarser cluster is represented by node-1 at the third level (in Figure 1 (d)). As one can see, each level reveals a unique pattern in the underlying network $\mathcal{G}_1$. This leads to the following question for the alignment task: *How can we align the clusters at different granularities across the input networks?* Such an alignment can not only uncover how the networks are aligned at the different cluster levels, but also might help the node-level alignment under the following hypothesis. If the cluster represented by node-1 in $\mathcal{G}_1$ is aligned with that represented by node-6′ in $\mathcal{G}_2$ at the coarsest level (in Figure 1 (e)), it might provide us with clues on how the two-node clusters represented by node-1 and node-2 are aligned with those represented by node-6′ and node-3′ at the next finer level (i.e., level-2). Furthermore, it might indicate how nodes $\{1,2,3,12\}$ are aligned with $\{6',3',11',13'\}$ at the original node level (in Figure 1 (f)). Formally, we define the multilevel network alignment problem.

Table 1: Symbols and Notations

Symbols	Definition
$\mathcal{G}_1$, $\mathcal{G}_2$	the input undirected networks
$\bar{\mathbf{A}}_1$, $\bar{\mathbf{B}}_1$	the adjacency matrices of $\mathcal{G}_1$ and $\mathcal{G}_2$
$\mathbf{A}_1$, $\mathbf{B}_1$	the symmetric normalization by degree matrix of $\bar{\mathbf{A}}_1$, $\bar{\mathbf{B}}_1$
$\mathbf{A}_l$, $\mathbf{B}_l$	the coarsened adjacency matrices at the l-th level
$\mathbf{P}_l$, $\mathbf{Q}_l$	the interpolation matrices at the l-th level
$\mathbf{H}_l$	the $n_2 \times n_1$ prior similarity matrix at the l-th level
$\mathbf{S}_l^*$	the output $n_2 \times n_1$ alignment matrix at the l-th level
$\mathcal{S}_{A_l}$, $\mathcal{S}_{B_l}$	the active indices of $\mathbf{A}_l$, $\mathbf{B}_l$ at the l-th level
n_1, n_2	# of nodes in $\mathcal{G}_1$, $\mathcal{G}_2$
m_1, m_2	# of edges in $\mathcal{G}_1$, $\mathcal{G}_2$
L	# of levels
$\mathrm{Tr}(\cdot)$, $\mathrm{nnz}(\cdot)$	the trace and the number of nonzero elements of a matrix
$\mathrm{vec}(\cdot)$, $\mathrm{mat}(\cdot)$	the vectorization and de-vectorization operators
$\otimes$	the Kronecker product operator

PROBLEM 1. *MULTILEVEL NETWORK ALIGNMENT PROBLEM.*

Given: *(1) adjacency matrices $\bar{\mathbf{A}}_1, \bar{\mathbf{B}}_1$ of two undirected (weighted) sparse networks $\mathcal{G}_1, \mathcal{G}_2$, (2) a sparse prior node similarity matrix $\mathbf{H}_1$ across two networks, and (3) the number of levels $L \geq 2$.*

Output: *a set of $n_2 \times n_1$ alignment matrices $\mathbf{S}_l^*$, $l = 1, \cdots, L$, where specifically $\mathbf{S}_1^*(x,a)$ represents the confidence that node-a in $\mathcal{G}_1$ is aligned with node-x in $\mathcal{G}_2$ at the input node level.*

2.2 Preliminaries #1: Node-Level Alignment

A classic node-level alignment algorithm is attributed to *IsoRank* [27] based on the *alignment consistency* by random walks on the product graph. With an additional normalization, it has the following optimization interpretation referred to as *FINAL* in [35].

$$\min_{\mathbf{s}_1} \ \alpha \mathbf{s}_1^T(\mathbf{I} - \mathbf{A}_1 \otimes \mathbf{B}_1)\mathbf{s}_1 + (1-\alpha)\|\mathbf{s}_1 - \mathbf{h}_1\|_2^2 \tag{1}$$

where $\mathbf{s}_1, \mathbf{h}_1$ are the vectorization of the alignment matrix $\mathbf{S}_1$ and the prior similarity matrix $\mathbf{H}_1$, respectively. $\mathbf{A}_1$ and $\mathbf{B}_1$ are the symmetrically normalized adjacency matrices by the degree matrices of $\bar{\mathbf{A}}_1$ and $\bar{\mathbf{B}}_1$ respectively. Besides, the prior node similarity $\mathbf{h}_1$ is to encode the prior alignment information (e.g., anchor links across two networks) and prevent trivial solutions (e.g., $\mathbf{s}_1 = \mathbf{0}$). When such anchor links are absent, we can construct it by some heuristics, e.g., degree similarity. Our proposed algorithm will be based on Eq. (1). The optimization in Eq. (1) is convex so that a global optimal solution can be obtained by the fixed-point algorithm:

$$\mathbf{S}_1 = \alpha \mathbf{B}_1 \mathbf{S}_1 \mathbf{A}_1 + (1-\alpha)\mathbf{H}_1 \tag{2}$$

with an $O(n^2)$ time complexity even with approximations [35].

2.3 Preliminaries #2: MMF

Although many multilevel methods (e.g., hierarchical clustering, algebraic multigrid) exist for mining a single network, it turns out that multiresolution matrix factorization (MMF) [15, 29] is particularly suited for network alignment task for the reason that we will explain in Section 3.2. Here, we give a short review of MMF.

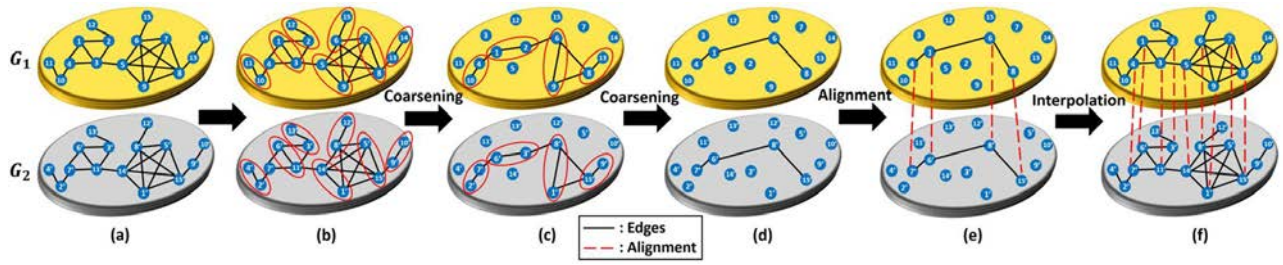

Figure 1: An illustrative example. (a) shows the input networks. (b)-(d) show the network coarsening process. (e) presents the alignment at the coarsest level and (f) shows parts of the node-level alignment across the input networks after interpolations.

Given a symmetric matrix $\mathbf{A}_1 \in R^{n_1 \times n_1}$, MMF explores the hierarchical cluster-within-clusters structure underlying the matrix $\mathbf{A}_1$ and factorizes $\mathbf{A}_1$ into several sparse orthogonal matrices and a core-diagonal matrix. This multilevel factorization is of the form

$$\mathbf{P}_{L-1} \cdots \mathbf{P}_1 \mathbf{A}_1 \mathbf{P}_1^T \cdots \mathbf{P}_{L-1}^T = \mathbf{A}_L \approx \tilde{\mathbf{A}}_L \tag{3}$$

where $\mathbf{P}_1, \cdots, \mathbf{P}_{L-1}$ are the sparse orthogonal matrices and the matrix $\tilde{\mathbf{A}}_L$ is the $\mathcal{S}_L$-core-diagonal matrix defined as below.

Definition 1. ***$\mathcal{S}_L$-core-diagonal matrix [15].*** *Denote a set of active indices as $\mathcal{S}_L = \{i_1, \cdots, i_k\} \subset \{1, \cdots, n_1\}$. Then a matrix $\tilde{\mathbf{A}}_L$ is defined as the $\mathcal{S}_L$-core-diagonal matrix under the condition that $\tilde{\mathbf{A}}_L(i,j) = 0$ unless $i = j$ or $i, j \in \mathcal{S}_L$.*

Throughout this paper, we refer to $\tilde{\mathbf{A}}_L(\mathcal{S}_L, \mathcal{S}_L)$ as the core matrix of $\tilde{\mathbf{A}}_L$. Note that $\tilde{\mathbf{A}}_L(\mathcal{S}_L, \mathcal{S}_L) = \mathbf{A}_L(\mathcal{S}_L, \mathcal{S}_L)$ according to how $\tilde{\mathbf{A}}_L$ is generated (see Appendix A). To compute these sparse orthogonal matrices, [15, 29] consider using the elementary rotation and compound rotation matrices. Among others, using the compound rotation matrices (see Appendix A) yields a more interpretable and compact hierarchical structure, which commonly resides in the underlying network. Therefore, in this paper, we use the parallel MMF with the compound rotations.

3 MULTILEVEL NETWORK ALIGNMENT

In this section, we present our solution to Problem 1. First, we present our multilevel network alignment framework from the optimization perspective. We analyze the theoretical condition on the perfect interpolation which allows no interpolation error across multiple levels. Then, we introduce the details of the proposed algorithm Moana, followed by further analysis of our algorithm.

3.1 Multilevel Optimization Formulation

Generally speaking, most of the existing multilevel approaches to graph mining problems (e.g., graph partitioning) follow similar strategies. They first hierarchically coarsen the network so that at the coarsest level, an approximation solution to the original problem can be obtained within an insignificant time. This approximation solution will then be sequentially projected to the finer levels by the *interpolation* matrices. Inspired by this generic strategy, our key idea is to use the interpolation matrices to efficiently estimate the alignment matrix at the finer level (e.g., $\mathbf{S}_l$ at the l-th level) from that at the next coarser level (e.g., $\mathbf{S}_{l+1}$). Since the alignment matrices hinge on two networks, different from the interpolations underlying a single network, the bilinear interpolations are required.

To derive the optimization formulation for our multilevel network alignment problem, without loss of generality, we focus on the first two levels for now. Denote two interpolation matrices $\mathbf{P}_1 \in R^{p_1 \times n_1}$ and $\mathbf{Q}_1 \in R^{q_1 \times n_2}$ where $p_1 \leq n_1, q_1 \leq n_2$ such that we can approximate the node-level alignment matrix $\mathbf{S}_1$ by $\mathbf{S}_1 = \mathbf{Q}_1^T \mathbf{S}_2 \mathbf{P}_1$ where $\mathbf{S}_2 \in R^{q_1 \times p_1}$ is the alignment matrix at the second level. By de-vectorization on $\mathbf{s}_1, \mathbf{h}_1$, Eq. (1) is equivalent to

$$\min_{\mathbf{S}_1} \ \alpha[\mathrm{Tr}(\mathbf{S}_1^T \mathbf{S}_1) - \mathrm{Tr}(\mathbf{S}_1^T \mathbf{B}_1 \mathbf{S}_1 \mathbf{A}_1)] + (1-\alpha)\|\mathbf{S}_1 - \mathbf{H}_1\|_F^2 \tag{4}$$

Plugging in $\mathbf{S}_1 = \mathbf{Q}_1^T \mathbf{S}_2 \mathbf{P}_1$, we have the objective function w.r.t. $\mathbf{S}_2$.

$$\begin{aligned} J(\mathbf{S}_2) =& \alpha[\mathrm{Tr}(\mathbf{P}_1^T \mathbf{S}_2^T \mathbf{Q}_1 \mathbf{Q}_1^T \mathbf{S}_2 \mathbf{P}_1) - \mathrm{Tr}(\mathbf{S}_2^T \mathbf{Q}_1 \mathbf{B}_1 \mathbf{Q}_1^T \mathbf{S}_2 \mathbf{P}_1 \mathbf{A}_1 \mathbf{P}_1^T)] \\ &+ (1-\alpha)\|\mathbf{Q}_1^T \mathbf{S}_2 \mathbf{P}_1 - \mathbf{H}_1\|_F^2 \end{aligned} \tag{5}$$

Notice that if the (semi-) orthogonality satisfies, i.e., $\mathbf{P}_1 \mathbf{P}_1^T = \mathbf{I}$ and $\mathbf{Q}_1 \mathbf{Q}_1^T = \mathbf{I}$, we can obtain the objective function at the second level which is of exactly the same form as Eq. (4), i.e.,

$$J(\mathbf{S}_2) = \alpha[\mathrm{Tr}(\mathbf{S}_2^T \mathbf{S}_2) - \mathrm{Tr}(\mathbf{S}_2^T \mathbf{B}_2 \mathbf{S}_2 \mathbf{A}_2)] + (1-\alpha)\|\mathbf{S}_2 - \mathbf{H}_2\|_F^2 \tag{6}$$

where $\mathbf{A}_2 = \mathbf{P}_1 \mathbf{A}_1 \mathbf{P}_1^T$, $\mathbf{B}_2 = \mathbf{Q}_1 \mathbf{B}_1 \mathbf{Q}_1^T$ and $\mathbf{H}_2 = \mathbf{Q}_1 \mathbf{H}_1 \mathbf{P}_1^T$. Equivalently, this can be viewed as coarsening $\mathbf{A}_1, \mathbf{B}_1$ into $\mathbf{A}_2, \mathbf{B}_2$ to be aligned at the second level by the interpolation matrices $\mathbf{P}_1$ and $\mathbf{Q}_1$, with the corresponding prior node similarity matrix $\mathbf{H}_2$.

In fact, the relationship between Eq. (4) and Eq. (6) applies to any two adjacent levels among all the L levels. This implies that as we coarsen the symmetrically normalized adjacency matrices of the input networks (i.e., $\mathbf{A}_1, \mathbf{B}_1$) into the coarsest level (i.e., $\mathbf{A}_L, \mathbf{B}_L$), we are always solving the same optimization problem but w.r.t. the different variables to find the alignment at different levels (e.g., $\mathbf{S}_L$). The benefits of this are three-fold. First, this ensures that the same theoretical properties and optimization algorithms at the finest node level (e.g., the convexity, the optimality, the convergence from [35]) will immediately apply to the coarse levels as well. Second, similar to most multilevel approaches, solving the alignment problem at the coarsest level is computationally more efficient. Third, provided that a set of 'good' (semi-) orthogonal interpolation matrices $\mathbf{P}_l, \mathbf{Q}_l$ can be found, we are able to obtain a set of well-represented adjacency matrices at the coarse levels that reveal the hierarchical cluster-within-clusters structure of the input networks.

3.2 Perfect Interpolation

Despite a large number of the proposed graph coarsening methods, to our best knowledge, few of them bear the (semi-) orthogonality of the interpolation matrices. For example, neither the heavy-edge matching [6, 13] nor the algebraic multigrid (AMG) coarsening [23] guarantees the semi-orthogonality. Moreover, since there are more variables at the finer levels than coarser levels, interpolation might introduce an interpolation error to the alignment matrix at the finer level. Even worse, in the multilevel setting, such an interpolation error could propagate or even diverge through different levels so that the node-level alignment might be sub-optimal or even misleading.

In this paper, instead of exploring the semi-orthogonal interpolation matrices, we seek to find a set of orthogonal matrices, i.e., $\mathbf{P}_l\mathbf{P}_l^T = \mathbf{I}$ and $\mathbf{P}_l^T\mathbf{P}_l = \mathbf{I}$. Indeed, by the following lemma, we show that the orthogonal interpolation matrices guarantee that the interpolation of the optimal alignment matrix from the coarser level is exactly the same as the optimal alignment matrix at the finer level.

Lemma 1. ***Perfect Interpolation.*** *The global optimal solution to the optimization problem at the finer level (e.g., Eq.* (4) *for level-1), denoted by* $\mathbf{S}_l$*, is exactly same as the interpolation of the optimal solution at the next coarser level (denoted by* $\mathbf{S}_{l+1}$*). That is,* $\mathbf{S}_l = \mathbf{Q}_l^T\mathbf{S}_{l+1}\mathbf{P}_l$ *if* $\mathbf{P}_l$ *and* $\mathbf{Q}_l$ *are orthogonal, where* $l = 1, \cdots, L-1$.

Proof. Without loss of generality, we prove $\mathbf{S}_1 = \mathbf{Q}_1^T\mathbf{S}_2\mathbf{P}_1$. For all the other levels, it is straightforward to show the same result. The optimal closed-form solution to Eq. (1) (and equivalently Eq. (4)) is $\mathbf{s}_1 = (1-\alpha)(\mathbf{I} - \alpha\mathbf{A}_1 \otimes \mathbf{B}_1)^{-1}\mathbf{h}_1$. Similarly, the alignment matrix between $\mathbf{A}_2, \mathbf{B}_2$ at the second level is computed by

$$\mathbf{s}_2 = (1-\alpha)[\mathbf{I} - \alpha(\mathbf{P}_1\mathbf{A}_1\mathbf{P}_1^T) \otimes (\mathbf{Q}_1\mathbf{B}_1\mathbf{Q}_1^T)]^{-1}\mathbf{h}_2$$

The difference between $\mathbf{S}_1$ and the interpolated alignment from $\mathbf{S}_2$ measured in the Frobenius norm is

$$\begin{aligned}
&\|\mathbf{Q}_1^T\mathbf{S}_2\mathbf{P}_1 - \mathbf{S}_1\|_F = \|(\mathbf{P}_1^T \otimes \mathbf{Q}_1^T)\mathbf{s}_2 - \mathbf{s}_1\|_2 \\
=&(1-\alpha)\|(\mathbf{P}_1^T \otimes \mathbf{Q}_1^T)[\mathbf{I} - \alpha(\mathbf{P}_1\mathbf{A}_1\mathbf{P}_1^T) \otimes (\mathbf{Q}_1\mathbf{B}_1\mathbf{Q}_1^T)]^{-1}\mathbf{h}_2 \\
&-(\mathbf{I} - \alpha\mathbf{A}_1 \otimes \mathbf{B}_1)^{-1}\mathbf{h}_1\|_2 \\
=&(1-\alpha)\Big\|\sum_{k=0}^{\infty}\alpha^k(\mathbf{P}_1^T \otimes \mathbf{Q}_1^T)[(\mathbf{P}_1\mathbf{A}_1\mathbf{P}_1^T)^k \otimes (\mathbf{Q}_1\mathbf{B}_1\mathbf{Q}_1^T)^k](\mathbf{P}_1 \otimes \mathbf{Q}_1)\mathbf{h}_1 \\
&-\sum_{k=0}^{\infty}\alpha^k(\mathbf{A}_1^k \otimes \mathbf{B}_1^k)\mathbf{h}_1\Big\|_2
\end{aligned}$$

where the third equation is by Neumann series due to the fact that (1) the eigenvalues of $\mathbf{A}_1, \mathbf{B}_1$ are in the range of $[-1, 1]$, and (2) $\mathbf{P}_1\mathbf{A}_1\mathbf{P}_1^T, \mathbf{Q}_1\mathbf{B}_1\mathbf{Q}_1^T$ share the same eigenvalues as $\mathbf{A}_1, \mathbf{B}_1$ respectively given that $\mathbf{P}_1$ and $\mathbf{Q}_1$ are orthogonal [24].

Due to the orthogonality of $\mathbf{P}_1, \mathbf{Q}_1$, the following equations hold.

$$\begin{aligned}
\mathbf{A}_1^k =&\mathbf{P}_1^T(\mathbf{P}_1\mathbf{A}_1\mathbf{P}_1^T)^k\mathbf{P}_1 \\
\mathbf{B}_1^k =&\mathbf{Q}_1^T(\mathbf{Q}_1\mathbf{B}_1\mathbf{Q}_1^T)^k\mathbf{Q}_1
\end{aligned}$$

Thus, we have that

$$\|\mathbf{S}_1 - \mathbf{Q}_1^T\mathbf{S}_2\mathbf{P}_1\|_F^2 = (1-\alpha)\Big\|\sum_{k=0}^{\infty}\alpha^k(\mathbf{A}_1^k \otimes \mathbf{B}_1^k - \mathbf{A}_1^k \otimes \mathbf{B}_1^k)\mathbf{h}_1\Big\|_2 = 0$$

which completes the proof. □

3.3 Multilevel Alignment Algorithm

Our multilevel alignment algorithm Moana contains three phases, including *coarsening* the input networks, *aligning* across the coarsest networks, and then *interpolating* the alignment matrix from the coarser levels to the finer levels.

A - Network coarsening. Based on Lemma 1, we want to find a set of orthogonal matrices to coarsen the input networks. However, even though the input adjacency matrix, say $\mathbf{A}_1$, is sparse, the computational complexity of $\mathbf{P}_1\mathbf{A}_1\mathbf{P}_1^T$ may still be $O(n^3)$ at worst if $\mathbf{P}_1$ is not sufficiently sparse. With an arbitrarily orthogonal matrix, the resulting matrix $\mathbf{A}_2$ at the next coarser level could be less informative and thus could fail to reveal the underlying structural information of $\mathbf{A}_1$. Thus, we seek to find a set of orthogonal interpolation matrices $\mathbf{P}_l$ and $\mathbf{Q}_l$ such that (1) they are sufficiently sparse, and (2) they are able to uncover the *hierarchical cluster-within-clusters* structure of the input networks. In this paper, we leverage a recently proposed multiresolution matrix factorization (MMF) algorithm that satisfies these requirements [15]. Specifically, for each input network, we use the parallel second order MMF algorithm (i.e., $k_1, \cdots, k_p \le 2$ in Eq. (25)) to find a set of rotation matrices $\mathbf{P}_l, \mathbf{Q}_l$ such that at the l-th level ($l \ge 2$),

$$\mathbf{A}_l = \mathbf{P}_{l-1}\cdots\mathbf{P}_1\mathbf{A}_1\mathbf{P}_1^T\cdots\mathbf{P}_{l-1}^T \tag{7}$$

$$\mathbf{B}_l = \mathbf{Q}_{l-1}\cdots\mathbf{Q}_1\mathbf{B}_1\mathbf{Q}_1^T\cdots\mathbf{Q}_{l-1}^T \tag{8}$$

where the active indices of $\mathbf{A}_l, \mathbf{B}_l$ are denoted as $\mathcal{S}_{A_l}$ of size λ_l and $\mathcal{S}_{B_l}$ of size μ_l, respectively. Specifically, at the coarsest level, the rotated matrices are denoted as $\mathbf{A}_L, \mathbf{B}_L$. Then we form the core-diagonal matrices $\tilde{\mathbf{A}}_L$ and $\tilde{\mathbf{B}}_L$ as detailed in Appendix A.

Remarks. Different from the traditional coarsening methods, such as the AMG-based methods, the MMF algorithm can be viewed as coarsening the network without reducing the size of the adjacency matrix. Due to its root in multiresolution analysis on networks, MMF offers a natural way to explore the *cluster-within-clusters* structure, which we elaborate as follows. Generally speaking, the multiresolution analysis on networks (e.g., diffusion wavelet [4]) aims to find a sequence of smoother spaces of the network. Each space captures the corresponding structured representation of the network (e.g., clusters) at a certain level by its basis (i.e., scaling functions) and the scaling coefficients. Specifically, in MMF, the scaling functions of $\mathbf{A}_1$ at the l-th level are formed by the rows of $\mathbf{P}_{l-1}\cdots\mathbf{P}_1$ indexed by $\mathcal{S}_{A_l}$, and $\mathbf{A}_l(\mathcal{S}_{A_l}, \mathcal{S}_{A_l})$ acts as the scaling coefficients. In fact, each row/column of $\mathbf{A}_l(\mathcal{S}_{A_l}, \mathcal{S}_{A_l})$ can be viewed as a node represented in the corresponding smooth space (or equivalently, clusters at level l) and these coefficients measure the strength of the interactions among the clusters at level l. Similarly, at the $(l+1)$-th level, the clusters at level l tend to be further clustered and hence MMF can explore the *cluster-within-clusters* structure of the networks. Thus, $\tilde{\mathbf{A}}_L, \tilde{\mathbf{B}}_L$ capture the coarsest cluster structures of the input networks.

B - Alignment across the coarsest networks. After the coarsening step (e.g., Eq. (3) on $\mathbf{A}_1$), the symmetrically normalized adjacency matrices of the input networks are transformed into the corresponding core-diagonal matrices, i.e.,

$$\tilde{\mathbf{A}}_L = \mathbf{\Pi}_A\begin{bmatrix}\tilde{\mathbf{A}}_{L_1} & \mathbf{0}\\ \mathbf{0} & \tilde{\mathbf{A}}_{L_2}\end{bmatrix}\mathbf{\Pi}_A^T,\ \tilde{\mathbf{B}}_L = \mathbf{\Pi}_B\begin{bmatrix}\tilde{\mathbf{B}}_{L_1} & \mathbf{0}\\ \mathbf{0} & \tilde{\mathbf{B}}_{L_2}\end{bmatrix}\mathbf{\Pi}_B^T \tag{9}$$

where $\tilde{\mathbf{A}}_{L_1} = \tilde{\mathbf{A}}_L(\mathcal{S}_{A_L}, \mathcal{S}_{A_L})$ and $\tilde{\mathbf{B}}_{L_1} = \tilde{\mathbf{B}}_L(\mathcal{S}_{B_L}, \mathcal{S}_{B_L})$ are the core matrices of $\tilde{\mathbf{A}}_L$ and $\tilde{\mathbf{B}}_L$ respectively. $\mathbf{\Pi}_A, \mathbf{\Pi}_B$ are the orthogonal permutation matrices to reorder the active indices of the matrices $\tilde{\mathbf{A}}_L, \tilde{\mathbf{B}}_L$ to be in the upper left part for the illustration purpose. Denote the inactive indices as $\overline{\mathcal{S}}_{A_L} = \{1, \cdots, n_1\} \setminus \mathcal{S}_{A_L}$ and $\overline{\mathcal{S}}_{B_L} = \{1, \cdots, n_2\} \setminus \mathcal{S}_{B_L}$. Accordingly, $\tilde{\mathbf{A}}_{L_2} = \tilde{\mathbf{A}}_L(\overline{\mathcal{S}}_{A_L}, \overline{\mathcal{S}}_{A_L})$ and $\tilde{\mathbf{B}}_{L_2} = \tilde{\mathbf{B}}_L(\overline{\mathcal{S}}_{B_L}, \overline{\mathcal{S}}_{B_L})$. Note that our algorithm does not need to explicitly compute such permutation matrices.

To solve the alignment between $\tilde{\mathbf{A}}_L$ and $\tilde{\mathbf{B}}_L$ at the coarsest level, we use the iterative fixed-point algorithm similar to Eq. (2).

$$\mathbf{S}_L = \alpha\tilde{\mathbf{B}}_L\mathbf{S}_L\tilde{\mathbf{A}}_L + (1-\alpha)\mathbf{H}_L \tag{10}$$

where $\mathbf{H}_L = \mathbf{Q}_{L-1}\cdots\mathbf{Q}_1\mathbf{H}_1\mathbf{P}_1^T\cdots\mathbf{P}_{L-1}^T$ is the corresponding prior similarity matrix at the coarsest level. By using the permutation matrices $\mathbf{\Pi}_A, \mathbf{\Pi}_B$, Eq. (10) can be rewritten as

$$\mathbf{\Pi}_B^T\mathbf{S}_L\mathbf{\Pi}_A = \alpha(\mathbf{\Pi}_B^T\tilde{\mathbf{B}}_L\mathbf{\Pi}_B)(\mathbf{\Pi}_B^T\mathbf{S}_L\mathbf{\Pi}_A)(\mathbf{\Pi}_A^T\tilde{\mathbf{A}}_L\mathbf{\Pi}_A^T)+(1-\alpha)\mathbf{\Pi}_B^T\mathbf{H}_L\mathbf{\Pi}_A$$

By denoting $\tilde{\mathbf{S}}_L = \mathbf{\Pi}_B^T\mathbf{S}_L\mathbf{\Pi}_A$ and $\tilde{\mathbf{H}}_L = \mathbf{\Pi}_B^T\mathbf{H}_L\mathbf{\Pi}_A$, the computation can be simplified to

$$\tilde{\mathbf{S}}_L = \alpha\begin{bmatrix}\tilde{\mathbf{B}}_{L_1} & \mathbf{0}\\ \mathbf{0} & \tilde{\mathbf{B}}_{L_2}\end{bmatrix}\begin{bmatrix}\tilde{\mathbf{S}}_{L_1} & \tilde{\mathbf{S}}_{L_2}\\ \tilde{\mathbf{S}}_{L_3} & \tilde{\mathbf{S}}_{L_4}\end{bmatrix}\begin{bmatrix}\tilde{\mathbf{A}}_{L_1} & \mathbf{0}\\ \mathbf{0} & \tilde{\mathbf{A}}_{L_2}\end{bmatrix}+(1-\alpha)\begin{bmatrix}\tilde{\mathbf{H}}_{L_1} & \tilde{\mathbf{H}}_{L_2}\\ \tilde{\mathbf{H}}_{L_3} & \tilde{\mathbf{H}}_{L_4}\end{bmatrix}$$

which allows the computation to be block-wise as follows:

$$\tilde{\mathbf{S}}_{L_1} = \alpha\tilde{\mathbf{B}}_{L_1}\tilde{\mathbf{S}}_{L_1}\tilde{\mathbf{A}}_{L_1} + (1-\alpha)\tilde{\mathbf{H}}_{L_1} \tag{11}$$

$$\tilde{\mathbf{S}}_{L_2} = \alpha\tilde{\mathbf{B}}_{L_1}\tilde{\mathbf{S}}_{L_2}\tilde{\mathbf{A}}_{L_2} + (1-\alpha)\tilde{\mathbf{H}}_{L_2} \tag{12}$$

$$\tilde{\mathbf{S}}_{L_3} = \alpha\tilde{\mathbf{B}}_{L_2}\tilde{\mathbf{S}}_{L_3}\tilde{\mathbf{A}}_{L_1} + (1-\alpha)\tilde{\mathbf{H}}_{L_3} \tag{13}$$

$$\tilde{\mathbf{S}}_{L_4} = \alpha\tilde{\mathbf{B}}_{L_2}\tilde{\mathbf{S}}_{L_4}\tilde{\mathbf{A}}_{L_2} + (1-\alpha)\tilde{\mathbf{H}}_{L_4} \tag{14}$$

Armed with the iterative fixed-point algorithm, the global optimal solutions to Eq. (11), Eq. (12) and Eq. (13) can be achieved and are denoted as $\tilde{\mathbf{S}}^*_{L_1}, \tilde{\mathbf{S}}^*_{L_2}, \tilde{\mathbf{S}}^*_{L_3}$ respectively. Furthermore, since both $\tilde{\mathbf{A}}_{L_2}$ and $\tilde{\mathbf{B}}_{L_2}$ are sparse diagonal matrices, the closed-form optimal solution of Eq. (14) can be easily computed by

$$\tilde{\mathbf{s}}^*_{L_4} = (1-\alpha)(\mathbf{I}-\alpha\tilde{\mathbf{A}}_{L_2}\otimes\tilde{\mathbf{B}}_{L_2})^{-1}\tilde{\mathbf{h}}_{L_4} \tag{15}$$

where $\tilde{\mathbf{s}}^*_{L_4} = \mathrm{vec}(\tilde{\mathbf{S}}^*_{L_4}), \tilde{\mathbf{h}}_{L_4} = \mathrm{vec}(\tilde{\mathbf{H}}_{L_4})$ and the operator $\otimes$ represents the Kronecker product. In this way, by the permutation matrices $\mathbf{\Pi}_A, \mathbf{\Pi}_B$, the optimal solution to the alignment problem at the coarsest level $\mathbf{S}^*_L$ is composed of $\mathbf{S}^*_L(\mathcal{S}_{B_L}, \mathcal{S}_{B_L})$, $\mathbf{S}^*_L(\mathcal{S}_{B_L}, \overline{\mathcal{S}}_{A_L})$, $\mathbf{S}^*_L(\overline{\mathcal{S}}_{B_L}, \mathcal{S}_{A_L})$ and $\mathbf{S}^*_L(\overline{\mathcal{S}}_{B_L}, \overline{\mathcal{S}}_{A_L})$ where

$$\begin{aligned}\mathbf{S}^*_L(\mathcal{S}_{B_L}, \mathcal{S}_{A_L}) &= \tilde{\mathbf{S}}^*_{L_1}, & \mathbf{S}^*_L(\mathcal{S}_{B_L}, \overline{\mathcal{S}}_{A_L}) &= \tilde{\mathbf{S}}^*_{L_2}\\ \mathbf{S}^*_L(\overline{\mathcal{S}}_{B_L}, \mathcal{S}_{A_L}) &= \tilde{\mathbf{S}}^*_{L_3}, & \mathbf{S}^*_L(\overline{\mathcal{S}}_{B_L}, \overline{\mathcal{S}}_{A_L}) &= \tilde{\mathbf{S}}^*_{L_4}\end{aligned} \tag{16}$$

Note that though the core matrices $\tilde{\mathbf{A}}_{L_1}, \tilde{\mathbf{B}}_{L_1}$ could be dense, their sizes $\lambda_L \times \lambda_L$ and $\mu_L \times \mu_L$ are very small (i.e., $\lambda_L \ll n_1, \mu_L \ll n_2$), which can be controlled by the parameter L. This is due to the fact of parallel MMF that the size of the core matrix decreases exponentially (e.g., $\lambda_L \approx 2^{-L}n_1$). Empirically, we find that λ_L, μ_L in the order of hundreds often achieves a good balance between effectiveness and efficiency, as we will show in Section 4.. Moreover, thanks to the fact that both $\tilde{\mathbf{A}}_{L_2}, \tilde{\mathbf{B}}_{L_2}$ are diagonal, the above computations are very efficient as we will show in the next subsection.

C - Interpolation. After the optimal alignment matrix $\mathbf{S}^*_L$ at the coarsest level is achieved, the alignment at each level $\mathbf{S}^*_l$ can be computed by the interpolation, i.e., $\mathbf{S}^*_l = \mathbf{Q}_l^T\mathbf{S}^*_{l+1}\mathbf{P}_l,\ l = 1,\cdots,L-1$.

As shown in the next subsection, the number of nonzero elements of $\mathbf{S}^*_L$ is $O(L^2m_H + nd_L)$, making the computations of interpolations possibly intense. To address this issue, we only preserve the top-K elements of each row/column based on their absolute values in $\mathbf{S}^*_L$. The entire algorithm is summarized in Algorithm 1. We use two criteria to terminate the iteration (line 7-9): (1) the change of $\tilde{\mathbf{S}}_{L_1}, \tilde{\mathbf{S}}_{L_2}, \tilde{\mathbf{S}}_{L_3}$ of two successive iterations is less than a threshold ξ, or (2) the maximum number of iterations $t_{\max}$ is reached.

Recall that the coarse-scale structures of the networks are captured by the core matrices (e.g., $\mathbf{A}_2(\mathcal{S}_{A_2}, \mathcal{S}_{A_2})$ and $\mathbf{B}_2(\mathcal{S}_{B_2}, \mathcal{S}_{B_2})$), the corresponding submatrix of the alignment matrix indicates how network clusters are aligned. For example, $\mathbf{S}^*_2(\mathcal{S}_{B_2}, \mathcal{S}_{A_2})$ indicates how clusters of network $\mathcal{G}_1$ and $\mathcal{G}_2$ are aligned at the second level.

Algorithm 1 Multilevel Network Alignment (Moana).

Input: (1) the adjacency matrices $\bar{\mathbf{A}}_1, \bar{\mathbf{B}}_1$ of two undirected networks $\mathcal{G}_1$, $\mathcal{G}_2$, (2) the sparse prior alignment preference $\mathbf{H}_1$, (3) the number of levels L, (4) the parameters α, K.

Output: the alignment matrices $\mathbf{S}^*_l,\ l = 1,\cdots,L$ between $\mathcal{G}_1, \mathcal{G}_2$.

1: Compute $\mathbf{A}_1, \mathbf{B}_1$ by symmetrically normalizing $\bar{\mathbf{A}}_1, \bar{\mathbf{B}}_1$;

▷ **Network coarsening.**

3: $\mathbf{P}_1,\cdots,\mathbf{P}_{L-1}$ and $\tilde{\mathbf{A}}_L \leftarrow \mathrm{MMF}(\mathbf{A}_1)$;

4: $\mathbf{Q}_1,\cdots,\mathbf{Q}_{L-1}$ and $\tilde{\mathbf{B}}_L \leftarrow \mathrm{MMF}(\mathbf{B}_1)$;

5: Compute the coarsest level $\mathbf{H}_L = \mathbf{Q}_{L-1}\cdots\mathbf{Q}_1\mathbf{H}_1\mathbf{P}_1^T\cdots\mathbf{P}_{L-1}^T$;

▷ **Alignment at the coarsest level.**

7: **while** not converged **do**

8: Update $\tilde{\mathbf{S}}_{L_1}, \tilde{\mathbf{S}}_{L_2}, \tilde{\mathbf{S}}_{L_3}$ by Eq. (11)-(13);

9: Compute $\tilde{\mathbf{s}}^*_{L_4}$ by Eq. (15) and $\tilde{\mathbf{S}}^*_{L_4} = \mathrm{mat}(\tilde{\mathbf{s}}^*_{L_4})$;

10: Compose $\mathbf{S}^*_L$ by Eq. (16);

▷ **Alignment interpolation.**

12: Preserve top-K elements in each row/column of $\mathbf{S}^*_L$;

13: **for** $l = L-1 \to 1$ **do**

14: Compute $\mathbf{S}^*_l = \mathbf{Q}_l^T\mathbf{S}^*_{l+1}\mathbf{P}_l$;

3.4 Algorithm Analysis

We analyze the effectiveness and efficiency of our proposed algorithm. The *perfect interpolation* (Lemma 1) indicates that in theory, by using orthogonal interpolation matrices, the alignment matrix at the finer level can be obtained from that at the coarser level without any interpolation error. Nonetheless, in practice, we might still introduce some alignment error at the coarsest level due to the fact that many matrices are not *fully multiresolution factorizable* (i.e., $\tilde{\mathbf{A}}_L \neq \mathbf{A}_L$) [15]. Having this in mind, we seek to quantify the alignment error due to the fact that $\mathbf{A}_L \neq \tilde{\mathbf{A}}_L, \mathbf{B}_L \neq \tilde{\mathbf{B}}_L$.

Theorem 1. ***Alignment error bound.*** *Denote $\delta_1 = \|\mathbf{A}_L - \tilde{\mathbf{A}}_L\|_F$, $\delta_2 = \|\mathbf{B}_L - \tilde{\mathbf{B}}_L\|_F$. Suppose the ranks of $\mathbf{A}_1, \mathbf{B}_1$ are r_1, r_2 whose values are often small due to the low-rank characteristics of many real-world networks. Then, the error of the output alignment matrix at level $l, l = 1,\cdots,L$ is bounded as*

$$\frac{\|\mathbf{S}^*_l - \mathbf{S}_l\|_F}{\|\mathbf{S}_l\|_F} \leq \frac{2\epsilon\kappa}{1-\epsilon\kappa} \tag{17}$$

where $\mathbf{S}^*_l$ is the alignment matrix at level l obtained by Algorithm 1, $\mathbf{S}_l$ is the ideally interpolated alignment from $\mathbf{S}_L$ which is computed by $\mathbf{A}_L$. The parameter κ is the condition number under Frobenius norm of the matrix $(1-\alpha)(\mathbf{I}-\alpha\mathbf{A}_1\otimes\mathbf{B}_1)$, and $\epsilon = \sqrt{\frac{\alpha}{2n}}(\delta_1 r_2 + \delta_2 r_1 + \delta_1\delta_2)$.

Proof. See Appendix B. □

For the efficiency analysis of Moana, we start with the Lemma 2 on the sparsity of the matrix $\tilde{\mathbf{H}}_{L_4}$ which paves the way to the complexity analysis.

Lemma 2. ***Sparsity of $\tilde{\mathbf{H}}_{L_4}$.*** *Suppose there are m_H nonzero elements in the sparse prior similarity matrix $\mathbf{H}_1$ and $m_H \ll n^2$. At the coarsest level, the number of nonzero elements of $\tilde{\mathbf{H}}_{L_4}$ is $O(L^2m_H)$.*

Proof. Denote the density of the nonzero elements in $\mathbf{H}_1$ as $\rho_1 = \frac{m_H}{n^2}$. Starting with the coarsening at the first level, the computation

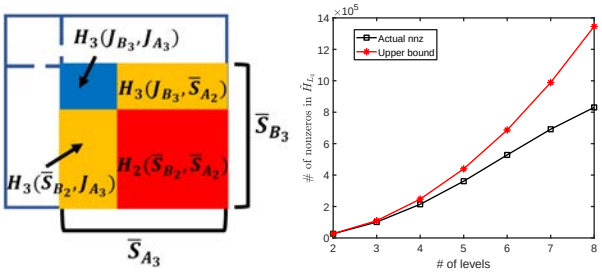

Figure 2: An illustration example of Lemma 2. (a) explains its proof where the indices have been reordered. (b) shows a case on Gr-Qc networks where $\rho_1 = 0.001, n = 5,241$.

of the matrix $\mathbf{H}_2$ is as follows.

$$\mathbf{H}_2(i,j) = (\mathbf{Q}_1\mathbf{H}_1\mathbf{P}_1^T)(i,j) = \sum_{p,q} \mathbf{Q}_1(i,q)\mathbf{H}_1(q,p)\mathbf{P}_1(j,p) \quad (18)$$

$$= \mathbf{Q}_1(i,i)\mathbf{H}_1(i,j)\mathbf{P}_1(j,j) + \mathbf{Q}_1(i,i)\mathbf{H}_1(i,p)\mathbf{P}_1(j,p) \quad (19)$$
$$+ \mathbf{Q}_1(i,q)\mathbf{H}_1(q,j)\mathbf{P}_1(j,j) + \mathbf{Q}_1(i,q)\mathbf{H}_1(q,p)\mathbf{P}_1(j,p)$$

The second equation is due to Eq. (25) where $k = 2$. That is, $\mathbf{Q}_1(i,q) \neq 0$ if $i_1^u = i$ and $i_2^u = q$ for some u, and similarly to $\mathbf{P}_1(j,p)$. Thus, $\mathbf{H}_2(i,j)$ can be nonzero if at least one of the $\mathbf{H}_1(i,j)$, $\mathbf{H}_1(i,p)$, $\mathbf{H}_1(q,j)$, $\mathbf{H}_1(q,p)$ are nonzero. In other words, each nonzero element in $\mathbf{H}_1$ can contribute to generating at most four nonzero elements in $\mathbf{H}_2$. Thus, the density of $\mathbf{H}_2$ is $\rho_2 \leq 4\rho_1$. Denote $\mathcal{S}_{A_l}, \mathcal{S}_{B_l}$ as the active indices of $\mathbf{A}_l, \mathbf{B}_l$ at the l-th level, and $\overline{\mathcal{S}}_{A_l}, \overline{\mathcal{S}}_{B_l}$ as the inactive indices. Since the second order MMF inactivates half of the current active indices [15], i.e., $|\overline{\mathcal{S}}_{A_2}| \approx |\overline{\mathcal{S}}_{B_2}| \approx \frac{n}{2}$, we have the number of nonzero elements $\text{nnz}(\mathbf{H}_2(\overline{\mathcal{S}}_{B_2}, \overline{\mathcal{S}}_{A_2})) \leq 4\rho_1(\frac{n}{2})^2 = \rho_1 n^2$. At the second level, thanks to the property of MMF that $\mathbf{P}_2(\overline{\mathcal{S}}_{A_2}, \overline{\mathcal{S}}_{A_2}) = \mathbf{I}$ and $\mathbf{Q}_2(\overline{\mathcal{S}}_{B_2}, \overline{\mathcal{S}}_{B_2}) = \mathbf{I}$, the computation of $\mathbf{H}_3 = \mathbf{Q}_2\mathbf{H}_2\mathbf{P}_2^T$ can be decomposed into

$$\mathbf{H}_3(\mathcal{S}_{B_2}, \mathcal{S}_{A_2}) = \mathbf{Q}_2(\mathcal{S}_{B_2}, \mathcal{S}_{B_2})\mathbf{H}_2(\mathcal{S}_{B_2}, \mathcal{S}_{A_2})\mathbf{P}_2^T(\mathcal{S}_{A_2}, \mathcal{S}_{A_2}) \quad (20)$$

$$\mathbf{H}_3(\mathcal{S}_{B_2}, \overline{\mathcal{S}}_{A_2}) = \mathbf{Q}_2(\mathcal{S}_{B_2}, \mathcal{S}_{B_2})\mathbf{H}_2(\mathcal{S}_{B_2}, \overline{\mathcal{S}}_{A_2}) \quad (21)$$

$$\mathbf{H}_3(\overline{\mathcal{S}}_{B_2}, \mathcal{S}_{A_2}) = \mathbf{H}_2(\overline{\mathcal{S}}_{B_2}, \mathcal{S}_{A_2})\mathbf{P}_2^T(\mathcal{S}_{A_2}, \mathcal{S}_{A_2}) \quad (22)$$

$$\mathbf{H}_3(\overline{\mathcal{S}}_{B_2}, \overline{\mathcal{S}}_{A_2}) = \mathbf{H}_2(\overline{\mathcal{S}}_{B_2}, \overline{\mathcal{S}}_{A_2}) \quad (23)$$

Similar to the analysis of Eq. (18), the density of the submatrix $\mathbf{H}_3(\mathcal{S}_{B_2}, \mathcal{S}_{A_2})$ is further increased by at most four times, and that of $\mathbf{H}_3(\mathcal{S}_{B_2}, \overline{\mathcal{S}}_{A_2}), \mathbf{H}_3(\overline{\mathcal{S}}_{B_2}, \mathcal{S}_{A_2})$ will be increased by at most twice. Note that the indices $\mathcal{J}_{A_3} = \mathcal{S}_{A_2} \setminus \mathcal{S}_{A_3}$ and $\mathcal{J}_{B_3} = \mathcal{S}_{B_2} \setminus \mathcal{S}_{B_3}$ are added into the inactive indices at the third level where $|\mathcal{J}_{A_3}| \approx |\mathcal{J}_{B_3}| \approx \frac{n}{4}$. And since the matrix $\mathbf{H}_3(\overline{\mathcal{S}}_{B_3}, \overline{\mathcal{S}}_{A_3})$ consists of four small blocks, including $\mathbf{H}_3(\mathcal{J}_{B_3}, \mathcal{J}_{A_3}), \mathbf{H}_3(\mathcal{J}_{B_3}, \overline{\mathcal{S}}_{A_2}), \mathbf{H}_3(\overline{\mathcal{S}}_{B_2}, \mathcal{J}_{A_3})$ and $\mathbf{H}_2(\overline{\mathcal{S}}_{B_2}, \overline{\mathcal{S}}_{A_2})$, the number of its nonzero elements is

$$\text{nnz}(\mathbf{H}_3(\overline{\mathcal{S}}_{B_3}, \overline{\mathcal{S}}_{A_3})) \leq 16\rho_1(\frac{n}{4})^2 + 2(\frac{n^2}{8})8\rho_1 + \rho_1 n^2 = 4\rho_1 n^2$$

By induction, at the L-th level, the total number of nonzero elements of $\mathbf{H}_L(\overline{\mathcal{S}}_{B_L}, \overline{\mathcal{S}}_{A_L})$ is

$$\text{nnz}(\mathbf{H}_L(\overline{\mathcal{S}}_{B_L}, \overline{\mathcal{S}}_{A_L})) \leq \sum_{l=2}^{L}(2l-3)\rho_1 n^2 \leq (L-1)^2 m_H \quad (24)$$

Thus, $\text{nnz}(\tilde{\mathbf{H}}_{L_4}) = \text{nnz}(\mathbf{H}_L(\overline{\mathcal{S}}_{B_L}, \overline{\mathcal{S}}_{A_L})) = O(L^2 m_H)$. □

We present an illustrative example of Lemma 2 in Figure 2, where Figure 2 (a) shows different parts of matrix $\mathbf{H}_L$ after some index reordering for the sake of illustration, and Figure 2 (b) gives a real case on the Gr-Qc networks where $\rho_1 = 0.001$, $n = 5,241$. We can observe that the actual number of nonzero elements in $\tilde{H}_{L_4}$ is much less than the analyzed upper bound, i.e., $(L-1)^2 m_H$, as L increases. Next, based on the Lemma 2, we give the complexity of the proposed Moana algorithm in Theorem 2, which states that the computational complexity of our proposed algorithm is *linear*.

Theorem 2. ***Complexity analysis.*** *The time complexity of Algorithm 1 is $O(mL + nd_L^2 t_{max} + L^2 m_H + LKn)$ and its space complexity is $O(L^2 m_H + L^2 Kn + nd_L)$. Here, m, n are the number of edges and nodes in the networks, $d_L = max(\lambda_L, \mu_L)$ is the size of core matrix. t_{max} is the number of iterations until convergence in the alignment phase and K is used for top-K preservation of $\mathbf{S}_L^*$. m_H is the number of nonzero elements in the matrix $\mathbf{H}_1$ and L is the number of levels.*

Proof. In Algorithm 1, the symmetric normalization of $\bar{\mathbf{A}}_1, \bar{\mathbf{B}}_1$ in Line 1 requires an $O(m)$ time complexity. In the network coarsening phase, the MMF on $\mathbf{A}_1, \mathbf{B}_1$ has an $O(mL)$ time and space complexity[1] where by a careful implementation, we use Graclus [6] for an extremely efficient clustering and avoid explicitly computing the Gram matrix in MMF. Note that we can compute $\mathbf{H}_l$ ($l = 2, \cdots, L$) in a same way as Eq. (20)-(23). Thus, by Lemma 2, the computation of the matrix $\mathbf{H}_L$ takes $O(Lm_H)$ as time complexity and $O(L^2 m_H + nd_L)$ as space complexity.

In the alignment phase, Line 8 has an $O(d_L^3)$ time complexity for Eq. (11), as well as $O(nd_L^2)$ for both Eq. (12) and Eq. (13). To compute Line 10, since there are $O(L^2 m_H)$ nonzero elements in $\tilde{h}_L$, the time complexity is $O(L^2 m_H)$. The space complexity to store the alignment matrix $\mathbf{S}_L^*$ is $O(L^2 m_H + nd_L)$ due to the nonzero elements.

In the interpolation phase, Line 13 costs $O(Kn)$ in both time and space. The analysis of Line 15 is analogous to that of Line 5 so Line 15 has an $O(LKn)$ time complexity and an $O(L^2 Kn)$ space complexity. Thus, the total time complexity is $O(m + nd_L^2 t_{\max} + L^2 m_H + LKn)$ and the space complexity is $O(L^2 m_H + L^2 Kn + nd_L)$. □

4 EXPERIMENTS

In this section, we present the experimental results of the proposed algorithm Moana. We evaluate it in the following aspects:

- *Effectiveness*: How accurate is our algorithm to align networks and how robust is our algorithm to the parameters?
- *Efficiency*: How fast and scalable is our algorithm?

4.1 Experimental Setup

Datasets. We evaluate the proposed algorithm on six real-world networks. The statistics of all datasets are summarized as follows.

- *Zachary's Karate Club:* This dataset contains 34 nodes and 78 edges. Each node is a member of the karate club and each edge represents the friendship between two members [33].
- *Gr-Qc network:* This collaboration network contains 5,241 nodes and 11,923 edges. Each node represents an author, and

[1] In [29], the complexity for a sparse matrix is given in the form of $O(\gamma c L n^2)$ where c is the cluster size, γ is the fraction of nonzero elements and hence $O(\gamma n^2) = O(m)$.

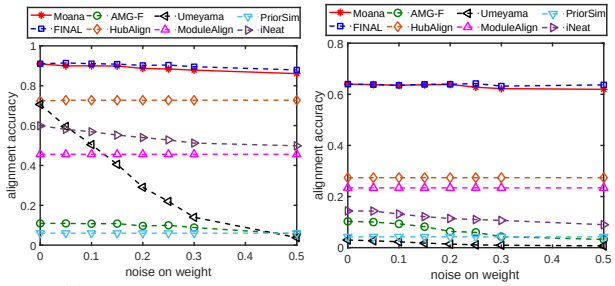
there exists an edge if two authors have coauthored together [17].

- *Google+ network:* This dataset contains 23,628 nodes and 39,194 edges. Nodes are the users of Google+ and an edge denotes that one user has the other user in his/her circles [18].
- *Amazon product co-purchasing network:* This network was collected from the Amazon website. Different nodes represent different products. If a product is frequently co-purchased with another product, there exists an edge between them. In total, there are 334,863 nodes and 925,872 edges in the network [32].
- *ACM coauthor network:* The ACM dataset is collected up to 2016 and it contains 2,381,688 papers. Each paper has a list of authors as well as the venue of the paper [28]. We construct a coauthorship network from the dataset where each node represents an author and each edge represents the coauthorship.
- *DBLP coauthor network:* The DBLP dataset is collected up to 2016 and it contains 3,272,991 papers [28]. Same as the ACM dataset, we construct an coauthorship network from the dataset.

Based on the above datasets, we construct the following five alignment scenarios for evaluations.

- *S1. Zachary vs. Zachary networks.* Given the adjacency matrix $\bar{\mathbf{A}}_1$ of the original network, we generate a random permutation matrix $\mathbf{P}$ and treat the permuted matrix $\bar{\mathbf{B}}_1 = \mathbf{P}\bar{\mathbf{A}}_1\mathbf{P}^T$ as the adjacency matrix of the second network. The permutation matrix $\mathbf{P}$ is used as the ground-truth alignment. We construct the prior similarity matrix $\mathbf{H}_1$ based on the node degree similarity.
- *S2. Gr-Qc vs. Gr-Qc networks.* The scenario is built same as *S1*.
- *S3. Google+ vs. Google+ networks.* This is built same as *S1*.
- *S4. Amazon co-purchasing vs. Amazon co-purchasing networks.* We randomly extract two subgraphs to be aligned from the entire network. The first subgraph has 74,596 nodes and 196,534 edges while the second subgraph has 66,951 nodes and 174,467 edges. There are 62,406 common nodes which are used as the ground-truth. We use node degree similarity as $\mathbf{H}_1$.
- *S5. ACM vs. DBLP coauthor networks.* We extract a subgraph from each coauthorship network. Specifically, the extracted ACM subgraph has 9,872 nodes and 39,561 edges, while the DBLP subgraph has 9,916 nodes and 44,808 edges. There are 6,325 common nodes as the ground-truth. We use the number of papers in different venues published by each author as the node attributes. We calculate $\mathbf{H}_1$ by the cosine similarity of the node attributes.

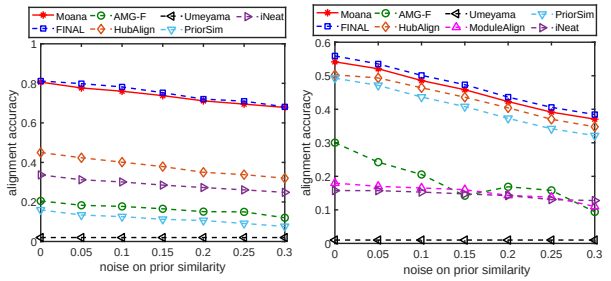
Implementation Details. As analyzed in Theorem 1, the zero-out operation in MMF implementation could introduce a certain alignment error at the coarsest level. To mitigate this issue, we run one iteration of the fixed-point update as the post-processing step: $\mathbf{S}_l^* = \alpha\mathbf{B}_l\mathbf{S}_l^*\mathbf{A}_l + (1-\alpha)\mathbf{H}_l$. This computation can be done in near-linear time with a locality sensitive hashing based implementation, thanks to the sparsity of the matrices. To evaluate the effectiveness of our proposed algorithm, we use the greedy match algorithm [27] as a post-processing to obtain the one-to-one mapping from the alignment matrix, followed by calculating the percentage of the ground-truth that can be correctly aligned as the accuracy.



Comparison Methods. We compare our algorithm Moana with the following existing network alignment algorithms, including (1) *FINAL* that uses the fixed-point algorithm on Eq. (4) [35], (2) *AMG-F* that first uses *AMG* [23] to coarsen the input networks at L levels and then aligns based on the coarsest networks, followed by interpolating the alignment matrix with the interpolation matrices generated by *AMG*, (3) *iNeat* [36], (4) *HubAlign* [11], (5) *Umeyama* [30], (6) *ModuleAlign* [10] that leverages the hierarchical clustering on the networks and (7) *PriorSim* which aligns based on the prior similarity matrix $\mathbf{H}_1$. Note that *iNeat* was originally designed to learn the nonnegative matrix factorization of the incomplete adjacency matrices. In our experiments, we use the low-rank eigen-decomposition of the input adjacency matrices since there are no missing entries in our setting.

Machines and Repeatability. All experiments are performed with four 3.6GHz Intel Cores and 256G RAM. Note that a large size of memory is only needed for running some comparison methods on large datasets (e.g., *Umayama* and *ModuleAlign* on *S4*). Our proposed algorithm is programmed in MATLAB. We will release the source code and the datasets after the paper is published.

4.2 Effectiveness Results



We first evaluate how the uniform noise on the edge weights influences the node-level alignment accuracy in scenarios *S2* and *S3*. The results are summarized in Figure 3. We have the following observations. First, our proposed algorithm Moana is very close to its single node-level alignment counterpart *FINAL*. Note that our algorithm can be viewed as an approximation of *FINAL* in terms of the node-level alignment. Specifically, our algorithm is only about 1.5% lower than *FINAL* in the worst case. In the meanwhile, the proposed Moana outperforms all the remaining methods that we compared against with respect to the node-level alignment accuracy. Second, our proposed algorithm, as well as *FINAL* are quite robust to the noise. This is due to the prior similarity matrix that works as the regularization and can mitigate the effects of noise on the networks. For *HubAlign* and *ModuleAlign*, since they are originally designed solely for unweighted networks, we replicate their results without any noise and therefore their curves are flat. On the other side, *Umeyama* is more sensitive to the noise. Third, our multilevel alignment algorithm achieves an accuracy improvement by up to 30%, compared with *HubAlign*, *ModuleAlign* and *iNeat* that are designed to leverage some special structural characteristics (e.g., hub nodes, hierarchical clustering, low rank) of the underlying networks. This improvement demonstrates the potential advantages in finding node-level alignment of our multilevel alignment method by exploring the richer patterns of networks.

Furthermore, we evaluate the impact on the alignment accuracy by the noise in the input prior similarity matrix $\mathbf{H}_1$ in the scenarios *S4* and *S5*. As one can see in the Figure 4, although most of the comparison methods have an accuracy drop due to the noise, our proposed algorithm still remains very close to *FINAL*. The results of *ModuleAlign* in the Amazon Product co-purchasing networks are not included because the algorithm cannot finish in a reasonable

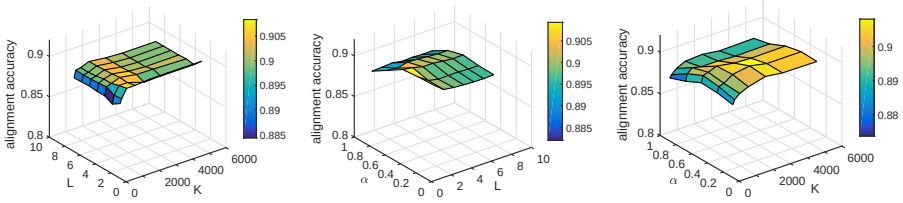
time on large networks (i.e., about 70k nodes) given its high time complexity $O(n^3 \log n)$ [10].



Parametric study on node-level alignment. There are three parameters K, L, α in the proposed algorithm. To be specific, α is the regularization parameter that controls the importance of the topology consistency, K is used to preserve top-K elements in $\mathbf{S}_L^*$, and L is the number of levels. We fix one of these parameters and study the impact of the other two parameters on the node-level alignment accuracy. The results are summarized in Figure 5. We have two main observations. First, the alignment accuracy is stable over a wide range of α, K and L. In particular, the performance first increases with respect to K, and it quickly becomes flat for $K \geq 500$. Notice that a small K can also accelerate the algorithm, and hence $K = 500$ is recommended in practice. On the other hand, recall that increasing L reduces the size of core matrices (i.e., λ_L, μ_L) and hence improves the efficiency of the alignment at the coarsest level, at a small expense in the alignment accuracy and the running time of MMF itself. We find that an L that leads to the size of core matrices (i.e., λ_L, μ_L) in the order of hundreds achieves a good balance between effectiveness and efficiency. Second, compared with the other two parameters (K, L), the regularization parameter α has a relatively larger impact on the alignment accuracy. This is because α balances the importance of the topology consistency and the prior alignment information in Eq. (1), and it directly influences the exact solution of its single node-level alignment.

The multilevel nature of Moana brings the potential to align clusters across different networks. To verify this, we further conduct an experiment to evaluate the cluster alignment accuracy on Gr-Qc networks. In particular, we view the nodes that are integrated into a single 'supernode' up to the l-th level (e.g., based on $\mathbf{P}_1, \cdots, \mathbf{P}_{l-1}$) as a cluster at level l. If a cluster at level l in network $\mathcal{G}_1$ share the most overlapped nodes with some cluster in $\mathcal{G}_2$, we treat the alignment between these two clusters as a ground-truth. With the output $\mathbf{S}_l^*(\mathcal{S}_{B_l}, \mathcal{S}_{A_l})$ matrices by Algorithm 1, we define the top-15% cluster alignment accuracy as follows. Given a ground-truth alignment between cluster i in $\mathcal{G}_1$ and cluster j in $\mathcal{G}_2$, if $\mathbf{S}_l^*(j, i)$ is among the highest top-15% entries within the j-th row and i-th column, we say there is a *hit*, i.e., the two clusters are correctly aligned. As Figure 6 shows, our algorithm can achieve a good cluster alignment accuracy at different levels.

A case study on the multilevel alignment. In addition to the quantitative comparisons, we also conduct a case study on the Zachary's Karate Club networks (*S1*) to further demonstrate our algorithm's capability to find the alignment among clusters at different granularities. We only show sample results in Figure 7 for clarity. Among others, Figure 7 (a) visualizes the input networks. Figure 7 (b) and (c) show the network structures at the two coarsest levels, respectively. To be specific, the nodes with a larger marker size represent the active indices of the coarsened matrices. Each of them represents a certain pattern (e.g., cluster) that is differentiated by the shape/color of the nodes. For example, in Figure 7 (b), the blue circle node with a larger size is one of the active nodes whereas the small blue nodes are inactivated during the MMF coarsening. As one can see, all these blue circle nodes form a cluster represented by the corresponding active node, and hence each network has three clusters in total in Figure 7 (b). The weighted interactions among the clusters are computed as the submatrix indexed by the active indices, and are represented by the thick solid lines. At the coarsest level (Figure 7 (c)), the clusters and their interactions are visualized similarly. In Figure 7 (d), the orange dashed lines show the alignment results among the active nodes at the coarsest level. In fact, since the active nodes represent different clusters, the correct alignment among the active nodes indicates that the clusters at the coarsest level are aligned correctly. Once the alignment at the coarsest level is done, we interpolate the results to the next finer level shown in Figure 7 (e). Likewise, we observe that the alignment after the first interpolation can unveil the alignment among the clusters at the finer level. Figure 7 (f) only shows parts of the interpolated node-level alignment for the sake of clarity. Overall, our algorithm can correctly align 32 out of 34 node pairs. This case study demonstrates that our algorithm can not only find the correct node-level alignment, but also unveil the meaningful alignment of the clusters in the networks at different granularities.

4.3 Efficiency Results

We first evaluate the efficiency of our algorithm (Moana) in terms of the balance between the running time and the node-level alignment accuracy. The results are summarized in Figure 8. As one can see, our algorithm obtains an up to 10× speedup compared with its single-level counterpart *FINAL* with a little loss in terms of the node-level alignment accuracy. For other alignment algorithms that explore the special characteristics of the networks (*HubAlign*, *ModuleAlign* and *iNeat*), our algorithm consistently outperforms them in terms of both efficiency and effectiveness, with the only exception of *iNeat* in Figure 8 (b) which runs faster at the cost of a much lower accuracy. Overall, we conclude from these results that

(a) Impact of K and L (fixing $\alpha = 0.5$). (b) Impact of α and L (fixing $K = 500$). (c) Impact of α and K (fixing $L = 5$).

Figure 9: Scalability of Moana.

the proposed Moana algorithm achieves a good balance between the running time and the alignment accuracy.

Scalability. We evaluate the scalability of our algorithm (Moana) based on the Amazon product co-purchasing networks w.r.t. (1) the number of edges while fixing $m_H = 3 \times 10^5$, and (2) m_H while fixing the size of networks $n = 5,000$. The results are summarized in Figure 9. We observe that the algorithm scales *linearly* w.r.t. both the number of edges in the networks and the number of nonzero elements in the prior similarity matrix $\mathbf{H}_1$, which is consistent with Theorem 2. *FINAL* which can be viewed as a special case when $L = 1$ (i.e., without coarsening), on the other hand, scales quadratically and is slower than the proposed algorithm, especially when the networks are large. We also observe from Figure 9 (a) that large L is beneficial in terms of efficiency as the size of networks becomes large. This is because coarsening the networks at more levels can further reduce the size of the core diagonal matrices.

5 RELATED WORK

Network Alignment. Multiple networks naturally appear in many real-world applications, including network alignment [35], subgraph matching [8], multi-network ranking [12] and so on. Among others, network alignment has attracted extensive research interests. Network alignment can be generally categorized into local network alignment and global network alignment. Local network alignment aims to align the small regions (e.g., motifs, small subgraphs, etc.) across multiple networks. Some recent works in this category include [3, 22]. However, the local alignment methods might be too restrictive to find the one-to-one node mappings and the alignment among more complicated large patterns of the networks. On the other side, many existing global network alignment algorithms explicitly or implicitly assume the *topology consistency*. That is, if two nodes are aligned together, their corresponding neighbors are likely to be aligned. For example, an early work *IsoRank* conducts a random walk in the Kronecker product graph and propagates the node pair similarities to the neighboring node pairs so that the similarities are smoothed [27]. *NetAlign* formulates the network alignment problem as an optimization problem and maximizes the number of neighboring node pairs that are aligned [1]. *BigAlign*

(as well as its variant *UniAlign*) [16] and *UMA* [34] assumes one network is a noisy permutation of the other network. Moreover, *IONE* attempts to leverage the network embedding for alignment [19] in a semi-supervised manner, under the assumption that the aligned nodes are close to each other in the embedding space. To further incorporate the attribute information, *COSNET* formulates the local consistency among the node attributes and the global topological consistency into a joint optimization problem [37]. *FINAL* [35] considers both node and edge attributes to calibrate the topology-based alignment. [7] further improves the efficiency by accelerating solving the Sylvester equation.

More recently, several network alignment methods attempt to exploit some special characteristics of real-world networks. For example, *HubAlign* aligns the hub nodes first and then all the remaining nodes [11]. In a different thread, *ModuleAlign* [10] and *CAlign* [2] leverage the cluster/community structures in the networks. However, none of these methods allows to find the alignment at more than two levels. Thanks to the low rank characteristics of many real networks, a recent work *iNeat* exploits the low rank structure of the alignment matrix, leading to a provable linear algorithm [36]. The alignment matrices in *iNeat* [36] and another early work *Umeyama* [30] are represented by the multiplication of three matrices, which seems to resemble the interpolation formula in our method. However, neither *iNeat* [36] or *Umeyama* [30] is able to find the alignment at the coarse levels, since they are both essentially single-level alignment methods.

Multilevel Approaches. The multilevel approaches have shown a strong performance in many graph mining problems. For example, *METIS* [13] and *Graclus* [6] are two well-known multilevel approaches to solve the graph partitioning problem. These two methods use a heavy-edge matching based graph coarsening approach, making themselves extremely efficient. On the other side, the algebraic multigrid methods which are originally designed for solving the linear systems, have been widely used to many graph related problems, such as [21, 23]. Most of the multilevel approaches follow the *coarsen-solve-interpolate* strategy. Indeed, our proposed network alignment algorithm follows this generic strategy as well.

Another closely related concept is the multiresolution analysis on graph that has played an important role in many research areas. For example, it has been widely used to design the pooling operations in the graph convolutional neural networks [5], an emerging area in machine learning and data mining. Besides, it has been applied to design the multiscale graph kernel as well [14]. In graph signal processing, the multiresolution analysis is extensively studied by many different methods, such as the graph diffusion wavelet [4], multiscale pyramid transform [26]. Moreover, the multiresolution matrix factorization, as an alternate to low rank characteristics [40], is able to factorize the input matrix at different scales [15].

6 CONCLUSION

Large multi-sourced networks from many application domains have greatly galvanized network alignment research. Most of the existing single-level alignment methods might overlook the rich patterns (e.g., *hierarchical cluster-within-clusters* underlying the networks) and/or bear a super-linear computational complexity. In this paper, we study the multilevel network alignment problem. We first drive a theoretical condition on perfect interpolation (Lemma 1). Based on that, we propose a carefully designed *coarsening-alignment-interpolation* multilevel algorithm Moana, which has a *linear* complexity in both time and space. We also drive an error bound of the alignment due to the coarsening step. We perform extensive experiments that demonstrate the efficacy of our algorithm on the node-level alignment and its capability of finding the alignment of the rich patterns (e.g., clusters) across the input networks.

A COMPOUND ROTATION MATRIX

The compound rotation matrix is formally defined as follows [15].

Definition 2. ***Compound rotation matrix.*** *The compound rotation matrix* $\mathbf{P}$ *of order* k *is a block diagonal orthogonal matrix as*

$$\mathbf{P} = \oplus_{(i_1^1,\cdots,i_{k_1}^1)}\mathbf{O}^1 \oplus_{(i_1^2,\cdots,i_{k_2}^2)} \mathbf{O}^2 \oplus \cdots \oplus_{(i_1^p,\cdots,i_{k_p}^p)} \mathbf{O}^p. \quad (25)$$

where $\{i_1^1,\cdots,i_{k_1}^1\},\cdots,\{i_1^p,\cdots,i_{k_p}^p\}$ are the subsets of $\{1,\cdots,n\}$ with $k_1,\cdots,k_p \le k$ and the matrices $\mathbf{O}^1,\cdots,\mathbf{O}^p$ are some orthogonal *Givens* rotation matrices. The operator $\oplus$ is defined to form the block diagonal matrix, i.e.,

$$\mathbf{P}(a,b) = \begin{cases} \mathbf{O}^u(q,r) & \text{if } i_q^u = a \text{ and } i_r^u = b \text{ for some } u,q,r \\ 0 & \text{otherwise} \end{cases}$$

By sequentially applying the compound rotation matrices, we can obtain a series of coarsened matrices as below

$$\mathbf{A}_1 \overset{\mathbf{P}_1}{\to} \mathbf{A}_2 \overset{\mathbf{P}_2}{\to} \cdots \overset{\mathbf{P}_{L-1}}{\to} \mathbf{A}_L \to \tilde{\mathbf{A}}_L$$

where $\tilde{\mathbf{A}}_L$ is formed by zeroing out all the nonzero elements that are neither on the diagonal of $\mathbf{A}_L$ nor inside the $\mathcal{S}_L$-core matrix.

B PROOF OF THEOREM 1

Denote $\Delta\mathbf{A} = \tilde{\mathbf{A}}_L - \mathbf{A}_L$ and $\Delta\mathbf{B} = \tilde{\mathbf{B}}_L - \mathbf{B}_L$. Consider two linear systems $\mathbf{W}_L\mathbf{s}_L = \mathbf{h}_L$ and $\tilde{\mathbf{W}}_L\mathbf{s}_L^* = \mathbf{h}_L$ where $\mathbf{W}_L = (1-\alpha)(\mathbf{I}-\alpha\mathbf{A}_L\otimes\mathbf{B}_L)$, $\tilde{\mathbf{W}}_L = (1-\alpha)(\mathbf{I}-\alpha\tilde{\mathbf{A}}_L\otimes\tilde{\mathbf{B}}_L)$ and $\mathbf{s}_L = \mathrm{vec}(\mathbf{S}_L)$, $\mathbf{s}_L^* = \mathrm{vec}(\mathbf{S}_L^*)$. Clearly, the solutions to these linear systems are the closed-form solutions of alignment matrices, e.g., $\mathbf{s}_L^*$ corresponding to $\mathbf{S}_L^*$ in line 11 of Algorithm 1. By denoting $\Delta\mathbf{W}_L = \tilde{\mathbf{W}}_L - \mathbf{W}_L$, we have

$$\begin{aligned}
\|\Delta\mathbf{W}_L\|_F &= \alpha(1-\alpha)\|\mathbf{A}_L\otimes\mathbf{B}_L - \tilde{\mathbf{A}}_L\otimes\tilde{\mathbf{B}}_L\|_F \\
&= \alpha(1-\alpha)\|\Delta\mathbf{A}\otimes\mathbf{B}_L + \mathbf{A}_L\otimes\Delta\mathbf{B} + \Delta\mathbf{A}\otimes\Delta\mathbf{B}\|_F \\
&\le \alpha(1-\alpha)(\|\Delta\mathbf{A}\|_F\|\mathbf{B}_L\|_F + \|\mathbf{A}_L\|_F\|\Delta\mathbf{B}\|_F + \|\Delta\mathbf{A}\|_F\|\Delta\mathbf{B}\|_F) \\
&\le \alpha(1-\alpha)(\delta_1 r_2\|\mathbf{B}_L\|_2 + \delta_2 r_1\|\mathbf{A}_L\|_2 + \delta_1\delta_2) \\
&= \alpha(1-\alpha)(\delta_1 r_2 + \delta_2 r_1 + \delta_1\delta_2)
\end{aligned}$$

[2] Distribution Statement "A" (Approved for Public Release, Distribution Unlimited)

where the fourth line is due to $\|\mathbf{A}\|_F \leq \text{rank}(\mathbf{A})\|\mathbf{A}\|_2$ [24] for any matrix and $\text{rank}(\mathbf{A}_L) = \text{rank}(\mathbf{A}_1)$. The last line is due to the fact that $\mathbf{A}_L, \mathbf{B}_L$ have the same eigenvalues of $\mathbf{A}_1, \mathbf{B}_1$ respectively and hence the largest eigenvalues are equal to 1. Besides, we have

$$\begin{aligned}\|\mathbf{W}_L\|_F &= (1-\alpha)\sqrt{n_1 n_2 + \alpha^2 \|\mathbf{A}_L \otimes \mathbf{B}_L\|_F^2} \\ &\geq (1-\alpha)\sqrt{n^2+\alpha^2} \geq (1-\alpha)\sqrt{2\alpha n}\end{aligned}$$

where $n = \min(n_1, n_2)$. Thus, by picking $\epsilon = \sqrt{\alpha}\frac{\delta_1 r_2 + \delta_2 r_1 + \delta_1\delta_2}{\sqrt{2n}}$, we can guarantee that $\|\Delta\mathbf{W}\|_F \leq \epsilon\|\mathbf{W}_L\|_F$.

According to the well-known sensitivity analysis of linear systems [9], we have

$$\frac{\|\mathbf{S}_L - \mathbf{S}_L^*\|_F}{\|\mathbf{S}_L\|_F} = \frac{\|\mathbf{s}_L - \mathbf{s}_L^*\|_2}{\|\mathbf{s}_L\|_2} \leq \frac{2\epsilon\kappa}{1-\epsilon\kappa} \tag{26}$$

where κ is the condition number under Frobenius norm of matrix $\mathbf{W}_L$, i.e., $\kappa = \|\mathbf{W}_L\|_F\|\mathbf{W}_L^{-1}\|_F$. By interpolating $\mathbf{S}_L$, at level l

$$\begin{aligned}\frac{\|\mathbf{S}_l^* - \mathbf{S}_l\|_F}{\|\mathbf{S}_l\|_F} &= \frac{\|\mathbf{Q}_l^T \cdots \mathbf{Q}_{L-1}^T(\mathbf{S}_l^* - \mathbf{S}_l)\mathbf{P}_{L-1}\cdots\mathbf{P}_l\|_F}{\|\mathbf{Q}_l^T \cdots \mathbf{Q}_{L-1}^T\mathbf{S}_l\mathbf{P}_{L-1}\cdots\mathbf{P}_l\|_F} \\ &= \frac{\|\mathbf{S}_L - \mathbf{S}_L^*\|_F}{\|\mathbf{S}_L\|_F} \leq \frac{2\epsilon\kappa}{1-\epsilon\kappa}\end{aligned} \tag{27}$$

ABSTRACT

Nowadays, online shoppers have paid more and more attention to detailed product descriptions, since a well-written description is a huge factor in making online sales. However, for a website with billions of product data like Alibaba, the writing efficiency of human copywriters cannot match the growth rate of new products. To address this issue, we propose a novel pointer-generator neural network to generate product description. In particular, coordinate encoders and a pattern-controlled decoder are utilized to improve generation quality with an attention mechanism. The coordinate encoders equipped with a Transformer and a gated convolutional unit is introduced to learn the source input representations. In the decoding phase, a pattern controlled decoder is proposed to control the output description pattern (such as category, length, and style) to ensure the quality of the description. For evaluation, we build a substantial collection of real-world products along with human-written descriptions. An extensive set of experiments with both human annotated data demonstrate the advantage of the proposed method for generation qualities. Finally, an online deployment shows significant benefits of our model in a real online shopping scenario, as measured by the click-through rate.

1 INTRODUCTION

The importance of content marketing for E-commerce has been significantly growing. Content marketing is one of the most effective ways for E-commerce websites to increase consumer engagement, namely because the customer chooses only to interact with the content that interests them, as opposed to traditional marketing. Major E-commerce sites, like Taobao, are gradually switching from trading platforms to content-based platforms since from users perspective the first is content consumption, followed by product consumption. On the Alibaba site, for example, there are many product oriented recommendations feeds flow, including product images, short videos, and recommendation reasons. However, the generation and maintenance of these content-based products require massive human costs. To reduce labor costs, product descriptions are expected to be automatically generated by the machine.

Generating product description is a difficult technical task of how to apply the state of art Natural Language Generation (NLG) technology to the field of E-commerce. Most human copywriters use product titles, attributes, and images, as well as the their own E-commerce industry experience to create product discriptions. Meanwhile, the writing techniques of copywriters can make a tremendous difference in the quality of generated product descriptions. Thus, it is a hugely difficult task to replace human being to

generate product description for a machine. Product title and properties are unstructured datasets which are cluttered and disordered. The machine needs to analyze the product title to capture essential product information. Due to the diversity of E-commerce platform, it is necessary to control the pattern of description writing. For example, in the home page on mobile devices, the length of product description should be as short as possible without losing essential information owing to the limited display space on mobile phones. Another example is controlling style in the product description. In sales & promotion, we expect to add marketing-styled information into product description.

Generating product description can be viewed as a special kind of natural language generation. In NLG communities, machine translation and summarization are similar tasks to text generation. But the difference is that the length of the product description is not strictly limited to be approximately equal to or less than that of the source text, which is a controlled algorithm parameter in this task. Besides, compared with the traditional summarization task, this project has more restrains: **1)** Do not display any irrelevant product information. The objectivity and accuracy of product description shall be ensured; **2)** Try to focus on essential product information, like product categories and brands; **3)** Try to control the pattern of writing, including length and style. For consumers and sellers, wrong information in the product description is disallowed. An E-commerce study conducted by NNgroup[1] found that 20% of overall task failures when the user failed to complete a purchase could be attributed to incomplete or unclear product information. There are many successful abstract generation methods for news and wiki, like pointer-generator [36], but lots of wrong information can be found from generator mode. When generating long description based on the product title and property, we need to pay attention to the consistency between description and product. Moreover, the sequence to sequence (seq2seq) method prefers to generate safer text. When generating long text, seq2seq method will produce a large number of duplicated sub-sequences which seriously affects the quality of the final text. Thus, how to grasp essential product information more accurately and generate the corresponding product descriptions is particularly important. In addition, many similar products have similar key information at the Alibaba site. As a result, the description produced by this vanilla attention-based method are also similar, which is terrible for recommending similar products. For this reason, the diversity of product description needs to be considered as well.

This paper puts forward an attention based and pattern controlled neural network to solve the above three restrains. For the first restrain, we refer to the pointer-generator mechanism which used to solve the problem of out of vocabulary (OOV) words, like the brand names and commodity names in our task. Besides, we introduce coordinate encoders equipped with transformer[41] and Gated Convolutional Neural Network (Gated-CNN)[15] to learn the dependencies and representations among the words of product titles and properties on the input side which aims to improve the keywords capture ability when generating the text. The experiment proves that these two methods can improve the category and band accuracy of the generated text. Regarding the second problem, we use a name entity recognition tool called Term Weight to extract keywords in text, such as style, material, marketing information, and others. These keywords are fed into the decoding phase to control the output style. The third constraint is handled by adding length vector for decoding phase. The traditional method of length control is to limit the maximum search depth of decoding by truncation, which is so violent that severely impacts user's experience. In this paper, a length vector is introduced to restore the length information of each time step. We automatically label the length of descriptions in the training phase and made model learn length information. Then, the length of the generated text can be restrained by setting customized length vector when decoding.

To the best of our knowledge, this work is the first attempt to apply the neural language generation technology to product description generation. Our contributions are three-fold:

1. We put forward a product description generation technology by multi-task learning, which is far advanced than traditional generation method by seq2seq model;
2. We introduce a pointer-generator architecture with coordinate encoders (Transformer and Gated CNN) to extract the source features, which can capture the local correlations and ensure the accuracy and diversity of output description generation;
3. We intervene in the pattern of the text, such as the length and the style of the product description, to reduce model development period when switching the shopping scenarios and enhance the category accuracy.

2 BACKGROUND

Given the input sequence of product title, our goal is to generate the product description. We discuss this description generation problem in the sequence-to-sequence problem setting. Suppose that the input sequence $x = (x_0, x_1, x_2 \ldots x_M)$ and the output sequence $y = (y_0, y_1, y_2 \ldots y_N)$.

2.1 Sequence to Sequence Model

Recently, sequence-to-sequence (seq2seq) model has been widely used in machine translation and summarization system. The seq2seq model usually contains two Recurrent Neural Network (RNN) components, an encoder and a decoder. The encoder gets the context vector of the source sequence x and the decoder transforms the context vector c to the target sequence, given x.

$$\boldsymbol{h}_t = f(\boldsymbol{h}_t, \boldsymbol{w}_t)$$

$$\boldsymbol{c} = g(\boldsymbol{h}_1, \boldsymbol{h}_2, ..., \boldsymbol{h}_N)$$

where h_t is the RNN hidden state at time t and w_t is the word embedding of word t. f is the activation function of RNN unit. In practice , gating mechanisms such as LSTM [19] and GRU [8] has been shown to exhibit better performance than vanilla RNN. The context vector C is also called the attention vector and is calculated using an attention mechanism [1] as a weighted sum of annotations of the encoder states.

$$C_j = \sum_{i=1}^{n} \alpha_{ji} h_i$$

[1] https://www.nngroup.com/reports/ecommerce-user-experience/

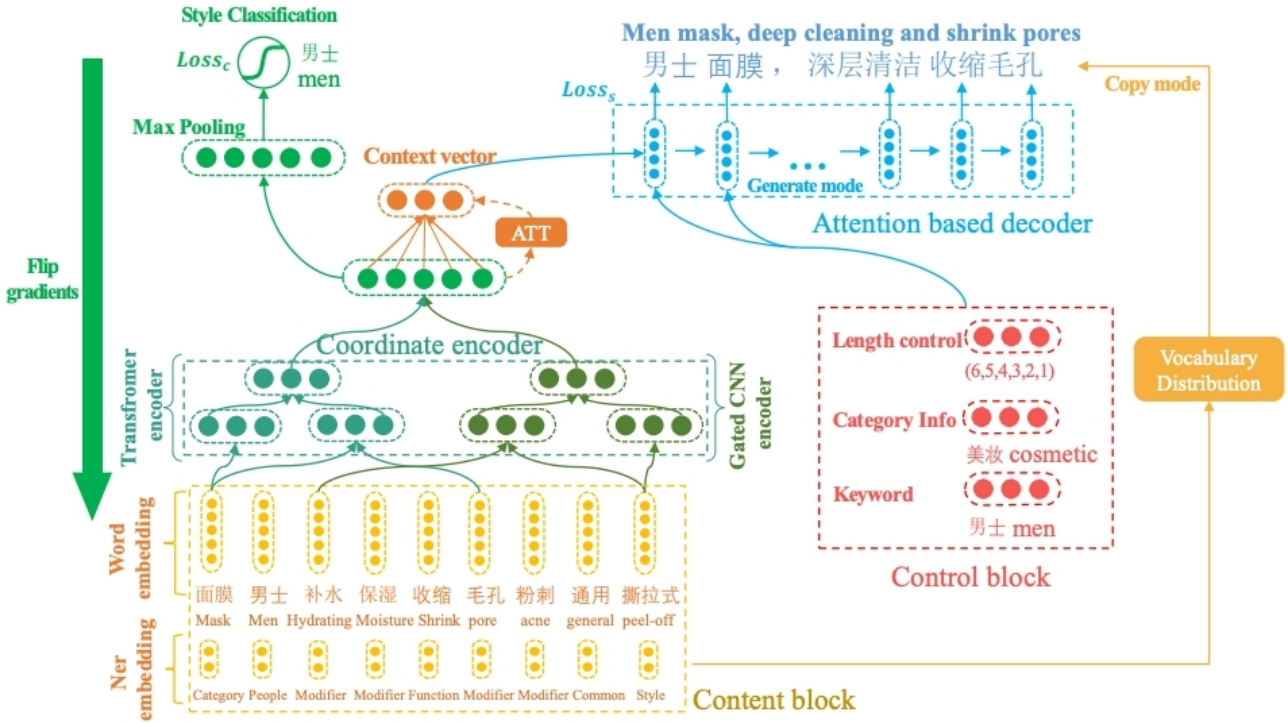

Figure 2: Architecture of Pattern Controlled Pointer-Generater Network.

Where a_{ji} are attention weights corresponding to each encoder hidden state output hi obtained as follows:

$$\alpha_{ji} = \frac{\exp(z_i)}{\sum_{k=1}^{n} \exp(z_k)}$$

Activations $z_k = a(d_{j-1}, h_k)$ are calculated by using a context function such as the dot product between the decoder state d_{j-1} and the encoder hidden states h_k. The decoder is also an RNN component, which is used to predict a target sequence,

$$\boldsymbol{d}_t = f(\boldsymbol{y}_{t-1}, \boldsymbol{d}_{t-1}, \boldsymbol{c})$$

$$p(y_t = w | y_{[0:t-1]}; x) = g(y_{t-1}, d_{t-1}, c)$$

where d_t is the decoder hidden state of time step t, y_t is the predicted output word symbol at t.

2.2 Copy mechanism model

The copy mechanism model [36] is a pointer-generator network, which is a hybrid between seq2seq network and pointer network [42]. This model allows both copying words via pointing and generating words from a fixed vocabulary which can be viewed as a balance between extractive and abstractive approaches. This model obeys the sequence-to-sequence architecture. Given the attention distribution a_t and the context vector $\boldsymbol{C}$, we can calculate the generation probability $p_{gen} \in [0, 1]$ as:

$$p_{gen} = f(C_t, s_t, y_t)$$

where f is a sigmoid function, s_t is decoder state and y_t is decoder input. In addition, p_{gen} is the soft switch to choose between generating a word from vocabulary or copying a word from source sentence according to the attention distribution a_t. The copy mechanism calculates the probability distribution over the extended vocabulary which consists of the vocabulary and all words from the source sentences:

$$P(w) = p_{gen} P_{vocab}(w) + (1 - p_{gen}) \sum_{i:w_i=w} a_i^t$$

Besides, the $P_{vocab}(w)$ is zero if w is an out-of-vocabulary (OOV) words. Similarly, a_i^t is zero if w not appear in the source sentence. In this way, the copying mechanism has the ability to deal with the issues of OOV words by repeating themselves which improves accuracy.

3 PATTERN CONTROLLED P-G NETWORKS

Although pointer-generator network gets good performance in practice especially in the field of summarization, it still works not so well in product description generation especially when generating a long description. The copy mechanism prefers to repeat source words with higher value of attention distribution which results in higher repetition of generated descriptions. Also, copy mechanism can't recognize the key information such as brand names and categories.

To deal with this issue, we proposed a Pattern-Controled Pointer-Generator Network (PGPCN) as shown in Figure 2. Basically, we use

the seq2seq model as the main building block. However, unlike the traditional RNN-based sequence model, we instead use coordinate encoders with attention mechanism to generate the context vector. Also, a style classification is added to encourage the encoder to attend to style-decorrelated tokens by gradients reverse. Finally, we use the features in the control module to generate outputs in decoders.

3.1 Content Block

Given the product title and property, we use a specialized Named Entity Recognition (NER) tool[2] for E-commerce to label entities in product title. In total there are 36 types of entities, which are of common interest in E-commerce scenario, such as "色"(color), "格"(style) and "修" (modifier). For example, in segmented product title "包Nike 品牌的色" (Nike red sweatpants with free shipping), "包"(Free shipping) is labeled as Marketing Service, "Nike" is labeled as Brand, "色"(Red) is labeled as Color and "" (Sweatpants) is labeled as Category. then we look up an embedding matrix E to get the word embedding $E = (e_0, e_1, e_2 \ldots e_D)$ and word NER embedding Ner to get the named entity recognition(NER) embeddings $Ner = (ner_0, ner_1, ner_2 \ldots ner_D)$. D denotes the dimension of embeddings and N denotes the vocabulary size. The input word vector $Xi = E_i + Ner_i$. By combining the NER information into the word vector, the model can easily recognize the important source words while striving to preserve them in the outputs at decode time to aid reproduction of factual product details.

3.2 Coordinate Encoder

To enhance the accuracy and diversity of the generated description, we fed the source token vectors of the product title and product properties into coordinate encoders (Transformers [41] feature attention networks with multiple attention heads and convolutional layers equipped with gated linear units [15]). Different from the traditional RNN encoder, the Transformer encoder and Gated-CNN encoder are parallel structures which can speed up training time. In recent work, Chen et al.[40] find that hybrid architectures with a Transformer encoder and an RNN decoder can outperform a pure Transformer model. They speculate that the Transformer encoder is better at encoding or extracting features than the RNN encoder. Thus, the Transformer encoder can improve the output accuracy of our model. CNNs are hierarchical networks, in that convolutional layers capture local correlations. The n-gram features captured by CNN encoder can enhance the diversity of the output description. Besides, our model is equipped with Gated Linear Units and residual connections [10].

For Transformer encoder, we compute the hidden state h_i^l as:

$$\overrightarrow{h}_i^l = \overrightarrow{h}_i^{l-1} + f(\text{self} - \text{attention}(\overrightarrow{h}_i^{l-1}))$$

Scaled dot-product attention is adopted as the basic attention function in the Transformer, which describes as:

$$\text{attention}(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})$$

where f represents a feed forward network with ReLU as the activation function and layer normalization.

As for convolutional encoder, the local context size depends on the size of kernel and number of layers. To keep the output length same as the input, the CNN model adds padding at each layer. Also, we add residual connections from the input of each convolution to the output of the block.

$$\overleftarrow{h}_i^l = \overleftarrow{h}_i^{l-1} + f_{cnn}(W^l[\overleftarrow{h}_{i-\lfloor k/2 \rfloor}^{l-1}, \ldots, \overleftarrow{h}_{i+\lfloor k/2 \rfloor}^{l-1}] + b^l])$$

where a convolutional kernel $k \in \mathbb{R}^{d \times q \times d}$ is applied to each possible window of q words. ConvS2S choose a Gated Linear Units (GLU) [10] which can be viewed as a gated variation of ReLUs.

$$f([A, B]) = A \otimes \sigma(B)$$

where A, B are the outputs of two stacked convolutional networks, $\otimes$ is the point-wise multiplication. The gates $\sigma(B)$ control which inputs A of the current context is relevant. At last, the encoder outputs are the average of Transformer outputs and Gated CNN outputs $h^l = \text{avg}(\overrightarrow{h^l}, \overleftarrow{h^l})$.

3.3 Attention based Decoder

Repetition is a severe problem for language generation task, especially for generating long text. We use the coverage model to solve this problem. A coverage vector $\boldsymbol{c}$ is maintained to keep track of which source words have been translated('covered') in the past decoding time steps.

$$c^t = \sum_{t'=0}^{t-1} a^{t'}$$

c^0 is initialized as a zero vector denotes that no source words have been translated. Intuitively, coverage vector is used as an additional input to the attention mechanism, which reminds the attention mechanism about its previous decisions.

$$e_i^t = v^T \tanh(W_h \boldsymbol{h}_i + W_s \boldsymbol{s}_t + w_c \boldsymbol{c}_i^t + \boldsymbol{b}_{attn})$$

The attention distribution is calculated as:

$$a^t = \text{softmax}(e^t)$$

Next, we use the attention distribution to produce a context vector $\boldsymbol{C}$ which is a weighted sum of the encoder hidden states:

$$C_t = \sum_i a_i^t h_i$$

3.4 Control Block

Although the end-to-end network described above can works very well, it still generate wrong informations in practice. Alse, the pattern of generated descriptions are uncontrollable which is inflexible for online deployment. To address this issue, we introduced a control block to intervene in the pattern of description in decoding phase.

As shown in Figure 2, there are three components in the control module: style control, length control, and category control. We use the style keywords to represent the text style, described as $\boldsymbol{k}$ which share the embeddings with input words:

$$k_i = E_{k_i} + Ner_{k_i}$$

[2]https://www.alibabacloud.com/zh/product/machine-learning

Also, we look up an embedding matrix E_{cate} to get the category embeddings $E_{cate_i} \in \mathbb{R}^{d^c \times N^c}$ where d^c represents the dimension of category embeddings and N^c represents the maximum size of category. As for length control, a vector $\boldsymbol{L}$ is maintained to represents the distance between each word i to the end $\langle EOS \rangle$. Suppose the length of output text is n, $\boldsymbol{L}$ can be described as:

$$\boldsymbol{L} = (L_0, L_1, ..., L_n)$$

where $L_i = distance(i, \langle EOS \rangle)$ is the distance from position i to the end. At the decoding phase, we initialize L_0 with the value of target length. In addition, the L_i will decrease one at each time step before it fed into the model. When L_i equals 0, it means next word is the end of the sentence $\langle EOS \rangle$ and prediction will be terminated. The length parameter tells the model how much longer until the ending of the decoder. Besides, we look up an embedding matrix $E_L \in \mathbb{R}^{d^l \times N^l}$ to get the length embeddings before we feed it into the encoder. Here, d^l denotes the dimension of the length embeddings and N^l denotes the maximum length of target text.

We follow the architecture of pointer-generator network, so the generation probability p_{gen} for timestep t is calculated from the context vector C_t, the decoder states S_t , the decoder input x_t and the pattern control parameter E_{Li}, E_{Cate_i}, k_i:

$$p_{gen} = \sigma(w_i^T \boldsymbol{C}_t + w_s^T \boldsymbol{S}_t + w_x^T \boldsymbol{x}_t + w_L^T \boldsymbol{E}_{\boldsymbol{L}t} + w_{cate}^T \boldsymbol{E}_{\boldsymbol{cate}t} + w_k^T \boldsymbol{k}_t + \boldsymbol{b})$$

3.5 Classification Block

As shown in Figure 2, we feed the encoder vector into a style classification network. We draw from a line of research in the style of [5, 13, 20, 33]. This method involves passing gradients through a gradient reversal layer, which multiplies gradients by a negative constant, i.e. -1, as they propagate back through the network. Intuitively, this encourages parameters to update away from the optimization objective.

If $Loss_s$ and $Loss_c$ are the losses from two different prediction task of our network, where s represents description generation task, and c represents classification task. Thus, the loss function of our multi-task framework becomes $Loss = Loss_s + Loss_c$. The classification loss $Loss_c$ can be described as

$$Loss_c = \mathbb{E}_{h^i \sim \mathcal{H}} \left[-\log p_c(k_j \mid h^i) \right]$$

where k_j is the style keyword represents the style of product description i as discussed in 3.4. However, when backpropagating from each prediction network to the encoder, we reverse the gradients of the networks that are predicting style. This means that the prediction networks still learn to predict style, but the encoder is forced to learn style-invariant representations which are not useful to these downstream tasks. We hope that such representations encourage the encoder to attend to style-decorrelated tokens. In this way, we can easily control the style from a encoder vector without style features. Then we can use the style parameter in control block to generate the text in a specified style.

4 EXPERIMENTS

4.1 DataSet

Our proposed method mainly requires two kinds of data: extended product description data and product title data[3]. These data are collected from **taobao**[4] a popular E-commerce website in China, since there is no public benchmark dataset for our task yet. We leverage the product description data from a product recommendation channel and product detail page. Displayed long descriptions are all written by experienced copywriters. We exclude the products whose descriptions are shorter than 8 Chinese characters and longer than 50 Chinese characters, since the product descriptions should be long enough to cover the essentials but short enough to keep it interesting. Moreover, product titles and property data are crawled from the detail page.

These two kinds of datasets are merged and organized as pairs, i.e.,(product title, product property and product description). Therefore, the dataset can be represented as $\langle T, D \rangle$, where T means the products' titles and the products' properties, and D means the products' descriptions. The details of our dataset are shown in Table 1.

4.2 Comparison Methods

To verify the effectiveness of our proposed model, we implement rich description generation methods. We compare our method with popular neural machine generation architectures, including:

- Vanilla sequence-to-sequence (**Seq2Seq**) is a basic encoder-decoder model based on LSTM unit and attention mechanism [1].
- Pointer-Generator (**Ptr-Gen**) [36] is a hybrid neural network model combing Seq2Seq-Gen with pointer network . Besides copying words from the input, it can also generate words from a predefined vocabulary.

[3]The dataset and code will be released soon.
[4]https://www.taobao.com

- Convolutional-based NMT (**ConvS2S**) [15] are hierarchical networks which is equipped with Gated Linear Units (GLU) and residual connections.
- Transformer-based NMT (**Trans**) [41] rely heavily on self-attention networks. Each token is connected to any other token in the same sentence directly via self- attention. Transformers feature attention networks with multiple attention heads which is more fine-grained, compared to conventional 1-head attention mechanisms.

4.3 Experiment Setup

For all experiments, we use the Xavier scheme [16] for parameter initialization, where weights are initialized using a normal distribution $\mathbf{W}_{i,j} \sim \mathcal{N}(0, \sigma)$, $\sigma = \sqrt{\frac{2}{n_{in}+n_{out}}}$; n_{in} and n_{out} are numbers of the input and output units of the network. We train all models using Adam with leaning rate $lr = 0.001$, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1e-8$. We use 128-dimensional word embeddings, 8-dimensional word ner embeddings and 512-dimendional hidden states for LSTM units in both encoder and decoder. For bidirectional implementations, we linearly transform the forward hidden states and backward hidden states into 512-dimensional states.

We implement all the models in Tensorflow1.4[5]. For Ptr-Gen[6] we modify the I/O of the code to fit our dataset. For ConvS2S and Transformer[7], we use an open-source Python library OpenNMT. All the models are trained on a single Tesla P100 GPU with a batch size of 128. At train time, we use maximum encoding step 10 and maximum decoding step size 50. All training instances are sorted by the target sequence length and partitioned into mini-batches. The shorter sequences are padded to have the same length as the longest sequence in the batch. All batches are shuffled at the beginning of each epoch. At test time, we use beam search with beam size 5 and maximum decoding step size 20.

For the dataset preprocessing, all models are implemented based on Chinese characters. We use a Chinese word tokenizer and a pre-trained Ner tool for E-commerce to segment and label entities. Finally, our vocabulary contains 50k words according to the word frequency and 36 word entities. More detailed network parameters are presented in Table 2.

4.4 Automatic Evaluation

To evaluate the content prediction performance, we use some standard metrics (eg., BLEU [32], ROUGE [26], METEOR [2]). BLEU metrics is widely used for text generation tasks, such as machine translation, summarization. The metric analyzes co-occurrences lexical n-grams units between the candidate and references. For BLEU metric, we report BLEU-1, BLEU-2 here. The ROUGE metric measures the description quality by counting the overlapping units (e.g., n-grams) between the generated candidate and reference descriptions. Following the common practice, we report the F1 scores for ROUGE-1, ROUGE-2, and ROUGE-L. In addition, the METEOR metric was introduced to address several weaknesses in BLEU. It is calculated based on an explicit alignment between the unigrams in the candidate and references. In this work, the METEOR scores are evaluated in exact word match mode. We obtain the BLEU and METEOR scores using the nlg-eval11[8] packages, and ROUGE scores using python-rouge12[9] package.

The results of the last group indicate that the control block is helpful for description generation. Pattern-Controled Pointer Generator Network (PGPCN) achieves higher BLEU, ROUGE and METEOR scores on test dataset than other methods. PGPCN is a hybrid architecture with a Transformer encoder and an RNN decoder. Transformer encoder is proved to be better at encoding and extracting features than the RNN encoder. Also, we use the copy mechanism and control block to improve the quality of the output description. We did a comparative experiment that only used word embeddings as encoder input without NER information as shown in the last two group of Table 3. The results show that encoder with multi-data input including word embeddings and NER embeddings helps the model to get better performance. By using the NER information, the model can easily recognize the important source words while striving to preserve them in the outputs at decode time. This is consistent with our expectation as discussed in Section 3.1.

Also, we calculate the differences of metric score in different length, here we compare Chinese character size of length 10 with length 20. We use LENGTH-GAP represents the average retention rate by dividing the metric score of length 10 into score of length 20. The results show that our PGPCN method can reserve more information in short length than the other method. This is because our model takes the length as a model parameter during training step, it can memorizes the distance to the end $\langle EOS \rangle$, so it will compress key information in advance. However, the model without length control can only get fixed length by truncating which will result in loss of information.

4.5 Key Information Retention Test

For product description, it is particularly important to retain some key information (i.e., band names, commodity names) which is an essential requirement to attract people. This information helps users understand the product and accurate the descriptions of products. The evaluation metric for this task is the error rate of the brand names (B-ACC.) and commodity names (C-ACC.) in the generated product description. If the key information is missing or getting wrong in the product description, this prediction will be marked as an error. We also test the model on the sampled online data from a real-world E-commerce website.

The results of each model on test sets are shown in Table 4, seq2seq achieves the worst results in accuracy task due to the simpleness of the model architecture. Also, we find that models with pointer-generator mechanism can get higher accuracy than regular generator model, since the pointer mechanism can copy the relevant words to the output text directly. The conventional NMT model like ConvS2S and Transformer perform poor in Accuracy metric. Both of them are stuck in the source words, while some words in product title are ambiguous due to the similarity of category between E-commerce product.

Table 3: BLEU, ROUGE (F1), and METEOR scores on the test set. Baselines on the top group are seq2seq. Bold scores are the best overall.

		BLEU-1	BLEU-2	ROUGE-1	ROUGE-2	ROUGE-L	METEOR	Info-Retention
Seq2Seq	Length 10	6.13	2.49	11.05	3.43	10.80	9.98	0.68
	Length 20	11.95	4.71	17.15	3.56	16.17	12.82	
Ptr-Gen	Length 10	7.29	3.68	12.94	5.68	12.91	13.70	0.72
	length 20	12.70	5.81	18.05	7.60	17.62	15.07	
ConvS2S	Length 10	7.54	3.71	13.98	7.78	13.17	14.81	0.71
	Length 20	13.41	6.22	20.62	8.34	20.21	17.61	
Trans	Length 10	7.97	3.73	13.39	7.76	13.36	13.95	0.71
	Length 20	13.71	6.58	20.09	8.35	19.91	16.59	
PGPCN$_{noNER}$	Length 10	7.43	3.12	12.70	7.17	12.43	13.15	0.75
	Length 20	12.09	5.55	17.73	7.22	17.32	14.87	
PGPCN	Length 10	**9.38**	**4.32**	**15.68**	**10.01**	**15.61**	**15.35**	**0.76**
	Length 20	**15.56**	**6.92**	**22.00**	**10.07**	**21.86**	**16.94**	

Table 4: Results of key info retention experiment. Bold scores are the best.

	Length	C-ACC.	B-ACC.	Repete RATE
Seq2Seq	10	3.72	4.98	7.76
	20	3.46	4.97	
Ptr-Gen	10	1.33	1.09	6.62
	20	1.15	1.03	
ConvS2S	10	2.58	2.57	**4.94**
	20	2.34	2.53	
Trans	10	1.57	2.96	6.94
	20	1.65	2.54	
PGPCN$_{noCB}$	10	1.27	0.90	5.17
	20	1.06	0.73	
PGPCN	10	**0.30**	**0.22**	5.36
	20	**0.28**	**0.21**	

Table 5: Manual evaluation results. Bold scores are the best. The improvements from baselines to PGPCN is statisti- cally signicant according to two-tailed t-test (p < 0.05).

Model	Completeness.	Consistency.	Readable.	Attract.
Seq2Seq	76.32%	62.90%	1.13	1.24
Ptr-Gen	93.13%	90.13%	3.52	2.92
ConvS2S	83.37%	80.23%	4.27	3.45
Trans	87.29%	82.95	4.53	3.67
PGPCN$_{nC}$	**94.51**%	91.07%	4.55	3.55
PGPCN	93.38%	**95.73**%	**4.60**	**3.96**

Moreover, the significant improvements on Accuracy metrics demonstrate that our method PGPCN can better recognize the commodity names and brand names after the intervention of the Control Block (CB). We also calculated the word repetition rate (Repete RATE.) of all description generated from each model. The results show that ConvS2S model performed best and got the lowest repetition rate. This is because the ConvS2S model has a robust capability to learn compressed expressions and address sentences with variable lengths. Also, the convolutional units can extract the N-gram features which is helpful to understand the text. As a result, our method has lower repetitive rate score than other non-convolutional methods.

4.6 Manual Evaluation

Like the previous work ([12], [39]), we also conduct manual evaluation on the generated product descriptions. As such, evaluation by human judges of the quality of generated text is the best measure of our methods' quality. We randomly sampled 500 products from our test datasets. Three experienced E-commerce website users were asked to measure the quality of the product descriptions. Three perspectives are considered during manual evaluation process: (1) **Completeness**, is the key information properly kept in the product description? (2) **Consistency**, is the generated description consistent with the given styles? (3)**Readability** (Readable), how fluent, grammatical the product description is? (4) **Attractiveness** (Attract.), how attractive the product description is?

Essential information retention is an extra and crucial requirement for product description generation. We use a very strict criterion for this property, the generated product description will be assessed as one only if it correctly retains both brand name and commodity name, otherwise 0. To make the annotation results more consistent and reliable, we excluded instances with divergent ratings (i.e., their variance is greater than the threshold). The readability and attractiveness are assessed with a score from 1 to 5 (i.e., 1 for worst and 5 for best).

The average results are shown in Table 5. The results indicate that our PGPCN method outperforms the conventional neural language generation method. The effects on Completeness show that all models built with copy mechanism can get a particularly good mark, since the copy mechanism can better retain the keywords from the inputs. The significant improvements to Attract metric demonstrate that our PGPCN can learn style information from the keywords parameter from the control block. Also, comparing with the PGPCN with no classification ($PGPCN_{nC}$), the PGPCN with classification can get a higher score on Consistency metrics. It mainly because the classification block can filter the irrelevant style by the gradient reverse. Considering all three metrics, our PGPCN produces more readable and more informative descriptions which show the advantages of classification and control block.

4.7 Online A/B Testing

This subsection presents the results of online evaluation in the product recommendation page scenario of an E-commerce mobile app with a standard A/B testing configuration. We deploy it in a real word product during E-commerce website sales day[10]. The A/B testing lasted for a half day, since millions of people visit our website during that sales day and we have got adequate users for testing. For online deployment, we generate fixed length description for about five hundred thousand sales product using PGPCN model. Moreover, we use different keywords to intervene in the description pattern, such as "新品" (new product) for new product scenario recommendation and "促" (promotion) for promotional products sales scenario. The baseline method uses several template description that only changing the product name. The A/B testing system split online users equally into two groups and direct them into two separate buckets respectively (about 1 million user views (UV) for each bucket). Then for users in the A buckets (i.e., the baseline group), the display product descriptions are generated by using a predefined template. While for users in B buckets (i.e., the experimental group), the display product descriptions are generated by the PGPCN method. We adopt the Click-Though Rate (CTR) to measure the performance of our description. In our recommendation scenario, product descriptions are displayed on the front page which is a crucial deciding factor in determining whether to click the product or skip to another. It can be obtained as:

$$CTR = \frac{product_click}{product_PV}$$

where product_click is the click times of the product, product_PV is the page view times of the product. We calculated the overall CTR for all products on sales day (from 20180920 12:00 to 20180920 22:00). We found that the performance in the experimental bucket is significantly better than that in the baseline bucket. PGPCN improved the CTR by 5.21% over the baseline. The results of the CTR improvement indicates that the users are more likely to click the products with the PGPCN generated descriptions.

[10]https://www.1688.com

4.8 Case Study

In this subsection, we show three realistic cases of the description generated by different methods. Generally, models without pointer-generator mechanism method achieve worse performance as shown in Table 6. The generator models are more likely to generate some irrelevant information such as Korea in the first example generate by Ptr-Gen. Also, we find that ConvS2S and Transformer prefer to generate some safe words, which may get a higher score at beam search step. However, this words can't help to improve the quality of the product description.

From the second case, we also found that the model without Control Block could not recognize the product category precisely. The Transformer model regard table lamp as robot toy which results in poor user experience. Consider the brand name of two examples, it is obvious that the model with pointer mechanism can recognize the brand information and copy it to the output. Besides, all method can produce fluent and grammatic descriptions due to the encoder-decoder sequential learning method.

We also give an example of how style keywords affect the output description as shown in Table 7. We use different keywords as the input of control parameter. Apparently, the results show that the keywords can control the description generation in different style. This is quite impressive, if we consider the user feature, we can generate personalized product description for different users according to their preference

5 RELATED WORK

Automatic text generation from structured data (Data-to-Text) is an import task in Natural Language Generation (NLG). Its primary goal is to produce readable text in natural language, from a non-linguistic data input. In NLG communities, machine translation[23, 38] and summarization [9, 44], which are two similar tasks to description generation. Machine translation aims for complete transduction of the sentence to be translated. Summarization condenses one long article to several sentences to highly summarize the article. Differently, this form of NLG is typically taken to require addressing (at least) two separate challenges: content selection, the selection of an appropriate subset of the input sequence [3, 4], and surface realization, producing text according to a given grammar.[21, 29]. Traditionally, these two challenges have been modularized and handled separately by generation systems.

Previous researches exploit NLG task in various domains. For example, Reiter et al. [34] generate weather forecasts from meteorological records and Chen and Mooney [6] generate sportscasting text from robot soccer events in RoboCup dataset. Christina Sauper et al. [35] investigate an approach for creating a multi-paragraph overview article. Jinpeng Wang et al. [43] present a statistical framework that generates product description from product attributes. A hierarchical semi-Markov method is proposed [25] which first associates the text sequences to corresponding records and then generates corresponding descriptions from these records. These works use a content selection way by selecting relevant material from source data and organizing them which is grammatically and syntactically. While this method is robust and portable across domains, output sequence often suffers from coverage and coherence problem.

Recently, sequence-to-sequence (Seq2Seq) neural network model based on encoder-decoder are widely used in existing NLG approached.Remi Lebret [24] introduces a neural model for concept-to-text generation. Chen [7] propose a general neural networks model based on attentional sequence-to-sequence model for text generation. Tianyu Liu et al. [28] proposed a novel structure-aware seq2seq architecture which consists of a field-gating encoder and description generator with dual attention. Mei, Bansal, and Walter [30] also proposed a seq2seq model with an aligner between weather records and weather broadcast. The model used one-hot encoding to represent the weather records as they are relatively simple and highly structured.

Moreover, pointer networks have been widely explored in abstract generation task. Pointer networks [42] allows to produce output sequence consisting of elements from the input-side words and have been used for task like extractive summarization [17, 37], machine translation [18] and dialogue generation [11]. In addition, it has also been shown to be helpful for geometric problems [42], question answering [22, 45, 46], code generation [27], and language modeling [31]. This model uses the soft attention distribution by Bahdanau et al.[1] which allows the model to learn alignments between modularity. Pointer-generator [36] network provided a viable new approach for abstractive text summarization by extending pointer network in a soft or hard way to decide whether to generate a token from the predefined vocabulary or the source sequence.

In this paper, derived from the general pointer-generator network, we propose coordinate encoders (Transformer [41] encoder and gated convolutional encoder [14, 15] equipped with self attention mechanism) to learn the representation of source input data and a pattern controlled decoder generates sentences using an attention mechanism. To the best of our knowledge, we make the first attempt to develop a neural data-driven solution for product description generation. Besides this study is launched on a dataset

with up to two million product description data, which is much higher than the data scale of previous studies and make the results more convincing.

6 CONCLUSION AND FUTURE WORK

Inspired by the neural language generation theory and the importance of content marketing of E-commerce, we proposed a neural model for product description generation. However, different from the conventional task of language generation, product description generation has more constraints like repetition and accuracy, since it is a divergent task. We address this problem with a pattern-controlled neural model by leveraging pointer-generator mechanism paradigm. The proposed model uses coordinate encoders combining the Transformer features with the Gated CNN features. In addition, we use a control block to intervene in the pattern (ie., length, category, style) of output description. Extensive experiments demonstrate the validity of the proposed method and the superiority of our approach over four language generation baselines. Finally, online A/B testing shows the significant business impact of our model in a mobile E-commerce app.

For further improvements, an interesting direction would be using user profile features to generate product descriptions. We find out one product may have different selling point in different user's perspectives, so it is possible for us to generate personalized descriptions for different users according to the user profile and preference. Another direction is how to combine the picture features into our model, and we can get more product information to enrich the generated description.

ABSTRACT

Reasoning is essential for the development of large knowledge graphs, especially for completion, which aims to infer new triples based on existing ones. Both rules and embeddings can be used for knowledge graph reasoning and they have their own advantages and difficulties. Rule-based reasoning is accurate and explainable but rule learning with searching over the graph always suffers from efficiency due to huge search space. Embedding-based reasoning is more scalable and efficient as the reasoning is conducted via computation between embeddings, but it has difficulty learning good representations for sparse entities because a good embedding relies heavily on data richness. Based on this observation, in this paper we explore how embedding and rule learning can be combined together and complement each other's difficulties with their advantages. We propose a novel framework IterE iteratively learning embeddings and rules, in which rules are learned from embeddings with proper pruning strategy and embeddings are learned from existing triples and new triples inferred by rules. Evaluations on embedding qualities of IterE show that rules help improve the quality of sparse entity embeddings and their link prediction results. We also evaluate the efficiency of rule learning and quality of rules from IterE compared with AMIE+, showing that IterE is capable of generating high quality rules more efficiently. Experiments show that iteratively learning embeddings and rules benefit each other during learning and prediction.

1 INTRODUCTION

Many Knowledge Graphs (KGs), such as Freebase [2] and YAGO [33], have been built in recent years and led to a broad range of applications, including question answering [4], relation extraction [36], and recommender system [49]. KGs store facts as triples in the form of *(subject entity, relation, object entity)*, abridged as (s, r, o). Some KGs also have an ontology with class and property expression axioms which place constraints on classes and types of relationships.

Knowledge graph reasoning (KGR) can infer new knowledge based on existing ones and check knowledge consistency. It is attracting research interest and is important for completing and cleaning up KGs. Two of the most common learning methods for KGR are embedding-based reasoning and rule-based reasoning [26].

One of the crucial tasks for embedding-based and rule-based reasoning is to learn embeddings and rules respectively. *Embedding learning methods* such as TransE [3], HolE [27] and ComplEx [35] learn latent representations of entities and relations in continuous vector spaces, called *embeddings*, so as to preserve the information

and semantics in KGs. Embedding-based reasoning is more efficient when there are a large number of relations or triples to reason over. *Rule learning methods* such as AMIE[10] aim to learn deductive and interpretable inference rules. Rule-based reasoning is precise and can provide insights for inference results.

With different advantages, both embedding and rule learning are important for KGR, while they still have their own difficulties and weaknesses.

Sparsity Problem for Embedding Learning. One of the main difficulties for embedding learning is the poor capability of encoding sparse entities. For example, Figure 1 shows correlation between entity frequency and entity link prediction results measured in mean reciprocal rank (MRR), where higher values means better results. In Figure 1, the blue line shows there are a large portion of entities having only a few triples, revealing the common existence of sparse entity. The yellow line shows that the prediction results of entities are highly related to their frequency, and the results of sparse entities are much worse than those of frequent ones.

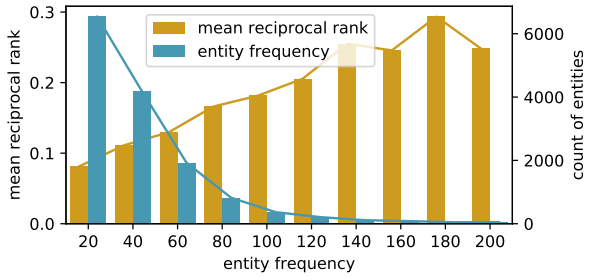

Figure 1: The numbers and mean reciprocal rank of different frequency entities based on ANALOGY results on FB15k-237.

Efficiency Problem for Rule Learning. The main difficulty in rule learning is the huge search space when determining rule structures and searching for support triples. For example, with a small KG containing 10 relations and 100 entities, the number of possible structures for a rule with 3 relations is 10^3 and the maximum number of supports for these rules is $100^{2*3} * 10^3 = 10^{15}$. Since the search space is exponential to the number of relations, it will be much larger for real KGs than this example.

With different advantages and difficulties, we argue that embedding learning and rule learning can benefit and complement each other. On the one hand, deductive rules can infer additional triples for sparse entities and help embedding learning methods encode them better. On the other hand, embeddings encoded with rich semantics can turn rule learning from discrete graph search into vector space calculation, so that reduce the search space significantly. Thus we raise the research question: **whether it is possible to learn embeddings and rules at the same time and make their advantages complement to each other's difficulties.**

In this paper, we propose a novel framework **IterE** that iteratively learns embeddings and rules, which can combine many embedding methods and different kinds of rules. Especially, we consider linear map assumption (Section 2.1) for embedding learning because it is inherently friendly for rule learning as there are special rule conclusions for relation embeddings in rules (Table 2). We also consider a particular collection of object property axioms defined in OWL2 (Table 1) for rule learning considering that semantics included in web ontology language are important for the development of knowledge graph.

IterE mainly includes three parts: (1) embedding learning, (2) axiom induction, and (3) axiom injection. Embedding learning learns embeddings for entities and relations, with input including triples existing in KG and those inferred by rules. Axiom induction first generates a pool of possible axioms with an effective pruning strategy proposed in this paper and then assigns a score to each axiom in the pool based on calculation between relation embeddings according to rule conclusions from linear map assumption. Axiom injection utilizes axioms' deductive capability to infer new triples about sparse entities according to axiom groundings and injects these new triples into KG to improve sparse entity embeddings. These three parts are conducted iteratively during training.

We evaluate IterE from three perspectives, 1) whether axiom improves sparse embeddings' quality and their predictions, 2) whether embedding helps improve rule learning efficiency and quality, and 3) how iterative training improves both embedding and rule learning during training. The experiment results show that IterE achieves both better link prediction performance and high quality rule learning results. These support our goal of making IterE complement the strengths of embedding and rule learning.

Contributions of our work are as follows:

- We propose an iterative framework that combines embedding learning and rule learning to explore the mutual benefits between them. Experiments show that it leads to better link prediction results using rules and embeddings together.
- We present a new method for *embedding learning with rules* based on axiom injection through t-norm based fuzzy logics. Experiments show that IterE can significantly improve embedding quality for the sparse part of a knowledge graph.
- We further identify a portfolio of ontology axioms for *rule learning with embedding* based on linear map assumption. Experiments show that IterE learns more high quality rules more efficiently than conventional rule learning systems.

2 PRELIMINARIES

2.1 Knowledge graph embedding

A KG $\mathcal{K} = \{\mathcal{E}, \mathcal{R}, \mathcal{T}\}$ contains a set of entities $\mathcal{E}$, a set of relations $\mathcal{R}$ and a set of triples $\mathcal{T} = \{(s, r, o)|s, o \in \mathcal{E}; r \in \mathcal{R}\}$. In a triple (s, r, o), the symbols s, r, and o denote subject entity, relation, and object entity respectively. An example of such triple is (Tokyo, *locatedIn*, Japan).

Knowledge graph embedding (KGE) aims to embed all entities and relations in a continuous vector space, usually as vectors or matrices called *embeddings*. Embeddings can be used to estimate the likelihood of a triple to be true via a score function $f : \mathcal{E} \times \mathcal{R} \times \mathcal{E} \rightarrow \mathbb{R}$. Concrete score functions are defined based on different vector space assumptions. We now describe two vector space assumptions commonly used in KGEs and their corresponding score functions.

(a) Translation-based assumption embeds entities and relations as vectors and assumes $\mathbf{v}_s + \mathbf{v}_r = \mathbf{v}_o$, in which $\mathbf{v}_s, \mathbf{v}_r$ and $\mathbf{v}_o$ are vector embeddings for s, r and o respectively. For a true triple, the relation-specific translation of subject embedding $(\mathbf{v_s} + \mathbf{v_r})$ is close to the object embedding $\mathbf{v_o}$ in embeddings' vector space.

Table 1: Conditions for object property expression axioms in OWL2 and translated rule formulation. OP refers to "ObjectProperty". OPE, with or without subscript, denotes Object Property Expression and x, y, z are entity variables. $\triangle_I$ is a nonempty set called object domain. $\cdot^{OP}$ is an object property interpretation function. When translating axioms into rule forms according to condition, we replace OPE in axioms with binary relation r in the context of knowledge graph and the number of OPE in EquivalentOP and the OPChain in SubOP is set to 2.

Object Property Axiom	Condition	Rule Form
ReflexiveOP(OPE)	$\forall x : x \in \triangle_I$ implies (x,x) $\in$ (OPE)^{OP}	(x, r, x)[1]
SymmetricOP(OPE)	$\forall x, y : (x, y) \in (OPE)^{OP}$ implies $(y, x) \in (OPE)^{OP}$	$(y, r, x) \leftarrow (x, r, y)$
TransitiveOP(OPE)	$\forall x, y, z : (x, y) \in (OPE)^{OP}$ and $(y, z) \in (OPE)^{OP}$ imply $(x, z) \in (OPE)^{OP}$	$(x, r, z) \leftarrow (x, r, y), (y, r, z)$
EquivalentOP(OPE_1 ... OPE_n)	$(OPE_j)^{OP} = (OPE_k)^{OP}$ for each $1 \leq j \leq n$ and each $1 \leq k \leq n$	$(x, r_2, y) \leftarrow (x, r_1, y)$
SubOP(OPE_1 OPE_2)	$(OPE_1)^{OP} \subseteq (OPE_2)^{OP}$	$(x, r_2, y) \leftarrow (x, r_1, y)$
InverseOP(OPE_1 OPE_2)	$(OPE_1)^{OP} = \{(x, y) \mid (y, x) \in (OPE_2)^{OP}\}$	$(x, r_1, y) \leftarrow (y, r_2, x)$
SubOP(OPChain(OPE_1 ... OPE_n) OPE)	$\forall y_0, \ldots, y_n : (y_0, y_1) \in (OPE)^{OP}$ and ... and $(y_{n-1}, y_n) \in (OPE_n)^{OP}$ imply $(y_0, y_n) \in (OPE)^{OP}$	$(y_0, r, y_2) \leftarrow (y_0, r_1, y_1), (y_1, r_2, y_2)$

(b) Linear map assumption embeds entities as vectors and relations as matrices. It assumes that the subject entity embedding $\mathbf{v}_s$ can be linearly mapped to object entity embedding $\mathbf{v}_o$ via relation embedding $\mathbf{M}_r$. In this case, for a true triple, the linear mapping of the subject embedding by the relation matrix ($\mathbf{v_s M_r}$) is close to the object embedding $\mathbf{v_o}$ in embeddings' vector space.

Thus the score function ϕ of two assumptions can be written as:

$$\phi_{translation} = sim(\mathbf{v}_s + \mathbf{v}_r, \mathbf{v}_o)$$
$$\phi_{linearmap} = sim(\mathbf{v}_s \mathbf{M}_r, \mathbf{v}_o) \quad (1)$$

where $sim(\mathbf{x}, \mathbf{y})$ calculates the similarity between vector $\mathbf{x}$ and $\mathbf{y}$.

From the assumption point of view, $\mathbf{v_s M_r} = \mathbf{v_o}$ (or $\mathbf{v_s} + \mathbf{v_r} = \mathbf{v_o}$) should exactly hold for true triples in the linear-map assumption (or translation-based assumption). From the modeling point of view, this is the optimization goal during learning, namely to be as close as possible to the equation in assumption. The learning process is done through either maximizing the objective or minimizing the error induced from assumptions given by their respective loss functions. Hence, the assumption equation usually does not exactly hold with learned embeddings, but their loss functions are designed to approach the assumption as much as possible.

In this paper, we adopt linear map assumption for embedding learning because many reasonable rule conclusions can be derived with relation embeddings based on this assumption (Table 2).

2.2 Rules Learning

Suppose $\mathcal{X}$ is a countable set of variables and C a countable set of constants. A rule is of the form $head \leftarrow body$, where $head$ is an atom over $\mathcal{R} \cup \mathcal{X} \cup C$ and $body$ is a conjunction of positive or negative atoms over $\mathcal{R} \cup \mathcal{X} \cup C$. An example of such rule can be:

$$(\mathrm{X}, hasMother, \mathrm{Y}) \leftarrow (\mathrm{X}, hasParent, \mathrm{Y}), (\mathrm{Y}, gender, \mathrm{Female}) \quad (2)$$

When replacing all variables in a rule with concrete entities in KG, we get a *grounding* of the rule. For example, one grounding of Rule (2) can be:

$$(\mathrm{Bob}, hasMother, \mathrm{Ann}) \leftarrow (\mathrm{Bob}, hasParent, \mathrm{Ann}), (\mathrm{Ann}, gender, \mathrm{Female}) \quad (3)$$

A grounding with all triples existing in knowledge graph is a *support* of this rule. For examples, if $(\mathrm{Bob}, hasMother, \mathrm{Ann}) \in \mathcal{K}$, $(\mathrm{Bob}, hasParent, \mathrm{Ann}) \in \mathcal{K}$ and $(\mathrm{Ann}, gender, \mathrm{Female}) \in \mathcal{K}$, then grounding (3) is a support for rule (2).

The results of rule learning is of the following form:

$$\alpha \; head \leftarrow body$$

in which $\alpha \in [0, 1]$ is a confidence score assigned to the rule by the learning method.

Incorporating logical rules into other learning system such as embedding learning is called *rule injection*. One way for rule injection is adding regularizer or other constraints to entity and relation representations by propositionalizing the rules. Another way is adding constraints to the constituent relations' representation in rules without direct effect on entity representations. As we want to get new information of sparse entities through rules, we chose propositionalization in this paper for rule injection.

2.3 OWL 2 Web Ontology Language Axioms

In this paper, instead of learning general Horn rules or closed-path rules as previous works[9][48], we are more interested in ontology axioms, the main components of knowledge graph ontologies, because they are important for enriching semantics in KGs.

OWL2 Web Ontology Language, informally OWL2[2], is an ontology language for Semantic Web with formally defined meaning and is a W3C recommendation. It defines multiple types of axioms, from which we select some of them as a guidance of rule structures. The selection is based on following principles: (i) the axioms are related with binary relations, the main components of rules in KG and (ii) they can infer new triples because rules are used to help add new information about sparse entities in this paper. Thus, we focus on object property expression axioms in OWL2 which are composed of binary relations in the context of KG. Finally, 7 types of object property expression axioms out of 14 are selected. The unselected axioms are mainly applied to help check the consistency in knowledge graph.

In OWL2, each axiom has its own condition revealing its semantics. The axiom is *satisfied* if its condition hold. We introduce the selected 7 types of object property expression axioms and their conditions in Table 1. We also translate the conditions of axioms into rule-form including a *head* and a *body* as introduced in the previous subsection. The translated rule forms are used to guide the structures of rules to be learned in this paper.

[1] the translated rule form of ReflexiveOP(OPE) only contain a *head*.

3 METHOD

Given a knowledge graph $\mathcal{K} = \{\mathcal{E}, \mathcal{R}, \mathcal{T}\}$, our goal is to learn embeddings and rules at the same time and make their advantages complement each other's difficulties. As discussed in Section 1, embedding learning methods suffer from the problem of data sparsity and rule learning methods have a very large search space.

In this paper, we propose a general framework **IterE** which learns embeddings and rules in an iterative manner and can be applied to many KGEs that are based on linear map assumption. It includes three main parts:(i) embedding learning, (ii) axiom induction and (iii) axiom injection. Figure 2 shows the key idea of IterE with these three iterative parts.

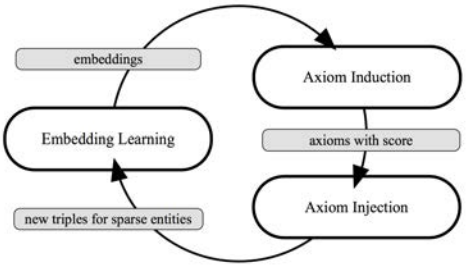

Figure 2: Overview of our IterE.

- **Embedding learning** learns entity embeddings **E** and relation embeddings **R** with a loss function $L_{embedding}$ to be minimized, calculated with input triples (s, r, o), each with a label related with its truth value. The inputs are of two types: triples existing in $\mathcal{K}$ and triples that do not exist in $\mathcal{K}$ but are inferred by axioms.
- **Axiom Induction** inducts a set of axioms $\mathcal{A}$ based on relation embeddings **R** from the embedding learning step, and assigns each axiom with a score s_{axiom}.
- **Axiom Injection** injects new triples about sparse entities in $\mathcal{K}$ to help improve their poor embeddings caused by insufficient training. The new triples are inferred from groundings of quality axioms with high scores in $\mathcal{A}$ from axiom induction. After axiom injection, with $\mathcal{K}$ updated, the process goes back to embedding learning again.

IterE is proposed based on the observation that embeddings learned with linear map assumption can fully support the axiom selected in this paper, while other assumptions such as translation-based assumption can't as pointed out in [50]. Inherently, for each type of axioms, a meaningful conclusion can be drawn with relation embeddings according to linear map assumption. For example, considering axiom `inverse`(*hasParent*, *hasChild*), if (*Mike*, *hasParent*, *John*) exists in knowledge graph, according to the condition and rule form of inverse axiom in Table 1, another triple (*John*, *hasChild*, *Mike*) can be inferred. Suppose embeddings of *Mike*, *John*, *hasParent* and *hasChild* are $\mathbf{v}_{Mike}$, $\mathbf{v}_{John}$, $\mathbf{M}_{hasChild}$ and $\mathbf{M}_{hasParent}$ respectively. According to the linear assumption for individual triples, we can get following two equations: $\mathbf{v}_{Mike}\mathbf{M}_{hasParent} = \mathbf{v}_{John}$ and $\mathbf{v}_{John}\mathbf{M}_{hasChild} = \mathbf{v}_{Mike}$. With these two equations, another equation can be deduced: $\mathbf{M}_{hasParent}\mathbf{M}_{hasChild} = \mathbf{I}$. Note that this conclusion equation is only related with two corresponding relation embeddings and is unrelated with concrete entities, thus it can be regarded as a general conclusion for axiom `inverse`(*hasParent*, *hasChild*). For other types of axioms, a general conclusion can be drawn in the same way. We list details of the conclusion for each type of axioms in Table 2. These conclusions about relation embeddings help guide axiom induction in this paper.

3.1 Embedding Learning

The input $\mathcal{I}$ of embedding learning is a set of triples with labels. Unlike previous KGEs, which only learn embeddings but not rules, positive input triple in IterE contains two parts: triples $(s, r, o) \in \mathcal{T}$ existing in original knowledge graph and triples $(s, r, o) \in \mathcal{T}_{axiom}$, where $\mathcal{T}_{axiom}$ is a set of triples inferred by axioms learned from embeddings. Negative input triples $(s', r', o') \in \mathcal{T}_{negative}$ are generated by randomly replacing s or o with $e \in \mathcal{E}$ or replacing r with $r' \in \mathcal{R}$ for $(s, r, o) \in \mathcal{T}$. Thus the input set $\mathcal{I}$ in IterE is as follows:

$$\mathcal{I} = \{((s, r, o), l_{sro}) | ((s, r, o)) \in \mathcal{T} \wedge \mathcal{T}_{axiom} \wedge \mathcal{T}_{negative}\} \quad (4)$$

where l_{sro} is the label for triple (s, r, o) to evaluate its truth value. $l_{sro} = 1$ for $(s, r, o) \in \mathcal{T}$ and $l_{sro} = 0$ for $(s, r, o) \in \mathcal{T}_{negative}$. For triples $(s, r, o) \in \mathcal{T}_{axiom}$ we assign $l_{sro} = \pi(s, r, o)$, where $\pi(s, r, o)$ is triple truth value predicted by axiom injection (Section 3.3).

With input $\mathcal{I}$, the loss function of embedding learning is calculated by mean of cross entropy loss among all n input triples and the training goal is to minimize the following loss function:

$$\min L_{embedding} = \frac{1}{n} \sum_{((s,r,o),l_{sro}) \in \mathcal{I}} [-l_{sro} \log(\phi(s, r, o)) - (1 - l_{sro}) \log(1 - \phi(s, r, o))] \quad (5)$$

As we adopt linear map assumption, the score function $\phi(s, r, o)$ for each triple (s, r, o) is defined as:

$$\phi(s, r, o) = sim(\mathbf{v}_s \mathbf{M}_r, \mathbf{v}_o) = \sigma(\mathbf{v}_s^\top \mathbf{M}_r \mathbf{v}_o) \quad (6)$$

in which $\mathbf{v}_s \in \mathbb{R}^{1\times d}, \mathbf{v}_o \in \mathbb{R}^{1\times d}$ are vector embeddings for subject and object entity. $\mathbf{M}_r \in \mathbb{R}^{d\times d}$ is matrix embedding for relation and σ denotes the sigmoid function. d is the embedding dimension. The similarity between two vectors is evaluated via dot product.

Our approach can be combined with many KGEs based on linear map assumption, such as DistMult[47] and ANALOGY[23]. In this paper, we adopt ANALOGY as it achieves state-of-the-art results on link prediction. ANALOGY is proposed to deal with an important kind of reasoning, analogy reasoning, in embedding learning. It imposes analogical structures among embeddings and requires linear maps associated with relations to form a commuting family of normal matrices. Specifically, the relation matrix embeddings are constrained as block-diagonal matrices with each diagonal block is either a real scalar, or a 2-dimensional real matrix in the form of $\begin{bmatrix} a & -b \\ b & a \end{bmatrix}$, where both a and b are real scalars.

After embedding learning, a collection of entity embeddings **E** and relation embeddings **R** are learned and **R** will be used in axiom induction.

3.2 Axiom Induction

Given relation embedding **R**, axiom induction aims to induce a set of axioms $\mathcal{A}$ and assign a confidence score to each axiom in $\mathcal{A}$. To achieve this, IterE firstly generates a pool of possible axioms $\mathcal{P}$

Table 2: Seven types of object property expression axioms selected from OWL2 ontology language. `OP` is the short for `ObjectProperty`. $\mathcal{K}$ denotes a KG and x, y, z are entity variables. v and M denote entity and relation embeddings respectively. I is identity matrix.

Object Property Axioms	Rule Form	According to Linear Map Assumption	Rule Conclusion
`ReflexiveOP`(r)	(x, r, x)	$\mathbf{v}_x\mathbf{M}_r = \mathbf{v}_x$	$\mathbf{M}_r = \mathbf{I}$
`SymmetricOP`(r)	$(y, r, x) \leftarrow (x, r, y)$	$\mathbf{v}_y\mathbf{M}_r = \mathbf{v}_x; \mathbf{v}_x\mathbf{M}_r = \mathbf{v}_y$	$\mathbf{M}_r\mathbf{M}_r = \mathbf{I}$
`TransitiveOP`(r)	$(x, r, z) \leftarrow (x, r, y), (y, r, z)$	$\mathbf{v}_x\mathbf{M}_r = \mathbf{v}_z; \mathbf{v}_x\mathbf{M}_r = \mathbf{v}_y,\ \mathbf{v}_y\mathbf{M}_r = \mathbf{v}_z,$	$\mathbf{M}_r\mathbf{M}_r = \mathbf{M}_r$
`EquivalentOP`(r_1, r_2)	$(x, r_2, y) \leftarrow (x, r_1, y)$	$\mathbf{v}_x\mathbf{M}_{r_2} = \mathbf{v}_y,\ \mathbf{v}_x\mathbf{M}_{r_1} = \mathbf{v}_y$	$\mathbf{M}_{r_1} = \mathbf{M}_{r_2}$
`subOP`(r_1, r_2)	$(x, r_2, y) \leftarrow (x, r_1, y)$	$\mathbf{v}_x\mathbf{M}_{r_2} = \mathbf{v}_y,\ \mathbf{v}_x\mathbf{M}_{r_1} = \mathbf{v}_y$	$\mathbf{M}_{r_1} = \mathbf{M}_{r_2}$
`inverseOP`(r_1, r_2)	$(x, r_1, y) \leftarrow (y, r_2, x)$	$\mathbf{v}_x\mathbf{M}_{r_1} = \mathbf{v}_y,\ \mathbf{v}_y\mathbf{M}_{r_2} = \mathbf{v}_x$	$\mathbf{M}_{r_1}\mathbf{M}_{r_2} = \mathbf{I}$
`subOP`(`OPChain`(r_1, r_2), r)	$(y_0, r, y_2) \leftarrow (y_0, r_1, y_1), (y_1, r_2, y_2)$	$\mathbf{v}_{y_0}\mathbf{M}_r = \mathbf{v}_{y_2},\ \mathbf{v}_{y_0}\mathbf{M}_{r_1} = \mathbf{v}_{y_1},\ \mathbf{v}_{y_1}\mathbf{M}_{r_2} = \mathbf{v}_{y_2}$	$\mathbf{M}_{r_1}\mathbf{M}_{r_2} = \mathbf{M}_r$

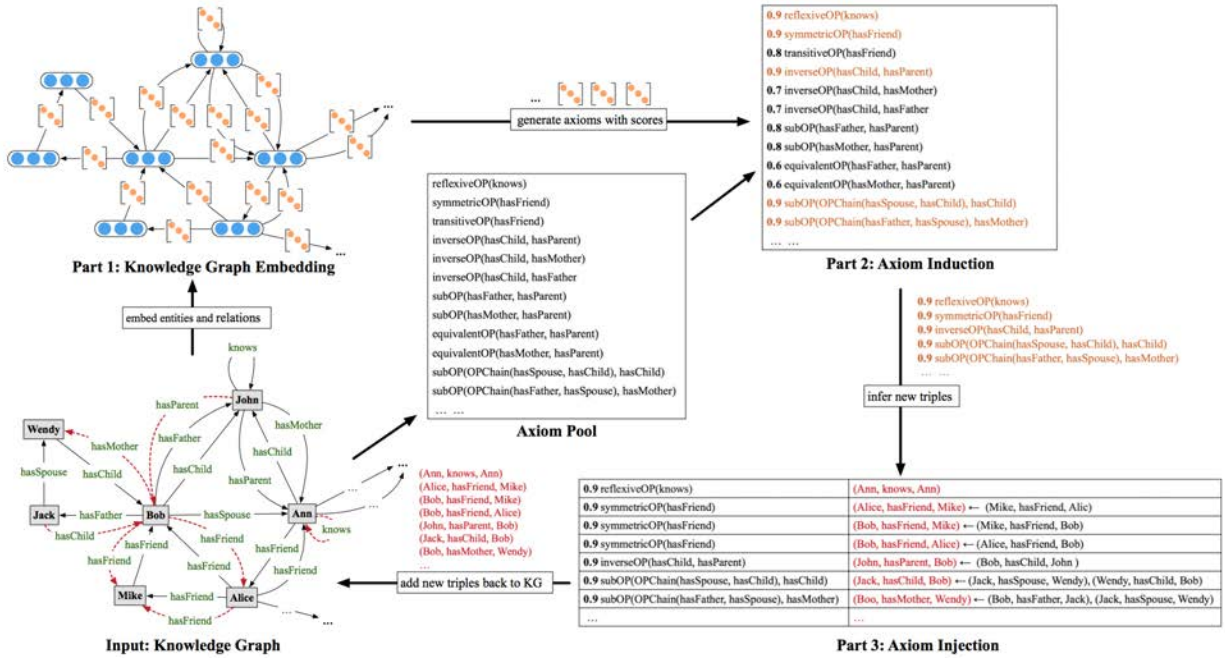

Figure 3: Detailed example for the process of IterE.

with an effective pruning strategy. Then it predicts a score of each axiom $a \in \mathcal{P}$ based on calculation with $\mathbf{R}$.

3.2.1 Axiom pool generation. Before calculating axiom scores with relation embedding $\mathbf{R}$, relation variables r, r_1, r_2, and r_3 in Table 2 should be replaced with concrete relations. Axiom pool generation generates a pool of possible axioms $\mathcal{P}$ by searching for possible axioms with the number of *support* greater than 1.

One intuitive way of searching for possible axioms is generating axioms by replacing all relation variable in each type of axioms with each relation and then check the number of support for them, but this suffers from a huge search space. Another way is to generate axioms via random walk on knowledge graph while this method can't ensure coverage of axioms. Therefore axiom pool generation is not an easy task because it has to achieve a good balance between search space and coverage of highly possible axioms.

In this paper, we propose a pruning strategy combining traversing and random selection. There are two steps for generating possible axioms for each relation $r \in \mathcal{R}$ in IterE.

- *step 1*: generate axioms or partial axioms: `ReflexiveOP`(r), `SymmetricOP`(r), `TransitiveOP`(r), `EquivalentOP`(r', r), `subOP`(r', r), `inverseOP`(r', r) and `subOP`(`OPChain`(r', r''), r), , in which $\{r', r''\}$ are relation variables to be replaced with relations in KG and r participants in the head of their rule forms.
- *step 2*: complete partial axioms via randomly selecting k triples $(e', r, e'') \in \mathcal{T}$ related with r. Replacing r' or r'' in partial axioms with relations that directly link to e' or e''.
- *step 3*: search for support of each axiom, and add those axioms with number of support larger than 1 into axiom pool $\mathcal{P}$.

The key point of whole process is choosing k, which is not trivial because a large k will lead to dramatic increase of search space while a small k will decrease coverage of axioms immediately. Thus a good choice of k should achieve followings: 1) the probability for $\mathcal{P}$ covering all highly possible axioms higher than t, named *including probability*. 2) k is as small as possible. We defined the highly possible axioms as axioms with existing probability larger than p in this paper and we name p as *minimum axiom probability*. We estimate the probability $p(r, a_x)$ that r replaces the relation variable in *head* of axiom a_x as:

$$p(r, a_x) = \frac{n}{N} \tag{7}$$

where N is the number of triples $(e', r, e'') \in \mathcal{T}$ and n is the number of support for axiom a_x in $\mathcal{K}$. Thus choosing k triples to satisfy two requirements mentioned above can be formulated as follows:

$$\min k \; s.t. \; 1 - \frac{C^k_{(1-p)N}}{C^k_N} > t \tag{8}$$

From above inequality in (8), following inequality can be reached:

$$k > N - N(1-t)^{\frac{1}{pN}} \tag{9}$$

Thus with fixed p, t, the best choice of k should be the upper bound v_u of equation $f(N) = N - N(1-t)^{\frac{1}{pN}}$. Fortunately, with $N \in [0, 10^{15}]$, this equation is monotone increasing and has small upper bound v_u. For example, when $p = 0.5, t = 0.95$, v_u is 6.

As the input of axiom pool generation is a fixed $\mathcal{K}$ during learning, axiom pool $\mathcal{P}$ only need to be generated once.

3.2.2 Axiom Predicting. Given current relation embedding $\mathbf{R}$ and axiom pool $\mathcal{P}$, axiom predicting predicts a score s_a for each axiom $a \in \mathcal{P}$ based on the rule conclusion for each type of axioms (column 4 in Table 2), in the form that $\mathbf{M}^a_1 = \mathbf{M}^a_2$, where $\mathbf{M}^a_1$ and $\mathbf{M}^a_2$ are matrices either from a single matrix or a product of two matrices. As rule conclusions are derived from ideal linear map assumption, $\mathbf{M}^a_1$ and $\mathbf{M}^a_1$ usually are not equal but similar during training. Thus, instead of matching $\mathbf{M}^a_1$ and $\mathbf{M}^a_2$, we estimate the truth of axiom a by similarity between $\mathbf{M}^a_1$ and $\mathbf{M}^a_2$ which is supposed to be related with Frobenius norm of their difference matrix:

$$s_a(F) = \|\mathbf{M}^a_1 - \mathbf{M}^a_2\|_F \tag{10}$$

$s_a(F)$ is then normalized as follows because the value of $s_a(F)$ for different type of axioms vary dramatically:

$$s_a = \frac{s_{max}(t) - s_a(F)}{s_{max}(t) - s_{min}(t)} \tag{11}$$

in which t is the type of axiom that a belongs to. $s_{max}(t)$ and $s_{min}(t)$ is the maximum and minimum Frobenius norm score among all type t axioms in $\mathcal{P}$. $s_a \in [0, 1]$ is the final score for axiom a and the higher s_a is the more confident that axiom a is.

3.3 Axiom Injection

Given knowledge graph $\mathcal{K}$ and possible axiom set $\mathcal{A}$, axiom injection utilizes axiom' deductive capability to infer a set of new triples $\mathcal{T}_{axiom}$ for sparse entities and predict their labels. $\mathcal{T}_{axiom}$ will be injected into embedding learning to reduce the sparsity of entities.

3.3.1 Sparse entities. We evaluate the sparsity of entities as follows:

$$sparsity(e) = 1 - \frac{freq(e) - freq_{min}}{freq_{max} - freq_{min}} \tag{12}$$

where $freq(e)$ is the frequency of entity e participating in a triple, as subject or object entity. $freq_{min}$ and $freq_{max}$ are the minimum and maximum frequency among all entities. $sparsity(e) \in [0, 1]$. $sparsity(e) = 1$ means e is the most sparse entity and $sparsity(e) = 0$ means the most frequent one. With $sparsity(e) > \theta_{sparsity}$, we regard entity e as a sparse entity, where $\theta_{sparsity}$ is a sparse threshold. We use $\mathcal{E}_{sparse}$ to denote the set of sparse entity in $\mathcal{K}$.

During axiom injection, triples related with sparse entities are injected into the input of embedding learning. In other words, in new inferred triples (s^a, r^a, o^a), either $s^a \in \mathcal{E}_{sparse}$ or $o^a \in \mathcal{E}_{sparse}$ or $\{s^a, o^a\} \in \mathcal{E}_{sparse}$. Thus after inferring all possible new triples, we filter those unrelated to sparse entities.

3.3.2 Predicting new triples and their labels. We utilize groundings to infer new triples, and the grounding for axioms considered in this paper can be generalized as the following form:

$$(s^a, r^a, o^a) \leftarrow (s_1, r_1, o_1), (s_2, r_2, o_2), ..., (s_n, r_n, o_n) \tag{13}$$

where the right side triples $(s_k, r_k, o_k) \in \mathcal{T}$ with $k \in [1, n]$ are generated from the body of axiom rule form and $(s^a, r^a, o^a) \notin \mathcal{T}$ is new inferred triples to be added into knowledge graph.

To predict label for (s^a, r^a, o^a), we first translate the grounding form in (13) in propositional logical expression:

$$(s_1, r_1, o_1) \wedge (s_2, r_2, o_2) \wedge ... \wedge (s_n, r_n, o_n) \Rightarrow (s^a, r^a, o^a) \tag{14}$$

then we model groundings through t-norm based fuzzy logics[17]. It regards the truth value of a propositional logical expression as a composition of constituent triples' truth value, through specific logical connectives (e.g. $\wedge$ and $\Rightarrow$). For example, the truth value of a propositional logical expression $(s_1, r_1, o_1) \Rightarrow (s_2, r_2, o_2)$ is determined by the true value of two component triples (s_1, r_1, o_1) and (s_2, r_2, o_2), via a composition defined by logical implication $\Rightarrow$. We follow the definition of composition associated with logical conjunction ($\wedge$), disconjunction ($\vee$) and negation ($\neg$) as [14]:

$$\pi(a \wedge b) = \pi(a) \cdot \pi(b) \tag{15}$$

$$\pi(a \vee b) = \pi(a) + \pi(b) - \pi(a) \cdot \pi(b) \tag{16}$$

$$\pi(\neg a) = 1 - \pi(a) \tag{17}$$

$$\pi(a \Rightarrow b) = \pi(\neg a \vee b) \tag{18}$$

in which a, b are logical expressions and $\pi(x)$ is the truth value of x. Given these compositions, the truth value of any propositional logical expression can be calculated recursively through Equation (15)-(18). For example, applying to propositional logical expression of grounding $g: \; (s_1, r_1, o_1) \wedge (s_2, r_2, o_2) \Rightarrow (s^a, r^a, o^a)$:

$$\pi(g) = 1 - \pi(s_1, r_1, o_1)\pi(s_2, r_2, o_2) + \pi(s_1, r_1, o_1)\pi(s_2, r_2, o_2)\pi(s^a, r^a, o^a)$$

To predict the truth value $\pi(s^a, r^a, o^a)$ for triples (s^a, r^a, o^a), inferred by axiom a according to grounding g_a, based on t-norm fuzzy logics, $\pi(s^a, r^a, o^a)$ can be calculated according to $\pi(g)$ and $\pi(s_1, r_1, o_1), \pi(s_2, r_2, o_2), ..., \pi(s_n, r_n, o_n) \in g_a$. In former example,

$$\pi(s^a, r^a, o^a) = \frac{\pi(g) - 1 + \pi(s_1, r_1, o_1)\pi(s_2, r_2, o_2)}{\pi(s_1, r_1, o_1)\pi(s_2, r_2, o_2)}$$

For the truth value of axiom a's grounding g, we evaluate it as the score of a generated by axiom induction, namely $\pi(g_a) = s_a$. For the truth value of triples existing in knowledge graph, we evaluate them with their training labels, thus $\pi(s, r, o) = 1$ for $(s, r, o) \in \mathcal{T}$, because existing triples are absolutely true. With these two types of truth value assignment, we can easily get the following result for triples (s^a, r^a, o^a) inferred by any type of axioms a:

$$\pi(s^a, r^a, o^a) = s_a \tag{19}$$

After axiom injection, a set of new triples $\mathcal{T}_{axiom} = \{(s^a, r^a, o^a) | s^a \in \mathcal{E}_{sparse} \text{ or } o^a \in \mathcal{E}_{sparse}\}$ are inferred via quality axioms and each new triple (s^a, r^a, o^a) is labeled with $l_{sro} = s_a$. Thus the input of embedding learning was updated, $\mathcal{I} = \{((s, r, o), l_{sro}) | (s, r, o) \in \mathcal{T} \wedge \mathcal{T}_{axiom}\}$. Then the process goes back to embedding learning.

4 EXPERIMENT

During experiments, we want to explore following questions: 1) whether axioms really help sparse entity embedding learning? To do this, we evaluate the quality of embeddings on link prediction task which is widely applied in previous knowledge graph embedding works; 2) whether embeddings really help rule learning overcome the huge search space and improve the quality of learned rules? To do this, we evaluate the efficiency of axiom learning with learning time and the quality with number and percentage of high quality axioms the method generate; 3) how does the iterative manner affect embedding learning and rule learning process? To this end, we show the changes of link prediction results, rule qualities and the number of triples injected along with different number of iterations.

4.1 Dataset

Four datasets are used in experiment, including WN18-sparse, WN18RR-sparse, FB15k-sparse, and FB15k-237-sparse. They are generated from WN18[3], WN18RR[7], FB15k[3] and FB15-237[34], four datasets that are commonly used in previous knowledge graph embedding work. WN18 and WN18RR are subsets of WordNet, a lexical knowledge graph for English. FB15k and FB15k-237 are subsets of a large collaborative knowledge base Freebase. The statistics of datasets are listed in Table 3.

We generate the sparse version of these datasets via changing the valid and test datasets which will be used for link prediction evaluation. In link prediction experiments, we want to explore whether axioms really contribute to sparse entity embeddings. Therefore, we only keep triples in test and valid dataset which involve at least one sparsity entity. In other words, for a test or valid triple (s, r, o), if either s or o is or both are sparse entity (Equation (12)), the triple will be kept in sparse dataset, otherwise, it will be filtered.

Table 3: Statistics of datasets.

Dataset	#E	#R	#Train	#Valid	#Test
WN18-sparse	40,943	18	141,442	3624(72.48%)	3590(71.8%)
WN18RR-sparse	40943	11	86835	1609(53.03)	1661(52.9%)
FB15k-sparse	14,951	1,345	483,142	18544(37.08%)	22013(37.26%)
FB15k-237-sparse	14541	237	272115	10671(60.8%)	12454(60.85%)

When deciding sparse entity hyperparameter θ, intuitively a principle is considered: the percentage of left triples in valid and test set should not be larger than 80% or less than 20% of original valid and test set for all datasets. Thus we choose $\theta = 0.995$ and regard entities e with $sparsity(e) > 0.995$ as sparse entity in this paper. Table 3 also shows the percent of triples left.

4.2 Training Details

For embedding learning, the number of negative samples is set to 6 and the number of scalars on the diagonal of each relation matrix is set to $\frac{d}{2}$ where d is embedding dimension. We initialize embeddings with uniform distribution $\mathbf{U}(-0.1, 0.1)$.

For axiom induction, we set the minimum axiom probability $p = 0.5$ and the including probability $t = 0.95$ for axiom pool generation. Based on these settings, the number of related triples selected for each relation is set as $k = 6$ according to Equation(9).

Details of axiom pools generated for all datasets are shown in Table 4, where we can see that the number of possible axioms in FB15k and FB15k-237 are much larger than WN18 and WN18RR because the number of axioms is highly related to the diversity of relations.

Table 4: Axiom pools details.

	ref.	sym.	tra.	equ.	inv.	sub.	sub.(Cha.)
WN18-sparse	0	3	1	2	19	2	72
WN18RR-sparse	0	3	1	1	3	1	22
FB15k-sparse	41	94	52	1872	2743	1872	59709
FB15k-237-sparse	5	30	27	197	192	197	5017

For axiom injection, considering that axioms with high scores are more reliable and less possible to introduce noise, we set a threshold θ for each dataset and regard axioms with scores $s_{axiom} > \theta$ as high quality axioms. We also set a maximum inferred triples m for axioms in each dataset, if one axiom will infer a lot of triples we ignore it because a huge number of triples inferred by one axiom will change the data distribution significantly and make the embedding training unstable.

During one iteration learning, we first train embedding learning for 10 epochs, and then conduct axiom induction and injection once. The maximum training iteration is set to 10 for WN18RR-sparse and FB15k-237-sparse and 50 for WN18-sparse and FB15k-sparse. We use Adam algorithm [19] during optimization with learning rate $lr = 0.001$. We apply grid search for the best hyperparameters based on the filter MRR on the validation dataset, with combinations from embedding dimension $d \in \{100, 200\}$ and l_1 regularizer weigh $\lambda \in \{10^{-4}, 10^{-5}, 10^{-6}\}$.

The final parameters are $d = 200, \lambda = 10^{-5}, \theta = 0.95, m = 20000$ for WN18-sparse, $d = 200, \lambda = 10^{-5}, \theta = 0.9, m = 10000$ for WN18RR-sparse, $d = 200, \lambda = 10^{-4}, \theta = 0.95, m = 100$ are for FB15k-sparse, and $d = 200, \lambda = 10^{-5}, \theta = 0.9, m = 1000$ are for FB15k-237-sparse.

4.3 Embedding Evaluation

We evaluate the quality of embeddings on link prediction tasks. Link prediction aims to predict the missing entity when given the other entity and relation in a triple, including subject entity prediction $(?, r, o)$ and object entity prediction $(s, r, ?)$.

4.3.1 Evaluation metrics. Given subject entity prediction task $(?, r, o)$ with right answer s, we first fit subject entity position with each entity $e \in \mathcal{E}$ and thus get a set of triples $\mathcal{T}_{subjectprediction} = \{(e, r, o) | e \in \mathcal{E}\}$. Then we calculate the score for each triple in $\mathcal{T}_{subjectprediction}$ according to Equation (6) and rank their scores in descending order. Thus the entity e in (e, r, o) with a higher rank is a more possible prediction. To evaluate how good the prediction is, we use the rank of (s, r, o) among all triples in $\mathcal{T}_{subjectprediction}$ as subject entity prediction evaluation result for (s, r, o), namely subject entity prediction rank $rank_s(?, r, o)$. The object entity prediction task is done in the same way and will get objection entity rank $rank_o(s, r, ?)$. The final prediction rank $rank(s, r, o)$ for (s, r, o) is the average of subject and object prediction rank:

$$rank(s, r, o) = \frac{1}{2}(rank_s(?, r, o) + rank_o(s, r, ?))$$

Table 5: Link prediction results with MRR and Hit@n on WN18RR-sparse and FB15k-237-sparse. Underlined scores are the better ones between ANALOGY and IterE(ANALOGY). Boldface scores are the best results among all methods.

Aggregating prediction rank for all test triples, we applied mean reciprocal predicting rank *(MRR)* and the percentage of predicting ranks within n *(Hit@n)* to evaluate the whole prediction result. These two metrics are widely used in previous work [35][23]. Generally, a higher *MRR* or *Hit@n* indicates a better prediction result.

We also apply $filter$ and raw setting. As mentioned in [41], when fitting subject or object entity position with other entities, we may generate triples existing in knowledge graph which are known to be true. It is not wrong if these triples are ranked higher than current test triple. With $filter$ setting, we filter the generated triples that exist in both train/valid/test dataset before ranking but not current test triple. raw means the setting of NO filtering.

4.3.2 Baselines. For baselines, one method from translation-based assumption TransE [3] and three methods based on linear map assumption, DistMult, ComplEx, and ANALOGY [4] are considered.

[3]the code for TransE is from https://github.com/thunlp/OpenKE. We train all dataset with learning rate 0.01, margin 1.0 and dimension 100 for maximum 3500 iterations.
[4]The code for DistMult, ComplEx and ANALOGY is from https://github.com/quark0/ANALOGY. We train them with the same parameter setting as [23] for maximum 500 iterations. For WN18-sparse, the parameters are dimension $d = 200$, regularizer weigh $\lambda = 10^{-1}$, negative weight $n = 6$ for DistMult and $d = 200$, $\lambda = 10^{-2}$, $n = 6$ for both ComplEx and ANALOGY. For WN18RR-sparse, the parameters are $d = 200$, $\lambda = 1-^{-1}$, $n = 3$ for DistMult, Complex and ANALOGY. For FB15k-sparse, the parameters are $d = 200$, $\lambda = 10^{-2}$, $n = 6$ for DistMult, Complex and ANALOGY. For FB15k-237-sparse, the parameters are dimension $d = 100$, $\lambda = 0.1$, $n = 6$ for ANALOGY and Complex and $d = 200$, $\lambda = 10^{-1}$, $n = 3$ for DistMult.

4.3.3 Results and analysis. To show how axiom helps sparse entity embeddings, we adopt two strategies: (1) Firstly, we evaluate how axioms directly improve entity embedding quality and compare link prediction results from our method, denoted as **IterE** in Table 5, with other baselines directly. (2) Secondly, we evaluate how axioms can help improve sparse entity link prediction utilizing its deductive ability. Thus we compare prediction results with embeddings and axioms, denoted as **IterE+axioms** in Table 5 with IterE and other methods. In IterE+axioms, if the test triple (s, r, o) are inferred by axioms during axiom injection, which means $(s, r, o) \in \mathcal{T}_{axiom}$, we regard it as correct and mark its prediction rank as 1.

The link prediction results are shown in Table 5. We analyze the results as follows: Firstly, the link prediction results of IterE competitive to ANALOGY, which means most of the triples injected into embedding learning are not noise, indicating that learning axioms from embeddings works well. Secondly, IterE outperforms baselines on WN18RR-sparse and FB15k-237-sparse, while are slightly improved on WN18-sparse and FB15k-sparse. These indicate that IterE helps sparse entities much more in WN18RR-sparse and FB15k-237-sparse than in WN18RR-sparse and FB15k-sparse. This is quite reasonable in our opinion, because among these four datasets, WN18RR-sparse and FB15k-237-sparse are more challenging and more sparse. They are created from WN18-sparse and FB15k-sparse via removing one relation of all inverse relation pair in the dataset and also their related triples because inverse relation pair is a significant pattern in these two datasets as first noted in [34]. Thirdly, the results of

IterE+axioms are improved compared with IterE in all datasets, especially on the most complex and sparse dataset FB15k-237-sparse. It indicates that the deductive capability of axioms can help the prediction of sparse entities further.

From the evaluation of link prediction, we can conclude that: (1) by injecting new triples for sparse entities, axioms help improve the quality of sparse entity embeddings and are more helpful in sparse KGs. (2) Combining axioms and embeddings together to predict missing links works better than using embeddings only. Both the deductive capability of axioms and the inductive capability of embeddings contribute to prediction and complement each other.

4.4 Rule Evaluation

We evaluate the learned rules/axioms from two perspectives: efficiency and quality. We compare our method with AMIE+[9][5] which is an improved rule mining system of widely used AMIE[10].

4.4.1 Evaluation metrics. The efficiency of rule learning is evaluated by learning time. The quality of rule learning is evaluated with the number of high quality rule (HQr) and their percentage. The quality of rules are evaluated by head coverage(HC) which is commonly used in pervious work, such as [10] and [29]. Head coverage for rule *rul* is defined as follows:

$$HC(rul) = \frac{\#(e, e') : support(rul) \wedge head(rul)(e, e')}{\#(e, e') : head(rul)(e, e')}$$

in which $head(rul)(e, e') = \{(e, r, e') \in \mathcal{T}\}$ if the head atom of *rul* is (X, r, Y). And $support(rul)$ is the supports for *rul*. We regard high quality rules as the rules with $HC > 0.7$ during test.

4.4.2 Results and analysis. Rule evaluation results are shown in Table 6. According to the time used to generate rules among all datasets, we can see that IterE learns rules more efficiently. For example, with FB15k-sparse and FB15k-237-sparse datasets, IterE costs 10 times less than AMIE+. This shows our pruning strategy works well. Among 4.72 seconds IterE cost for FB15k-237-sparse dataset, there is 4.55 seconds used for axiom pool generation and 0.17 seconds for axiom score calculation, namely axiom score calculation only cost 3.6% of the time. This means calculating axiom scores via embeddings is super efficient. We didn't include the time of embedding learning during this evaluation, as embedding learning is not devised mainly for rule learning, but for link prediction. The number of high quality rules shows that IterE generates more high quality rules than AMIE+ for each dataset and also achieves a higher percentage. This indicates that our axiom pool generation can filter meaningless axioms(rules) and achieve a good balance between small search space and coverage of highly possible axioms.

Further more, Figure 4 shows the changes of high quality axioms coverage and axiom percentage with different axiom score thresholds from IterE. For example, in 4(c), with axiom threshold 0.9, which means we select axioms with $s_a > 0.9$ from IterE for axiom injection, there are 23.4% axioms selected among all axioms and 46.4% high quality axioms included. And in 4(d), with axiom threshold 0.9, there are 53.9% axioms selected and 76.5% high quality axioms included. It illustrates that axiom scores calculated from embeddings are reliable because it is consistent with rule evaluation

[5]we run AMIE+ code from https://www.mpi-inf.mpg.de/departments/databases-and-information-systems/research/yago-naga/amie/

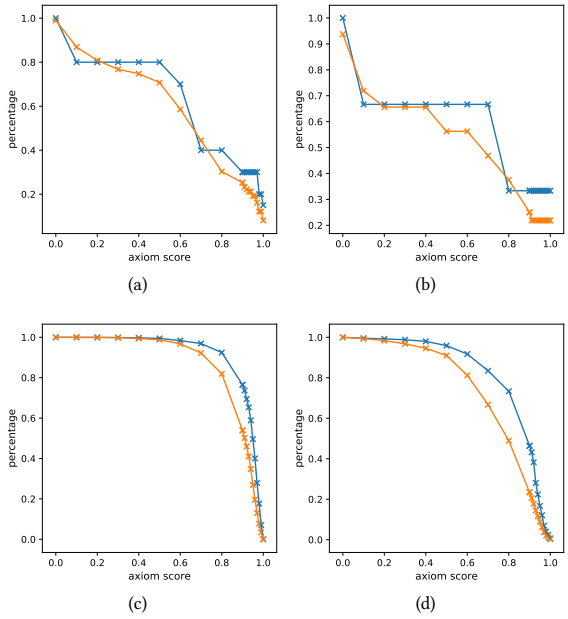

Figure 4: The coverage of high quality axioms (blue) and the axiom percentage (orange) with different axiom score thresholds. 4(a) is from WN18-sparse. 4(b) is from WN18RR-sparse. 4(c) is from FB15k-sparse. 4(d) is from FB15k-237-sparse.

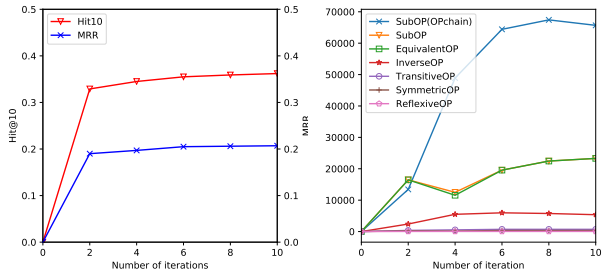
results. The results in 4(a) and 4(b) for WN18-sparse and WN18RR-sparse are not obvious because a few relations are contained in these two datasets and the number of learned rules is limited.

From rule evaluation results, we can conclude that (1) embeddings together with axiom pool generation help rule learning overcome large search space problem and improve rule learning efficiency, and (2) they also improve rule learning qualities and rules' reliable scores generated based on calculation with embeddings.



4.5 Iterative learning

To explore how iterative training improves embedding and rule learning during training, we show link prediction results on FB15k-237-sparse and number of injected triples at different iterations in Figure 5.

Figure 5 shows that the prediction results including Hit@10 and MRR become better as the training iteration increases and generally the number of injected triples increases during training and finally gets stable. The number of injected triples for `subOP` and `equivalentOP` in iteration 4 is less than iteration 3 which means axioms with high scores learned from previous iteration might get a lower score in the next iteration. This indicates that embedding learning effects rule learning. Thus from Figure 5, we can conclude that: (1) Iterative learning benefits embedding learning as the quality of embeddings gets better during training. (2) Iteratively learning benefits axiom learning because more axioms are learned and more triples are injected during training. (3) Axioms and embeddings influence and constrain each other during training.

Table 7: Examples from FB15k-237-sparse about the link prediction changes of test triples involving sparse entity. Following details are shown: the sparsity of subject and object entity in test triple, number within the square bracket beside the entity; the axiom that infers the test triple; the change of link prediction rank from ANALOGY to IterE; the change of link prediction rank from IterE to IterE+axiom.

Figure 5: 5(a) shows link prediction results, MRR and Hit@10, in different iterations. 5(b) shows the number of triples injected into embedding learning in different iterations.

4.6 Case study

In Table 7, we give a case study with 3 test triple examples which are inferred by axioms during training. Using the third one as an example, the test triple is (Jenny_McCarthy, /*type_of_union*, Marriage). Jenny_McCarthy is a person with only a few triples in KG and is a sparse entity with sparsity 0.997. Marriage is a type of union for people which has many links with individual person and its sparsity is 0.607. The subject prediction rank (?, /type_of_union, Marriage) in ANALOGY is 4199 and the object prediction (Jenny_McCarthy, /*type_of_union*, ?) is 2, from which we can see that the prediction for a sparse entity is much worse than a frequent entity. In IterE, this triple is predicted by rule (X, /*type_of_union*, Z) ← (X, *spouse*, Y), (Y, /*type_of_union*, Z) because there are (Jenny_McCarthy, *spouse*, Jim_Carrey) and (Jim_Carrey, /*type_of_union*, Marriage) in KG which can compose a grounding for previous rules. Thus during training, the test triple is inferred by IterE and injected into embedding learning. Thus the subject prediction is improved from 4199 to 33 compared with ANALOGY and the object prediction keeps the same. When we predict with both embeddings and axioms (IterE + axioms), the subject prediction is improved from 33 to 1 and the object prediction from 2 to 1 compared with IterE. Other two cases in Table 7 perform similar to the third one.

These examples show that: (1) adding triples that can be inferred by axioms back into training improves the prediction results of related sparse entities without hurting the results for non-sparse entities. (2) the deductive ability of axioms helps ensure truth value of triples with sparse entities, which, in our opinion, overcomes uncertainties and noises that effect embedding prediction.

5 RELATED WORK

In this paper, we focus on iteratively learning embeddings and rules from knowledge graphs. Thus the related work includes two parts: (1) embedding learning, (2) rule learning.

5.1 Embedding Learning

Knowledge graph embedding learns latent representations for entities and relations in continuous vector space. Normally entities are represented as vectors [3][27][35] and relations are represented as vectors [3][41][27] or matrices [47][28][23]. These embeddings are assumed to preserve the semantics in a knowledge graph such as the similarity between entities[30], the truth of triples[3]. For most embedding methods, the input are triples existing in knowledge graph and embeddings are trained based on different vector space assumptions, such as translation-based assumption in [3] [41] [22] [18], and linear map assumption in [28] [47] [35] [23]. Some methods do not follow specific vector space assumption for embeddings, and special neural networks are applied to train embeddings and assign reasonable scores for different triples. For example, neural tensor networks in [32], convolution neural network in [7] and shared memory neural network in [31]. Linear map assumption is adopted for embedding learning in this paper because of its simplicity and good property for rule learning, while other assumptions or neural network models don't have.

Besides triples in KGs, some embedding methods also utilize other information during learning, for examples, entity descriptions in [40][43][39][42], entity types in [12][45], entity images in [44], and paths in [11][21][25], which can be regarded as a kind of rules.

Rules, as useful information for reasoning, are also considered to assist embedding learning. Among these methods different types of rules are considered, for examples, [37] introduces one type of logical rule and three physical rules, [14] utilizes horn soft rules learned

from [9], [24] incorporates equivalence and inversion Axioms, and [13] considers two types of logical rules. To incorporate rules into embedding learning, some methods try to improve the embedding method's capability of modeling rules by various ways, such as encoding relations as convex regions in [15] and non-negativity constraints on entity representations in [8]. Some methods regard rules as guidance for embedding learning. For examples, [37] forms the whole learning process as a integer linear programming problem with conditions defined based on rules. [14] infers unlabeled triples according to input rules. [21] adds constrains for relation embeddings participating in path rules. [6] maps entity-tuple embedding into an approximately Boolean space and encourages a partial ordering over relation embedding based on implication rules. [8] adds approximate entailment constraints on relation representations. Some methods jointly embed rules and triples during learning, such as [13] which first learns rules based on embeddings from [3] and then retrains the embeddings incorporating with rules.

Aforementioned embedding methods with rules normally make rule learning detached from embedding learning and unrelated with embeddings. While our goal in this paper is not only an embedding learning system, but also a rule learning system in which rules are learned from embeddings and help improve embedding quality.

5.2 Rule learning

Rule is an important component for reasoning and has been studied in many previous works. Among rule learning works, different kinds of rules are adopted, for example, Horn rules in [9], closed path rules in [20] and general rules with both variables and constants and atoms occurring either positively or negatively in [16], frequent predicate cycles in [38], semantic association rules in [1]. These methods all consider the types of rules to learn from their structures, while in this paper, we consider rules based on their semantics because we think semantics are important for the development of knowledge graphs. Thus we adopt OWL2 object property expression axioms to form the types of rules to learn.

To calculate the confidence of rules, standard confidence or PCA confidence are usually used [9][16] which are based on searching for supports of rules in the whole knowledge graph. To reduce the search space, many rule learning systems have a pruning strategy. Apart from graph search, there are also some works trying to learn both structures and scores of rules based on deep neural models [48] or reinforcement learning [46][5].

Embeddings are also used to help rule learning and are used for different purposes. Some utilize embeddings to guide and prune the search for candidate rules[29]. Some make embeddings to complete the knowledge graph during rule learning[16]. Some use embeddings to assign scores for rules[47][13]. They all rely on calculations among embeddings and the way of calculations depends on specific embedding methods.

Different from these methods which mainly proposed to learning rules, we devote to learn embeddings and rules at the same time and make their advantages contribute to each other's learning.

6 CONCLUSION AND FUTURE WORK

In this paper, we discuss the advantages and disadvantages of two common knowledge graph reasoning methods, embedding-based method and rule-based method, and propose IterE that iteratively learns embeddings and rules in one model and enjoys the mutual benefit between them. In the future, we will continuously investigate combining inductive and deductive reasoning together and develop models that could unify different kinds of reasoning.

Language in Our Time: An Empirical Analysis of Hashtags

Yang Zhang
CISPA Helmholtz Center for Information Security
Saarland Informatics Campus
yang.zhang@cispa.saarland

ABSTRACT

Hashtags in online social networks have gained tremendous popularity during the past five years. The resulting large quantity of data has provided a new lens into modern society. Previously, researchers mainly rely on data collected from Twitter to study either a certain type of hashtags or a certain property of hashtags. In this paper, we perform the first large-scale empirical analysis of hashtags shared on Instagram, the major platform for hashtag-sharing. We study hashtags from three different dimensions including the temporal-spatial dimension, the semantic dimension, and the social dimension. Extensive experiments performed on three large-scale datasets with more than 7 million hashtags in total provide a series of interesting observations. First, we show that the temporal patterns of hashtags can be categorized into four different clusters, and people tend to share fewer hashtags at certain places and more hashtags at others. Second, we observe that a non-negligible proportion of hashtags exhibit large semantic displacement. We demonstrate hashtags that are more uniformly shared among users, as quantified by the proposed hashtag entropy, are less prone to semantic displacement. In the end, we propose a bipartite graph embedding model to summarize users' hashtag profiles, and rely on these profiles to perform friendship prediction. Evaluation results show that our approach achieves an effective prediction with AUC (area under the ROC curve) above 0.8 which demonstrates the strong social signals possessed in hashtags.

1 INTRODUCTION

The last decade has witnessed the explosive development of online social networks (OSNs). Leading players in the business, such as Facebook,[1] Twitter,[2] and Instagram,[3] have become the major platform for people to share life moments, communicate with each other, and maintain social relations. Moreover, OSNs have introduced many new notions into our society, such as "like", "share", and "check-in". One particular interesting notion of this kind is *hashtag*.

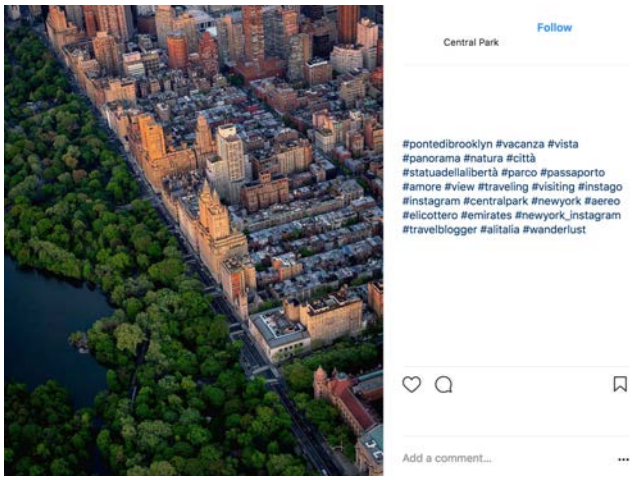

Figure 1: An Instagram post with multiple hashtags.

Created back in 2007, hashtags are designed to help users efficiently retrieve information on Twitter. With development, Instagram has become the major platform for hashtag-sharing. Nowadays, it is very common to see an Instagram post associated with multiple hashtags (see Figure 1 for an example). People also start to use hashtags for various purposes. For instance, many brands use hashtags to promote their products, such as #mycalvins and #shareacoke. Also, hashtags play a major role in various political movements, e.g., #blacklivesmatter and #notmypresident. More interestingly, hashtags have evolved themselves into a new-era language: People have created many hashtags the meanings of which do not exist in the natural language. For instance, #nomakeup attached to a photo indicates that the person in the photo did not wear any makeup; a user publishing #follow4follow means she will follow back others who follow her in OSNs. In another example, #tbt (throwback Thursday) indicates the corresponding photo was taken from old days.

The large quantity of hashtags has provided us with a new way to understand the modern society. Previously, researchers have studied hashtags from various angles [2, 12, 34, 37, 41, 42, 55, 58, 60, 65]. For

[2] https://twitter.com/
[3] https://www.instagram.com/

instance, Souza et al. have analyzed #selfie to understand the online self-portrait convention [58]. Mejova et al. use #foodporn to study people's dining preference on a global scale [37]. More recently, Zhang et al. investigate the (location) privacy risks stemming from sharing hashtags [65].

Most of these previous works have studied either a certain type of hashtags [34, 37, 41, 42, 58] or a certain property of hashtags [2, 55, 65]. Meanwhile, several general analyses concentrate on hashtags shared on Twitter [12, 60] which is a very different OSN from Instagram with respect to user group, popularity, and functionality [21, 35].

In this paper, we perform the first large-scale empirical study aiming at understanding hashtags shared on Instagram. Our analyses are centered around three research questions summarized from three different dimensions, i.e., the temporal-spatial dimension, the semantic dimension, and the social dimension.

1.1 Research Questions

Different hashtags exhibit different temporal patterns. Holiday-related hashtags, such as #newyear, may have periodic popularity, while the usage of some other hashtags may increase steadily over time. Besides, the information from the spatial dimension may also influence users' hashtag-sharing behavior: People are more (less) willing to share hashtags when they are at certain places. Therefore, we ask our first research question:

RQ1. *What are the temporal and spatial patterns of hashtags?*

As a new-era language, the semantics of hashtags can uncover many underlying patterns of the modern-style communication. Moreover, due to their inherent dynamic nature, some hashtags may change their meanings within a short time. We therefore ask:

RQ2. *Do hashtags exhibit semantic displacement?*

Following social homophily theory, we hypothesize that friends exhibit more similar hashtag-sharing behavior than strangers. In another way, hashtags possess strong signals for inferring users' social relations. To test this hypothesis, we ask:

RQ3. *Can hashtags be used to infer social relations?*

1.2 Contribution

We perform the first large-scale empirical analysis of hashtags shared on Instagram. We first sample in total 51,527 Instagram users from three major cities in the English-speaking world, including New York, Los Angeles, and London. We then collect all the posts that these users have shared from the end of 2010 to the end of 2015, and build three separate datasets. In total, our datasets contain more than 41 million Instagram posts shared together with 7 million hashtags.

To address **RQ1**, we first perform clustering to summarize hashtags' temporal patterns which results in four different clusters. In particular, one cluster of hashtags exhibits strong periodic popularity, some examples in this cluster are #snow, #bbq, and #superbowl. For the spatial dimension, we show that people in all the three datasets tend to share fewer hashtags at certain types of places, such as bars, while more at other types of places, e.g., parks.

For **RQ2**, we first adopt the skip-gram model [38, 39] to map hashtags to continuous vectors and demonstrate that these vectors can very well represent hashtags' semantics. Relying on the orthogonal Procrustes approach, we measure a hashtag's semantic displacement between two consecutive years as the distance between its two vectors trained at those years. Evaluation shows that a non-negligible proportion (more than 10%) of hashtags indeed shift their meanings to a large extent. We further define a notion, namely hashtag entropy, to quantify the uniformity of hashtags being shared among users, and observe that hashtags with low entropy are prone to semantic displacement: Correlation coefficients between semantic displacement and entropy in all the datasets are below -0.6.

To answer **RQ3**, we perform a friendship prediction task solely based on hashtags. We propose a bipartite graph embedding approach to learn each user's hashtag profile and conduct unsupervised friendship prediction based on two users' profiles' cosine distance. Extensive experiments show that our approach achieves an effective prediction with AUC (area under the ROC curve) above 0.8 in all the three datasets, and outperforms several baseline models by 20%. This indicates that hashtags indeed possess strong signals on social relations.

To the best of our knowledge, no previous works have studied hashtags' spatial patterns, semantic displacement, and social signals. We are the first to analyze hashtags from these angles.

We believe our analysis can benefit several parties. The conclusions drawn from answering **RQ1** and **RQ2** can help media campaigns to design more attractive hashtags to engage new customers. The semantic displacement result (from **RQ2**) can help researchers gain a deeper understanding of the OSN culture. The friendship prediction algorithm derived from answering **RQ3** shows that hashtags can also be used as a strong signal for friendship recommendation, which is essential for OSN operators.

1.3 Organization

The rest of the paper is organized as the following. We describe our dataset collection methodology with some initial analyses in Section 2. In Section 3, we investigate the temporal and spatial patterns of hashtags. Section 4 studies the semantic displacement of hashtags. In Section 5, we concentrate on using hashtags to infer social relations. Section 6 discusses the related work in the field. We conclude the paper in Section 7.

2 DATASETS AND INITIAL ANALYSES

In this section, we first describe our data collection methodology, then perform some initial analyses on hashtags.

2.1 Datasets Collection

We resort to Instagram to collect our datasets for experiments. Launched in October 2010, Instagram is a social network service concentrating on photo sharing. By now, it is the second most popular OSN with more than 1 billion monthly active users.[4] Instagram is the major social network for hashtag-sharing (Figure 1),

[4] https://instagram-press.com/our-story/

Table 1: Summary statistics of all the three datasets.

	New York	Los Angeles	London
No. posts	20,673,946	11,907,967	8,640,637
No. hashtags	4,095,575	3,071,158	1,702,675
No. check-ins	1,609,062	883,862	586,420
No. users	25,735	14,687	11,105
No. social links	82,964	36,434	12,900

many popular hashtags are strongly related to Instagram itself, e.g., #instagood and #instamood.

We collect our dataset relying on Instagram's public API on April, 2016. The first step is finding a sample of users [40]. In the literature, there exist multiple methods for this task. One is relying on the OSN's streaming API [46] which Instagram does not provide. Another way is generating random integers and query the Instagram API to see whether these numbers are valid user IDs [58]. However, this approach needs us to further investigate how Instagram users' IDs are distributed. In this paper, we instead sample users based on their locations following previous works [61, 65].

We concentrate on three major English-speaking cities including New York, Los Angeles, and London. In the first step, we query the API of Foursquare,[5] a location-based social network, to find all the Foursquare location IDs in the three cities. Then, we use Instagram's API to map all the Foursquare location IDs to the corresponding Instagram location IDs.[6] Next, we query all the obtained Instagram location IDs to get all users who have ever shared posts at those locations. As in previous works, we further perform some preprocessing to filter out the users matching any of the following criteria [3, 7, 44, 45, 57].

- users with less than 20 check-ins in each city
- users whose numbers of followers are above the 90th percentile (celebrities) or below the 10th percentile (bots)
- users not using human images in their profile photos[7]

In total, we obtain 51,527 Instagram user IDs. Then, we collect all these users' Instagram posts from the creation time of their accounts until December 31st, 2015. Each post is organized in the following format.

$$\langle \text{user ID, time, hashtags, location ID} \rangle$$

Note that a post is not necessarily associated with a set of hashtags or a certain location ID. We further query Instagram's API to extract users' social relationships. We consider two users to be friends if they follow each other [3, 7, 11].

We treat datasets collected from users in the three cities separately to ensure the robustness of our analyses. In total, the New York dataset (dataset collected from users sampled in New York) contains more than 20 million Instagram posts, the Los Angeles dataset contains 11 million posts, and the London dataset contains 8.6 million posts. Moreover, the three datasets contain more than 7 million hashtags. Table 1 presents some summary statistics of the datasets.

[5]https://foursquare.com/

[6]Instagram's API was connected with Foursquare's API until April 20th, 2016 (https://www.instagram.com/developer/changelog/).

[7]This is done with the help of Face++'s API.

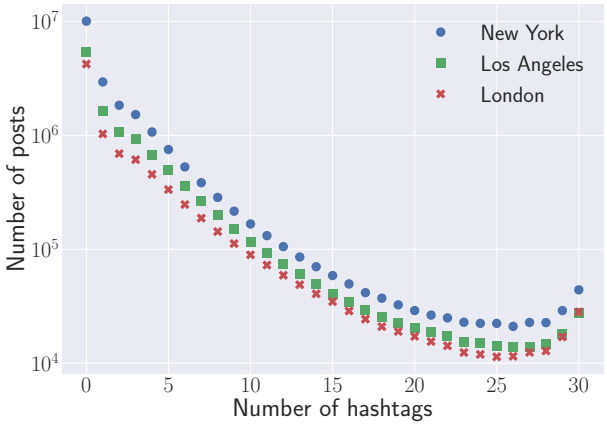

Figure 2: Distribution of the number of hashtags in each post in three datasets. The y-axis is in log scale. The proportions of posts with no hashtags are 48.69% in the New York dataset, 45.28% in the Los Angeles dataset, and 48.92% in the London dataset.

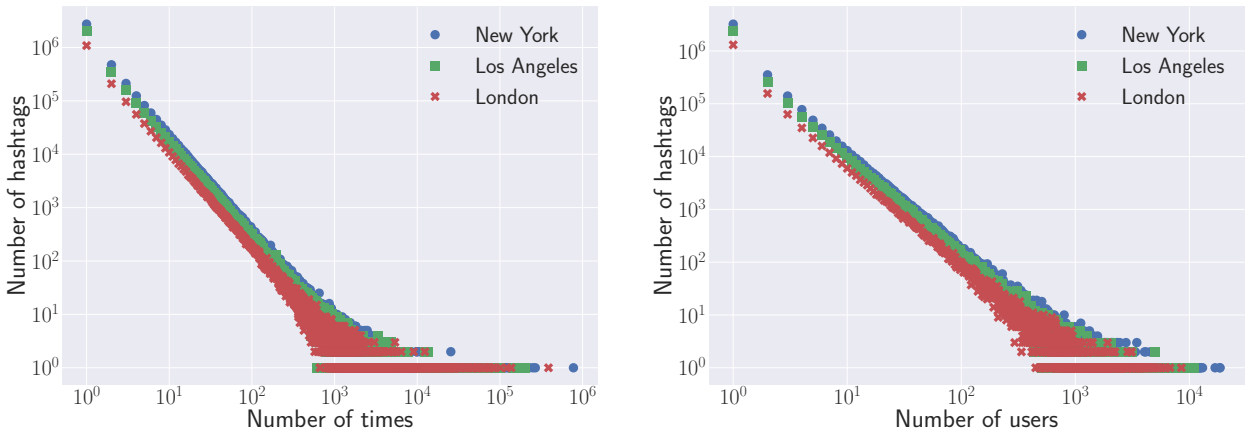
Table 2: Top 10 hashtags with the highest share times in three datasets.



New York	Los Angeles	London
#nyc	#love	#london
#love	#losangeles	#love
#tbt	#tbt	#instagood
#nofilter	#california	#travel
#brooklyn	#instagood	#summer
#latergram	#nofilter	#photooftheday
#instagood	#foodporn	#food
#art	#family	#art
#travel	#art	#instadaily
#summer	#fun	#architecture

Ethical Considerations. Our data collection is done through Instagram's public API in 2016. All the datasets are stored in a central server with restricted access. We further anonymize the datasets by removing all users' screen names, and replacing their Instagram IDs with randomly generated numbers. Our experiments are conducted on these anonymized datasets.

2.2 Initial Analyses

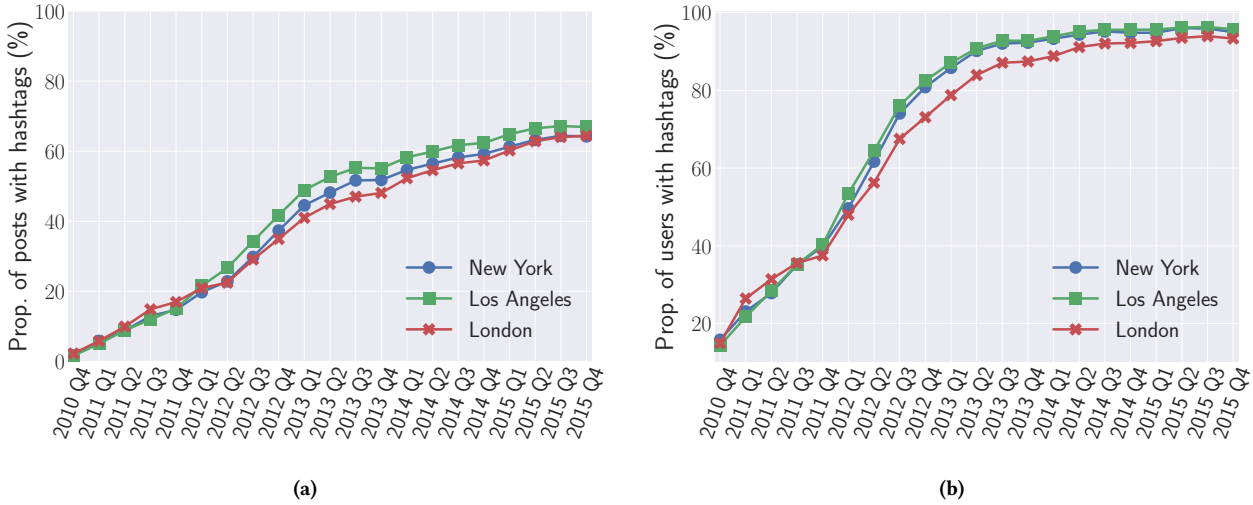


Figure 2 depicts the distribution of the number of hashtags in each post. We observe that more than half of the posts are associated with at least one hashtag in all the datasets. Moreover, there are around 30% posts associated with 1 to 3 hashtags. The small increase close to 30 is due to the fact that Instagram imposes an upper bound of 30 hashtags per post.[8]

[8]https://help.instagram.com/351460621611097

(a) (b)

Figure 3: (a) Distribution of the number of times a hashtag is shared in three datasets; (b) Distribution of the number of users a hashtag is used by in three datasets. Both x and y axes are in log scale.

(a) (b)

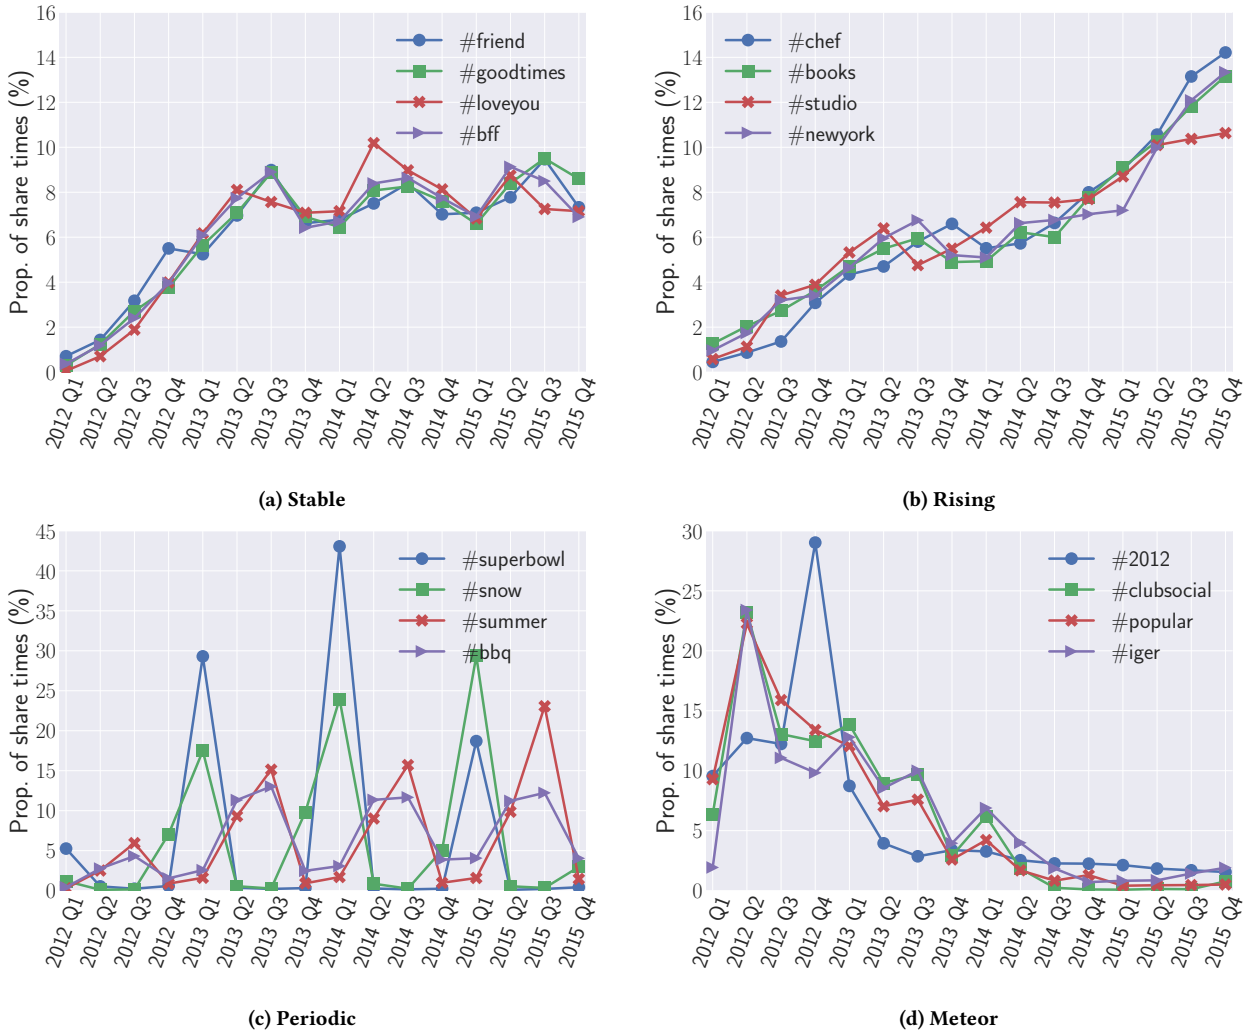

Figure 4: (a) Proportion of posts that are associated with hashtags from 2010 Q4 to 2015 Q4 in three datasets; (b) Proportion of users that use hashtags from 2010 Q4 to 2015 Q4 in three datasets. Q1 represents the first quarter of a year.

Figure 3a plots the distribution of the number of times each hashtag is shared, referred to as share times, while Figure 3b plots the distribution of the number of users each hashtag is used by. As expected, both distributions follow power law, i.e., most of the hashtags are shared only a few times and by a small number of users. Table 2 lists the hashtags with the highest share times. As our users are sampled by cities, many of these popular hashtags are related to city names, such as #nyc, #losangeles, and #london. However, general popular hashtags are captured as well, e.g., #love, #tbt, and #instagood. This indicates that our datasets are suitable for conducting the study.

Figure 4 depicts hashtags' general temporal patterns from 2010 until 2015. We see that in the fourth quarter of 2010 (2010 Q4) when Instagram was launched, there are less than 2% of the posts associated with hashtags, after 5 years (2015 Q4), the number becomes almost 70% (Figure 4a). Within the same time period, the proportion of users that ever use hashtags grow from 18% to 97% (Figure 4b). These results fully demonstrate the popularity of hashtags.

3 HASHTAGS IN THE TEMPORAL-SPATIAL DIMENSION

This section concentrates on our first research question: *What are the temporal and spatial patterns of hashtags?*. We start by investigating the temporal patterns of hashtags, then discuss the relation between hashtags and locations.

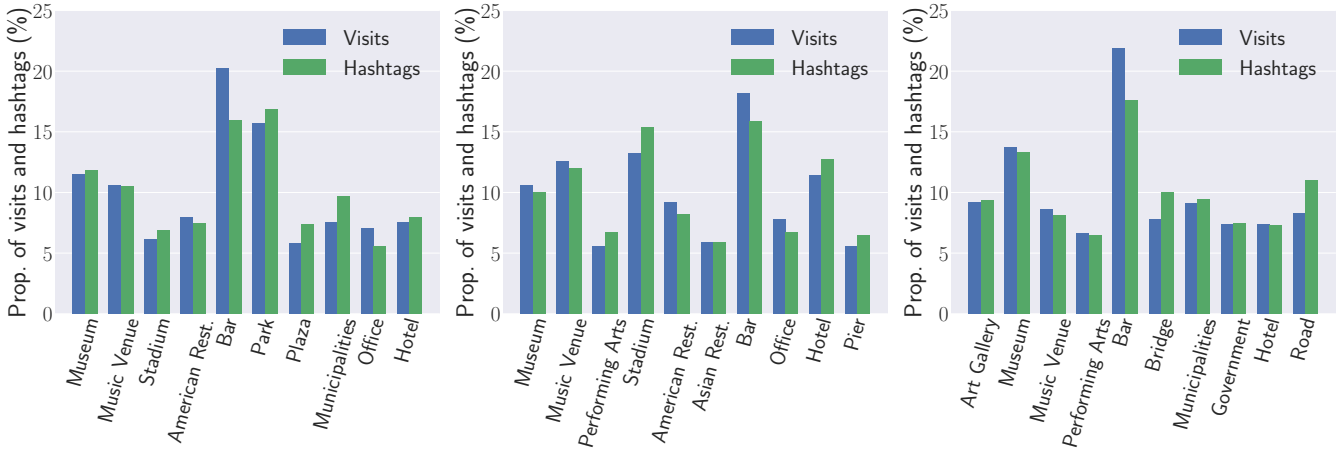
(a) Stable **(b) Rising**

(c) Periodic **(d) Meteor**

Figure 5: Temporal patterns of some example hashtags belonging to different temporal clusters in the New York dataset.

3.1 Temporal Patterns

We hypothesize that different hashtags exhibit different temporal patterns. Some hashtags should have periodic patterns, such as holiday-related ones, while others' share times may increase over time. Besides, there may exhibit other temporal patterns for hashtags. To perform a quantitative study, we resort to machine learning clustering to discover different temporal patterns.



We aggregate each hashtag's proportion of share times to the granularity of quarters starting from the first quarter in 2012 to the last quarter of 2015.[9] This indicates that each hashtag's temporal pattern is organized as a 16-dimension vector (4 years × 4 quarters). k-means is adopted to perform clustering. We first try to fit each hashtag's temporal patterns, i.e., the 16-dimension vector, directly to k-means, however, the resulting clusters are not very promising. This is due to the fact that some hashtags may share similar temporal patterns, however, their patterns' peak happen at different time, e.g., #christmas and #halloween.

Instead, we manually define features over each hashtag's temporal patterns which are described in Table 3. To ensure the robustness of our results, we concentrate on the top 1,000 hashtags in terms of share times [19]. In order to select a suitable number of clusters for k-means, i.e., k, we adopt the Silhouette value. Experimental evaluation suggests that $k = 4$ leads to the highest Silhouette value (around 0.6) in all the three datasets.

The resulting four clusters are named *Stable*, *Rising*, *Meteor*, and *Periodic* based on their temporal patterns. Their detailed descriptions are as follows.

- Stable: Hashtags in the first cluster in the beginning exhibit an increase in their usage. After a certain time point, their share times become stable.

[9]We neglect the data in 2010 Q4 and 2011 due to the small quantity as shown in Figure 4).

(a) New York (b) Los Angeles (c) London

Figure 6: Proportions of visits and hashtags shared at the most popular location categories in three datasets. Rest. in (a) and (b) means Restaurant.

Table 3: Features defined over each hashtag h's temporal pattern $\mathcal{T}_h$.

Description
Standard deviation of $\mathcal{T}_h$
Largest 3 values in $\mathcal{T}_h$
Mean of the 3 largest values in $\mathcal{T}_h$
Standard deviation of the 3 largest values in $\mathcal{T}_h$
Standard deviation of the 3 largest values' indices in $\mathcal{T}_h$
Smallest 3 values in $\mathcal{T}_h$
Mean of the 3 smallest values in $\mathcal{T}_h$
Standard deviation of the 3 smallest values in $\mathcal{T}_h$
Standard deviation of the 3 smallest values' indices in $\mathcal{T}_h$

- Rising: The share times of hashtags in this cluster increase steadily over time.
- Meteor: In this cluster, hashtags at some temporal point are suddenly shared a large number of times.
- Periodic: Hashtags in this cluster exhibit periodic popularity.

The sizes of the four clusters are not uniform. The Rising cluster is the largest one containing around 60% of all hashtags, followed by the Stable cluster (around 25%). Meteor, on the other hand, is the smallest cluster with around 7% of all hashtags.

Figure 5 depicts the temporal patterns of some hashtags in different clusters in the New York dataset. We can make several interesting observations. For instance, the Periodic cluster contains not only hashtags about seasons or holidays, such as #summer, but also those about season-related activities, such as #bbq. Moreover, hashtags describing (annual) sports events belong to this cluster as well, e.g., #superbowl. As expected, hashtags that are specific to a certain point of time are categorized in the Meteor cluster, one example is #2012. Interestingly, some hashtags that are specific to Instagram also belong to the Meteor cluster. For instance, #iger in the second quarter of 2012 gains a large popularity, while in 2015, no one uses it anymore.

3.2 Spatial Patterns

Next, we investigate the spatial patterns of hashtags. In particular, we are interested in at which types of places people are more willing to share hashtags. To get the type/category of a location in an Instagram post, we again resort to Foursquare (see Section 2). Foursquare organizes all its location categories into a two-level tree,[10] we focus on the fine-grained second-level which contains more than 300 different location types.

We pick the top 10 location categories that users visit the most number of times in each dataset within the corresponding city, and calculate the proportion of hashtags shared among these categories. For comparison, we further calculate the proportion of users' visits to locations under these categories.

Figure 6 plots the results. First of all, places belonging to the Bar category are among the most popular locations for people to visit in all the datasets. However, the proportions of hashtags shared at bars drop in all the cases, e.g., the drop in the London dataset is around 5%. This means people are less likely to share hashtags at bars. Another type of locations exhibiting the same result is Office. On the other hand, people are more willing to share hashtags at outdoor places, e.g., Park in New York, Pier in Los Angeles, and Road in London. These results show that the spatial information indeed influences users' hashtag-sharing behavior.

4 SEMANTIC CHANGE

In this section, we address our second research question: *Do hashtags exhibit semantic displacement?*. We start by describing how to express each hashtag's semantics, then focus on semantic displacement.

[10] https://developer.foursquare.com/docs/resources/categories

Table 4: 10 hashtags that are most semantically similar to #family, #sushi, and #r2d2 in the New York dataset.

#family	#sushi	#r2d2
#familytime	#sashimi	#c3po
#cousins	#nigiri	#droids
#aunt	#sushiporn	#bb8
#father	#spicytuna	#artoo
#mom	#chirashi	#astromech
#sisters	#sushiroll	#carbonite
#grandparents	#unagi	#xwing
#nephews	#sushirolls	#obiwankenobi
#familylife	#shrimptempura	#lukeskywalker
#siblings	#californiaroll	#starwars

4.1 Semantics of Hashtags

As a new-era language, hashtags convey interesting meanings. To study this, our first step is finding a tool to represent each hashtag's semantics. Here, we adopt the skip-gram model with negative sampling [38, 39]. Skip-gram, designed following the distributional hypothesis in linguistics, is essentially a shallow neural network model, it maps each word into a continuous vector which preserves the information of the word's contexts words in a large corpus.

In our case, we treat each hashtag as a "word", and all hashtags in a post as one "sentence". Then, we perform skip-gram over all the "sentences" for each dataset. We set each hashtag's vector's dimension to 300 following previous works [19, 38, 39].

To show the effectiveness of skip-gram on capturing hashtags' semantics, we perform a qualitative study to find some hashtags' most semantically similar ones with respect to the shortest cosine distance between learned vectors. Table 4 presents the results for #family, #sushi, and #r2d2 in the New York dataset. As we can see, all the semantically similar hashtags found for these hashtags indeed express quite similar meanings, e.g., #r2d2 is similar to #c3po, #droids, and #bb8.

4.2 Semantic Displacement

With the cultural evolution, some words in natural language exhibit semantic displacement, e.g., the word "gay". We are interested in whether semantic displacement can be observed on hashtags as well. Moreover, due to hashtags' inherent dynamic nature, their semantic displacement should be much faster than that of words which normally takes decades, therefore, our datasets spanning over 5 years are sufficient for this study.

To measure semantic displacement of each hashtag, we first split our datasets by years staring from 2011 to 2015. Then, we perform skip-gram to map hashtags in each year into a vector. This means each hashtag has up to 5 vectors. A *single semantic displacement* of a hashtag is measured over two consecutive years as the cosine distance of the hashtag's two vectors at those years. The *overall semantic displacement* of a hashtag is the mean of all its single semantic displacements.

However, the stochastic nature of the skip-gram model drives vectors learned at different years to reside at different coordinate axes. Therefore, we need to align each hashtag's vectors at different years together before calculating their cosine distance [19, 25]. To this end, we apply the orthogonal Procrustes approach used by Hamilton et al. [19]. Concretely, we use $M^{(t)} \in \mathbb{R}^{300\times|\mathcal{H}|}$ to represent the matrix containing all the hashtags' vectors' at year t, and $\mathcal{H}$ to represent the set of all hashtags. Then, we solve the following optimization objective function

$$\arg\min_{X} ||XM^{(t)} - M^{(t+1)}||_F$$
$$\text{subject to } XX^T = I$$

by applying singular value decomposition (SVD). Here, $||\cdot||_F$ denotes the Frobenius norm. After obtaining the result, we align vectors of a hashtag in two consecutive years together.

Again, to ensure the robustness of our results, we concentrate on the top 1,000 hashtags that are shared the most number of times. Our experimental evaluation shows that some hashtags indeed exhibit a large semantic displacement. In our three datasets, there are at least 10% of the hashtags with more than 0.4 overall semantic displacement. Given the fact that cosine distance lies in the range of $[0, 2]$,[11] the semantic shift is pretty large. Table 5 and Table 6 list the hashtags with the highest and lowest overall semantic displacement. We see that hashtags that are specific to Instagram have quite large semantic displacement, such as #insta, #nofilter, and #ig. Many of

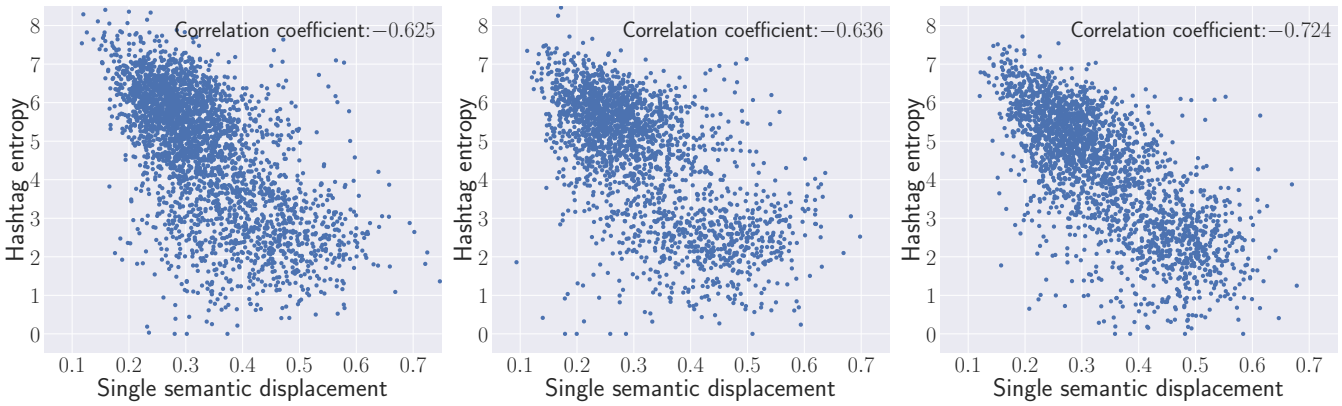


Table 5: 10 hashtags with the highest overall semantic displacement in three datasets.

New York	Los Angeles	London
#ontheroad	#hashtag	#iphoneography
#epic	#epic	#insta
#ilovemyjob	#hipstamatic	#world
#free	#winning	#today
#starwars	#nofilter	#popular
#winning	#insta	#potd
#pictureoftheday	#ig	#walking
#nofilter	#iphone	#ignation
#iphonography	#free	#instamoment
#yolo	#random	#studio

Table 6: 10 hashtags with the lowest overall semantic displacement in three datasets.

New York	Los Angeles	London
#nyc	#sweettooth	#pet
#beach	#dessert	#trees
#sky	#sweets	#beach
#sand	#trees	#tube
#eastriver	#palmtrees	#cat
#leaves	#soup	#kitty
#waves	#ocean	#skyscraper
#salad	#sunset	#thames
#sunset	#building	#smoothie
#pasta	#foodporn	#glutenfree

[11] Vectors learned by skip-gram are in $\mathbb{R}^{300}$, thus, the cosine distance is in $[0, 2]$.

(a) New York **(b) Los Angeles** **(c) London**

Figure 7: Relation between single semantic displacement and hashtag entropy in three datasets. Hashtag entropy is calculated on a yearly-base.

these hashtags are initially created to increase Instagram posts' popularity. We conjecture that when people are more used to these hashtags, they cannot attract as much attention as before, thus start to convey different meanings. On the other hand, we observe from Table 6 that nature-related hashtags are among those whose semantics stay rather stable, e.g., #sky, #trees, and #ocean. Also, food-related hashtags, such as #salad, #soup, and #smoothie, do not change their meanings that much.

Hamilton et al. show that high frequency words are less likely to change their meanings [19]. However, this is not the case for hashtags. We perform a correlation analysis between hashtags' frequency, i.e., share times, and single semantic displacement, and obtain a rather weak correlation (correlation coefficients are around -0.2 in all the datasets). Instead, we hypothesize that hashtags that are more uniformly shared among users are less likely to shift their meanings.

We propose *hashtag entropy* to measure each hashtag's sharing uniformity among users. Formally, a hashtag h, its entropy is defined as:

$$-\sum_{u \in \mathcal{U}} p(u,h) \log p(u,h)$$

where $\mathcal{U}$ denotes the set containing all the users and $p(u,h)$ represents the proportion of h shared by user u. It is worth noting that our hashtag entropy follows the same definition as the Shannon entropy: Higher entropy implies that the hashtag is more uniformly shared among users.

For each hashtag, we calculate multiple entropy at each year (from 2012 to 2015), then correlate each entropy with the corresponding single semantic displacement. Figure 7 depicts the results. In all the three datasets, we obtain strong negative correlation. In particular, the correlation coefficient in the London dataset is -0.724. These results show that if a hashtag is shared by many users in a similar frequency, i.e., high entropy, then it is less prone to semantic displacement.

5 HASHTAGS AND FRIENDSHIP

In this section, we address our last research question: *Can hashtags be used to infer social relations?*. We first describe our methodology on using hashtags for friendship prediction, then present the experimental evaluation.

5.1 Methodology

Social network is the major platform for people to share hashtags, this naturally leads to the question whether hashtags are related to people's social relations. To answer this question, we perform a friendship prediction task solely based on hashtags.

Friendship prediction is normally modeled as a binary classification task [1, 3, 4, 29, 31, 48, 57]. We can manually define features over two users' hashtags, and perform prediction either in a supervised manner (with the help of machine learning classifier) or an unsupervised manner. However, feature engineering is very time-consuming, and in many cases, the resulting features are not complete. Also, to define features over two users' hashtags, a natural approach is concentrating on their common hashtags. As most pairs of users share no common hashtags, this approach can be only applied to a small subset of user pairs, which cannot provide a complete picture on the relation between hashtags and social networks.

Instead, we choose to learn a hashtag profile, i.e., a feature vector, for each user, and compare two users' profiles to perform friendship prediction. As all users' hashtag profiles (feature vectors) are in the same dimension, this allows us to predict any pair of users' friendship.

Our hashtag profile learning follows the recent advancement of graph embedding [3, 13, 17, 20, 22, 32, 47, 50, 51, 53, 59, 62, 64]. In this setting, profiles are automatically learned following a general optimization objective function. Concretely, we organize users and hashtags into a weighted bipartite graph. For an edge connecting a user and a hashtag, its weight equals to the number of times the user shares the hashtag. We simulate a certain number of random walks starting from each user, referred to as *walk times*, on the

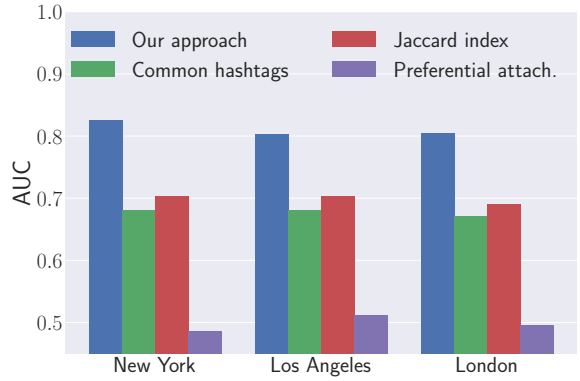

Figure 8: AUC for friendship prediction in three datasets. Preferential attach. means preferential attachment.

graph. The transition probability from each node to the next one follows the corresponding edges' weight. Each walk has a certain length, specified by the number of steps, which we refer to as *walk length*. This leaves us with a set of random walk traces. Then, we rely on the following optimization objective function to learn each user's hashtag profile.

$$\arg\max_{\theta} \prod_{v \in \mathcal{U} \cup \mathcal{H}} p(v|N(v);\theta)$$

Here, $N(v)$ denotes the neighborhood of node v[12] and $\theta(v)$ is the learned profile of node v. Moreover, $p(v|N(v);\theta)$ is modeled with a softmax function. Different from previous graph embedding approaches which define their objective functions following skip-gram [17, 47], our objective function is essentially the continuous bag-of-words (CBOW) model [38, 39]. We choose CBOW over skip-gram due to its better performance. In addition, we apply the negative sampling approach to speed up the learning process.

In the end, for any two users, we calculate their learned profiles' cosine distance, and predict them to be friends if the cosine distance is below a chosen threshold.[13] Note that our prediction does not need the knowledge of any existing friendships, therefore, it is unsupervised.

5.2 Evaluation

Experimental Setup. For each dataset, we randomly sample the same number of stranger pairs as the number of friend pairs to construct the negative cases. Then, we compute cosine distances for all friend and stranger pairs. AUC (area under the ROC curve) is adopted as the evaluation metric [3, 18, 56, 57]. There are mainly three hyperparameters in our model, i.e., walk length, walk times, and the dimension of the learned profile. Based on cross validation, we set them to 120, 80, and 512, respectively.

Baseline Models. We further establish three baseline models following the traditional link prediction approach [29], namely Jaccard index, common hashtags, and preferential attachment. Their formal definition is presented in Table 7.

[12]Following previous works [3, 17], $N(v)$ includes 10 nodes precedent and after v in all the random walk traces.

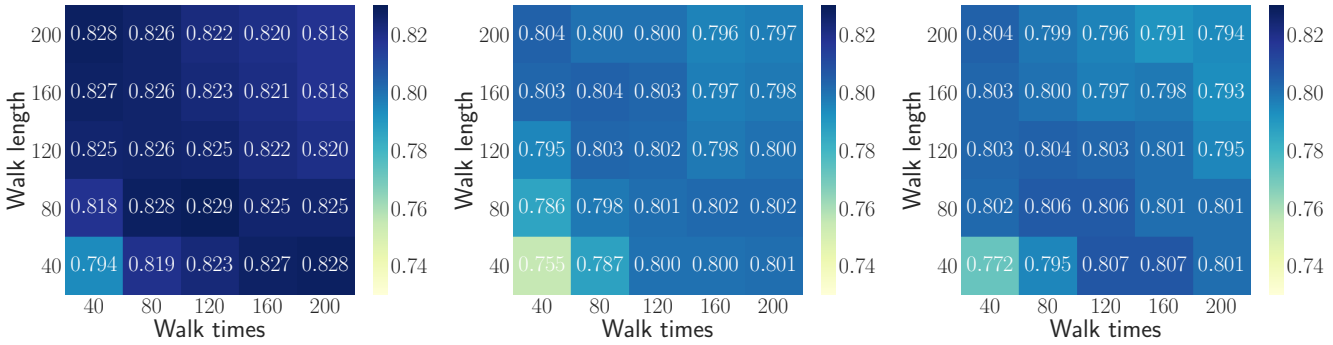
[13]We also learn a set of vectors for all hashtags, as we concentrate on friendship prediction, these hashtag vectors are simply neglected.

Table 7: Formal definition of baseline models for friendship prediction. $\mathcal{H}(u)$ is the set containing all the hashtags u has shared.

Baseline	Definition
Common hashtags	$\lvert\mathcal{H}(u) \cap \mathcal{H}(u')\rvert$
Jaccard index	$\frac{\lvert\mathcal{H}(u)\cap\mathcal{H}(u')\rvert}{\lvert\mathcal{H}(u)\cup\mathcal{H}(u')\rvert}$
Preferential attachment	$\lvert\mathcal{H}(u)\rvert \cdot \lvert\mathcal{H}(u')\rvert$

Results. Figure 8 depicts the AUCs for friendship prediction. In all the three datasets, we obtain more than 0.8 AUC which shows that hashtags can provide strong signals on inferring social relations. In particular, the prediction in the New York dataset achieves the best performance.

Our approach also outperforms all the three baseline models significantly. For the best baseline model, i.e., Jaccard index, we achieve around 20% performance gain in all the datasets. One of the major advantages of our approach is its ability to predict two users' friendship regardless of whether they share common hashtags. We observe that even for pairs of users sharing no common hashtags, our prediction still achieves a decent performance in all the datasets: 0.759 AUC in New York, 0.733 AUC in Los Angeles, and 0.728 AUC in London. This further demonstrates the effectiveness of our approach.



We also study the influence of hyperparameters on the prediction performance. Figure 9 depicts the heatmap when jointly tuning walk times and walk length. We see that when these two values are small, i.e., 40, the prediction results are relatively weak in all the three datasets. When increasing both, the performance gets better. However, the relation between the prediction result and the magnitude of the hyperparameters is not monotonic: When we set both walk times and walk length to 200, the prediction results drop in all cases. Note that we also perform the same study on the dimension of each learned profile, and observe that 512 leads to the best prediction.

6 RELATED WORK

Hashtags provide us with an unprecedented chance to understand the modern society. Researchers have studied hashtags from many perspectives [2, 5, 6, 8–10, 12, 14–16, 23, 24, 26–28, 30, 33, 36, 37, 41–43, 49, 52, 54, 55, 58, 60, 63, 65].

Souza et al. use #selfie to study the phenomenal self-portrait behavior in OSNs [58]. They collect a large dataset from Instagram, and show that the amount of posts associated with #selfie increases 900 times from 2012 to 2014. Moreover, their results suggest that posts with #selfie attract more likes and comments than others. The authors further show that there exist cultural variations of selfie behavior across countries.

Mejova et al. study food-related hashtags, such as #foodporn, on Instagram to understand people's dining behavior on a global scale [37]. They first show that desserts in social media are dominating over local cuisines. Then, they discover through hashtags

(a) New York **(b) Los Angeles** **(c) London**

Figure 9: Influence of walk length and walk times on the prediction performance in three datasets. Each value in the matrix represents the corresponding AUC.

that food can motivate people to engage in a healthier life style. Similar to #selfie, Mejova et al. show that posts associated with healthy-related hashtags attract more likes than others.

David et al. use hashtags together with the smiley face emoji to perform sentimental analysis on Twitter [10]. In this work, hashtags are used as the sentimental labels, and the authors summarize features over tweets. Evaluation results show that their classification achieves very effective performance.

Multiple works also use hashtags to study various political movements. Olteanu et al. analyze the demographics behind #blacklivesmatter, and conclude that African-Americans and young females engage more with the hashtag than others [42]. Manikonda et al. perform a comparative analysis of #metoo shared on Twitter and Reddit [34]. They observe that posts on Reddit concentrate on sharing personal stories while tweets express public support for the #metoo movement.

Zhang et al. study the privacy implications of sharing hashtags [65]. They first utilize a simple bag-of-words model and a random forest classifier to perform location prediction based on hashtags. Evaluation shows that their approach achieves more than 70% accuracy over fine-grained locations. Then, the authors propose a privacy-preserving system, namely Tagvisor, to mitigate the location privacy risks. Tagvisor implements three different obfuscation mechanisms including hiding, replacement, and (location category) generalization. Extensive experiments suggest that by obfuscating two hashtags, Tagvisor can successfully mislead the location prediction model, while maintaining a high-level utility with respect to hashtag semantics.

While the above works concentrate on either a certain type of hashtags or a certain property of hashtags, Ferragina et al. perform a general analysis of hashtags on Twitter [12]. In particular, they concentrate on the semantics of Twitter's hashtags. They first build a hashtag-entity graph over a large number of tweets. Then, the authors perform two natural language processing tasks, namely hashtag relatedness and hashtag classification, based on the features extracted from the constructed hashtag-entity graph. Experimental results show that this approach outperforms state-of-the-art solutions by a large extent. Besides targeting a different OSN than Ferragina et al. [12], we perform a much broader analysis on hashtags with several new angles, such as spatial pattern, semantic displacement, and social signal.

7 CONCLUSION

In this paper, we perform the first large-scale analysis on understanding hashtags shared on Instagram. Our study is centered around three research questions which aim at understanding hashtags from three different dimensions, i.e., the temporal-spatial dimension, the semantic dimension, and the social dimension. We collect three large datasets from Instagram containing more than 7 million hashtags shared over 5 years to perform our analyses.

We first show that hashtags can be categorized into four different clusters according to their temporal patterns, and people are more willing to share hashtags at certain places, such as parks. We then discover that some hashtags indeed exhibit large semantic displacement. Moreover, we propose a notion namely hashtag entropy and show the strong negative correlation between hashtag entropy and semantic displacement. In the end, we propose a bipartite graph embedding model to summarize users' hashtag profiles and rely on these profiles to perform friendship prediction. The effective prediction performance suggests that there is a strong connection between hashtags and social relations.

ABSTRACT

Recently, neural models for information retrieval are becoming increasingly popular. They provide effective approaches for product search due to their competitive advantages in semantic matching. However, it is challenging to use graph-based features, though proved very useful in IR literature, in these neural approaches. In this paper, we leverage the recent advances in graph embedding techniques to enable neural retrieval models to exploit graph-structured data for automatic feature extraction. The proposed approach can not only help to overcome the long-tail problem of click-through data, but also incorporate external heterogeneous information to improve search results. Extensive experiments on a real-world e-commerce dataset demonstrate significant improvement achieved by our proposed approach over multiple strong baselines both as an individual retrieval model and as a feature used in learning-to-rank frameworks.

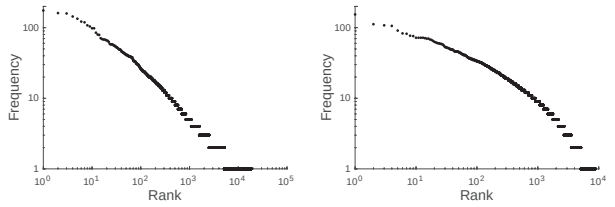
1 INTRODUCTION



Online shopping has become increasingly popular over the past decade. Those e-commerce sites normally sell a vast number of products at the same time and provide plenty of choices under each category. For instance, there are hundreds of million products in Amazon and over one billion in eBay. It is almost impossible for consumers to find items that they are interested in without the help of an effective product search engine. On the other side, an improvement in product search accuracy could bring massive revenue to online retailers [1].

In a typical product search scenario, users formulate queries using characteristics of the product of interest, for example, the producer's name, brand, or terms which describe the category of the product [38]. However, the lexical gap between queries and product descriptions [42] makes it difficult to exploit such traditional information retrieval models as LSI [5], BM25 [37], which focus more on lexical matching, in this application scenario.

The recent neural network-based models (sometimes also known as deep learning models) [27] provide a good solution to this problem with their advantages in semantic matching. Yet, despite great success of deep learning in processing speech (1D), image (2D), and video (3D) data, neural models are rather limited in dealing with *high-dimensional* graph-structured data, which, on the other hand, has been extensively studied in the existing IR literature (e.g., the graph-based ranking features PageRank [31], HITS [21]; the graph-based similarity metric SimRank [17]; the click graph-based smoothing and propagation models [4, 11, 18, 23, 45]; the heterogeneous graph-based query intent learning [35]).

In fact, the neural approach and the graph-based approach are based on two different types of *inductive biases* that are complementary to each other. The inductive bias for the former is the smoothness with respect to input features (i.e., $f(x+\epsilon) \approx f(x)$ for small ϵ). For example, given queries "multifunction printer" and "all-in-one printer", neural nets should give similar predictions. On the contrary, the graph-based approach is mostly based on the smoothness regarding node proximities where node can be queries, items, sessions, etc. (i.e., $f(x) \approx f(y)$ if node x and y are "close" in a given graph). For example, queries q_1 and q_4 sharing common neighbors within a densely connected subgraph in Figure 2 are assumed to have similar outcomes and therefore the knowledge towards one query can be transferred to the other. Admittedly, in theory, neural nets can automatically learn the latter structure with sufficiently large amount of data. However, besides extensive computational burden, it is infeasible to obtain enough data for long-tailed queries/items in e-commerce search (Figure 1) and extremely hard for neural nets to learn high-order proximities in practice. Thus, it becomes an interesting research question whether we can combine these two complementary approaches for better retrieval performance.

(a) query occurrence (b) product occurrence

Figure 1: The frequency-rank distribution (log-scale) of item and query occurrences in a sample of search logs from an e-commerce search engine, respectively.

In this paper, we propose to leverage the recent advances in *graph* [1] *embedding* techniques [12, 14] to integrate graph-structured data into a unified neural ranking framework. To the best of our knowledge, this is the first study on how to use the click-graph features in neural models for retrieval.

The benefits to allow neural retrieval models to incorporate graph-structured information are demonstrated in two-fold. Firstly, by integrating the click-graph features, our model can effectively overcome the query-item sparsity problem of the click-through data [11] and generalize better to unseen queries and long-tailed products. This is of great significance in the deep learning setting, where neural models not only require a large amount of data with sufficient coverage but also are prone to overfitting, which in turn causes poor retrieval performance on rare queries and reinforces the *rich-get-richer* effect [3]. Furthermore, we show that graphs can be used as convenient and efficient tools in our approach to fuse external heterogeneous information to improve search results, e.g., co-viewed items in a browsing session and co-purchased items in an order. Those features are, though, not very straightforward for existing neural ranking models to take advantage of.

From another perspective, our proposed approach can be seen as a way to tackle a side effect of neural networks, *unawareness of transitivity*, as their capacity (which can be loosely measured by the number of parameters) grows to fit non-smooth relations with limited data. For instance, as illustrated in Figure 2(a), query q_4 and q_5 share a common product click so that they tend to be queries with similar user intent and product p_3 (clicked through q_4) should also be considered somewhat relevant to q_5. However, neural network models themselves might not be aware of this transitive relation, because query-product pair (q_5, p_3) simply do not appear in the positive training examples and, when given sufficient capacity, neural networks do not require this relation to hold in order to preserve other positive relations either (see Section 5 for empirical evidence). While this issue can be implicitly mitigated to some extent with such regularization methods as L1/L2 penalties that merely "uninformatively" shrink the weights towards zero or with carefully designed neural architectures, it strongly motivates the direct use of graph-structured regularization towards utilizing the full potentials of neural networks for retrieval.

[1] In order to avoid confusion, we mostly use the word *graph* to refer to the collection of nodes and edges, and *network* to refer to the neural networks in this paper, although these two words are often used interchangeably in literature.

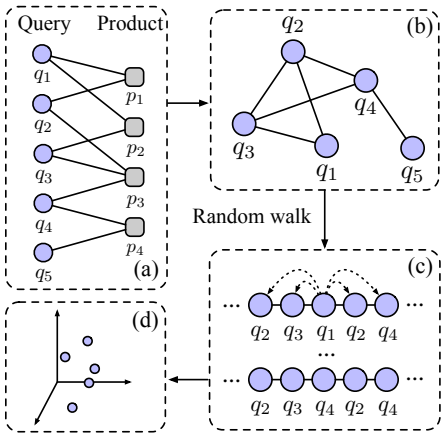

Figure 2: Graph embedding.

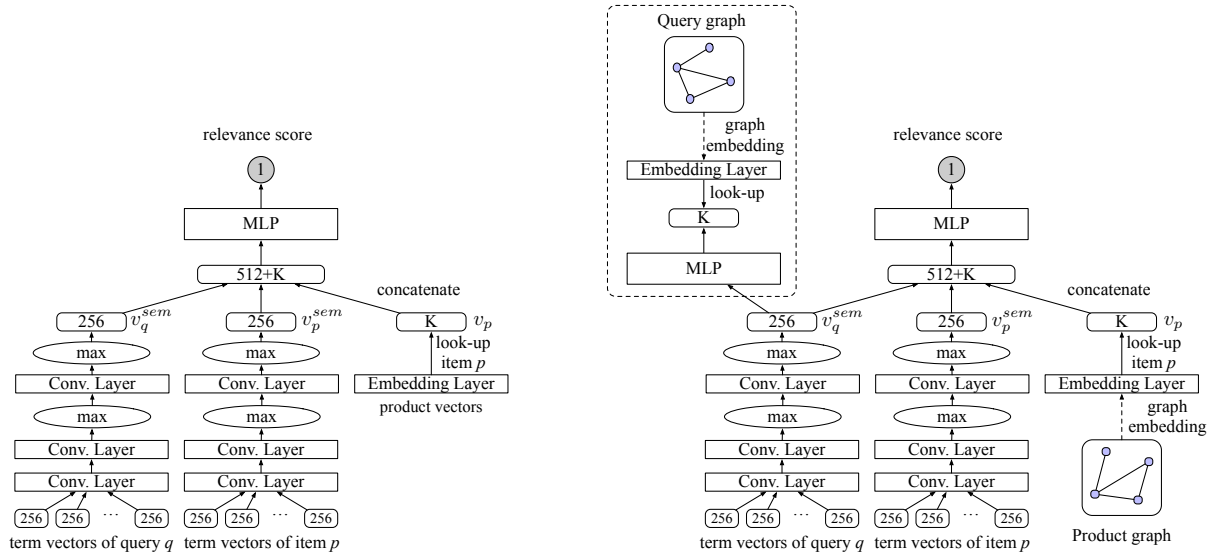
Finally, we evaluate our model on a real-world dataset of e-commerce search. Experimental results show that our model substantially outperforms state-of-the-art baselines both as an individual ranking model and as a feature in a learning-to-rank framework. Ablation study further demonstrates that the use of graph-embedding techniques leads to a significant improvement in retrieval performance.



To conclude, the major contributions of this work are as follows:

- We propose a Graph Embedding-based ranking model for Product Search (GEPS), which is, to the best of our knowledge, the first to integrate click-graph features into a unified neural ranking framework.
- Our proposed graph embedding-based approach can effectively (a) deal with the long-tail sparsity problem and (b) combine heterogeneous external information into neural models to improve search results.
- Through extensive experimental study on a publicly available e-commerce dataset, we show that GEPS can achieve significant improvement in retrieval performance compared with the existing work.

2 BACKGROUND: GRAPH EMBEDDING

As mentioned in Section 1, there are many "hand-crafted" graph-based features in the existing IR literature. However, the lack of an effective representation makes it hard to apply deep learning models to graph-structured data for automatic feature extraction. Recently, the extensive study on the *graph embedding* provides a good solution to this problem. In this section, we introduce two popular state-of-the-art graph embedding methods, Deepwalk [33] and LINE [41], by taking the query graph induced by click-through data as an example.

As shown in Figure 2(a-b), we construct a query graph by establishing links between each pair of queries if they have once led to clicks on an identical item. (A product graph can also be constructed similarly.) This query graph contains rich signals for retrieval, for edges in the graph may indicate semantic similarities of queries. Intuitively, two queries that are nearby in the query graph tend to be similar to each other, and hence the knowledge we have for one

(a) Neural Base Model: NeuBase

(b) Proposed Model: GEPS

Figure 3: Model Architecture. We use dashed-line arrows to represent assignment of graph embedding vectors to the parameters/weights in embedding layers. K denotes the embedding dimension.

query can also be transferred to the other, which can be especially useful for a tail query that rarely appears in search logs. Motivated by this kind of intuition, the goal of graph embedding is to obtain vector representations for each node in a graph, as shown in Figure 2(d), so that the proximities between nodes can be well preserved.

Perozzi et al. [33] propose Deepwalk based on a distributional hypothesis on graphs, nodes with similar neighborhood tend to be similar to each other, which is also called the *second-order proximity*. They first generate random walk sequences and then use the node in the middle to predict the other nodes within a given window (Figure 2(c)), so that nodes occurring in similar contexts of random walk sequences will have close embeddings, as in Skip-gram [26] developed in language modeling. Thus, query q_1 and q_4 are supposed to have similar vector representations.

Further, Tang et al. [41] propose LINE to take the *first order proximity* into consideration, for example, query q_4 and q_5 are connected by a direct link and therefore should have close embeddings as well. Meanwhile, graph embedding is made scalable to graphs with over millions of nodes and billions of edges by an edge sampling technique proposed in their work. Finally, the embedding vectors preserving the two kinds of proximities are obtained respectively in LINE, and they can either be used separately or combined in a supervised manner.

3 MODEL FRAMEWORK

3.1 Preliminaries and Notations

Like other neural ranking models, we use click-through data to train our models. The click-through data used in our study consists of queries and products with their co-clicked information. We denote the set of queries as Q and each query is represented by a collection of terms $q = \{t_1^{(q)}, ..., t_M^{(q)}\}$. Similarly, the set of products is denoted by P and each product by $p = \{t_1^{(p)}, ..., t_N^{(p)}\}$. We also denote as w the word vector for each term t with the same subscripts and superscripts, for example, $w_1^{(q)}$ denotes the word vector of $t_1^{(q)}$. For each query $q \in Q$, the set of clicked items are represented by P_q, and items that are presented in the SERP (search engine results page) but not clicked as $\overline{P_q}$.

The query graph and the product graph are defined as $G_{query} = (Q, E_Q)$ and $G_{product} = (P, E_P)$, respectively. After graph embedding, we can obtain graph embedding vectors e_q for each query $q \in Q$ and e_p for each product $p \in P$. The graph embedding procedures then can be defined as mappings, $g : G(V, E) \mapsto \{e_v, \forall v \in V\}$.

While our proposed model framework is not limited to any specific graphs G_{query} and $G_{product}$ as long as they can provide meaningful interaction information between their nodes (i.e., queries and products) for search, the reader can assume that the graphs of queries and products are induced by the click-through data as depicted in Figure 2(a-b) until further discussion in Section 3.3.

3.2 Proposed Model: GEPS

Our goal is to combine the advantages of both graph-based methods and neural approaches. In this section, we first introduce a simple yet typical neural network architecture for product search as the "base model", and then show how graph embedding techniques can be plugged into such neural network models to incorporate graph-structured information for better retrieval performance.

As shown in Figure 3(a), we represent terms of queries and product descriptions by their term vectors pre-trained on the whole corpus. Then, we input these term vectors to convolutional layers for semantic feature extraction, where the filter window is set to

three. Max pooling layers are used to reduce feature dimensions and eventually transform feature maps into a feature vector. We also use an id embedding vector v_p for each product, which is commonly used in e-commerce search engines to capture its intrinsic features not reflected in the product description. The semantic feature vector v_q^{sem} for the query and v_p^{sem} for the product along with the product vector v_p are concatenated into a long vector. Finally, we use an MLP (multi-layer perceptron) to output the relevance score.

To integrate graph-based features for products, we use graph embeddings to take the place of product id embeddings v_p in the network architecture described above. This is analogous to using pre-trained word embeddings instead of learning word vectors from scratch, which has already been proved to be both effective and efficient in natural language processing. We find it rather helpful to fine-tune these graph embeddings during training due to the unsupervised nature of graph embedding methods at hand.

While it is straightforward to incorporate product graph embeddings in the neural framework, making use of the query graph embeddings is quite challenging, because our retrieval model inevitably has to handle lots of new queries that are absent in the click-through data for training and hence do not have corresponding graph embedding vectors. [2] A tempting approach would be training a regression model f (e.g., CNN or RNN) with query terms as input that "mimics" the query graph embedding vectors, that is,

$$arg\min_{f} \|f(t_1^{(q)}, ..., t_M^{(q)}) - e_q\|_2^2, \tag{1}$$

and then use f to re-create embedding vectors for queries [3]. However, we find it hard to fine-tune query graph embeddings with this approach to achieve best performance; fine-tuning either the re-created vectors themselves or the model f could easily cause overfitting. Besides, it is not ideal to consider graph-based features and semantic features separately to model textual queries (different from the item side).

In our model, we propose to use an encoder-based approach to encode query-graph features in their corresponding semantic feature vectors. More specifically, we use an MLP to transform the semantic feature vectors v_q^{sem} into the same vector space as query graph embeddings e_q and try to minimize the reconstruction error as shown in Figure 3(b), that is,

$$\begin{aligned} min. \quad & \mathcal{L}_{re}(q) = \|\widetilde{e_q} - e_q\|_2^2 \\ st. \quad & \widetilde{e_q} = MLP(v_q^{sem}). \end{aligned} \tag{2}$$

Different from the other approach mentioned above, we can jointly optimize this reconstruction loss with the final ranking loss in the model training stage (see Section 3.4). Also, this encoder-based approach has an additional effect: the word vectors are further trained to capture relevance-based semantics [47] more accurately in such a way that the semantic vectors $v_q^{sem} = CNN(w_1^{(q)}, ..., w_M^{(q)})$ can better reconstruct high-order relevance relations encoded in the query graph. This approach actually shares a similar idea to *multi-task learning*, where relevant tasks (analogous to the graph embedding reconstruction here) are trained simultaneously for mutual regularization and knowledge transfer.

[2] Although there could also exist products missing in the click-through data, the proportion is much smaller in practice. We initialize them with all-zero vectors meaning without any prior knowledge. Empirically, this trick works well enough.

[3] A similar approach [34] is used by Pinter et al. to obtain embedding vectors for the out-of-vocabulary (OOV) words with a character-level RNN.

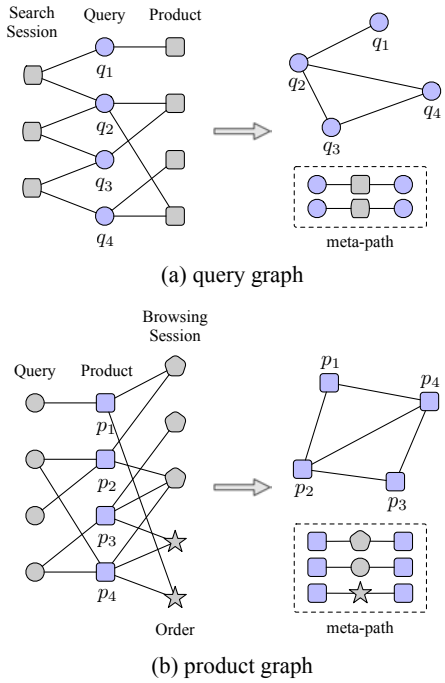


Figure 4: Fusing heterogeneous information with meta-paths.

Finally, it is worth mentioning that the proposed graph embedding-based approach can be used as a "plug-in" to boost the performance of almost any other neural retrieval model. Thus, the experimental results in this paper merely provide a lower bound for the performance of our proposed approach since we only use a simple base model for ease of demonstration.

3.3 Fusing Heterogeneous Information

Our proposed approach can utilize rich information on interactions between both queries and products contained in *graphs*, so that the knowledge we obtain from training data can be transferred to similar queries and correlated products for more accurate retrieval results. To fully take advantage of our graph-based approach, we can further incorporate fruitful external heterogeneous information, in addition to click-through data, into the graphs we use.

As shown in Figure 4(a), a search session may contain several queries; we can assume that the queries within a search session are more likely to share similar search intent. By regarding the heterogeneous relations among sessions, queries and products as a heterogeneous graph [35], we can use meta-paths [40] to construct the query graph. The semantics of graphs constructed by meta-paths are well interpretable, for example, the edge set E_{query} in Figure 4(a) contains all pairs of queries that are either issued in a search session or lead to clicks of an identical product.

We can also fuse more heterogeneous relations in the product graph as in Figure 4(b). In an e-commerce website, in addition to

direct search, customers also browse products through product category hierarchies, recommendations, etc.; products that are browsed at the same time can also be considered as somewhat related to each other. This can become especially useful in the cold-start scenarios where the products that are never clicked through any search queries. Besides, co-purchased items in the same order provide useful signals for search as well. Similarly, we make use of meta-paths to construct the product graph $G_{product}$.

Admittedly, more irrelevant factors and even data noises (e.g., unrelated queries in a session) are introduced into graphs as we fuse more heterogeneous information. Fortunately, our model is trained in a supervised manner so that the neural nets only extract useful features in terms of product search to produce the final results. Again, our proposed approach combines the advantages of both graph-based methods and deep learning approaches.

3.4 Model Training

In the training stage, we use a pairwise ranking loss to train our neural model. Given a search query q along with a positive product $p_+ \in P_q$ and a negative product $p_- \in \overline{P_q}$, the loss is defined as

$$\mathcal{L}_{rank}(q, p_+, p_-) = h(score(q, p_+) - score(q, p_-)), \tag{3}$$

where $score(q, p)$ is the relevance score given by our model for query-item pair (q, p) and h is the *smoothed hinge loss* [36],

$$h(x) = \begin{cases} 0 & x \geq 1, \\ 1/2 - x & x < 0, \\ (1-x)^2/2 & \text{otherwise.} \end{cases} \tag{4}$$

At the same time, we also minimize the reconstruction error as given in Eq. (2) for encoding graph embedding-based features in the query semantic vectors. To sum up, the overall loss function is

$$\mathcal{L} = \sum_{q \in Q} \sum_{p_+ \in P_q} \sum_{p_- \in \overline{P_q}} \mathcal{L}_{rank}(q, p_+, p_-) + \alpha \cdot \sum_{q \in Q} \mathcal{L}_{re}(q), \tag{5}$$

where α is a tunable parameter (we set $\alpha = 1$ in our experiments).

We apply the stochastic gradient descent (SGD) method with mini-batches to optimize the loss function given in Eq. (5). Meanwhile, the standard weight decay regularization and early stopping strategy are used to prevent overfitting. We also use gradient clipping in case gradient explosion happens. The batch size is set to 1024 and the weight decay is 10^{-4} in our experiments.

4 EXPERIMENTS

4.1 Research Questions

We are particularly interested in whether and, if so, how our proposed graph embedding-based approach can lead to performance gains in product search. We break down this principal research question into four individual ones to guide our experimental study:

RQ1. How does our proposed model GEPS compare to the state-of-the-art retrieval models?

RQ2. How does our graph embedding-based approach benefit neural models in dealing with the long-tail problem of click-through data?

RQ3. How does our graph embedding-based approach further benefit neural models by incorporating external heterogeneous information to improve search results?

Table 1: Dataset statistics.

Statistics	Value	
# products	184047	
# unique queries	26137	
Vocabulary size	181194	
Length of queries	2.66 ± 1.77	
Length of product descriptions	5.12 ± 2.04	
# items per order	1.34 ± 0.96	
	Original	Chronological
# queries (train/test)	35615/16218	28380/3011
# search sessions	26880	21505
# browsing sessions	349607	242852
# clicks	37705	30160
# views	1235380	857008
# orders	13506	9130

RQ4. How do graph embedding algorithms influence the performance of GEPS?

4.2 Experimental Setup

4.2.1 Dataset and Data Partition. In order to answer those research questions in Section 4.1, we evaluate our proposed model on the dataset from CIKM Cup 2016 Track 2 [4], which is also the only publicly available dataset of product search. The dataset contains five months of logs of an e-commerce search engine from 1st Jan to 1st Jun, 2016. We filter out the queries without textual information, for the search engine also allows "query-less" search.

In the **original data split**, the test set is obtained by taking the last queries of some sessions. However, with this data partitioning procedure, there could be larger overlaps between training topics and test topics than in real application scenarios, both lexically and semantically, for mainly two reasons: the queries in the same session but prior to a test query are very likely to share similar search intent; both the training and test sets are evenly distributed in the five-month period, not being significantly influenced by the topic shift in queries over time.

In order to simulate the real-world application scenario where models are trained using historical data and applied to unseen future queries, we also report experimental results with a **chronological data split**. We use the first four months' logs (until 1st May) for training and use the last month's test data for evaluation. Note that, we do not know those hidden search behaviors in the first four months (because they are not provided in the dataset), so the size of training data in this data split is only about 80 percent of that in the original data split and hence results on those two testbeds are not reasonably comparable. Also, the statistical significance of performance improvement could subsequently decline as the size of test data is reduced to 20 percent.

The detailed statistics about the dataset and data partitioning are listed in Table 1.

[4] https://competitions.codalab.org/competitions/11161

4.2.2 Baselines. We conduct comparison study with the following baseline methods.

- **LSI** (Latent Semantic Indexing) [5] is a classical vector space model in information retrieval. We set the dimension of vector spaces $K = 256$.
- **BM25** [37] is a very popular probabilistic model-based ranking function proposed by Robertson et al.
- **QLM** (Query-likelihood Model) with Jelinek-Mercer smoothing [48] is an effective entity search approach based on language models [42]. For each product p, we construct a statistical language model smoothed by the whole corpus,

$$P_\lambda(t|p) = (1-\lambda) \cdot P_{ml}(t|p) + \lambda \cdot P(t|C), \tag{6}$$

  where $P_{ml}(t|p)$ and $P(t|C)$ are simply given by relative counts of term t appearing in the description of product p and the whole corpus C, respectively. Then, we can obtain the relevance score for each product p given a query q according to Bayes' rule,

$$P(p|q) \propto P(p) \cdot P_\lambda(q|p) = P(p) \cdot \prod_{t \in C_q} P_\lambda(t|p), \tag{7}$$

  where $P(p)$ is the popularity of product p given by its click counts, and C_q is the collection of terms in query q. In our experiments, we set the smoothing parameter $\lambda = 0.01$ that turns out to be not very sensitive.
- **LSE** (Latent Semantic Entities) [42, 43] is a state-of-the-art latent vector space model for product search, which jointly learns vector representations of words and products from scratch. We choose 256 as the dimensions of both word vectors and product vectors.
- **VPCG** (Vector Propagation on Click Graphs) [18] is a state-of-the-art non-neural graph-based retrieval model that utilizes vector propagation on click graphs to overcome the above-mentioned long-tail problem and the lexical gap between queries and documents.
- **ARC-II** [15], **MatchPyramid** [32] are two state-of-the-art neural retrieval models . We use the implementations from the open-source toolkit MatchZoo[5] [9] specifically designed for neural IR. We set the embedding size to 256 and report the results achieved by the best of multiple model setups provided in MatchZoo.
- **NeuBase** (Figure 3(a)) is a variant of GEPS that does not use graph-based features (i.e., excluding the graph embedding-based components from GEPS) so as to investigate the performance improvement achieved by the proposed approach. In fact, this model is an extension of **C-DSSM** [39].

Since there exists little overlap between terms of queries and product descriptions (about 1.8%) [44] in our dataset, traditional retrieval models (LSI, BM25 and QLM) and LSE (originally based on product reviews instead of descriptions) from our baseline pools exhibit poor performances. For a more rigorous comparison, we also report the results of these models with augmented product descriptions by adding the terms of queries that led to clicks to the corresponding products.

[5] https://github.com/NTMC-Community/MatchZoo

Table 2: Retrieval performance. † indicates statistically significant improvement ($p < .01$) by the pairwise t-test over all the other baselines. We report performance gains in NDCG relatively to the original search results returned by the commercial search engine without re-ranking.

	Models	MRR	MAP	NDCG	Gain (%)
					Original data split
	LSI	.2223	.2117	.3536	+3.07

4.2.3 Evaluation Metrics. In our evaluation, we regard the items returned by the e-commerce search engine in the SERP for each test query as candidates, and evaluate ranking performance of different models on those candidates. The products shown in the SERP for each test query are automatically labeled based on user-specific actions by three grades of relevance, *irrelevant* (0), *somewhat relevant* (1), *very relevant* (2), which correspond to *not clicked*, *clicked*, and *clicked and purchased* products, respectively.

Three standard evaluation metrics, MRR (Mean Reciprocal Rank), MAP (Mean average precision) and NDCG (Normalized Discounted Cumulative Gain), are used for comparison. MRR measures the rank position of the first relevant (i.e., either *somewhat relevant* or *very relevant*) product which is important to attract users to keep browsing, while MAP measures the rank of all relevant products. In addition to the metrics that assume binary relevance, NDCG is used to capture multiple relevance levels, where product purchase is considered as the ultimate goal of the e-commerce search task.

4.3 As an Individual Retrieval Model

4.3.1 Retrieval Performance. To answer **RQ1** we list the results of baselines and the proposed model GEPS on the real-world testbed

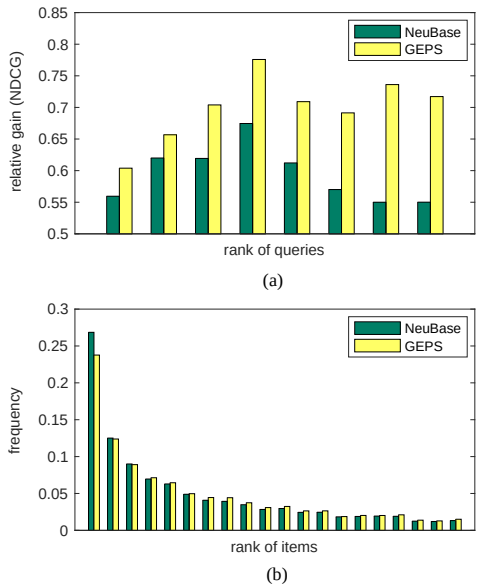

Figure 5: Retrieval performance regarding the long-tail problem of click-through data. (a) Relative gains in NDCG w.r.t. the popularity ranks of queries. (b) Frequencies of products appearing at the top-5 positions of ranking results returned by NeuBase and GEPS w.r.t. their popularity ranks.

in Table 2. As mentioned in Section 1, the traditional lexical-based models, LSI and BM25, do not perform well in the product search scenario even with augmented product descriptions by clicked queries. In contrast, neural retrieval models (i.e., ARC-II, MatchPyramid, NeuBase and GEPS) exhibit strong performances due to their advantages in semantic matching. Meanwhile, the click-graph based unsupervised model VPCG also provides a competitive baseline especially in the chronologically split dataset, which demonstrates the effectiveness of graph-based features in product search. By incorporating graph-structured data into the supervised neural retrieval model with the proposed graph embedding-based approach, GEPS can substantially outperform all the baseline methods in both data split settings, which proves the ability of GEPS to combine the advantages of graph-based models and neural network models.

To answer **RQ2**, we divide search queries into eight groups according to their occurrence frequency ranks in the click-through data as in Figure 1(a) and plot the averaged relative performance gains of NeuBase and GEPS in each group in Figure 5(a) [6]. In the last four groups where increasingly fewer training samples are provided, the performance of NeuBase starts to decline dramatically, while GEPS still remains robust. (Both of their relative gains increase in the first half of groups because the commercial search engine performs relatively better on popular queries.) This suggests that neural retrieval models indeed suffer from overfitting problems on those rare queries in the training data and our proposed graph embedding-based approach provides an effective solution.

[6]Due to limited space, we only report results in the original data split when conducting model analysis in the rest of this paper. Similar results can be obtained in the chronological data split.

Table 3: Ablation study in the original data split. *P_emb* and *Q_emb* denotes the graph embeddings of products and queries respectively, while *Heter* represents the integration of external heterogeneous information into models. We use +/− to denote cases with/without a certain feature in the model. All the improvements relative to their previous rows are statistically significant ($p < .01$) unless otherwise denoted by an asterisk.

P_emb	Q_emb	Heter	MRR	MAP	NDCG	Gain (%)
-	-	-	.4448	.4162	.4982	+45.22
+	-	-	.4529	.4275*	.5076	+47.97
+	-	+	.4640	.4387	.5160	+50.43
+	+	-	.4810	.4540	.5256	+53.22
+	+	+	.4955	.4704	.5378	+56.76

We also report the frequencies of products that appear at the top-k ($k = 5$) positions of the ranking results obtained by NeuBase and GEPS with regard to their frequencies of occurrence in the training data. Figure 5(b) shows that NeuBase tends to rank popular products higher and tail products lower than GEPS, which not only hurts search accuracy but also reinforces the *rich-get-richer* phenomenon [3] that might cause some long-term issues for e-commerce sales platforms. This further demonstrates that the proposed graph embedding-based approach can enable neural models to exploit graph-structured relations to make smoother predictions on the long-tailed products.

4.3.2 Ablation Study. To investigate **RQ3** and further answer **RQ2**, we conduct an ablation study of our proposed model. The results are shown in Table 3. We can conclude that incorporating graph embeddings of both products and queries can lead to significant performance improvement as a result of its successful treatment towards the long-tail problem of click-through data by comparing row 2 and row 4 to the baseline result row 1.

In addition, we can observe substantial performance gains when comparing row 2 and row 4 with their extended versions with external heterogeneous information in row 3 and row 5, respectively. This shows that the proposed approach is effective in taking advantage of heterogeneous information to improve search accuracy.

4.3.3 Analysis of Graph Embedding Methods. To answer **RQ4**, we analyze the performance of different graph embedding methods. As shown in Figure 6(a), Deepwalk performs slightly better than LINE with both embedding vectors preserving the first order proximity, the second order proximity, and their combination. This difference can be seen as a trade-off between efficacy and efficiency, for LINE runs relatively faster than Deepwalk as shown in Figure 6(b) thanks to its edge-sampling strategy (although they both have linear time complexity). Besides, it can lead to another marginal gain to concatenate embedding vectors obtained from Deepwalk with the *first order* embedding vectors obtained from LINE, because Deepwalk only considers the *second order* proximity to which the latter are complementary.

We also investigate how embedding dimensions influence the final performance. Overall, our proposed approach is quite robust to

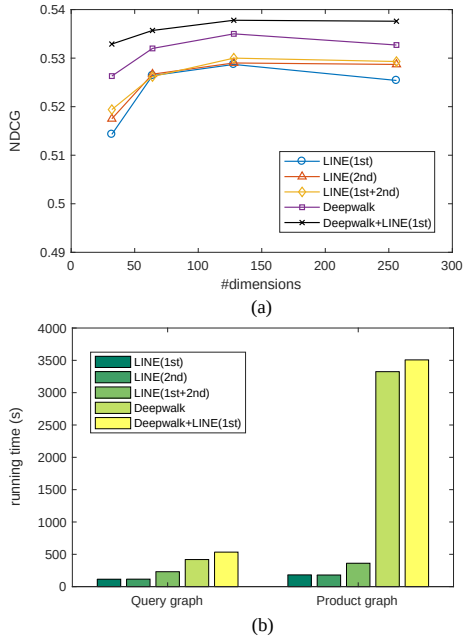

Figure 6: Performance of the graph embedding methods w.r.t. different number of dimensions $K \in [32, 64, 128, 256]$.

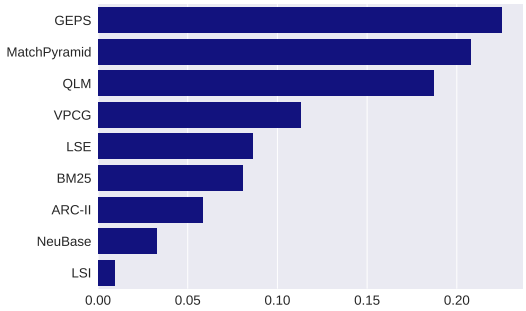

Figure 7: Importance scores of features used in GBDT.

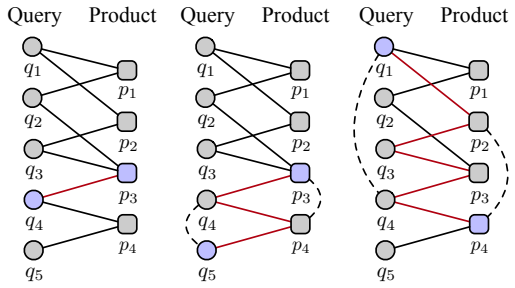
different graph embedding methods with different embedding sizes (Figure 6(a)). Throughout this paper, we use "Deepwalk + LINE (1st)" with $K = 128$ as the default setting.

4.4 As a Feature for Learning-to-rank Models

We continue to answer **RQ1** by evaluating the performance of GEPS as a feature in a learning-to-rank framework implemented with GBDT [10]. We choose seven handcrafted features motivated by Wu et al. [44] as our basic feature pool *Base*: (0) original ranks (which might contain some unreleased information used by the commercial search engine), (1) total click counts, (2) total view counts, (3) total purchase counts, (4) click-through rates, (5) the word lengths of the description of each product, (6) the logarithms of product price.

We can draw the following conclusions from the results shown in Table 4. First, GEPS is such a powerful feature that we can observe

Table 4: Retrieval performance as a feature in the learning-to-rank framework.



Models	MRR	MAP	NDCG	Gain (%)
			Original data split	
Base	.4249	.3973	.4876	+42.14
Base+QLM	.4878	.4568	.5266	+53.52
Base+LSE	.4450	.4160	.5000	+45.75
Base+VPCG	.4414	.4178	.4992	+45.50
Base+MatchPyramid	.4880	.4579	.5291	+54.24
Base+GEPS	**.4991**	**.4717**	**.5381**	**+56.87**
Base+QLM+LSE	.4828	.4525	.5227	+52.36
Base+LSE+MatchPyramid	.4976	.4673	.5359	+56.22
Base+QLM+MatchPyramid	.5113	.4791	.5434	+58.40
Base+LSE+GEPS	.5021	.4744	.5402	+57.46
Base+MatchPyramid+GEPS	.5120	.4827	.5459	+59.14
Base+QLM+GEPS	**.5207**	**.4913**	**.5520**	**+60.91**
Base+QLM+MatchPyramid+VPCG	.5124	.4819	.5454	+58.97
Base+QLM+LSE+MatchPyramid	.5162	.4843	.5475	+59.60
Base+QLM+LSE+GEPS	.5218	.4919	.5524	+61.03
Base+QLM+MatchPyramid+GEPS	**.5289**	**.4986**	**.5573**	**+62.45**

the largest performance improvement by adding GEPS to the feature pool. Second, GEPS is also complementary to other competitive retrieval approaches, especially the traditional language-modeling based approach *QLM* and the recently proposed neural architecture *MatchPyramid*; combining GEPS with QLM and MatchPyramid leads to a substantial improvement by 3.6% in NDCG over the best single model. However, it is interesting that we do not observe a significant improvement after combining GEPS with those features in the basic feature pool, possibly because most of the useful basic features can be automatically extracted from click-through data by GEPS. In addition, in Figure 7, we can see that GEPS is the most important feature when ensembling all the baselines with GBDT.

5 FURTHER DISCUSSION: RETRIEVAL AS LINK PREDICTION AND TRANSITIVITY

The goal of product search, especially from the perspective of neural network-based black box approaches, is to predict whether a given query-product pair (p, q) is relevant (and then rank all products according to the probability). In fact, this goal is exactly equivalent to predict whether a *link* exists in the bipartite click graph of queries and products as shown in Figure 8(a).

Nonetheless, the click graph used in the training stage can never be complete; there are inevitably many missing links partly because we can only access a limited sample of search logs and also because, given a query, some of the relevant products are not presented to customers by the search engine at all (though, this does not mean those products have no user impressions within other queries either). The good part is that we can obtain more information beyond those direct links thanks to the *transitivity* of relevance relations. To be more specific, products that are several hops from a given query (e.g., q_5 versus p_3 in Figure 8(b) and q_1 versus p_4 in Figure 8(c)) are more likely to be relevant than a totally random product. However, neural network models are not well aware of

(a) 1-hop (b) 3-hop (c) 5-hop

Figure 8: (a) Retrieval problems can be regarded as link prediction. (b-c) Products within several hops (e.g., 3 and 5 hops away) to a certain query tend to be relevant as well. In GEPS, such transitive relations are regularized by similar graph embeddings indicated by the dashed lines.

such transitivity although the one-hop relations can be perfectly maintained due to their strong expressive power.

In our proposed approach, we can effectively capture transitivity with graph embedding techniques, where correlations between queries and products are well preserved. For instance, in Figure 8(b), q_4 and q_5 as well as p_3 and p_4 have similar graph embeddings (i.e., $e_{q_4} \approx e_{q_5}$ and $e_{p_3} \approx e_{q_4}$) since they are close neighbors (i.e., the *first order proximity*) in the query graph and the product graph respectively, and therefore p_3 is considered as a relevant item to query q_5 because both features $[e_{q_4}, e_{p_3}]$ and $[e_{q_5}, e_{p_4}]$ indicate positive links in the click graph. It is the same case with 5-hop pair (q_1, p_4) in Figure 8(c) where q_1 and q_4 as well as p_2 and p_4 have similar neighbors (i.e., the *second order proximity*) and hence are also close to each other in the graph embedding space.

To empirically prove this point, we plot the distributions of relevance scores given by NeuBase, the proposed model GEPS and MatchPyramid for the pairs of queries and products that are *1 hop*, *3 hops* and *5 hops* away in the click graph along with *random* pairs in Figure 9. In the case of NeuBase, we can observe that the relevance scores for 3-hop and 5-hop query-product pairs drop quickly and their distributions are very similar to that of random pairs. On the contrary, GEPS can give smoothly decreasing scores as queries and products are farther away from each other in the click graph; the relevance score distribution for 3-hop query-product pairs is closer to that for 1-hop pairs, while the distribution for 5-hop pairs is somewhere between that for 3-hop pairs and that for random pairs. Table 5 supports our argument in a more rigorous way; without such proper regularization as graph structures, neural networks are likely to fit non-smooth relations without transitivity (e.g., 3-hop and 5-hop cases) as exactly appeared in the training data (i.e., 1-hop query-product pairs). To conclude, it is the ability to discriminate among those decreasingly relevant query-product pairs (3-hop, 5-hop and so on relatively to totally random) induced by transitivity that enables better ranking performance for GEPS.

Also shown in Figure 9 and Table 5, instead of stratifying query-product pairs of different distances in the click graph, MatchPyramid discriminates positive samples (i.e., 1-hop query-product pairs)

Table 5: AUC results of separating the pairs of queries and products within k hop(s) ($k \in [1, 3, 5]$) from farther pairs with relevance scores given by NeuBase and GEPS respectively .

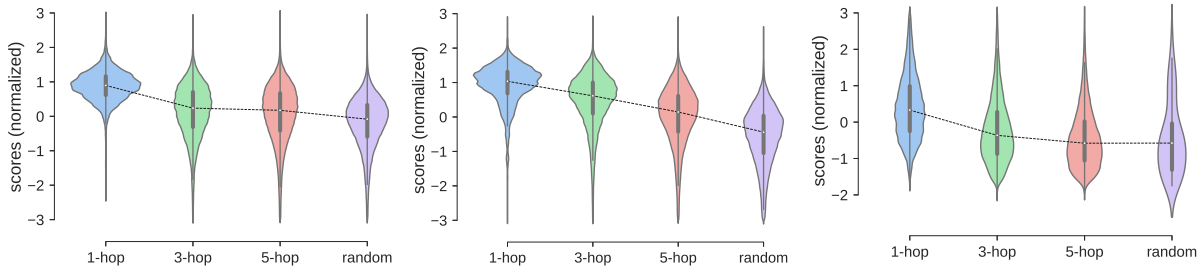
Model	within 1 hop	within 3 hops	within 5 hops
NeuBase	.833	.616	.627
GEPS	.824	.744	.749
MatchPyramid	.726	.664	.647

in a more fine-grained manner. This suggests that MatchPyramid tackles the issues of neural networks from a different perspective from graph-based approaches (actually by focusing on the semantic interaction between query terms and document terms with a properly designed neural architecture). This is also consistent with the fact that MatchPyramid and GEPS can substantially boost each other's performance as features in the learning-to-rank model as shown in Table 4 and Figure 7 (Section 4.4).

Furthermore, such transitive relevance relations can also be induced from more complicated graphs than click graphs, for example, the ones shown in Figure 4. This is also why it can lead to significant improvement when incorporating external heterogeneous information with our graph-embedding approach.

6 RELATED WORK

We review the related work of product search, neural models for IR and graph-based models for IR along with a brief comment on neural models with graph-structured data in a more general context.



6.1 Product Search

Product search has been attracting extensive research efforts. Duan et al. (2013) [8] propose a probabilistic generative model to analyze e-commerce search log for useful knowledge. Duan et al. (2015) [7] study the problem of learning query intent representation for product search and recommendation with a proposed language model. Karmaker Santu et al. [19] discuss issues and strategies when applying learning-to-rank models to the product search scenario. Also, Li et al. [22] propose an economic theory-based product search model to complement those product search models mainly adapted from the information retrieval literature.

Recently, Van Gysel et al. [42] propose a latent vector space model (LSE) to jointly learn distributional representations of words and products for better product retrieval performance. Ai et al. [1] exploit a hierarchical embedding model (HEM) that jointly learns semantic representations for various entities, including terms, products, users and queries, to tackle the problem of personalized search. These two embedding models largely inspire our work although neither of them leverages graph embedding techniques to encode rich graph-structured relationships in their embeddings.

6.2 Neural Information Retrieval

Our work is in the context of recent advances in neural information retrieval. Due to limited space, only some of the recent work is introduced here, and we refer the reader to the paper [27] by Mitra and Craswell for a comprehensive review. Huang et al. [16]

(a) NeuBase (b) GEPS (c) MatchPyramid

Figure 9: The distributions of relevance scores given to the pairs of queries and products that are k hops way from each other and given to random query-product pairs.

propose a deep structured semantic model (DSSM) to learn semantic representations of queries and documents with large-scale click-through data for web search, while Guo et al. [13] propose an interaction-focused deep relevance matching model (DRMM) that uses histogram-based features to capture lexical relevance between queries and documents for better retrieval performance. Mitra et al. [28] then attempt to combine those two approaches with a hybrid deep model Duet composed by a local model for exact term matching and a distributed model for semantic matching. Recently, Liu et al. [24] introduces knowledge graphs to neural search systems, which, however, is different from the intrinsic problem of transitive relevance in click-through data we study in this paper. In fact, our contribution is orthogonal to this line of research and therefore can be combined with the above mentioned neural retrieval approaches.

6.3 Graph-based Information Retrieval

Graph-based features are widely used and studied in the IR literature [30], e.g., Pagerank [31], HITS [21] and Simrank [17]. Yet, our work is more related to the following. Craswell and Szummer [4] use random walks on the click graph to produce probabilistic rankings for image search. Gao et al. [11] propose a random walk-based smoothing approach to overcome the sparsity problem of click-through data in web search. Click graphs are also used to learn semantic representations of queries and documents (e.g., [18, 45]) and to learn query intent (e.g., [23, 25]). Ren et al. [35] propose to use a heterogeneous graph that consists of queries, web pages, and Wikipedia concepts to improve search performance.

Graph-based IR approaches can depend on global information to make local decisions and hence are rather robust to sparse, complex and incomplete data. However, most of them also suffer from disadvantages as unsupervised methods. While combining them into a learning-to-rank framework as features is one possible way to overcome this limitation, it also motivates us to directly tackle this problem at the model level to combine both the advantages of unsupervised graph-based models and supervised neural models.

6.4 Neural Models with Graph-structured Data

In a more general context, GCN (Graph Convolutional Network) [6, 20] provides an alternative solution to incorporate graph-structured data into neural networks by generalizing the traditional convolutional filters from images to graphs. Berg et al. recently propose a model called GC-MC (Graph Convolutional Matrix Completion) that attempts to apply GCN to recommender systems in an unpublished preprint [2]. Monti et al. [29] later extend GC-MC to multi-graph cases and obtain promising results.

The proposed approach and GCN can both be seen as ways to regularize neural models with graph structures. The former uses an auxiliary task of reconstructing graph embeddings to achieve such goal, whereas GCN directly conditions the output of neural network on the adjacency matrix (i.e., $f(\cdot|A)$). Due to the latter fact, each prediction depends on the whole graph (or, at least, a local subgraph as approximation [46]) causing GCN not very scalable to such large graphs as in real-world search scenarios. On the contrary, graph embeddings can serve as an "intermediate" which decouples neural nets and graphs *per se* to reduce computational burden while still allowing neural nets to utilize graph structure information.

7 CONCLUSION

This paper introduces a Graph Embedding-based ranking approach for Product Search (GEPS) which leverages recent advances in graph embedding techniques to incorporate graph-structured data into neural models in Section 3. Through extensive experiments in Section 4, we demonstrate that our proposed approach can successfully combine both the advantages of graph-based retrieval models and neural retrieval models. To be more specific, experimental results show that GEPS enables neural models to effectively deal with the long-tail sparsity problem and combine heterogeneous external information to improve search accuracy. Finally, we point out the equivalence between retrieval tasks and link prediction tasks, and then discuss the advantage of GEPS in capturing relevance transitive relations on graphs in Section 5.

ABSTRACT

Multimodal dialogue systems are attracting increasing attention with a more natural and informative way for human-computer interaction. As one of its core components, the belief tracker estimates the user's goal at each step of the dialogue and provides a direct way to validate the ability of dialogue understanding. However, existing studies on belief trackers are largely limited to textual modality, which cannot be easily extended to capture the rich semantics in multimodal systems such as those with product images. For example, in fashion domain, the visual appearance of clothes play a crucial role in understanding the user's intention. In this case, the existing belief trackers may fail to generate accurate belief states for a multimodal dialogue system.

In this paper, we present the first neural multimodal belief tracker (**NMBT**) to demonstrate how multimodal evidence can facilitate semantic understanding and dialogue state tracking. Given the multimodal inputs, while applying a textual encoder to represent textual utterances, the model gives special consideration to the semantics revealed in visual modality. It learns concept level fashion semantics by delving deep into image sub-regions and integrating concept probabilities via multiple instance learning. Then in each turn, an adaptive attention mechanism learns to automatically emphasize on different evidence sources of both visual and textual modalities for more accurate dialogue state prediction. We perform extensive evaluation on a multi-turn task-oriented dialogue dataset in fashion domain and the results show that our method achieves superior performance as compared to a wide range of baselines.

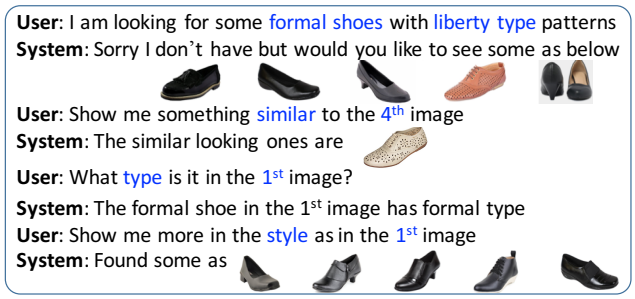

Figure 1: An illustrative example of multimodal dialogue for fashion retail, which demonstrates the importance of visual modality in understanding the inherent semantics. Keywords in blue correspond to images, where both modalities are crucial for dialogue state tracking.

an image sample instead of racking their minds for an appropriate text description, such as in search of fashion products. At the same time, it is more straight-forward for users to perceive information from system provided images rather than text based on supposition. In task oriented scenarios, multimodal dialogue systems can better help users achieve their goals such as finding specific fashion products or travel sights under the help of visual modality and has achieved superior performance [26].

Efficient operation of such dialogue systems requires a core component — belief tracker (or known as dialogue state tracking) that can track what has happened by modeling system outputs, user utterances, and context from previous turns *etc.* A belief tracker provides a direct way to validate the systems' understanding of user's goal at each step of the dialogue. At the same time, the output of the belief tracker also supports the downstream dialogue policy component to decide what action the system should take next. Such output offers an explicit way to evaluate whether the learned policy is reasonable. Therefore, the belief tracker component is essential for the final performance of a complete dialogue system.

However, since current dialogue systems are largely confined to textual modality, existing efforts on belief tracker are also limited primarily to text-based methods. Thus, it may fail to generate accurate belief states for multimodal systems, as the rich semantics inherent in visual modality are ignored. For example, in order to generate correct belief states for each turn of the dialogue as shown in Figure 1, the system needs to understand the visual features of the fourth image, the type and style of the first image, *etc.* Purely relying on text, the system would fail to obtain these useful semantics, and thus result in inaccurate belief states. Moreover, it may further affect the performance of other downstream dialogue system components. Therefore, the primary goal of our work is to build a multimodal belief tracker which is able to accurately understand multimodal evidence and adaptively integrate these modalities for dialogue state tracking.

Although we have shown that multimodal evidence is crucial for dialogue state tracking, it is non-trivial to correctly extract useful semantics and leverage them appropriately in dialogue state tracking. **First**, there exists the well-known semantic gap between the low-level visual cues and the high-level semantics (*e.g., style, fit*). Indeed, there are many studies focusing on the Vision-to-Language problems such as image captioning [27], visual storytelling [18] and visual question answering (VQA) [2], which have achieved good performance. Still, as pointed out in [10, 45], there exist strong language priors which lead to good superficial performance of these models without truly understanding the visual content. For example, for questions starting with "Do you see a ..." in VQA dataset, blindly answering "yes" can achieve 87% accuracy. **Second**, the heterogeneity between the visual and textual modalities makes it hard to incorporate them well to generate concrete belief states. Due to the difference in expressiveness, users tend to prefer image for illustrating certain concepts (*such as style, pattern*) while use text for describing others (*such as category, material*). Finding out these patterns of user behavior is essential for improving dialogue state tracking.

In this paper, we propose a neural multimodal belief tracker (**NMBT**) (see Figure 3) and apply it for semantic understanding across modalities and user intent tracking. First, to fill the semantic gap and avoid being misled by language priors, we develop a visual concept learner in a weakly-supervised manner by leveraging multiple instance learning [5] which reasons with sub-regions rather than the full image. The visual concept learner enables the tracker to understand fine-grained semantics of product images at the concept level. Second, to model user's behavior patterns regarding different modalities, the tracker employs an attention mechanism to adaptively attend to images and texts during dialogue state tracking at each turn. Conditioned on both textual contexts and visual contents observed so far, the model automatically learns to emphasize the evidence coming from user provided image, system provided image, or the text utterances for more accurate dialogue state tracking.

To the best of our knowledge, this is the first work for dialogue state tracking or belief tracking in multimodal dialogue systems. The main contributions for this work are as follows:

- We validate the importance of integrating multimodal evidence in dialogue state tracking and identify the critical challenges in understanding as well as leveraging such evidence.
- We delve into image sub-regions to learn concept level visual semantics and propose an adaptive attention mechanism for automatically deciding the evidence source for dialogue state tracking based on multimodal dialogue context.
- We conduct extensive experiments to evaluate the proposed method in various evaluation metrics and show superior performance over state-of-the-art methods.

2 RELATED WORK

2.1 Text-based Dialogue State Tracking

Since spoken interaction promises a natural, effective, and hands- and eyes-free method for human-computer interaction, together with the progress in natural language processing, dialogue systems have been mainly developed within textual modality. In this paper we focus on the dialogue state tracking (DST) task in task-oriented dialogue systems. Here, we summarize recent work on DST and discuss the major difference of our work.

Early dialogue systems used hand-crafted rules for DST, keeping track of a single top hypothesis for each slot of the belief state

[23, 46]. Such systems require no training data and allow developers to incorporate domain knowledge to boost performance. However, such methods fail to make use of the entire N-best hypothesis list, thus do not account for uncertainty in a principled way. In addition, uncertainty also arises from the inherent ambiguity of natural language.

Therefore, statistical DST methods are introduced to better solve the uncertainty problem. Generally speaking, the statistical methods can be categorized into two types, namely generative and discriminative approaches [12]. Generative approaches maintain a distribution over dialogue states, which is calculated by Bayes rules based on the history of observations (NLU results and previous system action) in each turn. Early generative approaches attempt to formalize the dialogue system as a Markov decision process (MDP) [24, 25, 44]. However, MDP models have an assumption that the state is observable, which cannot account for the uncertainty in either dialogue state or user act parsed by NLU. Therefore, [43] further proposed POMDP-based dialogue model, treating the dialogue state as hidden variable which can be inferred from system observations, and achieved better performance. However, since all possible states are enumerated in the above methods, it can be intractable when the state space is very large [12]. Also, as pointed out by [40], generative approaches must model all the correlations in the input features, so they cannot easily exploit arbitrary but potentially useful features.

Discriminative approches have the key benefits that they can incorporate a large number of features, and can be optimized directly for prediction accuracy. [3] proposed the first discriminative state tracking trained from data where features were taken from spoken language understanding (SLU) output and dialogue history. Subsequent work has explored numerous variations of this approach. For instance, [41] applied a ranking algorithm which has the ability to construct conjunctions of features. [15] applied a deep neural network as a classifier. More recently, [16] proposed an RNN-based DST to directly take automatic speech recognition results as input without extra semantic understanding and obtains better performance than those which only utilizes semantic features produced by external NLU. [30] proposed a CNN-based method to extract semantic features from raw ASR results and passed it to DST.

As observed in the dialogue state tracking challenges (DSTC), discriminative methods tend to dominate all other approaches [39]. Our work is also based on the discriminative statistical DST framework. However, existing approaches are constrained within textual modality while ignores the rich semantics inherent in visual images. In the emerging mutimodal dialogue systems, this information becomes essential for performance improvement. We thus take a step further towards understanding and adaptively using such multimodal evidence.

2.2 Multimodal Understanding

Another line of work related to ours lies in multimodal understanding, which focuses on recognizing inherent semantics of multimodal data [1] and exploits the relevance between different modalities [2, 7, 27]. In this work, we focus on understanding concept-level semantics within multimodal data, which relates to research of visual-semantic embedding, image captioning and visual question-answering (VQA).

With the aim of learning a mapping from images into a semantic space, visual-semantic embedding have shown to be effective in image-text ranking and zero-shot learning. There are some embedding models based on Canonical Correlation Analysis (CCA) [11] which learns a linear projection to maximize the correlation between two modalities [8, 9]. Kernel CCA [22] is further employed to extend to nolinear projection. Nevertheless, as point out in [38], scaling CCA to large amounts of data can be difficult. Another line of efforts train a joint embedding model with ranking loss. [7] learns linear transformation between visual and textual features with a single-directional ranking loss, which applies penalty to incorrect sentences ranked higher than correct ones. Bi-direction ranking loss is employed to boost the performance by further ensuring the correct image described by a sentence ranked higher than other images [19–21]. However, these works cannot be directly utilized by our work due to the difference in nature between our dialogue state tracking task and other tasks. In the above tasks, the semantics of image and text are to be aligned, while in the multimodal dialogue problem, the semantics of user intent come from either visual supplied evidence or textual inputs. Though certain semantics are presented by both modality, many of them only reside in one modality due to the concise nature of dialogues.

For image captioning, most existing methods adopt an encoder-decoder framework, which consists of a CNN visual encoder along with an RNN language decoder [27, 37]. The CNN encoder extracts visual feature from the image and feed it to the RNN decoder to generate a natural language text. Inspired by the advances in neural machine translation, some works further introduced the attention mechanism, which attends to different sub-regions of an image during decoding [42].

Compared to image captioning, VQA [2] shares a more similar task setting with multimodal dialogue, since it involves single-turn interaction through question and answer. VQA also utilized the encoder-decoder framework while the encoder side includes both image and question [2, 32]. The work of visual dialogue [4, 29] further handles multi-turn QA pairs as multimodal dialogue does. Even so, as pointed out in [29], these works should be categorized into image-grounded QA rather than multimodal dialogue. The reason lays on the way they utilize images. In VQA tasks, only one single image is involved and the conversation is centered on it. While in multimodal dialogue tasks, the model has to process multiple images which acts as supporting evidence.

However, as pointed out in [10, 45], most existing Vision-to-Language task performance should be attributed to the language prior and the models do not truly understand the images. While in our scenario, accurate understanding of visual image is rather important for intention inference. Therefore, we propose to extract explicit semantic concepts from image and feed to downstream dialogue tracker.

Recently, [33] contributed a large-scale benchmark dataset with 150K dialogue sessions and proposed two end-to-end models based on the hierarchical recurrent encoder decoder (HRED) framework [35] as baselines for response generation. We use their dataset while focus on the multimodal dialogue state tracking task.

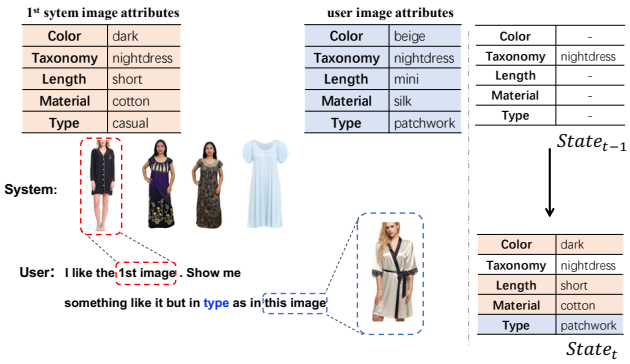

Figure 2: An example turn in multimodal dialogue. The model extracts semantics from both visual and textual input to update the dialogue state to $State_t$. Slots "Color", "Length" and "Material" are updated by understanding the system provided image. While "Type" is updated based on both textual and visual evidence from the user provided image.

3 MODEL

3.1 Task Definition and Model Overview

Our model is designed to tackle the problem of dialogue state tracking (DST) which maintains the belief state $\mathbf{S}_t$ in each turn during the dialogue flow. Different from traditional text-based task, we need to extract semantic concepts from both textual and visual modalities. An example is shown in Figure 2. Note that the slot values of a state are derived from not only the textual evidence, but also system provided and user provided visual evidences.

Suppose $T_t^{'}, V_t^{'}$ refer to the textual and visual parts of the system response in turn t, while T_t, V_t are those of the subsequent user posts, the task of multimodal dialogue state tracking can be stated as follows: in the t-th turn, given the dialogue context with messages from both user and agent sides $X_t = \{T_1^{'}, V_1^{'}, T_1, V_1, ..., T_t^{'}, V_t^{'}, T_t, V_t\}$, the model is supposed to give an estimation of the belief state $\mathbf{p}_t^k$ for each slot k:

$$\mathbf{p}_t^k = f^k(X_t), \tag{1}$$

where f^k represents the belief tracker for slot k, $\mathbf{p}_t^k$ is a $N_k + 1$ dimensional vector[1] which is a probability distribution over the values of slot k. The belief state $\mathbf{S}_t$ in turn t is defined as a collection of distributions over the values of all the N_s slots:

$$\mathbf{S}_t = [\mathbf{p}_t^1, \mathbf{p}_t^2, ..., \mathbf{p}_t^{N_s}]. \tag{2}$$

As described above, both the system and user messages may consist of a textual and a visual part where the textual part is a natural language utterance and the visual part refers to some images. It is worth noting that in our work, the visual part of system response $V_t^{'}$ usually contains zero or multiple images, while the user post V_t contains zero or only one image.

Specifically, our proposed model consists of three major parts:

- The basic textual network learns representations of the textual evidences by taking only the textual utterances from both system and user sides as inputs:

$$\mathbf{h}_t = f_{textual}(T_1^{'}, T_1, T_2^{'}, T_2, ..., T_t^{'}, T_t). \tag{3}$$

- The sub-region based visual concept learning part extracts concept level visual representation $\mathbf{v}$ for each image I. Given the image, it first embeds sub-regions and then maps to concepts under the multiple instance learning scenario:

$$\mathbf{v} = f_{visual}(I). \tag{4}$$

- The adaptive modality attention part predicts the belief state by integrating the textual and visual representations:

$$\mathbf{p}_t = f_{attn}(\mathbf{v}_t^{'}, \mathbf{v}_t, \mathbf{r}_t, \mathbf{h}_t), \tag{5}$$

where $\mathbf{v}_t^{'}$ and $\mathbf{v}_t$ denote the visual representation of system and user images respectively, $\mathbf{r}_t$ refers to the textual representation of user text T_t. The model learns to automatically emphasize on different sources of evidences for dialogue state tracking.

In the following part, we will explain the three parts in more detail. Since all the slots share a common model structure, for the convinience of description, we omit the slot subscript k in the following subsections and only describe the model architecture for a single slot.

3.2 Basic Textual Framework

We first introduce a basic textual framework upon which we will build our multimodal model. The framework is an hierarchical RNN model, which consists of a word-level encoder and an utterance-level encoder. In this framework, the textual inputs in the t-th turn are T_t and $T_t^{'}$. Suppose $\mathbf{T}_t$ and $\mathbf{T}_t^{'}$ are the embedding matrices obtained via one hot vectors of words in user post T_t and system response $T_t^{'}$ multiplying with the pre-trained word embedding matrix respectively. Under such processing, we actually represent each word in its semantic vector form, namely word vectors. We then employ a word-level RNN encoder, which takes as input a word vector at each time step, to learn the integrated semantic representations of T_t and $T_t^{'}$ respectively as follows:

$$\mathbf{r}_t = RNN_1(\mathbf{T}_t), \tag{6}$$

$$\mathbf{r}_t^{'} = RNN_1(\mathbf{T}_t^{'}), \tag{7}$$

where the word-level encoder is denoted as RNN_1. The concatenation of $\mathbf{r}_t$ and $\mathbf{r}_t^{'}$ is then fed into an utterance-level encoder, which is denoted as RNN_2. Therefore, we have

$$\mathbf{h}_t = RNN_2_CELL(\mathbf{h}_{t-1}, [\mathbf{r}_t, \mathbf{r}_t^{'}]), \tag{8}$$

where $\mathbf{h_t}$ is the output of RNN cell, and [,] denotes concatenation of vectors.

Note that $\mathbf{h_t}$ is the summary of information observed so far in turn t. In pure text-based systems, they usually directly fed $\mathbf{h_t}$ into a fully-connected layer followed by a softmax function to generate the probability distribution over the values of the slot:

$$\mathbf{g}_t = softmax(FC(\mathbf{h}_t)). \tag{9}$$

The dimension of the fully-connected layer is $d + 1$, where d is the number of possible slot values for this specific slot. The extra one dimension represents that this slot is not mentioned yet. As

[1] N_k is the number of values of slot k, while the extra one dimension represents that slot k is not mentioned in the dialogue yet.

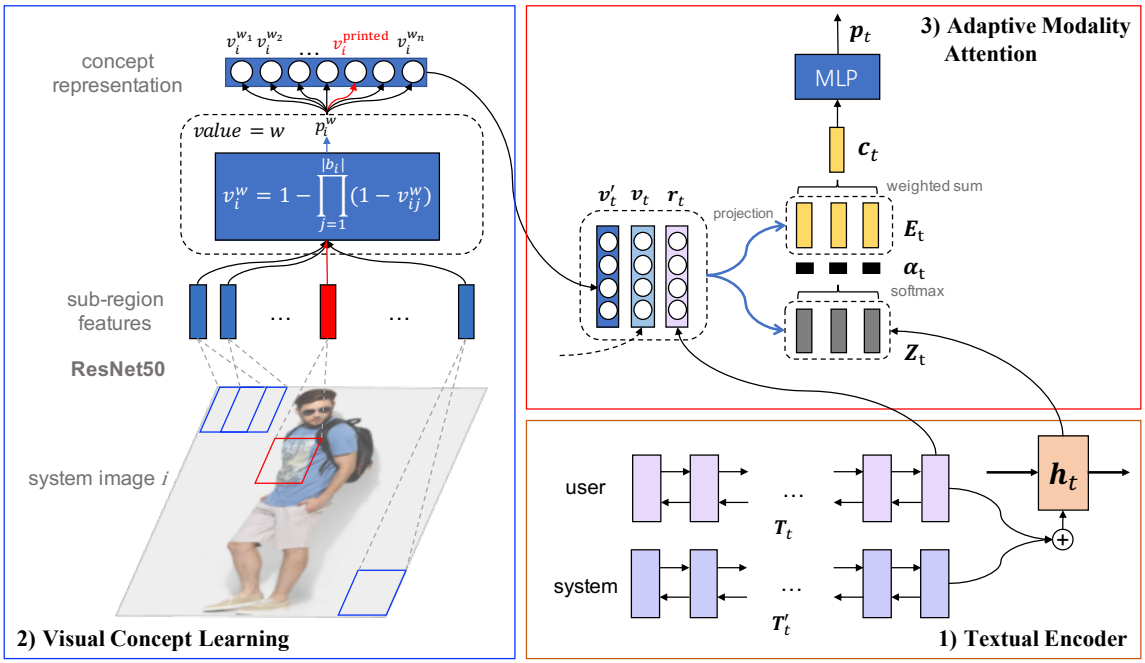

Figure 3: Overview of our proposed model. We first extract the features of user's and system's textual input evidences using two RNN networks and use them to update the textual base hidden state $\mathbf{h}_t$. In the visual concept learning stage, the model learns visual semantics by looking into image sub-regions and integrating probabilities under the multiple instance learning scenario. Finally, we apply the adaptive modality attention mechanism on different evidence sources to obtain the context vector $\mathbf{c}_t$, which is then fed into a MLP followed by a softmax activation to get the final belief state $\mathbf{P}_t$.

mentioned before, we have a totally of N_s slots. Thus, we maintain N_s such RNN pipelines for all the slots.

3.3 Sub-region based Visual Concept Learning

One of the major challenges in multimodal DST is to accurately extract visual concepts from images, which can be easily formulated as a multi-class or multi-label image classification problem with manual annotation. However, we notice that most visual concepts correspond to only a small sub-region of the image, such as the slots "Neck" and "Belt-loops". Studies like [6] have also shown that feeding the whole image into attribute classifiers leads to worse performance. Therefore, we delve into image sub-regions to harvest visual concepts.

Basically, for each individual image i, we define a bag b_i, which is a collection of the image's sub-regions (detailed in Section 4.3). An image is labeled positive for the concept w if there is at least one sub-region in the bag containing w, which is actually a multiple instance learning (MIL) problem. In this work, the sub-regions are squared areas which can overlap in case that some objects are cut up by the square boundary. Intuitively, suppose the probability of one sub-region j containing the concept w is v_{ij}^w, the probability of the whole image i containing w should be no less than the largest sub-region concept probability in the bag. At the same time, multiple sub-regions showing high probability of containing the concept w should result in increased probability but not over-exaggerated. A diminishing return characteristic is preferable for our case. Therefore, the probability of image i containing the concept w is defined as follows:

$$v_i^w = 1 - \prod_{j=1}^{|b_i|}(1 - v_{ij}^w), \tag{10}$$

where v_i^w is not larger than 1 and not less than the largest v_{ij}^w. When there are more v_{ij}^w being large, the incremental effect on v_i^w actually decreases.

We use the ResNet-50 without the last layer as the base network to learn the representation for image sub-region b_{ij} as $\mathbf{b}_{ij}$, and feed it into a fully-connected layer followed by a sigmoid activation to compute the sub-region level concept probability vector $\mathbf{v}_{ij}$:

$$\mathbf{v}_{ij} = \sigma(FC(\mathbf{b}_{ij}))), \tag{11}$$

where $\mathbf{v}_{ij}$ is a collection of Bernoulli distributions over each concept and v_{ij}^w is the probability of concept w.

At the whole image level, we obtain the image representation $\mathbf{v}_i$ for image i via

$$\mathbf{v}_i = 1 - \prod_{j=1}^{|b_i|}(1 - \mathbf{v}_{ij}). \tag{12}$$

3.4 Adaptive Modality Attention

When updating the dialogue state, each slot should emphasize on different evidence sources of the input. For example in Figure 2, the user said "... something like it but in type as in this image", which means that the value of "type" should be equal to that of the user given image, while the values of other primary slots should be the same as the chosen image ("the 1st image"). Another common

situation is that we can find an exact value in user text, such as "Show me more in purple colored type".

Generally speaking, there are three main sources of evidences for tracking dialogue states: the system provided images, user provided image [2] and user provided text. Note that the system provided text offers little useful clues about states, we thus only use it in context modeling as in Equation 8, and do not take it as an evidence source in a way similar to [30].

Essentially, we aim to get a context vector $\mathbf{c}_t$ as an attentive summarization of the three evidence sources: user provided image representation $\mathbf{v}_t$, system provided image representation $\mathbf{v}_t^{'}$, and user text representation $\mathbf{r}_t$. We then feed it into a fully-connected layer followed by a softmax activation to find the new distribution on values:

$$\mathbf{p}_t = softmax(FC(\mathbf{c}_t)). \tag{13}$$

The summarization vector $\mathbf{c}_t$ is obtained by combining the representations of the three evidence sources using a weight vector $\boldsymbol{\alpha}_t$, which is an probability distribution over the three input sources. How to decide the attention weights $\boldsymbol{\alpha}_t$ is essential to our model since emphasizing on the correct evidence source is critical for generating the right slot value. Therefore, we first use two projection matrices to map the three evidence vectors into a common space and obtain an concatenated evidence matrix $\mathbf{E}_t$:

$$\mathbf{c}_t = \sum_{m=1}^{3} \alpha_{t,m} \mathbf{E}_t(m), \tag{14}$$

$$\mathbf{E}_t = [\mathbf{W}_1 \mathbf{v}_t, \mathbf{W}_1 \mathbf{v}_t^{'}, \mathbf{W}_2 \mathbf{r}_t], \tag{15}$$

where $\mathbf{W}_1 \in \mathcal{R}^{h \times d}$ and $\mathbf{W}_2 \in \mathcal{R}^{h \times h}$ are projection parameters. m indicates the index of evidence source and $\mathbf{E}_t(m)$ is the m-th column vector of $\mathbf{E}_t$.

To get the attention distribution $\boldsymbol{\alpha}_t$, we first project the visual and textual evidences into a common space and then feed them along with the RNN output $\mathbf{h}_t$ into a neural network followed by a softmax activation:

$$\mathbf{Z}_t = [\mathbf{W}_3 \mathbf{v}_t, \mathbf{W}_3 \mathbf{v}_t^{'}, \mathbf{W}_4 \mathbf{r}_t], \tag{16}$$

$$k_{t,m} = score(\mathbf{Z}_t(m), \mathbf{h}_t), \tag{17}$$

$$\alpha_{t,m} = \frac{\exp(k_{t,m})}{\sum_{i=1}^{3} \exp(k_{t,m})}, \tag{18}$$

where $\mathbf{W}_3 \in \mathcal{R}^{h \times d}$, $\mathbf{W}_4 \in \mathcal{R}^{h \times b}$ are projection parameters mapping the textual and visual evidence $\mathbf{v}_t$, $\mathbf{v}_t^{'}$ and $\mathbf{r}_t$ into a common space. The *score* function yields a scalar measuring to what extent each evidence source is matched to the slot. It is based on the projected evidence source $\mathbf{Z}_t(m)$ and the textual encoder state $\mathbf{h}_t$. In our implementation, we parametrized it as a feed forward neural network which is jointly trained with all the other components.

$$score(\mathbf{Z}_t(m), \mathbf{h}_t) = \mathbf{w}_h^{\top} \tanh\left(\mathbf{Z}_t(m) + \mathbf{W}_g \mathbf{h}_t\right), \tag{19}$$

where $\mathbf{w}_h \in \mathcal{R}^h$, $\mathbf{W}_g \in \mathcal{R}^{h \times h}$ are the parameters to be learned, h, b are the model hyper-parameters in which b is the RNN hidden state size. Note that in our attention mechanism, we use different key and value matrices $\mathbf{Z}_t$ and $\mathbf{E}_t$ by projecting the evidence source into different spaces, since earlier works [28] have already suggested that the dual use of a single vector makes training the model difficult.

The intuition of this design is as follows: as defined in Section 3.2, the utterance-level hidden state $\mathbf{h}_t$ of the basic textual framework contains the long and short term information obtained from the textual side. More specifically, the long term information is an aggregation of previous dialogue evidences, such as whether certain slot has already been mentioned in history. While the short term information includes more recent evidences such as which slot is mentioned in the current user post. Both kinds of information can provide extensive clues on which modality should be attended to in the current turn. We thus feed the evidence source representations along with $\mathbf{h}_t$ through a single layer neural network (the *score* function) followed by a softmax activation to generate the attention distribution $\boldsymbol{\alpha}_t$ over different evidence sources.

We use cross entropy loss to measure the prediction results of belief tracker. Specifically, we have:

$$L = -\sum_{w} y_t^w \log p_t^w, \tag{20}$$

where w indicates a certain slot value, p_t^w is an element of $\mathbf{p}_t$ which is the probability that w is chosen as the new belief state, and y_t^w is the golden truth.

4 EXPERIMENT

In this section, we conducted extensive experiments to validate our NMBT's performance on the task of dialogue state tracking[3]. More specifically, we want to figure out:

- How much can the task of dialogue state tracking benefit by involving multimodal evidence ?
- Whether the image representations obtained by sub-region based visual concept learning perform better than the dense features extracted by the CNN models ?
- Has the adaptive attention mechanism really learned to pay attention to the correct modality ?

4.1 Data Preparation

The collection of training corpus is one of the bottlenecks for developing statistical dialogue system, due to the cost and concerns about privacy disclosure. Recently, [34] proposed a large-scale multimodal dialogue dataset which consists of about 150K conversation sessions between sale agents and shoppers. However, there is no dialogue state labels in the original dataset, we thus utilized the meta data provided by [34] to build the domain ontology[4] for dialogue act annotation. More specifically, we extracted slot-value pairs from the corpus using a two stage process. During the first stage, we defined a slot value dictionary and 81 natural language templates to extract slots using direct string matching techniques. During the second stage, we conducted manual correction. Finally, seven slots are considered and the number of their corresponding values are shown in Table 1. To train the sub-region based visual concept learning model, we also need to get a collection of images with labels in this domain. We extracted the labels of each image

[2] In the dataset, users only provide one image each time.

[3] The code is available at https://github.com/zhangzthu/NMBT

[4] The domain ontology means all the slots and their values to be involved in the study.

from the raw catalog which consists of text descriptions of each fashion item.

Table 1: The number of values of different slots.

Slot Name	# Value
material	114
style	17
color	47
type	56
fit	17
length	19
gender	3

In the dataset, the average turn number of dialogue sessions is 18.3, which is a lot larger than other text-based datasets [13, 14] and leads to greater difficulty.

4.2 Baselines

To evaluate the effectiveness of our proposed NMBT model, we compared it with the following baselines.

- **Seq2seq_DST** [17]: This model includes an encoder-decoder architecture with an attention mechanism to map an input utterance to a sequence of slot-value pairs. Note that Seq2seq_DST is different from RNN_DST in that the last hidden state of Seq2seq_DST's encoder is fed into an RNN decoder, rather than a MLP classifier.
- **CNN_DST**: A CNN based textual neural belief tracker[36], which utilizes a slot-specific filter to extract semantic features from raw inputs.
- **RNN_DST**: The textual only framework of our NMBT model. The hidden state of the utterance level encoder is fed into a MLP classifier to predict the belief state.
- **NBT**: A textual DST model which uses CNN to learn n-gram utterance feature from word embeddings. The utterance feature is then used for DST tracking [30].
- **M-RNN_DST**: We extended the RNN_DST model to multimodal scenario by feeding the image feature vectors of each turn as extra input of the untterance level encoder, which is similar to the Multimodal HRED model in [34]. The difference is that the last hidden state of the untterance level encoder is fed into a MLP with a softmax activation to predict the slot value rather than a natural language decoder.
- **M-NBT**: The multimodal version of NBT, in which we combined the ResNet-50 extracted image features with the text features obtained before the last layer of NBT to predict the dialogue state, similar as Multimodal HRED [34] does.

It is worth noting that Seq2seq_DST, CNN_DST, RNN_DST and NBT are representative textual-based models from the Dialogue State Tracking Challenge [13], while M-RNN_DST and M-NBT are two multimodal extensions based on strong textual baselines.

4.3 Experimental Setups

The training of our model is carried out in two stages. First, we pre-train the basic textual model and the visual concept detector respectively. Then we fuse them together to train the full NMBT model with adaptive modality attention. For the textual base component, both RNN encoders' hidden state sizes are set to 512, and the number of layers is 3. We use 300 as the dimension of word vectors, which are extracted by pre-trained GloVe model [31]. During training, we keep the extracted word embeddings fixed.

Table 2: The dialogue state tracking accuracy of different models.

Method	Overall	Slots			
		Style	Material	Color	Fit
Seq2seq_DST	51.1	80.0	84.7	47.7	51.2
CNN_DST	51.7	81.4	81.5	50.8	54.8
RNN_DST	51.2	80.4	85.1	49.5	51.5
NBT	52.0	84.9	66.1	49.3	47.9
M-RNN_DST	56.4	81.8	87.0	49.9	53.7
M-NBT	57.2	82.7	87.7	51.5	56.1
NMBT w/o SBVL	58.6	86.9	89.7	52.6	59.0
NMBT w/o Attn	57.5	81.3	88.0	54.3	56.8
NMBT	**59.8**	**87.9**	**92.3**	**55.6**	**60.6**

The sub-regions in visual concept learning are defined by sliding window. More specifically, we first resize the image to 468×468, and the size of image sub-region is 224×224 as in ResNet-50. With a stride size of 30, we finally get 81 (9×9) sub-regions for each image. The stride size is determined through mode validation, since a smaller size leads to computing complexity and a larger one may cut off a potential object. The size of image feature extracted by ResNet-50 is 2048, which is then fed into a MLP followed by a sigmoid activation to get $\mathbf{v}_{ij}$ (see Equation 10). The h in Section 3.4 is set to 100. Both MIL and adaptive modality attention parameters is trained using Adam optimizer with a learning rate of 0.001, and the momentum parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$.

4.4 Evaluation Protocols

We adopted the dialogue state tracking accuracy as the main metric to evaluate the performance of our model. In each turn, the model predicts a value for each slot k. For each slot, we can get a slot-wise accuracy. The overall accuracy is averaged over all slots. Each user utterance from the original corpus is annotated with a specific *state type*, which indicates its function, such as "*show orientations*" and "*show similar to*". To give a more elaborate comparison, we also provide the accuracy scores of each baseline model on different state types.

We also analysis the performance of visual concept detection. For each slot k, we picked out the value w with the highest probability v_{ij}^w as the predicted value for that slot. In this metric, we show the overall and slot-wise accuracy scores. To give a more intuitional understanding of how the visual concept extractor works, we visualize its v_{ij}^w results for some concept w in Figure 4. As described in Section 4.3, we get a 9×9 v_{ij}^w map for each image. In order to visualize these probabilities on the image, we simply resize the heat map to 464×464 by upsampling and apply a Gaussian filter. Note that the heat map here is not the "attention" heat map which is widely used in many attention-based visual models [42]. In our

model, v_{ij}^{w} is a binary classification probability, which indicates the probability that sub-region j contains concept w.

To validate the effectiveness of our adaptive modality attention mechanism, we conduct a case study with a visualization of the adaptive attention weights. Due to space limitation, we only visualize the attention weights of five representative slots.

4.5 Performance of Dialogue State Tracking

We first report the DST prediction performance on the overall accuracy score and accuracy scores of several representative slots. Besides the baseline methods described in Section 4.2, we also conduct two ablation studies on the sub-region based visual concept learning (**SBVL**) component and modality attention mechanism (**Attn**). The results are shown in Table 2. Note that we only report the result of some primary slots.

Some key observations are summarized as follows:

- First of all, as compared to textual-based methods, there is a significant improvement on both the overall and the slot-specific accuracy scores for those methods considering multimodal information. For example, the overall accuracy score of M-RNN_DST increases 5.2% as compared to that of its pure textual-based version RNN_DST. The overall accuracy score of M-NBT also shows similar improvement pattern comparing to that of NBT. It indicates that by involving images into dialogue state tracking, the model is able to extract more useful information for better tracking the user's intention. In fact, it is natural to use images in the fashion products shopping conversation scenario. As the example shown in Figure 1, the images carry detailed information about the user's requirements which can not be easily expressed using only textual utterances. Therefore, it is crucial to capture the visual evidence in dialogue state tracking under these multimodal scenarios.
- Secondly, by learning sub-region based concept level visual representations, our proposed model achieves better performance as compared to the multimodal models that leverage pre-trained model extracted visual features. We compared with several multimodal baselines and a variation of our model named NMBT w/o SBVL, in which we remove the sub-region based visual concept learning component while replace it with the pre-trained ResNet-50 to extract visual features. In Table 2, we observe that utilizing visual information by simply using representations learned by pre-trained ResNet-50 is not an efficient way. There exists a large performance gap between our method NMBT and M-RNN_DST, M-NBT. For instance, the overall accuracy score of NMBT is improved by 3.4% and 2.6% respectively as compare to that of M-RNN_DST and M-NBT. For our proposed model NMBT, when the sub-region based visual concept learning component is removed, the overall performance of resulting method NMBT w/o SBVL drops about 1.2%. These results validate the effectiveness of our proposed visual concept learning model. By using sub-regions of image rather than the whole image, the model manages to learn more accurate concepts with less background noise.
- Thirdly, by combining textual and visual evidences through adaptive modality attention mechanism, NMBT manages to learn a better integrated representation of multimodal evidences. In M-RNN_DST and M-NBT, the textual and visual representations are integrated by vector concatenation. In the ablation model NMBT w/o Attn, we removed the attention mechanism by redefining the context vector in Equation 13 as a concatenation of the column vectors in $\mathbf{E}_t$. Compared to these multimodal models, NMBT achieves better performance on both slot-specific and overall accuracy. Intuitively, it is a non-trivial task to fuse the visual and textual evidences together. The image provided by either system or user can be regarded as an attribute list, which acts as a candidate value set for belief state update. The textual utterances contain two important clues: the values of some slots which are explicitly expressed in the utterance, such as "looking for some **formal** shoes", and the control information which decides the source of each slot's update, such as "in the **style** as in the **1st** image". This mechanism can not be model by either simple feature concatenation as in M-RNN_DST, M-NBT, or the NMBT w/o Attn ablation which simply averages the three evidences. In contrast, our model learns to automatically emphasize on the different evidence sources for updating belief state based on the conversational context.

4.6 Fine-grained DST Performance Analysis

To give a more detailed analysis, we report the state type level accuracy on three representative types, as shown in Table 3. First we analyze the function of "*show similar to*" which means that the user requires the agent to show similar items to the currently selected product. The selected product can come from one of the three evidence sources, which favors our adaptive attention mechanism. Therefore, we observe that the performance of our method NMBT in this type is better than the averaged performance shown in Table 2, which means in this scenario where the modality choice appears frequently, the attention mechanism manages to emphasize the correct modality in most cases. Also, our NMBT method obtains higher accuracy compared to the baseline methods. Next we analyzed "*like show result*" which is similar to "*show similar to*" and thus we can get similar conclusion based on its results, which further verifies NMBT's performance on emphasizing different modalities. When coming to the "*like earlier show result*" type which means that the user requires items related to results shown several turns before, we observed that although NMBT still outperforms baseline methods, the margin is dwindled from 2.2% to 1.1%. The possible reason might be that in "*like earlier show result*", the agent needs to recall back to previous turns other than the current turn, which brings extra difficulty.

4.7 Evaluation of Visual Concept Learning Component

Learning good visual representations is crucial to the model's performance since it serves as the input to downstream modules of dialogue state tracking. We thus analyze the effectiveness of visual concept learning in terms of concept classification accuracy and report results in Table 4.

We found that the sub-region based visual concept learning (**SRVL**) can capture more accurate classification features by localizing the visual concept and reducing background noise. This statement can be concluded from Table 4, where the overall and several representative slot-wise concept prediction accuracy scores

Table 3: The comparison of DST accuracy of different methods over three state type, where "*show similar to*" and "*like show result*" indicate the user asks to recommend products similar to the current one, and "*like earlier show result*" means the user requires products similar to someone in previous turns. Several representative slot-specific accuracy scores and the average accuracy score are reported. Note that the accuracy scores here are calculated on state type level, which can not be compared with the results in Table 2.

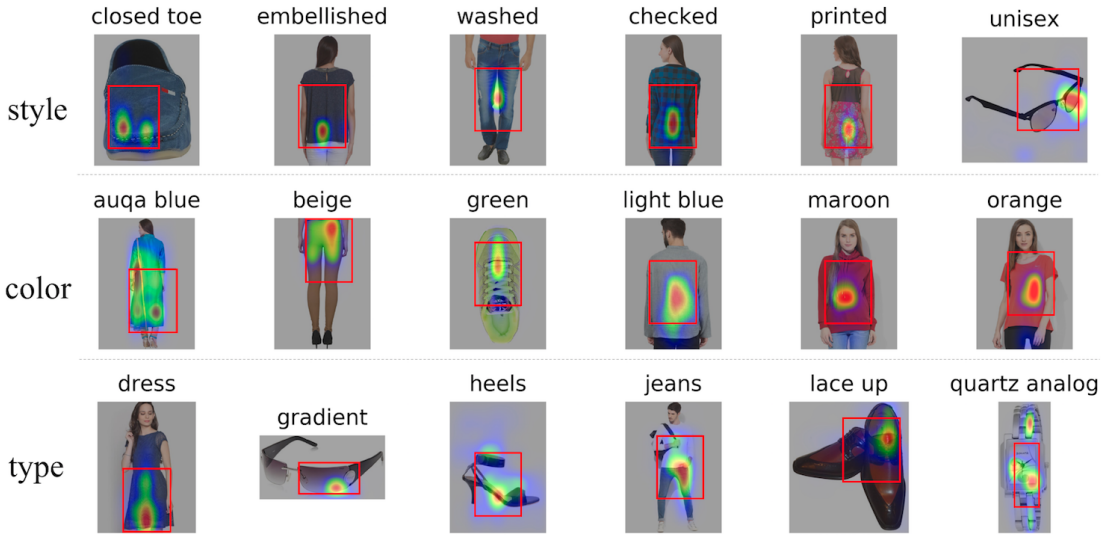

Figure 4: Sub-region based multiple instance learning for visual concept learning. We visualized the concept region probability of values such as *style*, *color* and *type*, where the three slots correspond to the three rows. The sub-region with the highest probability containing the concept is marked by a red rectangle.

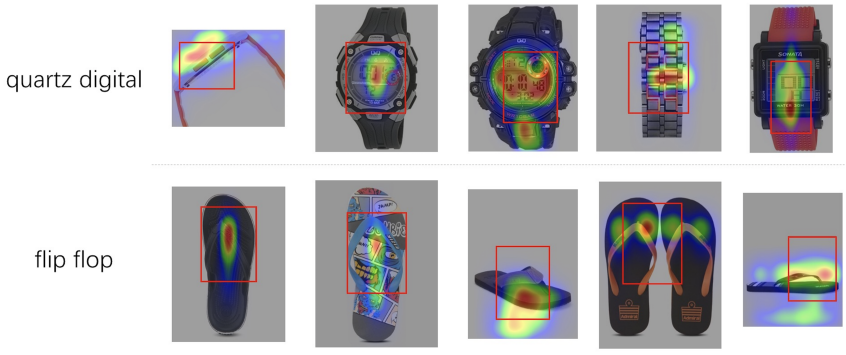

Figure 5: Visualization of the heat map of v_{ij}^{w} and the bounding box of *quartz digital* and *flip flop* concepts. We present multiple examples for the two concepts where the product images are taken in different orientations.

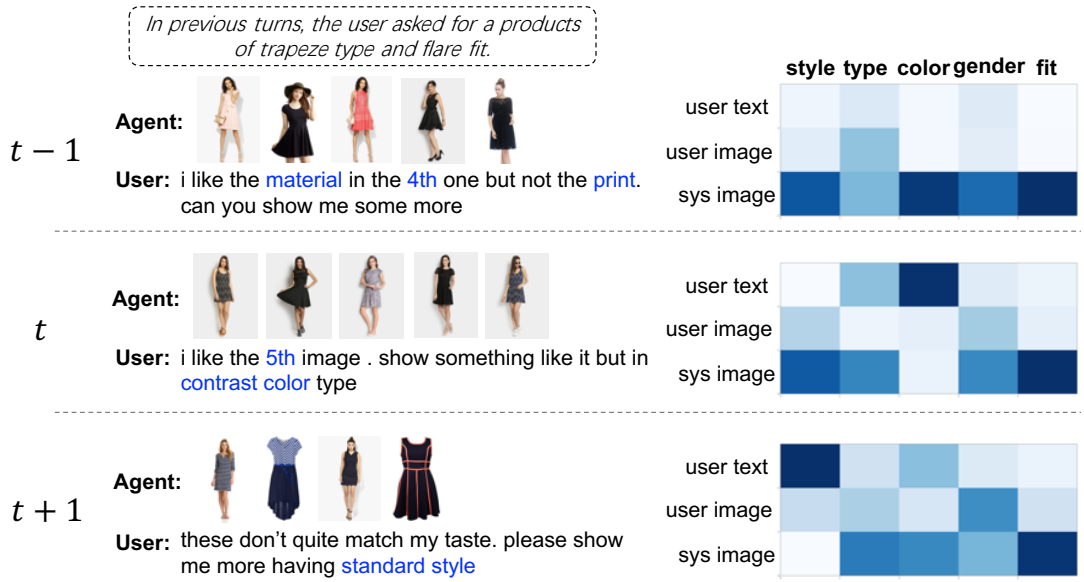

Figure 6: Visualization of modality attention weights. The attention weights of five major slots over the three evidence sources are plotted, where darker color indicates larger attention weight. Note that each column represents an attention distribution.

Table 4: The visual concept detection accuracy on different slots.

Method	Overall	Slots			
		Style	Material	Color	Fit
ResNet50	42.8	58.7	21.4	**42.8**	48.1
SRVL	**44.8**	**61.2**	**24.2**	42.0	**52.3**

are reported. We compare with the ResNet-50 model which directly uses the feature vector of the entire image to predict a concept. As shown in Table 4, by incorporating sub-region based visual concept learning, the accuracy score is improved by about 2.0%. Nevertheless, as it can be seen in the slot-specific result, the accuracy on "*color*" is dwindled by about 0.8%. This result is generally in line with our intuition, since the slot "*color*" is a more holistic concept which makes it more easily to be predicted with the overall image feature.

In order to validate whether our design of using image sub-regions is reasonable and whether our model can find those correct sub-regions for concepts, we visualize the spatial response map v_{ij}^{w} of some concepts as shown in Figure 4. The bounding box of the sub-region with the highest probability containing the concept is marked by a red rectangle. We can see from the visualization results that without bounding box annotations for training, our model is still able to locate and associate visual concepts with correct sub-regions. For example, in the "*closed toe*" picture, our model locates the sub-region on the toe part of a shoe, and in the "*washed*" example, our model focuses on the washed-styled pants rather than the T-shirts. For "*color*" prediction, the model focuses on the main body of each product which takes the most information about the product's color. These results indicate that the image representations given by sub-region based multiple instance learning indeed capture important visual classification concepts and can thus extract informative features for the task.

We further validate whether our proposed model can capture a concept presented in different orientations or poses. In fashion domain, the product images are often taken in different orientations, which requires the visual concept detector to identify a single concept in different modes. For example, as for the concept "*watch*", the model needs to identify it no matter its image is taken from the side or front, while the image features can be very different in this two cases. To validate whether our model fits this requirement, we conducted a more specific analysis by showing the heat map and bounding box of a single concept in images taken from different orientations. As demonstrated in Figure 5, we gave five images for two concepts, taken from at least three different orientations. For the concept of "*quartz digital*", our model can identify it by locating the feature of *knob*, *dial* and *band*, which are very different features. As for "*flip flop*", our model identifies its key characteristic, the *toe thong*, from different orientations. In the 4th image where there are two of it, the model is even able to find the *toe thong* feature for both identical objectives.

4.8 Case Study of Adaptive Modality Attention

As the adaptive modality attention is essential in our model, we conducted case studies by visualizing the modality attention weights to verify how it works in modeling multimodal conversations. As shown in Figure 6, we visualized the attention weights for our proposed model. Note that each column represents an attention distribution over the three sources where darker color indicates larger attention weight.

The result demonstrates that the adaptive modality attention mechanism is able to automatically emphasize the three sources based on both textual and visual contexts in multimodal dialogue,

even without specific supervision. For example in Figure 6, during the t-th turn, the user asked for products similar to the 5th one but with a different color, which indicates that the update of all slots except "*color*" should attend to system image. The corresponding attention weights fit this expectation, in which the colors of other slots is more shaded on "*sys image*", while that of "*color*" is more shaded on user text. In the $(t+1)$-th turn, the user asked for "*standard*" style products which is explicitly expressed in user text. Hence, the tracker of "*style*" pays more attention to user text. This case shows that the adaptive attention mechanism can capture the clues about which part is more important for each slot's update and thus boosts the overall performance.

5 CONCLUSION

In this work, we studied how visual evidence can be incorporated in the task of dialogue state tracking, and proposed a neural multimodal belief tracking model named NMBT, which seamlessly integrates and adaptively selects textual and visual information in multi-model dialogues. This model consists of a textual encoder which encodes textual utterances, a sub-region based visual concept detector which extracts concepts from image, and a multi-modality attention mechanism which adaptively attends to textual or visual evidence during conversations. Extensive experiments demonstrated that our model outperforms the state-of-the-art baselines. Results showed that dialogue state tracking in multimodal dialogues can significantly benefit from jointly considering multimodal evidences.

Multi-modal dialogue systems have many applications in real-world dialogue systems such as online shopping or virtual dialogue agent. We believe that this research direction is still in its infancy and our work may inspire many future studies.

ABSTRACT

Entity matching (EM), also known as entity resolution, fuzzy join, and record linkage, refers to the process of identifying records corresponding to the same real-world entities from different data sources. It is an important and long-standing problem in data integration and data mining. So far progresses have been made mainly in the form of model improvements, where models with better accuracy are developed when large amounts of training data is available. In real-world applications we find that advanced approaches can often require too many labeled examples that is expensive to obtain, which has become a key obstacle to wider adoption.

We in this work take a different tack, proposing a transfer-learning approach to EM, leveraging pre-trained EM models from large-scale, production knowledge bases (KB). Specifically, for each entity-type in KB, (e.g., location, organization, people, etc.), we use rich synonymous names of known entities in the KB as training data, to pre-train type-detection and EM models for each type, using a novel hierarchical neural network architecture we develop. Given a new EM task, with little or no training data, we can either fine-tune or directly leverage pre-trained EM models, to build end-to-end, high-quality EM systems. Experiments on a variety of real EM tasks suggest that the pre-trained approach is effective and outperforms existing EM methods.[1].

1 INTRODUCTION

Entity matching (EM), also known as entity resolution, fuzzy join, and record linkage, has numerous important applications such as knowledge fusion [29, 51], customer record deduplication [22, 61], etc. EM has been a long-standing problem in the data mining and data integration community, where extensive work has resulted in a long and fruitful line of research (e.g., see surveys in [28, 30, 45]).

A typical EM task in a relational setting, is to predict which records from two tables correspond to the same real-world entities. (EM in a graph setting such as knowledge graphs can be cast in a similar manner using graph connections [51]). Figure 1 shows an example of EM task. Given two tables of customer records with information such as customer names and addresses, we need to match records likely corresponding to the same person across the two data sources.

In this example, we can intuitively tell that the first two pairs of records are likely matches despite their differences in string representations – "Joe White" and "Joseph White" likely refer to the same entity, so do "CA" and "California". However minor string differences are not sufficient to ensure matches. To the contrary, there are many record pairs that have minor differences but are clearly non-matches. For example, in the last two pairs of records, "Sam A. Miller" and "Sam B. Miller" are likely not the same person, so are "Mark Johnson" and "Mary Johnson".

As we can see, these match/non-match decisions can be subtle, and are non-trivial to predict accurately. Existing EM approaches such as ML-based ones [10, 15, 61, 65], often require a large amount of training data (labeled match/non-match pairs) *each new EM task*, before accurate EM predictions can be made. It is clearly expensive, and sometimes impossible, to produce a large number of labeled data for *each EM task*, and this has become major obstacles to wider adoption of advanced EM techniques.

EM in real-world business applications. This study is conducted in the context of a commercial CRM (customer relationship management) system, where a pressing need is for enterprises using the CRM system, to match their customer records across data silos in different business applications (CRM, ERP, billing, service, etc.), so that these enterprises can have a unified view of their customers. Customer records are often in relational formats as shown in Figure 1, although the schema of the tables are not always known beforehand (e.g., data can be in non-standard databases or CSV files). A key requirement of EM in such applications, is that matching of customers should ideally work accurately out-of-box with little or no training data from *each enterprise*. EM applications like this make it difficult to apply advanced EM methods from the literature, which typically requires a large amount of labeled data [66].

Transfer learning for EM using pre-trained models. Partly motivated by the real-world EM application, we in this work take a very different tack. We argue that one does not need to re-train EM models from scratch for each new EM task, and we propose a novel transfer-learning approach using pre-trained EM models.

Specifically, our insight is that while each EM task may be different in its own ways (e.g., tables may have different attributes, and attributes have different importance, etc.), the types of attributes involved are often drawn from a set of common attributes (e.g.,

*Work done at Microsoft Research.
[1]We plan to release the pre-trained EM models, and are working through required processes to make this happen. Once approved these models will be released on GitHub at https://github.com/henryzhao5852/AutoEM.

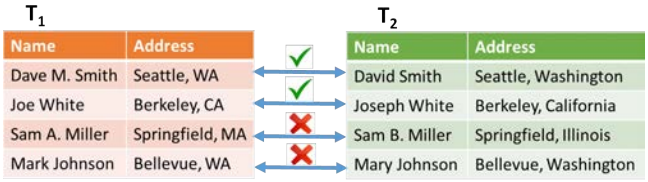

Figure 1: Example entity-matching between two tables.

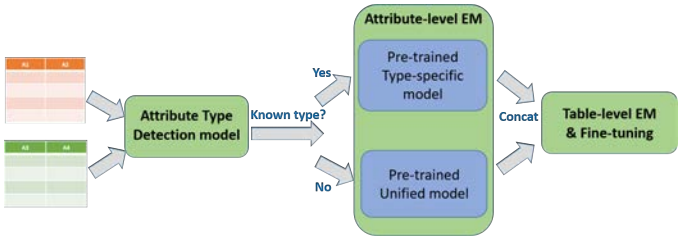

Figure 2: System architecture of end-to-end EM.

people-names, addresses, organizations, product-names, etc.). We observe that for each such attribute, the decision of match/non-match *at the attribute-level* can often be pre-trained and determined independent of the overall table-level EM task. For instance, in Figure 1, for the people-names domain, it is rather unambiguous that ("Joe White", "Joseph White") should match, while ("Sam A. Miller", "Sam B. Miller"), or ("Mark Johnson", "Mary Johnson") should not, irrespective of the EM tasks in question.

In addition, we observe that training data for these attribute-level match/non-match decisions are readily available in today's KBs, in the form of "synonymous names" for a large variety of entities (e.g., "Bill Gates" is also known as "William Gates" and "William H. Gates" in KBs). We leverage data harvested from KBs to pre-train accurate *attribute-level EM models* for a variety of domains, using a novel hierarchical deep model architecture we develop, which is shown to address shortcomings of existing methods.

Although the *attribute-level* EM decisions can be pre-trained and made separately, their contribution/importance to the overall *table-level* EM task can vary significantly. For instance, when matching two set of customer-records like in Figure 1, if the address-field of one table is "billing address" and the other is "mailing address", then they are not as important at the table-level (similarly, imagine if one phone-number field is "office-number" while the other is "cell-number"). In this work, we show that using pre-trained attribute-level EM models, and limited training data for each specific table-level EM task, we can quickly converge to accurate table-level EM predictions, through a fine-tuning step leveraging internal representations of these attribute-level EM models.

We would like to note that our pre-training approach to EM coincides with recent trends of employing pre-training models to NLP, including notable recent work such as BERT [26] that are shown to have great success.

Contributions. We make the following contributions.

- We propose a novel, end-to-end architecture for EM, that leverages large-scale and curated KB data, to pre-train models for both attribute type-detection, and attribute-level matches. For each new EM task, these attribute-level signals can be easily combined to produce an aggregate EM decision, using a small amount of training data.
- We develop a new hierarchical deep model to pre-train match/non-match for common types of attributes. This model leverages both character-level and word-level information and is designed to better handle complex attributes.
- We perform extensive experiments using KB data and real table data. Our results show that the proposed approach produces comparable or better results compared to state-of-the-art methods.

2 SYSTEM ARCHITECTURE

The EM problem we consider is simple to state: given two tables T_1 and T_2, with n and m records, respectively, determine for each record in T_1, if it matches with any record in T_2.

Figure 2 shows the end-to-end architecture of the proposed system. At a high level, the online EM prediction system has three main components: (1) Attribute-type detection; (2) Attribute-level EM; and (3) Table-level EM. We discuss each component in turn.

The first component is attribute-type detection, which takes a table as input, and predicts if each attribute/column in the table corresponds to a known KB type T. In the table of Figure 1, for instance, the first column is predicted as the KB type person, the second column as city, etc. These type-detection models are pre-trained offline using rich KB data from a commercial search engine. Specifically, KBs used by Google [5], Microsoft [32] and others have millions of entities for hundreds of common type such as person, city, organization, book, movie, etc. We leverage these (entity → type) data to train deep models to detect table column types. This component will be described in Section 4.

The second component is attribute-level EM models and is the central part of our system. It takes as input two entity values (e.g., "Dave M. Smith" and "David Smith" in Figure 1), and produces a score indicating the likelihood of match for the two input. We use two types of attribute-level EM models that are pre-trained offline:
(1) *Type-specific models*: For each known KB type T (e.g. person), we pre-train a separate model to predict match/non-match for values in T. We use synonymous entity names of type T in KB (e.g., "Bill Gates" is also known as "William Gates", "William Henry Gates" and "William H. Gates", etc.) as training data, and develop hierarchical deep models to learn name variations specific to each type T for accurate match/non-match decisions.
(2) *Unified model*: This is a single model that predicts match/non-match for values not in known KB types. While the model architecture is the same as the *type-specific models*, we use synonymous entity names taken from the *union* of many KB types, to pre-train a unified attribute-level EM that captures common name variations across different types (e.g., spelling variations). Such a model is reasonably accurate, and can be fine-tuned using limited training data to quickly fit a new type not known a priori.

As illustrated in Figure 2, at online prediction time the attribute-level EM can take two possible paths using the two types of models above, based on type-detection results. Specifically, if the type of a pair of attributes are detected to be a known KB type T, we apply the type-specific models for T (the upper path), otherwise we apply the general-purpose unified model (the lower path). We will describe this component in Section 3.

The final part of our system is the table-level EM. As discussed earlier, each table-level EM task can be different (e.g., different attributes, and different levels of importance for the same attributes). The table-level EM model starts from pre-trained attribute-level EM, and uses limited training data to quickly converge to aggregate EM decisions. This approach can also leverage pre-trained representations to fine-tune attribute-level EM for types that are not pre-trained, using limited (e.g., a few dozens) training data.

Terminology. Since in this work we will describe data coming from the contexts of relational tables and KBs, sometimes the same concept may be referred to using different names that are more natural in their respective contexts. For instance, "columns" or "attributes" that are more natural in tables, are better described as "entity-types" in KBs; similarly "attribute values" in tables are commonly described as "entity names" in KBs. While we try to keep the names consistent, we will use these names interchangeably in their corresponding contexts when appropriate.

3 ATTRIBUTE-LEVEL ENTITY MATCHING

We start by introducing our attribute-level EM models (in the middle of Figure 2), since they are the central part of the EM system, for which we develop novel hierarchical deep models. We defer the first component on type detection to Section 4, since we use simplified versions of the hierarchical models for type-detection.

Recall that attribute-level EM needs to take two attribute-values as input, and produce a score indicating their likelihood of match, which can be intuitively interpreted as "similarity".

3.1 Training data preparation

From Bing's knowledge graph [3, 32] (which is known as Satori and is similar to Google Knowledge Graph [5]), we select 40 head entity types that are deemed as common and useful for EM tasks (e.g., person, organization, city, book, etc.). In this KB (as well as other popular KBs [51, 56]), each entity e has an attribute called "alias", that lists all alternative/synonymous names of e. For example, the entity "Bill Gates" has alias "William Henry Gates", "William H. Gates", etc. These alternative names are clearly useful to train type-specific attribute-level EM models.

For positive examples, we take pairs of such alternative names, while filtering out pairs with no token overlap. The pairs that are listed as alternative names in KB but with no token overlap are likely semantic synonyms: e.g., "Lady Gaga" is also known as "Stefani Joanne Angelina Germanotta". Such semantic synonyms are too specific that are fine to memorize but difficult to generalize.

We would like to note that similar synonym data are also widely available in a similar manner from other KBs, such as the "also-known-as" relation in Wikidata [69], "alias" relation in Freebase [16], "foaf:nick" relation in DBpedia [12], "means" relation in YAGO [67], "alternateName" relation in Google Knowledge Graph [5]; as well as from standalone entity synonym data feeds [18, 21].

For negative examples, we use pairs of entities (e, e') in KB, whose names have some syntactic similarity. For example, we use "Bill Gates" and "Bill Clinton" as a pair of negative examples, as they resolve to different KB entities, but also share a common token in their names. The reason we require negative pairs to have syntactic similarity is that if the pair are completely different, it is trivial to determine that they should not match (e.g., "Bill Gates" and "Larry Page"). Such pairs would not be as helpful for models to learn. We generate "highly similar" pairs of names that are informative as negative examples as follows: for each entity e, we find top-100 entities in the same type, whose names are most similar to e (similarity to e is first decided based on the number of overlap tokens with e, and then based on Edit distance when there is a tie).

We note that for each canonical entity name from different types, on average we produce 2 to 5 positive examples (synonym names), and exactly 100 negative examples.

Our KB does not currently curates long-form physical mailing addresses (e.g., "206 South Cross Street, Little Rock, AR"), which however are common in EM tasks. In order to complement the KB for address data, we use query logs collected from the "Maps" vertical of the search engine, to obtain variations of addresses (in ways that users would type them), as well as their canonical addresses generated by the search engine. For example, a user query may be "206 South Cross Street, Little Rock, AR", and it is mapped to the canonical address "206 S Cross St, Little Rock, AR 72201" by the search engine. We collect such pairs of addresses as positive examples. And similar to KB types, negative examples are selected from high-similar address pairs that resolve to different canonical addresses. In total, we generate training data for addresses in 9 English-speaking locales (e.g. "en-us", "en-ca", "en-gb", "en-in", etc.), and use these as 9 additional types.

In total we pre-train EM models for these 49 attribute-types. We note that our approach of obtaining training data is general, and can be easily extended. For example, we could add types from KB, or use entity names in other languages from KB as additional types (most entities are curated to have names in many different languages). The same is true for addresses in other languages/locales.

3.2 Hierarchical Model for Attribute-level EM

We observe that positive examples of matching entity names exhibit complex structures and variations in different attribute-types. We make the following observations that motivate us to design a specific model architecture for attribute-level EM.

(1) First, we observe that sub-word/character-level matches are often important: for example, we have ("Dave Smith" = "David Smith"), and ("International Business Machine Corp" = "IBM Corp"), which requires character-level information to be modeled.

(2) In addition, word-level pairs are also an important source of information: for instance, we have ("Bill Gates" = "William Gates"), as well as ("William H. Gates" ≠ "William A. Gates") and ("Mary Miller" ≠ "Mark Miller"), etc. While character-level models are able to capture some of these, for long names with many tokens it can be difficult, such that explicit word-level models would be useful.

(3) Within one input, different words/characters may have different importance. For instance ("IBM Inc." = "IBM Corp."), since in the organization type words like "Inc." and "Corp." are not important; but ("IBM Corp." ≠ "IBS Corp."). The same is true for other types like person. This motivates us to introduce an intra-input, self-attention-like mechanism to learn character/word importance.

(4) Between two input, sometimes the word order may be different, e.g., ("Dave Smith" = "Smith, David"), which calls for an alignment-like, inter-input attention mechanism between the two input strings (reminiscent to attention used in machine-translation [13]).

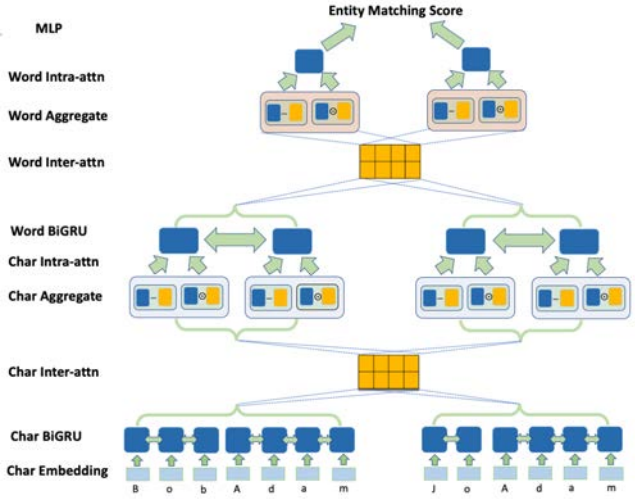

Figure 3: The hierarchical HI-EM model for attribute-level EM. The two input "Bob Adam" and "Jo Adam" at the bottom pass through a number of layers (GRU, attention, etc.), before producing a match score.

These observations motivate us to develop a hierarchical-EM model shown in Figure 3, which we will refer to as HI-EM for short. At a high level, the model has a hierarchical structure, which starts with character-level layers (the ones that start with "Char" in Figure 3), but also has upper-layers that explicitly capture word-level information (the layers that start with "Word"). With the hierarchical model, the character-level layers can not only capture fine-grained character-level variations, but also address the common out-of-vocabulary (OOV) issues. At the same time the word-level layers can explicitly leverage word-boundaries (separating characters in different words), which are especially beneficial for long input strings (e.g., data in types like address often have 5-10 words). We note that a similar idea of hierarchical models was recently explored in other contexts [74].

Additionally, for both the character-level and word-level, we introduce layers specifically designed for intra-input attention (within single input), and inter-input attention (between two input strings), which would help the model to learn character/word importance, as well as alignments between two input strings.

We now describe different layers of the model in turn in detail.

3.2.1 Character-level Layers for Word Representations.

We will first describe the 5 layers at the bottom of Figure 3. These are at the character-level to ultimately produce word-level representations, and their names all start with "Char". At a high level, we will first encode characters in the input, then look at the other input for alignments using attention, before aggregating to produce word representations for word-level layers.

Character Encoder. This part includes the first two layers: Char-Embedding, and Char-Bi-GRU. In the Char-Embedding layer, given a word $w_i, i \in [i, n]$, with its characters denoted as $c_{it}, t \in [1, l_i]$, we embed the characters to vectors through a character-embedding matrix W_e.

$$e_{it} = W_e * c_{it} \tag{1}$$

Then we pass the embedded vectors e_{it} to a recurrent neural network (RNN) block to obtain contextual information of the characters. In this work we use Bidirectional-Gated-Recurrent-Unit (BiGRU) [13] to capture both forward and backward information (similar to bidirectional LSTM [34]). The resulting character representation is denoted as hc_{it}.

$$hc_{it} = BiGRU(e_{it}) \tag{2}$$

Character Inter-input Attention. For each character representation hc_{it}, we adopt an inter-input attention layer to incorporate the character alignment $hc_j, j \in [1, l]$, where l refers to the length of whole character sequence from the other input. We use a bi-linear function with learned weight W_c to get the attention weights from the character sequence of the other input.

$$\alpha_j = hc_{it} * W_c * hc_j \tag{3}$$

For each character position it, the character information from the other attribute is summarized as

$$a_{it} = \sum_{j=1}^{l} \alpha_j hc_j \tag{4}$$

Character Aggregation and Intra-input Attention. For each character c_{it}, we produce a representation that is the concatenation of the element difference and multiplication between hc_{it} and a_{it}.

$$pc_{it} = [|hc_{it} - a_{it}|; hc_{it} \circ a_{it}] \tag{5}$$

We use the intra-attention layer to re-weight each combined character representation through a linear layer.

$$\beta_{it} = w_c * pc_{it} \tag{6}$$

The final representation for each word r_i is a weighted average of character representation.

$$r_i = \sum_{t=1}^{l_i} \beta_{it} * pc_{it} \tag{7}$$

We obtain word representation of each word from the two input strings, denoted as $r_i, i \in [1, n]$, and $r_j, j \in [1, m]$, where n, m are the total number words from the two input, respectively.

3.2.2 Word-level Layers for Attribute-value Representations.

On top of the character-level layers that produce word-level representations, we stack another set of word-level layers for overall attribute-value representations. These layers are designed similarly to include word encoding, inter-input attention, aggregation and finally intra-input attention, before producing a final representation for the full attribute value.

Word Encoder. We first use a BiGRU layer to contextualize each word representation $r_i, i \in [1, n]$.

$$hw_i = BiGRU(r_i) \tag{8}$$

And the same hw_j can be produced for $r_j, j \in [1, m]$.

Word Inter-input Attention. We have another inter-input attention layer to incorporate alignment information with the other input string $hw_j, j \in [1, m]$.

$$\alpha_j = hw_i * W_d * hw_j \tag{9}$$

$$a_i = \sum_{j=1}^{m} \alpha_j hw_j \tag{10}$$

Word Aggregation and Intra-input Attention. We again concatenate the element difference and multiplication of the word representation and the aligned word representation.

$$pw_i = [|hw_i - a_i|; hw_i \circ a_i] \tag{11}$$

Then we apply an intra-attention layer for final attribute-value representation z.

$$\beta_i = w_d * pw_i \tag{12}$$

$$z = \sum_{i=1}^{n} \beta_i * pw_i \tag{13}$$

We denote the final representations of the two input strings so computed as z_p and z_q, respectively.

3.2.3 Final Prediction.

The representation z_p, z_q for a pair of attribute values (P, Q) are concatenated and then pass through a multi-layer perceptron (MLP) layer to produce a final EM score.

$$score(P, Q) = MLP(z_p, z_q) \tag{14}$$

During training, we use logistic regression loss that averages over all N examples as the loss function.

$$loss = \frac{1}{N} \sum_{pos} log(\frac{1}{1 + e^{-score_{pos}}}) + \sum_{neg} log(\frac{1}{1 + e^{score_{neg}}}) \tag{15}$$

3.3 Transfer Learning for EM

For each attribute type T, we train a separate attribute-level EM model that captures the specific characteristics in T (e.g., synonymous tokens, token importance, etc.), which can then make highly accurate match/non-match decisions for data in type T.

However, even though we pre-train attribute-level EM for a large number of types, there will be attributes in EM tasks that are not in the known types. For those attributes we apply transfer-learning as follows, so that even for a new type not known a priori, we could quickly converge to a high-quality EM model.

We take the *union* of data in known attribute types, to build a general-purpose attribute-level EM model, which we will refer to as the *unified-model*. Such a model captures common variations general across many types (e.g., spell variations), and serves as a good starting point to train models for a new attribute-type. With limited training data for the new attribute-type, we take internal representations from the unified-model (right before the MLP layers in Figure 3), and add new MLP layers that can be fine-tuned using new training data to quickly converge to an EM model specific to the new type. Our experiments suggest that this transfer-learning approach produces high-quality results with limited training data.

Finally, for table level EM, we use a similar transfer-learning approach. Based on table attribute types, we use either type-specific attribute-level model or unified-model, to get internal representations every attribute pair (z in Equation (13)). We concatenate all representations, and add an MLP layer at the end for table-level EM. Such a model can be fine tuned end-to-end, using a small amount of table-level training data.

4 ATTRIBUTE TYPE DETECTION

In this section, we describe the first component of our system shown in Figure 2, which is for attribute type detection. Recall that for each value from input table column, we need to detect whether it belongs to known attribute-types T.

4.1 Training data preparation

Our training data used for attribute-type detection is similar to the data for attribute-level EM described in Section 3.1.

We use the same 40 common KB types, and 9 address types for type-detection. Note that each entity in the KB can be associated with one or more types. For example, entity "University of California" is of type "location", "organization", "educational institution", etc.; and entity "Harry Potter" is of type "written book", "film", "person", etc. Since the type hierarchy in the KB is such that types are not mutually exclusive but partially overlapping, and a string name can indeed belong to multiple types, we in this work formulate type-detection as a multi-hot classification problem – given an input string, predict all types it belongs to.

For each type T, we use names of entities in T, or $\{e \in T\}$ as positive examples for training. For negative examples, initially we use entities from $\{e' \notin T\}$. However, this turns out to be problematic, because KB types are often incomplete. For instance, while "University of California" has both types "organization" and "educational institution", another (smaller) university "Gonzaga University" only has type "educational institution" but not "organization" (which it a missing type)[2]. Note that because of the missing type, we may incorrectly use "Gonzaga University" as a negative example for "organization", which confuses the model.

To address this issue, we use a conservative approach to avoid selecting an entity $e \in T_1$ as a negative example for T_2, if its known type T_1 has positive correlation with T_2 (e.g., "organization" and "educational institution"). Specifically, for each pair of types T_1 and T_2, we compute their entity-instance-level point-wise mutual information (PMI) [46], defined as $\frac{|\{e|e \in T_1, e \in T_2\}| |\{e \in U\}|}{|\{e \in T_1\}| |\{e \in T_2\}|}$, where $\{e \in U\}$ is all the entities in the universe in the KB. If PMI> 0, then T_1 and T_2 are likely correlated and overlapping types. For instance, there are a substantial number of instances belonging to both "educational institution" and "organization", resulting in a positive PMI score. As such, we will not use *any* entity e of type "educational institution" as negative example of "organization", irrespective of whether e has type "organization". Formally, we use $\{e|e \notin T_1, \forall T_2 \ni e, PMI(T_1, T_2) < 0\}$ as the negative examples of T_1.

4.2 Type-detection Models

Figure 4 shows our Hierarchical entity-typing model (referred to as Hi-ET for short), for attribute type detection. We follow a similar hierarchical structure as the Hi-EM model.

We initially try to combine the type-detection task with the attribute-level EM task, using multi-task learning [23], given that they are similar intuitively. However our experiments show inferior quality in both tasks. We believe the reason lies in the fact that the "importance" of tokens in these two tasks are in fact opposite – to detect types for "University of California ", the token "University" is more important, but for EM (e.g., compare to "University of Colorado"), "California" is actually more important. Because of this reason we will design and train different models for type-detection.

[2]This problem of missing types can arise because types in KB are often generated from various sources (e.g., structured feeds, web data, etc.), which often do not cover Less popular entities as well as the head entities.

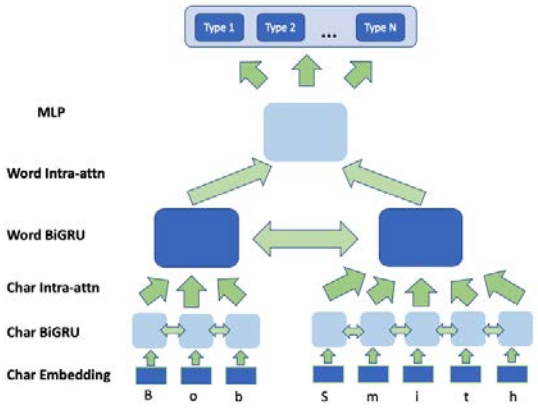

Figure 4: Our Hie-ET model to detect attribute types

Our type-detection model predicts 40 common KB types plus 9 address types. Since it can detect more than one type for each input value, we use one binary classifier for each target KB type, which is connected to the last layer of our model (Figure 4), for a total of 49 such classifiers. A benefit of this setup is that it can easily extend to new types, without needing to re-train existing models that have been tuned and tested.

The model in Figure 4 takes an input attribute value with n words $w_i, i \in [1, n]$, where each word contains l_i characters, written as $c_{it}, t \in [1, l_i]$. It produces C binary labels $(o_1, ...o_C) \in \{0, 1\}^C$ for the C pre-trained types. We describe each component of the model in Figure 4 below, using references to definitions in the attribute-level EM model from Section 3.

Word Level Representation. For each character $c_{it}, t \in [1, l_i]$, we first embed it into vectors e_{it} using Eq. 1 in Section 3. Then we use BiGRU layer (Eq. 2) to get contextual character representation hc_{it}. Using hc_{it}, we apply intra-attention (Eq. 6) to weight each contextual hidden state by importance. The final representation for each word r_i is a weighted average of representation hc_{it} (Eq. 7).

Attribute Level Representation. For each word representation $r_i, i \in [1, n]$, we first use another BiGRU layer (Eq. 8) to get contextual representation hw_i. Then we apply intra-attention (Eq. 12) to weight each contextual hidden state by importance. The final attribute representation z is weighted average of word contextual representation hw_i (Eq. 13).

Prediction layer. The representation z passes through an MLP layer. In our model, each binary output has it own MLP layer.

$$o_i = MLP_i(z), i \in [1, C] \tag{16}$$

Then the final output is the softmax of MLP output.

$$p_i = \text{softmax}(o_i) \tag{17}$$

Where $p_i = [p_{i0}, p_{i1}]$ indicates the probability of predicting the input value as the ith pre-trained type as true, and false, respectively.

During training, we use cross-entropy as our loss function, the final loss is the average of C classes over all examples.

$$L = -\frac{1}{N}\frac{1}{C}\sum_{ex}\sum_{i=1}^{C} y_{i0} log(p_{i0}) + y_{i1} log(p_{i1}) \tag{18}$$

Note that the model predicts types for one input value at a time. When predicting types for a column of k values, we simply compute an average score for the k values.

4.3 Transfer Learning for Type Detection

In our proposed EM system, we apply transfer-learning approach by directly using pre-trained type-detection models to detect if any table column/attribute corresponds to one of the known types.

Similar to transfer-learning in attribute-level EM (Section 3.3), we can also apply type-detection models to new types by first building a *unified-model*, which is trained using the union of data for all known types. For a new attribute type, we start from the representation of the unified-model, and use fine-tuning to produce an accurate model for a new type with little training data. Our experiments suggest that this is indeed the case – transfer-learning converges to high-quality type-detection models substantially faster than training from scratch.

5 EXPERIMENTS

In this section, we report experiments on different system components: Type Detection, Attribute-level EM and Table-level EM.

5.1 Type Detection Experiments

The goal of type detection is to accurately predict attribute types using pre-trained models. We report results on three experiments, entity-value type detection, table-column type detection, and transfer-learning for new types.

5.1.1 *Entity-value type-detection.*

Experimental setup. As discussed in Section 3.1, we use pre-trained models to detect 49 attribute-types, which include 40 common entity types from a KB, and 9 address types of different locales/markets ("en-us", "en-gb", etc.) from the "Maps" vertical of a search engine.

For each type T, we sub-sample at most 20K entities in T as positive examples (when a type has less than 20K entities we use all). For negative examples of T, we use entities not in T, filtered by the PMI procedure discussed in Section 4.1. This is to filter away negative examples that may be incorrect due to missing type labels (e.g., entity "Gonzaga University" has the type "educational institution" but is missing the type label "organization" in the KB. With PMI filtering we would not incorrectly use "Gonzaga University" as a negative example for "organization", since the two types are identified as overlapping/related). We randomly split the data into training (80%), development (10%) and test (10%).

We use PyTorch 0.4.1[55] to implement Hi-ET. We use random character embedding initialization with size 300. We use bidirectional GRU with 2 layers, and the size of each hidden layer is 300. For MLP, we use 2 linear layers of size 300 and ReLU as the non-linear activation function.

For training, we use batch size 32 and set dropout rate to 0.4 to help regularization. We use Adam [43] as the optimizer and use the default initial learning rate 0.001. We set gradient clipping threshold to 5.0 to increase stability. We finish the training after 5 epochs.

Experimental results. Figure 5 shows the precision-recall curves of entity-value type detection for the 49 types. In Figure 5(a) and 5(b), we can see that Hi-ET has high precision and recall for most of KB types, showing its ability to differentiate between entity values of different types. There are a few types (computer, architecture

venue, airline and sports facility) where the results are not as good. We found a main reason is the lack of positive training data – these types are small with less than 2000 entities in KB, which makes it difficult for deep models to learn. This is further exacerbated by the fact that entities from small types tend to be less popular and have more missing type information: if $e \in T_1$ but if the T_1 type is missing for e in the KB, we will incorrectly use e as a negative example of T_1, confusing the model. For small types and less popular entities, this tends to be more common, and is more difficult for our PMI-filtering approach to detect (Section 4.1).

Figure 5(c) shows precision/recall on 9 address types. It can be seen that despite the subtle differences of addresses from different markets (en-us, en-gb, en-ca, en-nz, etc.), where we intentionally remove obvious indicators such as all country tokens, our models still successfully differentiate addresses between different markets.

5.1.2 Table-column type-detection.

Experimental setup. For the table-column type-detection experiment, we use 1M Wikipedia tables as the test set, and evaluate precision/recall of two alternative methods: (1) our pre-trained Hi-ET models, which predict types using the average score of the first 10 values of each column; and (2) a keyword-based approach, which detects types based on keyword in Wikipedia table column-header (e.g., if a column-header contains the keyword "city" or "town", it is predicted to be of type city). Note that keyword is a strong baseline on Wikipedia, as Wikipedia tables are collaboratively edited by millions of editors [31], where column names are well-curated. In comparison, in enterprise CSV files and database tables, column headers are more likely to be cryptic or outright missing [24], which would make keyword search less effective.

We manually label 100 randomly selected columns, detected to be of type T. We report precision results from the 10 most common types in the interest of space.

Experimental results. Figure 7 shows that for most types (7/10), Hi-ET model has comparable or better results. However, quality results from Hi-ET can also be inferior to Keyword Search, notably for the entity type "food". Our analysis suggest that there is little sub-word pattern for this type (e.g., between apple, orange and banana), which is difficult for Hi-ET to generalize.

While Hi-ET is competitive for type-detection, we believe an ensemble of type-detection techniques that combine model-based, keyword-based, and even program-based [60, 72] approaches would be needed for best detection quality in practice.

5.1.3 Transfer-learning to new types.

Experimental setup. We also experiment whether our pre-trained type-detection models can be used in transfer-learning, to learn type-detection for other types faster and with less training examples. For this experiment, we use the same data from entity-value type detection (Section 5.1.1). We then select one type out of 49 types as the target-type for transfer-learning, and the remaining 48 types for pre-training. We compare two methods: (1) transfer-learning, using models fine-tuned from pre-trained type-detection models on 48 other types; and (2) learn-from-scratch, without using pre-trained models. For each method, we provide 200, 500 and 2000 examples from the target-type as training, and compare the resulting precision/recall curves.

Experimental results. Figure 6 compares the results with and without transfer-learning on 3 representative types. Similar results are observed in all other types (omitted here due to space constraints). We can see that with transfer-learning from pre-trained models, the model can learn a lot faster compared to learning-from-scratch, especially with little training data (e.g., 200 examples). We can see that results are better for types address and person, since these types have more regularity and are easier to learn. Data in type organization is more complex with more variations, which makes transfer-learning converge slower than other types.

Table 1: Statistics of types for attribute-level EM.

	Train	Dev	Test
Person	921230	3000	112312
Organization	271376	3000	31930
Movie	219574	3000	28832
Location	613792	3000	74062
Organism	5007	1629	1579
Local	85760	3000	10346
Book	21394	2745	2668
Software	2930	348	314

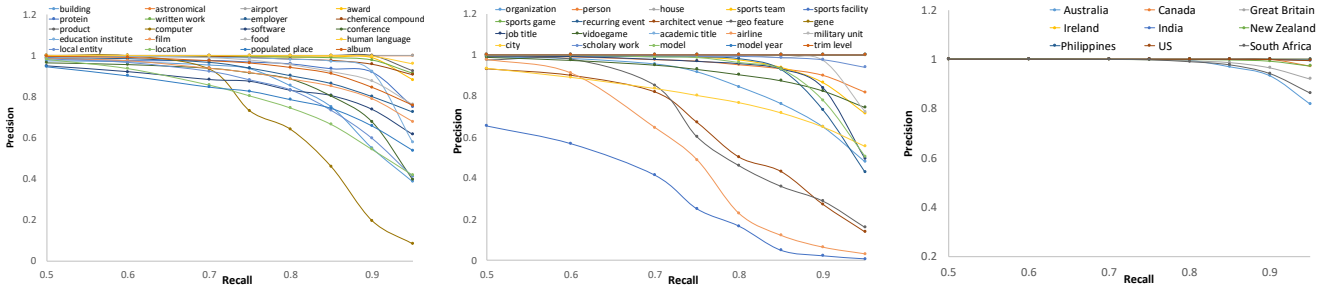
5.2 Attribute-Level Entity Matching

We conduct two experiments for attribute-level EM, pre-trained EM for known types, and transfer-learning for new types.

5.2.1 Experimental setup.

Data sets. As discussed in Section 3.1, for each entity e, we use synonymous names of e in KB (from the "alias" attribute, such as "Bill Gates" and "William Gates") as positive examples, and names of a different e' whose name is similar to e (by syntactic distance) as negative examples (e.g., "Bill Gates" and "Bill Clinton"). We split training pairs into train (80%) development (10%), and test (10%).

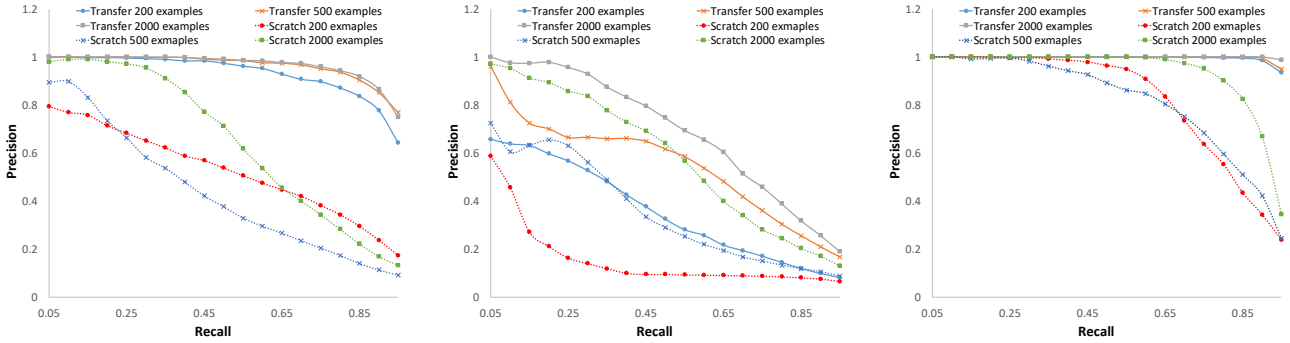
To evaluate pre-trained attribute-level EM of known types, we use 4 representative types: person, organization, location and movie, which show different types of name variations. The unified attribute-level model is trained using the union of these data.



For transfer-learning, we start from the unified model, and report results on 4 different types: organism, local, book and software. We report results after fine-tuning using 200, 500 and 2000 labeled examples. Table 1 reports statistics of these types.

We evaluate the model quality using two metrics: Mean Reciprocal Rank (MRR) and precision/recall.

Methods compared. We compare the folowing methods:



- **DSSM** [38] is one of the first deep models proposed for semantic similarity. DSSM uses DNN to represent each input in a continuous semantic space.
- **DeepER** [40] is proposed to use pre-trained word embedding for EM tasks.
- **DeepMatcher** [49] is also a deep model for EM problem with state-of-the-art results. We use its attribute matching component for attribute-level EM.
- **DeepMatcher (Unified)** is the same as DeepMatcher, but trained on unified data (union of data in different types).
- **Hi-EM** is the proposed EM model with hierarchical deep structure, trained using data for each type.
- **Hi-EM (Unified)** is Hi-EM trained on unified data.

Implementation details. To make fair comparison, we adopt same model settings for all methods. We set 300 as character/word

(a) First 20 Types from KB (b) 20 More Types from KB (c) 9 Types for Address in different locale

Figure 5: P/R curves of entity-value type-detection using Hi-ET model, for 40 KB entity types and 9 address types.

(a) Person (b) Organization (c) US Address

Figure 6: P/R curves for transfer learning using Hi-ET model, varying the amount of training data.

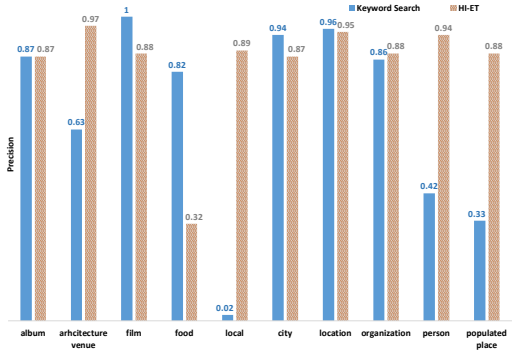


Figure 7: Comparision of Hi-ET and Keyword Search for Table-column type-detection across 10 most common types.

embedding size, 2 layers of size-300 for bidirectional GRU component, 2 layers of size 300 for MLP, and ReLU as nonlinear activation. For training, we use batch size of 32 and set dropout rate of 0.4. We use Adam as the optimizer with the default initial learning rate 0.001, and we set gradient clipping threshold at 5.0. We finish the training after 5 epochs (2 epochs for the unified data set). For each positive entity pair, we randomly select 5 negative examples for negative sampling.

For DSSM, we use character embedding, BiGRU for entity representations, and cosine similarity to compute match scores.

For DeepER, we use Glove [57] as the pre-trained word embedding, and fine-tune the embedding weights during training. For unknown words, we replace with 'UNK' token. We use BiGRU to get entity representations and MLP for final predictions.

For DeepMatcher, the authors present a design space of possible choices (with different neural network component). We report the configuration with the best performance in our experiments, which has character embedding, BiGRU component for attribute summarization, learnable distance (dot product) for attribute comparison and MLP for final predictions.

5.2.2 *Experimental Results.*

Pre-trained attribute-level EM for known types. Table 2 shows the MRR scores for attribute-level EM using pre-trained models on four different attribute types. The proposed Hi-EM produces better results than all other methods. DeepER does not perform well in this task, with lowest scores across all types. The reason is that DeepER uses word-based embedding with many OOV tokens. DSSM also has lower quality than DeepMatcher and Hi-EM, since it uses simple model architecture that does not consider interactions between two input strings. Finally, Hi-EM outperforms DeepMatcher in all types, showing the advantages of the hierarchical architecture, especially on complex attribute-types.

In the same table, we can see that Hi-EM (Unified) also achieves better quality than DeepMatcher (Unified). As expected, the unified models produce lower scores compared to the type-specific models.

Figure 8 reports the same experiments as above using precision/recall curves instead of MRR. The result is consistent with that

Table 2: MRR results for pre-trained attribute-level EM

	Person	Organization	Movie	Location
DSSM	0.888	0.850	0.844	0.853
Deep-ER	0.645	0.528	0.492	0.636
DeepMatcher	0.935	0.909	0.895	0.905
DeepMatcher (Unified)	0.924	0.893	0.894	0.896
Hi-EM	**0.943**	**0.925**	**0.924**	**0.911**
Hi-EM (Unified)	0.934	0.907	0.914	0.899

Table 3: MRR results for transfer-learning to new types

	Organism	Local	Book	Software
200 examples scratch	0.726	0.554	0.612	0.553
500 examples scratch	0.794	0.679	0.701	0.786
2000 examples scratch	0.828	0.804	0.790	0.810
0 example transfer	0.831	0.756	0.863	0.918
200 examples transfer	0.873	0.851	0.865	0.903
500 examples transfer	**0.884**	**0.853**	0.871	0.915
2000 examples transfer	0.881	0.849	**0.880**	**0.937**

of MRR, except in the movie type, where Hi-EM slightly underperforms DeepMatcher in some regions of the curve. An inspection of the errors suggest that the movie type has more synonymous name pairs that are semantic in nature – for example, the movie "Love Song" is also known as "Comrades: Almost a Love Story"; and "Star Crash" is also known as "Star Battle Encounters" or "Stella Star". These positive examples are all very specific and hard to generalize. At training time, Hi-EM overfits on these semantic examples, and produces high match scores for certain negative examples from the test data. Note that because the corresponding true-positive pairs have even higher match scores, in the MRR evaluation these high-scoring negative examples would not affect results. The P/R evaluation on the other hand, are more sensitive to the high-scoring negative examples, which affects precision.

We find other types of errors include name pairs that are inherently ambiguous (e.g., name pairs like "Rick Baker" and "Richard A. Baker" are marked as negative, but similar pairs like "Rick Barnes" and "Richard D. Barnes" would also be marked as positive), which makes it difficult to predict accurately. Finally abbreviation are also difficult to predict – Hi-EM is able to predict some pairs correctly (e.g., "IBM" and "International Business Machines Corp."), but get others wrong (e.g, "University of Geneva" and "UNIGE").

Transfer-learning for new types. Table 3 compares the MRR results between transfer-learning and train-from-scratch, with varying numbers of training data. We note that transfer-learning clearly helps, as there is a significant difference between k-example-transfer and k-example-scratch (for the same k). The difference is more pronounced when using fewer training examples. We also note that for many types (Organism, Book and Software), results from pre-trained unified-model (the line marked as "0 example transfer") already outperforms learn-from-scratch with 2000 examples, which is all the training examples we provide in this experiment.

Figure 9 reports precision/recall curves of the same experiment. We observe that these results are consistent with the MRR results.

5.3 Table-level Entity Matching

In this section, we evaluate our end-to-end EM on table data and compare with existing EM methods.

5.3.1 Experiment Setup.

Methods compared. We compare the following EM methods:

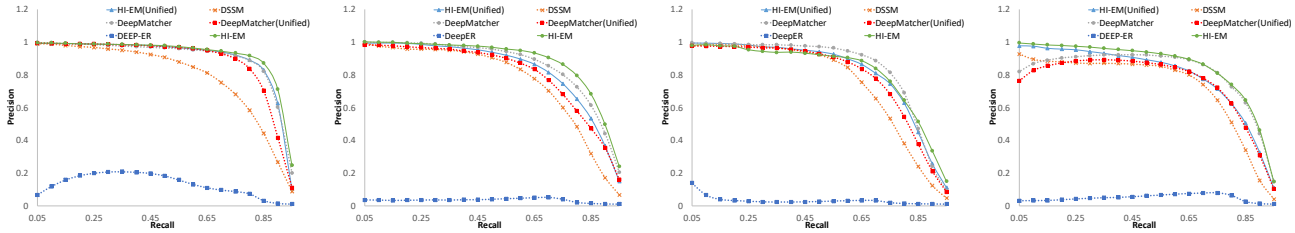
- **Magellan** [44] is a state-of-the-art feature-based EM system. We obtain it from GitHub[3] and use default settings.
- **DeepMatcher** [49] is a state-of-the-art deep EM model. We train the model from scratch, and use the same settings for attribute representations from attribute-level EM.
- **Hi-EM** is our hierarchical EM model trained from scratch, using the same settings from attribute-level EM.
- **Hi-EM (Unified)** is the same as Hi-EM, except that for all attributes we start with representations from the same unified attribute-level EM models that are pre-trained, and fine tune table-level EM based on table-level training data.
- **Hi-EM (Type)** is the same as Hi-EM, except that when attributes are detected as known types, we start with representations from type-specific attribute-level EM models, and fine tune table-level EM based on training data. This is the same as our end-to-end architecture outlined in Figure 2.

For both Hi-EM and DeepMatcher, we concatenate the representations of all attribute pairs and apply a 2 layer MLP of size 300 for final predictions.

Data sets. We use labeled data from a repository of EM tasks[4], which were also used in prior work [44]. There are a total of 24 EM tasks, each with a pair of tables, where some of the record pairs between the two tables were manually labeled as match/non-match. We exclude tasks whose corresponding data have quality issues (mainly due to formatting) and could not be run using the existing Magellan system, and ones that are very easy (e.g. matches are almost all exact, and all methods have over 0.95 $F1$). We use 8 remaining data sets that are more challenging EM tasks.

We evaluate model performance with varying number of training data. Specifically, for each data set, we randomly sample 5%, 10% and 20% labeled data as training, and use the remaining 80% as testing. We report $F1$ score on the test data. Note that the training data in most cases translate into just a few dozen labeled record pairs (there is one with only 13 training pairs), which is a small amount of training data.

To reduce randomness, we run deep models three times with different random seeds, and report an average $F1$. We keep the same random seed in each run between different deep models.



5.3.2 Experimental Results.

Table 4 shows $F1$ score across different data sets with varying amounts of training data. First, the Hi-EM (Type) achieves better quality than Hi-EM (Scratch) in 23 out of 24 settings, and it outperforms DeepMacher in 22 out of 24 settings, showing the benefit of a pre-training approach even with a small amount of training data.

Between Hi-EM (Type) and Hi-EM (Unified), Hi-EM (Type) produces better quality in 12/24 settings, and there are 6/24 settings for which the two methods are identical (since no columns are detected to be of known types). This is consistent with our finding in attribute-level EM that type-specific models are more accurate.

Compared to the feature-based EM Magellan, HI-EM (Type) outperforms Magellan in 20/24 settings. On the other hand, DeepMatcher is comparable to Magellan, which is consistent with what is reported in [49].

6 RELATED WORKS

In this section, we describe existing work in three related areas: Entity Matching, Deep Learning in NLP, and Transfer Learning.

Entity Matching. Entity matching, also known as entity resolution, fuzzy join, record linkage, among other names, has been a long-standing problem in the literature of data mining and data integration [28, 30, 33, 45]. Various techniques have been proposed, including ML-based approaches [10, 15, 61, 65] (based on positive/negative pairs labeled by users), and constraint-based methods [11, 19, 63, 70] (based on rules programmed by experts). Recently, two deep EM models, DeepMatcher [40], and DeepER [49], have been proposed and are shown to achieve better result quality.

We observe that most existing EM approaches require a large amount of training data, which is a significant barrier to wider adoption. We in this work propose a hands-off Auto-EM architecture, which leverages type-detection and attribute-level EM models that are pre-trained on a large amount of data from KBs. It is shown to achieve high EM quality with little training data.

Entity type detection. Unlike the literature on type classification in NLP (e.g., [50, 75]), which typically relies on natural language contexts, our task of entity type detection is for database tables and columns, where natural language contexts are absent. Our approach leverages only characteristics of entities, in a setting similar to [72].

Deep model in NLP. Tremendous progress have been made in applying deep models to NLP. Text-classification and similarity problems are particularly relevant to our problem.

Classification. Text classification [9] is a fundamental problem in NLP, for which neural network models are developed, including Convolution Neural Network (CNN) [42] and Recurrent Neural Network (RNN)[52]. Recently self-attention [68] is used as additional layer to improve performance, and [74] adopts hierarechical structure with self-attention over RNN for document classification.

Similarity. Learning textual similarity between two input is important in NLP, with applications including Natural Language Inference (NLI) [17, 71], Answer Selection (AS) [73], etc. Early deep models [38] treat each input independently. Recently approaches leverages input pairs [20, 35, 54, 62], and solve these tasks with a

similar architecture of input embedding layer, context encoding layer, interaction and attention layer, and finally output classification layer [47].

Transfer learning. Transfer learning has a long history [53], where the idea is to transfer knowledge from a problem with abundant training data, to a target-problem that is related but with limited data. Transfer learning has been successfully applied to domains such as computer vision and NLP [14].

In NLP, transfer learning approaches include the well-known word embedding [41, 48]. Recent approaches propose pre-train models with language model objectives [25, 37], with fine-tuning for specific tasks, which has achieved great success [27, 59].

7 CONCLUSION AND FUTURE WORK

In this work we propose an end-to-end system for EM, that leverages models pre-trained using rich KB data. With the help of transfer-learning, we show that table-level EM tasks can be trained with little labeled data.

Our deep models are not currently good at detecting attributes involving numeric values (e.g., currency and measurements). Using programmatic methods to detect and featurize these attributes could complement the deep models for better overall EM results, and are interesting directions for future work.

ABSTRACT

"User reviews" are becoming an essential component of e-commerce. When buyers write a negative or doubting review, ideally, the sellers need to quickly give a response to minimize the potential impact. When the number of reviews is growing at a frightening speed, there is an urgent need to build a response writing assistant for customer service providers. In order to generate high-quality responses, the algorithm needs to consume and understand the information from both the original review and the target product. The classical sequence-to-sequence (Seq2Seq) methods can hardly satisfy this requirement. In this study, we propose a novel deep neural network model based on the Seq2Seq framework for the review response generation task in e-commerce platforms, which can incorporate product information by a gated multi-source attention mechanism and a copy mechanism. Moreover, we employ a reinforcement learning technique to reduce the exposure bias problem. To evaluate the proposed model, we constructed a large-scale dataset from a popular e-commerce website, which contains product information. Empirical studies on both automatic evaluation metrics and human annotations show that the proposed model can generate informative and diverse responses, significantly outperforming state-of-the-art text generation models.

1 INTRODUCTION

Over the past few years, online shopping has experienced unimaginable growth. In e-commerce platforms, such as *Amazon*, *eBay* and *Taobao*, massive reviews from users are becoming increasingly important. From the seller viewpoint, however, reviews can be a double-edged sword. On the one hand, the more reviews, the more buys, but on the other hand, sellers have little or no control over buyer opinion. Therefore, efficient and constructive response to the target review/buyer can be critically important. If the buyers, especially those who send negative or doubting reviews, do not get a quick reply, they and other potential customers may turn to alternatives, which is unfavorable to the sellers and platforms.

Statistics[1] from a world leading e-commerce platform shows that sellers who provide high quality review responses could achieve a higher selling volume than those who rarely provide responses. However, only 2.98% of the reviews and 5.68% of the negative reviews receive responses. Furthermore, a large number of responses are universal replies which are based on the pre-defined templates/messages. Ideally, sellers should provide high-quality responses to address the personal needs from the target reviews. However, such cost can be prohibitive for most small-businesses, which inspires us to build a response writing assistant. After the algorithm automatically generates some candidate responses, the customer services could choose one and polish it, which makes the procedure more friendly and efficient.

Recently, deep neural network based methods have widely used in many natural language generation (NLG) tasks and have achieved great success, such as machine translation [3, 4, 10, 26], dialogue generation [23, 24], and text summarization [17, 22, 30]. Most of these models belong to a family of sequence-to-sequence (Seq2Seq) framework, which is composed of two parts: an encoder and a decoder. The encoder reads and encodes a source sentence into a hidden vector and the decoder outputs a target sentence based on

[1]More detail can be found in Appendices A.1.

Review: The quality is not very good and the sleeves will pill. It looks like the fabric is bad.

Seq2Seq+Attention: Thank you for your support and feedback. We will continue to work hard to provide you with better service and look forward to your next visit!

Real Response: Dear customer, thank you for choosing NAISHITU flagship store. Due to the composition of polyester, slight pilling is a normal phenomenon. It is recommended that you use fabric shaver to deal with. Looking forward to your next visit.

Figure 1: Given a review, the response generated by "Seq2Seq +Attention" model is trivial and universal. In contrast, the real response written by human contains some product information, like the *brand* (NAISHITU) and *material* (polyester).

Field	Value
Brand	NAISHITU
Material	polyester 57% cotton 43%
Process	easy care finishing
Style	casual style
Color	black
Size	185 / 2XL
...	...

Figure 2: An example of product information collected as a table.

the hidden vector. The attention mechanism [3, 16], which selectively focuses on parts of the source sentence during generation, is integrated into the Seq2Seq framework to improve the quality of long sequence generation.

Despite its enormous success, for review response generation task, however, the standard Seq2Seq+Attention model can only employ the textual reviews when generating responses. Intuitively, each review also has an associated product, and the product information can be critical and necessary to generate high-quality responses. Figure 1 illustrates an example. In this example, the given review is a negative review. Without employing the product information, the Seq2Seq+Attention model tends to generate trivial and universal responses like "*thank you for your support and feedback*", or "*we will continue to work hard to provide you with better service*" due to the high frequency of these patterns in the training data. These universal responses will give users a very bad user experience. In contrast, in real world, an experienced seller gives a response according to the corresponding product information, like the *brand* (NAISHITU) and the *material* (polyester). Without taking such product information into consideration, the algorithm can hardly generate such high-quality responses. Hence, integrating product information into the generation process has become a crucial part of the task.

In this work, the product information is collected as a factual table which contains many field-value records and an example is given in Figure 2. We follow Lebret et al. [12] to encode this table. The proposed model utilizes product information via a gated multi-source attention mechanism and a copy mechanism. The novel attention mechanism includes two attentions: review attention and product attention. For generation, we first obtain the review context vector by review attention which follows the existing attention techniques. Then, the review context vector is used to calculate the product context vector by product attention, which simulates the human response process of finding useful information in a product according to the issue mentioned in review. Finally, we obtain the final context vector through a Gated Multimodal Unit (GMU) [1], which is used to learn fusion transformations from multiple sources of information. By incorporating the copy mechanism [9], the decoder could directly copy the sub-sequences of review or product information into the response. Moreover, we employ self-critical sequence training (SCST) [21], a policy gradient reinforcement learning technique, to train the model, which reduces the exposure bias problem [20]. To evaluate the proposed model, we constructed a large-scale dataset from Taobao, which contained 100K (review, product information, response) triples. Experimental results on this dataset show the effectiveness of our method.

In summary, the contributions of this paper include the following three aspects:

(1) We introduce the task of review response generation in e-commerce platforms, which is valuable for customer service providers, but has not yet been well-studied.
(2) In order to address this problem, we propose leveraging a gated multi-source attention mechanism and a copy mechanism to integrate product information and employ policy gradient reinforcement learning in the training procedure to reduce the exposure bias problem.
(3) Experimental results based on both automatic evaluation metrics and human annotations demonstrate that the proposed model can generate informative and diverse responses, significantly outperforming state-of-the-art NLG models. We also release the large-scale review response generation dataset to enable future investigations.

2 PRELIMINARIES

In this section, we first formulate the review response generation task formally, and then introduce the field representation which will be used by our model.

Symbol	Description
$\boldsymbol{X}$	a review
$\boldsymbol{x}_i$	i-th word in review $\boldsymbol{X}$
$\boldsymbol{Y}$	a response
$\boldsymbol{y}_i$	i-th word in response $\boldsymbol{Y}$
$\boldsymbol{T}$	a table representing product information
$\boldsymbol{t}_i$	i-th word in the sequence composed by all value
$\boldsymbol{f}_i$	the field name of i-th word $\boldsymbol{t}_i$
$\boldsymbol{p}_i^+, \boldsymbol{p}_i^-$	the position of i-th word $\boldsymbol{t}_i$
$\boldsymbol{z}_i$	the field representation of i-th word $\boldsymbol{t}_i$
$\boldsymbol{h}_i^X$	hidden state of the review encoder
$\boldsymbol{h}_i^T$	hidden state of the product information encoder
$\boldsymbol{h}_i^Y$	hidden state of the response decoder
$\boldsymbol{c}_i^X$	the review context vector
$\boldsymbol{c}_i^T$	the product information context vector
$\boldsymbol{c}_i$	the final context vector

Table 1: Commonly used notations in this paper.

Word	Field Representation
NAISHITU	(**Brand**, 1, 1)
polyester	(**Material**, 1, 4)
57%	(**Material**, 2, 3)
cotton	(**Material**, 3, 2)
...	...
casual	(**Style**, 1, 2)
style	(**Style**, 2, 1)
...	...

Figure 3: The table is represented as a sequence of words (the first column) and their corresponding field representation (the second column).

2.1 Task Definition

We first introduce our key notations used in this paper. Table 1 lists the main notation we use. Let $\boldsymbol{X} = \{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n\}$ denote a review of length n, where $\boldsymbol{x}_i \in \mathbb{R}^{d_w}$ is the word embedding of i-th word. In the same way, let $\boldsymbol{Y} = \{\boldsymbol{y}_1, \boldsymbol{y}_2, \ldots, \boldsymbol{y}_m\}$ denote the corresponding response of length m. The product information is represented as a table $\boldsymbol{T}$, which is a combination of many field-value records. Figure 2 shows an example. In this example, we only show six fields: *brand*, *material*, *process*, *style*, *color* and *size*. Each value is a sequence of words and all values are concatenated as a long sequence $\{\boldsymbol{t}_1, \boldsymbol{t}_2, \ldots, \boldsymbol{t}_k\}$ (the first column in Figure 3) where $\boldsymbol{t}_i \in \mathbb{R}^{d_w}$ is the word embedding vector. To incorporate the field information, each word $\boldsymbol{t}_i$ also has a corresponding field representation $\boldsymbol{z}_i$ (the second column in Figure 3), which will be detailed in the next subsection. Given a review $\boldsymbol{X}$ and a table $\boldsymbol{T}$ representing the associated product information, the aim is to build a model that can generate a response $\boldsymbol{Y}$.

We formulate the response generation as a probabilistic model, which is trained to maximize the generation probability of $\boldsymbol{Y}$ conditioned on $\boldsymbol{X}$ and $\boldsymbol{T}$:

$$\begin{aligned} &\operatorname{argmax} P(\boldsymbol{Y}|\boldsymbol{X}, \boldsymbol{T}) \\ &= \operatorname{argmax} P(\boldsymbol{y}_1|\boldsymbol{X}, \boldsymbol{T}) \prod_{i=2}^{m} P(\boldsymbol{y}_i|\boldsymbol{y}_{1:i-1}, \boldsymbol{X}, \boldsymbol{T}). \end{aligned} \tag{1}$$

2.2 Field Representation

As seen in Figure 2 and Figure 3, the value of each field in the product information is split into separate words and the entire table is transformed into a large sequence $\{\boldsymbol{t}_1, \boldsymbol{t}_2, \ldots, \boldsymbol{t}_k\}$. Besides the value information, the field information is also crucial, especially for the product attention. For example, an user may mention "material" in his review, but not mention "polyester". If we know that the corresponding field of "polyester" is "material", it will be easier for the attention mechanism to work well. Lebret, Grangier, and Auli [12] proposed representing value's field information by its corresponding field name and its position in the field. The field representation of a word $\boldsymbol{t}_i$ in the table is described by a {field, position} pairs:

$$\boldsymbol{z}_i = \{\boldsymbol{f}_i, \boldsymbol{p}_i\}. \tag{2}$$

The pair $\{\boldsymbol{f}_i, \boldsymbol{p}_i\}$ indicates that $\boldsymbol{t}_i$ occurs in field $\boldsymbol{f}_i$ at position $\boldsymbol{p}_i$. The position $\boldsymbol{p}_i$ can be further divided as $(\boldsymbol{p}_i^+, \boldsymbol{p}_i^-)$ which represents the positions of the word $\boldsymbol{t}_i$ counted from the beginning and the end of the field respectively:

$$\boldsymbol{z}_i = \{\boldsymbol{f}_i, \boldsymbol{p}_i^+, \boldsymbol{p}_i^-\}, \tag{3}$$

where $\boldsymbol{f}_i \in \mathbb{R}^{d_f}$ and $\boldsymbol{p}_i^+, \boldsymbol{p}_i^- \in \mathbb{R}^{d_p}$ are the embedding vector of field name and positions, respectively. d_f is the field name embedding size and d_p is the position embedding size. For example in Figure 2, the second field-value record is (**Material**, polyester 57% cotton 43%). The word "polyester" is the first word of field "**Material**", counted from the beginning, and the fourth word counted from the end. So the field representation of "polyester" is (**Material**, 1, 4), as shown in the second row of Figure 3.

3 THE PROPOSED MODEL

3.1 Network Architecture

In this section, we describe the network architecture used in this paper, which is illustrated in Figure 4. The proposed model mainly includes four parts: an encoder to read the review (blue), an encoder to read corresponding product information (green), a Gated Multimodal Unit (GMU) (yellow) to learn fusion transformations, and a decoder to generate the response (red).

Review Encoder

We first transform each word in a given review to a one-hot vector in the size of the vocabulary. Next, we use a simple embedding

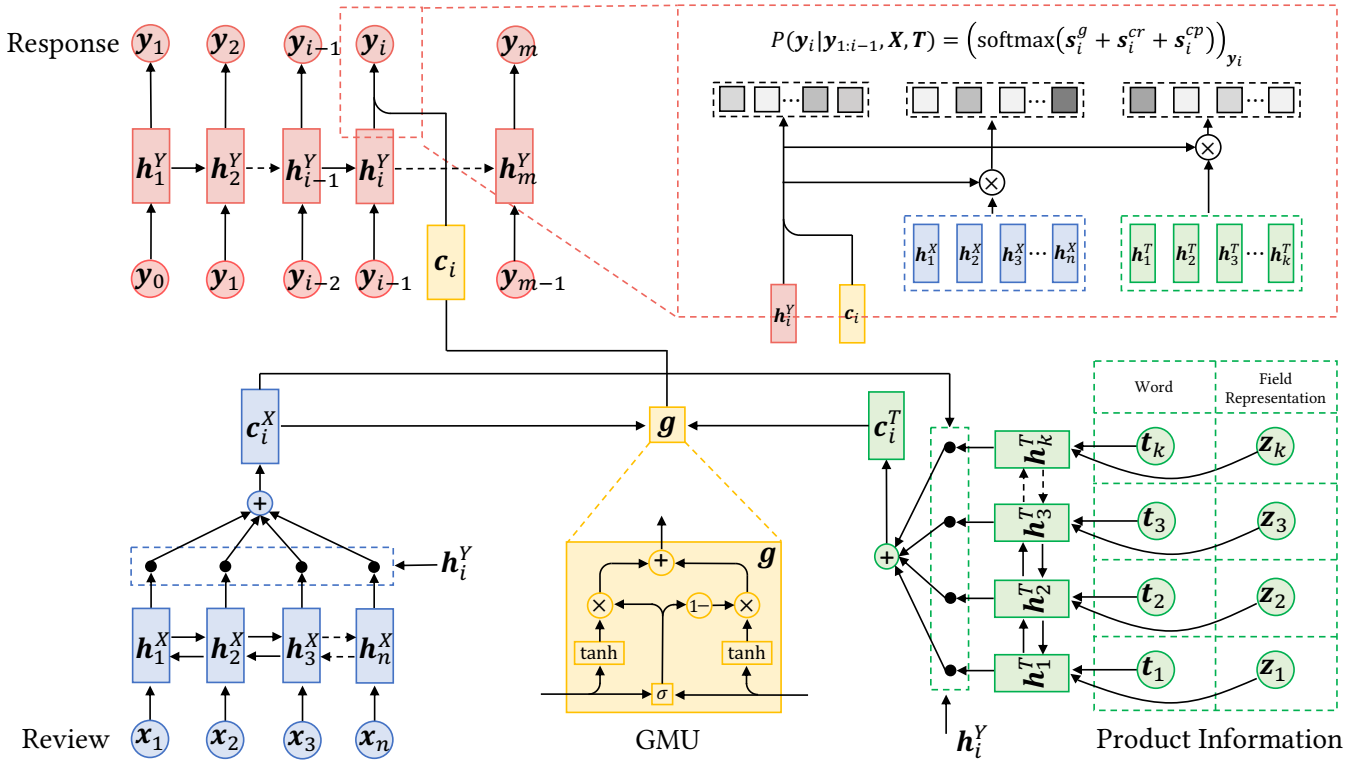

Figure 4: Architecture of our proposed model. It includes two encoder to read the review (blue) and corresponding product information (green) and a decoder to generate the response (red). A Gated Multimodal Unit (GMU) (yellow) is used to learn fusion transformations from multiple sources of information and a copy mechanism (top right corner) allows the decoder to directly copy from review or product information.

layer to encode each one-hot vector to a word vector $\boldsymbol{x}_i$. After we get the word-level review feature representation $\{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n\}$, the review encoder aims to encode each word $\boldsymbol{x}_i$ in the review into the hidden state $\boldsymbol{h}_i^X$. In this work, we use two-layer bidirectional recurrent neural network (BiRNN) with gated recurrent units (GRU) [4] to read the review. The bidirectional RNN can not only capture the previous contextual information but also the future contextual information. At each time step, the bidirectional RNN unit takes the word embedding $\boldsymbol{x}_i$ as input, and outputs a hidden state $\boldsymbol{h}_i^X$. Concretely, the formulas at step i are as follows:

$$\begin{aligned} \overrightarrow{\boldsymbol{h}}_i^X, \overleftarrow{\boldsymbol{h}}_i^X &= \text{BiGRU}^X(\boldsymbol{x}_i, \overrightarrow{\boldsymbol{h}}_{i-1}^X, \overleftarrow{\boldsymbol{h}}_{i+1}^X; \boldsymbol{\theta}_X), \\ \boldsymbol{h}_i^X &= \overrightarrow{\boldsymbol{h}}_i^X \oplus \overleftarrow{\boldsymbol{h}}_i^X, \end{aligned} \tag{4}$$

where $\overrightarrow{\boldsymbol{h}}_i^X, \overleftarrow{\boldsymbol{h}}_i^X \in \mathbb{R}^{d_h}$ is the forward hidden state and backward hidden state of the BiGRU^X at step i, respectively; $\oplus$ is the concatenation operation and $\boldsymbol{h}_i^X$ is the final hidden state at step i. $\boldsymbol{\theta}_X$ represents all the parameters of the BiGRU^X.

Product Encoder

Besides the review encoder, we also need a product encoder to read the product information. As described above, the product information is represented as a sequence of words $\{\boldsymbol{t}_1, \boldsymbol{t}_2, \ldots, \boldsymbol{t}_k\}$ and their corresponding field representation $\{\boldsymbol{z}_1, \boldsymbol{z}_2, \ldots, \boldsymbol{z}_k\}$. The basic structure of the product encoder is the same as that of the review encoder, i.e., two-layer bidirectional recurrent neural network (BiRNN) with gated recurrent units (GRU). The difference is that we feed the concatenation of word embedding $\boldsymbol{t}_i$ and the corresponding field representation $\boldsymbol{z}_i$ to the bidirectional RNN. Concretely, the formulas at step i are as follows:

$$\begin{aligned} \overrightarrow{\boldsymbol{h}}_i^T, \overleftarrow{\boldsymbol{h}}_i^T &= \text{BiGRU}^T(\boldsymbol{t}_i \oplus \boldsymbol{z}_i, \overrightarrow{\boldsymbol{h}}_{i-1}^T, \overleftarrow{\boldsymbol{h}}_{i+1}^T; \boldsymbol{\theta}_T), \\ \boldsymbol{h}_i^T &= \overrightarrow{\boldsymbol{h}}_i^T \oplus \overleftarrow{\boldsymbol{h}}_i^T, \end{aligned} \tag{5}$$

where $\overrightarrow{\boldsymbol{h}}_i^T, \overleftarrow{\boldsymbol{h}}_i^T \in \mathbb{R}^{d_h}$ is the forward hidden state and backward hidden state of the BiGRU^T at step i, respectively; $\boldsymbol{h}_i^T$ is the final hidden state. $\boldsymbol{\theta}_T$ represents all the parameters of the BiGRU^T.

Response Decoder

Once the review and product information is encoded, a decoding two-layer RNN with GRU is used to generate the response. The decoding process starts as soon as the decoder receives a starting symbol "<s>" ($\boldsymbol{y}_0$ in Figure 4) and ends when the decoder generates an ending symbol "<e>". On each step i, the decoder receives the word embedding of the previous word and outputs the decoder hidden state $\boldsymbol{h}_i^Y$:

$$\boldsymbol{h}_i^Y = \text{GRU}^Y(\boldsymbol{y}_{i-1}, \boldsymbol{h}_{i-1}^Y; \boldsymbol{\theta}_Y), \tag{6}$$

where $\boldsymbol{y}_{i-1}$ is the word embedding of the previous word and $\boldsymbol{h}_i^Y$ is the hidden state of the GRU^Y at step i. $\boldsymbol{\theta}_Y$ represents all the parameters of the GRU^Y. Next, the hidden state $\boldsymbol{h}_i^Y$ is used to calculate the context vector $\boldsymbol{c}_i$ by an attention mechanism which will be detailed in the below. Finally, $\boldsymbol{h}_i^Y$ and $\boldsymbol{c}_i$ together is used to generate the word $\boldsymbol{y}_i$.

Gated Multi-Source Attention Mechanism

After the review encoder and product encoder, we get the review feature representation $\{\boldsymbol{h}_1^X, \boldsymbol{h}_2^X, \ldots, \boldsymbol{h}_n^X\}$ and the product feature representation $\{\boldsymbol{h}_1^T, \boldsymbol{h}_2^T, \ldots, \boldsymbol{h}_k^T\}$. In view of the fact that the word in response at step i is often only related to a small part of the review or product information, we utilize a gated multi-source attention mechanism to generate a high-level representation of the review part and product part. The proposed attention mechanism is introduced to make the decoder access useful review or product information in generation and it includes three parts: a review attention, a product attention, and a Gated Multimodal Unit (GMU). We also hope the generated response to cover all the issues in user's review, not just one. Therefore, we introduce the coverage vector $\boldsymbol{r}_i$ [27] in each time step, which maintains the sum of attention value over all previous steps and records what we have covered before step i. $\boldsymbol{r}_i$ is also used as an input to the review attention. Concretely, We first calculate the coverage vector $\boldsymbol{r}_i$ and then calculate the review context vector $\boldsymbol{c}_i^X$ by the review attention according to the following formulas:

$$\begin{aligned} \boldsymbol{r}_i &= \sum_{j=1}^{i-1} \boldsymbol{a}_j^X, \\ e_{ij}^X &= (\boldsymbol{v}_X)^\top \tanh(\boldsymbol{W}_X \boldsymbol{h}_j^X + \boldsymbol{W}_{XY} \boldsymbol{h}_i^Y + \boldsymbol{W}_{Xr} \boldsymbol{r}_i), \\ \boldsymbol{a}_i^X &= \mathrm{softmax}(\boldsymbol{e}_i^X), \\ \boldsymbol{c}_i^X &= \sum_{j=1}^{n} a_{ij}^X \boldsymbol{h}_j^X, \end{aligned} \tag{7}$$

where $\boldsymbol{v}_X, \boldsymbol{W}_X, \boldsymbol{W}_{XY}$ and $\boldsymbol{W}_{Xr}$ are learnable parameters and $\boldsymbol{a}_i^X$ is the attention weight at step i.

For the product attention, in addition to hidden state $\boldsymbol{h}_i^Y$, the review context vector $\boldsymbol{c}_i^X$ is also employed in the calculation of product attention, which allows the model to find relevant information in product according to the issue mentioned in review. Concretely, The calculation is made by the following equations:

$$\begin{aligned} e_{ij}^T &= (\boldsymbol{v}_T)^\top \tanh(\boldsymbol{W}_T \boldsymbol{h}_j^T + \boldsymbol{W}_{TX} \boldsymbol{c}_i^X + \boldsymbol{W}_{TY} \boldsymbol{h}_i^Y), \\ \boldsymbol{a}_i^T &= \mathrm{softmax}(\boldsymbol{e}_i^T), \\ \boldsymbol{c}_i^T &= \sum_{j=1}^{k} a_{ij}^T \boldsymbol{h}_j^T, \end{aligned} \tag{8}$$

where $\boldsymbol{v}_T, \boldsymbol{W}_T, \boldsymbol{W}_{TX}$ and $\boldsymbol{W}_{TY}$ are learnable parameters and $\boldsymbol{a}_i^T$ is the attention weight at step i.

To combine multiple sources of information, we use the Gated Multimodal Unit (GMU) [1] to learn fusion transformations and obtain the final context vector $\boldsymbol{c}_i$. The purpose of GMU is to find a feature representation based on a combination of data from different sources. The GMU learns to decide how different sources influence the activation of the unit using multiplicative gates. The equations governing the GMU are as follows:

$$\begin{aligned} \boldsymbol{g}_i^X &= \tanh(\boldsymbol{U}_X \cdot \boldsymbol{c}_i^X), \\ \boldsymbol{g}_i^T &= \tanh(\boldsymbol{U}_T \cdot \boldsymbol{c}_i^T), \\ \boldsymbol{z}_i &= \sigma(\boldsymbol{U}_z \cdot (\boldsymbol{c}_i^X \oplus \boldsymbol{c}_i^T)), \\ \boldsymbol{c}_i &= \boldsymbol{z}_i * \boldsymbol{g}_i^X + (1 - \boldsymbol{z}_i) * \boldsymbol{g}_i^T, \end{aligned} \tag{9}$$

where $\boldsymbol{U}_X, \boldsymbol{U}_T$ and $\boldsymbol{U}_z$ are learnable parameters and $\boldsymbol{z}_i$ is the gate that control the fusion transformations of $\boldsymbol{c}_i^X$ and $\boldsymbol{c}_i^T$.

Copy Mechanism

Through the above attention mechanism, we get the final context vector $\boldsymbol{c}_i$. In order to generate the next word, we need to define a score function. We use the generation score function defined by the following equation:

$$\boldsymbol{s}_i^g = \boldsymbol{W}_g(\boldsymbol{h}_i^Y \oplus \boldsymbol{c}_i) + \boldsymbol{b}_g. \tag{10}$$

where $\boldsymbol{W}_g$ and $\boldsymbol{b}_g$ are learnable parameters and $\boldsymbol{s}_i^g$ is the generation score.

To allow the decoder directly copies the words of review or product information, we also introduce two copying scores: the score of copying from review and the score of copying from product. That is,

$$\begin{aligned} s_{ij}^{cr} &= \tanh((\boldsymbol{h}_j^X)^\top \boldsymbol{W}_{cr}) \cdot (\boldsymbol{h}_i^Y \oplus \boldsymbol{c}_i), \\ \boldsymbol{s}_i^{cr} &= \sum_{j=1}^{n} s_{ij}^{cr} \cdot \mathbf{1}_{\boldsymbol{x}_i}, \end{aligned} \tag{11}$$

and

$$\begin{aligned} s_{ij}^{cp} &= \tanh((\boldsymbol{h}_j^T)^\top \boldsymbol{W}_{cp}) \cdot (\boldsymbol{h}_i^Y \oplus \boldsymbol{c}_i), \\ \boldsymbol{s}_i^{cp} &= \sum_{j=1}^{k} s_{ij}^{cp} \cdot \mathbf{1}_{\boldsymbol{t}_i}, \end{aligned} \tag{12}$$

where $\boldsymbol{W}_{cr}$ and $\boldsymbol{W}_{cp}$ are learnable parameters. $\mathbf{1}_{\boldsymbol{x}_i}$ is a one-hot vector of length V (V is the vocabulary size), among which the values are only with a single 1 in word $\boldsymbol{x}_i$ and all the others 0. The final score function is defined as

$$\boldsymbol{s}_i = \boldsymbol{s}_i^g + \boldsymbol{s}_i^{cr} + \boldsymbol{s}_i^{cp}, \tag{13}$$

and the probability of $\boldsymbol{y}_i$ is

$$P(\boldsymbol{y}_i | \boldsymbol{y}_{1:i-1}, \boldsymbol{X}, \boldsymbol{T}) = (\mathrm{softmax}(\boldsymbol{s}_i))_{\boldsymbol{y}_i}. \tag{14}$$

The maximum-likelihood loss at step t is given by:

$$\mathcal{L}_i^{ml} = -\log(P(\boldsymbol{y}_i | \boldsymbol{y}_{1:i-1}, \boldsymbol{X}, \boldsymbol{T})), \tag{15}$$

and the total loss is:

$$\mathcal{L}^{ml} = \sum_{i=1}^{m} \mathcal{L}_i^{ml}. \tag{16}$$

In training, we optimize the loss $\mathcal{L}^{ml}$ in the dataset.

3.2 Reinforcement Learning

During the training process, we feed the ground-truth output sequences to decoder and train the model by minimizing loss (16), while during inference decoder generates the next word given the previous predicted words. The errors will accumulate as decoder outputs the sequence, which is known as exposure bias problem [20]. Due to this problem, the maximum-likelihood training does not always produce the best results on evaluation metrics such as

	size	length of reviews	length of responses	number of records
Train	80000	39.96	72.67	15.22
Test	10000	39.76	72.64	15.27
Valid	10000	39.68	72.99	15.24

Table 2: Corpora statistics. We also give the average length of reviews and responses, and the average number of records of the product information.

ROUGE and BLEU and usually produces sub-optimal results with respect to these metrics.

In order to address this problem, we try to learn a policy that directly maximizes a specific evaluation metric, rather than minimizing the maximum-likelihood loss. Since the evaluation metric is non-differentiable, the traditional supervised learning methods cannot be used. Specifically, we employ self-critical sequence training (SCST) [21], a reinforcement learning algorithm, to achieve this optimization procedure. In SCST, we produce two output sequences: $\hat{Y}$, which is obtained by greedy decode, and Y^s, which is obtained by sampling from distribution at each decoding step. The reward function $r(Y)$ is defined as the specific metric, and we minimize the reinforcement loss:

$$\mathcal{L}^{rl} = (r(\hat{Y}) - r(Y^s)) \sum_{i=1}^{m} \log(P(\boldsymbol{y}_i^s | \boldsymbol{y}_{1:i-1}^s, \boldsymbol{X}, \boldsymbol{T})) \tag{17}$$

That is, if the sequence Y^s obtains a higher reward than baseline $\hat{Y}$, we will increase the probability of Y^s and decrease if it obtains a lower reward. Optimizing the specific metric encourages the model to focus more on global meanings, rather than on word-level discrepancy.

Therefore, the final loss is given by:

$$\mathcal{L} = \lambda_{rl} \cdot \mathcal{L}^{rl} + (1 - \lambda_{rl}) \cdot \mathcal{L}^{ml}, \tag{18}$$

where λ_{rl} ($0 \leq \lambda_{rl} \leq 1$) is a scaling factor that control the balance between $\mathcal{L}^{rl}$ and $\mathcal{L}^{ml}$.

4 EXPERIMENTS

4.1 The Taobao Dataset

We create the Taobao dataset from taobao.com, the largest online shopping website in China. There are 100K (review, product information, response) triples in the corpus which all belong to the category of Clothes. The product information is collected from the product page in the website and it is organized as a factual table. In the corpus, the average length of reviews is 39 words and the average length of response is 72 words. The average number of records in the table of product information is 15. The detailed corpora statistics is given in Table 2. We will release the dataset after the paper is published.

In our experiments, we use 80% of the data for training, 10% for validation and 10% for testing.

Hyper-parameter	
vocab size	15000
word embedding	128
field embedding	32
position embedding	8
hidden size	256
batch size	16
learning rate	0.02
dropout rate	0.15
decay rate	0.8
gradient clipping	5

Table 3: Hyper-parameters used in all experiments (baseline models and our model).

4.2 Evaluation Metrics

To evaluate our approach, we performed experiments on the Taobao dataset, and used the following evaluation metrics to assess the generation quality:

- **ROUGE**: ROUGE [14] is a widely used automatic evaluation metric in text summarization. The ROUGE score is obtained using the `pyrouge` package[2]. we report ROUGE- 1, ROUGE-2 and ROUGE-L in this paper.
- **METEOR**: METEOR[3] [6] has several features that are not found in other metrics, such as stemming and synonymy matching. It has proved to have good correlation with human judgement.
- **BLEU**: BLEU [18] is widely used in neural machine translation. It measures word overlap between the generated text and the ground-truth. The BLEU score is calculated using the `NLTK` package[4], in which the score is an average of BLEU-1∼4.
- **Distinct**[5]: Distinct metric [13] measures how informative and diverse the generated responses are. Distinct-i represents the ratio of distinct i-gram in responses. We report Distinct-1 and Distinct-2 in this paper.
- **Human Evaluation**: We randomly sampled 100 cases and invited five volunteers to evaluate the generated responses of different models. For each triple (review, product information,response), volunteers are asked to give a score from {0,1,2}, which represents the quality of response. 0 means the response is irrelevant or disfluent with grammatical errors; 1 represents the response is related but not informative enough; and 2 indicates the response is not only related and natural, but also informative and interesting.

[2]https://pypi.org/project/pyrouge/
[3]http://www.cs.cmu.edu/~alavie/METEOR/
[4]https://www.nltk.org
[5]Since this metric is affected by the dataset size (as the size increases, the metric will tend to zero.), we only choose the first 200 cases to compute this metric.

Model	ROUGE-1	ROUGE-2	ROUGE-L	METEOR	BLEU	Distinct-1	Distinct-2
Seq2Seq + Atte	29.93	7.05	21.98	11.95	4.22	5.73	14.49
Pointer-Generator	29.71	6.94	21.76	12.25	4.66	6.25	17.29
Copynet	30.57	7.17	22.37	12.39	4.46	4.89	12.24
Copynet + PI	33.91	11.99	26.35	14.44	10.75	8.66	25.15
Our Model	**35.06**	**13.66**	**27.72**	**15.06**	**12.30**	**8.70**	**25.90**

Table 4: Comparison with previous models using various automatic evaluation metrics. Note that the baseline "Copynet + PI" utilizes product information as well.

Model	2	1	0
Seq2Seq + Atte	68.2%	13.6%	18.2%
Pointer-Generator	68.8%	15.8%	15.4%
Copynet	69.2%	12.2%	18.6%
Copynet + PI	70.0%	16.4%	13.8%
Our Model	72.6%	15.4%	12.0%
Human Performance	82.4%	10.8%	6.8%

Table 5: Human evaluation of the five models. We show the percentage of each score. We also give the human performance in the last row.

4.3 Setups

In this work, we compare our model to the following four baseline models:

- **Seq2Seq + Atte**: "Seq2Seq + Atte" represents the standard Seq2Seq model with attention mechanism. The detailed description can be found in [4].
- **Pointer-Generator**: "Pointer-Generator" is proposed in [22], which augments "Seq2Seq + Atte" via pointing that can copy words from the source text and use coverage mechanism to eliminate repetition.
- **Copynet**: "Copynet" [9] integrates copying mechanism that is similar to the pointing in "Pointer-Generator", but the implementation is different.
- **Copynet + PI**[6]: "Copynet + PI" augments "Copynet" with the product information. The sequence of words $\{t_1, t_2, \ldots, t_k\}$ which represents the table of product information is appended to the input review.

For the four baseline models and our model, we used mini-batch SGD with momentum to train these networks. The momentum was set to 0.9 and the initial learning rate was set at 0.02. After 10 epochs, the learning rate decayed every 4000 steps and the decay rate was 0.8. We employed the dropout technique with 15% dropout rate to avoid overfitting. To cope with the exploding gradient problem, gradient clipping was performed and we clipped the norm of the gradients at 5. The word embeddings were initialized by pre-trained embedding based on word2vec and then fine-tuned during training, but the field embedding and position embedding was randomly initialized. These three embedding size was set to 128, 32, and 8, respectively. For all models, we used two-layers GRU, and the hidden state size was set to 256. We used Jieba[7] as Chinese word segmenter and used a vocabulary of 15K words which was shared by the reviews and responses. These hyper-parameters are summarized in Table 3.

Since RL training is hard to converge from random initialization, we first train our model with the standard maximum likelihood loss (λ_{rl} is set to 0). After 30 epochs, we switch to RL training with λ_{rl} set to 0.99 and learning rate set to 0.0001. We choose the BLEU metric as the reward function. Our code will be made publicly available for reproducibility.

4.4 Automatic Evaluation

We first discuss the experimental results based on automatic evaluation metrics. Table 4 lists the results of four baseline models and our model. According to the results in Table 4, "Pointer-Generator" achieves better performance than "Seq2Seq + Atte" on all metrics except ROUGE and "Copynet" outperforms "Seq2Seq + Atte" on all metrics except Distinct 1~2, demonstrating the effectiveness of incorporating copy or pointing mechanism. Compared with other three baselines, "Copynet + PI" achieves significant improvement on all metrics. For example, it improves ROUGE-L by 3.98, BLEU by 6.29 and Distinct-2 by 12.91, compared with "Copynet". The results further verify our claim that product information is crucial and necessary for generating high-quality response, and the results on Distinct metric show that the diversity is increased greatly by incorporating product information. The last row of Table 4 shows the result of our model, which outperforms all four baseline models. For example, compared with "Copynet + PI", our model further improves ROUGE-L by 1.37, BLEU by 1.55 and Distinct-2 by 0.75, achieving start-of-the-art performance.

4.5 Human Evaluation

Table 5 gives the results of human evaluation. We give the percentage of each score, which is calculated by combining all the annotations together. We also calculated the variance of five volunteers' score. The result is 0.25, which demonstrates the fair inter-human agreements. From Table 5, it is clear that the models of incorporating product information ("Copynet + PI" and our model) generate much more relevant and informative responses (labeled as "2") and

[6]Copynet is the best-performed baseline (on most metrics) of the first three models, so we employ this method for PI integration.

Percent	ROUGE-1	ROUGE-2	ROUGE-L	METEOR	BLEU	Distinct-1	Distinct-2
20%	30.68	8.06	22.88	12.70	5.88	7.43	21.32
40%	31.95	9.41	24.12	13.25	7.53	7.69	21.99
60%	32.92	10.62	25.30	13.84	8.91	8.08	22.51
80%	33.62	11.68	26.16	14.31	10.25	8.51	24.58
100%	**35.06**	**13.66**	**27.72**	**15.06**	**12.30**	**8.70**	**25.90**

Table 6: The results (based on various automatic evaluation metrics) of the proposed model when using various sizes (20%, 40%, 60%, 80%, 100%) of product information.

Model	ROUGE-1	ROUGE-2	ROUGE-L	METEOR	BLEU	Distinct-1	Distinct-2
Our Model	**35.06**	**13.66**	**27.72**	**15.06**	**12.30**	**8.70**	**25.90**
− RL	34.59	13.39	27.27	14.50	12.23	8.23	24.61
− Gate	34.76	13.33	27.45	14.83	11.90	8.19	24.60
− Copy	34.82	13.44	27.64	14.93	11.95	7.92	23.47
− Field	34.72	13.35	27.40	15.02	12.19	8.30	24.80

Table 7: Ablation studies on different components. The results (based on various automatic evaluation metrics) of removing (−) some components are given.

less universal responses (labeled as "1") than other baseline models. Among them, our model achieves the best performance. 72.6% of responses generated by our model are labeled as score 2, improving "Copynet + PI" by 2.6%, and only 12.0% of responses are labeled as score 0. We also evaluated the performance of responses written by human, and the results are shown in the last row of Table 5. Human achieves 82.4% on score 2 (which outperforms our model by 9.8%), 10.8% on score 1, and only 6.8% on score 0. This results indicate that there is still a huge room for improvement and we will continue to improve our model in the future.

4.6 Analysis on Product Information

In the proposed framework, we employed the product information in the review response generation, which is an essential contribution of this study. In this section, we explore the impact of the product information in the model. To investigate the impact of these data, we performed experiments on using various sizes (20%, 40%, 60%, 80%, 100%) of product information. For instance, 20% means that we randomly sample 20% of the whole of product information. The results of the proposed model (based on various automatic evaluation metrics) when using various sizes of product information are shown in Table 6. We can find that, with an increase in the amount of product information, all evaluation metrics gradually grows as well, which indicating the usefulness and importance of the product information in review response generation.

4.7 Ablation Study

To analyze the effect of each component, we conducted ablation studies on components of the proposed model. Table 7 lists the results of the ablation studies based on various automatic evaluation metrics. The performance of full model is listed in the first row of Table 7. We also report the results of removing (−) some components, such as the RL training (−RL in Table 7), the GMU gate mechanism (−Gate), the copy mechanism (−Copy) and the field representation (−Field). The first thing we can observe is that the RL training helps improve the performance on all metrics. For example, ROUGE-L drops to 27.27 from 27.72 and METEOR drops to 14.50 from 15.06 when we removed the RL training. The GMU gate mechanism is also crucial: all evaluation metrics drops if it is removed and replaced with a concatenation operation of $\boldsymbol{c}_i^X$ and $\boldsymbol{c}_i^T$. To test the importance of copy mechanism, we performed an experiment that removed the copy mechanism and we observed a drop, indicating that directly copying from review of product information can be very useful. From the results, we found that the copy mechanism is especially useful in improving the Distinct metrics. Distinct-1 drops to 7.92 from 8.70 and Distinct-2 drops to 23.47 from 25.90 when removing the copy mechanism. Moreover, the using of field representation is necessary for improving performance, which can effectively help the model in incorporating product information.

4.8 Case Study

To compare the generated responses between different models, we give two examples on Figure 5. The case in the left of Figure 5 is a positive review and the case in the right is a negative review. Below the reviews, We show the generated responses of two best baselines ("Copynet" and "Copynet+PI") and our model. Since we used a Chinese dataset, we give the original Chinese text and the English

评论：质量不错，款式好。很显身材，也很上档次。
Review: Good quality and good style. The clothes are figure flattering and also very high grade.

Copynet: 亲，感谢您对我们的支持，您的满意是我们最大的动力，我们会继续努力，为您提供更优质的服务，期待您的再次光临！
Copynet: Dear, thank you for your support, your satisfaction is our greatest motivation, we will continue to work hard to provide you with better service. Looking forward to your next visit!

Copynet + PI: 亲，感谢您对我们的支持与信任，您的满意是我们的最高追求。后期您有任何需要我们帮助的地方，随时欢迎垂询，我们将一如既往地为您效劳！能为您服务是我们莫大的荣幸！伊芙心悦旗舰店，祝亲生活愉快！
Copynet + PI: Dear, thank you for your support and trust, your satisfaction is our highest pursuit. Please feel free to contact us if you need our help. We will continue to help you! It is our great honor to be able to serve you! EVE NY wishes you a happy life!

Our Model: 感谢您的欣赏和喜欢，每一寸面料的裁剪，都伴随着汗水的淋漓。每一件衣服的出品，我们都会倾之付出百分百的努力和用心，希望能给您带来更舒适的穿着体验，希望伊芙心悦的时尚优雅能成为您一生的知己，给予您贴心的呵护。伊芙心悦旗舰店期待您的下次光临！
Our Model: Thank you for your appreciation and love. The cut of every inch of fabric is accompanied by sweat. Every piece of clothing, we will pay 100% effort and care. We hope to bring you a more comfortable wearing experience, and hope that EVE NY's stylish elegance can become your life's confidant and give you intimate pampering. EVE NY looks forward to your next visit!

评论：描述尺码和实际尺码差太多了，害得我买了大号！退换太麻烦，我给别人穿吧！
Review: There is too much difference between the descriptive size and the actual size, which makes me buy a large size! It's too much trouble to return. I will give it to others!

Copynet: 亲，我们的尺码都是标准码的哦，您可以参考下尺码表的哦，您的满意是我们最大的动力，我们会继续努力，为您提供更优质的产品，更优秀的服务。您的满意是我们最大的追求，祝您生活愉快！
Copynet: Dear, our size is the standard size. You can refer to the size chart. Your satisfaction is our greatest motivation. We will continue to work hard to provide you with better products and better service. Your satisfaction is our greatest pursuit, I wish you a happy life!

Copynet + PI: 感谢您选购我们的产品。由于每个人体型不一样，另外款式设计的不同，每个人穿着感觉会不一样的哦。有空常来看看哦~ 祝您购物愉快! [cachecache 旗舰店]
Copynet + PI: Thank you for purchasing our products. Because each body type is different, and the style design is different, everyone will feel differently. Visit my shop when you are free ~ I wish you a happy shopping! [cachecache flagship store]

Our Model: 亲爱的顾客，非常感谢您对 cachecache 旗舰店的关注。因每款的设计理念和面料弹性不同，相对应的尺码上是可能稍有差异的呢，建议您先测量自身基本尺寸，再参考页面尺寸信息进行购买，您也可事先咨询客服，祝您购物愉快！
Our Model: Dear customer, thank you very much for your attention to the cachecache flagship store. Because each style design and fabric elasticity are different, the corresponding size may be slightly different. It is recommended that you first measure your basic size and then refer to the size information for purchase. You can also consult customer service in advance. I wish you a happy shopping!

Figure 5: Case study, comparing the two best baselines with our model. We show the responses of one positive review in the left and the responses of one negative review in the right. Red denotes some product information ("EVE NY" and "cachecache" are *brand* name.) and blue denotes the trivial and universal responses.

translation. From the results, we can see that Copynet without product information tends to generate universal responses whether the review is positive or negative, like "*your satisfaction is our greatest motivation*" and "*we will continue to work hard to provide you with better service*". These universal responses will give users a very bad user experience, especially when users give a negative review. Instead, the models with product information (Copynet + PI and our model) generate more diverse and informative responses. For different reviews and different products, they can give different responses. For example, these responses not only give an explanation, but also mention the shop name (EVE NY and cachecache flagship store), which carry more information and give users more friendly feeling.

5 RELATED WORK

Seq2Seq Framework There has been quite a bit of research on text generation based on sequence to sequence framework. Sutskever et al. [26] first proposed the Seq2Seq framework, which maps sequences to sequences. Then, the attention mechanism [3] is proposed in neural machine translation to enhance the ability of capturing long term dependency, which is also widely used in other text generation tasks and made great success. The copy mechanism (or Copynet) [9] is proposed to incorporate copying into the Seq2Seq learning framework, which enable the model to copy words from the source text. A similar phenomenon is observable in human language communication. The Pointer-Generator [22] is close to the Copynet model, with some small differences. For example, they

have an explicit switch probability to control the probability of generation or copy, while Copynet achieves the similar component through a shared softmax function. Different from Copynet and Pointer-Generator, our model achieves a copy mechanism that not only can copy text from review but also can copy from product information, which is very significant for the review response generation. Recently, some CNN-based [5, 8, 11, 28, 33] have been proposed to replace the recurrent structure in Seq2Seq and have achieved comparable performance while maintaining faster speed than RNN-based methods. For example, The Wavenet [28] and ByteNet [11] model used dilated convolutions to increase its receptive field in the encoder and decoder. In addition, the Transformer [29] model used multi-headed self-attention, which based solely on attention mechanisms, dispensing with recurrence and convolutions. We leave these as a future work.

Generation from Structured Data Generation text from structured data (e.g., a table) is also an important task in NLP. Lebret, Grangier, and Auli [12] proposed the representation of field using field name and position information. They generated text from Wikipedia infobox based a statistical n-gram model with local and global conditioning. Then, Liu et al. [15] proposed a structure-aware Seq2Seq method to model both content and structure of the table by local and global addressing, with a field-gating encoder and a dual attention mechanism. Sha et al. [25] presented an order-planning text generation model to capture the relationship between different fields and used such relationship to make the generated text more fluent and smooth. In our work, the product information is a structured data which is collected as a table. Different from them, the structured data is used as an auxiliary information and we need to model the interaction between the main text (review) and the structured text (product information). Wiseman et al. [32] found that even template based method exceed the performance of some neural models on some metrics in text generation conditioned on a small number of database records. We do not adopt template based method, since we find that it tend to generate universal responses. The work of Li et al. [7] also used product attributes in generation task. Different from us, they used attention-enhanced attribute-to-sequence model to generate product reviews, instead of review responses, for given attribute information. Our work also related to Xing et al. [34] and Wang et al. [30] which both incorporating auxiliary information in text generation. Xing et al. [34] proposed incorporating topic information into a Seq2Seq framework to generate informative and interesting responses for chatbots and Wang et al. [30] incorporated topic information into the convolutional Seq2Seq model in text summarization.

Generation with Reinforcement Learning Reinforcement learning trains an agent to maximize a reward function by interact with the external environment and has been used in many NLP tasks. Recently, many works have explored the use of reinforcement learning in text generation. When the metric that we want to optimize is not differentiable, the traditional supervised learning methods (such as optimizing the maximum-likelihood loss) cannot be used. Therefore, we can use an agent (in reinforcement learning algorithm) to perform discrete actions and obtain a reward. Ranzato et al. [20] first proposed a reinforcement learning method to train RNN-based sequence generation models, which based on the REINFORCE algorithm proposed by Williams [31]. Bahdanau et al. [2] used another reinforcement learning method, named actor-critic, to train neural networks to generate sequences. Rennie et al. [21] proposed self-critical sequence training to optimize the non-differentiable metric in image caption. Compared to previous supervised learning methods, their model leads to significant improvements. Then, Paulus, Xiong, and Socher [19] and Wang et al. [30] applied it to text summarization and demonstrate the superiority of these methods. In addition to being used in optimizing the non-differentiable metrics, reinforcement learning method can also be used in other ways. SeqGAN [35] addressed the differentiation problem in GAN by introducing the policy gradient methods when generating text, which bypasses the generator differentiation problem by directly performing gradient policy update. These works demonstrate the great potential of reinforcement learning method in NLP.

6 CONCLUSION

In this paper, we introduced the task of review response generation in e-commerce platforms, which is valuable for customer service providers, but has not yet been well-studied. To tackle this problem, we proposed a novel deep neural network model based on the Seq2Seq framework, which can incorporate external product information. A gated multi-source attention mechanism and a copy mechanism are utilized to leverage this product information. In addition, we used a reinforcement training technique to reduce the exposure bias problem. Experimental results based on both automatic evaluation metrics and human annotations demonstrated that the performance of the proposed model advances the state-of-the-art methods. A further analysis on each model component validates the effectiveness of our model and the case study demonstrates that our model can generate more informative and diverse responses than the baseline models.

A APPENDICES

A.1 More Detailed Statistics

We investigate the review data from taobao.com, the largest e-commerce website in China. Two product collections were randomly sampled, with 10K products for each. For the former one, the response rate of the negative reviews is above 80%, and the response rate for the latter one is below 20%. Statistics from these collections shows that the product selling volumes of these groups can be quite different, i.e., on average, 3545.79 items are sold per-product for high response rate group, and 3122.08 for low response rate group. In another experiment, we randomly sampled 500K products. For all the associated reviews, only 2.98% of the reviews and only 5.68% of the negative reviews have received the responses from sellers.

ABSTRACT

Building height estimation is important in many applications such as 3D city reconstruction, urban planning, and navigation. Recently, a new building height estimation method using street scene images and 2D maps was proposed. This method is more scalable than traditional methods that use high-resolution optical data, LiDAR data, or RADAR data which are expensive to obtain. The method needs to detect building rooflines and then compute building height via the pinhole camera model. We observe that this method has limitations in handling complex street scene images in which buildings overlap with each other and the rooflines are difficult to locate. We propose CBHE, a building height estimation algorithm considering both building corners and rooflines. CBHE first obtains building corner and roofline candidates in street scene images based on building footprints from 2D maps and the camera parameters. Then, we use a deep neural network named BuildingNet to classify and filter corner and roofline candidates. Based on the valid corners and rooflines from BuildingNet, CBHE computes building height via the pinhole camera model. Experimental results show that the proposed BuildingNet yields a higher accuracy on building corner and roofline candidate filtering compared with the state-of-the-art open set classifiers. Meanwhile, CBHE outperforms the baseline algorithm by over 10% in building height estimation accuracy.

1 INTRODUCTION

Building height plays an essential role in many applications, such as 3D city reconstruction [3, 30], urban planning [29], navigation [14, 32], and geographic knowledge bases [50]. For example, in navigation, knowing the height of buildings helps identify those standing out in a city block, which can then be used to facilitate navigation by generating instructions such as "turn left before an 18 meters high (five-story) building".

Previous studies for building height estimation are mainly based on high-resolution optical data [18, 48], synthetic aperture radar (SAR) images [7, 41], and Light Detection and Ranging (LiDAR) data [33, 44]. Such data, however, are expensive to obtain and hence the above approach is difficult to apply at a large scale, e.g., to all the buildings on earth. Moreover, such data is usually proprietary and not available to the public and research community. Recently, street scene images (or together with 2D maps) have been used for building height estimation [11, 46], which can be easily obtained at large scale (e.g., via open source mapping applications such as Google Street View [2] and OpenStreetMap [16]). Estimating building height via street scene images relies on accurate detection of building rooflines from the images, which then enables building height computation using camera projection. However, existing methods for roofline detection check the roofline segments only, which may be confused with overlapping buildings. As shown in Fig. 1, the roofline of building B may be detected as the roofline of building A because the rooflines of different buildings may be in parallel with each other, and the buildings have similar colors and positions in the street scene images.

In this paper, we present a novel algorithm named Corner-based Height Estimation (**CBHE**) to estimate building height for *complex street scene images* (with blocking problem from other buildings and trees). Our key idea to handle overlapping buildings is to detect not only the rooflines but also building corners. We obtain coordinates of building corners from building footprints in a 2D map (e.g., OpenStreetMap). We then map the corner coordinates into the

street scene image to detect building corners in the image. Corners of different buildings do not share the same coordinates, and it is easier to associate them with different buildings, as shown in Fig. 1.

CBHE works as follows. It starts with an upper-bound estimation of the height of a building, which is computed as the maximum height that can be captured by the camera. It then tries to locate a line (i.e., a roofline candidate) at this height and repeats this process by iteratively reducing the height estimation. Following a similar procedure, CBHE also locates a set of building corner candidates. Next, CBHE filters the roofline candidates with the help of the corner candidates (i.e., a roofline candidate needs to be connected to a corner of the same building to be a true roofline). When the true roofline is identified, CBHE uses the pinhole camera model to compute the building height.

In the process above, when locating the roofline and corner candidates, we fetch two sets of image segments that may contain building rooflines or corners, respectively. To filter each set of objects and identify the true roofline and corner images, we propose a deep neural network model named **BuildingNet**. The key idea of BuildingNet is as follows. Building corner has a limited number of patterns (e.g., " ", " ", " ", " "), while non-corner images may have any pattern. The same applies to the building rooflines. Thus, we model building corner (roofline) identification as an *open set* image classification problem, where each corner (roofline) pattern forms a class, while non-corner (non-roofline) images should be differentiated from them when building the classifier. To do so, BuildingNet learns embeddings of the input images, which minimize the intra-class distance and maximize the inter-class distance, and then differentiates different classes using a Support Vector Classification (SVC) model on the learned embeddings. When a new image comes, the trained SVC model will tell whether it falls into any corner (roofline) classes. If the image does not fall into any corner (roofline) classes, it is a non-corner image and can be safely discarded.

When estimating building height via the pinhole camera model, the result highly relies on the accuracy of the camera location due to GPS errors. Therefore, CBHE calibrates the camera location before roofline detection. To calibrate the camera location, CBHE detects candidate regions of all building corners in street scene images by matching buildings in street scene images with their footprints in 2D maps based on the imprecise camera location from GPS. Then, it uses BuildingNet to classify the corner candidates and remove those images classified as non-corner. From the remaining corner after the classification through BuildingNet, CBHE selects two corners with the highest score (detailed in Section 4.2) to calibrate the camera location via the pinhole camera model. We summarize our contributions as follows:

- We model building corner and roofline detection as an open set classification problem and propose a novel deep neural network named BuildingNet to solve it. BuildingNet learns embeddings of the input images, which minimize the intra-class distance and maximize the inter-class distance. Experimental results show that BuildingNet achieves higher accuracy on building corner and roofline identification compared with the state-of-the-art open set classifiers.
- We propose a corner-based building height estimation algorithm named CBHE, which uses an entropy-based algorithm to select the roofline among all candidates from BuildingNet. The entropy-based algorithm considers both building corner and roofline features and yields higher robustness for the overlapping problem in complex street scene images. Experiments on real-world datasets show that CBHE outperforms the baseline method by over 10% regarding the estimation error within two meters.
- We propose a camera location calibration method with an analytical solution when given the locations of two building corners in a 2D map, which means highly accurate result can be guaranteed with the valid building corners from BuildingNet.

We organize the rest of this paper as follows. We review related work in Section 2 and give an overview of CBHE in Section 3. The BuildingNet and entropy-based ranking algorithm are presented in Section 4, and the building height estimation method is detailed in Section 5. We report experimental results in Section 6 and conclude the paper in Section 7.

2 RELATED WORK

In this section, we review studies on camera location calibration and building heigh estimation. We also detail our baseline method [46].

2.1 Camera Location calibration

Camera location calibration aims to refine the camera location of the taken images, given rough camera position information from GPS devices or image localization [1, 25].

Existing work uses 2.5D maps (2D maps with height information) to calibrate camera locations. Arth et al. [4] present a mobile device localization method that calibrates the camera location by matching building facades in street scene images with their footprints in 2.5D maps. Armagan et al. [3] train a *convolutional neural network* (CNN) to predict the camera location based on a semantic segmentation of the building facades in input images. Their method iteratively applies CNN to compute the camera's position and orientation until it converges to a location that yields the best match between building facades and 2.5D maps. Camera location calibration using 2.5D maps can produce good results. The hurdle is the requirement of building height information for generating 2.5D maps, which may not be available for every building. Chu et al. [9] extract the position features of *building corner lines* (the vertical line of a corner) and then find the camera location and orientation by matching the extracted position features with building footprints in 2D maps. However, their method cannot handle buildings overlapping with each other or having non-uniform patterns on their facades.

2.2 Building Height Estimation

Building height estimation has been studied using geographical data such as high-resolution images, *synthetic aperture radar* (SAR) images, and *Light Detection and Ranging* (LiDAR) data.

Studies [18, 23, 31, 39, 48] based on high-resolution images (such as satellite or optical stereo images) estimate building height via methods such as elevation comparison and shadow detection, which may be impacted by lighting and weather condition when the images are taken. Similarly, methods based on height estimation is synthetic aperture radar (SAR) images [7, 37, 41] are mainly based

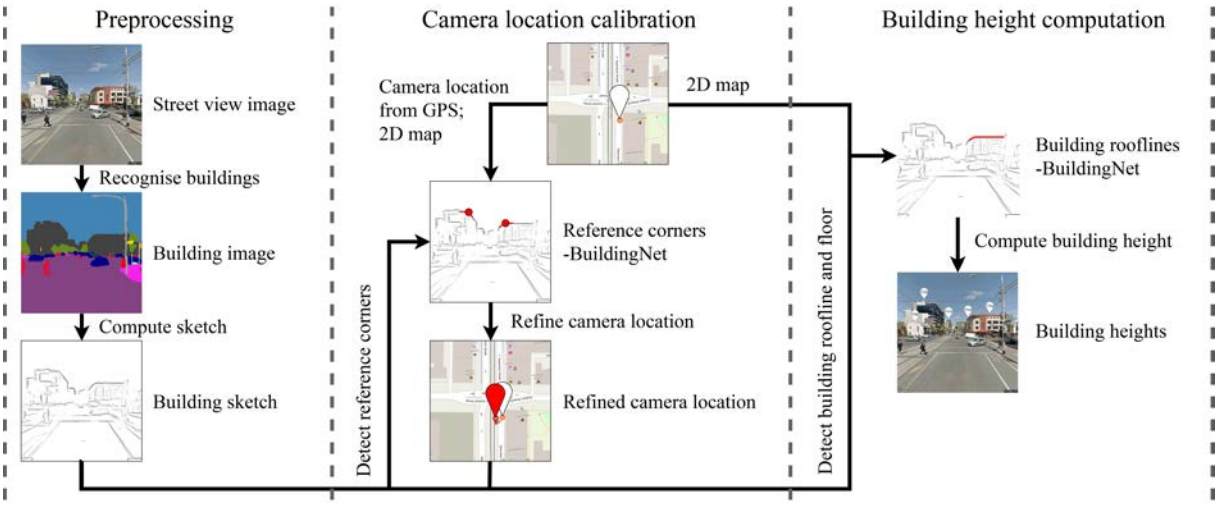

Figure 2: Solution overview

on shadow or layover analysis. Methods based on aerial images and aerial LiDAR data [33, 36] usually segment, cluster and then reconstruct building rooftop planar patches according to predefined geometric structures or shapes [48]. LiDAR data is expensive to analysis and has a limited operating altitude because the pulses are only effective between 500 and 2,000 meters [44]. A common limitation shared by the methods above is that the data that they use are expensive to collect, which significantly constraints the scalability of these methods.

Method based on street scene image and 2D map. Yuan and Cheriyadat propose a method for building height estimation uses street scene images facilitated by 2D maps [46]. Street scene images are widely available from Google Street View [2], Bing Street-Side [21] and Baidu Map [5], which makes building height estimation based on such data easier to scale. Yuan and Cheriyadat's method has four main steps: (i) Match buildings in a street scene image with their footprints in a 2D map via camera projection based on the camera location that comes with the image. Here, the camera location may be imprecise due to GPS error [15, 47]. (ii) Calibrate the camera location via camera projection with the extracted building corner lines from street scene images. (iii) Re-match buildings from a 2D map with those in the street scene image based on the calibrated camera location, and then detect building rooflines through edge detection methods. (iv) Compute building height via camera projection with camera parameters, calibrated camera location, the height of building rooflines in the street scene image, and the building footprint in the 2D map.

Our proposed CBHE differs from Yuan and Cheriyadat's method in the following two aspects: (A) In Step (ii) of their method, they calibrate camera location by matching building corner lines in the street scene image with building footprints in the 2D map. Such a method cannot handle images in urban areas where the corner lines of different buildings are too close to be differentiated, or the buildings have non-uniform patterns/colors on their facades which makes corner lines difficult to recognize. CBHE uses building corners instead of corner lines, which puts more restriction on the references for camera location calibration, and thus yields more accurate results. (B) In Step (iv) of their method, they use a local spectral histogram representation [26] as the edge indicator to capture building rooflines, which can be ineffective when buildings overlap with each other. CBHE uses the proposed deep neural network named BuildingNet to learn a latent representation of building rooflines, which has been shown to be more accurate in the experiments.

3 OVERVIEW OF CBHE

We present the overall procedure of our proposed CBHE in this section. We also briefly present the process of camera projection, which forms the theoretical foundation of building height estimation using street scene images.

3.1 Solution Overview

We assume a given street scene image of buildings that comes with geo-coordinates and angle of the camera by which the image is taken. Here, the geo-coordinates may be imprecise due to GPS errors. Google Street View images are examples of such images, and we aim to compute the height of each building in the image. As illustrated in Fig. 2, CBHE contains three stages:

- **Stage 1 – Preprocessing:** In the first stage, we pre-process the input image by recognizing the buildings and computing their sketches. There are many methods for these purposes. We use two existing models RefineNet [24] and Structured Forest [12] to identify the buildings and compute their sketches, respectively. After this step, the input image will be converted into a grayscale image with each pixel valued from 0 to 255 that contains building sketches, which enables identifying rooflines and computing the height of the building via camera projection.
- **Stage 2 – Camera location calibration:** Before computing building height by camera projection, in the second stage, we calibrate the camera location. This is necessary because a precise camera location is required in the camera projection, while the geo-coordinates that come with street scene images are imprecise due to GPS errors. To calibrate the camera location, we first detect building corner candidates in street scene images according

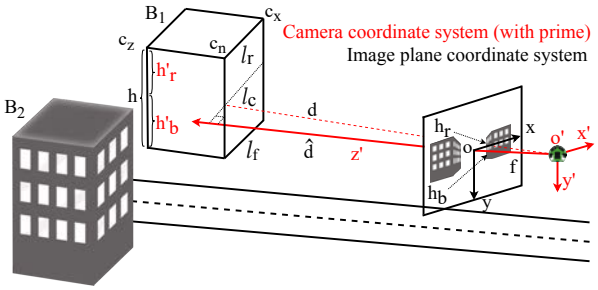

Figure 3: Geometric variables in the camera and the image coordinate systems (best view in color).

to their footprints in 2D maps and their relative position to the camera. Then, by comparing the locations and the projected positions of building corners (two corners), we calibrate the camera location via camera projection. In this stage, we propose a deep neural network named BuildingNet to determine whether an image segment contains a valid building corner. The BuildingNet model and the process of selecting two building corners for the calibration are detailed in Section 4.

- **Stage 3 – Building height computation:** In this stage, we obtain the roofline candidates of each building via weighted Hough transform and filter out those invalid roofline candidates via BuildingNet. Then we rank all valid rooflines by an entropy-based ranking algorithm considering both corner and roofline features and select the best one for computing building height via camera projection. The detailed process is provided in Section 5.

Since Stage 1 is relatively straightforward, we focus on Stages 2 and 3 in the following Sections 4 and 5, respectively. Before diving into these two stages, we briefly discuss the idea of camera projection and present the frequently used symbols.

3.2 Camera projection

We use Fig. 3 to illustrate the idea of camera projection and the corresponding symbols. In this figure, there are two coordinate systems, i.e., the camera coordinate system and the image plane coordinate system. Specifically, $\{o', x', y', z'\}$ represent the camera coordinate system, where origin o' represents the location of the camera. The camera is set horizontal to the sea level, which means that plane $x'z'$ is vertical to the building facades while the y'-axis is horizontal to the building facades. We use $\{o, x, y\}$ to represent the image plane coordinate system, where origin o is the center of the image, and plane xy is parallel to plane $x'y'$.

In Fig. 3, there are two buildings B_1 and B_2 that have been projected onto the image. For each building, we use l_r, l_f, and l_c to represent the roofline, the floor, and the line on the building projected to the x-axis (center line) of the image plane xy. Corners c_n, c_x, and c_z are the corner nearest to the camera, the corner farthest to the y-axis of the image plane when projected to the image plane (along the x-axis), and the corner closest to the y-axis of the image plane when projected to the image plane (along the z-axis), respectively. The height h of the building is the sum of the distance between l_r and l_c and the distance between l_c and l_b. These two distances are denoted as h'_r and h'_b, and the projected length of h'_r in the image plane xy is denoted by h_r. Since the camera is set horizontal to the sea level, the height of h'_b is the same as the height of the car or human beings who captured the street scene image, which can be regarded as a constant.

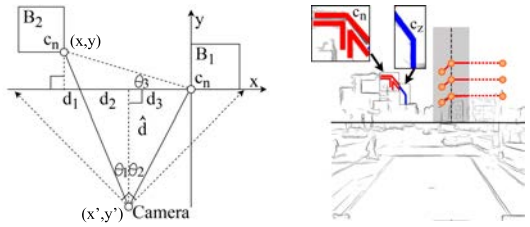
Table 1: Frequently used symbols

Notation	Description
h_r	the height of a building above images' center line
h_b	the height of a building below images' center line
d	the distance from the camera to c_n of a building
$\hat{d}$	the projected length of d onto the z-axis
f	the focal length of the camera
l_r	a building roofline
c_n	the corner nearest to the camera
c_x	the corner farthest to o in the image plane
c_z	the corner closest to o in the image plane

Let d be the distance from the camera o' to corner c_n, $\hat{d}$ be the projected length of d onto the z'-axis, and f be the focal length of the camera (i.e., the distance between the image center o and the camera center o'). Based on the *pinhole camera projection*, the height of a building can be computed as follows:

$$h = h'_r + h'_b = h_r \cdot \hat{d}/f + h'_b \tag{1}$$

In this equation, the focal length f comes with the input image as its metadata. The distance $\hat{d}$ is computed based on the geo-coordinates of the building and the camera, as well as the orientation of the camera. The geo-coordinates of the building are obtained from an open-sourced digital map, OpenStreetMap, while the geo-coordinates and orientation of the camera come with the input image from Google Street View. Due to GPS errors, we describe how to calibrate the location of the camera in Section 4. The height h_r is computed based on the position of the roofline l_r which is discussed in Section 5. Table 1 summarizes the symbols that are frequently used in the rest of the discussion.



4 CAMERA LOCATION CALIBRATION

When applying camera projection for building height estimation, we need the distance $\hat{d}$ between the building and the camera. Computing this distance is based on the locations of both the building and the camera. Due to the error of GPS, we calibrate the camera location in this section.

4.1 Key Idea

We use two building corners in the street scene image with known real-world locations for camera location calibration. To illustrate the process, we project Fig. 3 to a 2D plane, as shown in Fig. 4a, and assume that corner c_n of building B_1 and building B_2 are two reference corners.

We consider a coordinate system with corner c_n of building B_1 as the origin, and the camera orientation as the y-axis. Let θ_1 and θ_2 be the angles of corner c_n of B_1 and corner c_n of B_2 from the orientation of the camera, respectively. Then the ratio of d_2/d_3 is determined by the position of these two reference corners in the image. θ_3 represents the angle between the line connecting corner c_n of B_1 and corner c_n of B_2 and x-axis, and it can be computed

(a) (b)

Figure 4: (a) geometric variables of Fig. 3 in plan view. (b) the left building shows the formation of c_n and c_z, while the right building illustrates how to find corner candidates.

according to the camera's orientation and the relative locations of the two reference corners in 2D maps. Therefore, we can compute the coordinates (x, y) of corner c_n of building B_2 in the coordinate system. With θ_1, θ_2, and the coordinate (x, y), we compute the y coordinate of the camera as follows:

$$y' = \frac{x - y \cdot tan\theta_1}{tan\theta_1 + tan\theta_2} \tag{2}$$

Since the x coordinate of the camera is equals to $y' \cdot tan\theta_2$, we obtain the relative position of the camera to the corner c_n of building B_1. Thus, camera location calibration becomes the problem of matching two building corners with their positions in the image.

The real-world location of the building corners can be obtained from 2D maps, and we need to locate their corresponding positions in the street scene image based on the (inaccurate) geo-coordinates of the camera. For a pinhole camera, matching a 3D point in the real world to a 2D point in the image is determined by a 3×4 camera projection matrix as follows:

$$\alpha \cdot p = [I|0_3] \begin{bmatrix} R & t \\ 0_3^T & 1 \end{bmatrix} \begin{bmatrix} p' \\ 1 \end{bmatrix}, \; I = \begin{bmatrix} f & 0 & 0 \\ 0 & f & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{3}$$

where a real-world point $p' = (x', y', z')^T$ can be projected to its position $p = (x, y, 1)^T$ in the image plane; α is the parameter that transfers pixel scale to millimeter scale [28]; $[I|0_3]$ is the camera matrix determined by focal length f; R is the camera rotation matrix, while t is a 3-dimensional translation vector that describes the transformation from the real-world coordinates to the camera coordinates.

Since the image geo-coordinates may be inaccurate, we can only compute rough locations of the building corners. Based on the rough position of each corner, we then iteratively assume a height h_r for each building to obtain the gradient of its rooflines, as shown in Fig. 4b. We use 120×120 sub-images with the horizontal position and the assumed height of the corner as their center for building corner detection. A building corner consists of two rooflines or a roofline with a building corner line, as shown in Fig. 4b. For each building, we only consider their corners c_n and c_z. There are three types of formation for corner c_n as illustrated by the red lines on the left-hand side building in Fig. 4b, and there is one type of formation for corner c_z as illustrated by the blue lines. Based on the detected building corner candidates, we use BuildingNet described Section 4.2 to filter out non-corner image segments, and then select the two reference corners which is discussed in Section 4.2.

We assume the camera location error from Google Street View API to be less than three meters due to its camera location optimization [20]. If the camera location we compute is more than three meters away from the one provided by Google Street View API, we use the camera location from Google Street View API directly. We further improve the estimation accuracy by a multi-sampling strategy, which uses the median height among results from different images of the same building taken at different distances.

4.2 BuildingNet

We formulate building corner detection as an object classification problem, which first detects candidate corner regions for a specific building by a heuristic method, and then classifies them into different types of corners or non-corners.

We classify images that may contain building corners into five classes. The first four classes correspond to images containing one of the four types of building corners, i.e., corner c_n, c_z of the left-hand side buildings, and corner c_n, c_z of the right-hand side buildings (" ", " ", " ", " "). The last class corresponds to non-corner images which may contain any pattern except the above four types of corners (e.g., they could contain trees, lamps or power lines), and should be filtered out. Such a classification problem is an *open set* problem in the sense that the non-corner images do not have a unified pattern and will encounter unseen patterns. To solve this classification problem, we build a classifier that only requires samples of the first four classes in the training stage (can also take advantage of non-corner images), while can handle all five classes in the testing stage. To enable such a classifier, we first propose the *BuildingNet* model based on LeNet 5 [22] and triplet loss functions, which learns embeddings that map potential corner region image segments to a Euclidean space where the embeddings have small intra-class distances and large inter-class distances.

4.2.1 Triplet Relative Loss Function. As shown in Fig 5, an input of BuildingNet contains three images. Two of them (x^p and x^t) contain the same type of corner, and we name them the target (x^t) and positive (x^p), respectively. The other image x^n contains another type of corners (or a non-corner image if available), and we name it negative. BuildingNet trains its inputs to d-dimensional embeddings based on a *triplet relative loss* function inspired by Triplet-Center Loss and FaceNet [17, 35, 40, 43], which minimizes the distances within the same type of corners, and maximizes the distances between different types of corners as follows:

$$l = \sum_{i=1}^{N} \alpha \cdot ||f(x_i^t) - f(x_i^p)||_2^2 + (1 - \alpha) \cdot \frac{||f(x_i^t) - f(x_i^p)||_2^2}{||f(x_i^t) - f(x_i^n)||_2^2} \tag{4}$$

where $\alpha \in [0, 1]$ is the weight of intra-class distance in the d-dimensional Euclidean space; $(1 - \alpha)$ is the weight of the ratio between intra-classes distance and inter-class distance, which aims to separate different classes in the d-dimensional Euclidean space; N is the cardinality of all input triplets. Function f computes the d-dimensional embedding of an input image, and we normalize it to $||f(x)||_2^2 = 1$. Different from existing loss function based on triplet selection [35, 42], *triplet relative loss* function can minimise the intra-class distance and maximize the inter-class distance by means of their relative distance.

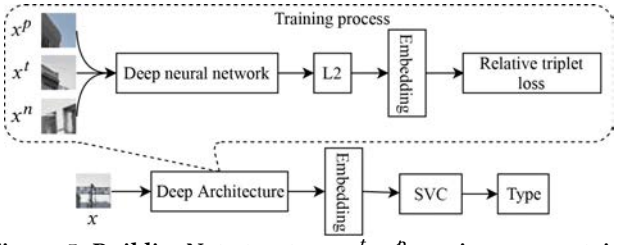


Figure 5: BuildingNet structure. x^t, x^p are images containing the same corner type. x^n is an image containing another corner type or non-corner, x is a testing image.

4.2.2 Hard Triplet Selection. Generating all possible image triplets for each batch during the training process will result in a large amount of unnecessary training data (e.g., x^t and x^p are too similar, while x^n is way different). It is crucial to select triplets that contribute more to the training phase. In BuildingNet, we accelerate convergence by assigning a higher selection probability to triplets that may contribute more to the training process. The probability of selecting a negative image x_i^n to form a training triplet is:

$$p(x_i^n) = \frac{e^{||f(x_i^n)-f(x^t)||_2^2-m}}{\sum_{i=1}^{k} e^{||f(x_i^n)-f(x^t)||_2^2-m}},\ i=[1,k]$$
$$m = min(||f(x_i^n)-f(x^t)||_2^2 - ||f(x^t)-f(x^p)||_2^2),\ i=[1,k] \tag{5}$$

Here, k is the total number of negative images in a batch. After randomly choosing x^t and x^p for a triplet, we compute the Euclidean distance between x^t and x^p, as well as the distances between x^t and the k negative images x^n in the batch. Let m be the minimum Euclidean distance between x^t and any x^n, which can be positive or negative. Then, the negative image x_i^n similar to x^t will have a higher probability to be selected.

After the training process, we obtain a d-dimensional embedding for each input image. We then learn a support vector classifier [8] based on these embeddings for corner region image classification.

4.3 Entropy-based Ranking

BuildingNet can filter out non-corner images. Among the remaining corner candidates, we select the two corners with the highest score as the reference corners. Reference corner selection relies on multiple factors: the length and edgeness (detailed in Section 5) of the lines forming the corner, the number of other corner candidates (c_n, c_x, and c_z) of the same building with the same assumed height, and the position of the corner in the image. We take the position of the corner into consideration because, empirically, corners close to one quarter or three-quarters (horizontally) of the image yield more accurate matching between their positions in the image and their footprints in 2D maps. We also consider their real-world locations because a corner close to the camera will be clearer and has higher accuracy when matching them to their footprints in 2D maps. Therefore, we define the score of each corner candidate as:

$$[s_{c_1},...,s_{c_k}]' = \begin{bmatrix} \lambda,\omega,\tau,\rho,d|c_1 \\ \vdots \\ \lambda,\omega,\tau,\rho,d|c_k \end{bmatrix} \cdot \begin{bmatrix} w_\lambda \\ \vdots \\ w_d \end{bmatrix} \tag{6}$$

where k is the number of corner candidates from all buildings; c_i is the ith corner candidate; s_{c_i} is the score of the ith corner candidate; λ is the detected length of the two lines that form a corner, while ω is the sum of the edgeness of the two lines; τ is the number of other corner candidates of the same building with the same assumed height; ρ is the minimum distance from the corner to a quarter or three-quarters of the image, and d is the distance from the corner to the camera; w_λ, w_ω, w_τ, w_ρ, w_d are the weight of these parameters. Parameters λ, ω, τ and ρ correlate with the score positively, while parameter d correlates with the score negatively.

We use an entropy-based ranking method to compute the weights of parameters $(w_\lambda, ..., w_d)^T$. Shannon entropy is a commonly used measurement of uncertainty in information theory [38]. The main idea of the entropy-based ranking algorithm is to compute the objective weights of different parameters according to their data distribution. If the samples of a parameter vary greatly, the parameter should be considered as a more important feature and thus should be given a larger weight.

For building corner classification, there are $n = 5$ parameters and $m = k$ samples. We denote the decision matrix as r, where r_{ij} is the value of the ith sample under the jth parameter. Before applying the entropy-based ranking algorithm, we pre-process these parameters by Min-max scaling as follows:

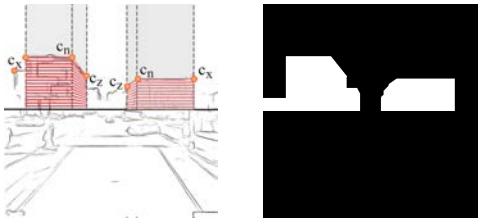
$$r_{ij} = \begin{cases} (r_{ij} - \min_j(r_{ij}))/(\max_j(r_{ij}) - \min_j(r_{ij})), & \text{iff positive} \\ (r_{ij} - \min_j(r_{ij}))/(\max_j(r_{ij}) - \min_j(r_{ij})) + 1, & \text{iff negative} \end{cases} \tag{7}$$

where positive and negative mean that the jth parameter is positively/negatively correlated with the value of r. After Min-max scaling, the entropy of each parameter based on the normalized decision matrix r' is defined as:

$$e_j = -ln(m)^{-1} \cdot \sum_{j=1}^{m} r'_{ij} \cdot ln(r'_{ij}),\ r'_{ij} = r_{ij} / \sum_{j=1}^{m} r_{ij} \tag{8}$$

where r' is the standardized r. Based on the entropy of each parameter, the weight of each parameter is computed by:

$$w_j = (1 - e_j)/(n - \sum_{j=1}^{m} e_j),\ j=[1,n] \tag{9}$$



After computing the weight of each parameter, we apply them to all corner candidates and rank all the candidates by their scores to obtain the best two as the reference corners.

5 ROOFLINE DETECTION

Building height estimation requires detecting the roofline of each building. In this section, we present our method for roofline candidate detection in Section 5.1, and our method for the true roofline selection in Section 5.2. We further present a strategy for handling tall building (over 100 meters) in Section 5.3.

5.1 Roofline Candidate Detection

We consider the rooflines from corner c_n to the corner next to c_n, along the positive direction of the x'-axis in the camera coordinate system, and the one from corner c_z to the corner next to corner c_z

(a) (b)

Figure 6: (a) the heuristic method for roofline candidate detection. (b) the mask of detected buildings.

along the negative direction of the z'-axis in the camera coordinate system. The corner between corner c_z and corner c_x is corner c_n if they are adjacent to each other, as shown in Fig. 3, and we take this situation to simplify the explanation.

Similar to corner candidate detection, as shown in Fig. 6a, we find all roofline candidates of each building by a heuristic method, which projects the rooflines of each building according to its relative location to the camera in the real world, together with the camera's parameters. To do so, we first assume h_r of a building to be the maximum height that can be captured, which means that at least a roof corner (c_n, c_x, and c_z) is visible in the image. If corner c_n is visible, the maximum height computed via camera projection is:

$$h_r = \hat{d} \cdot (h_I / 2f) \tag{10}$$

where h_I is the height of the street scene image; $\hat{d}$ is the distance from corner c_n to the camera projected to the z'-axis of the camera coordinate system. If corner c_n is invisible, we use c_z as the reference corner when computing the maximum height of a building in the same way. With the maximum height of the building, we compute the position of corner c_n, c_x, and c_z in the image. We then apply Hough transform to the input edge map in Fig. 2 to detect roofline candidates, and the roofline candidates from c_n to c_x need to match the computed position of c_n and c_x. Similarly, the roofline candidates from c_n to c_z need to match the computed position of c_n and c_z. Instead of using the typical Hough transform for line detection, which takes binarized images as the input, we sum the value of all pixels valued from 0 to 255 within a line as its weight, and name the summed value as the **edgeness** of a roofline candidate, which reflects the visibility of a line in the edge map.

We iteratively reduce the assumed height with a step length of 0.5 meters until $h_r = 0$ and collect all candidate rooflines. Similar to reference corner detection, we formulate the true building roofline detection as an open set classification and ranking problem.

5.2 Roofline Classification and Ranking

There are three types of rooflines: (i) Roofline from c_n to c_x; (ii) Roofline from c_n to c_z of the left hand side buildings; (iii) Roofline from c_n to c_z of the right hand side buildings, as shown in Fig. 4c. We use BuildingNet to filter these candidates and find the true roofline, which is similar to the corner candidate validation process in Section 4.2. Based on the valid roofline candidates from BuildingNet, we weight each roofline candidate l_r by its detected length λ, edgeness ω, and the number of corners τ with the same assumed

Algorithm 1: Roofline pre-processing

Inputs: buildings B, tree area T, edge map E;
Output: updated buildings B;
M = null;
forall *building b in B* **do**
  // buildings are ordered by whether they have a detectable corner, and then their distance to the camera;
  forall *roofline* l_r *in* $b.L_r$ **do**
    // traverse all roofline candidates of building b;
    forall *pixel* $p \in l_r$ **do**
      if $M(p)$ **then**
        l_r.delete(p);
    $l_{r(ini)} = l_r$;
    forall *pixel* p *in* l_r *and* $p \notin l_r$ *and* $!M(p)$ **do**
      if $connected(p, l_r)$ *and* $T(p)$ **then**
        l_r.add(p);
    // update the length and edgeness of l_r;
    $\lambda_{l_r} = len(l_r)$;
    $\omega_{l_r} = E(l_{r(ini)}) * len(l_r)/len(l_{r(ini)})$;

height of the same building. We rank all roofline candidates via the entropy-based ranking algorithm in Section 4.3, as follows:

$$[s_{l_{r_1}}, ..., s_{l_{r_k}}]' = \begin{bmatrix} \lambda, \omega, \tau | l_{r_1} \\ \vdots \\ \lambda, \omega, \tau | l_{r_k} \end{bmatrix} \cdot \begin{bmatrix} w_\lambda | l_r \\ \vdots \\ w_\tau | l_r \end{bmatrix} \tag{11}$$

where k is the number of roofline candidates for a specific roofline; l_{r_i} is the ith roofline candidate; $s_{l_{r_1}}$ is the score of the ith roofline candidate. w_λ, w_ω and w_τ are the weight of these parameters based on all candidates of a specific roofline of a building, and all three parameters are positively correlated with the score s. The value of τ depends on the number of corners (c_n, c_x, and c_z) with the same assumed height as the roofline candidate, and its value is {0, 1, 2, 3}. We discussed how to detect references corners in Section 4.2, and the difference in detecting the corners of a specific building is that we do not consider ρ and d in Equation 6 and all corner candidates here are those of a specific building corner.

Different from building corners, which can only be visible or invisible, rooflines can also be partially blocked by other objects (trees in particular). Therefore, before we apply the ranking algorithm, we pre-process the length λ and edgeness ω which are affected by the blocking via Algorithm 1 as follows:

When estimating building height, we first separate buildings into two classes: (i) with at least one valid corner; (ii) without any valid corner. Then, we process buildings in class (i) according to their distance to the camera. After all the buildings in class (i) have been processed, we process the buildings in class (ii) according to their distance to the camera. After we obtain the height of a building, we mark the scope of the building in the street scene image, as shown in Fig. 6b (i.e., height has been obtained).

After detecting the roofline candidates of a building, we refine the λ_{l_r} of each roofline candidate using the following equation:

(a) (b)

Figure 7: (a) an image with an upward-looking view. (b) the corresponding image with a horizontal view.

$$\lambda_{l_r} = \lambda_{l_r(ini)} - \sum_{p \in l_r} M(p) + \sum_{p\ in\ l_r} T(p) \tag{12}$$

where $\lambda_{l_r(ini)}$ is the detected length of a roofline candidate l_r. $M(p)$ checks whether a pixel p within a roofline belongs to a building's scope in the street scene image that has been processed and closer to the camera, or within another building's roofline that has been processed but farther to the camera. We remove pixel p from a roofline if $M(p)$ is true. $T(p)$ checks whether a pixel p, which is in the extended line of l_r but within the projected scope of the roofline, has been blocked by trees. If there do exist these pixels and they connect to the detected roofline segment, we add them to the roofline. Accordingly, we update the edgeness of a roofline as:

$$\omega_{l_r} = (1 + \lambda_{l_r(ini)}/\lambda_{l_r}) \cdot \sum_{p \in l_r} E(p) \cdot (1 - M(p)) \tag{13}$$

where E is the input edge map of the original image, $\lambda_{l_r(ini)}$ and λ_{l_r} are the initial and prolonged length of the roofline, respectively.

5.3 Tall Building Preprocessing

Height estimation for tall buildings (over 100 meters) requires the camera to be placed far away from the buildings with an upward-looking view to capture the building roof. For images with an upward-looking view, all building corner lines will become slanted. Typically, we take the upward-looking view as 25 degrees as an example to show the strategy that we use for handling tall buildings.

We first compute a plane-to-plane homography [51], which maps an image with an upward-looking view to the corresponding image with a horizontal view. Here, we use the homogeneous estimation method [10], which solves a 3×3 homogeneous matrix h that matches a point in an upward-looking image (Fig. 7a) to a horizontal-view image (Fig. 7b) using the Equation 14:

$$A \cdot h = \begin{bmatrix} x_1 & y_1 & 1 & 0 & 0 & 0 & -x_1X_1 & -y_1Y_1 & X1 \\ 0 & 0 & 0 & x_1 & y_1 & 1 & -x_1X_1 & -y_1Y_1 & X1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ x_n & y_n & 1 & 0 & 0 & 0 & -x_nX_n & -y_nY_n & Xn \\ 0 & 0 & 0 & x_n & y_n & 1 & -x_nX_n & -y_nY_n & Xn \end{bmatrix} \cdot h = 0 \tag{14}$$

where the homogeneous matrix $h(|h| = 1)$ is represented in the vector form as $h = (h_{11}, h_{12}, h_{13}, h_{21}, h_{22}, h_{23}, h_{31}, h_{32}, h_{33})^T$; n is the number of point pairs, which should be no less than four to validate the homogeneous equation; (X_i, Y_i) represents a point in the upward-looking image and (x_i, y_i) represents the corresponding point in the resultant image with a horizontal view. Vector h minimizes the algebraic residuals, and $A \cdot h$ is a standard result of linear algebra. Subject to $h = 1$, the least eigenvalue of $A \cdot A^T$ is given by the eigenvector, and this eigenvector can be obtained from the singular value decomposition (SVD) of A.

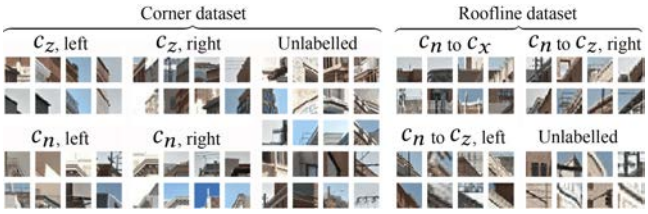


Figure 8: Examples of four types of corners, three types of rooflines, and the corresponding unlabelled images.

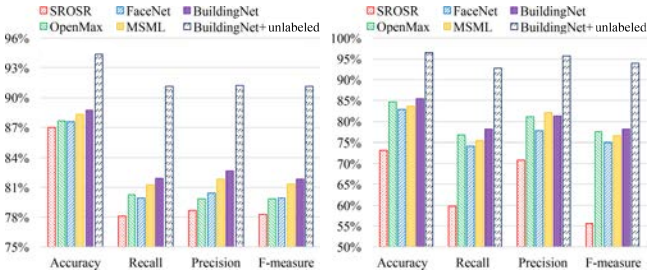
6 EXPERIMENTS

In this section, we first evaluate our proposed BuildingNet model for building corner and roofline classification and then evaluate our proposed CBHE algorithm for building height estimation.

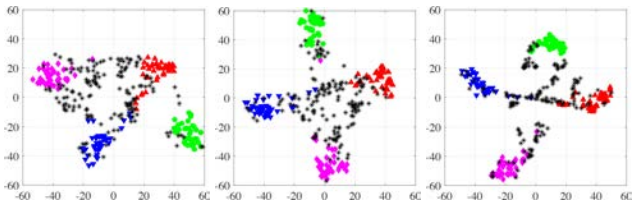
6.1 Datasets



In our experiments, we obtain building footprints (geo-coordinates) from OpenStreetMap and building images from Google Street View, respectively. For the experiments on building height estimation, we use two datasets:

(i) **City Blocks**, which contains 128 buildings in San Francisco. We collect all Google Street View images (640×640 pixels) with camera orientation along the street. We set the view of the camera is 90 degrees, and the focal length can be derived via the camera parameters provided by Google. We do not need to consider the camera rotation matrix R and the translation vector t due to the image preprocessing of Google Street View. We obtain the building height ground truth from high-resolution aerial maps (e.g., NearMap [13]).

(ii) **Tall Buildings**, which contains 37 buildings taller than 100 meters in San Francisco, Melbourne, and Sydney collected by us via Google Street View API. We set the camera with an upward-looking view (25 degrees) to capture their rooflines. The building hight ground truth comes from Wikipedia pages of these buildings or derived from NearMap [13].



For building corner classification, we crop images from City Blocks dataset. We generate the corner dataset semi-automatically, where we crop 28×28 pixels image segments from street scene images, and then manually label whether an image segment contains a building corner (and the type of corner). The training dataset that we collected contains 10,400 images, including 1,300 images of each type of building corner (i.e., a total of 5,200 building corner images) and 5,200 non-corner images. The testing dataset contains 1,280 images, including 160 images for each type of building corners and 640 non-corner images. The training data and testing data come from different city blocks.

Following a similar approach, we collect a roofline dataset. For each roofline candidate, we extend the upper and lower 10 pixels of the roofline to obtain a $21 \times W$ image segments, where W is the length of the roofline, and we further resize (rotate if the roofline is not a horizontal line) the image to 28×28 to generate same-size inputs for BuildingNet. The training dataset includes 7,800 images, including 1,300 images for each type of rooflines (i.e., a total of

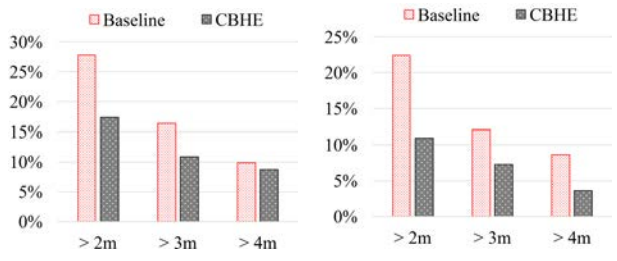
3,900 building roofline images) and 3,900 non-roofline images. The testing dataset contains 960 images, including 160 images for each kind of roofline and 480 non-roofline images.

6.2 Effectiveness of BuildingNet

Building corner and roofline classification is an open set classification problem where the invalid corner or roofline candidates do not have consistent features. To test the effectiveness of BuildingNet, we use two open set classifiers as the baselines: *SROSR* [49] and *OpenMax* [6]. SROSR uses the reconstruction errors for classification. It simplifies the open set classification problem into testing and analyzing a set of hypothesis based on the matched and no-matched error distributions. OpenMax handles the open set classification problem by estimating the probability of whether an input comes from unknown classes based on the last fully connected layer of a neural network. Further, we use two loss functions based on triplet selection to illustrate the effectiveness of our proposed triplet relative loss function. The loss function in *FaceNet* [35] makes the intra-class distance smaller than inter-class distance by adding a margin, and the one in *MSML* [45] optimizes the triplet selection process towards selecting hard triplets in each in training.

Hyperparameters. For the OpenMax, we use the LeNet 5 model to train on the building corner and roofline dataset for 10K iterations with the default setting in Caffe [19]. We then apply the last fully connected layer to OpenMax for classification. For our BuildingNet, we pre-train LeNet 5 with the MNIST dataset and fine-tune it with our collected building corner and roofline images. Further, since BuildingNet can also take advantage of unlabeled data (known unknown [34]) during training, we also pre-train a LeNet 5 model based on MNIST dataset (0 to 4 as the labeled data and 5 to 9 as the unlabeled data) and fine-tune it with our data. We set the learning rate as 0.1 with the decay rate of 0.95 after each 1K iterations (50K iterations in total). The batch size is 30 images for each class, the embeddings that BuildingNet learns are 128-dimensional, and the α in the triplet relative loss function is 0.5. We perform 10-fold cross-validation on the models tested, and then compute the accuracy, precision, recall, and F_1 score of different models, which are summarized in Figure 9.

On the corner dataset, BuildingNet achieves an accuracy of 94.34%, and its recall, precision, and F_1 score are all over 91% when using both labeled and unlabeled data for training. Compared with SROSR and OpenMax, BuildingNet improves the accuracy and F_1 score by more than 6% and 10%, respectively. When trained with labeled data only, BuildingNet still has the highest accuracy and F_1 score (i.e., 88.72% and 81.8%), which are 1.1% and 2% higher than OpenMax, respectively. Compared with the two loss functions in MSML and FaceNet which are also based on triplet selection, our proposed loss function can improve the accuracy and F_1 score by more than 0.4% and 0.5%, respectively. For the roofline dataset, the proposed BuildingNet again outperforms the baseline models consistently. These confirm the effectiveness of BuildingNet.



To further illustrate the effectiveness of BuildingNet, we visualize the embeddings generated by three triplet based loss functions on the corner dataset, as shown in Fig. 10. Compared with random triplet selection with margin (FaceNet) and hard triplet selection with margin (MSML), our triplet relative loss function obtains better classification result with smaller average intra-class distance and larger average inter-class distance after the same number of epochs.

6.3 Effectiveness of CBHE

We evaluate the performance of CBHE on City Blocks and Tall Buildings in this subsection.

6.3.1 Building height estimation on City Blocks. Figure 11 shows the building high estimation errors of the baseline method [46] and CBHE over the City Blocks dataset. It shows the percentage of buildings where the height estimation is greater than 2, 3, and 4 meters, respectively. In both city blocks, CBHE achieves a smaller percentage of buildings than that of the baseline [46].

In particular, in the first city block (Fig. 11a, which has been used in [46]), CBHE has 10.4%, 5.5%, and 1.2% fewer buildings than those of the baseline with height estimation errors greater than 2, 3, and 4 meters, respectively. Note that the results of the baseline method are obtained from their paper [46] since we are unable to obtain

(a) City block 1 (b) City block 2

Figure 11: The errors of the baseline method [46] and CBHE on City Blocks.

(a) Images used by the baseline (b) Images used by CBHE

Figure 12: City block street scene images at the same spots.

their source code. Also, even though CBHE is run on the same city block as the baseline in this set of experiments, the images that we used are more challenging to handle as the trees in the street scenes have grown larger which block the buildings (cf. Fig. 12).

Fig 11b shows the result in a second city block (which was not used in [46]). As we are unable to obtain the source code of the baseline method, the result is based on our implementation of their method. CBHE again outperforms the baseline. It has 11.5%, 4.8%, and 5% fewer buildings than those of the baseline with height estimation errors greater than 2, 3, and 4 meters, respectively.

6.3.2 Building height estimation on Tall Buildings. For tall buildings, the camera needs to be placed far away with an upward-look view to capture the building roofline. We capture the building images 250 meters away from the buildings via Google Street View API. Fig. 13 presents examples of the street scene images for tall building height estimation. For each street scene image, we first rotate it to the horizontal view according to Equation 14, and then compute the height of the buildings according to Section 5.

Figure 13: Tall building examples (best view in color).

The baseline method [46] cannot be applied to tall buildings, and here we only show the result of CBHE. As shown in Table 2, more than 53% of the tall buildings have a height estimation error of less than five meters and 73.33% of the tall buildings have an error of less than 10 meters.

Table 2: CBHE for tall building height estimation.

Absolute error	Percentage	Relative Error	Percentage
>5m	45.9%	>5%	40.5%
>10m	27.0%	>10%	13.5%

The errors of tall buildings may seem larger due to the camera projection (i.e., the errors are multiplied by a larger multiplier for tall buildings). However, we would like to emphasize that the relative errors are still quite low, e.g., since the tall buildings are taller than 100 meters, even a 10-meter error is less than 10% and is barely notable in reality.

(a) (b) (c) (d)

Figure 14: Challenging examples (best view in color).

6.4 Error Analysis

We summarize the challenging cases for CBHE in this section. These challenging scenarios will be explored in future work.

For those buildings whose rooflines are entirely blocked by other objects such as trees, CBHE will ignore them, or output a wrong estimation. Take Fig. 14a as an example, the trees on the left-hand side of the image block the roof of the green colored building heavily, resulting in a line below the roof to be identified as the roofline. Additionally, if the corners of a building are not detectable, lines from other buildings behind this building may also impact the result. As illustrated in Fig. 14b, the roofline of a building behind the blue colored building was detected as its roofline.

In dense city areas, the buildings may overlap with each other, and it is difficult to match all buildings with their boundaries in a 2D map accurately. Take Fig. 14c as an example, building ② is blocked by building ① and building ②'s corners have a similar horizontal position to building ⑤. Therefore, CBHE regards the rooflines of building ⑤ as the rooflines of building ②, which results in the estimated height of building ② being 77.41m, although its real height is 24.53m. Moreover, the height of building ⑤ is also wrong because the incorrect rooflines of building ② block the rooflines of building ⑤. In Fig. 14d, the blue shaded building mask on the right-hand side is wrongly assigned to the building ② (between building ① and building ③) because it is closer to the camera with the similar position to building ③.

7 CONCLUSIONS

We proposed a corner-based algorithm named CBHE to learn building height from complex street scene images. CBHE consists of camera location calibration and building roofline detection as its two main steps. To calibrate camera location, CBHE performs camera projection by matching two building corners in street scene images with their physical locations obtained from a 2D map. To identify building rooflines, CBHE first detects roofline candidates according to the building footprints in 2D maps and the calibrated camera location. Then, it uses a deep neural network named BuildingNet that we proposed to check whether a roofline candidate indeed is a building roofline. Finally, CBHE ranks the valid rooflines based on an entropy-based ranking algorithm, which also involves building corner information as an essential indicator, and then computes the building height through camera projection. Experimental results show that the proposed BuildingNet model outperforms two state-of-the-art classifiers SROSR and OpenMax consistently, and CBHE outperforms the baseline algorithm by over 10% in building height estimation accuracy.

ABSTRACT

Advertising (ad for short) keyword suggestion is important for sponsored search to improve online advertising and increase search revenue. There are two common challenges in this task. First, **the keyword bidding problem**: hot ad keywords are very expensive for most of the advertisers because more advertisers are bidding on more popular keywords, while unpopular keywords are difficult to discover. As a result, most ads have few chances to be presented to the users. Second, **the inefficient ad impression issue**: a large proportion of search queries, which are unpopular yet relevant to many ad keywords, have no ads presented on their search result pages. Existing retrieval-based or matching-based methods either deteriorate the bidding competition or are unable to suggest novel keywords to cover more queries, which leads to inefficient ad impressions.

To address the above issues, this work investigates to use generative neural networks for keyword generation in sponsored search. Given a purchased keyword (a word sequence) as input, our model can generate a set of keywords that are not only relevant to the input but also satisfy the domain constraint which enforces that the domain category of a generated keyword is as expected. Furthermore, a reinforcement learning algorithm is proposed to adaptively utilize domain-specific information in keyword generation. Offline evaluation shows that the proposed model can generate keywords that are diverse, novel, relevant to the source keyword, and accordant with the domain constraint. Online evaluation shows that generative models can improve coverage (COV), click-through rate (CTR), and revenue per mille (RPM) substantially in sponsored search.

1 INTRODUCTION

Advertising (ad for short) keyword suggestion is an important task for sponsored search which is one of the major types of online advertising and the major source of revenue for search companies. In sponsored search, a search engine first retrieves a set of advertisements whose keywords match a user issued query. It then ranks these advertising candidates according to an auction process by considering both the ad quality and the bid price of each ad [3]. Finally, the chosen advertisement is presented in a search result

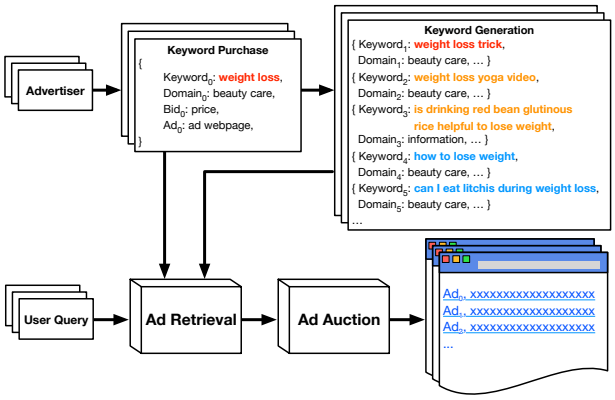

Figure 1: The sponsored search with keywords generated by our model. The red/orange/blue keywords are the keywords which have more than 3/less than 3/no ads on the impression webpage respectively.

page. Therefore, ad keywords are vital for ads to gain access to the auction process and have the chance to be displayed on a search result page.

However, there are two common challenges that should be addressed in sponsored search. The first one is the **keyword bidding problem**: due to the Matthew effect [29], the hot ad keywords become too expensive for most of the advertisers, because too many advertisers bid on such keywords. As a result, many advertisers cannot survive in the auction process to get their desired ad impressions. As reported in [43], 55.3% advertisers have no ad impression, and 92.3% advertisers have no ad click at all, which is mainly caused by low bid price or improper keywords that they bid. The second issue is **inefficient ad impressions**: a substantial proportion of search queries, which are unpopular yet relevant to many ad keywords, have less competitive ads (46.6% search queries) even no ads (41.0% search queries) on their search result pages as reported in [43]. Because of the two reasons, the expectation of advertisers is not satisfied and the revenue of search engines is also not optimized.

To address these problems, several prior studies have been conducted in keyword generation or suggestion [2, 8, 13, 23, 30]. Most of these studies adopt matching methods based on the word co-occurrence between ad keywords [8] and queries [13]. However, these methods tend to suggest popular keywords to advertisers, which will deteriorate the bidding competition. In addition, these approaches cannot suggest novel ad keywords which do not appear in the corpus.

Recently, deep learning technologies have been applied in many natural language tasks, such as machine translation [39], ad keyword suggestion [15], and query rewriting [18]. However, it's not trivial to adapt these neural networks to the ad keyword generation task, due to two major challenges. **First**, the generated ad keywords should be diversified and relevant to the original keywords to cover more user queries, which is not supported by existing neural models applied in keyword and query generation tasks. **Second**, the generated ad keywords should satisfy many constraints in sponsored search. For instance, to provide relevant yet unexplored ads for users, it is necessary to satisfy the domain constraint which means that the generated keywords should belong to the domain of the source keyword or several appropriate domains. For instance, a keyword in the *health care* domain should only match the keywords from the same domain to ensure the ad quality, while a keyword from the *information* domain could match those from various domains, such as *entertainment* and *shopping*, to cover diverse user queries.

In this paper, we investigate to use generative neural networks in the task of ad keyword generation. Given the purchased keyword as input, our generative model can suggest a set of keywords based on the semantics of the input keyword, as shown in Figure 1. The generated keywords are diverse and even completely novel (the blue keywords) from those in the dataset. This generative approach can address the aforementioned problems in two ways. **First**, our model is able to generate diverse, novel keywords, instead of merely suggesting the existing popular keywords in the dataset, which can recommend keywords for advertisers to alleviate the keyword bidding problem and retrieve ads by keyword reformulation for sponsored search engines to address the inefficient ad impression issue. **Second**, to improve the quality of the generated keywords, we incorporate the domain constraint in our model, which is a key factor considered in sponsored search to display ads. Through capturing the domain constraint, our model learns both semantic information and domain-specific information of ad keywords during training, and is consequently able to predict the proper domain category and generate the ad keyword based on the predicted category. In addition, our model uses reinforcement learning to strengthen the domain constraint in the generation process, which further improve the domain correlation and the keyword quality.

To summarize, this paper makes the following contributions:

- This work investigates to use generative neural networks for keyword generation in sponsored search, which addresses the issues of keyword bidding and inefficient ad impressions.
- We present a novel model that incorporates the domain constraint in ad keyword generation. The model is able to predict a suitable domain category and generate an ad keyword correspondingly. A reinforcement learning algorithm is devised to adaptively utilize domain-specific information in keyword generation, which further improves the domain consistency and the keyword quality.
- We perform offline and online evaluation with the proposed model, and extensive results demonstrate that our model can generate diverse, novel, relevant, and domain-consistent keywords, and also improves the performance of sponsored search.

2 RELATED WORK

2.1 Keyword Generation

A variety of methods has been proposed for generating and suggesting the keywords for advertisements, as ad keywords play a critical role in sponsored search. Joshi and Motwani [23] collected text-snippets from search engine given the keyword as input, and

constructed them as a graph model to generate relevant keywords based on the similarity score. Abhishek and Hosanagar [2] further improved the graph model, which computes the similarity score based on the retrieved documents. Chen et al. [8] applied concept hierarchy to keyword generation, which suggests new keywords according to the concept information rather than the co-occurrence of the keywords itself. Fuxman et al. [13] made use of the query-click graph to compute the keyword similarity for recommendation based on a random walk with absorbing states. Ravi et al. [32] introduced a generative approach, a monolingual statistical translation model, to generate bid phrases given the landing page, which performs significantly better than extraction-based methods. Recently due to the advances of deep learning, various neural network models have been applied to ad keyword suggestion. Grbovic et al. [15] proposed several neural language models to learn low-dimensional, distributed representations of search queries based on context and content of the ad queries within a search session. Zhai et al. [41] applied an attention network which is stacked on top of a recurrent neural network (RNN) and learns to assign attention scores to words within a sequence (either a query or an ad).

2.2 Query Generation

Another related research topic is query generation, which is widely studied and applied in organic search. It improves user experience by either expanding (reformulating) a user's query to improve retrieval performance, or providing suggestions through guessing the user intention, according to the user's behaviour pattern (query suggestion). Some previous studies adopt query logs to generate queries by handcrafted features such as click-through data [11, 25, 35, 42], session based co-occurrence [17, 20, 22] or query similarity [4, 6, 12]. Recently, artificial neural networks have been applied in query processing. A hierarchical recurrent encoder-decoder model [38] is introduced to query suggestion. He et al. [18] proposed a learning to rewrite framework consisting of a candidate generating phase and a candidate ranking phase for query rewriting. Song et al. [37] use an RNN encoder-decoder to translate a natural language query into a keyword query. An attention based hierarchical neural query suggestion model that combines a session-level neural network and a user-level neural network to model the short- and long-term search history of a user is proposed by Chen et al. [7]

2.3 Generative Neural Network

Recently, generative neural networks have been applied in many natural language tasks, such as machine translation [39], dialogue generation [34], and query rewriting [18]. Sutskever et al. [39] apply an end-to-end approach, a sequence to sequence (Seq2Seq) model, on machine translation tasks. Shang et al. [34] further introduce the Seq2Seq model to dialogue generation tasks with novel attention mechanisms. Although the Seq2Seq model is capable of generating a sequence with a certain meaning, it isn't suitable for diversified sequence generation as argued in [27]. Therefore, latent variable based models are proposed to address the diversity and uncertainty problem. Serban et al. [33] introduce latent variables to a hierarchical encoder-decoder neural network to explicitly model generative processes that possess multiple levels of variability. Zhou and Wang [45] propose several conditional variational autoencoders to use emojis to control the emotion of the generated text. Zhao et al. [44] use latent variables to learn a distribution over potential conversational intents based on conditional variational autoencoders, that is able to generate diverse responses using only greedy decoders.

3 MODEL

3.1 Background: Encoder-Attention-Decoder Framework

We first introduce a general encoder-attention-decoder framework based on sequence-to-sequence (Seq2Seq) learning [39], which is a widely used generative neural network. The encoder and decoder of the Seq2Seq model [39] are implemented with GRU [9, 10].

The encoder represents an input sequence $X = x_1 x_2 \cdots x_n$ with hidden representations $\boldsymbol{H} = \boldsymbol{h}_1 \boldsymbol{h}_2 \cdots \boldsymbol{h}_n$[1] , which is briefly defined as below:

$$\boldsymbol{h}_t = \mathbf{GRU}(\boldsymbol{h}_{t-1}, \boldsymbol{e}(x_t)), \tag{1}$$

where $\boldsymbol{e}(x_t)$ is the embedding of the word x_t, and GRU is gated recurrent unit [9].

The decoder takes as input a context vector $\boldsymbol{c}_t$ and the embedding of a previously decoded word $\boldsymbol{e}(y_{t-1})$, and updates its state $\boldsymbol{s}_t$ using another GRU:

$$\boldsymbol{s}_t = \mathbf{GRU}(\boldsymbol{s}_{t-1}, [\boldsymbol{c}_{t-1}; \boldsymbol{e}(y_{t-1})]), \tag{2}$$

where $[\boldsymbol{c}_{t-1}; \boldsymbol{e}(y_{t-1})]$ is the concatenation of the two vectors, serving as input to the GRU network. The context vector $\boldsymbol{c}_t$ is designed to attend to the key information of the input sequence during decoding, which is a weighted sum of the encoder's hidden states as $\boldsymbol{c}_{t-1} = \sum_{k=1}^{n} \alpha_k^{t-1} \boldsymbol{h}_k$, and α_k^{t-1} measures the relevance between state $\boldsymbol{s}_{t-1}$ and hidden state $\boldsymbol{h}_k$. Refer to [5] for more details.

Once the state vector $\boldsymbol{s}_t$ is obtained, the decoder generates a token by sampling from the generation distribution $\boldsymbol{o}_t$ computed from the decoder's state $\boldsymbol{s}_t$ as follows:

$$y_t \sim \boldsymbol{o}_t = P(y_t \mid y_1, y_2, \cdots, y_{t-1}, \boldsymbol{c}_t), \tag{3}$$

$$= \mathrm{softmax}(\mathbf{W_o} \boldsymbol{s}_t). \tag{4}$$

3.2 Task Definition and Overview

Our problem is formulated as follows: Given a purchased ad keyword $\boldsymbol{X} = (x_1, x_2, \cdots, x_n)$ (a word sequence)[2] and the corresponding domain category d_x obtained from a domain classifier, the goal is to predict a suitable target domain category d_y and generate a target keyword $\boldsymbol{Y} = (y_1, y_2, \cdots, y_m)$ (a word sequence) that is coherent with the domain category d_y. Essentially, the model estimates the probability: $P(\boldsymbol{Y}, d_y | \boldsymbol{X}, d_x) = P(d_y | \boldsymbol{X}, d_x) \prod_{t=1}^{m} P(y_t | y_{<t}, d_y, \boldsymbol{X}, d_x)$. The domain categories are adopted from the sponsored search engine, which consists of k domain categories, such as *beauty care*, *shopping*, and *entertainment*.

Building upon the encoder-attention-decoder framework, we propose the Domain-Constrained Keyword Generator (DCKG) to generate diversified keywords with domain constraints using three mechanisms. **First**, DCKG incorporates a latent variable sampled from a multivariate Gaussian distribution to generate diversified

[1] Throughout the paper, a bold character (e.g., $\boldsymbol{h}$) denotes the vector representation of a variable (h).

[2] Throughout the paper, a keyword refers to a word sequence, but not a single word.

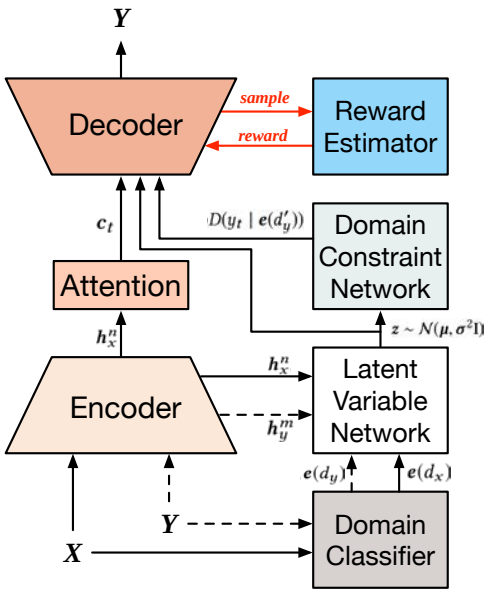

Figure 2: Overview of DCKG. The dashed arrow is used only in supervised training. The red arrow is used only in reinforcement learning. During reinforcement learning, DCKG infers a set of keyword samples and get their rewards from the reward estimator, which are used to further train our model to improve the quality of generated keywords.

keywords. **Second**, a domain constraint network is proposed to facilitate generating domain-consistent keywords, which imposes more probability bias to domain-specific words. **Third**, DCKG further optimizes the decoder to adjust the word generation distribution with reinforcement learning.

An overview of DCKG is presented in Figure 2, which illustrates the dataflow of DCKG in supervised learning, reinforcement learning, and inference processes. In supervised learning, the source keyword $X = (x_1, x_2, \cdots, x_n)$ and the target keyword $Y = (y_1, y_2, \cdots, y_m)$ are fed to the encoder to generate the hidden representations $\boldsymbol{h}_x^n$ and $\boldsymbol{h}_y^m$, meanwhile, they are fed to the domain classifier to obtain their domain categories d_x and d_y respectively. The domain categories are further converted to the domain embeddings $\boldsymbol{e}(d_x)$ and $\boldsymbol{e}(d_y)$ to encode the domain-specific information in DCKG. Then, the latent variable $\boldsymbol{z}$ is sampled from a multivariate Gaussian distribution, which is determined by a recognition network that takes the hidden representations and the domain embeddings as input. Given the latent variable $\boldsymbol{z}$, the hidden representation of source keyword $\boldsymbol{h}_x^n$, and the domain embedding $\boldsymbol{e}(d_x)$, DCKG predicts the target keyword category d'_y and generate the domain-specific word score $D(y_t \mid \boldsymbol{e}(d'_y))$. Finally, the decoder takes as input the context vector $\boldsymbol{c}_t$ generated by attention mechanism, the latent variable $\boldsymbol{z}$, and the domain-conditioned word score $D(y_t \mid \boldsymbol{e}(d'_y))$ to generate the target keyword Y.

During the inference process, DCKG has the input of only the source keyword $X = (x_1, x_2, \cdots, x_n)$ to generate a target keyword, conditioned on the latent variable sampled from a prior network which is approximated by the recognition network during supervised training.

During the reinforcement learning process, DCKG first infers a set of keyword samples. Then, these samples are fed to the reward estimator to get their rewards, considering both domain-specific and semantic information. Finally, these rewards are applied to train our model using reinforcement learning to further improve the quality of generated keywords.

3.3 Supervised Learning

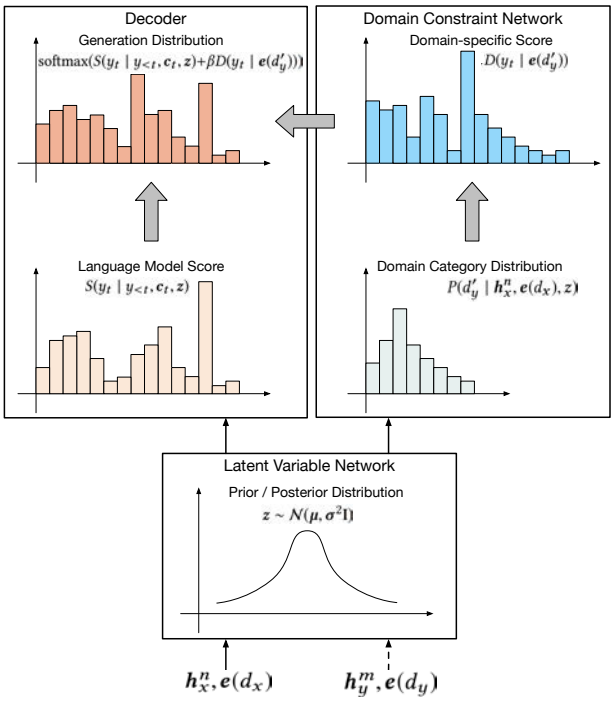

Figure 3: Computation flow of DCKG. The dashed arrow is used only in supervised learning to model the posterior distribution. During the inference process, the latent variable z is sampled from the prior distribution, and then fed to the domain constraint network and to the decoder. In the domain constraint network, the latent variable is used to predict the domain category distribution to obtain the target domain category d'_y, which is then used to compute the domain-specific score. In the decoder, the latent variable is used to compute the language model score. Finally, the language model score and the domain-specific score are combined to estimate the distribution for word generation.

We will concentrate on introducing the latent variable network, the domain constraint network, and the decoder network, as shown in Figure 3. The domain classifier is adopted from the sponsored search engine with parameters fixed during training. It generates a one-hot domain category distribution d_x for a keyword. A category is converted to a domain category embedding as follows:

$$\boldsymbol{e}(d_x) = \mathbf{V_d} d_x, \tag{5}$$

where $\mathbf{V_d}$ is a random initialized domain category embedding matrix which will be learned automatically.

3.3.1 Latent Variable Network. Building upon the encoder-attention-decoder framework, our model introduces a latent variable to project ad keywords to a latent space. By this means, the model can generate diversified keywords conditioned on different latent variable sampled from the latent space. Specifically, we adopt the conditional variational autoencoder (CVAE) [36] as the latent variable network, which is successfully applied in language generation tasks [44, 45].

DCKG assumes the latent variable $\boldsymbol{z}$ follows a multivariate Gaussian distribution, $\boldsymbol{z} \sim \mathcal{N}(\boldsymbol{\mu}, \sigma^2\mathbf{I})$. The latent variable network consists of a prior network and a recognition network to model the semantic and domain-specific information of ad keyword in the latent space.

In the training process, the recognition network takes as input the semantic representations $\boldsymbol{h}_x^n, \boldsymbol{h}_y^m$ and the domain embeddings $\boldsymbol{e}(d_x), \boldsymbol{e}(d_y)$ of the source keyword $\boldsymbol{X}$ and the target keyword $\boldsymbol{Y}$, to approximate the true posterior distribution, as $q_\phi(\boldsymbol{z} \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{h}_y^m, \boldsymbol{e}(d_y)) \sim \mathcal{N}(\boldsymbol{\mu}, \sigma^2\mathbf{I})$.

In the inference process, the prior network takes only the semantic representation $\boldsymbol{h}_x^n$ and the domain embedding $\boldsymbol{e}(d_x)$ of the source keyword $\boldsymbol{X}$ as input, to sample latent variables from the prior distribution, $p_\theta(\boldsymbol{z} \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x)) \sim \mathcal{N}(\boldsymbol{\mu}', \sigma'^2\mathbf{I})$. The prior/posterior distribution can be parameterized by neural networks such as a multilayer perceptron (MLP) as follows:

$$\left[\boldsymbol{\mu}, \sigma^2\right] = \mathbf{MLP}(\boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{h}_y^m, \boldsymbol{e}(d_y)), \tag{6}$$

$$\left[\boldsymbol{\mu}', \sigma'^2\right] = \mathbf{MLP}(\boldsymbol{h}_x^n, \boldsymbol{e}(d_x)), \tag{7}$$

To alleviate the inconsistency between the prior distribution and the posterior distribution, we add the KL divergence term to the loss function as follows:

$$\mathcal{L}_1 = KL(q_\phi(\boldsymbol{z} \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{h}_y^m, \boldsymbol{e}(d_y)) \,\|\, p_\theta(\boldsymbol{z} \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x))) \tag{8}$$

3.3.2 Domain Constraint Network. The domain constraint network is designed to model the domain-specific information of ad keyword. The output of the network is further incorporated into the process of keyword generation to improve the quality of generated keywords in sponsored search. It plays two roles in our model: first, predicting an appropriate domain category given a latent variable; second, endowing the generated keyword with the target domain features.

Essentially, it predicts a domain category distribution conditioned on the latent variable sampled from a multivariate Gaussian distribution. Once the domain category distribution is determined, we can sample a target domain category by an argmax operation. However, argmax operation is non-differentiable and the training signal cannot be backpropagated. Inspired by the Gumbel-Max trick [16, 28], we adopt Gumbel-Softmax [19] as a differentiable substitute to generate a sample from the domain category distribution, which is defined as follows:

$$\boldsymbol{\epsilon} \sim \mathbf{U}(0, 1), \tag{9}$$

$$\boldsymbol{g} = -\log(-\log(\boldsymbol{\epsilon})), \tag{10}$$

$$\boldsymbol{o}_d = \mathbf{U_d}\,\mathbf{MLP}(\boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{z}), \tag{11}$$

$$P_{real}(d'_y \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{z}) = \mathrm{softmax}(\boldsymbol{o}_d), \tag{12}$$

$$P_{sample}(d'_y \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{z}) = \mathrm{softmax}((\boldsymbol{o}_d + \boldsymbol{g})/\tau) \tag{13}$$

where $\boldsymbol{\epsilon}$ is a sample from the uniform distribution $\mathbf{U}(0, 1)$, $\boldsymbol{g}$ is a sample from the Gumbel distribution $\mathbf{Gumbel}(0, 1)$, $\boldsymbol{o}_d$ is the logits computed by a MLP and a projection matrix $\mathbf{U_d} \in \mathbb{R}^{k \times n}$; $P_{real}(d'_y \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{z})$ is the real distribution of the predicted domain category used in the inference process, $P_{sample}(d'_y \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{z})$ is the sample distribution used in the training process, and τ is a temperature used to adjust the shape of the sample distribution, which is annealed during training.

In supervised learning, we use the ground-truth domain category d_y of a keyword as the supervision signal in the loss function, such that the domain constraint network can predict the target domain category as expected, which is defined as follows:

$$\mathcal{L}_2 = -\mathbf{E}_{q_\phi(\boldsymbol{z} \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{h}_y^m, \boldsymbol{e}(d_y))}[\log P_{real}(d'_y \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{z})] \tag{14}$$

Another task of the domain constraint network is to compute the domain-specific score of a generated word from the domain category distribution. The domain-specific score is added to the word generation distribution in the decoder to endow a generated keyword with desirable domain-specific features. When the target domain category distribution is obtained, the target domain embedding can be computed as follows:

$$\boldsymbol{e}(d'_y) = \mathbf{V_d} P(d'_y \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{z}), \tag{15}$$

where $\mathbf{V_d}$ is the domain category embedding matrix as introduced in Eq. 5. Subsequently, taking the target domain embedding as input, the domain word score is generated as follows:

$$D(y_t \mid \boldsymbol{e}(d'_y)) = \mathbf{W_d}\,\mathbf{MLP}(\boldsymbol{e}(d'_y)), \tag{16}$$

where $D(y_t \mid \boldsymbol{e}(d'_y))$ is the domain-specific score of a generated word, which models the domain-specific features of a target keyword, $\mathbf{W_d}$ is the domain word embedding matrix.

3.3.3 Decoder Network. The decoder of DCKG incorporates the latent variable and the domain word score to generate an ad keyword. Taking as input the latent variable $\boldsymbol{z}$ and the context vector $\boldsymbol{c}_t$, the language model score of a generated word, which captures the semantic information in a keyword, is generated as follows:

$$\boldsymbol{s}_t = \mathbf{GRU}(\boldsymbol{s}_{t-1}, [\boldsymbol{c}_{t-1}; \boldsymbol{z}; \boldsymbol{e}(y_{t-1})]), \tag{17}$$

$$S(y_t \mid y_{<t}, \boldsymbol{c}_t, \boldsymbol{z}) = \mathbf{W_s}\boldsymbol{s}_t, \tag{18}$$

where $S(y_t \mid y_{<t}, \boldsymbol{c}_t, \boldsymbol{z})$ is the language model score and $\mathbf{W_s}$ is the semantic word embedding matrix.

Finally, the decoder combines the language model score and the domain-specific score with a factor β and then normalizes the result to the word generation distribution, which is defined as follows:

$$P(y_t \mid y_{<t}, \boldsymbol{c}_t, \boldsymbol{z}, \boldsymbol{e}(d'_y)) = \mathrm{softmax}(S(y_t|y_{<t}, \boldsymbol{c}_t, \boldsymbol{z}) + \beta D(y_t|\boldsymbol{e}(d'_y))), \tag{19}$$

where β is a domain constraint factor that controls the influence of the domain-specific information in the final word generation distribution, and is fixed to 1.0 during supervised training. The generation loss of the decoder is given as below:

$$\mathcal{L}_3 = -\mathbf{E}_{q_\phi(\boldsymbol{z} \mid \boldsymbol{h}_x^n, \boldsymbol{e}(d_x), \boldsymbol{h}_y^m, \boldsymbol{e}(d_y))}[\sum_{t=1}^{m} \log P(y_t \mid y_{<t}, \boldsymbol{c}_t, \boldsymbol{z}, \boldsymbol{e}(d'_y))]. \tag{20}$$

3.3.4 Loss Function. The final loss to be minimized in supervised learning is the combination of the KL divergence term $\mathcal{L}_1$, the domain prediction loss $\mathcal{L}_2$, and the generation loss $\mathcal{L}_3$:

$$\mathcal{L} = \max(\delta, \mathcal{L}_1) + \mathcal{L}_2 + \mathcal{L}_3, \tag{21}$$

where the max operation and the factor δ are used to balance the KL divergence term and other loss function for better optimization, which is known as the free bits method in [24].

3.4 Reinforcement Learning

One major disadvantage of DCKG described above is the domain constraint factor β is fixed for all the keywords in any domain. However, the optimal factor should be determined by the semantic and domain-specific information of a keyword dynamically. A lower β value leads to keywords containing less domain-specific features, while a higher value results in keywords that are less fluent or relevant but contain more domain-specific features, as shown in Section 4.4. Therefore, we propose a reinforcement learning algorithm that is able to learn different β values for different keywords.

3.4.1 Policy Network. To explore suitable β values for different keywords, we first define a value space $\mathcal{B}$ which contains feasible β values. The main idea is to choose the best β value by a policy network to achieve the maximum reward with respect to the evaluation metrics, which can be implemented in three steps: first, generate a set of keywords with different β values sampled from $\mathcal{B}$, given the same source keyword and latent variable; second, obtain the reward of each keyword using the reward estimator; third, update the policy network to choose the β value that leads to a maximum reward. The policy network $\pi_\psi(\beta \mid \boldsymbol{X}, \boldsymbol{z})$, parameterized by ψ, is formally given below:

$$\boldsymbol{o}_b = [\boldsymbol{h}_x^n; \boldsymbol{e}(d_x); \boldsymbol{z}; \boldsymbol{e}(d'_y)], \tag{22}$$

$$\pi_\psi(\beta \mid \boldsymbol{X}, \boldsymbol{z}) = \text{softmax}(\mathbf{W_b}\,\mathbf{MLP}(\boldsymbol{o}_b)), \tag{23}$$

where $\mathbf{W_b} \in \mathbb{R}^{b \times n}$ is a matrix projecting the input vector $\boldsymbol{o}_b$ to the action space $\mathcal{B}$.

We use the REINFORCE algorithm [40], a policy gradient method, to optimize the parameters by maximizing the expected reward of a generated keyword as follows:

$$\mathcal{J}(\psi) = \mathbb{E}_{\beta \sim \pi_\psi(\beta|\boldsymbol{X},\boldsymbol{z})}[R(\boldsymbol{X}, \boldsymbol{z}, \beta)], \tag{24}$$

where $R(\boldsymbol{X}, \boldsymbol{z}, \beta)$ is the normalized reward of a generated keyword. It is noteworthy that the policy network cannot be optimized through supervised learning, as the ground-truth β value is not observable.

3.4.2 Reward Estimator. The reward estimator is designed to provide a reward balancing the domain-specific information and the semantic information for a generated keyword. To estimate the reward, given the source keyword $\boldsymbol{X}$, the latent variable $\boldsymbol{z}$, and the target domain category d'_y as the same input, we first sample a set of β values $\{\beta_1, \beta_2, \cdots, \beta_k\}$, and infer a set of keyword samples $\{\boldsymbol{Y}_1, \boldsymbol{Y}_2, \cdots, \boldsymbol{Y}_k\}$ based on different β samples using the proposed model. Then, we use the domain classifier to predict the domain category d_{y_i} of each keyword $\boldsymbol{Y}_i$. The agreement γ between d'_y and d_{y_i} is treated as an evaluation metric of the domain-specific information, which is defined as follows:

$$\gamma_i = \begin{cases} 1, & \text{if } d'_y = d_{y_i} \\ 0, & \text{if } d'_y \neq d_{y_i} \end{cases} \tag{25}$$

Subsequently, we use the generation probabilities computed by a language model and DCKG as an evaluation metric of the semantic information. Finally, the min-max normalization is applied to rescale the rewards $\{r_1, r_2, \cdots, r_k\}$ for each β_i and $\boldsymbol{Y}_i$. This process is defined as follows:

$$r_i = \gamma_i(\lambda P_{LM}(\boldsymbol{Y}_i) + (1-\lambda)P_{DCKG}(\boldsymbol{Y}_i)), \tag{26}$$

$$R_i(\boldsymbol{X}, \boldsymbol{z}, \beta_i) = \frac{r_i - \min(\{r_i\})}{\max(\{r_i\}) - \min(\{r_i\})}, \tag{27}$$

where r_i is the reward for each β_i and $\boldsymbol{Y}_i$, γ_i is the domain category agreement, P_{LM} and P_{DCKG} are the generation probabilities modeled by a language model and our DCKG respectively, $\lambda \in (0, 1)$ is a weight to balance these two generation probabilities.

And the gradient is approximated using the likelihood ratio trick [14] as:

$$\nabla\mathcal{J}(\psi) = R(\boldsymbol{X}, \boldsymbol{z}, \beta)\nabla\log\pi_\psi(\beta \mid \boldsymbol{X}, \boldsymbol{z}), \tag{28}$$

This RL component encourages the model to choose for each keyword an optimal factor β that will lead to both higher domain category agreement and generation quality. Through reinforcement learning, we can further improve the quality of keywords generated by DCKG, resulting in more relevant, fluent, and domain-specific keywords.

4 EXPERIMENTS

4.1 Dataset

Table 1: Statistics of the dataset.

Pairs		Details	Keywords	Queries
Training	43,756,585	Number	4,419,555	19,203,972
		Length	3.96	5.40
Validation	10,000	Number	9,504	9,997
		Length	3.73	5.21
Test	10,000	Number	9,474	9,996
		Length	3.74	5.21

We sampled about 40 million query logs from Sogou.com, and each sample consists of a <*ad keyword, user query*> pair. When the search engine retrieves ads based on their owners' purchased keywords, the ad keyword must be relevant to the user query. Therefore, we treat user queries as target keywords to train our model. In other words, the input to our model is a purchased ad keyword ($\boldsymbol{X}$), and the expected output is a user query ($\boldsymbol{Y}$). We randomly sampled 10,000 pairs for validation and test. The statistics are presented in Table 1.

4.2 Implementation Details

Our model was implemented with Tensorflow [1]. The encoder and decoder do not share parameters and each has 4-layer GRU

networks with 1024 hidden neurons in each layer. The word embedding size is set to 1,024. The vocabulary size is limited to 40,000. The MLP is implemented as a one-layer linear transformation with a tanh activation function. The parameters of the MLP and the embedding matrix share the same hidden size $n = 1,024$. All the parameters and embeddings are randomly initialized and tuned during end-to-end training.

We adopted top $k = 25$ frequent domain categories produced by the domain classifier, which is a key component used in the sponsored search engine. The domain classifier is a support vector machine [21] trained on a large human-labeled corpus. The accuracy of the 25-class classification is 92.65%. The temperature τ is set to 3.0 at the beginning, and is annealed to 0.1 during supervised learning. The factor δ is set to 5.0. The value space $\mathcal{B}$ consists of $b = 21$ values in the range $[0, 5]$ with an interval of 0.25. The generation probability factor λ is set to 0.9.

Our model is trained in two stages: supervised learning is first used to model the semantic information and the domain-specific information of keywords; reinforcement learning is then used to adaptively utilize domain-specific information in the generation process. We used the Adam optimizer with a mini-batch size of 100. The learning rate is 0.0001 for supervised learning and 0.00001 for reinforcement learning. The models were run at most 10 epochs for supervised learning and 2 epochs for reinforcement learning. The training process of each model took about a week on a Tesla V100 GPU machine.

4.3 Baselines

As aforementioned, this paper is the first work to address the domain constraint factor in ad keyword generation. We did not find closely-related baselines in the literature.

Although retrieval-based approaches proposed in previous studies are able to recommend relevant keywords from the dataset, these methods cannot generate novel keywords and thus deteriorate the bidding competition problem. Furthermore, as the dataset consists of <*ad keyword, user query*> pairs, retrieval-based methods can only suggest keywords which are already covered by the search engine. Consequently, the coverage and revenue of the search engine cannot be improved more than those methods which can generate novel keywords. Due to these reasons, we didn't consider retrieval-based methods as our baselines.

Nevertheless, we chose two suitable generative models as our baselines:

- A modified Seq2Seq model [39]. First, the target domain category is predicted by the domain constraint network and is embedded into a category vector. Then, the vector serves as input to each decoding position.
- A modified CVAE model [36] considering the domain constraint information, which is implemented similarly to DCKG but without reinforcement learning.

4.4 Automatic Evaluation

We evaluated the quality of keywords generated by different models using several automatic metrics. To evaluate the performance in metrics except for perplexity[3], we generated 10 keywords for each purchased ad keyword using different models (for DCKG and CVAE, keywords were generated conditioned on 10 sampled latent variables using greedy search; for Seq2Seq, keywords were inferred using beam search with $beamsize = 10$). Due to the uncertainty caused by the latent variable in our model and the CVAE baseline, we repeatedly tested all the models for 10 times. The averaged performance, the standard deviation, and the significance test results were reported for these models [4]. The bold number indicates the best performing model, which outperforms all other models significantly (2-tailed t-test, $p - value < 0.01$).

4.4.1 *Metrics.*

- Perplexity: We adopted perplexity to evaluate the generation quality with respect to grammar and fluency. The perplexity here is computed by the generation distribution in the models themselves.
- Perplexity$_{LM}$: We trained a language model on our dataset, and used this language model to calculate the perplexity of keywords generated by different models.
- Accuracy: To evaluate whether the model can generate domain-constrained keywords, we adopted the domain accuracy as the agreement between the expected domain category (as predicted by the model, see Eq. 12) and the domain category of a generated keyword predicted by the domain classifier.
- Distinct-n: We calculated the proportion of distinct n-grams to all the n-grams in generated keywords to evaluate the diversity.
- Novelty$_{ALL/AD}$-n: To evaluate the novelty of the generated keywords, we counted the distinct n-grams that don't appear in all the corpus (ALL) or not in the purchased ad keyword set (AD). Novelty$_{ALL}$-n means the percentage of totally novel n-grams that have not been observed in the corpus.

4.4.2 *Results.*

The results are shown in Table 2 and Table 3, from which we made the following observations:

First, DCKG obtains the best performance in domain accuracy, distinct, and novelty. The improvement in domain accuracy shows that our model can enhance the domain consistency of the generated keywords, thanks to the reward we applied in reinforcement learning. DCKG can generate more diverse and novel keywords than baselines, which can be attributed to the latent variable network we adopted and the domain constraint we considered. Our model has better perplexity and perplexity$_{LM}$ than Seq2Seq but slightly worse than CVAE, because DCKG is tuned to satisfy the domain constraint more by reinforcement learning than fit to the language generation probability. Nevertheless, the disadvantage in perplexity and perplexity$_{LM}$ harms the grammaticality of the generated keywords but less influences the overall performance, as shown in the following experiments.

Second, the novelty scores indicate that our model can generate more novel n-grams than the baselines. The generative models can generate novel keywords which have not been purchased yet so

[3] We generated the ground-truth target keyword using greedy search for calculating the perplexity.

[4] For the deterministic Seq2Seq model, we tested 10 models which achieve the top 10 performance in the validation set. These models differ in different training steps.

Table 2: Automatic evaluation.

Model	Perplexity		Perplexity$_{LM}$		Accuracy		Distinct-2		Distinct-3		Distinct-4	
	avg.	std.	avg.	std.	avg.(%)	std.(%)	avg.(%)	std.(%)	avg.(%)	std.(%)	avg.(%)	std.(%)
Seq2Seq	18.82	0.033	12.26	0.022	76.84	0.054	39.09	0.028	46.78	0.033	53.02	0.041
CVAE	**10.76**	0.021	**8.24**	0.023	77.40	0.057	69.58	0.051	83.04	0.060	90.32	0.065
DCKG	11.21	0.025	8.94	0.034	**84.61**	0.080	**71.07**	0.077	**84.26**	0.065	**91.26**	0.051

Table 3: Novelty evaluation.

Model	Novelty$_{ALL}$-2		Novelty$_{ALL}$-3		Novelty$_{ALL}$-4		Novelty$_{AD}$-2		Novelty$_{AD}$-3		Novelty$_{AD}$-4	
	avg.	std.	avg.	std.	avg.(%)	std.(%)	avg.(%)	std.(%)	avg.(%)	std.(%)	avg.(%)	std.(%)
Seq2Seq	0.54	0.005	5.33	0.015	15.53	0.020	2.65	0.010	12.40	0.026	24.73	0.019
CVAE	2.01	0.016	16.03	0.058	38.38	0.119	8.18	0.024	33.49	0.085	57.64	0.099
DCKG	**2.60**	0.021	**18.23**	0.056	**41.48**	0.114	**9.34**	0.035	**36.01**	0.095	**60.40**	0.106

that the bidding competition problem can be alleviated as aforementioned. For retrieval-based methods, the Novelty$_{ALL}$ scores, which count n-grams that are never observed in the corpus, will be zero since they can only suggest existing keywords from the corpus.

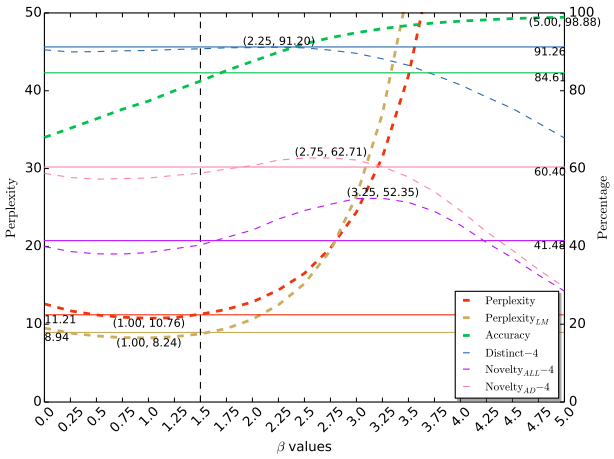

Figure 4: Performance curve with varying β. The dashed curve is the performance of DCKG with manually fixed β in different metrics. The bold curves (perplexity, perplexity$_{LM}$, accuracy) show the change of rewards which are used reinforcement learning (see Eq. 26). The horizontal line is the performance of DCKG with dynamic β tuned by RL. The dashed vertical line is an auxiliary line to compare DCKG with fixed $\beta = 1.5$ to DCKG with dynamic β optimized by RL. Left axis: Perplexity and Perplexity$_{LM}$. Right axis: Accuracy, Distinct-4, Novelty$_{ALL}$-4, and Novelty$_{AD}$-4.

4.4.3 Effect of β. In order to investigate the influence of the domain constraint factor β in DCKG, we tested the performance of DCKG with different fixed $\beta \in \mathcal{B}$. The results are shown in Figure 4. As we can see, the domain accuracy of DCKG improves continuously with the increase of β (the green curve), indicating that β is critical to satisfying the domain constraint in keyword generation because larger β applies more domain-specific information in keyword generation. DCKG achieves the best performance in perplexity and perplexity$_{LM}$ with $\beta = 1$ since this value is the default β value during supervised learning. However, when β becomes larger, DCKG performs worse in the perplexity metrics. It is thus important to balance the domain constraint and the language generation quality. Therefore, we apply reinforcement learning to find an optimal β for different instances dynamically.

It is noteworthy that DCKG with the dynamically determined β outperforms DCKG with the manually adjusted β. For example, although the performance of DCKG in perplexity and perplexity$_{LM}$ is approximately equal to DCKG with the fixed $\beta = 1.5$, the domain accuracy of DCKG outperforms DCKG with the fixed $\beta = 1.5$ (**84.61** vs. 82.49). Moreover, the novelty score and the diversity score of DCKG are also better than DCKG with the fixed $\beta = 1.5$, for instance, the Distinct-4 of DCKG is better than DCKG with any fixed $\beta \in \mathcal{B}$ (**91.26** vs. 91.20), indicating that the domain constraint can further improve the quality of generated keywords.

4.5 Manual Evaluation

In manual evaluation, we tested whether the generated keywords are relevant to the source keyword and consistent with the expected domains, such that they are suitable to be suggested to advertisers. We manually evaluated the relevance and the grammaticality of keywords generated by different models. We randomly sampled 100 purchased ad keywords from the test set, and generated 10 keywords for each purchased ad keyword using different models as in automatic evaluation. Five experienced annotators were recruited to judge the relevance (*Relevant/Irrelevant*) of 3000 pairs of generated and purchased keywords. The grammaticality of a generated keyword is also considered during annotation, as bad grammaticality leads to the ambiguity in the meaning and thus results in irrelevance rating. We used majority voting to obtain the final label of annotation. Moreover, as domain accuracy is critical to measuring how well the models satisfy domain constraint, we also reported the automatic measure in these tables. The bold number indicates the best performing model, which outperforms all other models significantly (2-tailed sign test, $p - value < 0.05$).

4.5.1 Metrics.

- Precision (P): Precision is defined as the ratio of the number of relevant keywords generated to the number of total keywords generated.
- Recall (R): Recall is the proportion of relevant keywords generated by a model to all the relevant keywords pooled from all models' results. Similar to [23], the relevant keywords from all the models are pooled together and are treated as the entire relevant set. This metric is useful to compare the ability to cover the potential relevant keywords.
- Accuracy (A): Similar to the preceding section, this metric is the agreement between the expected domain category, predicted by the model, and the domain category of a generated keyword, predicted by the domain classifier (SVM).
- F-measures: We adopted four F-measures to quantify the overall performance including F(PR), F(PA), F(RA), and F(PRA). Each F-measure is defined as the harmonic mean of all factors, where P/R/A indicate precision/recall/accuracy respectively.

Table 4: Manual evaluation.

Model	Seq2Seq	CVAE	DCKG
Precision	0.948	0.954	**0.970**
Recall	0.325	0.332	**0.343**
Accuracy	0.761	0.774	**0.847**
F(PR)	0.483	0.491	**0.503**
F(PA)	0.808	0.832	**0.892**
F(RA)	0.440	0.454	**0.480**
F(PRA)	0.534	0.548	**0.574**

4.5.2 Annotation Statistics. We calculated the statistics to measure inter-rater agreement. For relevance rating, the percentage of the pairs that all 5 judges gave the same label is 85.1%, the percentage of the pairs that 4 judges gave the same label (4/5 agreement) amounts to 8.8%, and the percentage for 3/5 agreement is 6.1%. We further computed the free-marginal kappa [31] to measure inter-rater consistency. The free-marginal kappa is 0.856, indicating adequate inter-rater agreement.

4.5.3 Results. The results are shown in Table 4. As it can be seen, DCKG obtains the best performance in all the metrics, indicating that our model can generate relevant and grammatical keywords. The best precision shows that more relevant keywords are generated by DCKG. Our model also achieves the best recall, indicating that DCKG is able to cover more potential user queries than other models. In addition, DCKG outperforms other models in domain accuracy, indicating that incorporating the domain constraint appropriately can enhance the quality of generated keywords. Moreover, DCKG ranks highest for all the four F-measures, showing that our model is superior considering all these factors.

4.6 Online Evaluation

In online evaluation, we examined whether the sponsored search engine can retrieve and present more relevant ads using the keywords generated by our model. We applied the generative models in the keyword reformulation method to facilitate the ad retrieval process of sponsored search (see Figure 1). Specifically, we collected 5 million purchased ad keywords, and then used each model to generate 10 keywords for each purchased keyword. We used these generated keywords as the reformulated keywords to retrieve original ads. The original keyword reformulation method, based on handcrafted rules and templates, is one of the retrieval methods in the ad retrieval process of the sponsored search engine, which retrieves about 2% unique ads. We added the keywords generated by our models to the keyword reformulation method of the sponsored search engine, which is called the enhanced keyword reformulation method. To make a fair comparison, the enhanced keyword reformulation methods of all models run ten days in our A/B online test system on Sogou.com, where 10% user queries are selected into the test system. We compared the performance of the enhanced keyword reformulation method with the original keyword reformulation method, and reported the relative gain in percentage for all the metrics as the final result. The bold number indicates the best performing model, which outperforms all other models significantly (2-tailed t-test, $p - value < 0.05$).

4.6.1 Metrics.

- Coverage (COV): Coverage is defined as the percentage of web pages that contain at least one ad.
- Click-through rate (CTR): Click-through rate is the ratio of page views that lead to a click to the total number of page views.
- Revenue per mille (RPM): Revenue per mille is the revenue of the search engine per one thousand page views.

4.6.2 Results. The results are shown in Table 5. As it can be seen, DCKG obtains the best performance in all the metrics. Results show that keywords generated by DCKG can cover more user queries than those by other models. The click-through rate scores indicate that the new ads which are matched with ad keywords from DCKG lead to more user clicks, because the generated keywords (user queries) are of higher quality and more relevant. The revenue is improved because the click-through rate increases, which verifies that our model can contribute more ad impressions in sponsored search.

Although the Seq2Seq model can also retrieve more ads, the improvements in all metrics are the lowest in the three models, as the diversity and the quality of the generated keywords are lower than ours. CVAE outperforms Seq2Seq because CVAE is able to model diversity with latent variables. However, as CVAE incorporate the domain constraint in a fixed way, it cannot balance the semantic information and the domain-specific information in the generation process. DCKG further improves the diversity and the quality of generated keywords by tuning the β factor dynamically with reinforcement learning. The results of online evaluation agree with those of automatic evaluation, indicating that DCKG can generate the most diverse, novel and domain consistent keywords among the three models.

4.7 Case Study

Several sample keywords generated by different models are shown in Table 6. We can see that keywords generated by Seq2Seq have

Table 5: Online evaluation. The number reported in each metric is the increased proportion compared to the original keyword reformulation method of the sponsored search engine, which retrieves about 2% unique ads.

Day	Seq2Seq			CVAE			DCKG

lower diversity than other models since it tends to generate keywords with the same prefix in similar meanings using beam search [26], such as the 3rd and 4th keywords generated by Seq2Seq. Moreover, it can only predict one target domain category since it is a deterministic model, which cannot handle the task of generating different keywords from multi-domain categories.

In comparison, CVAE and DCKG are able to predict multiple domain categories as well as generate diverse keywords according to these domain categories. However, in CVAE, the domain constraint is not addressed properly in some cases, as it takes a fixed way to combine the domain-specific information with the semantic information. For example, although the 6th generated keyword, "what meat will lead to fat if I eat during weight loss", is relevant to the source keyword, it is inconsistent with its domain category "information" since the domain-specific information is less considered than the semantic information in this case. By contrast, DCKG is able to choose a proper domain constraint factor to balance the domain-specific information and the semantic information for each instance. Hence, the generated keywords are both relevant to the source keyword and consistent with their domain categories.

In order to validate the influence of the domain constraint factor β in the generated keywords, we presented several sample keywords generated by DCKG with different β values in Table 7. Take the 6th keyword in Table 6 as an example. Given the source keywords "weight loss weight loss" and its domain category "beauty care", our model predicts a target domain category "information", and then generates keywords with different β values while other parameters are fixed.

Table 7: Sample keywords conditioned on different β with domain accuracy (Acc.) and relevance (Rel.).

As shown in Table 6, when β equals to 0.00, the target keyword belongs to the source domain category "beauty care" but violates the target domain category "information" since the keyword is generated regardless of the domain-specific information. With the increase of β, the domain accuracy improves since more domain-specific information is involved in the model, but the relevance decreases in some instances because the model faces with the compatibility of controlling semantic and domain-specific information. For example, the keywords generated when $\beta = 2.00/3.00$, are both consistent to the target domain category and relevant to the source keyword. However, when β increases to 4.00/5.00, the generated keywords are not relevant to the source keyword anymore, as a high β value will harm the quality of generated keywords severely.

5 CONCLUSION

In this paper, we investigate the use of generative neural networks for ad keyword generation. We propose a Domain-Constrained Keyword Generator (DCKG) to generate diversified and domain-consistent keywords. A latent variable network is designed to model the diversity and a domain constraint network to satisfy the domain constraint in supervised learning. To further leverage the domain-specific information in keyword generation, we propose a reinforcement learning algorithm to adaptively utilize domain-specific information in keyword generation. Offline evaluation shows that the proposed model can generate keywords that are diverse, novel, relevant to the source keyword, and accordant with the domain constraint. Online evaluation shows that generative models can improve coverage (COV), click-through rate (CTR), and revenue per mille (RPM) substantially in sponsored search.

ABSTRACT

In many applications, it is important to characterize the way in which two concepts are semantically related. Knowledge graphs such as ConceptNet provide a rich source of information for such characterizations by encoding relations between concepts as edges in a graph. When two concepts are not directly connected by an edge, their relationship can still be described in terms of the paths that connect them. Unfortunately, many of these paths are uninformative and noisy, which means that the success of applications that use such path features crucially relies on their ability to select high-quality paths. In existing applications, this path selection process is based on relatively simple heuristics. In this paper we instead propose to learn to predict path quality from crowdsourced human assessments. Since we are interested in a generic task-independent notion of quality, we simply ask human participants to rank paths according to their subjective assessment of the paths' *naturalness*, without attempting to define naturalness or steering the participants towards particular indicators of quality. We show that a neural network model trained on these assessments is able to predict human judgments on unseen paths with near optimal performance. Most notably, we find that the resulting path selection method is substantially better than the current heuristic approaches at identifying meaningful paths.

1 INTRODUCTION

Many applications require information about the semantic relation between two (or more) words, concepts, or entities. For example, a recommender system needs to recommend items related to a user's browsing history, a task allocation agent needs to match people's experiences and skills to a pool of problems to maximize problem-solving efficiency, and a household robot given the instruction to "wash the plates" needs to infer that a dishwasher could be used. Open-domain knowledge graphs such as ConceptNet (27) allow us to characterize such semantic relationships in the form of relational paths. Compared to the use of word embeddings (21) for characterizing relatedness, knowledge graphs have the potential advantage of producing easier-to-understand characterizations, and they can capture relationships that go beyond what is encoded in standard word embeddings (33).

Typical knowledge graphs (KGs), such as DBpedia and WikiData, are concerned with named entities and their relations (e.g. "Abraham Lincoln" is one of "United States Presidents"). In this paper, however, we are concerned with capturing semantic relationships between common nouns or concepts, which requires a commonsense KG such as ConceptNet. Despite its indisputable value, however, effectively using ConceptNet in applications comes with a unique set of challenges. The knowledge captured in ConceptNet is, by design, often informal, subjective and vague. Due to the fact that ConceptNet partly consists of unverified crowdsourced assertions, it is also noisier than many other KGs. Furthermore, many commonsense assertions are true only under some circumstances and to some extent. For example, ConceptNet encodes that "popcorn" is required for "watching a movie", which captures the useful commonsense knowledge that eating popcorn is associated with watching a movie, but the statement that popcorn is *required* is nonetheless false. In addition, ConceptNet only disambiguates concepts to a coarse part-of-speech level (e.g. noun meaning vs verb meaning of the word "watch"). Finally, a lot of concepts are linked by the generic "RelatedTo" relation, which covers relationships as diverse as collocations ("Tire $\xleftrightarrow{\text{RelatedTo}}$ Spare"), hypernyms ("Tire $\xleftrightarrow{\text{RelatedTo}}$ All Seasons Tire"), co-meronyms ("Tire $\xleftrightarrow{\text{RelatedTo}}$ Exhaust"), homonyms ("Tire $\xleftrightarrow{\text{RelatedTo}}$ Tier"), and very loosely related terms ("Tire $\xleftrightarrow{\text{RelatedTo}}$ Clothes").

Because of those challenges, few authors use relational paths from ConceptNet in applications. In particular, while several authors have found the knowledge encoded in ConceptNet to be highly valuable, they typically restrict themselves to using relationships that are directly encoded as an edge. For example, Speer et al. (27) showed that ConceptNet can be used to improve word embeddings by incorporating the intuition that words which are linked by an edge in ConceptNet should be represented by similar vectors.

We believe that this common restriction to direct edges is due to the lack of sufficiently accurate methods for filtering nonsensical paths, or conversely, for identifying the most natural paths. This path selection problem is the focus of our paper.

In existing work (11, 19), the problem of selecting high-quality ConceptNet paths has been addressed in a heuristic way (see Section 4). While some intuitions about high-quality paths can easily be formulated (e.g. shorter paths tend to be more informative than longer paths, the nodes occurring in natural paths tend to have similar word vector representations), such heuristic methods still fail to filter out many nonsensical paths, and conversely sometimes erroneously filter out highly valuable paths. For example, the best path between "lead" and "poison" found by one of the standard heuristics (pairwise baseline, see Section 4.3) is "Lead $\xleftrightarrow{\text{Synonym}}$ Take $\xleftrightarrow{\text{DistinctFrom}}$ Give $\xleftrightarrow{\text{RelatedTo}}$ Poison", which uses the verb meaning of "lead", despite the fact that the noun meaning (i.e. the poisonous chemical element Pb) is more relevant in this case.

Rather than trying to construct increasingly intricate heuristics, we propose to learn to predict path quality using a neural network model. To this end, we rely on crowdsourced assessments about the *naturalness* of ConceptNet paths. Specifically, to collect training data, human annotators were asked to choose the more natural path among a pair of paths, without any guidance on how to interpret naturalness. This notion of naturalness was chosen because it is intuitively easy to understand for crowdsourcers (as opposed to e.g. terms such as "semantic coherence" or "predictive value"). The term is also deliberately vague, as we do not want to steer annotators towards particular types of features. The resulting pairwise judgments are then used to train a neural network to predict a latent naturalness score, which can be used for path ranking or path selection.

The main contribution of our work is to show that people's intuitive understanding of naturalness is sufficiently coherent to be used as training data for a data-driven path selection method. To this end, we train a simple neural network model to predict latent naturalness scores that are predictive of human pairwise judgments. We find that our model can predict such judgments with a performance that is close to the optimum suggested by the inter-annotator agreement (Sec 4.2). For example, the best path found by our model for the above example is "Lead $\xrightarrow{\text{HasProperty}}$ Toxic $\xleftrightarrow{\text{RelatedTo}}$ Lethal $\xleftrightarrow{\text{RelatedTo}}$ Poison". We also show, for a number of different evaluation tasks, that our method allows us to select semantically more meaningful paths than the previously proposed heuristics.

2 RELATED WORK

Knowledge graphs: KGs explicitly encode relationships between different entities as subject-predicate-object triples. Such triples can be seen as defining a graph, where the subject and object entities refer to nodes of the graph and the predicates correspond to edge labels. KGs are typically constructed by a domain expert, via crowdsourcing, or by extracting assertions from a natural language corpus (6). In this work, we used ConceptNet (20), one of the most comprehensive commonsense knowledge graphs with 46 relation types, nearly 1 million concepts (words and phrases), and nearly 3 million edges (i.e. triples). ConceptNet partly obtained through crowdsourcing, but also incorporates external sources such as OpenCyc (18), WordNet (22), Verbosity (29), DBPedia (2), and Wiktionary[1].

Knowledge base construction by crowdsourcing: While the use of crowdsourcing for constructing knowledge bases has already been well studied, most existing approaches focus on knowledge acquisition. This can involve, for instance, direct collaborative editing of a knowledge base (3, 31) or indirect construction of a knowledge base through the use of an interactive game (29). In contrast to these works, our focus is on using crowdsourcing for learning how to detect noisy paths within an existing knowledge graph.

An important challenge with crowdsourcing is the fact that there will inevitably be disagreements within the collected data. One framework (1) suggests that this can be due to (i) the inclusion of low-quality participants, (ii) an ambiguous interpretation of the input data and (iii) an ambiguous definition of the labels that crowdsourcers are required to provide. In our work, we mitigated the first issue with a quality control mechanism (Section 4.1). To address the remaining two issues, we will rely on a probabilistic generative model to interpret the provided ratings.

Word embeddings: Word embedding methods (21, 24) represent each word in a relatively low-dimensional space of typically around 300 dimensions, which is estimated from word co-occurrence statistics. With most training procedures, vector differences represent abstract relations in the resulting embedding space: for example, $\mathbf{v}_{\text{king}} - \mathbf{v}_{\text{queen}} \approx \mathbf{v}_{\text{man}} - \mathbf{v}_{\text{woman}}$, in which $\mathbf{v}_{\text{word}}$ represents the embedding of a given word.

Both KGs and word embeddings capture aspects of meaning, and can thus to some extent be seen as alternatives. One advantage of word embeddings is that they capture types of knowledge which are difficult to encode symbolically. For example, the cosine similarity between word vectors tends to correlate very strongly with human perceptions of word similarity. On the other hand, although related words are often close to each other in the embedding space, it is difficult to "reverse-engineer" and describe the specific relation from the vector difference (5). Moreover, when multiple relations exist between two concepts (e.g. "France $\xleftrightarrow{\text{BorderWith}}$ Germany" and "France $\xleftrightarrow{\text{AllyWith}}$ Germany"), the vector difference can only reflect an aggregate. Apart from issues which arise because of the use of vectors, there are also some problems that are more generally related to the use of co-occurrence statistics for representing meaning. As a simple illustration of such problems, a system (16) incorrectly assumes that garlic has wings, because of the prevalence of phrases such as "garlic chicken wings".

Given the complementary nature of the KGs and word embeddings, it is perhaps not surprising that several studies have found it to be beneficial to integrate these two types of resources. Some studies (e.g., (10, 27, 33)) reported that knowledge graphs can be used to improve embeddings to achieve better results on various benchmark tasks such as synonym selection and analogy question solving. Conversely, embeddings can also be incorporated into methods that rely on paths in knowledge graphs, for example to

[1] https://www.wiktionary.org/

cluster such paths (11), or as features for a path selection method, as in our work.

Path Features in Applications: Several prior works have described systems that incorporated knowledge graph paths as features. For example, Boteanu and Chernova (4) used ConceptNet to solve analogy questions (e.g., "dog is to animal as banana is to fruit") by comparing similarities between paths. Lin et al. (19) proposed models for learning the embeddings of paths and showed that they performed better on problems such as relation prediction compared to embeddings computed by previous methods. Guu et al. (12) proposed to answer compositional queries (e.g., "Q: What is the population of the capital of Russia?" "A: Russia $\xrightarrow{\text{Capital}}$ Moscow $\xrightarrow{\text{Population}}$ 12.2 million") by traversing the knowledge graph in *vector space*, representing traversal as a series of matrix-vector multiplications. Das et al. (8) proposed a recurrent neural network (RNN) model with attention mechanism to reason over entities and relations in a knowledge graph, and observed improved performance in path query answering upon that by Guu et al. (12).

Among many applications, knowledge graph completion (i.e., inferring missing relations from existing paths) has been a popular target. Lao and Cohen (17) used path features for knowledge graph completion in the path ranking algorithm (PRA). Gardner et al. (11) incorporated embeddings of the *relations*, allowing the system to recognize semantically similar relations, such as "(river) runs through (city)" and "(river) flows through (city)." Neelakantan et al. (23) built upon the same PRA idea, but used an RNN to model paths. Toutanova et al. (28) proposed a dynamic programming algorithm that can incorporate both edge and vertex features and reported better performance on knowledge graph completion. While all of the above-mentioned knowledge graph completion works use some version of PRA to generate paths, Xiong et al. (32) trained a reinforcement learning agent for path generation that rewards accuracy, efficiency and diversity, and demonstrated better performance than PRA-generated paths.

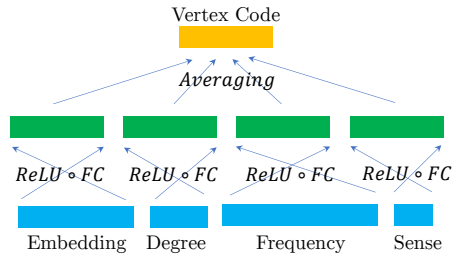
Path Selection: The number of paths between two nodes in a knowledge graph tends to grow exponentially with path length. In addition, while each type of path can be viewed as encoding a kind of semantic relationship, for many paths this relationship is difficult to interpret. Thus, all of the works described above mitigate the scalability and/or quality problem via heuristics. To limit the number of paths, Boteanu and Chernova (4) stopped the path search after a pre-defined number of nodes are explored. Lao and Cohen (17) and Guu et al. (12) limited the maximum path length. To obtain natural paths, Gardner et al. (11) favored paths that contain words with higher embedding similarity. Lin et al. (19) calculated the quality of paths using a heuristic based on vertex degree and network flow.

We note that while ConceptNet has been proven useful, most works only use direct edges, with one work (4) being a notable exception. For other types of knowledge graphs, it was already shown that incorporating longer relational paths can be highly beneficial, and there is no reason to assume that this situation would be any different for ConceptNet. For instance, while there is an intuitively obvious semantic relationship between the words "beach" and "sun", there is no direct edge connecting these words in ConceptNet. However, this relationship can be uncovered by observing that ConceptNet contains the path "Beach $\xleftrightarrow{\text{RelatedTo}}$ Sunbathing $\xleftrightarrow{\text{RelatedTo}}$ Sun". Nevertheless, to enable more effective use of such relational paths from ConceptNet, we believe that more work is needed on how to avoid nonsensical paths, which is the focus of this paper.

3 METHOD

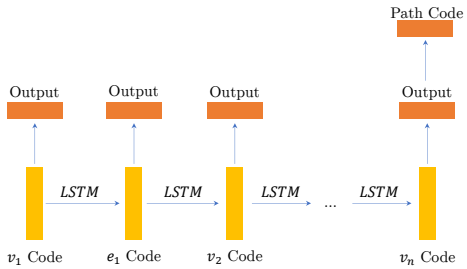
3.1 Problem Formulation

Our goal in this work is to train a classifier for predicting path quality based on crowdsourced information. Specifically, we ask human annotators to assess the *naturalness* of ConceptNet paths. Rather than trying to provide guidelines on how naturalness should be understood, we simply rely on annotators' intuitive understanding of this notion. This has several advantages, including the fact that we do not steer annotators towards particular indicators and the fact that this makes the annotation task much easier. Moreover, given that we are interested in a task-independent form of path quality (i.e., our focus is on eliminating non-sensical and uninformative paths, rather than on selecting the best paths for a particular application), it is not clear what further guidance would be meaningful for annotators. As we will discuss in more detail in Section 4.2, despite the lack of guidance on how naturalness should be understood, we observed a high inter-annotator agreement in practice.



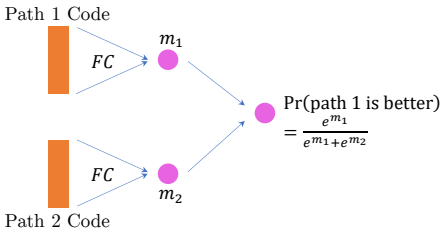
Clearly, however, asking participants to provide ratings on an absolute scale is problematic: people have varying thresholds for naturalness, and these thresholds may also change over time. After observing a large number of unnatural paths, people may lower their thresholds to be more willing to accept a path as natural, and vice versa. Therefore, we instead asked participants about pairwise comparisons: determining which of two given paths is more natural. In this setting, if one path is more natural than the other, two raters would provide the same answer even if they maintained different absolute naturalness thresholds, or if they shifted their underlying absolute threshold unconsciously over time.

If the two paths are equally (un)natural, the selected answer would be more or less arbitrary, and even the same annotator might not consistently give the same answer when presented with the same pair more than once. Therefore, in our model, we assume that answers to these pairwise comparison questions are probabilistically generated from a latent naturalness score. Specifically, each path is assumed to have a latent naturalness score m, such that for a pair paths with scores m_1 and m_2, the observed answer is drawn from a Bernoulli distribution, with probability $e^{m_1}/(e^{m_1} + e^{m_2})$ that the first path is selected. The problem we consider is to learn a model that can predict the naturalness score m of a given path, using crowdsourced answers of pairwise comparisons as supervision signal.



3.2 Model

In the big picture, our model consists of an encoder and a pairwise predictor. The encoder is a long short-term memory (LSTM) network (13) that transforms a path into a code vector. The predictor then takes the path codes and computes the probability that one path is more natural than the other. Each path is represented by an alternating sequence of vertex and edge representations, $(v_1, e_1, v_2,$



$e_2, ..., e_{n-1}, v_n$). Each vertex representation is a list of n_v features, $v_i = (\mathbf{v}_{i,1}, \mathbf{v}_{i,2}, ..., \mathbf{v}_{i,n_v})$, with j-th feature being a d_j^v-dimensional vector. The edge representations are structured similarly. The features which we use are summarized in Section 3.4.

(a) The encoding of a vertex.

(b) The encoding of the path.

(c) The predictor model.

Figure 1: LSTM model architecture. Blue (bottom) cells represent raw features (of variable lengths). Green (middle) cells represent transformed features (of length l_f). Orange (top) cells represent the final code for the vertex (of length l_f). The encoding of an edge is computed in a similar fashion. The codes (yellow) for vertices and edges are successively processed by an LSTM network. The last state $\mathbf{h}_{2n-1}$ (orange) is used as the code for the entire path. The path codes (orange) first pass separately through fully-connected layers (with shared weight) with an output dimension of 1. A softmax layer then calculates the probability that path 1 is more natural than path 2.

A standard LSTM architecture can only process sequential data of the same dimension. Thus, vertex and edge representations must first pass through an encoder. Figure 1a depicts how a neural network encodes a vertex into a vertex code of pre-defined length l_f. Each feature (such as the word embedding and absolute frequency in some large corpus) is transformed through a rectified linear unit (ReLU)-activated fully-connected (FC) layer to a vector of length l_f. The overall code is the average of the vectors. The encoding of an edge to the same length l_f is conducted in a similar fashion. Figure 1b depicts the way in which the path code is calculated. After the codes for each vertex and edge are computed, they are sequentially aggregated by an LSTM network. The last state $\mathbf{h}_{2n-1}$ is interpreted as the code of the path. As shown in Figure 1c, the predictor then outputs the pairwise comparison result. It first transforms each path code to a score (m_1 and m_2) using linear layers with shared weight. The softmax function is then applied to the two scores to calculate a probability. While the network predicts pairwise comparisons, it is the score m_i produced by the network – or, at least, the ordering induced by the scores – that matters for applications.

The problem we consider falls under the broad umbrella of learning to rank, for which many algorithms have already been proposed. We use an LSTM encoder because it elegantly deals with variable length input, while most other methods can only take fixed length input representations.

3.3 Training

We used the negative-log-likelihood (NLL) loss as our objective function, along with the Adam optimization algorithm (14). Although the neural network model seems like a natural choice for the data generation process described in Section 3.1, here we show that the predicted scores m indeed converge to the latent scores from which the pairwise comparison results were generated, up to a constant difference.

Consider two paths with scores m_1 and m_2. According to our generative model, the first path is selected with probability $p_{m_1 m_2} = e^{m_1}/(e^{m_1}+e^{m_2})$. Note that from $e^{m_1}/(e^{m_1}+e^{m_2}) = e^{m_1'}/(e^{m_1'}+e^{m_2'})$ it follows that $m_1 - m_1' = m_2 - m_2'$ by simple algebra. This means that if our system can correctly predict the probabilities $p_{m_1 m_2}$, for any pair of paths, then it must be the case that there is a fixed constant c such that for each path with naturalness score m, the predicted naturalness score m' is such that $m = m' + c$.

It remains to be shown that the NLL objective will indeed lead our neural network model to predict the correct probabilities. Specifically, assume that observations $\{y_i \sim \text{Bernoulli}(q_\theta(\mathbf{x}_i))\}_{i=1}^n$ are given, where $\mathbf{x}_i$ is the feature representation of a given pair of paths and $q_\theta(\mathbf{x}_i)$ is the corresponding output of our neural network model when the parameters are set as θ. We show that minimizing the NLL objective will result in parameters ϕ such that $q_\theta = q_\phi$. For any fixed $\mathbf{x}_i$, given a set of observations $\{(\mathbf{x}_i, y_{i,1}), ..., (\mathbf{x}_i, y_{i,n_i})\}$, we define the expected data likelihood with respect to q_i to be as follows:

$$\mathbb{E}_{q_i}\left[\Pr(y_{i,1:n_i}|\mathbf{x}_i)\right] = \mathbb{E}\left[\prod_{j=1}^{n_i}\left[y_{i,j}q_i + (1-y_{i,j})(1-q_i)\right]\right].$$

When $y_{i,1:n_i}$ is generated by Bernoulli $(q_\theta(\mathbf{x}_i))$, it can be shown that $\arg\max_{q_i} \mathbb{E}_{q_i}\left[\Pr(y_{i,1:n_i}|\mathbf{x})\right] = q_\theta(\mathbf{x}_i)$. For the entire dataset $\{(\mathbf{x}_1, y_1), .., (\mathbf{x}_n, y_n)\}$, since the y_i's are independent of each other

given $\mathbf{x}_i$, the expected joint likelihood for the entire dataset

$$\mathbb{E}_{q_\phi}\left[\Pr(y_{1:n}|\mathbf{x}_{1:n})\right] = \mathbb{E}\left[\prod_{j=1}^{n}\left[y_j q_\phi(\mathbf{x}_j) + (1-y_j)(1-q_\phi(\mathbf{x}_j))\right]\right]$$

is then maximized for $q_\phi(\mathbf{x}) = q_\theta(\mathbf{x})$ for all $\mathbf{x}$. Therefore, we can simply minimize NLL (i.e. $-\log\left[\Pr(y_{1:n}|\mathbf{x}_{1:n})\right]$).

Note in particular that the network will converge to optimal predictions even with only one answer for each pair, which we can exploit to maximize the diversity of the crowdsourced annotations: by only collecting a single annotation for each pair of paths, a broader range of paths can be assessed (with a fixed budget) than with multiple annotations per pair. While each individual answer will to some extent be arbitrary (e.g., the fact that path 1 was selected could mean that path 1 is more natural or that both paths are approximately equally natural and that path 1 was selected by chance), because the network is trained on many different pairs, it will still learn to differentiate between clear-cut cases and borderline cases.

3.4 Features

In this section, we describe the features we used to encode vertices and edges. The number in parenthesis after each feature name indicates the dimension of that feature.

Vertex embedding (300) This feature is taken directly from the 300-dimensional GloVe (24) embedding, pre-trained on the Common Crawl[2] dataset with 840 billion tokens. In some experiments, we used principal component analysis (PCA) to first reduce the dimensionality of this feature before inputting it into the neural network.

Vertex frequency (1) This feature is a scalar representing the frequency of the given word. We estimated the (unnormalized) frequency using Zipf's law (35) from word occurrence ranks, which can be derived from the pre-trained GloVe embedding since it orders words by frequency. For example, the word "science" is ranked 717th, and is thus assigned a frequency of 1/717=1.39e-3.

Vertex degree (1) This feature is the number of neighbors (in both directions) of the vertex in the graph, representing how well connected the word is within ConceptNet.

Vertex sense score (1) This feature is a number between 0 and 1 representing how consistent is the overall meaning of the vertex compared to its neighbors on the left and right. For example, the sense score for the word "book" in the path "Knowledge $\xleftarrow{\text{HasA}}$ Book $\xleftrightarrow{\text{RelatedTo}}$ Restaurant" would be quite low because it is used in two different senses . On the other hand, the sense score for "book" in "Knowledge $\xleftarrow{\text{HasA}}$ Book $\xleftrightarrow{\text{RelatedTo}}$ Paper" would be high. We believe that a lower sense score would result in the path being considered less natural. In calculating this feature, we borrow and extend the idea of "word sense profile" proposed by (7). The details of the sense score calculation can be found in the appendix of the extended version[3].

Edge ends similarity (1) For an edge connecting two vertices (s, t), this feature is the cosine similarity of the embeddings of s and t.

Edge direction (3) This feature is a one-hot vector that represents if the edge is forward ("Dog $\xrightarrow{\text{IsA}}$ Animal"), backward ("Wheel $\xleftarrow{\text{HasA}}$ Car"), or bidirectional ("Big $\xleftrightarrow{\text{Antonym}}$ Small").

Edge relation (46) This feature is a one-hot vector that represents the relation type of the edge.

Edge provenance (6) In ConceptNet, each edge is derived from at least one source. In the case of multiple sources, the weight is the sum of the weights across all sources. However, weights across sources are not directly comparable; for example, nearly all edges from WordNet have a weight of 2.0, while those from Wiktionary have a weight of 1.0. This does not necessarily mean that WordNet is more reliable than Wiktionary. Thus, we encode the provenance of an edge using a 6-dimensional vector, with one component for each possible source: WordNet, DBpedia, Verbosity, Wiktionary, OpenCyc, and Open Mind Common Sense (26). When an edge has only one source, its component in the vector has a value equal to the weight, and all other entries are 0. When an edge has multiple associated sources, we split the weight across the sources using the most common weight of each source (e.g., 2.0 for WordNet).

Edge sense score (1) Similar to the vertex sense score, this feature is also a number between 0 and 1 characterizing the consistency of meaning, but at an edge level. Again, the details are included in the extended version[3].

4 EXPERIMENTS

In this section, we first describe our data collection procedure. Then we present an evaluation of the collected data and learned model.[4]

4.1 Data Collection

For our experiments, we used Amazon Mechanical Turk to collect pairwise human rating data. Each questionnaire consisted of 73 pairs, including 60 genuine pairs and 13 quality-control pairs. The quality-control pairs consisted of an obviously good path and an obviously bad path. The good paths were manually specified and meant to be very natural and straightforward (e.g., Email $\xrightarrow{\text{UsedFor}}$ Communication $\xleftarrow{\text{UsedFor}}$ Telephone). To generate bad paths, words and relations were sampled independently at random (e.g., "Beautiful $\xrightarrow{\text{IsA}}$ Other $\xleftrightarrow{\text{RelatedTo}}$ Them $\xleftarrow{\text{MotivatedBy}}$ Rug"). We only used answers from questionnaires for which all 13 quality-control questions were answered correctly. The genuine pairs consisted of randomly sampled paths from ConceptNet. We used a number of different strategies to sample these paths, as outlined below. Overall, around 1,500 valid responses were collected, giving us around 90,000 pairs of paths to use in different settings of the experiment.

4.2 Inter-Annotator Agreement

The human annotators were provided with a generic question: "which of the two paths is more natural?" Different participants may interpret this question slightly differently, focusing on different aspects of naturalness. Thus, one important question is how much humans agree with each other about naturalness. Establishing the inter-annotator agreement level is also useful because it serves as an intrinsic, model-agnostic performance upper bound.

[2] http://commoncrawl.org/

[3] https://arxiv.org/pdf/1902.07831.pdf

[4] The code and data for the experiments can be found at https://github.com/YilunZhou/path-naturalness-prediction

Our default data collection strategy is to obtain only one answer for each pair of paths. This strategy maximizes the coverage of our dataset, while still allowing the model to make probabilistic predictions, as discussed in Section 3.3. However, to evaluate the inter-annotator agreement, we also collected a multi-response dataset, with 59 questions each answered by 16 different participants.

Table 1 summarizes the results of an analysis of this dataset. The first column lists the different possible opinion splits for a given question; for example, 13/3 corresponds to a question for which 13 people preferred one of the paths, and 3 people preferred the other. The second column shows how many of the 59 questions have a given opinion split.

The last two columns of Table 1 refer to results obtained by our model trained in the 1st setting described below in Section 4.3. The third column shows the number of questions predicted correctly, i.e. the number of questions for which the prediction of our model coincides with the majority opinion of the human participants. The last column is the model's average confidence in the majority consensus. The 8/8 row does not include prediction statistics because there is no majority consensus for these questions.

A number of conclusions can be drawn from these results. First, given the disagreement levels shown in the second column, the theoretically best performing model, which always predicts the majority preference, would achieve 70.1% accuracy on this dataset. This shows that while people do not agree with each other on all of the questions, for the majority of pairs, human annotators do have a clear preference. Note that we should not expect a perfect agreement, since in some cases both of the paths may be equally natural or equally unnatural. This is illustrated in Table 2, which shows examples of pairs with different opinion splits. As can be seen from these examples, the fact that there is no majority for a given pair does not necessarily mean that the paths involved are of low quality. It simply means that the two paths are approximately equally natural.

As can be seen from the third column in Table 1, when there is a clear human consensus about which of the two paths is most natural, our model can predict this with a very high accuracy; e.g. for all questions where the opinion split was 14/2 or better, the majority view was predicted correctly. Furthermore, there is a strong positive correlation between the confidence scores predicted by our model, shown in the last column, and the amount of disagreement among human annotators. Our model is thus able to distinguish between cases where the difference in naturalness is clear-cut and cases where human annotators would be undecided.

Opinion Split	# Q	# Correct	Avg Conf
8/8	7	NA	NA
9/7	11	5	52.2%
10/6	6	5	60.1%
11/5	8	7	64.4%
12/4	11	7	56.6%
13/3	5	4	70.0%
14/2	5	5	72.5%
15/1	4	4	76.2%
16/0	2	2	89.8%

Table 2: Pairs of paths with different opinion splits (OS). In each cell the most favored path is shown on top.

4.3 Prediction Accuracy

4.3.1 Experimental Setup. In this set of experiments we studied how well our model can predict human judgements in three settings.

- In the 1st setting, we first determined a set of 100 words. To this end, starting from the center word "science", we performed a random walk on ConceptNet, considering only elementary-school-level nouns[5], until 100 different words had been sampled. We then sampled pairs of paths with 4 or less nodes in the subgraph induced by these 100 words. This dataset included about 10,000 paths. The training set contains 40,000 pairs sampled from 8,000 paths, and the test set contains 1,000 pairs put together from the remaining 2,000 paths. This evaluation allows us to assess the performance of our system in a domain-specific setting, since the model is evaluated on paths involving the same words as those in the training paths (but nonetheless different paths). This performance is recorded in Table 3.
- In the 2nd setting, we collected another set of 100 words using the same method as above, but using "money" as the center word, while additionally ensuring that there is no overlap between this set of 100 words and those from the "science" dataset. We then collected 1,000 paths among those 100 words, and put them into 500 pairs, which we use to evaluate models trained on the "science" dataset. In this way,

[5]http://www.k12reader.com/

we can assess the transfer learning performance of our model. This performance is recorded in Table 4.

- In the 3rd setting, we selected the nouns, verbs and adjectives from the 5,000 most frequent English words in the Corpus of Contemporary American English[6], for a total of 3,887 words. We then sampled 80,000 paths of up to 5 nodes, which we split into 20,000 training pairs and 20,000 testing pairs (ensuring that there are no overlapping paths between training and testing sets). Compared with the 1st setting, this represents much wider coverage of the set of words (i.e., embedding space), but much sparser coverage of paths, allowing us to assess the performance of our model in an open-domain setting. This performance is recorded in Table 5.

To put our performance into context, we also considered the following four heuristic baselines, all of which have similar mechanics: computing a score for each path (as does our model), and then selecting the path with the higher score.

Source-Target Baseline (ST-B) scores paths using the cosine similarity between the embeddings of the source and target words (note that the two paths in a pairwise comparison do not typically start and end with the same words);

Pairwise Baseline (Pair-B) scores paths using the average cosine similarity of all word pairs connected with an edge in the path;

Resource Flow Baseline (Flow-B) scores paths using the "path reliability" method proposed by Lin et al. (19) with the idea that a path is better if there are less branches out of the path;

Length Baseline (Path-B) scores paths solely by their length, and favors shorter paths to longer ones.

We performed a grid search of two hyper-parameters: vertex embedding dimension in $\{2, 10, 50, 100, 300\}$ and path code length in $\{1, 2, 5, 10, 20\}$. For the first hyper-parameter, we used principal component analysis (PCA) for dimensionality reduction. We also tested one-hot encodings of words for the 1st setting. For the other settings, this one-hot encoding cannot be used, because it cannot generalize to unseen words (2nd setting) or scale to a large number of words (3rd setting). In addition, Length-B performance is only available for the 3rd setting, because for the first two settings we did not explicitly control for path length. As a result, the vast majority of paths are of the cutoff length of 4, and path length is not predictive.

4.3.2 Quantitative Analysis. For the first setting (Table 3), we can see that performance was relatively insensitive to embedding dimension and code length, as long as both were sufficiently high. However, performance on the 2nd setting (Table 4) dropped significantly with higher embedding dimensions, suggesting an overfitting problem, with an embedding dimension of 2 achieving best generalization performance. This suggests that a model that was trained on one domain can indeed successfully be applied to another domain, as long as the embedding dimension is small enough to allow for sufficient generalization. In the 3rd setting (Table 5), we found that a higher embedding dimension is necessary, most likely because the range of meanings is more diverse for this dataset, which includes not only nouns, but also verbs and adjectives.

Pair-B		57.5				
Flow-B		46.8				
Length-B		55.8				

Table 5: Test accuracy (in percentage) in the open-domain setting of the most frequent English words.

For all three settings, considering the level of agreement found in Section 4.2, we found that the performance of our model approaches the expected performance upper bound. Moreover, our

model performs substantially and consistently better than all of the baselines. In fact, in Table 5 we can see that only one of the baselines is able to outperform the simple path length heuristic (Length-B), and only in a minimal way.

4.3.3 Qualitative Analysis. To qualitatively compare how our model prediction differs from the baselines, Table 6 presents the best paths between the words "health" and "computer" (of up to 4 nodes) selected by our method and the two strongest baselines.

We can see that the top paths found by the pairwise baseline lack variety, most likely due to the high embedding similarity between "health" and "care". In addition, the length baseline does not perform satisfactorily because the shortest paths are not easily understandable without more explanation, with nearly all relations being the generic "$\xleftrightarrow{\text{RelatedTo}}$". By contrast, our model (trained on the 3rd open-domain setting) selects paths that overcome both drawbacks. It covers a wider variety of concepts such as "virus" and "expensive" and favors longer paths with smoother transition of node semantics.

In another evaluation, we inspect paths for which our model and the pairwise baseline significantly disagree. We randomly sampled 120,000 paths from the entire ConceptNet graph and use the two methods to predict their quality. Table 7 lists paths that are predicted to be among the top 10% most natural by our model but are in the bottom 10% according to the pairwise baseline. Table 8 conversely shows paths that are among the 10% least natural according to our model but the 10% most natural according to the baselines. Paths in both tables were selected at random.

As we can see, the paths in Table 7 are intuitively quite meaningful, with all paths using some rather uncommon but relevant words, which is perhaps clearest in the last example (Hechsher refers to a certification given to a food product that complies with Jewish religious law and Kashrut refers to the set of Jewish dietary laws). By comparison, the paths in Table 8 mostly use very common but uninformative words. This analysis suggests that the pairwise baseline suffers from the so-called hubness problem, i.e. the problem that in high-dimensional vector space embeddings, there are typically a few central objects which are highly similar to many of the other objects (25), an issue which is known to affect word embeddings (9). The pairwise baseline favors paths with very common words, even if they are not semantically related, because these words act as hubs in the word embedding.

4.4 Ablation Study on Feature Importance

To discern the contribution of each feature to the prediction performance, we trained variants of our model with subsets of the full feature set. For this analysis, we used the 3rd evaluation setting with the best performing hyper-parameters (embedding dimension of 100 and path code length of 10). The results are summarized in Table 9.

We can see that leaving out the edge ends similarity feature hurts performance most. This is also in accordance with the fact that pairwise baseline in Table 5, which only uses this feature, performs best among the four baseline methods. Furthermore, the second-highest reduction is found when leaving out the vertex embedding feature. Finally, we see that neither vertex features nor edge features alone can achieve optimal prediction performance.

4.5 Naturalness as a Path Selection Criterion

Next we discuss three experiments which are aimed at assessing how well naturalness indicates path quality. We start with an intrinsic evaluation of the semantic coherence of natural paths, after which we discuss two extrinsic tasks: information retrieval and analogy inference.

4.5.1 Semantic Coherence. Let us define the *type* of a path as the sequence of relations appearing in that path, e.g. the type of the path "A $\xrightarrow{\text{IsA}}$ B $\xrightarrow{\text{HasA}}$ C" is ($\xrightarrow{\text{IsA}}$, $\xrightarrow{\text{HasA}}$). In this experiment, we consider pairs of nodes in ConceptNet that are connected with a relational path of a given type, as well as a one-step relation (e.g., "A $\xrightarrow{\text{HasA}}$ C"). In this situation, we call the latter relation a *path-summarizing (PS) relation* for the considered path type. Many path types uniquely determine the PS relation, or at least narrow down the set of candidate PS relations to a small number. For instance, for a path of type ($\xrightarrow{\text{IsA}}$, $\xrightarrow{\text{HasA}}$) we would expect to only see $\xrightarrow{\text{HasA}}$ as the PS relation. However, due to the presence of noise in ConceptNet, some relations of this type will actually have a different PS relation. Motivated by this view, as an intrinsic evaluation task, we propose to assess the extent to which a path selection method is able to select *semantically coherent* paths in terms of the variability of the PS relations among the selected paths.

In particular, for a set of paths, we first determine a mapping from path types to counters of PS relations: $\{p_1 \rightarrow [(r_{11}, c_{11}), (r_{12}, c_{12}), ..., (r_{1n}, c_{1n})], ..., p_m \rightarrow [(r_{m1}, c_{m1}), (r_{m2}, c_{m2}), ..., (r_{mn}, c_{mn})]\}$, in which each p_i is a path type, each r_{ij} is one of 46 relation types from ConceptNet, and each c_{ij} is the number of times the relation r_{ij} was found as a PS relation for path type p_i. The average entropy of the PS relations is then defined as:

$$\frac{-\sum_{i=1}^{m}\left[C_i \cdot \sum_{j=1}^{n} p_{ij}\ln(p_{ij})\right]}{C},$$

where $C_i = \sum_{j=1}^{n} c_{ij}, C = \sum_{i=1}^{m} C_i, p_{ij} = c_{ij}/C_i$. A higher average entropy suggest a higher proportion of spurious PS relations and thus less semantically coherent paths.

Using the 3,887 words from the 3rd setting, we generated 126,600 length-4 paths whose source and target nodes are also directly connected by a relation (i.e. the PS relation). Our model was applied to rank the paths by naturalness. Based on this ranking, we calculate the average entropy of top N% natural paths, where N varies from 10 to 100, and plot the result in Figure 2. We compared our model to Pair-B, the best-performing baseline for predicting naturalness. The entropy for a random shuffle of the dataset is also depicted for comparison. We see that using our model to select the most natural paths consistently leads to the lowest entropy. Note that all three methods will converge to the same entropy at the 100% mark, at which point all paths are used, regardless of the path selection method.

4.5.2 Information Retrieval. When using a search engine, users often provide under-specified queries, e.g. because they assume that the search engine is "smart" enough to infer their true intention or because they do not actually have a clear idea on how to formulate a better query. Moreover, even if a query is unambiguous, it may use different terms than those appearing in the most relevant documents. To deal with such issues, many information retrieval

systems rely on some form of query expansion (34), a strategy for automatically adding semantically related keywords to the user's query. In this experiment, we study the performance of a query expansion method based on natural ConceptNet paths.

We use the TREC 2004 Robust Retrieval Track dataset (30), commonly known as ROBUST04, consisting of 250 queries and around 260,000 documents. Each query from this dataset typically consists of 2 or 3 words, and is associated on average with 1,000 annotated documents (marked as either positive or negative). We use a simple TF-IDF retrieval model, in which the TF-IDF weighting scheme is used to vectorize both the documents and the queries and the cosine similarity is used as the ranking metric. Following the work by Kotov and Zhai (15), we focus on hard queries, which are defined as those with Precision at 10 (P@10) performance of 0 when only using the original query terms. We then evaluate how the performance can be improved by expanding the query with terms that are selected using a given strategy. There are 44 examples of such hard queries among the original 250 queries.

To expand queries based on ConceptNet, we first find all paths, consisting of up to 4 nodes, which connect any two of the query terms. For example, if the query is "drug crime organization", we find paths between the pairs (drug, crime), (drug, organization), and (crime, organization). We then add the words from the most natural paths to the original query. In particular, we add a fixed number of words by processing the paths in the order defined by the chosen path ranking method. To this end, we have considered the following strategies for ranking paths:

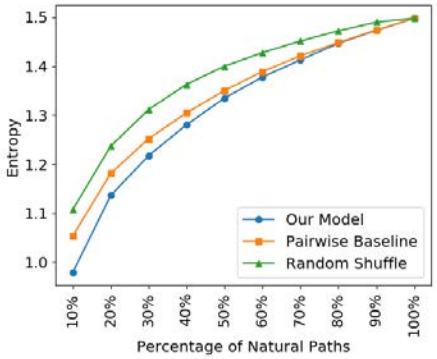

Figure 2: Average entropy of path-summarizing relations for different proportions of natural paths.

(1) naturalness score, which is calculated from our model trained on the open-domain (3rd) setting;
(2) pairwise score, which is the pairwise baseline;
(3) length score, which is the length baseline (i.e. shorter paths are better), with random tie-breaking;
(4) random score, which assigns a random score to each path;
(5) naturalness+length score, which first favors shorter paths, but uses our naturalness score to rank paths with same length.

To put our results into context, we also compared this method with a query expansion strategy based on the GloVe word embedding. Specifically, in this case we add the words that are closest to the query words, ordered by their cosine similarity in the vector space. Note that each of the considered strategies will yield an ordered list of possible words to add to the query. We study the retrieval performance of using different cut-offs in this list.

The P@10 and MAP performances are shown in Figure 3. We can see that for both evaluation metrics, the naturalness+length score achieves the highest performance, suggesting that while nodes in shorter paths are generally more relevant to original queries, considerable gains can be made by using naturalness to rank paths of the same length. The word embedding model also performs well, but it cannot reach the best overall performance of the two naturalness based methods.

4.5.3 Analogy Inference. Boteanu and Chernova (4) used relation paths to solve analogy questions of the following form:

```
Question: Dog:Animal::
       A: Table:Chair
       B: Apple:Fruit
       C: Fast:Slow
       D: Ice:Cold
```

The goal is to select the word pair which has the same relation as the query pair (e.g. the correct answer in the question above is *B* because dog is a type of animal, and apple is a type of fruit). In their proposed method, the quality of the analogy $a : b :: c : d$ (meaning a is to b as c is to d) is calculated using the proportion of overlapping relations on paths connecting (a, b) and (c, d) respectively. Boteanu

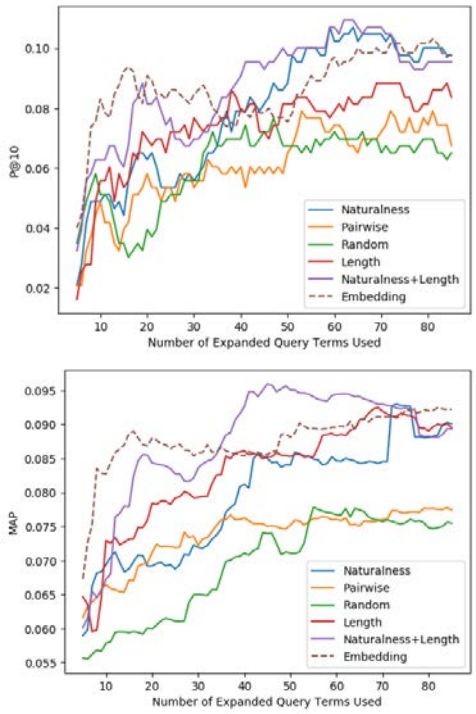

Figure 3: Performance of query expansion for hard queries in terms of Precision at 10 (P@10, top) and Mean Average Precision (MAP, bottom).

and Chernova (4) considered paths of two (i.e. direct connection) and three (i.e. with an intermediate hop) nodes.

We found that when direct connections exist between words in the query pair, using only these direct connection (and not including 3-node paths) achieves the best performance. However, not all query pairs have direct connections, in which case we are required to use 3-node paths. For our dataset of 85 questions, 74 have associated direct edge connections. Thus, we study the effect of only considering the most natural paths, rather than all of them, on the remaining 11 questions. Figure 4 shows the performance of the prediction as a function of the proportion of 3-node paths used. Using our model to filter 3-node paths, the best performance is obtained when only the 30% most natural paths are considered. As a comparison, the pairwise baseline is not able to outperform a random selection.

Across all three evaluations, we consistently find that including all (or too many) paths leads to sub-optimal performance, due to the inclusion of noisy paths, and that our proposed method outperforms existing heuristics based on word embedding and path length.

5 CONCLUSIONS

Our work is motivated by the observation that commonsense knowledge graphs such as ConceptNet are noisy and informal, and that many of the relational paths in such knowledge graphs are therefore non-sensical. This means that the only way in which applications can successfully make use of relational paths from such resources is by relying on a method to filter out these non-sensical paths. While

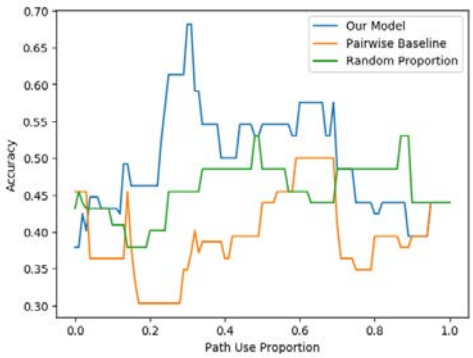

Figure 4: Performance on the 11 analogy questions for which direct connections are not available, using various proportions of natural paths.

this problem has already been studied by others, previous solutions relied on relatively simple heuristics to select higher-quality paths, which we found to perform poorly in practice. In fact, in the extrinsic evaluation tasks, we found that some heuristics were not even able to outperform random selection (Figures 3 and 4).

Rather than engineering more sophisticated heuristics, the solution we proposed in this paper is to take a data-driven approach and learn the concept of path *naturalness* based on crowdsourced judgments. The main insights we obtained are as follows:

(1) although we intentionally left the interpretation of naturalness open to crowdsourcers, they do largely share a common perception of this concept;
(2) this concept can be effectively learned by an LSTM model, with accuracy close to an empirical upper bound derived from the inter-annotator agreement level; and
(3) our learned model outperforms previously proposed heuristics as a path selection method in several intrinsic and extrinsic evaluation tasks.

ABSTRACT

The growth of the Web in recent years has resulted in the development of various online platforms that provide healthcare information services. These platforms contain an enormous amount of information, which could be beneficial for a large number of people. However, navigating through such knowledgebases to answer specific queries of healthcare consumers is a challenging task. A majority of such queries might be non-factoid in nature, and hence, traditional keyword-based retrieval models do not work well for such cases. Furthermore, in many scenarios, it might be desirable to get a short answer that sufficiently answers the query, instead of a long document with only a small amount of useful information. In this paper, we propose a neural network model for ranking documents for question answering in the healthcare domain. The proposed model uses a deep attention mechanism at word, sentence, and document levels, for efficient retrieval for both factoid and non-factoid queries, on documents of varied lengths. Specifically, the word-level cross-attention allows the model to identify words that might be most relevant for a query, and the hierarchical attention at sentence and document levels allows it to do effective retrieval on both long and short documents. We also construct a new large-scale healthcare question-answering dataset, which we use to evaluate our model. Experimental evaluation results against several state-of-the-art baselines show that our model outperforms the existing retrieval techniques.

1 INTRODUCTION

With the growth of the Web in recent years, a vast amount of health-related information is now publicly available on the Internet. Many people use online health information platforms such as WebMD[1] and Patient[2] to search for information regarding the symptoms, diseases, or any other health-related information they are interested in. In addition to consumers, often doctors and healthcare professionals need to look into knowledgebases that contain detailed healthcare information about diseases, diagnosis, and procedures [8, 31]. Despite the abundance of available information, it might be difficult for healthcare consumers to navigate through these documents to get the required healthcare information. Hence, effective retrieval techniques are required to allow consumers to efficiently use such platforms. Since healthcare documents usually include several details about the disease such as it's symptoms, preventive measures, and common treatments, they are usually more elaborate, compared to other factual documents, which describe well-known facts (e.g., population of a town, capital of a city, or any other entity), and are very specific in nature. Hence, in such cases, it might be desirable to provide the consumers with a short piece of text that succinctly answers their queries. Furthermore, many questions that users have about health-related topics are very abstract and open-ended in nature, and hence traditional search methods do not work well in such cases.

Prompted by the success of deep neural networks in language modeling, researchers have proposed several techniques that apply neural networks for effective information retrieval [9, 21] and question answering [33, 38]. This has been facilitated primarily due to the development of large training datasets such as TREC [35] and SQuAD [25]. However, both these datasets are primarily composed of factoid queries / questions, and the answers are generally short in length. Hence, systems trained on such datasets cannot perform

[1] https://www.webmd.com/

What would happen if I didn't take antithyroid medicines?
It is usually advisable to treat an overactive thyroid gland (hyperthyroidism). Untreated hyperthyroidism can cause significant problems with your heart and other organs. It may also increase your risk of complications should you become pregnant. However, in many cases there are other treatment options. That is, radioactive iodine or surgery may be suitable options. See the separate leaflet called Overactive Thyroid Gland (Hyperthyroidism) for details of these other treatment options .

Figure 1: An example of a healthcare question, and it's corresponding answer. The question and answer do not have any overlapping words. The highlighted text corresponds to the most relevant answer snippet from the document.

well in a setting where a large proportion of the queries are non-factoid and open-ended, and the documents are relatively longer in length. Figure 1 shows an example of a typical question that a consumer would have regarding antithyroid medicines, and it's corresponding answer paragraph, selected from the website Patient. This problem and the domain provides some unique challenges which require us to build a more comprehensive retrieval system.

- **Minimal overlap between question and answer words:** There is minimal or no word overlap between the question and answer text. As there are no matching terms, traditional keyword-based search mechanisms will not work for answering such questions.
- **Length of question and answer:** The question is longer than a typical search engine query. The answer is also typically longer than a sentence. Although, for illustration purposes, we show a short paragraph, in many cases, the answer, as well as the document containing it, might be even longer. Hence, neural semantic matching algorithms will not be effective in such cases, as they are ideally designed for short sentences. Therefore, an effective retrieval system would require a mechanism to deal with documents of varied lengths.
- **Non-factoid nature:** The question is very open-ended in nature, and does not ask for any specific factual details. As such, a majority of the machine comprehension models are trained on datasets like SQuAD, which are comprised of factoid QA pairs. Such systems do not work well in a setting where the desired answer is more elaborate.

To overcome these problems, we propose **HAR**, a **H**ierarchical **A**ttention **R**etrieval model for retrieving documents for healthcare related queries. The proposed model uses a cross-attention mechanism between the query and document words to discover the most important words that are required to sufficiently answer the query. It then uses a hierarchical inner attention, first over different words in a sentence, and then over different sentences in a document, to successively select the document features that might be most relevant for answering the query. Finally, it computes a similarity score of a document with the query, that could be used to rank different documents in the corpus, given a query. The use of hierarchical attention also enables it to find the most important sentences and words, that could be important to answer a query, without the need of using an explicit machine comprehension module. To evaluate the performance of our model, we construct a large scale healthcare question answering dataset, using knowledge articles collected from the popular health services website Patient. Although we use this model in the healthcare domain, where the questions are usually non-factoid in nature, and the documents are longer due to the presence of detailed description about different medical procedures, our model is more generic, and can be used in any domain where the questions are open-ended, and the documents are longer.

The rest of this paper is organized as follows: Section 2 gives an overview of the existing techniques related to our work. In Section 3, we describe our proposed neural retrieval model called HAR, and provide the details about its architecture and the training procedure, including the optimization for the HAR model. The details about the data collection and annotation have been described in Section 4. In Section 5, we give details about our experimental evaluation, and the metrics and baseline techniques used in the evaluation process. Finally, Section 6 concludes the paper, with possible directions for future research.

2 RELATED WORK

2.1 Document Ranking

Document retrieval and ranking is a classical problem in the information retrieval community, which has attracted significant interest from researchers for many years. Early methods in informational retrieval were largely based on keyword-based query-document matching [27, 29, 30]. With the advancement of machine learning algorithms, better retrieval mechanisms have been proposed. Logistic Inference [7] used logistic regression probabilities to determine the relevance between queries and documents. In [14], the authors used Support Vector Machine (SVM) based approach for retrieval, which allows the retrieval system to be trained using the search engine click logs. Other traditional techniques in information retrieval include boosting-based methods [6, 41]. TF-IDF based similarity [26] and Okapi BM25 [28] are the most popularly used term-based techniques for document search and ranking. However, such techniques usually do not perform well, when the documents are longer [18], or have minimal exact word overlap with the query.

2.2 Neural Information Retrieval

With the success of deep neural networks in learning feature representation of text data, several neural ranking architectures have been proposed for text document search. Deep Structured Semantic Model (DSSM) [13] uses a simple feed-forward network to learn the semantic representation of queries and documents. It then computes the similarity between their semantic representations using cosine similarity. Convolutional Deep Structured Semantic Model (CDSSM) [34] uses convolutional layers on word trigram features, while the model proposed in [22] uses the last state outputs of LSTM encoders as the query and document features. Both these models then use cosine similarity between query and document representations, to compute their relevance. In [12], the authors

propose convolutional neural network models for semantic matching of documents. The Architecture-I (ARC-I) model proposed in this work also uses a convolutional architecture to create document-level representation of query and document, and then uses a feed-forward network to compute their relevance. The InferSent Ranker [11] proposed recently also uses a feed forward network to compute the relevance between query and documents, by summing up their sentence embeddings. However, all these methods use the document-level semantic representation of queries and documents, which is basically a pooled representation of the words in the document. However, in majority of the cases in document retrieval, it is observed that the relevant text for a query is very short piece of text from the document. Hence, matching the pooled representation of the entire document with that of the query does not give very good results, as the representation also contains features from other irrelevant parts of the document.

To overcome the problems of document-level semantic-matching based IR models, several interaction-based IR models have been proposed recently. In [9], the authors propose Deep Relevance Matching Model (DRMM), that uses word count based interaction features between query and document words, while the Architecture-II (ARC-II) proposed in [12] uses convolution operation to compute the interaction features. These features are then fed to a deep feed-forward network for computing the relevance score. The models proposed in [4, 40] use kernel pooling on interaction features to compute similarity scores, while MatchPyramid [23] uses the dot product between query and document word vectors as their interaction features, followed by convolutional layers to compute the relevance score. Other methods that use word-level interaction features are attention-based Neural Matching Model (aNMM) [42], that uses attention over word embeddings, and [36], that uses cosine or bilinear operation over Bi-LSTM features, to compute the interaction features. The Duet model proposed in [21] combines both word-level interaction features, as well as document-level semantic features, in a deep CNN architecture, to compute the relevance. One common limitation of all these models is that they do not utilize the inherent paragraph and sentence level hierarchy in documents, and hence, they do not perform well in case of longer documents. By using a powerful cross attention mechanism between query and document words, our model can effectively determine the most relevant document words for a query. It then uses hierarchical inner attention over these features, which enables it to effectively deal with long documents. This is especially helpful in cases where the relevant information in the document is a very small piece of text.

2.3 Information Retrieval for Healthcare

Early works in the domain of information retrieval for medicine and healthcare used tradition search methods such as TF-IDF [19] and BM25 [17]. MedQA [45] uses hierarchical clustering along with TF-IDF for answering definitional questions asked by physicians. Th question-answering system proposed in [5] aimed at helping clinicians to search for treatments for any disease. However, their system is tailored to answer one specific type of questions, and cannot be used to answer open-ended questions. As discussed in [15], physicians also often need to use such systems, and they have limited time to browse through every returned document. Hence, medical retrieval needs to be accurate, and should precisely serve the requirements of the users. Retrieval in this domain is complex, attributed to the non-factoid nature of queries, and longer documents. Hence, traditional IR techniques or semantic matching algorithms do not work well on such datasets.

3 THE PROPOSED MODEL

In this section, we introduce our proposed Hierarchical Attention Retrieval (HAR) model, which uses deep attention mechanism for effective retrieval. The detailed architecture of our model is shown in Fig. 2. HAR is a novel neural network model that uses two powerful attention mechanisms to overcome the shortcomings of existing document retrieval models. Given a query q, the model computes a relevance score r_i with each candidate document d_i in the document knowledgebase $\mathcal{D}$. The different components of our model are described in detail below.

3.1 Word Embeddings

The input layer in our model is an embedding lookup function which converts the query and document words into fixed K-dimensional word vectors using a lookup matrix $\boldsymbol{E} \in \mathbb{R}^{V \times K}$ of V pre-trained word embeddings such as GloVe [24] or Word2Vec [20]. Let $\{w_t^q\}_{t=1}^m$ be the words in q. Let l be the number of sentences in document d, and $\{w_t^{id}\}_{t=1}^n$ be the words in sentence i in d. This layer converts each of the words in q and d into the word vectors $\{e_t^q\}_{t=1}^m$ and $\{e_t^{id}\}_{t=1}^n$, respectively. Here, m and n are the number of words in query and each of the document sentences, respectively.

3.2 Encoder

We use two bidirectional RNN (Bi-RNN) [32] encoders to encode the inter-document temporal dependencies within query and documents words, respectively. This layer consists of two RNN layers in different directions, whose output is concatenated to get the H-dimensional contextual representation of each word. We choose GRU [2] over vanilla-RNN or LSTM [10] because of its high performance and computational efficiency. Since we split the documents into short sentences, GRU performs equally well as LSTM, because the encoder does not need to deal with very long sequences.

3.2.1 Query Encoder. The query encoder contains a simple Bi-GRU layer, which takes the query word embeddings $\{e_t^q\}_{t=1}^m$ as the input, and outputs the contextual representation $U^q = \{u_t^q\}_{t=1}^m \in \mathbb{R}^{m \times H}$.

$$u_t^q = BiGRU_Q(u_{t-1}^q, e_t^q) \tag{1}$$

3.2.2 Document Encoder. Since documents are usually longer than queries, we encode each sentence in the document separately, using a sentence-level Bi-GRU encoder. Given a sentence i, this layer takes the sentence word embeddings $\{e_t^{id}\}_{t=1}^n$ as the input, and returns the contextual word embeddings $U^{id} = \{u_t^{id}\}_{t=1}^n \in \mathbb{R}^{n \times H}$. After encoding each of the l sentences in the document through this encoder, the new document representation is $\{U^{1d}, .., U^{ld}\} \in \mathbb{R}^{l \times n \times H}$.

$$u_t^{id} = BiGRU_D(u_{t-1}^{id}, e_t^{id}) \tag{2}$$

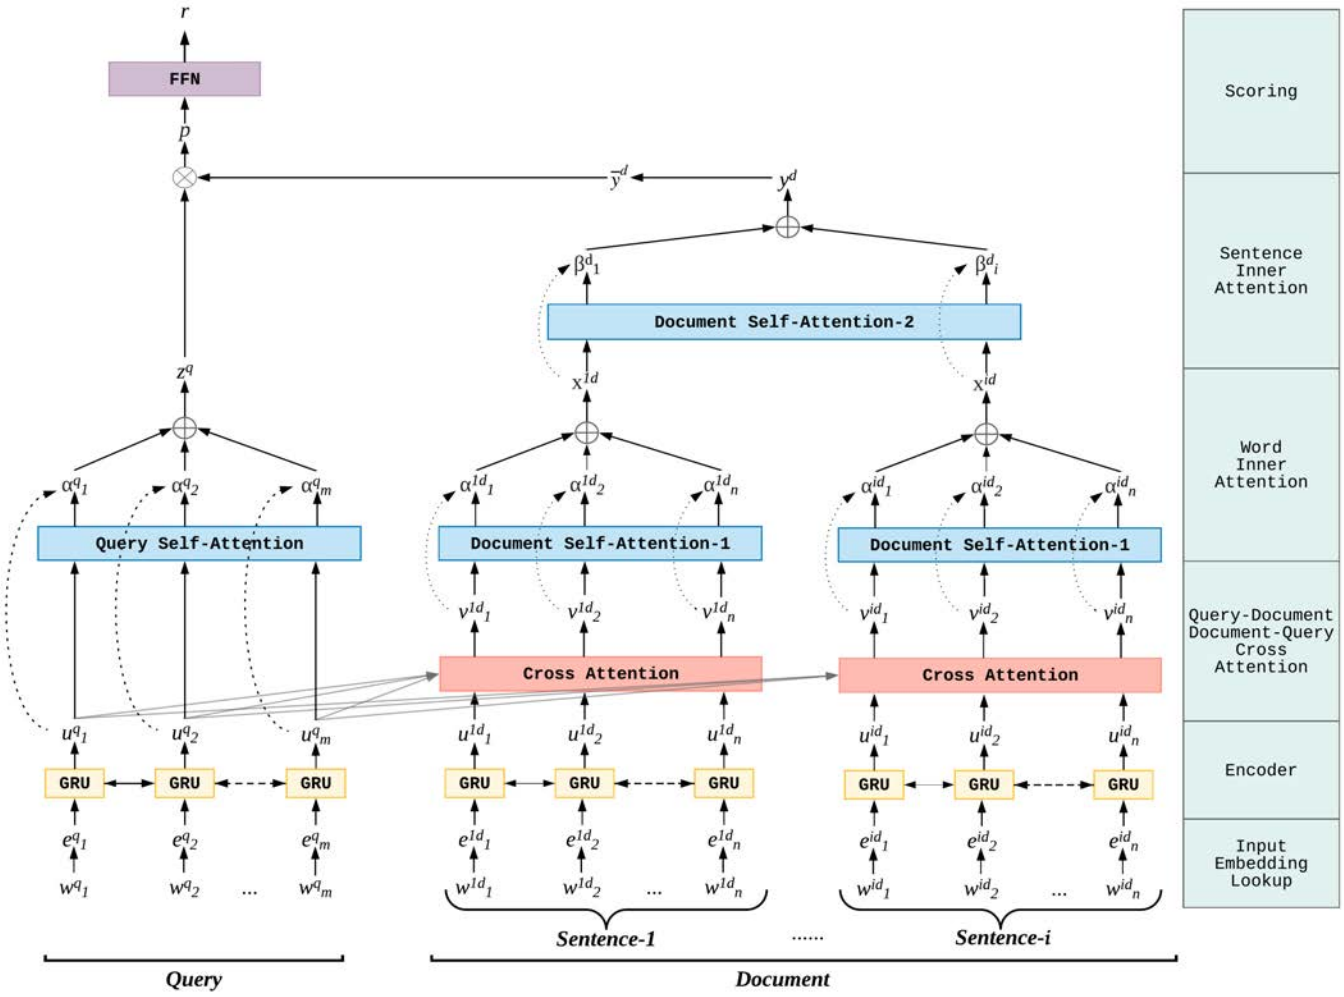

Figure 2: Architecture of the proposed HAR model.

3.3 Cross Attention between Query and Document

This layer is used to fuse the information from query words to the document words. It computes the relevance of each query word with respect to each word in the document. As we use a hierarchical modeling for documents, this layer can compute the attended embeddings of each word in sentence i in d with each word in the query q. We use the cross attention mechanism proposed in [39, 44], as this method has been proven to show superior performance in state-of-the-art reading comprehension systems. The attention layer computes the relevance between each pair of query and document words, using their contextual embeddings generated by the respective encoders. To calculate the relevance of query words with respect to document words, and vice-versa, we use bi-directional attention mechanism [33], which is composed of document-to-query attention $D2Q$ and query-to-document attention $Q2D$. This is done by first computing a similarity matrix $S \in \mathbb{R}^{n \times m}$, which is then normalized over each row and column, using a normalization operation such as softmax. This generates normalized similarity matrices $\overline{S}_{D2Q} \in \mathbb{R}^{n \times m}$ and $\overline{S}_{Q2D} \in \mathbb{R}^{n \times m}$, respectively. Finally, the attention matrices $A_{D2Q} \in \mathbb{R}^{n \times H}$ and $A_{Q2D} \in \mathbb{R}^{n \times H}$ can be computed as described below.

Let $s_{xy} \in \mathbb{R}$ be an element of the similarity matrix S from row x and column y. Given $U^{id} \in \{U^{1d}, .., U^{ld}\}$ and U^q as inputs, the final output $V^{id} = \{v_t^{id}\}_{t=1}^n \in \{V^{1d}, .., V^{ld}\}$ of the cross attention layer can be computed as follows:

$$s_{xy} = w_c^T \cdot [u_x^{id}; u_y^q; u_x^{id} \odot u_y^q] \tag{3}$$

$$\overline{S}_{D2Q} = \text{softmax}_{\text{row}}(S) \tag{4}$$

$$\overline{S}_{Q2D} = \text{softmax}_{\text{col}}(S) \tag{5}$$

$$A_{D2Q} = \overline{S}_{D2Q} \cdot U^q \tag{6}$$

$$A_{Q2D} = \overline{S}_{D2Q} \cdot \overline{S}_{Q2D}{}^T \cdot U^{id} \tag{7}$$

$$V^{id} = [U^{id}; A_{D2Q}; U^{id} \odot A_{D2Q}; U^{id} \odot A_{Q2D}] \in \mathbb{R}^{n \times 4H} \tag{8}$$

In the above equations, ; is the concatenation operation, $\odot$ is element-wise multiplication, $\cdot$ is matrix multiplication, and $w_c \in \mathbb{R}^{3H}$ is a trainable weight vector.

3.4 Query Inner Attention

To encode variable length queries into a fixed size embedding, we use the self attention mechanism proposed in [16]. The importance of different words varies from document to document, and is dependent on the context in which they are used. This layer allows the model to give higher priority to more important words while creating a pooled representation of the query. This ensures that the query representation contains features from more significant words. Let A be the dimension of the pooled representation. Given query features $U^q = \{u_t^q\}_{t=1}^m$ as the input, this layer generates a pooled representation of $z^q \in \mathbb{R}^H$ as follows:

$$c_t^q = w_q^T(\tanh(W_q u_t^q)) \tag{9}$$

$$\alpha_t^q = \frac{\exp(c_t^q)}{\sum_{j=1}^m \exp(c_j^q)} \tag{10}$$

$$z^q = \sum_{t=1}^m \alpha_t^q u_t^q \tag{11}$$

3.5 Document Hierarchical Inner Attention

Since documents are longer in length, it is not necessary that the entire document is relevant to a query. In fact, in most cases, it is observed that part of the document that is relevant to a query is just a few sentences. Even inside each sentence, different words might have varying relevance to the query. Furthermore, because of the varied lengths of documents, a mechanism is required to get a fixed-dimensional representation of the document. Hence, we use a two-level hierarchical inner attention (as proposed in [43]), to get the document embedding.

3.5.1 Level-1: Attention over words in a sentence. The first level in our hierarchical attention encodes each sentence independently from other sentences at word-level, resulting in a fixed-dimensional representation of each sentence. This layer computes the importance of each word within the sentence, and then creates a pooled representation of each sentence weighted by the attention weights. For each sentence i in the document d, this layer takes the output vectors $V^{id} = \{v_t^{id}\}_{t=1}^n \in \mathbb{R}^{n \times 4H}$ from the cross-attention layer as the input, and returns a sentence vector $x^{id} \in \mathbb{R}^{4H}$.

$$c_t^{id} = w_{d1}^T(\tanh(W_{d1} v_t^{id})) \tag{12}$$

$$\alpha_t^{id} = \frac{\exp(c_t^{id})}{\sum_{j=1}^n \exp(c_j^{id})} \tag{13}$$

$$x^{id} = \sum_{t=1}^n \alpha_t^{id} v_t^{id} \tag{14}$$

3.5.2 Level-2: Attention over sentences in a document. To ensure that the sentences more relevant to the query are given higher importance while computing the similarity score, we use a second inner attention, to compute the document representation. This layer takes the sentence embeddings $\{x_i^d\}_{i=1}^l$ as the input, and returns a document vector $y^d \in \mathbb{R}^{4H}$ as the output.

$$b_i^d = w_{d2}^T(\tanh(W_{d2} x^{id})) \tag{15}$$

$$\beta_i^d = \frac{\exp(b_i^d)}{\sum_{j=1}^l \exp(b_j^d)} \tag{16}$$

$$y^d = \sum_{j=1}^l \beta_j^d x^{jd} \tag{17}$$

3.6 Score Computation

The final layer in our model computes the score between the query representation z^q and document representation y^d. Since the dimension of y^d is 4 times the dimension of z^q, we first pass y^d through a feed-forward layer to compute $\overline{y}^d \in \mathbb{R}^H$. After this, we compute the similarity vector $p \in \mathbb{R}^H$ by performing element-wise multiplication of z^q and $\overline{y}^d$. Finally, we pass p through a feed-forward network to compute the final relevance score $r \in \mathbb{R}$.

$$\overline{y}^d = w_{d3}^T y^d + b_{d3} \tag{18}$$

$$p = z^q \odot \overline{y}^d \tag{19}$$

$$r = w_f^T p + b_f \tag{20}$$

3.7 Optimization

3.7.1 Negative sampling. Many retrieval datasets, such as the ones created using user click-logs, only have the query-document pairs, which serve as the positive data for the model. However, for the model to have sufficient discriminative power to give a score to every document proportional to their relevance with the query, the model also needs negative query-document pairs during the training process. Hence, we do negative sampling to generate negative data samples of query-document pairs for our model. For each query, the negative samples are composed of the following:

- *Irrelevant negative samples:* For the model to have a sufficient discriminative power that is needed to distinguish documents at a high level, we sample negative documents that have very low relevance to the query.
- *Partially relevant negative samples:* We define partially relevant negative documents as those that might have some relevance to the query, either due to some overlapping words, or because they are from the same topic, but do not contain the correct answer for the query. As suggested in [37], having such samples in the training dataset gives a higher discriminative power to the model,

as compared to a model trained with randomly sampled negative pairs.

3.7.2 Loss function. We use pairwise maximum margin loss [14] as the objective function to be minimized. Given a query q, positive document d^{pos}, and k negatively sampled documents $\{d_1^{neg}, .., d_k^{neg}\}$, the loss is given by:

$$\mathcal{L} = \sum_{i=1}^{k} max(0, M - score(q, d^{pos}) + score(q, d_i^{neg})) \quad (21)$$

Here, M is the margin, by which we want the score of positive query-document pair to exceed that of a negative query-document pair.

4 HEALTHQA DATASET

We will now introduce the dataset created in this work to train and evaluate the proposed HAR model. We call this dataset *HealthQA*. It consists of question and document pairs from the healthcare domain. The details of this dataset are described below:

4.1 Knowledge Articles

To create HealthQA dataset, we collected healthcare articles from the popular health-services website Patient. We scraped all the articles from the *Health Topics* section of Patient. The website contains articles from a diverse set of healthcare domains such as child health, mental health, sexual health, details about treatments and medications, and several other healthcare domains. The articles on this website are much more detailed, as compared to other healthcare knowledgebases like MedlinePlus[3]. In total, we collected 1,235 health articles, with each article having an average of 6 sections. As the sections themselves are very long in these articles, we use each section as one document.

Figure 3 shows the distribution of percentage of documents with respect to the length of the documents (number of words). We can see that the proportion of documents with less than 50 words is very less (5%). The dataset contains a large number of documents with 100-200 words, and a high proportion of documents containing more than 200 words.

4.2 Question-Answer Pair Generation

To create healthcare-related questions, we employed human workers from diverse age groups, and from different countries. For the dataset to have a diverse set of questions and answers that different people might have about healthcare, we hired six annotators, consisting of a combination of freelancers, graduate and undergraduate students. To ensure high quality of the dataset, and low error rates, we ensured that all the annotators had good English skills. For each document, workers were instructed to create 1 to 3 questions that can be asked using the information given in the document. They were encouraged to use simple language in the queries, so that the questions follow the style of those asked by a common person, without any domain expertise in healthcare. All the generated questions also underwent an additional round of cross validation by the authors, and any query-document pairs with errors or insufficient context were either corrected or discarded.

[3]https://medlineplus.gov/

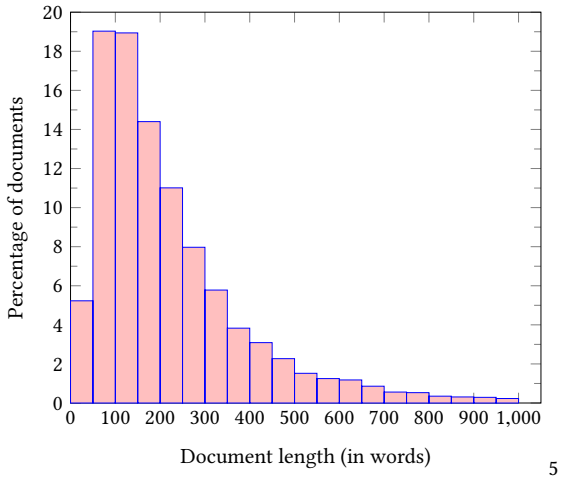

Figure 3: Percentage of documents vs. number of words.

It was found that many articles on Patient have several subtitles, roughly one subtitle per paragraph, and in most cases, these subtitles could be rephrased into valid questions. Some of the titles have incomplete context, which can be made into a valid question by rephrasing them. Hence, workers were also allowed to use the subtitles as questions, by rephrasing them into valid questions.

Figure 4 shows the percentage of different types of questions in our dataset. The questions with the type “How" and “Why" are mostly non-factoid in nature. Such questions are open-ended, and require detailed answers. Although the questions with the type “What", that are generally factoid, have a large proportion in our dataset, after manual analysis, we found that a large proportion of such questions are also non-factoid. Examples of such questions include *“What is the outlook of gaming disorder?"*.

Table 1: Statistics of the HealthQA dataset.

Number of articles	1,235
Number of documents (article sections)	7,355
Number of questions	7,517
Average length of questions (in words)	8.04
Average length of documents (in words)	233.4
Average number of sentences in documents	13.54
Average length of sentences (in words)	17.24

5 EXPERIMENTAL RESULTS

5.1 Evaluation Metrics

We compare the performance of HAR with various baseline techniques using the following evaluation metrics:

- **Recall@K:** Recall@K for a query is defined as the ratio of the number of relevant documents in top-K retrieved documents, with respect to the total number of relevant documents for that query. This is averaged over all the queries in the dataset. Since, in our case, each query has only one relevant document, Recall@K

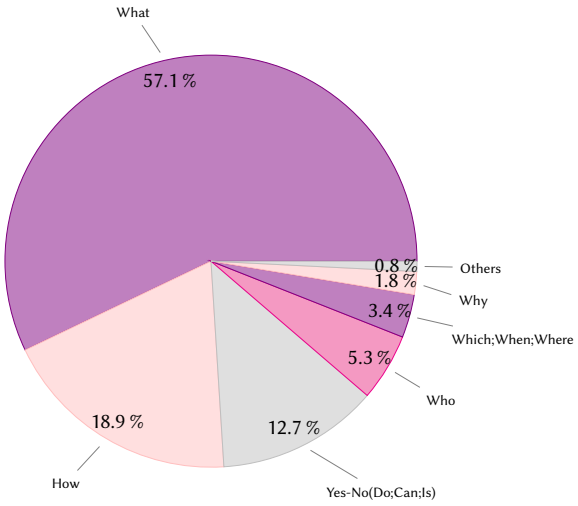

Figure 4: Percentage of questions by type.

denotes the percentage of queries whose correct document was present in the top-K retrieved documents.

$$Recall@K = \frac{1}{Q_{test}} \sum_{i=1}^{Q_{test}} \frac{\#\text{ relevant documents in top-K for query } i}{\#\text{ total relevant documents for query } i} \tag{22}$$

- **Mean Reciprocal Rank (MRR):** The reciprocal rank is defined as the inverse of the rank of the first correct document d^{pos} for a given query. MRR is the mean of the reciprocal rank for all the queries in the test set. Since we have only one correct document for every query, MRR is well suited for our evaluation. As compared to Recall@K, MRR also takes into account the ranking order in the evaluation.

$$MRR = \frac{1}{Q_{test}} \sum_{i=1}^{Q_{test}} \frac{1}{rank(d^{pos}) \text{ of query } i} \tag{23}$$

5.2 Baseline Methods

For performance comparison, we use the following state-of-the-art retrieval models as the baselines:

- **TF-IDF:** This is the standard baseline for retrieval tasks, that uses TF-IDF representation for both the query and document, and cosine similarity as the similarity function.
- **CDSSM [34]:** It is an extension of DSSM, that uses a CNN-based model on letter trigrams from query and document as input features, and then computes the cosine similarity to calculate the relevance between query and document representation.
- **ARC-II [12]:** This model first computes the interaction feature vector between query and document using CNN layers. It then computes the score for the query-document interaction vector using feed-forward network.
- **MV-LSTM [36]:** It is a neural semantic matching model that was proposed to find semantic similarity between a pair of sentences. The model uses the word embeddings obtained by passing the sentences through a Bi-LSTM, and then computes an interaction vector using cosine similarity, or a bilinear operation. It finally passes the interaction vector through a feed-forward network to compute the similarity score. In our implementation, we use cosine similarity to compute the interaction vector.
- **DRMM [9]:** It is a state-of-the-art neural ranking model that uses cosine similarity between query and document word vectors to compute their similarity, and then computes a histogram-like interaction vector by binning the cosine similarity scores into pre-defined intervals. It then passes these features through a feed-forward network to compute the scores.
- **KNRM [40]:** It is a recently proposed neural ranking model that first computes cosine similarity between each query word with each of the document words. It then performs kernel pooling, followed by a feed-forward network to compute the relevance score.
- **aNMM [42]:** This model first computes an interaction matrix by computing the cosine similarity between each of the query and document words. Similar to DRMM, this model also performs binning to compute a fixed-dimensional interaction vector. However, instead of using the counts of word-pairs that fall into a bin as its features, this model uses the total sum of the similarity between those word pairs as the bin features. It also uses an attention mechanism over the query word vectors, which is then combined with the interaction vector to compute the final relevance scores.
- **Duet [21]:** It is a recently proposed hybrid neural matching model that uses the word-level interaction, and document-level similarity, in a deep CNN architecture, to compute similarity between two documents.
- **MatchPyramid [23]:** This model computes pair-wise dot product between query and document word vectors to compute an interaction matrix. It then passes this matrix through CNN layers with dynamic pooling to compute the similarity score.

5.3 Implementation Details

We implemented our model in Keras [3], with TensorFlow [1] as the backend. The model was trained using Adadelta optimizer [46], with an initial learning rate of 2.0. We used one Bi-GRU layer (one forward and one backward), and each GRU layer had an output dimension of 150 units. The maximum number of words in query, and each document sentence was set to 15, and sentences greater than 15 words were split into multiple sentences. The maximum number of sentences in each document was set to 20. All the attention layers had a dimension of 300. We used a feed-forward network with 3 layers to compute the final score from the similarity vector. Additionally, we used dropout of 0.2 after each layer. For each query, we had one positive document, 3 partially relevant negative documents, and 6 irrelevant negative documents. For all the neural baselines, we used an open-source implementation MatchZoo[4]. The TF-IDF baseline was implemented using the `scikit-learn`[5] package.

We used GloVe [24] pre-trained word vectors with 300 dimensions. Since healthcare documents contain some medical words which cannot be found in GloVe, we used randomly initialized embeddings for such out-of-vocabulary words. We experimented with

[4]https://github.com/NTMC-Community/MatchZoo
[5]http://scikit-learn.org/stable/index.html

training GloVe word vectors on our document corpus, but it was found that the original pre-trained GloVe outperformed our medical word embeddings. We hypothesize that it was due to the fact that our corpus contained far lesser documents than those used in the original GloVe. Also, it is observed that people usually do not use very complex medical words in their queries, and hence, most of the queries were composed of words that were present in the pre-trained GloVe.

The dataset was split into three parts: train, validation, and test. The number of queries in each split were 5,274, 1,109, and 1,134 respectively.

5.4 Results

In this section, we present the results obtained in the experimental evaluation of the proposed HAR model.

5.4.1 Quantitative comparison against state-of-the-art models. Table 2 shows the performance of HAR against the baseline retrieval models on the HealthQA dataset. For computing Recall@K, we set K as 1, 3, and 5. As we can see, the results for HAR are consistently better than all other baselines, across all the metrics, which can be attributed to its strong performance.

- **Effect of long documents on model performance:** We can observe from Table 2 that TF-IDF has very low performance on our dataset. With the exception of ARC-II, the performance of TF-IDF is consistently lower than all the other models. This can be attributed to the non-factoid nature of our dataset, as well as the long length of documents in the corpus. Hence, a keyword-based method cannot perform well on such dataset, since its performance largely depends on the word overlap between the query and the document. In such cases, embedding-based methods yield better performance in general, as they can correlate queries and documents based on their semantic representation.
- **Document-representation based semantic similarity methods:** One key observation from our results is that neural models that match query with documents solely based on their document-level representation do not work well for retrieval problems. CDSSM computes the representation of query and document separately, and then computes the similarity between their vector representations. Although using semantic representations can help in dealing with the problems that arise where the queries do not have matching words with the documents, this concept only works in problems such as sentence or paraphrase matching, where the length of both the documents being matched is similar. In case of retrieval, queries are typically much shorter compared to the documents. Moreover, the actual part in the document that is relevant to the query is only a few words or sentences. Hence, the vector representation of the document contains features from other parts of the documents that are irrelevant to the query. This leads to the poor performance of such models for retrieval tasks.
- **Effect of word interactions:** With the exception of ARC-II, other baselines such as MV-LSTM, DRMM, KNRM, aNMM, Duet, and MatchPyramid use some form of embedding-based pair-wise keyword interaction in the feature representation of the query-document pair. This results in their better performance compared to other baselines. Using word-level interaction features based on their vector representation allows the models to deal with the problems faced by traditional word matching methods such as TF-IDF. However, by computing interaction in the early stages of the model, these models do not have any mechanism to incorporate the underlying structure of the query and document in the interaction feature generation or scoring process. This leads to their poor performance in a setting where the documents are longer in length.

By using a cross attention mechanism between the query and document, HAR is able to model the interaction features between the query and document words, while retaining the overall semantic meaning of the document sentences. The self attention mechanism then facilitates focussing on sentences and words in the document that are most relevant to the query. This mechanism helps HAR to achieve the highest performance compared to all other baseline methods. Most importantly, HAR achieves a considerably high MRR and Recall@1 against all other methods. This implies that, in most of the cases, our model is able to rank the correct document with the highest score, demonstrating a higher reliability of HAR.

In Figure 5, we show the performance of HAR and other baseline methods on each of the question types given in Figure 4. Although questions of the type *"what"* are relatively easier to answer (as they contain many factoid questions), our model outperforms other baselines on these questions. We can also see that HAR gives high performance on question types *"how"* and *"why"*, which are non-factoid in nature, and difficult for a retrieval system. The performance of HAR is consistently higher than the baselines across all other question categories as well.

5.4.2 Qualitative results. For qualitative evaluation of the performance of HAR, we show an example of a question, and the retrieved document, obtained by MatchPyramid and HAR, in Figure 6. We compare with MatchPyramid, since it is the strongest baseline among all the other methods. The question shown here is about *"the effect of wisdom tooth removal on brushing"*. Although the document returned by MatchPyramid is relevant to the topic, which is *wisdom teeth removal*, it is not the one that can correctly answer the query. MatchPyramid computes interaction features at an early stage in the model. It does not retain the original query and document, and computes scores solely based on the interaction features. Due to this, the main intent of the question can sometimes be lost, as shown in the example here. By using a powerful attention mechanism, HAR has the ability to discriminate between two similar documents, based on the intent of the query. Hence, HAR is able to retrieve the correct document for the question.

5.4.3 Using HAR for answer extraction. As mentioned earlier, an added advantage of using the hierarchical attention mechanism is that it allows the model to discover the most probable answer snippet from the long document. This can be done by comparing the attention weights of different sentences in level-1 of hierarchical inner attention over documents. Since sentences with high attention weights have more contribution towards generating the document representation, they are likely to be more relevant to the query, as compared to sentences with low attention weights.

In Figure 7, we illustrate how the attention weights can be used to extract the most probable answer from the document. We show

Table 2: Comparison of HAR model with other baseline models on HealthQA dataset.

Model name	MRR	Recall@1	Recall@3	Recall@5
TF-IDF	60.597	36.576	81.740	96.909
CDSSM	64.461	44.274	81.335	93.418
ARC-II	50.366	29.847	61.858	78.539
MV-LSTM	75.145	58.882	90.262	97.385
DRMM	74.082	57.078	90.081	99.008

one question, and it's corresponding highest-ranked document. The self-attention weights over the query words are highlighted in blue, while the self-attention weights at sentence level (level-1) of the document hierarchical attention are shown in red.

The question shown in Figure 7 is about *Alopecia Areata*, which is a condition that leads to hair loss in many people, mainly because the immune system of a person starts attacking the hair follicles. The question asks about the diagnosis procedure for this condition, demonstrated by the use of the word *test*. Since diagnosis is the main intent of this question, the feature representation uses highest

Will removal of wisdom teeth affect my brushing ?	
MatchPyramid answer (incorrect): Most people need two or three days off work to recover from the effects of the anaesthetic after they have had wisdom teeth removed. Those with a more physical job may need an extra day or two. If your job involves driving you should be fine to return after 24 - 48 hours after having had anaesthetic, but you need to use your own judgement and seek advice from your dentist if you are unsure.	**HAR answer (correct):** You may find it uncomfortable to brush shortly after having wisdom teeth removed, especially around any wounds. For this reason, your dentist might recommend that you use a mouthwash to help keep the area clean.

Figure 6: An example of a question and its answer retrieved by MatchPyramid (left) and HAR (right).

attention weight for the word *test*, followed by other words that are useful in the question. The document here has the highest attention weight for the first sentence, that contains the answer to this question. Other highlighted sentences in the document are those which can provide additional information supporting the answer for this question.

Do I need any tests, for Alopecia Areata ?

Usually not . the diagnosis is usually based on the typical appearance of the bald patches . If there is doubt about the cause of the hair loss , sometimes some blood tests or a skin scraping from a bald patch may be done to rule out other causes . A small sample of skin (skin biopsy) is sometimes taken to look at under the microscope . Occasionally you may need some tests to check for other autoimmune diseases . For example , if you have certain other symptoms , you might need to have blood tests to check your blood count and thyroid function . Usually blood tests come back entirely normal with alopecia areata .

Figure 7: An example of a question and its answer document with highlightings based on the attention weights. The attention weights for the question are obtained from the query self attention, and those for document are obtained from level-2 self attention.

5.5 Performance Analysis

5.5.1 Effect of attention mechanism. To quantitatively evaluate the effect of various components used in our HAR on the model performance, we compare the performance of HAR against its two variants. These are described below:

- **HAR without cross-attention:** To evaluate the effect of using cross-attention mechanism on model performance, we evaluate the performance of a variant of HAR that does not use cross-attention between query and document words. This model uses an inner attention over query words, and a hierarchical inner attention over document words and sentences. By removing the cross attention, the model is not able to use the interaction features between query and document word vectors in the scoring process. We refer to this model as *HAR-WCA*.
- **HAR without cross and hierarchical attention:** This is an even simpler version of HAR that neither uses cross-attention between query and document words, nor the hierarchical inner attention in the document. This model uses similar encoder as HAR for query and document, and then uses only one level of inner attention to get the query and document representations. It then computes the scores between these vectors similar to the scoring process used in HAR. It does not incorporate the underlying document structure in the scoring process due to the removal of hierarchical attention. We refer to this model as *HAR-simple*.

Model name	MRR	Recall@1	Recall@3	Recall@5
HAR-simple	82.139	69.883	94.770	99.008
HAR-WCA	83.667	72.047	95.942	99.369
HAR	**87.877**	**78.900**	**96.844**	**99.639**

Table 3: Performance comparison of HAR and its variants.

Table 3 shows the performance comparison of HAR with two of its variants. The performance of both *HAR-WCA* and *HAR-simple* is worse than the full model. We believe that since *HAR-simple* uses a single long encoder for documents, it is not able to embed the contextual dependencies in the encoded embeddings. Also, it does not use cross-attention, thereby ignoring the keyword-interaction features. The performance of *HAR-WCA* is slightly better than that of *HAR-simple*. Since each sentence sequence is much smaller than the full document, the encoded representation is able to embed the context of the sentence in each word.

5.5.2 Hyperparameter sensitivity and model convergence. As mentioned earlier, by splitting the documents into short sentences and using the hierarchical attention mechanism, HAR does not need to deal with long sequences. This allows the model to be achieve high performance using computationally efficient GRU, which can effectively model short sequences. We also find that by using GRU, the model is able to converge quickly, as compared to a model that uses LSTM. We also evaluated the performance of HAR by varying different parameters of our model, such as the number of GRU hidden units and the number of feed-forward layers. We find that these parameters only have a marginal impact (~1% MAP reduction) on the performance of our model. In Figure 8, we show the convergence of HAR and other baselines over training epochs. We show the MRR of different models on test queries, as the number of training epochs increase. We can see that HAR converges faster as compared to other baselines, demonstrating a better learning ability of our model.

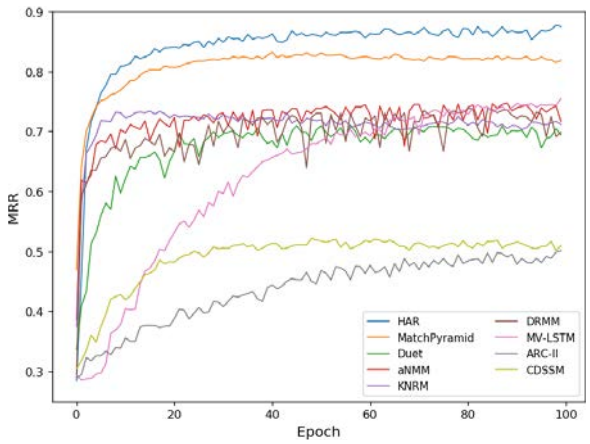

Figure 8: MRR convergence with training epochs.

6 CONCLUSION

In this paper, we proposed a novel deep neural network architecture to rank documents for healthcare related queries. The model uses a combination of powerful attention mechanisms to develop a robust retrieval system. This attention mechanism also enables the model to discover highly probable answer snippets from the documents, without the need for using a computationally expensive machine comprehension module. The model has been carefully designed by considering the special characteristics of question-answering in healthcare domain, such as the open-ended nature of queries, and longer document length.

To evaluate the proposed HAR model, we constructed a novel consumer-oriented healthcare question answering dataset, HealthQA. This dataset is comprised of questions that consumers typically ask about health-related topics. We evaluated our proposed model on this dataset, against several state-of-the-art baseline techniques. Our experimental results show that our model outperforms these techniques by a wide margin. We also show how our model can be used to extract the most probable answer snippets from the highly-ranked documents. We hope that our proposed model will be useful for both healthcare and information retrieval communities, to make healthcare information more accessible to the people.

ABSTRACT

As the popularity of adblocking has soared over the last few years, publishers are increasingly deploying anti-adblocking paywalls that ask users to either disable their adblockers or pay to access content. In this work we propose ShadowBlock, a new Chromium-based adblocking browser that can hide traces of adblocking activities from anti-adblockers as it removes ads from web pages. To bypass anti-adblocking paywalls, ShadowBlock takes advantage of existing filter lists used by adblockers and hides all ad elements stealthily in such a way that anti-adblocking scripts cannot detect any tampering of the ads (e.g., absence of ad elements). Specifically, ShadowBlock introduces lightweight hooks in Chromium to ensure that DOM states queried by anti-adblocking scripts are exactly as if adblocking is not employed. We implement a fully working prototype by modifying Chromium which shows great promise in terms of adblocking effectiveness and anti-adblocking circumvention but also more efficient than the state-of-the-art adblocking browser extensions. Our evaluation on Alexa top-1K websites shows that ShadowBlock successfully blocks 98.3% of all visible ads while only causing minor breakage on less than 0.6% of the websites. Most importantly, ShadowBlock is able to bypass anti-adblocking paywalls on more than 200 websites that deploy visible anti-adblocking paywalls with a 100% success rate. Our performance evaluation further shows that ShadowBlock loads pages as fast as the state-of-the-art adblocking browser extension on average.

1 INTRODUCTION

The deployment of adblocking technology has been steadily increasing over the past few years. PageFair reports that more than 600 million devices globally use adblockers as of December 2016 [1]. Many reasons contribute to the popularity of adblocking. First, lots of websites show flashy and intrusive online ads that negatively impact user experience. Second, the pervasiveness of targeted or personalized ads has incentivized a global ecosystem of online trackers and data brokers, which in turn raises concerns for user privacy. Third, the inclusion of numerous advertising and tracking scripts causes excessive website bloat resulting in slower page loads. The rise of adblocking has jeopardized the ad-powered business model of many online publishers. For example, U.K. publishers lose nearly 3 billion GBP in revenue annually due to adblocking [2].

In response to adblocking, many publishers have deployed JavaScript-based, client-side anti-adblockers to detect and circumvent adblockers. An anti-adblocker typically consists of two components: detection and reaction. For adblocker detection, common practices include checking the absence of ad elements and proactively injecting bait ad elements [33]. Both practices exploit the fact that adblockers make observable changes to the DOM by either blocking relevant requests or hiding DOM elements directly [37]. As a result, these DOM changes can be perceived by the detection part of anti-adblockers through invocation of JavaScript APIs such as `getElementById()`. After adblocker detection, the reaction component can perform different subsequent operations. It can be aggressive paywalls that prevent users from accessing the content or even switching ad sources.

Adblockers have addressed anti-adblockers in one of the following three ways: (i) blocking the JavaScript code of anti-adblockers using filter lists [29], (ii) disrupting anti-adblocker code based on program analysis [39], and (iii) hiding the trace of adblocking to fool anti-adblockers [37]. The first countermeasure is currently adopted by the adblocking community using filter lists such as Anti-Adblock Killer and Adblock Warning Removal [29]. However, the coverage and accuracy of these filter list is lacking. Our manual evaluation on 207 websites using anti-adblockers with visible reactions (i.e. warning message or paywall), only less than 30% of them are correctly identified by Adblock Warning Removal [4] or Anti-Adblock Killer [5]. This is likely due to the manual nature of filter list curation and maintenance which is cumbersome and error-prone. The second countermeasure of rewriting JavaScript to deactivate anti-adblockers is prone to false positives causing site breakage with unacceptable user experience degradation [39]. The third countermeasure of hiding the trace of adblocking, as

implemented in prior work [37], is not stealthy because it injects new JavaScript which is easily detectable by anti-adblockers.

In this paper, we aim to completely hide the traces of adblocking in a stealthy manner by going deep into the browser core. This is analogous to the rootkits in the OS kernel where user applications are unable to detect the presence of a malicious process [36]. Since the browser core is at a lower level (more privileged), it is in theory capable of hiding the states of adblockers from the anti-adblockers while presenting an ad-free view to the user. Specifically, since anti-adblocker is implemented as client-side JavaScript, it can only access web-page states through a number of predefined Web APIs including the ones used to probe the the presence/absence of ad elements. These APIs are standardized by W3C and implemented eventually by web browsers. ShadowBlock hooks any JavaScript API that can potentially distinguish the difference before and after hiding ad elements, and assures no information about the element hiding can be leaked through such API.

We tackle three major challenges in designing and implementing ShadowBlock. First, existing adblockers' model of blocking ad-related URLs (e.g., scripts, iframes, images) does not fit well in our requirement of presenting the same exact DOM view as if no adblocker is employed. For example, if a DOM element is not even retrieved, ShadowBlock would have no way to fake its size, dimension, and other properties. Second, given that the Web APIs suite and the rendering process implemented in modern web browsers are highly complex and intertwined, there may exist unexpected channels that leak information about adblocking deployment. To achieve stealthy adblocking, we need to ensure that no such channel discloses differentiable information about our element hiding action in a conclusive way. Third, modern web browsers make significant efforts in improving their page loading and rendering performance. As we develop ShadowBlock on open-sourced Chromium, we need to minimize the overhead it incurs during the page load process.

Contributions. We summarize our key contributions as follows.

(1) We design a well-reasoned solution where we present two different views to anti-adblockers and users. On one hand, ad elements are never directly blocked (so they remain visible to anti-adblockers); on the other hand, these ads are stealthily hidden from users.
(2) We reuse the rules from filter lists used by adblocking browser extensions to element hiding decisions. On top of existing lists that are community-backed and have been widely adopted, we replicate 98.3% of their ad coverage according to manual inspection over Alexa Top 1K websites, with less than 0.6% breakage rate.
(3) We design and implement a fully functional prototype which is open-sourced at the time of publication. We evaluate the effectiveness of ShadowBlock prototype on 207 websites with visible anti-adblockers. We pick real anti-adblockers with different trigger mechanisms and of different complexity. All of them are successfully evaded by our new adblocker design.
(4) Our performance evaluation of ShadowBlock shows that it loads pages comparably fast as Adblock Plus on average, in terms of Page Load Time and SpeedIndex.

2 BACKGROUND AND RELATED WORK

2.1 Adblockers And Filter Lists

Mechanisms. Adblockers rely on manually curated filter lists to identify ads on web pages. EasyList and EasyPrivacy are two most widely used filter lists to block online ads and trackers, with about 71000 and 15000 rules [8], respectively. These lists consist of two types of rules which are basically regular expressions. One of them is HTTP rules that block HTTP requests to URL addresses that are known to serve ads. For example, the first filter rule below blocks all third-party HTTP requests to amazon-adsystem.com, preventing any resource on this domain from being downloaded. The other type is HTML rules, which generally hides HTML elements that are identified as ads. For example, the second filter below hides all HTML elements with ID `promo_container` on wsj.com.

```
||amazon-adsystem.com^$third-party
wsj.com###promo_container
```

It is noteworthy that HTML rules are mostly only introduced to complement HTTP rules while dealing with first-party text ads. This is because these text ads are directly embedded into the HTML itself with no associated additional resource loads, making it inevitable to be included while the browser downloads the web page. Otherwise, HTTP rules are preferred as they prevent ad resources from being loaded in the first place, saving unnecessary network traffic and avoiding execution of ad-related scripts to speed up page loading and rendering.

Limitations. A group of volunteers that maintain filter lists carry out the manual process to add new rules, correct and remove erroneous or redundant rules all based on informal feedback from users [7]. Due to its crowd-sourced nature, this laborious effort faces challenges from both the completeness and soundness. In the context of adblocking, the former results in missed ads and the latter often translates to site breakage or malfunction [23]. At the same time, as adblockers gain their popularity rapidly (11% of global Internet population is blocking ads as of December 2016 [1]), online publishers are also fast adopting countermeasures against adblockers that we summarize below.

2.2 Countermeasures Against Adblockers

Concealing ad signatures. First, online advertisers can bypass rules on filter lists by concealing the signatures these lists use to identify ads. At a high level, this line of countermeasures attempts include first-party advertising and rotation of ad serving domains. First-party advertising exploits the fact that many rules on filter lists are designed to block ads from being loaded from third-party servers. Instead, ads are served from the same domain of the web page hosting them and their nature as ads is concealed as normal content [11]. However, adblockers can easily hide any HTML element on a web page by applying HTML rules that are crafted to target elements based on any combination of their CSS/HTML properties. In other words, any CSS selectors used to create and/or locate ads elements, can also let adblockers identify and hide these elements in turn.

Domain name rotation is another tactic for obfuscating advertising content. It relies on ad rotation networks that serve ads from

frequently-changing, or even automatically generated [38] domain names, which overwhelms volunteers that maintain the filter lists so they are hard to keep pace with the rule updates. This can result in, however, the indifferent blocking of all third-party resources on websites that show such ads [9]. By only whitelisting legitimate scripts that support core functionalities, any possible ads or tracking JavaScript are prevented from running, leaving no chance for loading domain rotating ads. Moreover, AdBlock Plus recently launched its Anti-Circumvention Filter List [3] that specifically counter "circumvention ads", including ads adapting the two countermeasures above.

Deploying anti-adblockers. Second, many publishers choose to deploy anti-adblocker JavaScript code to battle the rise of adblocking. Specifically, such client-side scripts consist of two main components, *trigger* that detects the presence of adblockers by checking whether ads or bait elements are still present, and *reaction* that can display warning messages and/or simply report the results to a remote server [33, 39]. Prior work [29] showed that 686 out of Alexa top-100K websites detect and visibly react to adblockers on their homepages. Even worse, these visible ones only account for less than 10% of all anti-adblockers [39]. Zhu et al. [39] showed that among Alexa top-10k websites, 30.5% are countering adblockers in some form, with most of them being silent reporting. In summary, because of their flexibility and ease of deployment, anti-adblockers are considered the most widely used countermeasure against adblockers adopted by online publishers.

2.3 Countermeasures Against Anti-adblockers

Dedicated anti-adblocking filter lists. As a response, adblockers attempt to circumvent anti-adblockers by blocking their JavaScript code snippets, whitelisting bait scripts/elements, or hiding warning notifications. To this end, adblockers once again rely on manually curated filter lists such as Anti-Adblock Killer [5] and Adblock Warning Removal [4]. These lists either trick anti-adblockers' trigger so they cannot detect adblockers, or mute their reaction component to prevent responses after successful detection.

```
/kill-adblock/js/function.js$script
@@||removeadblock.com/js/show_ads.js$script
ilix.in,urlink.at,priva.us###blockMsg
```

For example, the first HTTP rule above blocks the code snippets containing implementation of an anti-adblocking library `KillAdBlock`, and the second whitelists a bait script file named `show_ads.js` that is used to detect adblockers. The third HTML rule hides the warning message with ID `blockMsg` issued by the associated anti-adblocker. However, our manual evaluation (§4) shows that these lists targeting anti-adblockers are generally ineffective. Only less than 30% of the anti-adblocking warning messages can be removed by the state-of-the-art filter lists. This is again partly because of the crowdsourcing nature of these lists, and also the rising popularity of third-party anti-adblocking services that deploy sophisticated techniques dedicated for detecting/circumventing adblockers [33].

Disrupting anti-adblocker code. Other than the filter lists that have been officially adopted by adblockers, there are also research efforts for detecting and evading anti-adblockers. One solution to measure the anti-adblockers is to perform program analysis techniques that automatically determine if a script functions for anti-adblocking purposes. Such analysis can be static that is based on syntactic and structural features extracted from JavaScript code, and utilizes machine learning approaches to classify the code from ground-truth-labeled training data [29]. It can also be dynamic that captures JavaScript behavior at runtime by collecting and analyzing differential execution trace with the adblocker turned on and off [39]. After successfully pinpointing the critical conditions that are used by anti-adblockers to assert/react against the presence of adblockers, one can choose to rewrite these conditions to prevent the anti-adblockers from functioning. This approach is generally intrusive (patching Javascript can be tricky and cause breakage) and easy to evade. Indeed, the overall success rate of this strategy is shown to be only less than 80%.

Hiding adblockers. Besides disrupting the functionalities of anti-adblockers, researchers also have proposed a way to hide the trace of using adblockers, or known as *stealthy adblocking*. In [37], Storey et al. created a shadow copy of the DOM that anti-adblockers operate on before any adblocking actions take place, and then redirects all JavaScript APIs (e.g. `getElementById()`) that can be used to detect the presence of ad elements to the copy instead of the original DOM. However, this so-called rootkit-style stealthy adblocker has inherent drawbacks. First, unless it lives in browser core and with significant engineering efforts, the underlying DOM mirroring and propagation are difficult to be complete in all cases. This is especially problematic in the context of web browsing as any site breakage causes unacceptable user experience degradation. Second, even with a perfect implementation, maintaining a live copy of complicated data structures such as DOM poses a prohibitively high overhead onto the rendering performance of modern web browsers. Given that modern browsers place significant emphasis on performance, heavy operations like such at runtime are generally not acceptable.

3 SHADOWBLOCK

In this section, we first provide an overview of ShadowBlock's architecture. We then discuss ShadowBlock's two building blocks: (1) the identification of ad elements by translating filter list rules to per-element hiding decisions and (2) the concealment of our hiding actions. Finally, we summarize the modifications we make in the relevant modules of Chromium.

3.1 ShadowBlock Overview

Figure 1 illustrates ShadowBlock's architecture. It consists of two sub-systems: one translates rules from filter lists and use them for identifying ad elements in DOM to hide; the other hooks necessary points in Chromium to ensure that the hiding actions are transparent to the trigger/detection component of anti-adblockers. Recall from Section 2.1 that filter lists contain tens of thousands of rules that either block HTTP requests to fetch ad resources or hide HTML ad elements. To prevent exposing adblocking actions to anti-adblockers, we need to hide the changes in DOM or other states (e.g. resource loads) introduced by adblocking because these changes can be detected by anti-adblockers through JavaScript APIs such as `getElementById()`. In order to do so, we first allow all HTTP requests to proceed, then mark any element that results in ads, and subsequently hide the marked elements. It is important that we

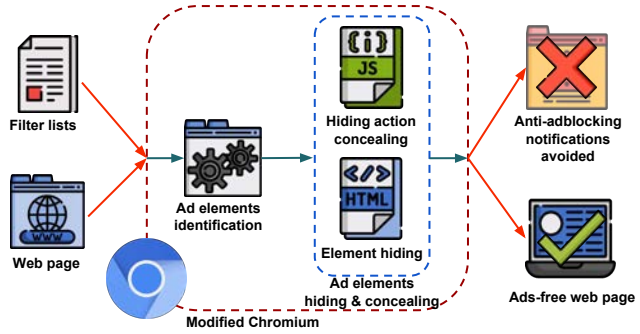

Figure 1: Architectural overview of ShadowBlock

allow these elements to be retrieved so when the anti-adblocking script queries the state of the element, ShadowBlock will be able to generate valid responses (e.g., dimension of the element).

3.2 Identifying Ad Elements

Next, we explain our approaches for marking different types of ad elements. In general, there are two types of elements: (1) those that are statically embedded in the HTML, and (2) those that are dynamically created by JavaScript. First, some ad elements are statically embedded in the HTML, including ad images, iframes, media files (i.e. video and audio). Such ad elements can be typically identified by matching against the HTML rules on filter lists. Second, ad scripts usually *create* new ad elements that display advertising content. These dynamically created elements should be identified, marked, and hidden.

Ad elements loaded statically. ShadowBlock does not need to do anything special for such elements. Ad filter lists already contain extensive rules that cover them. For example, the rule `||googlesyndication.com/safeframe/` in EasyList blocks the HTML file from https://tpc.googlesyndication.com/safeframe/1-0-23/html/container.html on site cnbc.com, which prevents a container frame used by Google Ads from being loaded. To hide such an ad element, ShadowBlock needs to first identify the iframe element with the blocked URL as its source attribute and then hide it.

Alternatively, Easylist rules may hide ads based on element properties (e.g., element id). We simply reuse these rules to match elements in the page, and mark them accordingly.

Ad elements generated dynamically by ad scripts. There are generally two cases. The easy and the hard. For the easy case, the dynamically generated ads may contain URLs or ids that already show up on Easylist. This allows us to directly mark them as ads using very much the same strategy as mentioned above.

For the hard case, the dynamically generated elements are not on Easylist. This is because it is assumed that ad scripts are blocked upfront and therefore there is no need to block the elements generated by them. In ShadowBlock, in contrast, we need to allow ad scripts to load and execute, which mandates us to track such elements.

To identify elements dynamically created by ad scripts, we need to attribute each element to the script that created it. More formally, we can define this process of attribution as tracking the *data provenance* of HTML elements using taint analysis. Note that there are in general two types of element creation that can be initiated by a script: (1) control-flow-based creation, in which the script directly invokes JavaScript API (e.g. `createElement(tagName)`) and only propagates data from itself into the new element; and (2) data-flow-based creation, in which the script uses data from sources other than itself into the new element (e.g. `createElement(fetchTagNameFromServer())`). Dynamic taint analysis [31] can accurately track the data provenance through taint propagation for both types. Simply put, taint analysis involves *taint source* (where data comes from), *taint sink* (where data ends), and *propagation policies* that define how that tainted data are propagated through the program execution. In our case, all data derived from an identified ad script as "tainted" (i.e., data downloaded through an ad URL, or retrieved/generated by an ad script), then such data can be tracked standard taint analysis propagation policies for JavaScript (e.g., [27]). Finally we will hide any tainted HTML elements (i.e. taint sinks).

Unfortunately, such dynamic taint analysis at runtime usually incurs significant overhead for web browsing [31]. In addition, we argue that the cases where taint analysis will be required are limited. Specifically, even if ad elements take dynamically fetched data, e.g., `createElement(fetchTagNameFromServer())`, they are most likely created by ad scripts. This is sufficient for us to mark the element and hide it (irrespective of what data are actually fetched from the server). The reasoning is that if we consider extension-based adblockers as our baseline, the dynamically created element wouldn't even exist in the first place (as the script as a whole would have been blocked). Based on the above, we devise a simple technique which we call *execution projection* using the call stack information extensively (which are used for various other purposes as well [30, 32]). At a high level, we maintain an "execution stack" that keeps track of what scripts are being executed at any given time point, and mark an element as ad if there is *any* ad script in the stack when the element is being created. For example, consider a simple ad script `ad_loader.js` in Code 1.

```
1 var ad_img = document.createElement("img");
2 ad_img.src = "https://some_ad_publisher.com/ad.jpg";
3 document.body.appendChild(ad_img);
```

Code 1: Example ad script `ad_loader.js`

In this example, at the time of the image element creation, `ad_loader.js` would be at the top of the execution stack because it is being executed.

After attributing elements to ad scripts, which are identified using filter lists, we can mark all ad elements and hide them accordingly. We illustrate this projection/marking process in Figure 2. In more complex cases, there can be many scripts in the executing stack, because code in one script can invoke functions in other scripts, and so on. More importantly, ad scripts can invoke non-ad libraries (e.g. jQuery) to create ad elements so the top script in stack at the time of element creation is not necessarily ad script. To tackle this challenge, we need to scan the entire execution stack. If there is any ad script in the execution/invocation chain, ShadowBlock should mark the element being created as ad. This is because any script (ad-related or not) invoked by a known ad script should

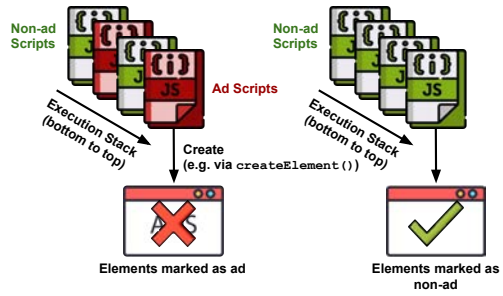

Figure 2: Execution projection for marking script-created ad elements

never have been executed in the first place, given that adblocking extensions simply block the whole ad script altogether.

Note that our approximate solution does not handle a special case when an element is created via a JavaScript API that gets overridden (hooked) by an ad scripts . Since client-side JavaScript is allowed to override (i.e. injecting code containing a callback to its own) arbitrary JavaScript API functions (e.g. `createElement()`) with its own version, we would see ad script in the stack when an element is being created via the API overridden by an ad script. In this case, we may mistakenly mark a non-ad element as ad when the overriding ad script does not propagate any data into the newly created element. To tackle this issue, at the time of element creation, we would need to further check whether the code injected by the overriding ad script alters the element. If it alters the element then we mark the element as ad, and non-ad otherwise.

```
var original = document.createElement;
document.createElement = function (tag) {
  new_elem = original.call(document, tag);
  report_statistic_to_server(new_elem);
  return new_elem;
};
```

Code 2: API overriding with the element intact

```
var original = document.createElement;
document.createElement = function (tag) {
  new_elem = original.call(document, tag);
  ad_elem = change_to_ad_elem(new_elem);
  return ad_elem;
};
```

Code 3: API overriding with the element altered

3.3 Stealthily Hiding Ad Elements

After identifying ad elements, ShadowBlock needs to stealthily hide them so as to not leaving its trace to anti-adblockers. Next, we discuss how we realize such stealthiness through CSS property access API hooking.

Choice of hiding mechanism. We first need to decide how to hide ad elements within Chromium. Given the complexity of modern web browsers and API standards, we can hide an HTML element in several different ways. To better understand different hiding mechanisms, we illustrate Blink's rendering process in Figure 3 [16]. Blink's rendering path, from parsing an HTML file to the pixel display on user's screen, can be summarized in the following phases.

(1) **Parse** flat HTML and CSS in plain-text to DOM and CSS Object Model (CSSOM) in tree structure.
(2) **Combine** DOM and CSSOM to Render Tree, which captures all the visible DOM content and all the CSSOM style information for each node.
(3) **Paint** the rendered pixels to user's display according to Render Tree.

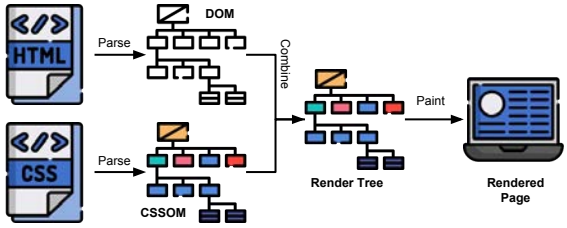

Figure 3: Rendering Path for Blink

In theory, each of these 3 phases contain APIs/modules that we can leverage for hiding an HTML element (or in other words, preventing it from being rendered). We outline different possible strategies to hide HTML elements below:

(1) **DOM/CSS layer**: (i) remove the element from DOM; (ii) set the element's style to `display:none`, `visibility:hidden` or `opacity:0`
(2) **Render Tree layer**: remove the `LayoutObject` (i.e. a styled node) from Render Tree
(3) **Paint layer**: prevent the region in pixels associated with the element from being painted

Note that generally, the higher-layer (i.e. closer to DOM/CSS layer) we tweak around in the hierarchy, more engineering effort is required for ensuring its stealthiness against anti-adblockers, while narrower gap we have to bridge for translating the identified ad HTML elements to the data structure corresponding to that layer (e.g. CSS properties for DOM/CSS layer, `PaintBlock` for Paint layer etc.). In contrary, the lower-layer (i.e. closer to Paint layer) our modifications reside, fewer unexpected channels there are that can potentially leak the hiding activities, but at the same time more engineering efforts are required for translating the identified ad elements to that layer's data structure.

After investigating different possibilities, we find the CSS property `visibility:hidden` achieves the most suitable trade-off for our objective. It persists in phase (1), functions in phase (2) of the rendering path, and eventually affects both Render Tree and painted/rendered page in phase (2) and (3). On one hand, `visibility` is a property associated with every HTML element so we can easily identify after marking its effective element as ad, without the need of further tracing. On the other hand, unlike `display:none`, it by design preserves the space taken up by the hidden element so it causes no side-effect to the layout of the document, minimizing the impacted points that need to be hooked for covering the hiding action. Figure 4 shows the visual difference between their respective effects. Compared to `opacity:0` that also preserves the occupied space, `visibility` is a categorical CSS property instead of numerical as `opacity` so its implementation in Chromium is considerably less complex, simplifying our hooking logic as well.

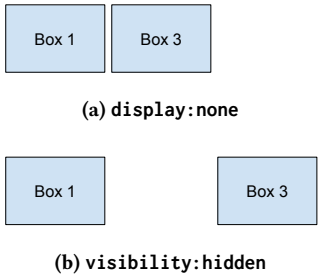

Figure 4: Comparison of toggling different CSS properties (Box 2 is hidden)

Hooking for concealing hiding actions. After hiding the target ad element by setting its `visibility` CSS property value [21] to `hidden`, we next need to cover any traces that result from this change of value and can be detected by anti-adblockers. Since anti-adblocking scripts are client-side JavaScript code, which can only access the change of states happened in the page through JavaScript Web APIs [22], we search through the source code of Chromium, analyze relevant modules and locate the following three categories of APIs that are impacted by the `visibility` CSS property:

- **CSS/Style-related**: changing a CSS property value immediately affects its own return value to JavaScript APIs via `getComputedStyle()`. We hook this value to `visible` to fool anti-adblockers. Fortunately, for our case, setting `visibility:hidden` preserves the space the element occupies, so it does not collapse the page layout nor affect other relevant CSS properties such as `offsetHeight/offsetWidth`.
- **Event-related**: flipping the `visibility` property prevents an element from receiving some DOM events, such as `onfocus`. Since anti-adblockers can leverage these events as a side-channel to infer the real visibility of an element, we hook relevant modules in Chromium so hidden elements can receive these events just like visible elements.
- **Hit-testing-related**: another effect of setting `visibility:hidden` is Blink treats elements with it as inapplicable to Hit Testing, which checks if an element is clickable by users in their viewpoints. This removes the hidden element from return values to APIs like `elementFromPoint()`, which can potentially be used by anti-adblockers to differentiate hidden elements from visible ones. We hook relevant modules in Blink to cover it.

Since all JavaScript APIs, to our best knowledge, directly or indirectly rely on the modules above to determine an element's visibility, we ensure the completeness of our hooking against potential information leakage to client-side anti-adblockers. It is worth noting that to avoid affecting existing `visibility:hidden` CSS property value, in Chromium we create a new `visibility:fake-visible` value that completely mimics what `visibility:hidden` behaves, except for the points that are intentionally hooked. Moreover, since `visibility` is a CSS property that inherits from parent node to child nodes, we can make the identified ad elements invisible to user's display even though we only identify the top-most element as ad according to filter lists.

3.4 Chromium Modification

Next, we describe our modifications to Chromium for implementing ShadowBlock. We start with a brief introduction of Chromium's architecture, then move to the instrumentation we use for identifying ad elements, and lastly discuss the modules we leverage for hiding identified ad elements and hook for eliminating the traces resulted from the hiding action. We implement the prototype of ShadowBlock with 1307 LOC (1265 LOC addition and 42 LOC deletion) in C++ on top of Chromium [1]. Note that we re-use `SubresourceFilter` [18] and `libadblockplus` [10] for parsing filter lists with production-level robustness.

Chromium Architecture. Chromium's rendering engine is called Blink and its JavaScript engine is called V8. Blink [6] is responsible for fulfilling the rendering path shown in Figure 3, in which its core module renders all HTML elements and handles their `visibility` CSS properties we use for hiding ad elements. V8 [19] handles the compilation and execution of all JavaScript code, including the ad scripts ShadowBlock needs to identify and anti-adblocker scripts that intend to detect our hiding action over ad elements. Blink has a bindings module to handle interactions between rendering and JavaScript execution. Rendering related script tasks are passed through bindings module. For example, JavaScript API calls such as `getComputedStyle()` are handled through the bindings module.

Instrumentation for identifying ad elements. As discussed in Section 3.2, there are three types of ad elements ShadowBlock needs to identify.

First, for ad elements generated by ad scripts, we rely on execution projection. In Chromium, we leverage `blink::SourceLocation::Capture` to capture the full `v8::v8_inspector::V8StackTrace` that includes the entire JavaScript call stack[2] at any given time point. It serves as the underlying stack tracing mechanism for V8's debugger/inspector, and has therefore been optimized with low overhead [20].

Second, we instrument the constructor of `blink::Element` class in Blink, which captures the earliest point of creation event for all HTML elements. Because of V8's single-threading nature, we can safely associate the current stack trace to the element creation event, and scan the stack to match the scripts in it against filter lists. If it is a match, we then mark the element as ad. Additionally, we instrument the `DispatchWillSendRequest` event in both `blink::FrameFetchContext` and `blink::WorkerFetchContext` to intercept the point when an ad script loads another script, and mark the loaded script as ad script. By adding such loaded ad scripts to a set, we match the stack trace against them as well at element creation, ensuring we can mark all ad elements.

Third, for elements loaded with resources that match rules in the filter lists, we intercept the `AttributeChanged` event in `blink::`

[1]We open source our implementation at https://github.com/seclab-ucr/ShadowBlock to allow reproducibility as well as help future extensions by the research community.
[2]We admit that there are cases where asynchronous tasks are not correctly captured by the default V8 call stack trace. However, we argue this incompleteness only translates to very limited number of missing ads according to our manual evaluation in Section 4.2.

Element and match the URL against filter lists, if it is a match we mark this element as ad. For element hiding rules, we adopt libadblockplus [10], a C++ wrapper library around the core functionality of Adblock Plus to parse filter lists and generate the CSS selectors for matching ad elements for a particular domain. Then, we mark the ad elements that match the generated CSS selectors by calling ContainerNode::QuerySelectorAll().

Since many web pages are dynamic due to JavaScript execution over time, we also need to monitor attribute changes of each element. For this purpose, we instrument the AttributeChanged event and match any element with newly changed attributes against CSS selectors from HTML rules. We mark an element as ad if it is a match, or un-mark the element if this element has been marked but it is not matched this time. Note that in order for minimizing the number of matches needed to perform, we conduct the first batch match (via QuerySelectorAll()) after the load event of DOM is fired, and then match elements upon their attribute changes. This design choice leaves a short period of time (few milliseconds) between page navigation and load DOM event in which ads are displayed. We make this trade off to reduce the overhead incurred by QuerySelectorAll(). In comparison, adblocking extensions such as Adblock Plus inject CSS rules when document.readyState turns interactive [26], which happens before the load event. However, it is important to note that most ads in current web ecosystem are loaded in an asynchronous manner and are unlikely to appear before the load event in first place.

Stealthy modifications for hiding ad elements. As mentioned earlier, we leverage visibility CSS property to hide identified ad elements by creating a new fake-visible enumerate and visually hide elements with this enumerate, as if it behaves as hidden. In the meantime, we hook relevant modules in both Blink and its bindings with V8 to ensure the stealthiness of our hiding action. More specifically, for eliminating traces accessible by CSS/Style-related APIs, we hook CSSComputedStyleDeclaration::GetPropertyCSSValue in Blink and force return visible to queries about hidden elements. For event-related APIs, we hook Element::IsFocusableStyle() and other conditions that determine if an element can receive events. Lastly, we hook ComputedStyle::VisibleToHitTesting() so ad elements are still regarded "visible" from the viewpoint perspective of Blink. In principle, our hooking guarantees that the identified ad elements are invisible to user's display as pixels on screen but appear as visible to APIs accessible to client-side JavaScript.

4 EVALUATION

We evaluate ShadowBlock in terms of its (1) stealthiness against anti-adblockers, (2) ad coverage, and (3) performance as as compared to adblocking extensions.

4.1 Stealthiness Analysis

Takeaway: ShadowBlock has 100% success rate against anti-adblockers whereas state-of-the-art anti-adblocking filter lists have only 29% success rate.

Experimental Setup. To evaluate the stealthiness of ShadowBlock, we use previously reported [39] 682 websites with visual anti-adblockers. We manually analyze these websites and find that 207 of them still use visible anti-adblockers. For each website, we perform stealthiness comparison as follows.

(1) Open a website with four Chromium instances simultaneously. Each instance has a different profile configuration: (i) no modification or extension; (ii) Adblock Plus extension with EasyList only; (iii) Adblock Plus extension with EasyList, Anti-Adblock Killer list, and Adblock Warning Removal list; and (iv) ShadowBlock using EasyList.
(2) Scroll the page down to the bottom and wait for 30 seconds after the load event has fired to ensure complete page load.
(3) Capture the full-page screenshots (including content after scrolldown) for all browser instances.
(4) Manually inspect the screenshots: compare (i) and (ii) to determine if the page has visual anti-adblocker. If so, further compare (ii) and (iii) to check whether anti-adblocking filter lists evade the anti-adblocker, compare (iii) and (iv) to check whether ShadowBlock achieves the evasion.

Table 1: Breakdown of stealthiness analysis

Tool	Notification	Ad switching	Crypto-mining
Total	201	5	1
ShadowBlock	201 (100%)	5 (100%)	1 (100%)
Filter lists	59 (29%)	1 (20%)	0 (0%)

Results. In addition to visible anti-adblocking notifications, we also consider ad switching and crypto-mining reactions from websites. Table 1 compares ShadowBlock with anti-adblocking filter lists for each of these anti-adblocking reactions. "Notification" refers to websites that show anti-adblocking notifications such as paywalls. "Ad switching" refers to websites that switch their ad sources upon detection of adblockers. "Crypto-mining" refers to the websites that load crypto-mining scripts to mine crypto-currencies on detection of adblockers [28]. We note that ShadowBlock has 100% success rate as compared to 29% success rate of anti-adblocking filter lists.

Case Studies. Below we discuss a few interesting examples of anti-adblockers that ShadowBlock successfully handles but filter lists do not. Note that besides visible anti-adblocking notifications, we also include one example discovered in the wild that uses non-visual countermeasure against adblocker users.

Ad source switching. On detecting adblockers, some websites switch their ad sources to sources that are currently not blocked by filter lists. Figure 5a and 5b show an example from golem.de. Since ShadowBlock stealthily hides the original ads, the ad source switching script is never triggered. Therefore, unlike what Figure 5b shows in which adblocking extensions fail to remove the replaced ad, ShadowBlock successfully hides it.

Silent reporting. Besides visible reaction, anti-adblockers can also choose to silently report the adblocking status to back-end servers to collect adblocking statistics. For example, varmatin.com uses Code 4 to place a bait with keywords on EasyList to track adblocking users and report the status to back-end server. ShadowBlock handles such cases and these statistics are never reported.

(a) Original ad

(b) Replaced ad

Figure 5: Ad switching behavior on golem.de

```
function checkAds() {
  if ($(document.getElementById('adsense')).css('display'
      ) !== 'none' && $('#myadsblock').length === 1) {
    dataLayer.push({
      'DimAdBlock': 'Unblocked'
    });
    window.adblockdetected = false;
  } else {
    dataLayer.push({
      'DimAdBlock': 'Blocked'
    });
    window.adblockdetected = true;
  }
}
```

Code 4: Code snippet on varmatin.com **of silent anti-adblocker**

Crypto-currency mining. Some websites have started to employ cryptojacking as a response to adblocking [28]. To this end, websites use anti-adblockers to detect use of adblockers and load scripts to mine a crypto-currency on user's browser. Mining crypto-currencies consumes processing power on user's machine. For example, knowlet3389.blogspot.com blocks organic content on detection of adblockers and asks users of allow crypto-currency mining for monetization instead. Code 5 shows the crypto-currency mining script on knowlet3389.blogspot.com.

```
setInterval(function() {
  try {
    var a3 = document.getElementById('AdSense3');
    if (a3.offsetHeight < 33 || a3.clientHeight < 33) {
      throw "Fuck U AdBlock!";
    }
  } catch (err) {
    miner.start(CoinHive.IF_EXCLUSIVE_TAB);
  }
}, 5487);
```

Code 5: Code snippet on knowlet3389.blogspot.com **for mining crypto-currency**

4.2 Ad Coverage Analysis

Takeaway: ShadowBlock achieves 97.7% accuracy, with 98.2% recall and 99.5% precision in blocking ads on Alex top-1K websites.

Experimental Setup. For ad coverage analysis, we use ShadowBlock on Alexa top-1K sites and measure its accuracy in terms of

(a) Adblock Plus

(b) ShadowBlock

Figure 6: Minor visual breakage caused by ShadowBlock

true positive (TP), false negative (FN), true negative (TN), and false positive (FP). We define TP, FN, TN, and FP as:

TP: All ad elements on a page are correctly hidden.
FN: At least one ad element on a page is not hidden.
TN: No non-ad element on a page is incorrectly hidden.
FP: At least one non-ad element on a page is incorrectly hidden.

For each website, we perform ad coverage comparison as follows.

(1) Open a website with three Chromium instances simultaneously. Each profile has a different profile configuration: (i) no modification or extension; (ii) Adblock Plus extension with EasyList; and (iii) ShadowBlock using EasyList.
(2) Scroll the page down to the bottom and wait for 30 seconds after the `load` event has fired to ensure complete page load.
(3) Capture the full-page screenshots (including content after scrolldown) for all browser instances.
(4) Manually inspect the screenshots: compare (i), (ii) and (iii) to determine if the website has any FPs or FNs.

Results. Table 2 shows the breakdown of our manual analysis. We evaluate results in terms of TPs, FNs, TNs, and FPs. Note that we are able to perform our analysis on 943 out of Alexa top-1000 websites. The remaining websites failed to properly load primarily due to server-side errors (e.g., 404).

False Positive Analysis. From Table 2, we note that ShadowBlock has only 0.5% false positive rate. However, they are still critical as they might lead to user experience degradation. We further investigate false positives to diagnose their root cause.

theatlantic.com is an example of false positive. Figure 6 shows that ShadowBlock incorrectly hides organic content at the bottom of the page. On further investigation, we find that an ad script `ads.min.js` loads another script `script.js` that hooks JavaScript API methods. In this case, even when a non-ad element is being processed it would go through same hooked JavaScript API methods. Since our ad marking heuristics check for the presence of ad scripts on execution stack it will incorrectly mark such elements as ads. In comparison, extension-based adblockers block the request for downloading `ads.min.js` in the first place, so the hooking script never gets executed. As discussed in Section 3.2, we can deal with

Table 2: Breakdown of ad coverage analysis

Event	TP	FN	TN	FP
Count	926 (98.2%)	17 (2.8%)	938 (99.5%)	5 (0.5%)

this issue by checking whether or not the overridden API alters the elements and hiding the elements altered by ad scripts.

False Negative Analysis. From Table 2, it can be seen that ShadowBlock has only 2.8% FNs. We further investigate FNs and identify that they are again caused by corner cases not covered by ShadowBlock and that they can be handled by performing taint analysis.

sohu.com is an example of false negative. On further investigation, we find that sohu.com uses a non-ad script (not on Easylist) to load both ads and non-ad content on the page. Since ShadowBlock only attributes elements created by ad scripts as ads, it misses dual-purpose scripts. It's noteworthy that this should be a rare case, as it is contrary to the common practice of using dedicated third-party scripts to create and load ad elements that most ad publishers exercise today. These publishers normally deploy third-party ad scripts because they have a complex bidding system and prefer dominant control over their ad modules

```
"resource": {
  "type": "text",
  "text": "Guangzhou, Audi TT 82.2K RMB off",
  "md5": "",
  "click": "http://dealer.auto.sohu.com/882054/promotion/
      article?id=7360579",
  "imp": [],
  "clkm": [],
  "adcode": "Guangzhou, Audi TT 82.2K RMB off",
  "itemspaceid": "15770"
}
```

Code 6: JSON snippet on sohu.com **for loading ads (translated from Chinese)**

We can tackle this issue by implementing the taint analysis approach discussed in Section 3.2. Specifically, Code 6 shows the snippet of a JSON file on sohu.com containing parameters required to create ad elements. In this case, we will need to first mark the JSON object as ad-related, or tainted, and whenever any piece of the data derived from it propagates to any element field (e.g. the URL in JSON's `click` field is used to set an element's `src` attribute), we mark the element as ad. In comparison, extension-based adblockers intercept the network request to load such ad JSON based on its URL in the first place, which effectively prevents the resulting ad HTML element from being created.

Similarly, we observe FNs on youtube.com where ShadowBlock is unable to hide all video ads. Our manual analysis shows that youtube.com leverages the Media Source Extensions (MSE) API [25] to load video segments through AJAX requests as byte streams. Unlike the standard HTML `video` tag that loads videos as HTTP requests, youtube.com loads ad videos in `Blob` objects [24] which are downloaded by JavaScript on the fly. ShadowBlock cannot identify video ads loaded as `Blob` objects, because both ad and non-ad objects are generated by the same non-ad script and assigned to a single HTML `video` element. Unlike our strategy that relies on differentiating ad scripts, extension-based adblockers block the AJAX requests to fetch ad video segments based on their URLs, which achieves the goal of ad removal. As discussed earlier, taint tracking can be used to address this challenge.

Even through we show that tainting is the ultimate solution to the FN cases encountered during our evaluation, we argue that it a comprehensive taint engine poses prohibitively high runtime overhead in the context of web browsing [27, 31]. More importantly, our evaluations have shown the sufficient accuracy of ShadowBlock with the lightweight stack-based execution approximation, as discussed in Section 3.2.

4.3 Performance

Takeaway: we use two web performance metrics: Page Load Time (PLT) and SpeedIndex. ShadowBlock speeds up page loads by 5.96% in terms of median PTL and 6.37% in terms of median SpeedIndex, on Alexa top-1000 websites.

Page Load Time (PLT). PLT has been the de-facto standard metric for measuring web performance. PLT can be computed by timing the difference between certain browser events using the Navigation Timing API [12]. In order to minimize variations introduced by the initial network setup (e.g., establishing TCP connection with server), we measure the time between `responseStart` [15] and `loadEventStart` [14] events.

SpeedIndex. PLT does not capture a real user's visual perception of webpage rendering process. For example, two pages A and B can have exactly the same PLTs, but page A can have 95% of its visual content rendered by a certain time point while page B has only rendered 30%. From the user perception perspective, page A outperforms page B but they are equally good in terms of PLT. To address this issue, SpeedIndex [17] was proposed to capture the visual progress of *above-the-fold* content, i.e., content in the viewport without scrolling. Unlike PLT, SpeedIndex measures how visually complete a webpage looks at different points during its loading process. Specifically, the page loading process is recorded as a video and each frame is compared to the final frame, for measuring completeness. SpeedIndex is computed using the following formula:

$$SpeedIndex = \int_{t_{begin}}^{t_{end}} 1 - \frac{VisualCompleteness}{100},$$

where t_{begin} and t_{end} represent the time points of the start (i.e. `responseStart` event in our case) and end (i.e. `loadEventStart` event in our case) of video recording, respectively. $VisualCompleteness$ measures the difference of the color histogram for each frame in the video versus the histogram at frame t_{begin}, and compares it to the baseline (difference of histogram at t_{begin} and t_{end}) to determine how "complete" that video frame is.

We emulate DSL network condition by throttling Chromium [13] to 4 Mbps downlink bandwidth and 5ms RTT latency for all responses to best mitigate measurement volatility across different browser instances. [3] For each site, we first load the webpage to generate its resource cache, then we re-load the webpage 10 times and average the measured PLT and SpeedIndex for each page load. Note that our warm-up strategy ensures most of the static non-ad resources are cached, while ad resources dynamically generated by JavaScript execution are not. This is intended, because we want to minimize the variability introduced by irrelevant factors such as processing non-ad network traffic.

[3] We also run another configuration with 750 Kbps downlink bandwidth and 100ms RTT latency to emulate a regular 3G condition [13] and observe similar median trends for both PLT (DSL -5.96% vs 3G +0.30%) and SpeedIndex (DSL -6.37% vs 3G -7.07%) with respect to Adblock Plus.

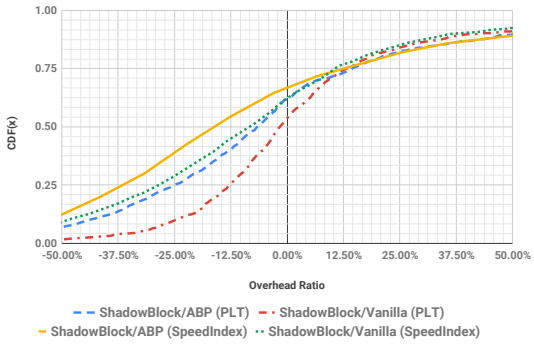

Figure 7: CDF for performance metrics

We compute relative ratio of PLT/SpeedIndex across two different configuration pairs (A) ShadowBlock and vanilla Chromium; and (B) ShadowBlock and Adblock Plus (EasyList + Anti-blocking lists), which are denoted as $Conf_A$ and $Conf_B$, respectively.

$$\frac{PLT_{Group_A} - PLT_{Group_B}}{PLT_{Group_B}}$$

$$\frac{SpeedIndex_{Group_A} - SpeedIndex_{Group_B}}{SpeedIndex_{Group_B}}$$

Overall, both PLT and SpeedIndex show that ShadowBlock speeds up page load time as compared to not only Adblock Plus but also vanilla Chromium. In comparison to Adblock Plus, ShadowBlock speeds up page loads by 5.96% in terms of median PTL and 6.37% in terms of median SpeedIndex. In comparison to vanilla Chromium, ShadowBlock speeds up page loads by 1.03% in terms of median PTL and 5.22% in terms of median SpeedIndex.

The distributions of PLT and SpeedIndex in Figure 7, also confirm this trend. We surmise that ShadowBlock's speed up with respect to Adblock Plus is because ShadowBlock's in-browser modifications, versus Adblock Plus's JavaScript-level implementation, inherently incur less overhead without the necessity of communications between browser core and extension code. For the speed up with respect to vanilla Chromium, it can be explained because ShadowBlock avoids the rendering and painting work for hidden ad elements.

5 DISCUSSIONS AND LIMITATIONS

Hiding instead of blocking. As discussed in Section 3.3, ShadowBlock is designed to visually hide ad elements. Compared to extension-based adblockers that prevent ad resources from loading, ShadowBlock's hiding strategy is inherently limited in two ways. First, ShadowBlock loads the ads and then hides them, thus does not save any network bandwidth. Second, it allows ad resources to load and ad-related scripts to execute, thus exposes users to online tracking. However, we argue that ShadowBlock can complement other tracker blocking approaches that obfuscate and anonymize user-identifiable data [34, 35] which do not require blocking ad requests or stopping script execution.

Completeness of implementation. As discussed in Section 3.2, a sufficiently complete yet lightweight taint analysis engine is required to tackle all the FN cases we encounter during ad element identification. However, given the adequate accuracy and practical runtime overhead level, we consider our execution projection technique a sufficient and necessary simplification of taint tracking conceptually.

Adversary from publishers. Modern websites enforce strong isolation among different scripts running in the same document. Violating such policies would normally raise substantial awareness to owners of other scripts or the website itself. This isolation also helps establish the assumption that ad scripts should never interact with non-ad elements in the same page. However, As soon as the publishers become aware of our approach, they might attack ShadowBlock by pro-actively breaking this assumption to cause collateral damage. For example, an ad script can intentionally modify an attribute of a non-ad element without changing its semantics (e.g. by changing the text encoding). In this case, if we blindly follow the taint tracking and mark the element with taint as ads, we might end up hiding benign elements. To address this challenge, we will need an equivalence test on the semantics of the cases with and without tainting.

Alternatively, an adversary may attempt to detect ShadowBlock. Even though we have closed all normal channels (JavaScript APIs) from leaking information about the presence of ShadowBlock. The adversary may still use more extreme means such as side channels. For instance, if we conduct taint analysis, we slow down the JavaScript execution and therefore they can potentially detect ShadowBlock by timing. However, we argue that this will be extremely challenging if not impossible, because there exist many browsers with different versions of JavaScript engines. There are simply too many possibilities if an adversary observes that the execution is slightly slower (it can even be just a slow machine).

6 CONCLUSIONS

In this paper, we propose ShadowBlock— a Chromium based stealthy adblocking browser. In addition to blocking ads it hides the traces of adblocking, making it insusceptible to anti-adblocking. Compared to the current state-of-the-art adblocking extensions, that block resources, ShadowBlock allows resources to load and keeps track of them. Later it hides the loaded resources and fakes their states to JavaScript APIs used by anti-adblockers. Through manual evaluation, we find that ShadowBlock (i) achieves 100% success rate in evading visual anti-adblockers; (ii) replicates 98.2% of ads coverage achieved by adblocking extensions; and (iii) causes minor visual breakage on less than 0.6% of the tested websites. In addition, we evaluate ShadowBlock's performance and find that it loads web pages as fast as adblocking extensions in terms of SpeedIndex and Page Load Time, on average. In summary, ShadowBlock constitutes a substantial advancement for building adblockers invisible to anti-adblockers and presents an important advancement in the rapidly escalating adblocking arms race.

ABSTRACT

Learning continuous representations of nodes is attracting growing interest in both academia and industry recently, due to their simplicity and effectiveness in a variety of applications. Most of existing node embedding algorithms and systems are capable of processing networks with hundreds of thousands or a few millions of nodes. However, how to scale them to networks that have tens of millions or even hundreds of millions of nodes remains a challenging problem. In this paper, we propose *GraphVite*, a high-performance CPU-GPU hybrid system for training node embeddings, by co-optimizing the algorithm and the system. On the CPU end, augmented edge samples are parallelly generated by random walks in an online fashion on the network, and serve as the training data. On the GPU end, a novel parallel negative sampling is proposed to leverage multiple GPUs to train node embeddings simultaneously, without much data transfer and synchronization. Moreover, an efficient collaboration strategy is proposed to further reduce the synchronization cost between CPUs and GPUs. Experiments on multiple real-world networks show that *GraphVite* is super efficient. It takes only about one minute for a network with 1 million nodes and 5 million edges on a single machine with 4 GPUs, and takes around 20 hours for a network with 66 million nodes and 1.8 billion edges. Compared to the current fastest system, *GraphVite* is about 50 times faster without any sacrifice on performance.

1 INTRODUCTION

Networks are ubiquitous in the real world. Examples like social networks [19], citation networks [27], protein-protein interaction networks [30] and many more cover a wide range of applications. In network analysis, it is critical to have effective representations for nodes, as these representations largely determine the performance of many downstream tasks. Recently, there is a growing interest in unsupervised learning of continuous node representations, which is aimed at preserving the structure of networks in a low-dimensional space. This kind of approaches has been proven successful in various applications, such as node classification [23], link prediction [14], and network visualization [31].

Many works have been proposed on this stream, including DeepWalk [23], LINE [32], and node2vec [8]. These methods learn effective node embeddings by predicting the neighbors of each node and can be efficiently optimized by asynchronous stochastic gradient descent (ASGD) [25]. On a single machine with multi-core CPUs, they are capable of processing networks with one or a few millions of nodes. Given that real-world networks easily go to tens of millions nodes and nearly billions of edges, how to adapt node embedding methods to networks of such large scales remains very challenging. One may think of exploiting computer clusters for training large-scale networks. However, it is a non-trivial task to extend existing methods to distributed settings. Even if distributed algorithms are available, the cost of large CPU clusters is still prohibitive for many users. Therefore, we are wondering whether it is possible to scale node embedding methods to very large networks on a single machine, which should be particularly valuable for common users.

Inspired by the recent success of training deep neural networks with GPUs [5, 13], we would like to utilize such highly parallel hardware to accelerate the training of node embeddings. However, directly adopting GPUs for node embedding could be inefficient, since the sampling procedure in node embedding requires excessive

random memory access on the network structure, which is at the disadvantage of GPUs. Compared to GPUs, CPUs are much more capable of performing random memory access. Therefore, it would be wise to use both CPUs and GPUs for training node embeddings. Along this direction, a straightforward solution is to follow the mini-batch stochastic gradient descent (mini-batch SGD) paradigm utilized in existing deep learning frameworks (e.g. TensorFlow [1] and PyTorch [22]). Different from deep neural networks, the training of node embeddings involves much more memory access per computation. As a result, mini-batch SGD would suffer from severe memory latency on the bus before it benefits from fast GPU computation. Therefore, other than mini-batch SGD, we need to design a system that leverages distinct advantages of CPUs and GPUs and uses them collaboratively to train node embeddings efficiently.

Overall, the main challenges of building an efficient node embedding system with GPUs are:

(1) **Limited GPU Memory** The parameter matrices of node embeddings are quite large while the memory of a single GPU is very small. Modern GPUs usually have a capacity of 12GB or 16GB.
(2) **Limited Bus Bandwidth** The bandwidth of the bus is much slower than the computation speed of GPUs. There will be severe latency if GPUs exchange data with the main memory frequently.
(3) **Large Synchronization Cost** A lot of data are transferred between CPUs and GPUs. Both the CPU-GPU or inter-GPU synchronizations are very costly.

In this paper, we propose a high-performance CPU-GPU hybrid system called *GraphVite* for training node embeddings on large-scale networks. *GraphVite* takes full advantages of CPUs and GPUs by co-optimizing the node embedding algorithm and the system. Specifically, we observe that existing node embedding methods typically consist of two stages, i.e. network augmentation and embedding training. In the first stage, an augmented network is constructed by random walks on the original network, and positive edges are sampled on the augmented network. In the second stage, node embeddings are trained according to the samples generated in the previous stage. Since the augmentation stage involves excessive random access, we resort to CPUs for this part. The training stage is assigned to GPUs as it is mainly composed of matrix computation.

In *GraphVite*, the above challenges are addressed by three components, namely parallel online augmentation, parallel negative sampling and collaboration strategy. In parallel online augmentation, CPUs augment the network with random walks and generate edge samples in an online fashion. In parallel negative sampling, the edge samples are organized into a grid sample pool, where each block corresponds to a subset of the network. Then GPUs iteratively fetch orthogonal blocks and their corresponding embeddings in each episode. Because GPUs do not share any embeddings, multiple GPUs can perform gradient updates with negative sampling in its own subset simultaneously. With such a design, the problem of limited GPU memory is solved as each GPU only stores the subset of node embeddings corresponding to the current sample block. The problem of limited bus bandwidth is mitigated since model parameters are transferred only when GPUs change their blocks. No inter-GPU synchronization is needed and CPU-GPU synchronization is only needed at the end of each episode. The collaboration strategy further reduces the synchronization cost between CPUs and GPUs on the sample pool.

We evaluate *GraphVite* on 4 real-world networks of different scales. On a single machine with 4 Tesla P100 GPUs, our system only takes one minute to train a network with 1 million nodes and 5 million edges. Compared to the current fastest system [32], *GraphVite* is 51 times faster and does not sacrifice any performance. On a network with 66 million nodes and 1.8 billion edges, *GraphVite* takes only around 20 hours to finish training. We also investigate the speed of *GraphVite* under different hardware configurations. Even on economic GPUs like GeForce GTX 1080, *GraphVite* is able to achieve a speedup of 29 times compared to the current fastest system.

Organization Section 2 reviews existing state-of-the-art node embedding methods and points out the challenges of extending these methods to GPUs. Section 3 introduces our proposed system in details. We present our experiments in Section 4, followed by extensive ablation studies in Section 5. Section 6 summarizes the related work, and we conclude this paper in Section 7.

2 PRELIMINARIES

In this section, some preliminary knowledge is introduced. We first review existing state-of-the-art node embedding methods, followed by a discussion on the main challenges of extending these methods to GPUs.

2.1 Node Embedding Methods Review

Given a network $G = (V, E)$, the goal of node embedding is to learn a low-dimensional representation for each node. The learned embeddings are expected to capture the structure of the network. Towards this goal, most existing methods train node embeddings to distinguish the edges in E (i.e. positive edges) from some randomly sampled node pairs (i.e. negative edges). In other words, edges are essentially utilized as training data. Since many real-world networks are extremely sparse, most existing embedding methods conduct random walks on the original network to introduce more connectivity. Specifically, they connect nodes within a specified distance on a random walk path as additional positive edges. For example, LINE [32] uses a breadth-first search strategy on low-degree nodes, while DeepWalk [23] uses a depth-first search strategy for all nodes. Node2vec [8] developed a mixture of the above two strategies.

Once the network is augmented, node embeddings are trained on samples from the augmented network. Typically, the embeddings are encoded in two sets, namely **vertex** embedding matrix and **context** embedding matrix. For an edge sample (u, v), the dot product of $\mathbf{vertex}[u]$ and $\mathbf{context}[v]$ is computed to predict whether the sample is a positive edge. This encourages neighbor nodes to have close embeddings, whereas distant nodes will have very different embeddings.

Overall, the computation procedures of these node embedding methods can be divided into two stages: **network augmentation** and **embedding training**. Algorithm 1 summarizes the general framework of existing node embedding methods. Note that the first

stage can be easily parallelized, and the second stage can be parallelized via asynchronous SGD. In most existing node embedding systems, these two stages are executed in a sequential order, with each stage parallelized by a bunch of CPU threads.

2.2 Challenges for Hybrid Node Embedding System

Inspired by the recent success of training neural networks with GPUs, we are interested in building a node embedding system by leveraging the power of GPUs, which can benefit the embedding training stage. Since the first stage of network augmentation involves extensive memory random access, CPUs are more suitable for this stage. As a result, we desire to develop a hybrid CPU-GPU system for training node embeddings. A common approach for a hybrid machine learning system is the mini-batch SGD paradigm, which is widely adopted in existing deep learning frameworks such as TensorFlow [1] and PyTorch [22]. In mini-batch SGD, model parameters are stored on GPUs and training data is iteratively passed to GPUs in batches.

However, mini-batch SGD cannot be applied directly to node embedding on large networks. Take a scale-free network with 50 million nodes and 1 billion edges as an example. (1) The size of the augmented network goes to 373 GB large, which may overwhelm the memory of most servers. We need to figure out a way to generate the augmented network and edge samples on the fly. (2) The embedding matrices are much larger than the parameter matrices in deep neural networks. Either **vertex** or **context** matrix consumes 23.8 GB memory, which is beyond the memory limit of any single GPU. As a result, both the **vertex** and **context** embedding matrices have to be stored in the main memory, and transferred to the GPUs in small parts during training. See Table 1 for a detailed analysis of the memory cost.

For the second problem, while transferring parameters from CPUs and GPUs sounds feasible, it will become a bottleneck if we consider the bus bandwidth between CPUs and GPUs. Consider training d-dimensional embeddings with n edge samples. There is $O(nd)$ computation workload and also $O(nd)$ memory access if the samples are not overlapped with each other. Since the computation speed of GPUs is way faster than the speed of bus transfer, the entire system will be bounded by the speed of parameter transfer from CPUs to GPUs severely. Indeed, such a system is even worse than its CPU parallel counterpart, which is verified in our experiments (see Table 3).

	Size	Example	Memory cost
nodes	$\|V\|$	$5 * 10^7$	191 MB
edges	$\|E\|$	$1 * 10^9$	7.45 GB
augmented edges	$\|E'\|$	$5 * 10^{10}$	373 GB
vertex	$\|V\| \times d$	$5 * 10^7 \times 128$	23.8 GB
context	$\|V\| \times d$	$5 * 10^7 \times 128$	23.8 GB

Table 1: Memory cost of node embedding on a scale-free network with 50 million nodes and 1 billion edges.

Another challenge in a hybrid system is the large synchronization cost. Since the system is distributed on multiple CPUs and GPUs, there is necessary data (e.g. parameters and edge samples) shared across sub tasks. A trivial but safe solution is to synchronize the shared data frequently, which will result in huge synchronization cost. To achieve high speed performance, the system should reduce shared data as much as possible, and use a collaboration strategy to minimize synchronization cost between devices.

3 *GRAPHVITE*: A HYBRID CPU-GPU NODE EMBEDDING SYSTEM

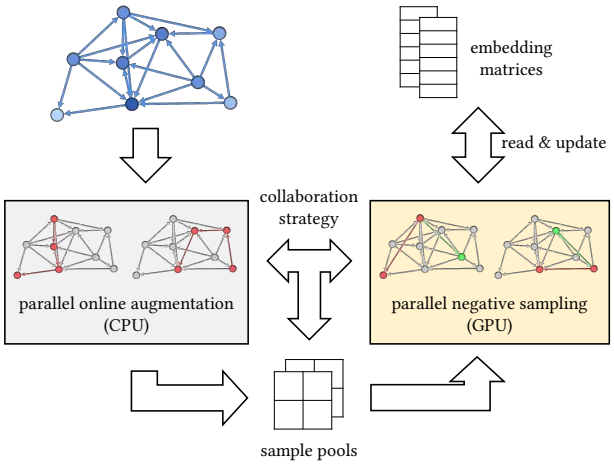

Figure 1: Overview of our hybrid system. The gray and yellow boxes correspond to the stages of network augmentation and embedding training respectively. The former is performed by parallel online augmentation on CPUs, while the latter is performed by parallel negative sampling on GPUs. The two stages are executed asynchronously with our collaboration strategy.

In this section, we introduce a high-performance hybrid CPU-GPU system called *GraphVite* for training node embeddings. Our

system leverages distinct advantages of CPUs and GPUs and addresses the above three challenges. Specifically, we propose a parallel online augmentation for efficient network augmentation on CPUs. We introduce a parallel negative sampling to cooperate multiple GPUs for embedding training. A collaboration strategy is also proposed to reduce the synchronization cost between CPUs and GPUs.

3.1 Parallel Online Augmentation

As discussed in Section 2.1, the first stage of node embedding methods is to augment the original network with random walks. Since the augmented network is usually one or two magnitude larger than the original one, it is impossible to load it into the main memory if the original network is already very large. Therefore, we introduce a parallel online augmentation, which generates augmented edge samples on the fly without explicit network augmentation. Our method can be viewed as an online extension of the augmentation and edge sampling method used in LINE[32]. First, we draw a departure node with the probability proportional to the degree of each node. Then we perform a random walk from the departure node, and pick node pairs within a specific augmentation distance s as edge samples. Note that edge samples generated in the same random walk are correlated and may degrade the performance of optimization. Inspired by the experience replay technique widely used in reinforcement learning [15, 20], we collect edge samples into a sample pool, and shuffle the sample pool before transferring it to GPUs for embedding training. The proposed edge sampling method can be parallelized when each thread is allocated with an independent sample pool in advance. Algorithm 2 gives the process of parallel online augmentation in details.

Algorithm 2 Parallel Online Augmentation

```
1:  function ParallelOnlineAugmentation(num_CPU)
2:      for i ← 0 to num_CPU − 1 do                    ▷ paralleled
3:          pool[i] ← ∅
4:          while pool is not full do
5:              x ← DepartureSampling(G)
6:              for u, v ∈ RandomWalkSampling(x) do
7:                  if Distance(u, v) <= s then
8:                      pool.append((u, v))
9:                  end if
10:             end for
11:         end while
12:         pool[i] ← Shuffle(pool[i])
13:     end for
14:     return Concatenate(pool[·])
15: end function
```

Pseudo Shuffle While shuffling the sample pool is important to optimization, it slows down the network augmentation stage (see Table 7). The reason is that a general shuffle consists of lots of random memory access and cannot be accelerated by the CPU cache. The loss in speed will be even worse if the server has more than one CPU socket. To mitigate this issue, we propose a pseudo shuffle technique that shuffles correlated samples in a much more cache-friendly way and improves the speed of the system significantly. Note that most correlation comes from edge samples that share the source node or the target node in the same random walk. As such correlation occurs in a group of s samples for an augmentation distance s, we divide the sample pool into s continuous blocks, and scatter correlated samples into different blocks. For each block, we always append samples sequentially at the end, which can benefit a lot from CPU cache. The s blocks are concatenated to form the final sample pool.

3.2 Parallel Negative Sampling

In the embedding training stage, we divide the training task into small fragments and distribute them to multiple GPUs. The sub tasks are necessarily designed with little shared data to minimize the synchronization cost among GPUs. To see how model parameters can be distributed to multiple GPUs without overlap, we first introduce a definition of *ϵ-gradient exchangeable*.

Definition 1. ***ϵ-gradient exchangeable.*** *A loss function $L(X;\theta)$ is ϵ-gradient exchangeable on two sets of training data X_1, X_2 if for small $\epsilon \geq 0$, $\forall\theta_0 \in \Theta$ and $\forall\alpha \in \mathbb{R}^+$, exchanging the order of two gradient descent steps results in a vector difference with norm no more than ϵ.*

$$\begin{cases} \theta_1 \leftarrow \theta_0 - \alpha\nabla L(X_1;\theta_0) \\ \theta_2 \leftarrow \theta_1 - \alpha\nabla L(X_2;\theta_1) \end{cases} \tag{1}$$

$$\begin{cases} \theta_1' \leftarrow \theta_0 - \alpha\nabla L(X_2;\theta_0) \\ \theta_2' \leftarrow \theta_1' - \alpha\nabla L(X_1;\theta_1') \end{cases} \tag{2}$$

i.e. $\|\theta_2 - \theta_2'\| \leq \epsilon$ is true for the above equations.

Particularly, we abbreviate *0-gradient exchangeable* to *gradient exchangeable*. Due to the sparse nature of node embedding training, there are many sets that form *gradient exchangeable* pairs in the network. For example, for two edge sample sets $X_1, X_2 \subseteq E$, if they do not share any source nodes or target nodes, X_1 and X_2 are *gradient exchangeable*. Even if X_1 and X_2 share some nodes, they can still be *ϵ-gradient exchangeable* if the learning rate α and the number of iterations are bounded.

Based on the gradient exchangeability observed in node embedding, we propose a parallel negative sampling algorithm for the embedding training stage. For n GPUs, we partition rows of **vertex** and **context** into n partitions respectively (see the top-left corner of Figure 2). This results in an $n \times n$ partition grid for the sample pool, where each edge belongs to one of the blocks. In this way, any pair of blocks that does not share row or column is *gradient exchangeable*. Blocks in the same row or column are *ϵ-gradient exchangeable*, as long as we restrict the number of iterations on each block.

We define *episode* as the block-level step used in parallel negative sampling. During each episode, we send n orthogonal blocks and their corresponding **vertex** and **context** partitions to n GPUs respectively. Each GPU then updates its own embedding partitions with ASGD. Because these blocks are mutually *gradient exchangeable* and do not share any row in the parameter matrices, multiple GPUs can perform ASGD concurrently without any synchronization. At the end of each episode, we gather the updated parameters from all GPUs and assign another n orthogonal blocks. Here *ϵ-gradient exchangeable* is controlled by the number of total samples

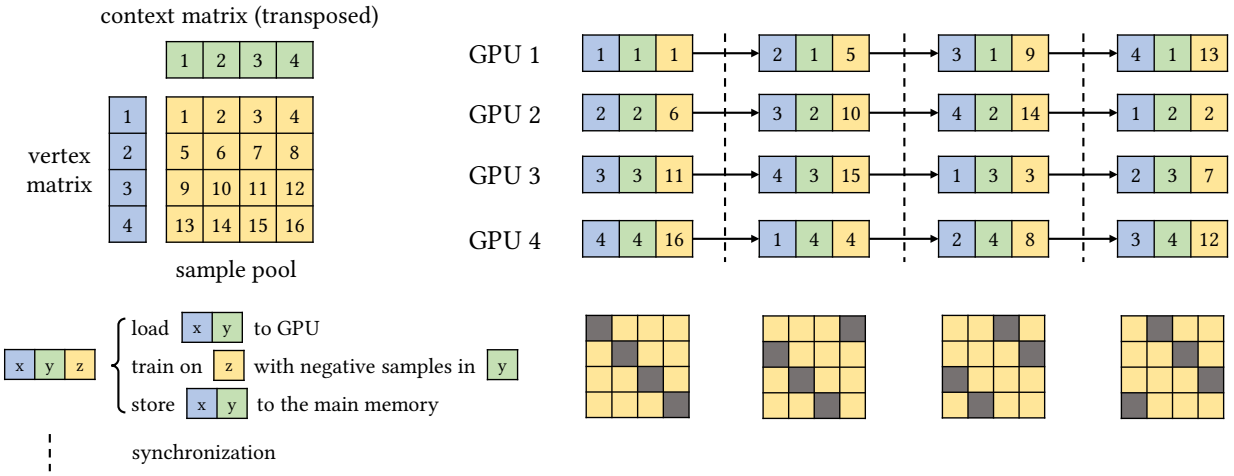

Figure 2: Illustration of parallel negative sampling on 4 GPUs. During each episode, GPUs take orthogonal blocks from the sample pool. Each GPU trains embeddings with negative samples drawn from its own context nodes. Synchronization is only needed between episodes.

in n orthogonal blocks, which we define as *episode size*. The smaller episode size, the better *ϵ-gradient exchangeable* we will have for embedding training. However, smaller episode size will also induce more frequent synchronization. Hence the episode size is tuned so that there is a good trade off between the speed and *ϵ-gradient exchangeable* (see Section 5.3). Figure 2 gives an example of parallel negative sampling with 4 partitions.

Typically, node embedding methods sample negative edges from all possible nodes. However, it could be very time-consuming if GPUs have to communicate with each other to get the embeddings of their negative samples. To avoid this cost, we restrict that negative samples can only be drawn from the **context** rows on the current GPU. Though this seems a little problematic, we find it works well in practice. An intuitive explanation is that with parallel online augmentation, every node is likely to have positive samples with nodes from all context partitions. As a result, every node can potentially form negative samples with all possible nodes.

Note that although we demonstrate with the number of partitions equal to n, the parallel negative sampling can be easily generalized to cases with any number of partitions greater than n, simply by processing the orthogonal blocks in subgroups of n during each episode. Algorithm 3 illustrates the hybrid system for multiple GPUs.

Algorithm 3 Parallel Negative Sampling

```
function ParallelNegativeSampling(num_GPU)
    vertex_partitions ← Partition(vertex)
    context_partitions ← Partition(context)
    while not converge do
        pool ← ParallelOnlineAugmentation(num_CPU)
        block[·][·] ← Redistribute(pool)
        for offset ← 0 to num_GPU − 1 do
            for i ← 0 to num_GPU − 1 do                ▷ paralleled
                vid ← i
                cid ← (i + offset)  mod num_GPU
                send vertex_partitions[vid] to GPU i
                send context_partitions[cid] to GPU i
                train block[vid][cid] on GPU i
                receive vertex_partitions[vid] from GPU i
                receive context_partitions[cid] from GPU i
            end for
        end for
    end while
end function
```

3.3 Collaboration Strategy

Our parallel negative sampling enables different GPUs to train node embeddings concurrently, with only synchronization required between episodes. However, it should be noticed that the sample pool is also shared between CPUs and GPUs. If they synchronize on the sample pool, then only workers of the same stage can access the pool at the same time, which means hardware is idle for half of the time. To eliminate this problem, we propose a collaboration strategy to reduce the synchronization cost. We allocate two sample pools in the main memory, and let CPUs and GPUs always work on different pools. CPUs first fill up a sample pool and pass it to GPUs. After that, parallel online augmentation and parallel negative sampling are performed concurrently on CPUs and GPUs respectively. The two pools are swapped when CPUs fill up a new pool. Figure 1 illustrates this procedure. With the collaboration strategy, the synchronization cost between CPUs and GPUs is reduced and the speed of our hybrid system is almost doubled.

3.4 Discussion

Here we further discuss some practical details of our hybrid system.

Batched Transfer In parallel negative sampling, the sample pool is assigned to GPUs by block, which is sometimes very large for the

Dataset	YOUTUBE	FRIENDSTER-SMALL	HYPERLINK-PLD	FRIENDSTER
$\|V\|$	1,138,499	7,944,949	39,497,204	65,608,376
$\|E\|$	4,945,382	447,219,610	623,056,313	1,806,067,142
Evaluation Task	47-class node classification	100-class node classification	link prediction	100-class node classification

Table 2: Statistics of the datasets used in experiments

memory of a GPU. Instead of copying the whole sample block to a GPU, we transfer the sample block by a small granularity. In this way, the memory cost of edge samples on GPUs becomes negligible.

Bus Usage Optimization When the number of partitions equals the number of GPUs, we can further optimize the bus usage by fixing the context partition for each GPU. In this way, we save the transfer of *context* matrix and further reduce the synchronization cost between CPUs and GPUs.

Single GPU Case Although parallel negative sampling is proposed for multiple GPUs, our hybrid system is compatible with a single GPU. Typically a GPU can hold at most 12 million node embeddings. So a single GPU is sufficient for training node embeddings on networks that contain no more than 12 million nodes.

4 EXPERIMENTS

In this section, we verify the effectiveness and efficiency of *GraphVite*. We first evaluate our system on YOUTUBE, which is a large network widely used in the literature of node embeddings. Then we evaluate *GraphVite* on three larger datasets.

4.1 Datasets

We use the following datasets in our experiments. Statistics of these networks are summarized in Table 2.

- YOUTUBE [19] is a large-scale social network in the Youtube website. It contains 1 million nodes and 5 million edges. For some of the nodes, they have labels that represent the type of videos users enjoy.
- FRIENDSTER-SMALL [37] is a sub-graph induced by all the labeled nodes in FRIENDSTER. It has 8 million nodes and 447 million edges. The node labels in this network are the same as those in FRIENDSTER.
- HYPERLINK-PLD [16] is a hyperlink network extracted from the Web corpus [1]. We use the pay-level-domain aggregated version of the network. It has 43 million nodes and 623 million edges. This dataset does not contain any label.
- FRIENDSTER [37] is a very large social network in an online gaming site. It has 65 million nodes and 1.8 billion edges. Some nodes have labels that represent the group users join.

4.2 Compared Systems

We compare *GraphVite* with the following node embedding systems.

- LINE [32] [2] is a CPU parallel system based on C++. We parallel its network augmentation stage for fair comparison with other methods.
- DeepWalk [23] [3] is a CPU parallel system based on Python and gensim [26].
- node2vec [8] [4] is another CPU parallel system based on Python and gensim [26].
- LINE in OpenNE [2] [5] is a GPU system based on the Python and TensorFlow [1].

Although DeepWalk and node2vec are implemented in Python, their computation is fully paralleled by Cython code without GIL, which is comparable to C++ implementations.

4.3 Implementation Details

Our implementation generally follows the open source codes of LINE [2] and DeepWalk [3]. We adopt the asynchronous SGD [25] in GPU training, and leverage the on-chip shared memory of GPU for fast forward and backward propagation. We also utilize the alias table trick [8, 32] to boost parallel online augmentation and parallel negative sampling.

Our hyperparameters are set according to the settings in LINE [32] and DeepWalk [23]. We treat networks as undirected graphs. During the network augmentation stage, we sample random walks with a length of 40 edges. We use a degree-guided strategy to partition both **vertex** and **context** matrices. More specifically, we first sort nodes by their degrees and then assign them into different partitions in a zig-zag fashion, as illustrated in Figure 3. We tune the episode size to maximize the speed of our hybrid system. During the embedding training stage, negative samples are sampled with a probability proportional to the 3/4 power of the node degrees. For each positive sample, we draw 1 negative sample and scale the gradient of the negative sample by 5 to match the gradient scale in LINE. We follow the initial learning rate of 0.025 and the linear learning rate decay mechanism in LINE and DeepWalk. We only adopt the *O3* optimization in *g++* and *nvcc*. We do not use any non-standard optimizations or low precision training [17, 39], though they may further improve the speed of our system.

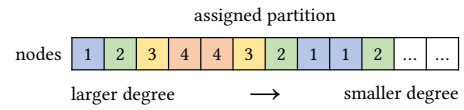

Figure 3: Degree-guided node and context partition strategy in the case of 4 partitions.

We define a training epoch as training $|E|$ positive edge samples. For YOUTUBE, the length of random walk is set to 5, and the total

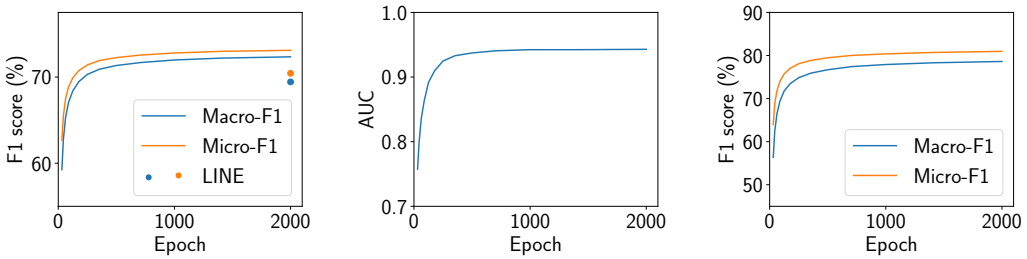
Table 4: Results of node classification on YOUTUBE

number of training epochs is set to 4,000. For the other 3 datasets, the length of random walks is set to 2, and the total number of training epochs is set to 2,000 since they are denser. The dimension of node embeddings is set to 128 except on FRIENDSTER, where we use 96. For other hyperparameters, we follow their default values in previous works. For fair comparison, we report the training time of all methods with the same number of training epochs. We parallel the network augmentation in LINE. For DeepWalk, we store the random walks in memory, which is the fastest setting.

4.4 Results on YOUTUBE



We first evaluate our hybrid system on the widely-used YOUTUBE dataset. We compare the speed and performance of *GraphVite* with existing systems of node embedding. For existing systems, we replicate their parallel implementations and report their training time under the same number of training epochs. Table 3 presents the speed of different systems. Among all existing systems, LINE [32] takes the minimal total time to run. However, the GPU implementation of LINE in OpenNE is even worse than its CPU counterpart, possibly due to the mini-batch SGD paradigm it uses. Compared to the current fastest system, LINE, *GraphVite* is much more efficient. With 4 GPUs, our system finishes training node emebdding on a million-scale network in only one and a half minutes. Even on a single GPU, *GraphVite* takes no more than 4 minutes and is still 19 times faster than LINE.

One may be curious about the performance of node embeddings learned by *GraphVite*. Therefore, we compare the performance of *GraphVite* with existing systems on the standard task of multi-label node classification. Note that normalizing the embeddings or not yields different trade off between Micro-F1 and Macro-F1 metrics. For fair comparison, we follow the practice in [32] and train one-vs-rest linear classifiers over the normalized node embeddings. Table 4 summarizes the performance over different percentages of training data. It is observed that *GraphVite* achieves the best or competitive results in most settings, showing that *GraphVite* does not sacrifice any performance. In some small percentage cases, *GraphVite* falls a little behind DeepWalk. This is because *GraphVite* uses negative sampling for optimization, while DeepWalk uses both hierarchical softmax and negative sampling, which could be more robust to few labeled data.

4.5 Results on Larger Datasets

	FRIENDSTER-SMALL	HYPERLINK-PLD	FRIENDSTER
1 GPU	8.78 hrs	-	-
4 GPU	2.79 hrs	5.36 hrs	20.3 hrs

Table 5: Results of time on larger datasets. We only evaluate HYPERLINK-PLD and FRIENDSTER with 4 GPUs since their embedding matrices cannot fit into the memory of a single GPU.

(a) Friendster-small (b) Hyperlink-PLD (c) Friendster

Figure 4: Performance curves of *GraphVite* on larger datasets. For Friendster, we plot the results of LINE for reference. The other systems cannot solve any of these datasets within a week.

	Parallel Online Augmentation	Parallel Negative Sampling (4 GPUs)	Collaboration Strategy	Micro-F1	Macro-F1	Training time
Single GPU baseline				35.26	20.38	8.61 mins
	✓			41.48	29.80	6.35 mins
		✓		34.38	19.81	2.66 mins
	✓	✓		41.75	29.30	2.24 mins
GraphVite	✓	✓	✓	41.89	29.46	**1.46 mins**

Table 6: Ablation of main components in *GraphVite*. Note that the baseline has the same GPU implementation with *GraphVite* and parallel edge sampling on CPU. The baseline should be regarded as a very strong one.

To demonstrate the scalability of *GraphVite*, we further test *GraphVite* on three larger networks. We learn the node embeddings of Friendster-small with 1 GPU and 4 GPUs. For Hyperlink-PLD and Friendster, since their embedding matrices cannot fit into the memory of a single GPU, we only evaluate them with 4 GPUs. Table 5 gives the training time of *GraphVite* on these datasets. The training time of baseline systems is not reported here, as all existing systems cannot solve such large networks in a week, except LINE [32] on Friendster-small. Compared to them, *GraphVite* takes less than 1 day to train node embeddings on the largest dataset Friendster with 1.8 billion edges, showing that *GraphVite* can be an efficient tool for analyzing billion-scale networks.

We also evaluate the performance of the node embeddings on these datasets. For Friendster-small and Friendster, we test their node embeddings on multi-label node classification. The test set is built on the top-100 communities of Friendster and has a total of 39,679 nodes. We do not normalize the learned embeddings during evaluation, and report Macro-F1 and Micro-F1 based on 2% labeled data. For Hyperlink-PLD, we adopt link prediction as the evaluation task since node labels are not available. We randomly exclude 0.01% edges from the training set, and combine them with the same number of uniformly sampled negative edges to form a test set. Each edge sample is scored by the cosine similarity of two node embeddings. We report the AUC metric for link prediction. Figure 4 presents the performance of *GraphVite* over different training epochs on these datasets. On Friendster-small, we also plot the performance of LINE for reference. Due to the long training time, we only report the performance of LINE by the end of all training epochs. It is observed that *GraphVite* converges on all these datasets. On the Friendster-small dataset, *GraphVite* significantly outperforms LINE. On the Hyperlink-PLD, we get an AUC of 0.943. On Friendster, the Micro-F1 reaches about 81.0%. All the above observations verify the performance of our system.

5 ABLATION STUDY

To have a more comprehensive understanding of different components in *GraphVite*, we conduct several ablation experiments. For intuitive comparison, we evaluate these experiments on the standard Youtube dataset. We only report performance results based on 2% labeled data due to space limitation. All the speedup ratios are computed with respect to LINE [32].

5.1 What is the contribution of each main component?

In the *GraphVite*, parallel online augmentation, parallel negative sampling, and the collaboration strategy are the main components in the sytem. Here we study how these components contribute to the performance of our system. We compare *GraphVite* with a strong baseline system with single GPU. Specifically, the baseline has the same GPU implementation as *GraphVite*, while it uses the standard parallel edge sampling instead of parallel online augmentation, and executes two stages sequentially.

Table 6 shows the results of this ablation. Compared to the baseline, we notice that parallel online augmentation helps improve the quality of node embeddings, since it introduces more connectivity

to the sparse network. Besides, parallel online augmentation also accelerates the system a little, as it reuses nodes and reduces the amortized cost of each sample. With parallel negative sampling, we are able to employ multiple GPUs for training, and the speed is boosted by about 3 times. Moreover, the collaboration strategy even improves the speed and does not impact the performance.

5.2 Is it necessary to perform pseudo shuffle?

In parallel online augmentation, *GraphVite* performs pseudo shuffle to decorrelate the augmented edge samples, while some existing systems [8, 23] do not shuffle their samples. We compare the proposed pseudo shuffle with three baselines, including no shuffle, a full random shuffle and an index mapping algorithm. The index mapping algorithm preprocesses a random mapping on the indexes of samples and saves the time of computing random variables.

Table 7 gives the results of different shuffle algorithms on a single GPU. It is observed that all shuffle algorithms are about 1 percent better than the no shuffle baseline. However, different shuffle algorithms vary largely in their speed. Compared to the no shuffle baseline, the random shuffle and index mapping algorithms slow down the system by several times, while our pseudo shuffle has only a little overhead. Therefore, we conclude that pseudo shuffle is the best practice considering both speed and performance.

Shuffle algorithm	Micro-F1(%)	Training time
None	40.41	3.60 mins
Random shuffle	41.61	17.1 mins
Index mapping	41.21	12.1 mins
Pseudo shuffle	**41.52**	**3.98 mins**

Table 7: Results of performance and speed by different shuffle algorithms. The proposed pseudo shuffle algorithm achieves the best trade off between performance and speed.

5.3 What is a practical choice for episode size?

In parallel negative sampling, *GraphVite* relies on the property of gradient exchangeability to ensure its approximation to standard SGD. While the smaller episode size provides better exchangebility, it will increase the frequency of synchronization over rows of the embedding matrices, and thus slows down embedding training. To quantify such influence in speed and performance, we examine our system on 4 GPUs with different episode sizes.

Figure 5 plots the curves of speed and performance with respect to different episode sizes. On the performance side, we notice that the performance of *GraphVite* is insensitive to the choice of the episode size. Compared to the single GPU baseline, parallel negative sampling achieves competitive or slightly better results, probably due to the regularization effect introduced by partition. On the speed side, larger episode size achieves more speedup since it reduces the amortized burden of the bus. The speed drops at very large episode size, as there becomes only a few episodes in training. Therefore, we choose an episode size of $2 * 10^8$ edge samples for YOUTUBE. Generally, the best episode size is proportional to $|V|$, so one can set the episode size for other networks accordingly.

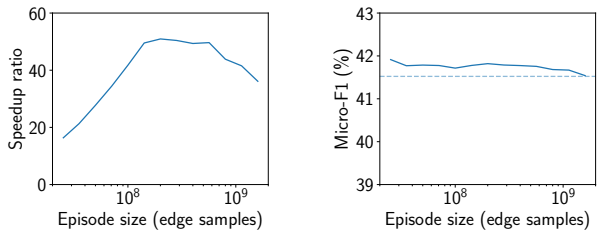


Figure 5: Speed and performance of *GraphVite* with respect to different episode sizes. The dashed line represents the single GPU baseline without parallel negative sampling.

5.4 What is the speedup w.r.t the numebr of CPUs and GPUs?

In *GraphVite*, both online augmentation and negative sampling can be parallelized on multiple CPUs or GPUs, and synchronization is only required between episodes. Therefore, our system should have great scalability. To verify that point, we investigate our system with different number of CPU and GPU. We change the number of GPU from 1 to 4, and vary the number of sampler per GPU from 1 to 5. The effective number of CPU threads is $\#GPU * (\#sampler\ per\ GPU + 1)$ as there is one scheduler thread for each GPU.

Figure 6 plots the speedup ratio with respect to different number of CPUs and GPUs. The speedup ratio almost forms a plane over both variables, showing that our system scales almost linearly to the hardware. Quantitatively, *GraphVite* achieves a relative speedup of 11× when the hardware is scaled to 20×. The speedup is about half of its theoretical maximum. We believe this is mainly due to the increased synchronization cost, as well as increased load on shared main memory and bus when we use more CPUs and GPUs.

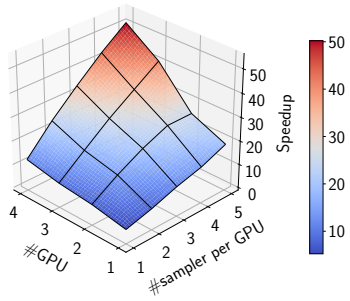

Figure 6: Results of speedup under different number of hardware. It is observed that the speedup is almost linear to the number of CPUs and GPUs.

5.5 Does the hardware configuration matter?

Up to now, all experiments are conducted on a server with Xeon E5 CPUs and Tesla P100 GPUs. One might wonder whether such a high performance depends on the specific hardware configuration. Therefore, we further test our system on an economic server with Core i7 CPUs and GTX 1080 GPUs.

Table 8 compares the results from two configurations. Different hardware does have difference in speed, but the gap is marginal. The time only increases to 1.6× when we move to the economic server. Note that this two configurations are almost the best and the worst in current machine learning servers, so one could expect a running time between these two configurations on his own hardware.

Hardware	CPU threads	GPU	Training time
Tesla P100 server	6	1	3.98 mins
	24	4	1.46 mins
GTX 1080 server	3	1	6.28 mins
	12	4	2.48 mins

Table 8: Training time of *GraphVite* under different hardware configurations. Generally *GraphVite* may take a time between these two configurations on most hardware.

6 RELATED WORK

Node embedding has been proven effective in a wide range of applications, such as node classification [10], link prediction [14], and network visualization [31]. Many different methods [4, 8, 23, 24, 32, 33, 35, 36] have been proposed to learn node embeddings that preserve the structure of networks from different aspects. Among them, DeepWalk [23], LINE [32] node2vec [8] and VERSE [33] are built on either edge or path samples of networks, which makes them the most scalable methods of all. Our work follows this stream and is related to these methods.

Node Embedding Algorithm Generally, node embedding algorithms consist of two stages, namely network augmentation and embedding training. The network augmentation stage is widely adopted in existing methods [4, 8, 23, 24, 32] to improve the performance of learned embeddings on sparse networks. DeepWalk [23] and node2vec [8] augment networks by generating random paths according to different distributions. The edge samples derived by path are correlated in those methods. LINE [32] directly adds edges to networks and generates independent edge samples. GraRep [4] and NetMF [24] take different powers of the adjacency matrix as augmentation. Our parallel online augmentation generates decorrelated edge samples using pseudo shuffle, and thus is close to the augmentation in LINE. However, our augmentation does not need to store the whole augmented network, which saves a lot of disk and memory usage compared to existing methods.

In the embedding training stage, most existing node embedding algorithms [8, 23, 32] train node embedding with standard negative sampling [18] in a shared memory space. While there is a parallel word embedding algorithm [29] that restricts negative sampling within the context partition of each worker, it still needs to transfer rows of embedding matrices between each worker for positive samples. By contrast, our parallel negative sampling trains on orthogonal sample blocks and does not need any transfer between worker during an episode. The most related method is the distributed SGD used in large-scale matrix factorization algorithms [3, 6, 38, 40]. These methods divide the input matrix into $n \times n$ blocks and factorize orthogonal blocks simultaneously. Different from these methods, our system mainly focuses on the negative sampling technique and is designed for the node embedding task.

Node Embedding System From the perspective of system, our work belongs to the parallel implementation of node embedding. There are many CPU parallel systems, including DeepWalk [3], LINE [2], node2vec [4] and VERSE [6]. These systems use asynchronous SGD [25] in embedding training and exploit multiple CPU threads for acceleration. Due to the limited computation speed of CPUs, such systems cannot scale to ten-million-scale networks without a large CPU cluster. Recently, there are some GPU parallel systems [2] built on deep learning frameworks like TensorFlow [1] or PyTorch [22]. Since existing frameworks are based on mini-batch SGD paradigm, these systems severely suffer the problem of limited bus bandwidth, and are even worse than their CPU counterparts. Compared to them, *GraphVite* is a hybrid CPU-GPU system that leverages distinct advantages of CPUs and GPUs, and uses them collaboratively to train node embedding, which makes it much faster than either pure CPU or mini-batch-SGD based systems.

In addition, parallel word embedding systems [9, 11, 18, 28] are also very related to our work, since they share similar embedding training and negative sampling steps with node embedding. Among these methods, Wombat [28] and BlazingText [9] accelerate training with GPUs. Wombat only supports single GPU. BlazingText can scale to multiple GPUs, but it simply makes a copy of the parameter matrices on each GPU. Our system is more efficient than BlazingText in two aspects. First, our system partition the parameter matrices and consumes less memory on each GPU. Second, our system requires less synchronization cost, as GPUs do not share any rows in the parameter matrices.

7 CONCLUSION

In this paper, we present a high-performance CPU-GPU hybrid system for node embedding. Our system extends existing node embedding methods to GPUs and significantly accelerates training node embeddings on a single machine. With parallel online augmentation, *GraphVite* efficiently utilizes CPU threads to generate augmented edge samples for node embedding training. With parallel negative sampling, *GraphVite* enables training node embeddings on multiple GPUs without much synchronization. A collaboration strategy is also developed to reduce the synchronization cost between CPUs and GPUs. Experiments on 4 large networks prove that *GraphVite* significantly outperforms existing systems in speed without sacrifice on performance. In the future, we plan to generalize our system to semi-supervised settings and graph neural networks, such as graph convolutional networks [12], graph attention networks [34], and neural message passing networks [7].

ABSTRACT

A considerable body of research has demonstrated that online search data can be used to complement current syndromic surveillance systems. The vast majority of previous work proposes solutions that are based on supervised learning paradigms, in which historical disease rates are required for training a model. However, for many geographical regions this information is either sparse or not available due to a poor health infrastructure. It is these regions that have the most to benefit from inferring population health statistics from online user search activity. To address this issue, we propose a statistical framework in which we first learn a supervised model for a region with adequate historical disease rates, and then transfer it to a target region, where no syndromic surveillance data exists. This transfer learning solution consists of three steps: (i) learn a regularized regression model for a source country, (ii) map the source queries to target ones using semantic and temporal similarity metrics, and (iii) re-adjust the weights of the target queries. It is evaluated on the task of estimating influenza-like illness (ILI) rates. We learn a source model for the United States, and subsequently transfer it to three other countries, namely France, Spain and Australia. Overall, the transferred (unsupervised) models achieve strong performance in terms of Pearson correlation with the ground truth (> .92 on average), and their mean absolute error does not deviate greatly from a fully supervised baseline.

1 INTRODUCTION

Syndromic surveillance systems aim to provide timely estimates about the prevalence of a disease in a population. Their main source of information is based on doctor assessments about the probable health status of patients given a set of symptoms. For example, to monitor the rate of influenza, syndromic surveillance relies on a network of doctors who report on a daily or weekly basis the number of patients exhibiting related symptoms, such as fever, cough or a sore throat. Recent research efforts have shown that this traditional approach can be complemented by alternative methods trained on data from online user activity, e.g. social media or online search behavior [43]. Applications vary from modelling dengue fever [24] to depression [17], but particular research focus has been drawn to influenza, an infectious disease that is responsible for 290-650,000 deaths worldwide on an annual basis.[1] Data from the microblogging platform of Twitter [15, 32, 50] as well as from search engines [21, 35, 53, 67] combined with statistical natural language processing methods have produced promising outcomes, which in some occasions have been incorporated into national influenza surveillance schemes [9, 63]. The main advantages of these complementary methods are timeliness, and sampling from a larger segment of the population, including people who may not visit a doctor while being ill. It is also commonly cited that such approaches may be very useful in regions where health infrastructure is poor or absent. However, this is often impractical as the proposed machine learning solutions rely on training data which apart from the user-generated inputs, need to contain confirmed disease rates at the target location, broadly referred to as "ground truth". This data is typically provided by existing syndromic surveillance systems. Hence, for locations where ground truth is not available, user-data driven approaches are not realistically applicable.

In this paper, we propose a statistical framework to circumvent problems associated with no training data in some geographic regions. Our approach is based on the broad notion of transfer learning, where we aim to transfer parts of the knowledge gained while solving a certain task to better solve a different, but related one [49]. In particular, our goal is to transfer a well-performing disease rate inference model from a source location, where supervised learning is possible, to a target location, where supervision is not possible, given the lack of ground truth. We focus our experiments on influenza (flu) and utilize Google search query statistics as our descriptive variable for aggregate, population-level, online user activity. For example, the US Centers for Disease Control and Prevention (CDC) monitor and report influenza-like illness (ILI) rates on a weekly basis, providing sufficient ground truth to learn a function that maps online search query frequencies to these rates. In our experiments we show that we can adapt this function to derive estimates of ILI rates at different locations (outside the US). Language may or may not differ between the source and target locations. Online search statistics can be obtained for these target locations, but we assume that there is no ground truth data.

The proposed approach comprises 3 steps. After learning a source regression model (step 1), we seek ways to map the selected source search queries to sets of queries in the target location. To derive this mapping we deploy a hybrid metric, which combines a semantic similarity with a time series correlation component (step 2). Semantic similarities are estimated using cross-lingual or monolingual word embeddings and correlations are computed using query frequencies. Finally, query weights from the source model are transferred to the identified target queries (step 3). This framework is evaluated on three transfer learning tasks, where the source model is always based in the US, and the target countries are France, Spain and Australia. While ground truth is available for all the target countries, we only use it to evaluate the performance of the transferred models. Transferred models, assessed on four flu seasons (2012 to 2016), can accurately estimate the peak of each flu season, achieving on average Pearson correlations greater than .92 and root mean squared errors comparable to the ones obtained by the corresponding fully supervised models ($\leq$ 21.6% increase in errors). Therefore, they can be considered as practical solutions for locations that lack historical ground truth data.

Main contributions. A novel, end-to-end transfer learning framework is proposed for mapping a disease model trained on online search data from a location, where ground truth is available, to a location, where ground truth is not available. Variations of this model are investigated, exploring different query mapping functions using semantic or temporal similarities or combinations of the two. In addition, we empirically show that our approach works in three case studies, two of which require a transfer to a different language (English to French or Spanish), and one that maintains the same language (English), but demands a model transfer to a different hemisphere (US to Australia).

2 DATA SETS

We use two sources of data, namely Google search query frequency statistics and ILI rates from established health organizations.

Google search query frequency statistics. Time series of weekly search query frequencies were retrieved through Google Correlate. A frequency represents the weekly search activity of a query (number of times issued) within a geographical region. It is normalized by dividing by the total number of search queries issued during that week. This normalization controls for variations in the number of searches issued each week which can be due to a variety of causes, including summer vacations, responses to news events, and a longer-term trend of increased web usage [45]. Normalized query frequencies are subsequently standardized, such that their time series have a zero mean and a standard deviation of one. This results in expressing query frequencies under the same units for different geographical regions with potentially varying population sizes and search usage patterns. We obtained weekly frequencies of search queries from September 1, 2007 to August 31, 2016 inclusive (470 weeks) for US, France, Spain, and Australia. Given that an exhaustive list of user search queries was not available to us, we extracted them by first using a set of 12 flu-related queries per country as a seed to Google Correlate and then iterating through this process (using correlated queries as new seeds). This process extracted 34,121, 29,996, 15,673 and 8,764 queries for US, France, Spain and Australia, respectively. Queries were not limited to the topic of flu, given that various other spurious queries may also correlate with the seeds.

ILI rates. We obtained weekly ILI rates for the US, France, Spain and Australia from their established syndromic surveillance systems, namely the Centers for Disease Control and Prevention (CDC), GPs Sentinelles Network (SN), Spanish Influenza Sentinel Surveillance System (SISSS), and Australian Sentinel Practices Research Network (ASPREN), respectively.[2] ILI rates represent fraction of the population that has been diagnosed with influenza-like symptoms.[3] The data spans from September 1, 2007 to August 31, 2016 inclusive, which covers approximately 9 consecutive influenza seasons. Note that for Spain, we only have ILI rates from week 40 in a year to week 20 in the following year. The prevalence of influenza outside this period is typically very low.[4] We denote the ILI rates from each syndromic surveillance system using the corresponding country code (US, FR, ES, and AU).

In our experiments we are transferring a flu model trained on US data to one of the other three countries. To provide some insight about the difficulty of the task, we have plotted the historical ILI rates for all countries in Fig. 1. ILI rates may correlate between countries, e.g. the Pearson correlation between the US and FR rates is equal to .6 ($p \approx 3 \cdot 10^{-54}$), but peaks and troughs are occurring at different times and with very different intensity. The US and AU ILI rates are negatively correlated ($-.4$, $p \approx 8 \cdot 10^{-17}$), as expected, since these countries are situated in different hemispheres and influenza is strongly seasonal. The optimal correlation we can obtain by shifting the ILI rate time series is equal to .68 (US-ES). Notably, the metric for ILI may differ in the countries we considered in this paper. Therefore, in our experiments we are working with a standardized representation of ILI (z-score).

3 METHODS

Disease rate estimation from online search data is commonly formulated as a regression task [21, 35]. The aim is to learn a function $f\colon \mathbf{X} \rightarrow \mathbf{y}$ that maps the input space of search query frequencies, $\mathbf{X} \in \mathbb{R}^{n \times s}$, to the target variable, $\mathbf{y} \in \mathbb{R}^{n}$, representing disease rates; n denotes the number of samples and s is the size of the feature space, i.e. the number of unique search queries we are considering. More specifically, $\mathbf{X}$ contains the time series of search query frequencies, and $\mathbf{y}$ represents a rate of disease diagnoses in a population (as reported by a health agency) at corresponding times. The time interval for computing the frequency of queries is often set to one week to match the frequency of syndromic surveillance reports.

Regression approaches require observations of the target variable $\mathbf{y}$ (ground truth) for training a machine learning model. This restricts the application of such techniques to areas where historical disease rates are available. We attempt to address this limitation by proposing a transfer learning methodology, that maps an existing disease model, $f\colon \mathbf{X} \rightarrow \mathbf{y}$, from a source location, where disease rates are available, to another location, where disease rates are not possible to obtain. We define the source domain as $\mathcal{D}_S = \{(\mathbf{x}_i, y_i)\}$,

[2] Links: **CDC** (US), `cdc.gov`; **SN** (FR), `websenti.u707.jussieu.fr/sentiweb`; **SISSS** (ES), `eng.isciii.es/ISCIII`; **ASPREN** (AU), `aspren.dmac.adelaide.edu.au`

[3] ILI is defined as the presence of high fever plus cough or sore throat [11, 46].

[4] In Figs. 1 and 2, we have set the missing ILI rates for ES to zero for visualization purposes. However, we are not using these rates to train or evaluate models for ES.

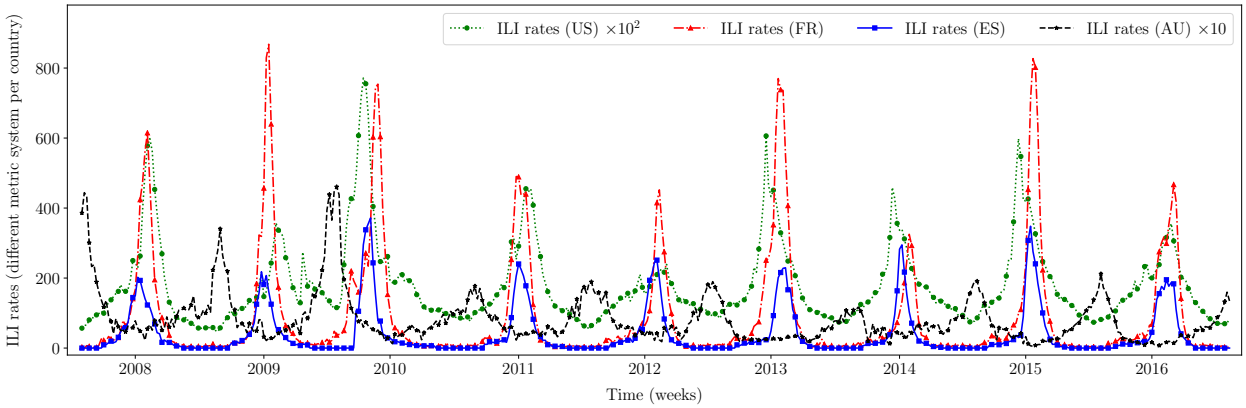

Figure 1: ILI rates for the United States (US), France (FR), Spain (ES) and Australia (AU).

$i \in \{1, \ldots, n\}$, where $\mathbf{x}_i$ is an s-dimensional vector holding the frequencies of the s queries for the time interval i, y_i is the corresponding disease rate, and n is the number of observations. The target domain is denoted by $\mathcal{D}_\mathrm{T} = \left\{\mathbf{x}'_i\right\}$, $i \in \{1, \ldots, m\}$, where $\mathbf{x}'_i$ is a t-dimensional vector of the frequencies of the t queries in the target domain that are going to be associated with the s queries in the source domain. No ground truth is available for the target domain. Note that t need not equal s, thus allowing one-to-many query mappings. In theory, the m time intervals may precede or overlap the n time intervals in the source region. In our experiments, we the m target intervals are always after the n source intervals.

3.1 User search behavior in different countries

As the transfer learning framework is detailed in the next paragraphs, it will become apparent that it is grounded on a fundamental assumption, which is that online user search behavior will be similar in the source and the target countries. Narrowing this assumption down to our specific task, this implies that the conditional probability of issuing a query q under a certain health status h (with or without experiencing disease symptoms), $P(q|h)$, will be similar for the populations of the source and the target countries. Relevant literature offers some evidence about this with regards to user search behavior for various health-related themes [1, 3, 25, 68]. In addition, we also provide some empirical evidence using our data. Table 1 shows the average query frequency over the corresponding ILI rate ratio for three basic queries in the US and AU. It also shows these ratios for translations of these queries in FR and ES (e.g. flu → grippe (FR) → gripe (ES)). The main observation is that these ratios do not vary much over the time span of our data, which is almost a decade. Although this is a limited observation, in that it does not involve many different search queries, it serves as a strong indication that user search behavior, at least for this specific area of interest, has similarities among different countries. The transfer learning framework, described in the following paragraphs, tries to exploit these similarities.

3.2 Transfer learning framework

The proposed transfer learning framework consists of three steps which are described in detail in the following sections.

3.2.1 *Step 1 — Learning a regression function in the source domain.*

Regularized regression has been successfully applied to various text regression tasks, including the estimation of disease rates from social media or online search data [32, 35]. In this paper, we use elastic net [74] as our regression function, similarly to previous work on the topic [35, 37]. Elastic net combines ℓ_1-norm regularization, commonly known as the *lasso* [58], with ℓ_2-norm, or *ridge* [26], regularization. In addition to the sparsity encouraged by the ℓ_1-norm regularization, the ℓ_2-norm regularizer attempts to address model consistency problems that arise when collinear predictors exist in the input space [69], which is common in text regression tasks [34, 36, 54]. Given $\mathbf{X} \in \mathbb{R}^{n \times s}$ and $\mathbf{y} \in \mathbb{R}^n$ from the source domain $\mathcal{D}_\mathrm{S}$, we apply a constrained version of elastic net which solves the following optimization problem:

$$\underset{\mathbf{w}, \beta}{\operatorname{argmin}} \left(\|\mathbf{y} - \mathbf{X}\mathbf{w} - \beta\|_2^2 + \lambda_1 \|\mathbf{w}\|_2^2 + \lambda_2 \|\mathbf{w}\|_1 \right) \text{ subject to } \mathbf{w} \geq 0, \quad (1)$$

where $\lambda_1 > 0$, $\lambda_2 > 0$ are respectively the ℓ_1-norm and ℓ_2-norm regularization parameters, and β denotes the intercept term. The non-negativity constraint for $\mathbf{w}$ may result in a worse performing model for the source country, but, at the same time, makes the weight transfer from a source to a target country more comprehensible (positive weights are easier to interpret) and eventually more accurate in terms of performance (see Section 4.2).

Due to the seasonal nature of influenza, our dataset of candidate queries contains a significant number of confounders, i.e. queries with frequencies that are correlated to ILI rates, but have no link to flu, such as '*college basketball*' or '*spring break*'. To remove these unrelated queries we applied a semantic filter based on word embedding representations, similar to the one proposed in [38, 72, 73]. Word embeddings were trained on the English Wikipedia corpus using the `fastText` method [12]. A topic about flu, $\mathcal{T}$, was defined as a simple set of two flu-related terms, $\mathcal{T} = \{$'flu', 'fever'$\}$. For each of the source queries, we calculate a similarity score defined as the product of the cosine similarities between the embeddings of the terms in $\mathcal{T}$ and $\mathbf{e}_\mathrm{q}$, i.e.

$$g(\mathbf{q}, \mathcal{T}) = \cos\left(\mathbf{e}_\mathrm{q}, \mathbf{e}_{\mathcal{T}_1}\right) \times \cos\left(\mathbf{e}_\mathrm{q}, \mathbf{e}_{\mathcal{T}_2}\right), \quad (2)$$

where each cosine similarity component is mapped to $[0, 1]$ via $(\cos(\cdot, \cdot) + 1)/2$.[5] Queries from the source domain with $g \leq .5$ are

[5] This resolves misleading similarity scores based on different sign combinations.

Table 1: Mean ratio of query frequency over ILI rate (and standard deviation of the mean) in four countries.

Search queries	US	FR	ES	AU
flu (US/AU), grippe (FR), gripe (ES)	.036 (.010)	.033 (.012)	.032 (.011)	.031 (.016)
symptoms of flu (US/AU), symptômes de la grippe (FR), síntomas de gripe (ES)	.030 (.009)	.031 (.012)	.029 (.009)	.027 (.014)
flu in children (US/AU), grippe chez le bébé (FR), gripe en el bebé (ES)	.017 (.007)	.020 (.008)	.019 (.009)	.022 (.010)

filtered out and are not considered in our experiments. The remaining queries are used to train an elastic net. This operation further reduces the selected queries to a subset Q_S, i.e. the ones that have been allocated a nonzero weight.

3.2.2 Step 2 — Mapping source to target queries. The identified and weighted set of search queries in the source domain (Q_S) should be mapped to a set of queries in the target domain from a potential pool of target query candidates ($\mathcal{P}_T$). Queries about the same topic may vary in their textual formulation, especially when they are issued by users located in different countries. Even in cases, where countries share the same language, cultural and socioeconomic differences may result into different querying preferences. Thus, simple approaches, where search queries from the source country are translated or directly mapped to queries in the target country, are not effective.[6] In our approach, we utilize word embeddings (mono- or cross-lingual) to map source to target queries based on their broad semantic relationship. We consider both one-to-one and one-to-many query mappings from the source to the target domain. In addition, the weight associated with each source query reflects on how correlated the query is with the modeled disease rate. Therefore, another desired property is to map source queries to target ones based on their pairwise temporal correlation as this may enhance the statistical relevance of the mapping. Consequently, there is a trade-off between mapping based on semantic similarity and based on the similarity in temporal correlation. To capture both, we define a combined similarity metric, Θ, that is the weighted sum of a semantic similarity Θ_s and a correlation similarity, Θ_c, i.e.

$$\Theta = \gamma\Theta_s + (1-\gamma)\Theta_c\,, \tag{3}$$

where $\gamma \in [0,1]$ controls the relative weighting of each. When $\gamma = 1$ the mapping is based only on semantic similarity. Conversely, when $\gamma = 0$ the mapping is based only on the correlation similarity.

Semantic similarity (Θ_s)**.** If the source and target domains have different languages, a translation module is required. For this purpose, we deploy cross-lingual word embeddings. Cross-lingual embeddings are trained using corpora from multiple languages, and can be used to compute word similarities in different languages [57, 60, 61]. Empirical evidence indicates that they can also facilitate better knowledge transfer between languages [2, 44, 47]. The majority of cross-lingual word embedding models are trained by exploiting sources of monolingual text alongside a smaller cross-lingual corpus of aligned text [56]. The alignment can be made at word [2, 5, 18, 41, 57, 60], sentence [39, 75], and document level [44, 62]. In this paper, we utilize a method for learning bilingual word embeddings proposed by Smith *et al.* [57].

First, for each of the source and target languages, we respectively learn a word embedding space based on monolingual text. For all languages considered in our experiments (English, French and Spanish) we obtained word embeddings by applying `fastText` on corresponding Wikipedia corpora [12].[7] The dimensionality of the word embeddings was set to $d = 300$. Then, we used a core selection of exact translation pairs ($\sigma \rightarrow \tau$) from the source to the target domain language to generate bilingual embeddings. Given the embedding matrices of this alignment dictionary, $\mathbf{E}_\sigma$ and $\mathbf{E}_\tau$ both $\in \mathbb{R}^{m\times d}$, where m, d denote the number of translation pairs and the dimensionality of the word embedding respectively, we learn a transformation matrix $\mathbf{W} \in \mathbb{R}^{d\times d}$ such that $\mathbf{E}_\tau \approx \mathbf{E}_\sigma\mathbf{W}$. $\mathbf{W}$ is an orthogonal matrix learned by minimizing the squared Euclidean distance between $\mathbf{E}_\sigma$ and $\mathbf{E}_\tau$, i.e.

$$\underset{\mathbf{W}}{\operatorname{argmin}} \|\mathbf{E}_\sigma\mathbf{W} - \mathbf{E}_\tau\|_2^2\,, \text{ subject to } \mathbf{W}^\top\mathbf{W} = \mathbf{I}\,. \tag{4}$$

The orthogonality constraint ensures that the transformation works both ways, that is $\mathbf{E}_\tau \approx \mathbf{E}_\sigma\mathbf{W}$, $\mathbf{E}_\sigma \approx \mathbf{E}_\tau\mathbf{W}^\top$, and $\mathbf{E}_\tau \approx \mathbf{E}_\tau\mathbf{W}^\top\mathbf{W}$ [57]. In addition, Artexte *et al.* have empirically shown that it also improves the performance of machine translation [4]. The exact solution of Eq. 4 is given by $\mathbf{W} = \mathbf{V}\mathbf{U}^\top$, where $\mathbf{E}_\tau^\top\mathbf{E}_\sigma = \mathbf{U}\Sigma\mathbf{V}^\top$ is the singular value decomposition of $\mathbf{E}_\tau^\top\mathbf{E}_\sigma$ [4, 23].

A query's embedding is defined as the average of the embeddings of its tokens, an effective practice for short texts [8, 42, 66, 72]. We denote with $\mathbf{v}_{S_i}, \mathbf{v}_{T_j}$ both $\in \mathbb{R}^{1\times d}$, the embeddings of a source query (from Q_S) and of a target query from $\mathcal{P}_T$, respectively. Then, an element ω_{ij} from the cosine similarity matrix $\Omega \in \mathbb{R}^{s\times|\mathcal{P}_T|}$ between the embeddings of source and valid target queries is given by $\omega_{ij} = \left(\mathbf{v}_{S_i}\mathbf{W}\,\mathbf{v}_{T_j}^\top\right) / \left(\|\mathbf{v}_{S_i}\mathbf{W}\|_2\|\mathbf{v}_{T_j}\|_2\right)$. Note that the cosine similarities are computed after projecting the embeddings of the source domain to the target domain using the transformation matrix $\mathbf{W}$.

In theory, we can directly use ω_{ij} to determine the k most similar target queries to the source query, thus providing a one-to-many mapping. However, in practice when conducting translations based on cross-lingual word embeddings, this may result in the presence of "hubs", i.e. target words or queries that are similar to unrealistically many different source words, a development that reduces the performance of translation [18, 57]. Smith *et al.* mitigate this effect by using an inverted softmax ranking, described next [57].

Given q_i in the source language, its translation is determined by finding candidate target queries q'_j that maximize the probability defined by

$$P_{j\rightarrow i} = \frac{\exp\left(\eta\,\omega_{ij}\right)}{\alpha_j \sum_{z=1}^{s}\exp\left(\eta\,\omega_{iz}\right)}\,, \tag{5}$$

where α_j is a normalization factor that ensures $P_{j\rightarrow i}$ is a probability, and s is the number of source queries in the vocabulary. The inverted softmax estimates the probability $P_{j\rightarrow i}$ that a candidate target query translates back to the source query, rather than

[6] We have empirical evidence about this, obtained during the first stages of this work.

[7] The embeddings were obtained from `github.com/facebookresearch/fastText`

the other way around, $P_{i\to j}$ [18, 57]. If a target query is a hub, then the denominator in Eq. 5 will be large, preventing this target query from being selected. The parameter η is learned by maximizing the log probability over the alignment dictionary ($\sigma \to \tau$), i.e., $\text{argmax}_\eta \sum_{\text{pairs } ij} \ln\left(P_{j\to i}\right)$. The top-$k$ queries from $\mathcal{P}_\text{T}$ with the highest pairing probability ($P_{j\to i}$) are then selected as possible translations of the source query q_i. Finally, we compute the semantic (cosine) similarity score Θ_s between the source query q_i and the target query q_j using $\Theta_\text{s}(q_i, q_j) = \left(\mathbf{e}_{q_i}\mathbf{W}\,\mathbf{e}_{q_j}^\top\right) / \left(\|\mathbf{e}_{q_i}\mathbf{W}\|_2 \|\mathbf{e}_{q_j}\|_2\right)$, where $\mathbf{e}_{q_i}$, $\mathbf{e}_{q_j}$ are the embeddings of q_i, q_j, respectively. Our experiments report results for a variety of values of k.

If the language in the source and the target domain is the same, the previously described approach is not applicable. Given potential differences in querying preferences across different countries, some of the source queries, Q_S, may not be present in the pool of candidate target queries, $\mathcal{P}_\text{T}$. Therefore, we use cosine similarity to map each source query to the k most similar target ones using the common word embedding space for the shared language.

Temporal correlation similarity (Θ_c)**.** We compute the Pearson correlation between the frequency time series of the source and target queries over a fixed period (set to 5 years in our experiments). Since the flu season may be offset in the target domain with respect to the source domain, we computed the maximum correlation between these two frequency time series using a shifting window of $\pm\xi$ weeks. The range of possible values for ξ is determined based on the seasonal offset between the source and target countries (see Section 4). Given a source query, q_i, and a target query, q_j which is a member of a mapping set $\mathcal{T}_i$ (consisting of $k \geq 1$ queries from $\mathcal{P}_\text{T}$), and their associated daily search frequencies, $\mathbf{x}_i(t)$ and $\mathbf{x}_j(t)$, respectively, the temporal correlation similarity, Θ_c, is given by

$$\Theta_\text{c}(q_i, q_j) = \rho\left(\mathbf{x}_i(t), \mathbf{x}_j(t + l_{ij})\right), \tag{6}$$

where $\rho(x_i(t), x_j(t + l_{ij}))$ denotes the optimal Pearson correlation coefficient between $\mathbf{x}_i, \mathbf{x}_j$ within the shifting window. Note that the optimal window is independently computed for each target query in $\mathcal{T}_i$, and thus optimal shifts may vary.

3.2.3 Step 3 — Weighting target queries. In the previous steps, we have established that a source query q_i, which has received a regression weight w_i, is mapped to a set, $\mathcal{T}_i$, of $k \geq 1$ queries in the target domain. If $k = 1$, then we can directly assign w_i to the single target query. If $k > 1$, then the source query's weight, w_i, should be distributed across these k mapping target queries. To perform this, we have considered two alternatives:

- **Uniform.** We divide the source query weight, w_i, by the number of queries q'_j in $\mathcal{T}_i$, and assign each query in $\mathcal{T}_i$ a weight equal to $w'_j = w_i/k$.
- **Non-uniform.** The k target query weights are determined based on each target query's similarity score $\Theta_{ij}, j \in \{2, \ldots, k\}$, with the source query (see Eq. 3). More specifically, a target weight w'_j is defined as $w'_j = w_i\Theta_{ij'} / \sum_{q'_j \in \mathcal{T}_i} \Theta_{ij'}$.

To obtain a baseline performance estimate, we randomly shuffle the established query mappings in Step 2, and then transfer the source weights to k target queries using the uniform approach. We repeat this process multiple times and report the mean performance of these randomized transfer learning models.

4 EXPERIMENTS

We deploy the proposed transfer learning framework to estimate ILI rates in three target countries without using any ground truth from these countries to supervise modeling. US is always set as the source country, while the target countries are FR, ES and AU. We assess the performance of the proposed model, comparing it to various baselines, and also provide a qualitative analysis, aiming to interpret some of the intrinsic properties of our approach.

Settings. After applying the semantic filter (Eq. 2) to the pool of 34,121 US queries, 1,403 queries were retained. The applied evaluation protocol is as follows. We train a source model (US) using the first 5 flu seasons (2007-12). A flu season is conventionally defined as the 1-year long period from the first week in September to the last week of August in the next year.[8] Prior to applying elastic net, we maintain search queries that have a $\geq .3$ Pearson correlation with the US ILI rates (these queries may vary per training fold). We then transfer the model to FR, ES, and AU and test it in the following flu season (2012-13). Then, we move our training data window to include the 2012-13 flu season and remove the first flu season (2007-08), and test in the following season (2013-14), so that we still have 5 flu seasons to train. We repeat this process until we have tested on the last flu season in our data set (2015-16), evaluating performance 4 times in total. The window size (ξ) used for identifying optimal correlations between the frequency time series of the source and target queries (see Section 3) is set to ±6 weeks for FR and ES. The window is the same for AU, although prior to applying it, the query frequency time series are shifted by 6 months to account for the seasonal difference in the northern and southern hemispheres. For the one-to-k mapping from a source to a set of target queries, we explore sizes up to $k = 5$ (values > 5 did not yield any different insights). We measure the performance of transferred models by comparing our estimates with their national public health estimates, using Pearson correlation (r), mean absolute error (MAE), and root mean squared error (RMSE). Regression errors are computed after reverting inferences back to their corresponding non standardized values.

Baseline models. To demonstrate the effectiveness of our transfer learning framework, we compare it with four baseline models:

- **Random**. After determining the mapping between source and target queries, the pairs (one-to-k) are randomly permuted. The source query weight is uniformly distributed across the mapped k target queries. We repeat this process 2,000 times and report the average inference performance. This random assignment of query weights provides a possibly worst case baseline.
- **Transfer component analysis (TCA)**. TCA is a transfer learning approach that aims to learn transfer components across source and target domains in a reproducing kernel Hilbert space using maximum mean discrepancy [48]. After we map source to target queries, TCA is applied to source and target query frequencies.
- **Unsupervised query selection based on semantic similarity**. We apply a semantic filter (described in Eq. 2) to remove queries that are irrelevant to the flu topic. The term pairs {'grippe',

[8] Note that for AU this may result into including the end of a flu season and the beginning of the next in training and test folds.

Table 2: Performance estimates for the US→FR transfer learning task. Different values of γ determine how queries are mapped from the source to the target domain (γ=1: semantic similarity only, γ=0: temporal correlation only, $\gamma \in (0,1)$: joint similarity score). Numbers in parentheses represent the standard deviation of the error. The best performance among all transfer learning models is denoted in bold. The best performance among models under a common γ value is underlined. Only the best random mapping performance (R) is enumerated per choice of γ. The last two rows show the performance of the baseline models.

k: number of target queries (1-to-k mapping), **w**: weighting approach, **U**: uniform, **NU**: non-uniform, **C**: correlation, **R**: random

'fièvre'}, {'gripe', 'fiebre'} and {'flu', 'fever'} are used to define this semantic filter in FR, ES and AU, respectively. Queries with $g \leq .5$ are filtered out and are not considered in our experiments. The mean weekly frequency of the retained queries is regarded as a proxy of the estimated ILI rates. These estimates are in different scale with the true ILI rates, thus we only report their Pearson correlation (r).

- **Supervised learning**. We first apply a semantic filter (see point above) to the queries of each target country. We then train an elastic net, after maintaining only queries that have a moderate correlation with the ground truth ($r \geq .3$ with the target values in the training data). This is inline with previously proposed, state-of-the-art supervised models for the task [38] and is considered as the top performance we could obtain, if we had access to ground truth in the target countries.

4.1 Quantitative analysis

Performance estimates are enumerated in Tables 2, 3, and 4 for each transfer learning task (US→FR, US→ES, US→AU). We first explored the extreme cases of $\gamma = 0$ and $\gamma = 1$ (Eq. 3) that result to using only temporal correlation or semantic similarity, respectively.

For $\gamma = 0$, spurious queries could be included in the target domain's mappings. This is a result of the way the pool of target queries, $\mathcal{P}_T$, was originally formed (see Section 2). Seasonal search queries, correlating with the occurrence of flu incidents in a population, are very likely to be selected as mappings, e.g. "symptoms flu" was mapped to "ski serre chevalier" in the US→FR task. Seasonal activities or expressions may change in time, and thus such queries are very unstable predictors. In fact, the best average performance we can obtain for $\gamma = 0$ is considerably worse (MAEs of 61.532, 25.977 and 42.348 for FR, ES, and AU) than for alternative values. Setting $k = 1$ provides the best results on average. In general, performance is not affected much by different choices of weighting (uniform, non-uniform) or the number of queries in a mapping (k).

For $\gamma = 1$, we obtain on average more accurate estimates than for $\gamma = 0$. As a precursor to the joint similarity, we also introduce a correlation-based weighting scheme (denoted by "C"), which uses the optimal correlation between source and target queries (after

Table 3: Performance estimates for US→ES transfer learning task. Please refer to Table 2's caption for further information.

k: number of target queries (1-to-k mapping), **w**: weighting approach, **U**: uniform, **NU**: non-uniform, **C**: correlation, **R**: random

deploying a shifting window) to determine the proportion of the source weight that will be allocated to the k mapped queries. In countries that deploy a translation module based on bilingual word embeddings, the "C" scheme ($k = 2$ or 3) outperforms the other two (uniform, non-uniform). For the US→AU task, where high semantic similarity often means that very similar queries are being mapped to each other (given the common language), the optimal model is obtained for $k = 1$, and thus, no further distribution of the weights is required. With or without the "C" weighting scheme, better performance is achieved compared to setting $\gamma = 0$ (MAEs of 46.788/48.77, 33.224/34.834 and 34.509/30.275 for FR, ES, and AU).

The joint similarity scheme attempts to combine the positive attributes of semantic and correlation based similarities. To assess its potential contribution, we performed a grid search using 9 values of γ (from .1 to .9), and presented the results for the best performing one (γ_{opt}). For completeness, we also show results for the default choices of $\gamma = .5$ and $k = 1$. Firstly, the application of the joint similarity leads to significant performance improvements in all tasks (MAEs of 34.052, 22.658 and 22.043 for FR, ES, and AU). Secondly, the best performing model consistently occurs for $k = 1$, i.e. for one-to-one query mappings, where no weight redistribution is required. Finally, although results do not deviate much from the default settings of $\gamma = .5$ and $k = 1$, there are discrepancies between the optimal γ value for each task ($\gamma_{\text{opt}} = .5$, .2 and .9 for FR, ES, and AU). One possible explanation may be that this is an artefact of the intrinsic characteristics (size, semantic/temporal similarities) of the pool of candidate target queries used for each task (see Section 4.2).

Better performance is always obtained (in terms of MAE and RMSE) compared to the random mapping allocation baseline ("R"), the best performance estimates of which per γ value are provided. The same holds for TCA, which performs even worse than random (results are omitted). One explanation for this is that TCA fails to capture the time series structure of this particular data set, an essential property for producing a meaningful solution. Furthermore, the optimal models (joint similarity) outperform the unsupervised baseline in terms of correlation, the only metric which is relevant in this case. Finally, compared to the fully supervised elastic net, the transfer learning unsupervised approach reaches to a comparable performance, which is worse by 23.15%, 5.55%, and 17.5% (in terms of RMSE), for FR, ES, and AU, respectively.

Fig. 2 plots the time series of a selection of these estimates, including the ones of the best performing models, in comparison to the ground truth, for each target country. We can see how estimates become significantly better when the joint similarity is

Table 4: Performance estimates for the US→AU transfer learning task. Please refer to Table 2's caption for further information.

k: number of target queries (1-to-k mapping), **w**: weighting approach, **U**: uniform, **NU**: non-uniform, **C**: correlation, **R**: random

used versus its extremes. The transferred models can very often estimate the peak of the flu season accurately. This includes the time of occurrence as well as its intensity. Notably, ILI rates in the target countries differ in terms of scale compared to ones of the source, but the proposed models are capable of capturing different scales effortlessly, providing further evidence about the user search behavior similarities among different countries (Section 3.1). At the same time, most models show some inaccuracies, especially during the time periods with very moderate flu circulation (e.g. summer).

4.2 Qualitative analysis

A fair criticism for the proposed framework is that in a practical scenario the optimal values for γ and k cannot be validated. However, we have already demonstrated that the default settings of $\gamma = .5$ and $k = 1$ provide very satisfactory performance in all our case studies. Fig. 3 looks further into this, depicting performance estimates (MAE) for different values of γ. As discussed previously, optimal γ values differ per target country. Interestingly, all error trends are monotonically decreasing (as γ increases) until they reach a minimum, and then begin to monotonically increase. We argue that γ_{opt} reflects on the actual pool of candidate target queries ($\mathcal{P}_{\text{T}}$), although we have a small sample size to be able to empirically prove this. In our data, the average correlation over the average semantic similarity ratio between all source-target query pairs is equal to 1.143, .982 and 2.261, for the FR, ES, and AU tasks respectively. These ratios depend on characteristics of the target queries which we are not controlling for in our approach. They do correlate with the respective optimal γ values (.5, .2, and .9), an insight that can be used to make a more informed choice of γ in future applications of the proposed framework.

Table 5 lists the top-5 query mappings that were the most impactful in the ILI estimates on average during the 10 weeks with the lowest and greatest MAEs (for the optimal transfer models). Impact is determined by the percentage of an estimated ILI rate that is contributed by a query (frequency × weight / estimated ILI rate). The identified pairs during the weeks with the lowest errors are topically coherent (about flu) and in many occasions are accurate translations from the source to the target language. On the other hand, pairs responsible for the largest errors include inaccurate translations that sometimes lead to an off-topic target query selection. For example, "24 hour flu" is mapped to "grippe intestinale" (impact: 13.2%),[9] "child fever" to "sinusitis" (7.7%), and "child temperature" to "warmer" (9.8%). Nevertheless, it is encouraging

[9] "Grippe intestinale" translates to "stomach flu" (formally "viral gastroenteritis").

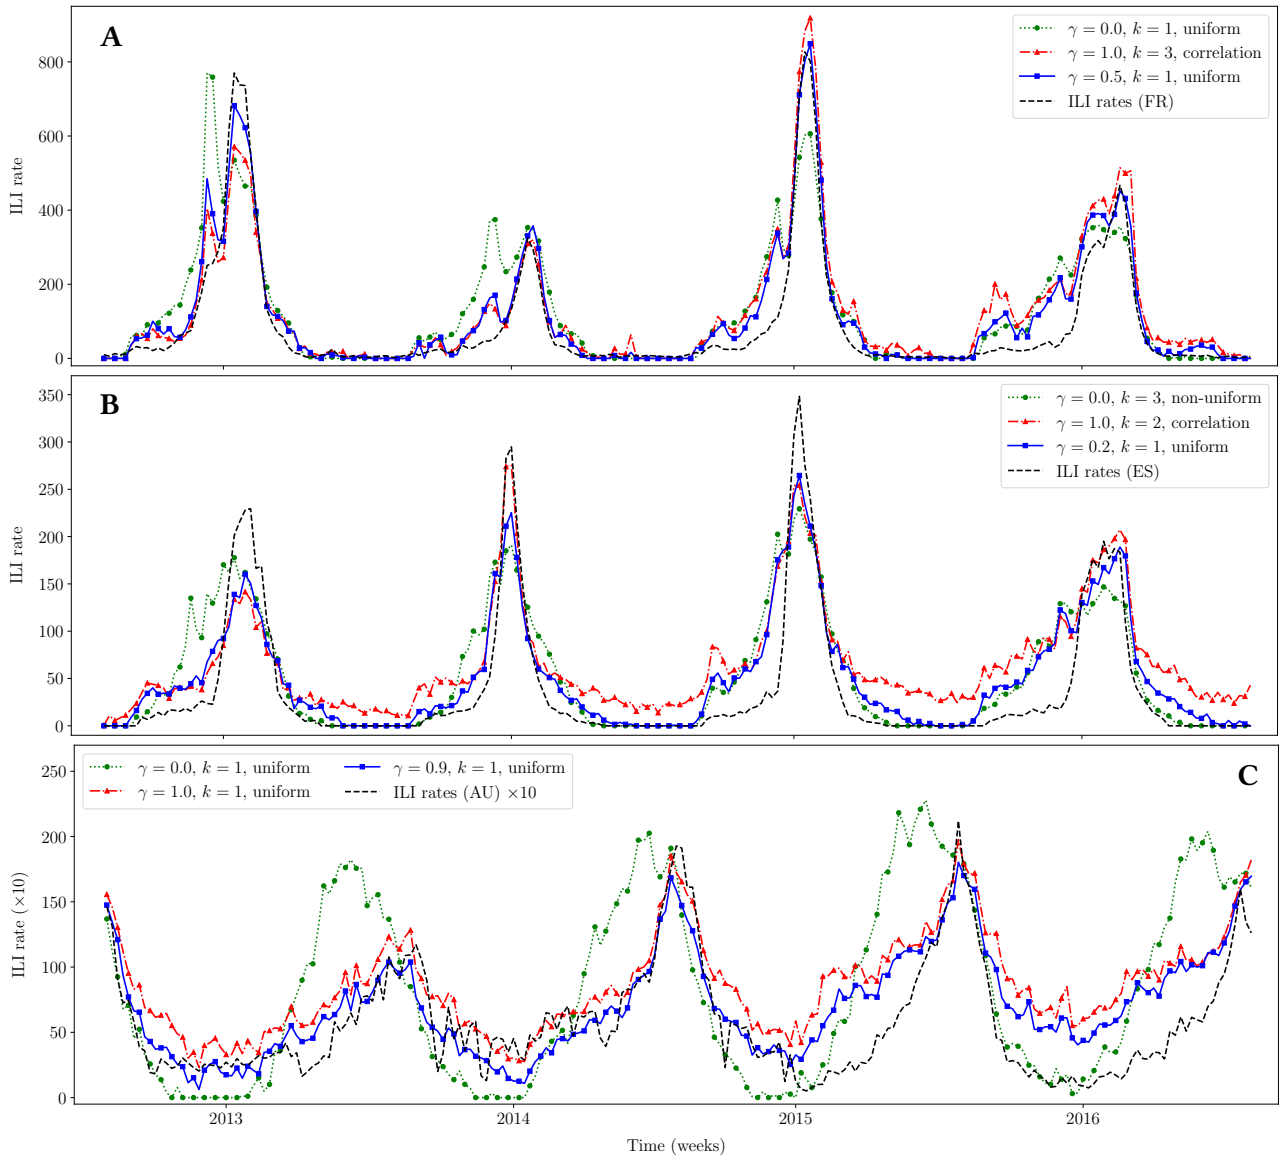

Figure 2: Comparison of transfer learning models for estimating ILI rates in France (A), Spain (B) and Australia (C) with the corresponding actual ILI rates obtained by health agencies in these countries.

that some of these mappings may have been avoided by carefully preprocessing the target query candidates to avoid spurious queries.

The optimal joint similarity transfer models do not improve by increasing the number of target queries ($k > 1$). An interpretation for that might be drawn by the fact that for $k = 1$ at most 77.9% of the selected target queries are unique (at least 22.1% are repetitive selections). Hence, the method seems to be converging to a subset of queries already for $k = 1$. As k increases, the error increases monotonically. This might be due to the existence of various spurious queries in the feature space which are being introduced as additional mappings.

Finally, the choice of adding a non-negativity constraint to the regularized regression function for the source domain (Eq. 1), was also empirically justified. When it is removed, we can learn a more accurate source model for the US, but the MAE on the target countries increases on average by 20.6%, 21.6%, and 20.5% for FR, ES, and AU respectively. This confirms our original assumption that transferring negative weights is a harder task, and thus, error-prone.

5 RELATED WORK

The fundamental properties of transfer learning have been thoroughly discussed in relevant literature [6, 7, 40, 49, 59, 65]. In contrast to traditional machine learning methods, which assume that the training and test data belong to the same domain, i.e. they are drawn from the same feature space and distribution, transfer learning aims to improve the learning function in a target domain by

Table 5: Top-5 target queries (with source mappings) in terms of mean ILI estimate impact (%) in the 10 weeks with the lowest and greatest MAE (all test periods), for all target countries (TC), based on their respective optimal transfer learning models.

TC	Mappings during accurate estimates	Mappings during inaccurate estimates
FR	flu incubation period → grippe durée (10.9), cough fever → la toux (6.3), how to treat flu → comment soigner une grippe (6), fever flu → fièvre de la grippe (5.47), flu treatment → traitement de la grippe (4.95)	24 hour flu → grippe intestinale (13.24), influenza a treatment → grippe traitement (8.07), remedies for colds → rhume de cerveau (6.75), child temperature → température du corps (6.37), child fever → fièvre adulte (6.04)
ES	symptoms of flu → symptômes grippe (9.04), fever flu → con gripe (7.49), cough fever → la tos (6.34), flu incubation period → cuanto dura una gripe (5.19), how to treat a fever → para bajar la fiebre (5.03)	mucinez for kids → tratmiento de la grippe (20.76), child fever → sinusitis (7.76), influenza a treatment → con gripe (7.02), symptoms pneumonia → bronquitis (6.04), child temperature → temperatura corporal (5.62)
AU	treatment for the flu → flu treatment (9.85), cough fever → cough and fever (8.05), flu type → influenza type (5.37), symptoms of flu → symptoms of flu (5.11), flu incubation period → flu incubation period (5.03)	24 hour flu → flu duration (11.51), child temperature → warmer (9.77), how to treat a fever → have a fever (6.94), tamiflu and breastfeeding → flu while pregnant (6.81), robitussin cf → colds (5.18)

transferring knowledge from a related, source domain. This concept has been successfully applied to various tasks, including text classification [14, 16, 22, 48], part of speech tagging [10, 28], machine translation [20, 29], and image classification [19, 30, 71].

In this work, we present a statistical framework for transferring a disease surveillance model from a source country, where supervised learning is applicable, to a target country, where no ground truth is available. We formulate it as a cross-lingual transductive regression task [49], which poses the following challenges: (a) ground truth is not available in the target domain, and (b) features (queries) may not belong in the same feature space due to linguistic or cultural differences. Due to (a), multi-task learning models, such as this solution for ILI [72], cannot be used because they still require partial ground truth from the target domain to capture the relationship between the different tasks [13]. To solve (b), a few studies have attempted to learn a mapping of both source and target languages to the same space [27, 55, 57, 64]. For example, Prettenhofer and Stein used unlabeled documents along with a word translation oracle to automatically induce task-specific, cross-lingual correspondences for cross-lingual text classification [55]. In this paper, we used cross-lingual word embeddings to align different languages [57].

Methods have also been proposed for reducing the distance between the source and target features [48, 70]. For example, Pan *et al.* proposed TCA to learn transfer components across source and target domains in a reproducing kernel Hilbert space using maximum mean discrepancy [48]. Zhou *et al.* constructed a sparse feature transformation matrix based on compressive sensing theory to map the weight vector of classifiers learned from the source domain to the target domain [70]. However, their tasks are very different from the regression task studied in this paper. These models were not able to capture efficiently the time series structure in our data.

Finally, the topic of disease modelling, and in particular of ILI, from online user-generated content has been extensively studied in the literature. The vast majority of methods proposed supervised solutions, using social media or search engine data together with disease rates from an established health authority [15, 21, 32, 33, 35, 38, 50, 52, 53, 67]. A few unsupervised methods have also been attempted, but they showcased moderate accuracy in terms of correlation [31, 51]. Our approach is able to provide accurate estimates without using any ground truth in the target locations.

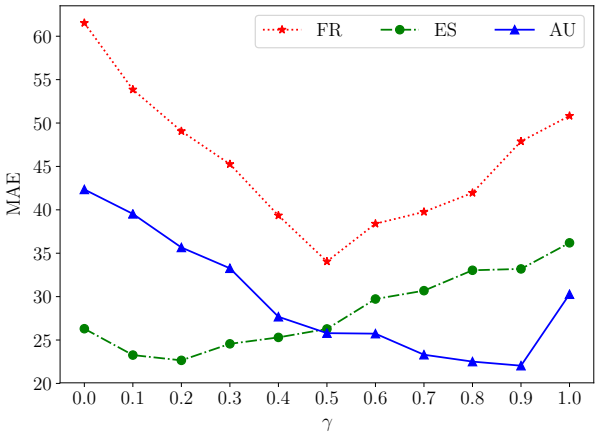

Figure 3: MAE under different γ values for the transfer learning models for FR, ES, and AU ($k = 1$).

6 CONCLUSIONS

Prior work on estimating disease rates from online user-generated content relies heavily on supervised learning models. Such models require ground truth data which is usually provided by public health organizations. Syndromic surveillance data, however, is either sparse or absent from locations with a poor healthcare infrastructure. This is somewhat ironic as it is often stated that web-based approaches hold considerable promise for regions that lack an established health surveillance system. This paper proposes a transfer learning framework as a potential solution to this problem. We leverage semantic and temporal relationships to map a supervised model from a source to a target location. We show that we can obtain a satisfactory performance ($r > .92$ on average) that does not deviate much from a fully supervised model ($\leq 21.6\%$ increase in RMSE), without using any ground truth from the target domain.

There is a number of avenues for future work. It is highly desirable to perform a study where the target country is from a low or middle income region. However, such a study is complicated, since the lack of ground truth data does not allow the performance to be quantified. Nevertheless, a qualitative study that demonstrated ILI estimates that followed an expected seasonal pattern would be of value. Our experiments on regions with ground truth data allowed us to investigate parameters k and γ, i.e. the choice for the one-to-k mapping and the relative weight assigned to the semantic and temporal similarities. Our analysis indicated that a one-to-one ($k = 1$) mapping performed best on average, and that the optimal γ differed per target country. Although we attempted to justify both outcomes, further experiments on other regions are needed to understand the effect of these parameters better.

ACKNOWLEDGMENTS

This work has been supported by the EPSRC grants EP/K031953/1 and EP/R00529X/1. The authors would like to acknowledge RCGP, PHE and SISSS for providing anonymized and aggregated syndromic surveillance data. Special thanks to Amparo Larrauri (SISSS) and Richard Pebody (PHE). We also thank Simon Moura and Peter Hayes for providing constructive feedback.

ABSTRACT

We contribute by quantifying the effect of network latency and battery consumption on mobile app performance and retention, i.e., user's decisions to continue or stop using apps. We perform our analysis by fusing two large-scale *crowdsensed* datasets collected by piggybacking on information captured by mobile apps. We find that app performance has an impact in its retention rate. Our results demonstrate that high energy consumption and high latency decrease the likelihood of retaining an app. Conversely, we show that reducing latency or energy consumption does not guarantee higher likelihood of retention as long as they are within reasonable standards of performance. However, we also demonstrate that what is considered reasonable depends on what users have been accustomed to, with device and network characteristics, and app category playing a role. As our second contribution, we develop a model for predicting retention based on performance metrics. We demonstrate the benefits of our model through empirical benchmarks which show that our model not only predicts retention accurately, but generalizes well across application categories, locations and other factors moderating the effect of performance.

1 INTRODUCTION

Nowadays there is an app for almost everything with Apple AppStore, Google Play and other major marketplaces offering millions of apps to users [48]. While the total number of apps on the marketplaces is high, a large fraction of them vanish without ever attracting a significant user base, and the majority of the rest struggle to maintain their user base over time. Specifically, studies on mobile app usage suggest that over a quarter of installed apps are only used once [25], and even apps used for more than a day are unlikely to stay relevant longer than a fortnight [46].

While low retention of apps is well known [9, 10], surprisingly little is known about the conditions that drive users to abandon apps. Indeed, existing research has mostly focused on identifying factors that result in poor user perceptions without quantifying their effect on user behaviour. For example, performance related characteristics and technical problems have been shown to be a leading factor for abandoning apps [15], a major source of frustration, and a common complaint in app reviews [27, 28]. However, *the point at which they result in users abandoning apps* is currently not known. Improving our understanding of the relationship between user behaviour and these factors would be of significant academic and commercial interest as, among others, it would deepen our understanding of mobile interactions and how they are influenced by context [4, 7, 14, 36], provide marketers information about which factors most contributed to the success or failure of an app [12, 23], and allow developers to better understand how to improve their app [3, 40].

Traditionally, mobile app performance has been analyzed by capturing performance metrics either on the network level or using active monitoring on the user's mobile device [1, 5, 24]. Unfortunately both approaches are limited in their capability to capture and quantify performance and its effect on mobile app usage. Network level measurements only capture performance factors related to networking, ignoring other factors such as energy completely. Additionally, relating network measurements to specific applications is difficult [1]. Active client monitoring captures richer set of performance factors and allows relating them with specific applications, but suffers from limited generality due to performance being sensitive to the current context of the user. For example, ambient temperature and mobility affect an app's energy use [37]

while latency is influenced by mobility, network operator, communication technology and available network infrastructure [20]. Characterizing performance would thus require collecting a large number of samples to ensure all relevant contexts are captured – something that would take prohibitively long or require battery heavy sampling when performed on individual device [20, 22].

In this paper, we contribute by quantifying the relationship between mobile application performance and retention, i.e., whether users are willing to continue using an app. We perform our analysis by fusing two large-scale datasets of *crowdsensed* measurements collected by piggybacking on information collected by mobile apps. Crowdsensing allows reaching a larger pool of users and usage contexts by taking advantage of existing application distribution channels, such as mobile app marketplaces. By piggybacking on mobile app data, the overhead of data collection is minimized and separate instrumentation of the devices is avoided, unlike in intrusive client-side monitoring. The first dataset we consider consists of detailed information about network latency [47] and the second contains information about energy consumption and mobile app usage [32]. To analyze the combined effect of these performance factors, we build on statistical survey analysis methods (hot deck multiple imputation [2, 41]) to fuse the datasets together. Our analysis focuses on energy consumption and latency as they have been shown to be key components in shaping user's perceptions of apps [23, 27]. Indeed, energy drain is known to be a major source of frustration and cognitive burden as users are forced to actively take countermeasures to prolong their battery lifetime [6, 38, 39]. Importance of energy is also reflected by the high popularity of energy saving apps on mobile marketplaces [32]. Latency, in turn, affects user engagement and results in shorter interactions and higher degree of frustration [11, 18]. While importance of these performance parameters has been established beyond doubt, their effect on continued mobile application usage is currently not understood.

Our analysis reveals that both high energy consumption and high degree of latency decrease the likelihood of retaining an app. Conversely, we show that decreasing latency or battery consumption does not guarantee higher likelihood of retention - as long as they are within reasonable standards of performance. However, what is considered reasonable depends on what the users have been accustomed to, with the app category, device characteristics, and network characteristics having an influence. For example, we find the level of expected latency to be lower in Finland than in USA, thanks to faster network infrastructure and consequently differing user expectations. To provide further insights into app retention and abandonment, as our second contribution, we develop a model that *predicts the extent that performance affects retention*. We demonstrate the benefits of our model through empirical benchmarks which show that our model not only predicts retention accuracy, but generalizes well across application categories, locations and other factors moderating the effect of performance.

Summary of Contributions:

- We demonstrate that latency and energy, two key performance metrics for mobile apps, have a significant adverse effect on mobile app retention and abandonment and that this effect is stable across most application categories. However, we also conversely demonstrate that improving latency and energy drain does not guarantee improvements in retention as long as the performance metrics are within reasonable levels.
- We derive *critical points* for popular applications and application categories, demonstrating that the point where performance has a significant effect varies depending on the level of performance people are accustomed to, as well as the functionality and category of the application.
- We further explain our findings through a model that predicts the extent that performance affects retention. Our model achieves an overall error of 1.4 percentage points (measured using Mean Absolute Error MAE) of retention across all data.

Table 1: Summary statistics of application usage and network connectivity datasets.

Dataset	Samples	Users	Apps	Time
NetRadar [47]	875,907	-	-	Jan 1 - Dec 31, 2016
Carat [32]	19,608,938	25,402	48,770	Jul 1 - Dec 31, 2016
Combined	1,000,058 (Latency) 2,819,748 (Energy)	1,241	243	Jul 1 - Dec 31, 2016

2 DATASETS AND PREPARATION

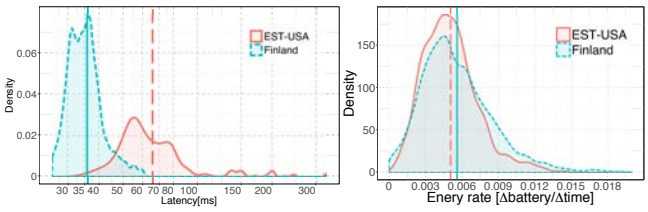
We quantify the effect of performance-related variables on long-term application usage by analyzing two large-scale crowdsensed datasets. Our first dataset, NetRadar [47], contains information about network performance at different locations, whereas the second dataset, Carat [32], contains information about mobile application usage and energy drain of applications.[1] To analyze overall impact of performance, we fuse the two datasets using coarse-grained location and timezone information. While instrumenting a single application to monitor both energy and latency is technically feasible, in practice the functionalities for sampling network or energy differ significantly, which would make attracting sufficiently large user base difficult. Indeed, network profilers are typically used sporadically instead of continuous data collection. Continually collecting network performance measures, on the other hand, would significantly increase energy overhead from sampling and thus be contrary to the original purpose of energy-awareness apps.

After combining the datasets, we select those countries with highest amounts of data for our analysis. In the intersection of the two datasets, 91% of data is from Finland and USA, and 93% of the USA data is from Eastern USA. This is mainly due to demographics of the user populations of the mobile apps which were used to collect measurements. As a result, we focus our analysis in Finland and USA (EST - Eastern Standard Time). In the remainder of the paper we use EST-USA to refer to the measurements collected from USA that are included in our analysis. The datasets considered in our study are summarized in Table 1.

2.1 Network Latency

Latency directly influences the response time of applications and consequently has a major impact on the observed performance. Several application categories, such as on-line gaming and web conferencing [49], require low latency while for many others it can

[1]The datasets are available through separate license agreements. More information can be found at http://carat.cs.helsinki.fi and http://www.netradar.com/.



cause frustration even if it is not critical for running the app [11, 18]. For these reasons, we consider latency as a performance - related parameter in our experiments. As source of latency data we consider data collected through NetRadar, a mobile app designed for end-users to help diagnose network conditions [47]. The data considered in our analysis consists of samples collected during cellular network connectivity and contain timestamp, average RTT latency calculated during a 5 second window interval, mobile network information in the form of mobile country code (MCC) and mobile network code (MNC), and GPS location. We restrict our analysis on cellular network connectivity as Wi-Fi has higher bandwidth than cellular technologies and as its performance has less variation overall [16, 17]. Another reason to limit on cellular networks is that this guarantees our analysis to capture a broad range of usage contexts and higher spectrum of mobility patterns.

Figure 1a compares the latency distributions of Finland and EST-USA in the NetRadar dataset. The two locations have distinct latency distributions with Finland having lower expected latency than EST-USA (median 36ms vs. 66ms). The overall variation within Finland is several orders of magnitude smaller with the majority of values being within 45ms. For EST-USA, latency is mostly in the range between 40 to 100ms, but we can observe smaller peaks at around 140ms and even at 200ms. While the values of the distributions differ, the shape of the two distributions is similar with both being long-tailed and skewed towards lower values. To put the values into context, most latencies for Finland are below 70ms which is within LTE network range. For EST-USA, the majority of values is within LTE range, but we can also observe values over 100ms which are likely to correspond to 3G connectivity - or even 2G at the end of the tail. This would suggest there are differences in network infrastructure, or mobile subscriptions, within the two locations. These differences in latency distributions, and characteristics of the underlying network infrastructure motivate us to consider the two locations separately in our analysis.

2.2 Energy Consumption

Our second performance factor, energy, has been shown to be an active source of frustration and a cognitive burden as users actively seek to prolong their battery lifetime [6, 38, 39]. As source of energy consumption measurements we consider Carat [32], a popular mobile energy-awareness application. Carat samples the device whenever battery level changes. Each sample contains current battery level, timestamp, list of running applications and additional attributes, such as device uptime and battery state.

As unit of analysis we consider *energy rates* which correspond to the relative change in battery in a given time interval. Formally, let Δb denote change in battery between successive samples, and let Δt denote the difference in timestamps. Energy rate is then defined as the mean change in battery over the interval, i.e., $e = \Delta b/\Delta t$. We only consider samples where rate is positive (negative rate indicates charging), battery state is not charging (AC or USB), and device uptime has increased from last sample (device has not been turned off in between). We restrict our analysis to samples collected from Android devices as information about running applications cannot be accessed on other platforms and because the sampling granularity on Android devices is better than on iOS devices.

(a) Latency (b) Energy rate

Figure 1: Comparison of latency and energy rate distributions between Finland and Eastern USA.

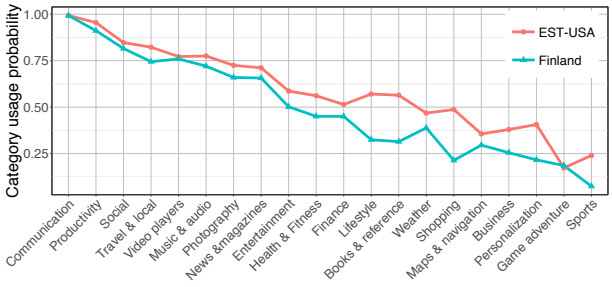


Figure 2: App category use profile differs between locations.

To study energy consumption of application a, we take all rates e_a containing a in the list of currently running apps and calculate the mean rate $\overline{e_a}$ for the application. Since energy consumption fluctuates due to environmental variables (e.g., Wi-Fi and strength of cellular signal) and specific system settings (e.g., screen brightness or use of location tracking), and other currently running applications, we represent energy consumption using the 95% standard error of the mean (SEM) confidence interval [32] given by

$$e_{a,range} = \overline{e_a} \pm h \cdot \frac{\sigma_a}{\sqrt{n_a}}, \quad (1)$$

where $h = 1.96$ is the confidence interval coefficient, σ_a is the standard deviation, and n_a is the number of samples containing a.

Figure 1b compares energy consumption distributions of Finland and EST-USA. Compared to latency, the distributions are closer to each other (mean rate 0.0056 for Finland cf. 0.0051 for EST-USA) and have similar variance, with 44% and 45% of apps exceeding the average in Finland and EST-USA, respectively. To put these values into context, the means correspond to around 5 battery life while most apps are in the range of 5-9 hours. Note that Carat flags applications with very heavy energy drain as hogs and recommends the user to remove them [32]. For this reason applications with very low expected battery life are rare in the dataset.

While the two locations have similar energy consumption distributions, they differ in terms of application usage patterns. This is illustrated in Figure 2, which shows the usage frequency of each category for both locations. EST-USA has higher overall application usage, and the two locations differ in terms of the relative importance of application categories. In our analysis, we separately consider the moderating effect of application category. Motivated by these differences in application category use, we analyze also energy separately across the two locations.

2.3 Retention Rate

The main focus of our work is on analyzing and quantifying how performance related factors affect long-term user behavior. As measure of user behavior we consider n day retention rate, which is the fraction of users continuing to use an app n days since first use. Retention is widely used to measure the success of apps as higher retention corresponds to higher adoption and level of engagement [46]. As source of retention information we use the list of running applications collected by Carat. The list of applications contains all applications running on the device, including those related with the operating system and those pre-installed by the manufacturer. To ensure our analysis focuses on actual usage, we filter the applications by (i) removing all apps for which no category information is found on Google Play; and (ii) removing pre-loaded applications that have not been seen on the foreground, such as Google Exchange Services (com.google.android.exchange).

To estimate retention, let d_a^u denote the number of days between first and last use of an application a by user u in the Carat data. To ensure retention is not influenced by the data collection period, we only consider cases where we have measurements for 7 days before first use, and 7 days after last use. Similarly, to ensure the estimated retention patterns are sufficiently robust, we only consider users that have at least 14 days of data, and apps that have at least 10 users that have used them for more than a day. The n day retention rate of a, denoted r_n^a, is then given by the fraction of users whose retention time d_a^u is higher than n, i.e.,

$$r_n^a = \frac{\#U_{a,n}}{\#U_a} \cdot 100 \tag{2}$$

where U_a is the set of users to use a, and $U_{a,n} \subseteq U_a$ is the subset of users for whom $d_a^u \geq n$. Note that retention rate is cumulative so a user with $d_a = 3$ days also contributes to day 1 and 2 retention.

Table 2 compares the average retention over the first 7 days across the two locations for the 5 most popular applications. From the table we can observe the two locations to have distinct retention patterns with Finland having higher mean retention than EST-USA, but also much higher variation. To highlight differences in usage across the locations, as part of the table, we have also included the number of users, number of samples and summary statistics of the performance variables for the apps. While the number of users tends to be lower in EST-USA than in Finland, we can observe that the number of samples to characterize each performance variable is enough for both locations. In terms of retention behavior, one of the applications, Dropbox, has lower latency but higher energy drain in Finland than in EST-USA, which suggests that it is used in differing situations. These differences in retention and usage patterns further serve to illustrate the need to consider the measurements separately.

2.4 Combining Datasets

Different performance factors are typically closely linked with each other. For example, latency results in energy drain, and networking technology has a major impact on energy use [26, 37, 47]. To analyze and quantify the combined effect of performance factors, we thus need to combine measurements in the two datasets. We perform the combination using hot deck multiple imputation, a widely used method for aligning two datasets that overlap only partially [2, 30, 41]. The idea in hot deck imputation is to fill in missing values (in the combined set) with items that are similar (in the individual data sets). In our analysis we consider the combined dataset as our primary source of analysis as this ensures the usage contexts where performance is captured are comparable across the datasets.

Data Fusion: We combine the datasets using a combination of timestamp, and coarse grained location information given by Mobile Country Code (MCC), Mobile Network Code (MNC) and reverse geocoding of the GPS (time zone from the cellular coverage). The sampling periods of the datasets differ and hence we first need to align them temporally. We perform the alignment by creating hourly bins and mapping each sample in NetRadar and Carat to the closest bin. Next, we match the (MCC, MNC, Time zone) tuples across the two datasets in each bin and calculate hourly latency values for a given location as medians of all matching measurements. The measurements in the combined dataset are summarized in Table 1. In total, the combined dataset comprises 243 applications and 1,241 users from July to December, 2016. This is translated in terms of samples to $1,000,058$ measurements for analyzing latency, and $2,819,748$ measurements for analyzing energy. The reason for differing sample counts for energy and latency is that we perform the matching separately for each application and category considered in our analysis. As the energy dataset is originally larger, this results in a higher total sample count of energy.

Validity: We demonstrate the validity of the combined dataset by comparing statistical characteristics extracted from the combined data against those extracted from the individual datasets. First, we compare mean latency and energy of the individual datasets to those of the combined set. The mean and standard deviation values for both latency (Finland, mean = 38.27, SD = 12.31; EST-USA, mean = 87.45, SD = 61.34; combined, Finland mean = 36.7, SD = 6.6; EST-USA, mean = 84.4, SD = 53.4) and energy (Finland, mean = 0.0053, SD = 0.012; EST-USA, mean = 0.0059, SD = 0.016; combined, Finland mean = 0.0056, SD = 0.003; EST-USA, mean = 0.0051, SD = 0.0023) are closely aligned, suggesting that the statistical characteristics of the individual datasets are preserved in the fusion. Second, we compare the sample distributions between the combined and individual datasets using Kolmogorov-Smirnov distribution tests. No statistically significant differences were found (latency: Finland $KS = 0.104$; EST-US $KS = 0.096$, $p > 0.05$; energy: Finland $KS = 0.04$; EST-US $KS = 0.05$, $p > 0.05$).

Representativeness: We assess whether the energy distribution of Eastern USA is representative of USA as a whole by comparing energy distributions of all samples from USA against those matched to Eastern USA based on timezone information. Again, no significant differences were found ($KS = 0.06$, $p > 0.05$).

2.5 Privacy

We consider only aggregate-level data derived from anonymous user records. We consider country level granularity due to privacy reasons and the need for additional application permissions for collecting finer grained location information of individual users. For Carat, the privacy protection mechanisms are detailed in [32] and for NetRadar in [47]. Users of both apps are informed about the collected data and consent from their devices.

Table 2: Retention rate variation, energy and latency, and influence of app performance in retention for top 5 categories (a) and applications (b) together with statistical analysis results of the importance of performance on retention. Darker colors reflect statistical significance ($p \leq 0.05$).

3 QUANTIFYING EFFECT OF PERFORMANCE ON RETENTION

In this section, we *quantify*, for the first time, the impact of performance related factors on long-term user behavior, as reflected by retention. We focus on latency and energy as the main performance related variables and analyze them using the Netradar and Carat datasets described in the previous section (see Sections 2.1 and 2.2). We first consider the impact of latency and energy individually, showing they indeed have a significant influence on retention. We proceed to quantify the point where the effect of performance becomes significant, demonstrating that we can identify a *critical* point beyond with performance has a clear effect. We also demonstrate that the effects of energy and latency are moderated by user expectations and by application functionality. We end the section by analyzing the combined effect of latency and energy, showing them to have a complex relationship where neither variable alone is capable of explaining retention.

3.1 Performance Influences Retention

We begin our analysis by demonstrating and quantifying the overall influence of latency and energy as *individual* performance-related variables on retention, analyzing their combined effect in Sec. 3.6. Both latency and energy have been shown to affect user experience [27], and hence to have an indirect effect on long term user behavior. However, whether they have a direct effect on retention has not been previously established. We assess overall effect using Kruskal-Wallis test and considering the five most popular application categories (Communication, Productivity, Tools, Music & Audio, and Social) and applications (Dropbox, Facebook Messenger, Whatsapp, Facebook, Twitter). For each day of the retention period ($1-15$ days), we compare the mean performance of those that stop using the application and those that retain it.

Table 2 shows results of statistical tests at both category-level and app-level together with corresponding retention and performance values. From the results, we can observe that performance indeed affects retention, but the effect is moderated by application category and popularity of the app. We can also observe the effects to reflect differing interaction patterns across application categories. For example, messaging apps (Facebook messenger and Whatsapp) that require users to wait for response are not influenced by latency but energy drain has significant effect on their retention. On the other hand, productivity apps, which tend to be used for shorter periods of time, demonstrate significant effect for latency but not for energy. Comparing effects across number of days, we can observe users to have different levels of tolerance for poor performance depending on application category. For example, Music apps show no effect on latency at day 1, and even at day 7 they only show an effect in Eastern USA where latency is higher than in Finland. However, at day 15 latency has a significant effect for both locations. Similarly, effects of energy are higher for later days for both Facebook and Twitter, suggesting users are willing to tolerate more performance issues with them – potentially because other factors, such as user experience, are more important during the first few days.

Table 3: Retention rate difference of $high$ and low groups proportions for app categories and apps: L: Latency, E: Energy; O: Overall, C: Communications, P: Productivity, T: Tools, S: Social, M: Music, w: Whatsapp, fm: Facebook Msg., fa: Facebook, d: Dropbox, t: Twitter.

Area, Factor	O	C	P	T	S	M	w	fm	fa	d	t
Finland, L	63	67	58	26	65	67	10	84	30	57	45
Finland, E	69	63	78	50	67	63	50	43	69	78	51
EST-USA, L	24	32	10	18	25	10	10	10	10	10	31
EST-USA, E	52	10	64	25	11	29	10	10	10	10	10

3.2 Level of "Critical Point" in Performance

Previous section demonstrated that both latency and energy have an overall effect on retention. We next analyze the relationship

between performance related variables and retention in more detail, showing that we can identify clear points where decrease in performance results in lower retention. We refer to these points as *critical points* of performance. Conversely, we demonstrate that improving performance beyond this point has no influence on retention.

We carry out the analysis by splitting users into two performance groups using a threshold v on the two performance factor, and compare the retention in the two groups using a test of proportions (i.e., a two-tailed z-test). We iterate over different values of v considering values between the 10^{th} and 90^{th} percentile identifying the range of values where retention is significantly different. We omit the lowest and highest 10 percentiles as these resulted in the smaller group having insufficient data for assessing statistical significance. In the following we refer to the two user groups as *high* and *low* depending on which side of v the average performance of users in the corresponding group is.

Table 3 shows the percentile of latency and energy after which the test of proportions indicates difference in retention rate between the low and high groups to be statistically significant ($p < 0.05$). We show percentiles instead of exact performance values due to the fact that the values vary across categories and applications depending on which samples include the category or application. From the results we can see clear differences in the points where performance start to influence retention. Mirroring the results of previous section, we can see that both the category and application moderate the results Besides the category and application, we can also observe *location* to heavily moderate the level where performance starts to influence retention. In Finland, significant differences start to occur only at higher percentiles, whereas in Eastern USA significances start to appear earlier. As an example, latency higher than 60^{th} percentile has significant effect of retention across all application categories in Finland, whereas in USA the effect is significant already from 30^{th} percentile onwards. Similarly, energy starts to have an effect at much earlier percentile in Eastern USA than in Finland. For latency, this difference can be partially explained by differences in network infrastructure, with users in Finland having lower latency and less variability than users in Eastern USA. However, for energy this is not the case with the distributions being similar across the two locations. Consequently, this suggests that users at different locations either assign different importance to energy or have different levels of tolerance.

3.3 Difference in the Effect of Performance

In the previous section we showed there to be a critical point beyond which performance starts to have a significant effect on retention. We next analyze the extent at which individual performance factors start to have a significant effect on retention during app usage.

To perform this analysis, we first calculate the difference in retention percentage between the high and low groups. Figure 3 shows the results. We identify in the figure the percentile where the changes first become significant and can start to be quantified (critical point depicted as vertical line). Points where the difference is negative correspond to cases where retention drops in line with performance degradation. From the figure we can observe the *strength* of significance to vary considerably across locations, categories, and applications. We also can see that, depending on the category, the percentile at which performance differences become significant varies between energy and latency, with one factor typically having a significant effect much earlier than the other. We also can observe that for a few cases, the performance factor does not seem to influence the retention (gray background). Most of these cases correspond to communications apps, such as Whatsapp and Facebook messenger, which are commonly used within social circles and whose usage is moderated by level of social activity [44]. Even if the performance of these apps would be suboptimal, replacing them would require the user's entire social circle to migrate to a new service, which is unlikely to happen rapidly.

Table 4: Critical Point and ΔP for top 5 categories and apps.

	Critical Point, EST-US			Critical Point, Fin		
Category	Energ.	Lat.	ΔP	Energ.	Lat.	ΔP
Communication	10	27	-17	64	67	-3
Productivity	N/A	10	N/A	79	58	21
Tools	24	28	-4	50	23	27
Social	11	16	-5	67	58	93
Music	29	10	19	64	67	-3
App	Energ.	Lat.	ΔP	Energ.	Lat.	ΔP
Whatsapp	N/A	10	N/A	74	11	63
Facebook Msg.	10	10	0	84	N/A	N/A
Facebook App.	19	10	9	87	30	57
Dropbox	46	10	36	80	57	23
Twitter	70	31	39	N/A	45	N/A

To further analyze these differences in significance, Figure 4 compares the difference in critical points (CP) between energy and latency, represented as difference in percentiles ΔP. In the Figure we consider the collection of all applications across all categories for both, Finland and Eastern USA. Interestingly, when the effect of latency is perceived first, the area of ΔP covers a wider percentile range than in the opposite case. Indeed, when latency is the first to have an effect, energy becomes significant only at much later percentages. This relation is explored in Table 4 for all categories and apps considered in our analysis. We analyze this relation by calculating a (Kendall) correlation between CPs for both factors. We observe a positive correlation between CPs for both categories (0.51, $p = 0.04$) and apps (0.62, $p = 0.05$). From the table, we see indeed greater difference between energy and latency when latency is perceived first to decrease performance. We can observe that this relation is three-times as significant for apps than for categories. Intuitively, energy consumption of a particular application may take a long time for the user to discover, while network conditions can change rapidly within seconds and minutes. Therefore bad latency can be discovered much quicker than high energy consumption. Higher latency may also affect the energy consumption of the device, which can result in retention decreasing faster. Because latency is a shorter-term phenomenon than battery life, the decreased retention is easily attributed to latency instead of both energy consumption and latency.

3.4 Effects on Highly-Rated Apps

Besides performance, app functionality and user interface design can influence user satisfaction and ultimately retention. To demonstrate that effects of performance on retention are robust across

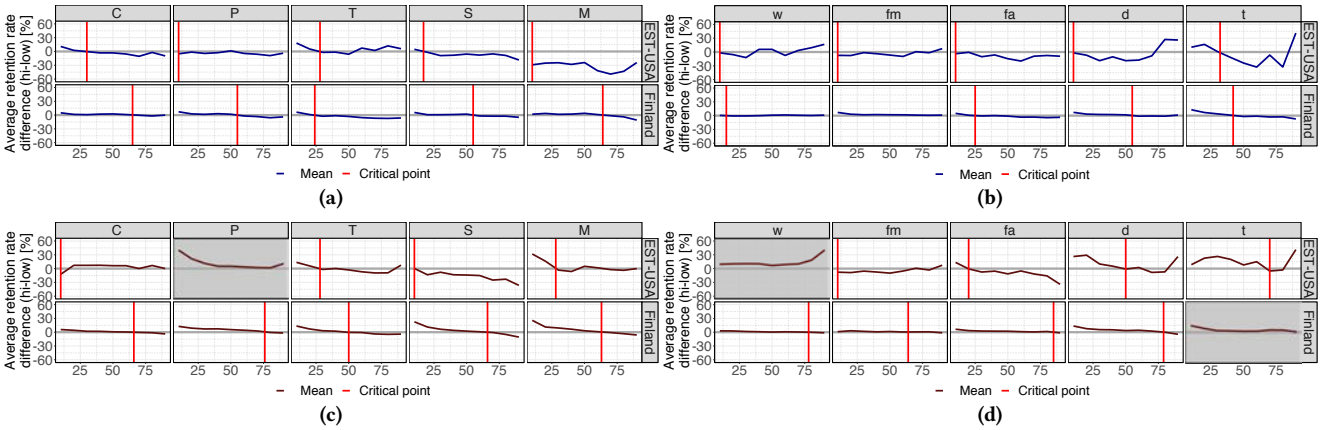

Figure 3: Average retention difference for *high* and *low* groups. (a), (b) Latency, (c), (d) Energy. Categories: O: Overall, C: Communications, P: Productivity, T: Tools, S: Social, M: Music; Apps: o: overall, w: Whatsapp, fm: Facebook Msg., fa: Facebook App., d: Dropbox, t: Twitter

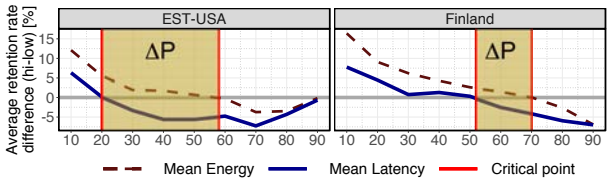

Figure 4: Overall average retention difference for *high* and *low* groups combining latency and energy "critical point" thresholds.

other factors, we analyze 10 applications that are not among the top apps of their categories but have high user satisfaction. As proxy for user satisfaction, we consider the star rating of the apps on Google Play store. As these applications have predominantly received high ratings, users are likely satisfied with the functionalities and user interface design of the apps. We omit most popular applications to avoid possible popularity biases influencing the retention of these apps. For our selection of apps, we also ensured that any negative ratings would not be caused by differences in functionality between commercial and free versions of the app, e.g., due to high amount of advertisement or restricted functionality.

Table 5 shows results together with the applications and their ratings. We applied the same method to calculate the critical point(CP) and difference (*DeltaP*) (see Sec. 3.2). Latency has higher impact than energy for apps that highly depend on displaying on-line content, such as Viaplay. Retention of apps used for personalization, such as Zedge, is more influenced by energy variations. The critical points behave similarly for apps with similar functionality. For example, for both eBay and Aliexpress the critical point on latency is low whereas users are more tolerant to energy. As both applications focus on online shopping are used only intermittently, the importance of latency is understandable. However, for utility apps, such as AVG and Avast, no clear patterns can be identified. Indeed, Avast is more sensitive to latency whereas AVG is more sensitive to energy. In summary, our results show that even for applications with high user ratings, clear critical points can be identified, suggesting that performance indeed has a major influence on their retention. Our analysis also suggests that the relative importance of latency and energy is dependent on the functionality of the app.

Table 5: Effect of performance in case study apps. r: retention, CP: Critical Point ,E: Energy, L: Latency; App: ag: AVG antivirus, aa: Avast antivirus, ac: Avast cleanup, f: Firefox, ae: Aliexpress, e: Ebay, v: Viaplay, h: Here WeGo, s: Sports tracker, z: Zedge; Categories: T: Tools, C: Communication, SH: Shopping, E: Entertainment, MA: Maps, H: Health, PE: Personalization.

3.5 Other Factors

To further demonstrate the robustness of our findings, we next demonstrate that the effect of performance is robust across other factors influencing user perceptions and retention.

Data Freshness: We repeated our analysis for effect of energy considering a snapshot of Carat data collected between May 2018 and October 2018. We consider the same five categories and applications as in Sec. 3.1. The mean retention of all categories and apps decreased compared to 2016 with particularly Tools and Dropbox witnessing steep decline. The critical point shifted to a higher percentile for communication (9 percentiles) and music and audio (5 percentiles), but decreased for the other three categories (percentile differences: 11 for productivity, 5 for social, 40 for tools). For the individual apps, the critical point shifted to a lower percentile for four

apps. The sole exception was Twitter, for which we were unable to obtain a clear critical point earlier. In the 2018 data, the critical point is at 66^{th} percentile, which is in line with the other apps. The results thus suggest that the effect of energy on retention is robust over time. In fact our results suggest it has increased in importance since most critical points have shifted to lower percentiles.

Robustness against Energy Saving Mechanisms: To rule out potential biases resulting from the fact that our application data was collected using an energy-awareness app, we repeated our analysis on all applications with energy rates lower than the average energy rate across all apps. For these apps neither Carat nor energy-efficiency mechanisms of the operating system trigger warnings, suggesting the effects of performance are direct result of user perceptions while using the app. The overall effect of energy persists. However, since their overall energy usage is low compared to other apps, critical points shift on average to a 17 percentile higher point.

3.6 Combined Effect of Latency and Energy

We next assess the combined effect of energy and latency by performing a cost-benefit analysis that looks at the combined effect on retention when the importance of individual factors is varied. To perform the analysis, we define a linear cost function that determines the overall effect of the two performance variables as a weighted combination of their individual effect. We consider different relative weightings to see how the importance of individual factors affects retention. Formally, let r_l and r_e denote the differences in retention between the *high* and *low* groups (See Section 3.2), and lw and ew the weights of latency and energy, respectively. Given energy e and l, we estimate retention for a given performance level, denoted $R(e, l)$, using

$$R(e, l) = \frac{r_e \cdot ew + r_l \cdot lw}{ew + lw}. \quad (3)$$

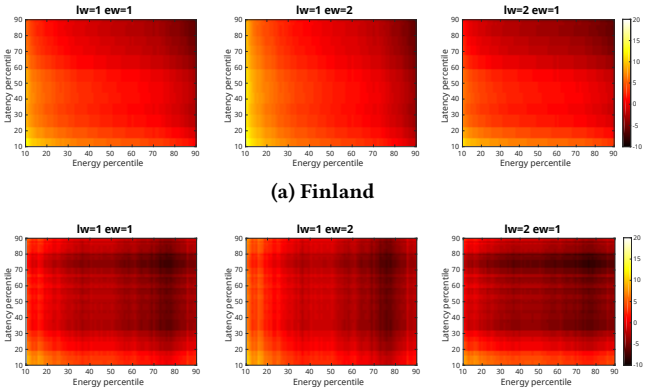

Figure 5 shows the results of our analysis as series of heatmaps. Each heatmap shows the combined effect of latency (y-axis) and energy (x-axis) on retention for different percentiles (10-90) and different weights lw and ew. In the figure, lighter colors reflect retention improvement and darker ones worsened retention. The scale is in percentage units of retention.

From the figure we can observe the effect of performance factors to be non-linear with neither variable clearly dominating the other. When latency is twice as important as energy, the effect on retention is slightly higher than in the opposite case. However, even in this case there is a lot of variation and a highly complex relationship between the two performance variables.

4 MODELING RETENTION

Having *quantified* the effect of performance on retention, we next develop a mode for *predicting the degree to which performance affects retention*. The model is important to estimate how users will respond to apps during their evolving life span, e.g., different releases with extra processing and network functionality.

Model specification: In our general model, app retention is influenced by M factors $F_i, |1 <= i <= M$. Each factor F_i has a performance threshold ϵ_i, whose changes affect the overall retention. Thus, ϵ_i depicts the starting point to quantify how incremental poor performance of a factor impacts app retention. By analyzing

(a) Finland

(b) EST-USA

Figure 5: Retention behaviour for performance-related factor given different weights of latency lw and energy ew.

changes in performance relative to ϵ_i, it is possible to estimate the amount of influence that a performance level has on retention. We estimate retention using a step function as depicted in equation 4, where x is the performance value for a factor, e.g., 30 ms for latency; and $g_i(x)$ is an exponential probability function that approximates the retention rate of the factor given expected performance.

$$R_i(x) = \begin{cases} 0, & x \leq \epsilon_i \\ g_i(x), & x > \epsilon_i \end{cases} \quad (4)$$

We then quantify the overall impact on retention by aggregating the influence of each individual factor. The overall impact of app performance on retention, R, is determined by the factor $F_i \in M$ whose influence on retention is highest, i.e. $R = max(R_i)$. The expected retention rate is then calculated from the uninfluenced retention rate curve $r(x)$ by division as follows $r'(x) = r(x)/R$

Experimental Setup: We assess performance of our model by performing a 80/20 split for each country (Baseline). We also perform a cross-country validation between Finland and EST-USA subsets by training our model with data from Finland and predicting EST-USA retention based on expected performance, and vice versa. Following same approach, we also analyze the effect of mixing data from Finland and EST-USA (Mixed) into a single subset to predict retention. We then compare the performance of our model when predicting retention based on combined factors.

Individual factor prediction: The top part of Table 6 shows the results of the baseline. We can observe that our model indeed is able to predict retention values with lower error rate, specially for Finland as it is the country that has most of the data for our analysis. We then explore Cross-country validation. The *Cross-country* sections of Table 6 shows the results for both latency and energy. From the result, we can observe that the error rate increases slightly compared to the country baseline. Our model has an average overall prediction MAE of 2.25, which depicts an overhead of 46% when compared with the baseline. However, we can observe a small error window in retention based expected latency for (EST-USA → Finland), in this case, the error is reduced in 5%. The slightly overhead is due to the fact that critical points in which performance starts to be perceived by users is different in each country. For

Table 6: MAE for categories (model data → predicted), O: Overall, C: Communications, M: Music, P: Productivity, S: Social, T: Tools

Retention estimation	O	C	M	P	S	T
(Baseline) Latency						
Finland (80%) → (20%)	0.91	0.54	1.67	0.98	0.83	1.72
EST-USA (80%)→(20%)	1.90	3.33	10.03	2.86	3.15	2.13
(Baseline) Battery						
Finland (80%) → (20%)	0.63	0.30	0.75	0.73	1.12	1.08
EST-USA (80%)→(20%)	1.51	2.49	3.87	1.69	3.70	2.77
(Cross-country) Latency						
Finland → EST-USA	3.58	5.00	31.99	3.76	7.13	2.29
EST-USA → Finland	1.66	6.49	37.06	3.39	8.15	2.01
(Cross-country) Battery						
Finland → EST-USA	2.29	5.84	4.98	2.21	15.49	4.61
EST-USA → Finland	1.53	1.30	5.67	2.18	21.29	4.18
(Mixed Finland + EST-USA)						
Latency (80%)→(20%)	0.82	0.50	1.10	0.85	0.61	1.49
Battery (80%)→(20%)	0.28	0.27	0.83	0.56	1.11	1.04
(Mixed Finland + EST-USA)						
Combined Latency+						
Battery (80%)→(20%)	0.29	0.45	0.97	0.35	0.47	0.51

instance, when training our model with latency data from Finland to predict EST-USA, we can observe that the observed latency in Finland is between 30 − 45 ms while the ground truth of EST-USA consists of values around 51 − 147 ms. Clearly, the accuracy prediction of our model is reduced due to this issue.

On the other hand, when analyzing a specific application category, we observe a higher error rate, particularly when trying to generalize the data from EST-USA to Finland. The errors for categories are influenced by the number of samples and applications included in the subset that is used to train the model (see Table 2). Additionally, the dominant applications of each category can differ in the two locations. For instance, in the case of the Music category, most of the collected data for Finland is from the *Spotify* app, while in the case of EST-USA, most of the data is from the *Pandora Music* app (not available for installation in Finland), which explains the higher rate of error for the Music category. Similarly, the Tools category contains significant variation across the locations which explains worse predictive performance. However, for categories with similar usage patterns the results are well aligned across the two countries, like in the case of the Productivity category.

We then proceed to analyze the performance of our model when mixing the data of Finland and EST-USA to predict retention. The bottom of Table 6 shows the results. We can observe that our model improves significantly when mixing data from both countries. Indeed, we can observe very accurate predictions with marginal errors up to 1.49 for all the categories and for both factors.

Combined factor prediction: We analyze the effect on retention when multiple performance factors are taken into consideration. Since the accuracy of the prediction clearly is improved when mixing the data of both countries, we perform a 80/20 validation using both mixed datasets for both energy and latency. In the combined effect, the value of retention is constrained by the factor that influences the performance the most. In other words, the factor that is perceived first by users. Table 6 also shows the results for the combined prediction. Compared to the results of individual factors (Baseline, Cross-country and Mixed), we can observe an improvement in overall retention prediction. We can observe a maximum marginal error of 0.51 for all the categories, which depicts around a 50% reduction in error when compared with our mixed model that performs the best in the individual factor analysis.

5 DISCUSSION

On data validity: The Carat application used as source of energy measurements records samples whenever the battery level changes, and may not be able to record data when the phone is in sleep mode, depending on the operating system version. Therefore, the data we see here is biased towards active use, and the resulting battery life values represent the remaining time for actively using the device with a given application running 100% of the time. In the dataset, the most common e (around 0.005) represents an active battery life of 5 hours. To mitigate these biases, we ensure selecting the location and apps with the most samples to foster better characterization of performance factors. Similar considerations apply to the NetRadar dataset used as source of latency data, which is predominantly collecting data whenever users explicitly request network performance assessment or periodically at user configurable intervals (between 1 and 120 minutes).

Data Quantity: Our validation of the retention prediction model suggests that number of training samples is critical for ensuring high quality predictions. In the case of Finland, data from several hundreds of users was obtained while for US only few tens of users were retained after data fusion. Our data was collected from two mobile applications that have been in long-term usage worldwide, suggesting that crowdsensing is indeed essential for capturing sufficient quantity of measurements. However, our results also highlight the difficulties when *multiple* crowdsensing datasets need to be combined in that their intersection might be small, limiting the power of statistical analyses carried on it.

Fusion of Large-Scale Passive Data: We combined passive measurements from NetRadar and Carat datasets in our analysis. While we ensured that statistically the dataset combination is representative by analyzing and estimating similarity metrics of each dataset individually, we experienced a high reduction of available samples in the fused dataset, mainly due to limited coverage of USA in the NetRadar dataset. However, data fusion is necessary to ensure the quality of contexts that we study. For example, the location, time, operators and communication technologies, etc, must be matched between the records of the two datasets. In other words, there is a trade-off between data data size and data quality. In addition, the individual nature of each dataset (NetRadar - infrastructure, Carat - App usage) also acted as a filter in the combination process, as extra manipulation was required to match attributes in both datasets, e.g., reverse geocoding in the GPS of NetRadar to match the timezones of Carat data records. We were able to model the combined relation that energy and latency have on retention by merging the two datasets. Our methodology also provided insights about the relationship between performance factors that was initially hidden, but revealed when the different sources were combined, similar to recent observations [13] . Specifically, we observe that when latency starts affecting retention, large variations in energy efficiency are possible before retention is affected further. However,

when battery life issues cause lower retention, latency can vary less before retention degrades further.

Energy efficiency models can influence retention: Extending battery life for smartphones is a primary research topic in academy and industry. Mobile devices are equipped with awareness mechanisms that monitor energy consumption based on applications usage and resources utilization. Smartphones then can decide based on this information whether to stop, outsource, or moderate the execution of tasks to save energy. While these mechanisms indeed induce gains in energy as the computation of tasks are reduced, they can foster a collateral damage in the perception that users have towards apps. For instance, iOS devices implement a low power mode mechanism that reduces computation of applications in the background to save energy [43] . This suggests that app performance is reduced and augmented dynamically based on application usage. This can potentially affect retention as the responsiveness of applications is degraded. By using our model in conjunction with energy efficiency models, it is possible to equip smartphones with a smarter mechanism that can save energy without degrading performance to an extent in which it is not tolerable to users anymore. As shown in Sec. 3.5, both the overall effect and existence of critical points are robust against effects of these mechanisms.

Influence of performance depends on usage patterns: Application usage patterns can be very different. For example, Dropbox is a productivity application which mostly runs on the background synchronizing photos. When the user interacts with it, they do so to find or share a file, using it infrequently and for a short period of time, which results in smaller influence of performance degradation. On the other hand, Facebook and Twitter apps provide a continuous feed of updates enabling users to spend hours reading, watching, and interacting with content. Not only does this presenting a larger window of opportunity for performance issues to manifest, but this highlights how different usage patterns are likely to influence the importance of different performance factors.

6 RELATED WORK

Mobile App Quality: Previous research on mobile app quality has focused on exploring user perception of mobile apps. Common techniques include usability studies [42], contextual inquiries [19], sensor data logging [33], interviews [27], and text mining on user reviews [23]. These studies generally focus on the user's perception instead of factors that affect it. Ickin et al. [27] list bugs, performance issues, and poor match with user needs as factors that influence quality perceptions while Chen et al. [12] show that app ratings are key driver for app downloads. While these factors affect app perceptions, studies do not explain how these perceptions translate into changes in behaviour. Our research addresses this gap with existing studies, focusing specifically on the effect of app performance.

Mobile App Performance: There has also been research looking at modeling application performance through the steps involved by the user's task [40] and the response time perceived by the user. Most relevant aspects causing bottlenecks in app performance have been shown to be network communication and processing costs. There have been research efforts to study network performance metrics and relate them with user satisfaction [1, 24]. The general idea is to capture features, such as bitrate, jitter and delay metrics, and to use machine learning to predict user response times [5, 8, 31]. Approaches for dynamic resource augmentation have been proposed to alleviate bottlenecks, relying solely on the device's resources [45] or remote infrastructure [21]. While performance has been modeled and improved, the level at which it starts to influence user perceptions has not been quantified previously.

Effect of Energy: Human interface studies have shown that 80% of mobile users will take steps to improve their battery life [39]. Past work have termed unnecessarily high energy consumption in applications as *energy bugs* [34] and identified their possible causes, such as the environment or settings of the smartphone [37] and programming problems [35]. Regardless of the cause, an app that reduces battery life may end up getting uninstalled by users [3], and possibly replaced by a different app. Many applications try to improve energy consumption by controlling processes on the device, or helping users identify energy hungry applications [32] and raising the level of energy awareness among users [3].

Effect of Network Quality: Network quality has been studied mainly through the influence of latency on user experience in desktop contexts and within specific application categories, e.g. online gaming [11, 49], education and video streaming [29, 50]. Studies on the former have shown that latency reduces session times, and that users actively seek countermeasures to reduce latency. In education, latency has been a barrier for real-time interaction and collaboration, e.g., in Second Life. These findings, however, do not directly translate to mobile apps, since network quality can change abruptly depending on the technology (WiFi, 3G, LTE) and traffic conditions. Moreover, network quality also influences battery life, raising the impact of network quality on users.

7 SUMMARY AND CONCLUSION

The present paper contributed by quantifying the influence of two performance factors, latency and energy, on app retention. We find poor performance to increase likelihood of app abandonment. However, the point at which the effect becomes significant depends on what the user is accustomed to, with app category, device characteristics and network characteristics having an influence. For example, Finland has lower expected latency than USA thanks to faster network infrastructure, and consequently user expectations differ between the two countries. Conversely, we find that improving app performance does not have any positive influence on retention as long as performance is within reasonable performance standards. Our results also indicate that latency and energy have a combined effect on app retention, but in most cases the effect of latency is perceived before energy. Lastly, we built a model that estimates retention based on the expected performance of an application. Performance validation considering cross-country performance demonstrated good performance across all application categories. However, this was moderated by application categories with those categories with limited overlap suffering in performance.

BotCamp: Bot-driven Interactions in Social Campaigns

Noor Abu-El-Rub

mueen@unm.edu

ABSTRACT

Bots (i.e. automated accounts) involve in social campaigns typically for two obvious reasons: to inorganically sway public opinion and to build social capital exploiting the organic popularity of social campaigns. In the process, bots interact with each other and engage in human activities (e.g. likes, retweets, and following).

In this work, we detect a large number of bots interested in politics. We perform multi-aspect (i.e. temporal, textual, and topographical) clustering of bots, and ensemble the clusters to identify campaigns of bots. We observe similarity among the bots in a campaign in various aspects such as temporal correlation, sentimental alignment, and topical grouping. However, we also discover bots compete in gaining attention from humans and occasionally engage in arguments. We classify such bot interactions in two primary groups: agreeing (i.e. positive) and disagreeing (i.e. negative) interactions and develop an automatic interaction classifier to discover novel interactions among bots participating in social campaigns.

CCS CONCEPTS

• **Information systems → Online advertising**; **Web mining**; *Clustering*; Social networking sites.

1 INTRODUCTION

Social networking sites bring people closer to each other and facilitate fast and convenient information flow. However, modern social media sites suffer from user accounts that work towards fast and automated building of social capital and exploiting the social influence to sway public opinion. Such user accounts (commonly named as bots) perform scheduled posting [26], near-automated registrations [27], and chronological deletions [11] among many other unsocial and non-human behavior.

To multiply the effect, instead of creating super smart bots, botmasters employ a large number of naive bot accounts to attain their objectives. Not surprisingly, humans tend to believe repeatedly encountered information from diverse sources [22]. Thus, a swarm of bots can potentially run successful advertising campaigns to promote products, election campaigns to win races, and organizational campaigns to recruit for ideological groups. To understand the fullest potential of a swarm of bots, in this paper, we perform an empirical study on bot activities in social campaigns and develop a technique to detect and classify bot-driven interactions in social campaigns. Quantifying bot-driven interactions in social campaigns can be useful for political parties, advertising agencies, charitable organizations among many others. Early detection and characterization of bot participation in campaigns will help campaigns flourish organically.

Figure 1: An example of bot interactions. Politically motivated bots are discussing trend manipulation.

An example of bot behavior in Twitter at the time of U.S. Presidential Election in 2016 is given in Figure 1. The user account `@JaredWyand` was an active supporter of Trump campaign. The account has been detected by both DeBot [9] and Botometer [12] systems due to its high frequency of tweets and content similarity. The account is currently suspended by Twitter. The tweet shown here has been retweeted 1.2K times. The two other users copied the tweet shortly after that [6]. These users are also detected as bots by DeBot [1] *and* Botometer[2], however, they are not suspended by Twitter at the time of writing. The content of the tweets shows that bot accounts are promoting a specific topic in Twitter's ranking system by frequently tagging relevant hashtags. The content shows that bot accounts are tracking progress of competing political campaign.

Note that every bot account has a human owner who can post in natural language in between scheduled posts.

The example demonstrates that bot accounts collaborate towards an objective i.e. making a topic trending. It also demonstrates that bots exhibit negative sentiments towards competing campaigns.

In this work, we develop a system to detect bot-driven interaction in campaigns categorized by general topics. For example, we have detected five major campaigns interacting under the "U.S. Election 2016 topic". Three of the bot-driven campaigns are taking sides of the candidates. The objective of the two of the remaining bot-driven campaigns is to gain human attention by adopting popular topics such as U.S. Election. Our system, named **BotCamp**, continuously collects bots for a given topic and detects bots using the DeBot system [9]. BotCamp identifies bots that are posting similar content on the campaign topic, and accumulates such bots over a long time to create graph structures on various aspects such as retweets, mentions, shared media and hashtags. We develop a heuristic cluster ensembling approach to combine communities detected from these graphs, which leads to discovering bot-driven interactions.

In this work, we have collected bot activities related to social campaigns in U.S. election. We analyze the campaigns to understand their information flow and status after campaigns are over. All data and code are made public [2].

The rest of the paper contains a discussion section in related work and background (2), an overview section describing the framework (3), an experimental section showing ensembling and interaction classifier evaluation (4), and the last section concludes the work (5).

Disclaimer: We do not address the question, "who" create and operate bot accounts. We define bots as the accounts that show signs of automation. We collect empirical evidence of "how" bots are involved in social campaigns and reason about "why" bots are involved. To the best of our knowledge, this work is one of the very first to generalize bot interactions on social media.

2 RELATED WORK AND BACKGROUND

2.1 Related Work

Our work combines two independent streams of research on social media: campaign detection and bot detection. Campaign detection works mostly focus on finding campaigns based on *one* specific aspect of messaging, such as message similarity [19][18][23], URL bursts [20], retweet structure [17]. We combine several other messaging aspects such as mentions, hashtags, and media sharing. All of these works detect clusters/communities in some messaging graphs. Such communities may include both bots and humans, hence existing work cannot separate the bot-driven part of the campaign.

DARPA Bot Challenge suggests an estimated 15% of Twitter accounts are bots [25]. Existing bot detection techniques are either supervised [12][14] and unsupervised [9]. Since our goal is to identify campaign specific bots, we opt for an unsupervised technique, DeBot [9].

Bot activities related to campaigns have been studied previously that associated bot activities with political entities [16][3][24]. Our goal is to explore beyond politics to sports, entertainment, marketing, etc., at a much larger scale of thousands of bot accounts.

Bots have been categorized based on their roles as individual users, independent of campaigns they take part in [21]. In contrast, we categorize bots based on their type of interactions in social campaigns.

2.2 Social Campaigns

Definition of campaign has been diverse in the literature, mostly attributed as unethical and illegal cases of social campaign. For example, coordinated campaigns [19], spam campaigns [13], promoted campaigns [15], fraud campaigns [8], and incentivized campaigns [4, 5] are some of the characterizations of campaigns.

In general, we define a social campaign as a group of concepts aligned to an objective that a group of people want to achieve. For example, `#antivax` and `#autism` are concepts supported by people who want to abolish vaccination. Another example is a fund-raising campaign started by Peter Dunn (`@PeterThePlanner`) in Indiana to support homeless people immediately before a blizzard hit Indianapolis. $41K was raised organically from various organizations and individuals for `@WheelerMission`. Therefore, a social campaign should not be perceived as purely inorganic or organic. Instead, considering that both humans and bots are involved together, we propose to quantify the level of bot and human participation in social campaigns. Quantifying organic participation in campaigns can be useful for political parties, advertising agencies, charitable organizations among many others.

2.3 Bot Detection

Automated accounts, a.k.a *bots*, are tweeting/re-tweeting always. Bots are controlled by computer programs. There may exist automated accounts which are not harmful such as `@countforever`, but most bots pretend to be human, entice people to follow them, and/or share ideas. DeBot is a parameter-free unsupervised system [9], that constantly collects data from Twitter and detects bots based on their synchronicity at intervals of 180 minutes. Number of bots DeBot detects in an interval depends on the topic, time of day, bot presence and sampling rate. Note that, Twitter streaming API provides a 1% of sample. In a successful interval, DeBot detects few bot-clusters containing tens of bots.

DeBot is a near real-time system that exploits highly unusual activity correlation across users as an indicator of bot behavior. The authors show that even if millions of active users interact at a time instance, human users are not likely to have more than tens of synchronous postings at random [10]. Although we use DeBot as an integral part of the detection system, we can replace DeBot by any other topic-specific near real-time system.

3 BOT INTERACTIONS IN CAMPAIGNS

3.1 The Framework

Figure 2 shows the BotCamp framework. There are three components of the system: Keyword Generator, Campaign Detector and Interaction Detector. We describe each of the components below.

Keyword Generator: BotCamp continuously collects trending hashtags to maintain related keywords to a seed set of keywords. The motivation behind such a keyword generator is to adapt with

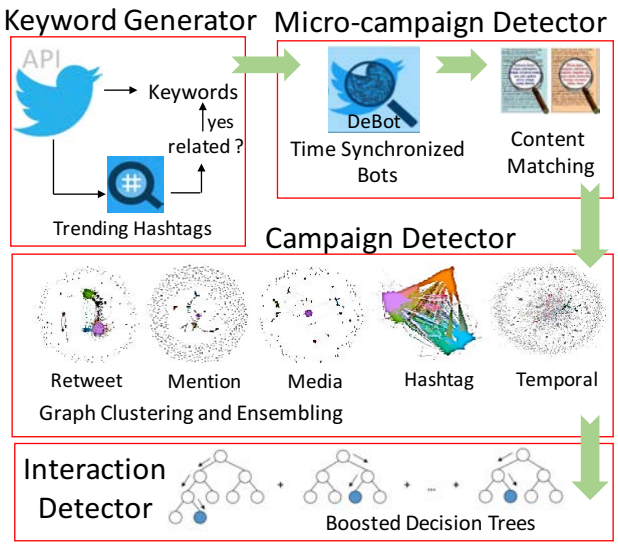

Figure 2: BotCamp framework

changing campaign dynamics. Trending keywords related to a campaign can be changed frequently. For example, to monitor the U.S. election, we started with a seed of twenty keywords including general topics such as `election`, `Trump`, `Clinton`, etc. After the U.S. election, the seed set grew to 231 keywords including `MAGA` ("short form of Make America Great Again"), `PodestaEmails`, and `CrookedHillary`. We collect the top 50 trends in twitter in every three-hour interval. If more than 50% of the tweets containing a trend also contains a seed keyword, we add the trend to seed set. In short campaigns, the seed set remains almost identical for the lack of dynamics in the campaigns. In long campaigns (i.e. election campaigns), keywords can be weighted based on their recency. The keywords can be both in support or in favor of parties involved in a campaign. We have labeled the sentiment associated with the keywords manually for the U.S. dataset.

Campaign Detector: We use the keywords in an instance of DeBot system that detects synchronized bots within an interval of three hours. We use the recommended threshold of 0.99 correlation to detect bots. DeBot outputs clusters of bots that we further analyze to detect clusters of bots that are both temporally synchronous and textually similar. BotCamp accumulates bots for a duration that is sufficient for the campaign to reach a stable state. We have accumulated at least one week of bots for all of our experiments. After bots are collected, we produce five graphs capturing various aspects of campaigns (e.g. retweet graph, hashtag graph, etc.). BotCamp detects communities in these graphs based on modularity optimization algorithm [7]. We develop a cluster ensembling technique that combines the communities from different aspects into consensus communities representing campaigns.

Interaction Detector: BotCamp consists of a classifier that categorizes the interaction between pairs of campaigns. The classifier is trained on a manually labeled set of interactions. We consider two types of interactions: *agreeing* and *disagreeing* interactions. We produce a set of 94 novel features that are indicative to various interaction types. The classifier is AdaBoost ensemble classifier, we use the classifier to categorize all possible pairs of interacting campaigns, and quantify bot participation in a campaign. Figure 3 shows examples of such interactions.

In the next two sections, we elaborate on the the campaign and interaction detectors.

3.2 Campaign Detector

Our campaign detection system is a two step process: Content matching and Graph clustering.

3.2.1 **Content Matching.** DeBot produces a set of unusually synchronous bots. Although a group of unlikely synchronous bots typically works towards a campaign, there can be spurious synchronous groups that are just naively periodic. In this step, we detect bots that are posting not only at close time instances, but also similar content. We consider each synchronous cluster detected by DeBot, and calculate the text and hashtag similarity among the bots in the cluster. *Text similarity* between two users u and v is defined by the Jaccard similarity of their set of unigrams. More precisely, if $G(u)$ is the set of unigrams extracted from the tweets made by u, excluding the stop words, the text similarity between u and v is:

$$SimText(u,v) = \frac{G(u) \cap G(v)}{G(u) \cup G(v)}$$

The similarity within a cluster C is

$$SimText(c) = \frac{\sum_{\forall u,v \in C} SimText(u,v)}{|C| * (|C|-1)/2}$$

Hashtag similarity between two users u and v is defined by the Jaccard similarity of their set of hashtags. More precisely, if $H(u)$ is the set of unigrams extracted from the hashtags made by u, the hashtags similarity between u and v is:

$$SimHashtag(u,v) = \frac{H(u) \cap H(v)}{H(u) \cup H(v)}$$

The hashtag similarity within a cluster C is

$$SimHashtag(c) = \frac{\sum_{\forall u,v \in C} SimHashtag(u,v)}{|C| * (|C|-1)/2}$$

We define a micro-campaign as a cluster of temporally synchronous bots, C, having either $SimText(C) \geq 0.5$ or $SimHashtags(C) \geq 0.5$. Note that such micro-campaigns are formed based on three hours of information.

3.2.2 **Graph Construction.** Once BotCamp accumulates micro-campaigns detected in three hour batches for over the duration of the campaign, the system creates five graphs namely: *retweet*, *media*, *hashtag*, *mention* and *temporal* graphs. The objective is to study the underlying interaction among micro-campaigns on various aspects over the duration of the campaign. Since the graphs are based on three hour long captures, the graphs are crude approximations of the graphs that we could produce if we had all data available. We describe each of these graphs below.

Retweet Graph

Retweets usually mean endorsement. Hence, we create a undirected retweet graph where nodes are bots, and we add an edge between two bots when they retweet from each other at least once, encoding

Figure 3: (left) Agreement interaction among bots. (middle and right) Disagreement interactions.

their mutual endorsements. In contrast, we can create a directed retweet graph by adding edges from the retweeting node to the original author node.

Mention Graph

In public conversations, bots mention (i.e. adding @ before an account name) other accounts in tweets. Mentions are typically used to draw attention of the person being mentioned. Thus, mentions are useful to express agreement, disagreement, endorsement, promotion, etc. We create a mention graph by adding an edge between two bots if they mentioned each other.

Media Graph

Bots in the same campaign proliferate the same information. Memes, photos, and videos are typically more expensive to create compared to tweets, however, such media are more attractive. Determined campaigns spend resources to create media and employ automated accounts to share the media. We create the media graph on bots by connecting two bots that share the exact same URL media.

Hashtag Graph

Hashtag is a powerful way to organize content for better searching. Information seekers often use hashtags to learn discussion items about a topic. Competing campaigns fight for strong position on common discussion topics (e.g. `#Oscars`). Campaigns also want to make hashtags trending (See Figure 1). Thus, tagging the same hashtag may mean either agreement or disagreement; at weaker level than mentions. If two bots have more than 50% of their hashtags common (i.e. $SimHashtags(u, v) = \frac{H(u) \cap H(v)}{H(u) \cup H(v)} \geq 0.5$), we add an edge between them to create the hashtag graph.

Temporal Correlation Graph

Synchronous bot activities indicate that bots using the same scheduler (e.g. a random posting interval generator or a human leader). We add an edge between two bots if they have been correlated at least once in their campaign lifetime for three hours interval regardless of their content similarity. Since we are using Debot we know that all bots are temporally correlated at least once with other bots, however, this graph exposes further correlations that could happen along the campaign life duration.

3.2.3 **Graph Clustering and Ensembling.** We consider building larger campaigns from the micro-campaigns by clustering the individual graphs mentioned in the previous section and ensembling the clusters across various aspects.

To cluster the graphs, we use a state-of-the-art technique called Louvain Modularity to cluster bots [7]. The algorithm uses greedy modularity optimization method and has linear complexity, thus it run fast on large dataset. We run the algorithm on the five graphs respectively. For each graph, we produce clusters of bots, therefore, each bot will belong to five clusters of various aspects.

Ensembling clusters from the five graphs enable detection of interesting patterns that independent aspect alone cannot reveal. We propose an ensembling method to detect campaign. First, we define a dissimilarity matrix A between bots participating in a campaign, where we compute the pairwise distance between two bots as:

$$A_{i,j} = 1 - \frac{\|Community(i) \cap Community(j)\|}{\|Community(i))\|}$$

Where $Community(i)$ refers to the set of communities that user i belongs to. The resulting distance matrix A contains normalized values range between 0 to 1. Where 0 indicates that the two bots appeared in the same cluster in all graphs, and 1 means the two bots did not appear in any common cluster. Then, we use average linkage hierarchical clustering to cluster bots and choose a restrictive threshold to stop unnecessary cluster merging. The merging starts with the most similar bots and stop when threshold is *0.8*. The selected threshold is chosen because it ensemble bots in one community if all bots share one common community on average with all other bots within the campaign. For verification, we conducted a small experiment on a sample of labeled bots in the U.S. Election, where labels are either Trump or Clinton supporter, we used different threshold and reported the Normalized Mutual Information (NMI) with the labeled data. the largest NMI was reported at 0.8.

3.3 Interaction Detector

Once we find a set of campaigns, we are interested to study the interactions among them. The simplest starting point is to consider pair-wise interactions. We consider developing a machine learned

classifier to automatically classify interactions in agreeing and disagreeing categories.

We label interactions between a pair of campaigns by manually checking the tweets, replies and retweets where bots from both campaigns participated. Such interactions can be largely categorized in two classes: agreeing and disagreeing. The example in the Introduction can be treated as a disagreeing interaction between the Trump and Clinton supporting bots. One may consider creating a full scale of classes between -3 and 3, 0 being the neutral class, instead of a two-class problem. However, the cost associated with labeling hundreds of pairs of campaigns is significant. In contrast, any neutral interaction can also be thought of as weak agreement, and thus, a two-class formulation is chosen. We manually labeled 80 campaign interactions where 57.5% are disagreement interaction and 42.5% are agreement.

3.3.1 **Feature Generation and Selection.** We start with a set of 94 features. The features are from four categories: time-based, sentiment-based, user-based features and network-based features. We describe a subset of features from each category below.

(1) *Time-based Features:* Temporal features help revealing bots that are collaboratively working toward the same objective or operated by the same software. Features such as the number of temporally correlated bots can be useful to understand the relation between a pair of campaign. Similarly, average interval time between mentions and number of bots involved in conversational interaction can indicate the interaction type. Usually, conversations with small intervals between mentions can be an indication for argument and disagreement.
(2) *Sentiment-based Features:* While retweet interaction almost always indicates agreement, mention interaction is controversial in nature. Bots and cyborgs could engage in arguments to support or attack a certain topic. To understand the nature of these conversations, we investigate entities sentiment within each conversation using IBM Watson Natural Language Understanding API [1]. For each conversation, we create various features describing the number of sentiment disagreement, difference of average sentiment over all entities to understand bots opinion polarity towards topics.
(3) *Content-based Features:* Usually, campaigns that share common objective tend to have more agreement than disagreement towards specific topics, and vice versa. We create features that characterize the relationship between two interacting campaigns. Examples include number of common topics, hashtags and media between two campaigns.
(4) *Network-based Features:* In addition to these three categories, we summarize bots and campaign connectivity using features that describe network topology such as ratio of friends to followers for a user.

Although indirect interactions are possible, we consider only direct interactions in the forms of retweets and mentions between campaigns. We obtain 94 features from four categories. We perform feature selection to identify the best features based on their importance weights in a decision tree model using Gini importance. After feature selection, the set is reduced to 15 features. Most informative features are content-based, temporal-based and sentiment-based features. The complete list of features is available in the supporting webpage [2].

3.3.2 **Training the Classifier.** We employ an AdaBoost model trained on decision tree classifier (CART) with ten weak learners. Information Gain is used to measure the quality of splits, then predictions from different learners are combined using weighted majority vote to produce the final prediction. Our choice for Adaboost is a result of lack of labeled data. Quantifying the sentiment of an interaction needs significant effort because of short length of tweets (The character limit for tweets is 280) and many alternative usages (emoji, abbreviation, etc.). Boosting the decision tree helps tackle these challenges.

4 EXPERIMENTAL EVALUATION

4.1 BotCamp by Numbers

We describe the BotCamp framework in numbers for the U.S. Election campaigns. First, we start with 20 seed keywords, the keyword generator component expands the set to 231 keywords in 60 days. Using the campaign detector, we collect a set of 75 million tweets from 6 million users talking about the election. The number of bots detected is 120K. We exclude clusters that are not matching in content and identify 29K bots from different micro-campaigns. We construct five graphs: retweet (7162 bots with 30811 edges), mention (1137 bots with 785 edges), hashtags (4122 bots with 731687 edges), media (954 bots with 10385 edges) and temporal (29840 with 73623). Graph clustering and ensembling are performed to obtain clusters of 29K bots and ensemble them into 231 campaigns. From the interaction classifier, we identify 87 disagreement interactions and 2700 agreement interactions between bot campaigns.

The above set of numbers are reproducible using the dataset provided in our supporting webpage [2]. However, U.S. Election 2016 has already happened, which limits comparison to alternative methods. To facilitate experimental comparison, we made our code public in the supporting webpage, it only requires a set of keywords to run for days to weeks, and produce interacting campaigns.

4.2 Evaluation of Interaction Classifier

We evaluate the boosted decision tree classifier using a 10-fold cross-validation technique. The average and standard deviation of classification performance is described in the Table 2. The results strongly suggest that the feature set can capture the manually labeled training data. The low standard deviation suggests consistency across random samples.

We consider applying the classifier to the unlabeled pairs of campaigns that have some form of interactions (i.e. retweet, mentions, etc.) between them. The results are shown in the Table 3

We have identified 87 disagreeing pairs of campaigns during U.S. election that include disagreement over debate results, email controversy, etc. The result suggests that while some campaign domains are non-competitive in nature, others are controversial leading to disagreement interactions.

4.3 Example Campaigns

This project has identified several small to large campaigns with bot participation in Twitter. Are they meaningful campaigns? - is

Table 1: Example campaigns in the U.S. Election. The bot accounts may be suspended currently.

Campaign	Bots Examples	Number of Bots
Trump Supporters	RWB4Trump, usfortrump Vegans4Trump, TXChiks4Trump MyVoteIs4Trump, Hyperslw4Trump	480
Clinton Supporters	Hillary2016MN IL4Hillary, voteforourlives Liberalibrarian, Hope012015	304
Sanders Supporters	1Birdie4Sanders BernieEvents, BernItUpTV i_AM_theChange, drJimWas4Bernie	100

Table 2: Model Performance

	Accuracy	Precision	Recall
Average	87.5%	98%	83.6%
Variance	0.025	0.003	0.049

Table 3: Interaction Summary

Number of Interactions	Interactions Agreement	Interactions Disagreement
2,790	6.88%	3.11%

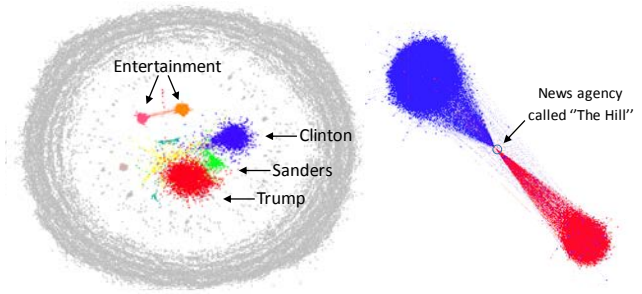

Figure 4: (left) Detected campaigns are shown on an undirected retweet graph (red for Trump supporters, blue for Clinton supporters, green for Sanders supporters). (right) Campaigns found by considering a directed retweet graph. Node in the middle is a news agency called The Hill. Colors indicate strong sentiment polarity towards different candidates based on hashtags.

the natural follow up question. We have investigated the campaigns manually to identify their objectives. Tagging all accounts in all campaigns is labor intensive. We take a 10% random sample of bot accounts to identify the objective, by navigating through their profile and rendering the last 15 tweets. In this section, we first show examples of a few campaigns (see Table 1). We name the campaigns based on the objectives we identified.

(1) **Trump Supporters**: In this campaign, all bots supported candidate Trump in U.S. presidential election in 2016. Their names, profile pictures and tweets show that they mostly care about politics. The bot accounts show strong retweet interactions among them.
(2) **Clinton Supporters**: All bots in this campaign are supporting Clinton. All their tweets are mostly political tweets. Number of Clinton supporting bots is less than that of Trump supporting bots.
(3) **Sanders Supporters**: All bots in this campaign supported candidate Sanders in the U.S. election 2016.

To provide a comprehensive picture, we show all of the campaigns detected by BotCamp in U.S. election dataset on an undirected retweet graph in the Figure 4. In addition to the supporters of three prominent candidates, several other small campaigns exist. The two loosely connected campaigns that we labeled as *Entertainment* campaigns are consisted of bots interested in variety of topics including politics, but mostly celebrity news. We explain the weak communication between the campaigns as an artifact of partially complete dataset. Note that Twitter API provides 1% of tweets.

The Figure 4(left) shows that politically motivated bots rarely retweet mutually across parties. This is not surprising, however, the directed retweet graph in the Figure 4(right) shows that the campaigns retweet from a common news source named *The Hill*.

5 CONCLUSION

Online social media is tremendously important for the future of democratic governance. Automated activities on social media create opportunities for manipulation, misinformation and distrust. This paper demonstrates that social campaigns can be corrupted by inorganic interactions among bots and develops a technique to classify inorganic interactions among and within campaigns. We show empirical evidence of various interactions among campaigns. However, this work is merely one step towards better monitored social media, significant effort must be made to protect human users from inorganic interruptions.

ABSTRACT

Signal strength maps are of great importance to cellular providers for network planning and operation, however they are expensive to obtain and possibly limited or inaccurate in some locations. In this paper, we develop a prediction framework based on random forests to improve signal strength maps from limited measurements. First, we propose a random forests (RFs)-based predictor, with a rich set of features including location as well as time, cell ID, device hardware and other features. We show that our RFs-based predictor can significantly improve the tradeoff between prediction error and number of measurements needed compared to state-of-the-art data-driven predictors, *i.e.,* requiring 80% less measurements for the same prediction accuracy, or reduces the relative error by 17% for the same number of measurements. Second, we leverage two types of real-world LTE RSRP datasets to evaluate into the performance of different prediction methods: (i) a small but dense Campus dataset, collected on a university campus and (ii) several large but sparser NYC and LA datasets, provided by a mobile data analytics company.

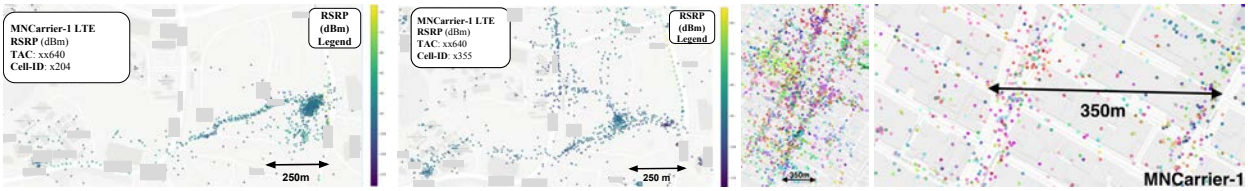
1 INTRODUCTION

Cellular providers rely on key performance indicators (*a.k.a.* KPIs) to understand the performance and coverage of their network, as well as that of their competitors. KPIs usually include wireless channel measurements (the most important of which for LTE is arguably the reference signal received power, *a.k.a.* RSRP) as well as other performance metrics [17] (*e.g.,* throughput, delay, frequency band, location, time) associated with the measurement. Signal maps consist of a large number of measurements of KPIs and are of crucial importance to cellular operators, for network management, maintenance, upgrades, operations and troubleshooting [19].



Although cellular providers can collect measurements on the network edge themselves (*e.g.,* via wardriving [31]), they increasingly choose to outsource the data collection to third parties for a variety of reasons, including: cost, liability related to privacy concerns of collecting data on end-user devices, and lack of access to competitor networks. Mobile analytics companies (*e.g.,* OpenSignal [22], RootMetrics [28], Tutela [30] *etc.*) crowdsource measurements directly from end-user devices, via standalone mobile apps [22], or measurement SDKs [30] integrated into partnering apps. Thus large scale signal maps collection is achieved, but the measurements can be sparse in space (depending on end-user location) and time (measurements are collected infrequently so as to not drain user resources, such as battery or cellular data). Either way, signal strength maps are expensive for both carriers (paying millions dollars to third parties) and crowdsourcing companies (most of which use cloud services, thus collecting more measurements increases their operational cost). Moreover, trends, such as (i) 5G dense deployment of small cells and (ii) smart city and IoT deployments, will only increase the need for accurate performance measurements [4, 9, 14, 16], while data may be sparse, unavailable, or expensive to obtain.

Our goal in this paper is to improve the tradeoff between cost (number of measurements) and quality (*i.e.,* coverage and accuracy) of signal maps via signal strength prediction from limited measurements. In general, there are two approaches in RSRP prediction: propagation models and data-driven approaches. Our approach falls in the second category and we employ a powerful machine learning framework that naturally incorporates multiple features. More specifically, we make the following contributions.

1. RFs RSRP prediction framework. We develop a powerful machine learning framework based on random-forests (RFs), considering a rich set of features including, but not limited to, location, time, cell ID, device hardware, distance from the tower, frequency band, and outdoors/indoors location of the receiver, which all of them affect the wireless properties. To the best of our knowledge, this is the first time that location, time, device and network information are considered jointly for the problem of signal strength prediction. We assess the feature importance and we find cell ID, location, time and device type to be the most important. Moreover, this is the first time that RFs have been applied to the signal maps estimation problem. Prior work on data-driven prediction for signal maps was primarily based on geospatial interpolation

techniques [8, 20, 24], which do not naturally extend beyond location features. We show that our RFs-based predictors can significantly improve the tradeoff between prediction error and number of measurements needed, compared to state-of-the-art data-driven predictors. They can achieve the lowest error of these baselines with 80% less measurements; or they can reduce the *RMSE* (root mean square error) by 17% for the same number of measurements.

2. Real-world datasets. Our study leverages two types of real-world datasets: (i) a small but dense Campus dataset collected on a university campus; and (ii) several large but sparser NYC and LA datasets, provided by a mobile data analytics company. Examples are depicted in Fig. 1 and information about the datasets is provided in Table 2. We use these datasets to evaluate and contrast different methods and gain insights into tuning our framework. For example, cell ID is an important feature in areas with high cell density, which is encountered in urban areas such as Manhattan Midtown; in contrast, cell ID should be used to train cell-specific RFs in suburban areas. Furthermore, time features are important in cells with less dispersed measurements, *i.e.,* concentrated in fewer locations. To the best of our knowledge, the NYC and LA datasets are the largest used to date for RSRP (or other signal strength) prediction, in terms of any metric (number of measurements, geographical scale, number of cells *etc.*). They contain 10.9 million LTE data points in areas of $300km^2$ and $1600km^2$ for NYC and LA respectively, instead of at most tens of km^2 and tens of thousands of measurements in [13] or smaller scale in [8, 15, 20, 24].

The structure of the rest of the paper is as follows. Section 2 presents our random forests-based prediction approach as well as baselines and prior work for comparisons. Section 3 presents the available signal map datasets. Section 4 provides evaluation results. Section 5 concludes the paper.

2 RSRP PREDICTION

2.1 Problem Statement

RSRP Definition. Although there are many KPIs related to received signal strength (RSS), including RSRP, RSRQ (reference signal received quality), RSSI (RSS Indicator), in this paper we focus specifically on reference signal received power (RSRP), defined by 3GPP in [12]. This choice is both because RSRP is widely used for various operations in LTE (*e.g.,* cell selection, handover decisions [10], network quality assessment *etc.*) and as a case study that can potentially be applied to prediction of other RSS metrics. Typically, RSRP is reported in dBm by UEs (user equipment) as the average power over several, narrow-band, control channels.

LTE Cells vs. Tracking Areas. A serving LTE cell is uniquely identified by the CGI (cell global identifier) which is the concatenation of the following identifiers: the MCC (mobile country code), MNC (mobile network code), TAC (tracking area code) and the cell ID. We abbreviate and refer to CGI as cell ID or *cID*. LTE also defines Tracking Areas (which we will refer to as LTE TA) by the concatenation of MCC, MNC and TAC, to describe a group of neighboring cells, under common LTE management for a specific area.

The RSRP Prediction Problem. Our goal is to predict the RSRP value at a given location, time, and potentially considering additional contextual information (Section 2.3), based on available measurements either in the same cell *cID* or in the same LTE TA. Table 1 summarizes our prediction methods and related work.

2.2 Model-Based Prediction: LDPL

As a representative baseline from the family of model-based predictors, we consider the Log Distance Path Loss (LDPL) propagation model [25], which is simple yet widely adopted in the literature (*e.g.,* [2], [8]). LDPL predicts the power (in dBm) at location $\vec{l}_j$ at distance $||\vec{l}_{\text{BS}} - \vec{l}_j||_2$ from the transmitting basestation (BS *a.k.a.* cell tower), as a log-normal random variable (*i.e.,* normal in dBm) [2]:

$$P_{cID}^{(t)}\left(\vec{l}_j\right) = P_0^{(t)} - 10n_j \log_{10}\left(||\vec{l}_{\text{BS}} - \vec{l}_j||_2/d_0\right) + w_j^{(t)}. \quad (1)$$

[1]We consider two cases regarding path loss exponent (PLE) n_j.

Homogeneous LDPL: Much of the literature assumes that the PLE n_j is the same across all locations. We can estimate it from Eq. (1) from the training data points.

Heterogeneous LDPL: Recent work (*e.g.,* [2, 8]) considers different PLE across locations. We considered several ways to partition the area into regions with different PLEs, and we present *knn* regression, where we estimate $\widehat{n_j}$ from its k nearest neighbors, weighted according to their Euclidean distance, which we refer to as "LDPL-knn".

2.3 Proposed Data-Driven Prediction: RFs

We apply Random Forests (RFs) regression. RFs are an ensemble of multiple decision trees [5], which provides a good trade-off between

[1] $P_0^{(t)}$ is the received power at reference distance d_0 (typically $1m$), calculated by the free-space path loss (Friis) transmission equation for the corresponding downlink frequency, gain and antenna directionality, and $\vec{l}_{\text{BS}}$ the location of the transmitting antenna. n_j, *i.e.,* PLE, has typical values between 2 and 6. The log-normal shadowing is modeled by $w_j^{(t)} \sim \mathcal{N}(0, \sigma_j^2(t))$ (in dB), with variance $\sigma_j^2(t)$ assumed independent across different locations. The cell, cID, affects several parameters in Eq. (1), including P_0, w_j, the locations of transmitting ($\vec{l}_{\text{BS}}$) and receiving ($\vec{l}_j$) antennas.

Table 1: Overview of RSRP Prediction Methodologies evaluated in this paper. Methods proposed in this paper are marked in bold. Methods in regular font are prior art, evaluated as baselines for comparison. Methods in light gray font are reviewed but not implemented in this paper.

(1) Model Based (Radio Frequency Propagation Model)		1(a) $LDPL$ Eq. (1) (Log Distance Path Loss)	1-(b) **LDPL – knn** (heterogeneous PLE)	1(c) WINNER I/II [6], COST 231 [27], Ray Tracing [32], Hata Model [29] *etc.*	Limitations: Requires environment's info *e.g.,* topology, street width, BSs height, 3D map.
Data Driven	(2) Geospatial Interpolation[8]	2(a) OK: Ordinary Kriging	2-(b) OKD:OK Detrending (hybrid of model and data)	2-(c) OKP: OK partitioning (spatial heterogeneous)	(4) Other Data-Driven: 4(a) Bayesian Compressive Sensing [15]. Limitation: no arbitrary features. 4(b) Deep Neural Nets [11] Limitation: Needs 3D Map/LiDAR Data.
	(3) Random Forests (RFs)	3(a) $RFs_{x,y}$ [26] Spatial Features: $\mathbf{x} = (l^x, l^y)$	**3-(b)** $RFs_{x,y,t}$ **Spatiotemporal:** $\mathbf{x} = (l^x, l^y, d, h)$	**3(c)** RFs_{all} **Full Feats: (and in some scenarios:** cid**)** $\mathbf{x} = (l^x, l^y, d, h, dev, \|\|\vec{l}_{BS} - \vec{l}_j\|\|_2, freq_{dl}, out)$	

bias and variance by exploiting the idea of bagging [5]. An RSRP value P can be modeled as follows given a set of features vector $\mathbf{x}$.

$$P|\mathbf{x} \sim \mathcal{N}(RFs_{\mu}(\mathbf{x}), \sigma^2_{\mathbf{x}}) \quad (2)$$

where $RFs_{\mu}(\mathbf{x})$, $RFs_{\sigma}(\mathbf{x})$ are the mean and standard deviation respectively of the RSRP predictor, $\sigma^2_{\mathbf{x}} = RFs_{\sigma}(\mathbf{x}) + \sigma^2_{RFs}$ and σ^2_{RFs} is the MSE of the predictor. The prediction $\widehat{P} = RFs_{\mu}(\mathbf{x})$ is the MLE (maximum likelihood estimation) value minimizing the MSE.

For each measurement j in our data, we consider the following full set of features, available via the Android API:

$$\mathbf{x}^{\mathbf{full}}_{\mathbf{j}} = (l^x_j, l^y_j, d, h, cID, dev, out, ||\vec{l}_{BS} - \vec{l}_j||_2, freq_{dl})$$

• *Location* $\vec{l}_j = (l^x_j, l^y_j)$. These are the spatial coordinates and the only ones considered by previous work on data-driven RSS prediction [8, 20] or in the context of localization [19, 26].

• *Time* features $\mathbf{t_j} = (d, h)$, where d denotes the weekday and h the hour of the day that the measurement was collected. Using h as a feature implies stationarity in hour-timescales, which is reasonable for signal strength statistics.

• *The cell ID, cID*. This is a natural feature since RSRP is defined per serving cell, *i.e.,* the CGI defined in Section 2.1.

• *Device hardware* type, dev. This refers to the device model (*e.g.,* Galaxy9 or iPhone X) and *not* to device identifiers. This feature captures (i) the different noise figures (NF), *i.e.,* electronic interference, and reception characteristics across different devices and (ii) the RSRP calculation may differ across devices and manufacturers [12].

• *The downlink carrier frequency*, $freq_{dl}$. Radio propagation and signal attenuation heavily depend on frequency calculated by *EARFCN* (E-UTRA Absolute Radio Frequency Channel Number).

• $out \in \{0, 1\}$ is an approximate indicator of outdoors or indoors location, inferred from Android's GPS velocity sensor.

• *Euclidean distance* $||\vec{l}_{BS} - \vec{l}_j||_2$, of the receiver at location $\vec{l}_j$ from the transmitting antenna BS (base station or cell tower).

Among the above features, the cell ID cID is particularly important, as it will be shown in Section 4.2.1. When there is a large number of measurements with the same cID, it is advantageous to train a separate RFs model per cID, using the remaining features:

$$\mathbf{x}^{\mathbf{-cID}}_{\mathbf{j}} = (l^x_j, l^y_j, d, h, dev, out, ||\vec{l}_{BS} - \vec{l}_j||_2, freq_{dl}).$$

When there are a few measurements per cID, then we can treat cID as one of the features in $\mathbf{x}^{\mathbf{full}}_{\mathbf{j}}$. We denote as $\text{RFs}_{x,y}$, $\text{RFs}_{x,y,t}$, RFs_{all} the RFs predictors with only spatial (l^x, l^y), spatial (l^x, l^y) and temporal (d, h), and all features, respectively. In Section 4, we assess feature importance in different datasets.

Why RFs for Data-Driven Prediction? First, RFs can naturally incorporate all aforementioned features, since geospatial interpolation [8, 24] does not naturally extend to arbitrary features. Second, RFs, partition the feature space with axis-parallel splits [21].

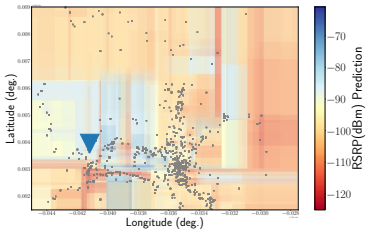

Figure 2: Example of decision boundaries chosen by $\text{RFs}_{x,y}$ for Campus cell x306. We can see that RFs can naturally identify spatially correlated measurements, *i.e.,* regions with similar wireless propagation characteristics.

An example of decision boundaries produced by $\text{RFs}_{x,y}$ is depicted in Fig. 2. One can see the splits according to the spatial coordinates (lat, lng) and the produced areas agree with our knowledge of the placement and direction of antennas on campus. Automatically identifying these regions with spatially (and temporal) correlated RSRP comes for free to RFs and is particularly important in RSRP prediction because wireless propagation has different properties across neighborhoods [26]. In contrast, prior art (OKP, [8]) requires additional preprocessing for addressing this spatial heterogeneity.

2.4 Baseline: Geospatial Interpolation

State-of-the-art approaches in data-driven RSS prediction [8, 13, 20, 24] have primarily relied on geospatial interpolation, which however is inherently limited to only spatial features (l^x, l^y). The best representative of this family of predictors is ordinary kriging (OK) [20] and its variants [8], which are used as baselines for comparison in this paper.

Ordinary Kriging (OK): It predicts RSS at the testing location $\vec{l}_j = (l^x_j, l^y_j)$ as a weighted average of the K nearest measurements in the training set: $P_j = \sum_{i=1}^{K} w_i P_i$. The weights w_i are computed by solving a system of linear equations that correlate the test with the training data via the semivariogram function $\gamma(h)$ [8].

Ordinary Kriging Partitioning (OKP) [8]: Voronoi-based partitioning is used to identify regions with the same PLE and apply a distinct OK model in each region. It is comparable to the heterogeneous LDPL, yet is impractical for city wide signal maps.

Ordinary Kriging Detrending (OKD) [8, 24]: OK assumes spatial stationarity, which does not hold for RSRP. OKD incorporates a version of LDPL in the prediction in order to address this issue [8]. This can be thought as a hybrid approach of geospatial and LDPL and serves as our baseline for comparison in this paper.

3 DATA SETS

Table 2 summarizes the two datasets used in this paper. The first is a campus dataset and the second consists of two city-wide datasets from NYC and LA. Fig. 1 depicts some examples and Table 3 summarizes representative LTA TAs examples used in our evaluation.

Table 2: Overview of Signal Maps Datasets used in this study.

Dataset	Period	Areas	Type of Measurements	Characteristics	Source
Campus	02/10/17 - 06/18/17	Univ. Campus Area $\approxeq 3km^2$	LTE KPIs: RSRP, [RSRQ]. Context: GPS Location, timestamp, dev, cid. Features: $\mathbf{x} = \left(l_j^x, l_j^y, d, h, dev, out, ||\vec{l}_{\text{BS}} - \vec{l}_j||_2\right)$	No. Cells = 25, No. Meas $\approxeq$ 180K Per Cell Density: 0.01 - 0.66 (Table 3) Overall Density: 0.06	Ourselves [3]
NYC & LA	09/01/17-11/30/17	NYC Metropolitan Area $\approxeq 300km^2$ / LA metropolitan Area $\approxeq 1600km^2$	LTE KPIs: RSRP, [RSRQ, CQI]. Context: GPS Location, timestamp, dev, cid. EARFCN. Features:$\mathbf{x} = \left(l_j^x, l_j^y, d, h, cid, dev, out, ||\vec{l}_{\text{BS}} - \vec{l}_j||_2, freq_{dl}\right)$	No. Meas NYC $\approxeq$ 4.2M, No. Cells NYC $\approxeq 88k$ Density NYC-all $\approxeq 0.014\ N/m^2$ / No. Meas LA $\approxeq$ 6.7M, No. Cells LA $\approxeq$ 111K Density LA-all $\approxeq 0.0042\ N/m^2$	Mobile Analytics Company

3.1 Campus dataset

Dataset Overview. We collected the first dataset on UC Irvine campus. This Campus dataset is relatively small: 180,000 data points, collected by seven different users, using 2 cellular providers. In terms of geographical area, it covers approximately $3km^2$, as the devices move between locations (*e.g.,* housing, office *etc.*) on campus. Some examples are depicted in Fig. 1(a)-(b). Although small, the cells in this dataset exhibit a range of characteristics (reported in Table 4) regarding the (i) number of measurements, (ii) mean and variance of RSRP and (iii) dispersion and density (*e.g.,* multiple measurements over time on the same or nearby locations).

Data Collection. We developed a user-space app [1, 3] that uses the Android APIs to obtain radio layer and other information needed for RSRP prediction. Although the design of the monitoring system itself is challenging, we defer to [3] due to space limitations. No personally identifiable information is collected.

3.2 NYC and LA datasets

Dataset Overview. The second type consists of much larger datasets: 10.9M measurements in total, covering approx. $300km^2$ and $1600km^2$ in the metropolitan areas of NYC and LA, respectively, for a period of 3 months (Sep'17 - Nov'17). Key characteristics are summarized in Table 2. An example of the NYC Midtown Manhattan neighborhood is depicted in Fig. 1(c)-(d). While these are large datasets, they are also relatively sparse in space and heterogeneous. For example, the density is now approx. 300 measurements per cell on average and up to the order of 20 thousands max. We only consider cells with more than 100 measurements. There is also sparsity in time: unlike the Campus dataset, there are no longer multiple measurements at different times for the same location.

Data Collection. This dataset was collected by a major mobile analytics crowdsourcing company and shared with us. They collect measurements from a large user base infrequently so as to not burden each end-users, which explains the smaller overall density of the dataset, as shown in Table 2. Each location data point is accompanied by rich network and contextual information, except for device or other personal identifiers.

3.3 Common Description of Datasets

Data Format. For the purposes of RSRP prediction, we use the same subset of information from all datasets, *i.e.,* RSRP values and the corresponding features defined in Section 2.1. We utilize GeoJSON format to represent and process our data, which offers several practical advantages.

Properties of Datasets. For each dataset, the following metrics describe characteristics that affect RSRP prediction.

• *Data Density:* Number of measurements per unit area (N/m^2).

Table 3: NYC and LA datasets**: LTE TAs Examples.**

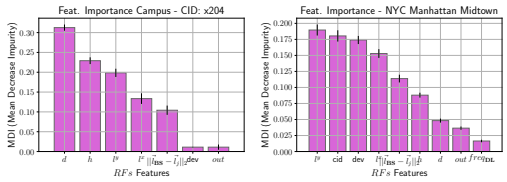
	NYC (MNC-1) Manhattan Midtown	NYC (MNC-1) E. Brooklyn	LA (MNC-2) Southern
No. Measurements	$\approxeq$ 63K	$\approxeq$ 104K	$\approxeq$ 20K
Area km^2	$1.8km^2$ (Fig. 1 (c-d))	44.8 km^2	220 km^2
Data Density N/m^2	$\approxeq 0.035$	$\approxeq 0.002$	$\approxeq 0.0001$
No. Cells $\|C\|$	429	721	353
Cell Density $\|C\|/km^2$	238.3	16.1	1.6

• *Cells Density:* Number of unique cells (*cid*s) per unit area, *i.e.,* $|C|/km^2$. The higher it is, the more *cID* helps as a feature.

• *Dispersion:* In order to capture how concentrated or dispersed are the measurements in an area, we use the Spatial Distance Deviation (*SDD*) metric [18], defined as the standard deviation of the distance of measurement points from the center.

OpenCellID. Both the LDPL and in the RFs predictors need the distance between the transmitting antenna and the receiver's location (where RSRP is measured or predicted), $||\vec{l}_{\text{BS}} - \vec{l}_j||_2$. To that end, we lookup the location of the BS, $\vec{l}_{\text{BS}}$, using the public APIs of a popular online crowdsourced database opencellid.org.

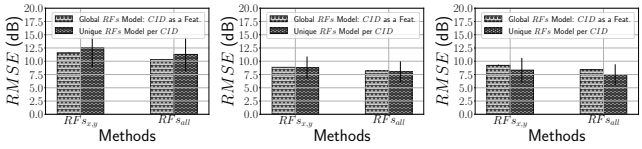
4 PERFORMANCE EVALUATION



4.1 Setup

4.1.1 RFs *Setup.* The most important hyper-parameters for RFs are the number of decision trees, *i.e.,* n_{trees}, and the maximum depth of each tree, *i.e.,* $\max_{depth}$. We used a grid search over the parameter values of the RFs estimator [23] in a small hold-out part of the data to select the best values. For the Campus dataset, we select $n_{trees} = 20$ and $\max_{depth} = 20$ via 5-Fold Cross-Validation (*CV*); larger $\max_{depth}$ values could overfit RFs. For the NYC and LA datasets, we select $n_{trees} = 1000$ and $\max_{depth} = 30$; more and deeper trees are needed for larger datasets. One important design choice is what granularity we choose to build our RFs models: per *cID* or per LTE TA (defined in Section 2.1).

•*Training per cID:* We can train a separate RFs model per cell using all features except *cID* ($\mathbf{x_j^{-cID}}$), since RSRP is measured per serving cell, but requires many measurements per cell. This is the case in Campus dataset but not in NYC and LA datasets.



•*Training per LTE TA:* Another option is to train one RFs model per LTE TA and use *cID* as one of the features in $\mathbf{x_j^{full}}$. This is particularly useful in the NYC dataset, where there are less measurements per cell unit area, insufficient to train a model per *cID*. In urban areas, there is very high cells density in a region and data points from different cells in the same LTE TA can be useful.

4.1.2 Baselines' Setup. For LDPL-knn: we select empirically $k = 100$ neighbors for the Campus dataset and $k = 10\%$ of the training data points in each cell for the NYC and LA datasets. For *Geospatial Predictors,* the number of neighbors was empirically set to $k = 10$; a larger k did not show significant improvement. An exponential fitting function of the semivariogram function $\gamma(h)$

(a) Cell x204 (b) Manhattan Midtown TA

Figure 3: For Campus dataset (a) : Feature Importance for cell x204 (RFs built per distinct cell). Cells' data are depicted in Fig. 1. For NYC dataset, (b) shows the MDI score for one LTE TA for MNC-1.

(a) MNC-1, NYC Manhattan Midtown (urban) (b) MNC-1, East Brooklyn (suburban) (c) MNC-2, Southern LA (suburban)

Figure 4: RMSE in NYC and LA datasets. This figure makes multiple comparisons: (1) urban vs suburban LTE TAs; (2) cID as feature vs. training a different RFs model per cID; (3) providers MNC-1 vs. MNC-2.

was selected [8]; the maximum lag (h) was set to 200m, as in [8], for the Campus and NYC environments, while it was set to 600m for the LA suburban environment. The empirical semivariogram $\widehat{\gamma(h)}$ was calculated per $10m$ [8].

4.1.3 Splitting Data into Training and Testing. We select randomly 70% of the data as the training set $\{\mathbf{X}_{train}, \mathbf{P}_{train}\}$ and 30% of the data as the testing set $\{\mathbf{X}_{test}, \mathbf{P}_{test}\}$ for the problem of predicting missing RSRP values. The results are averaged over $S = 5$ independent random splits. These default choices are used unless otherwise stated. An exception is Fig. 5, where we vary the size of training set and we show that our RFs-based predictors degrade slower than baselines with decreasing training size.

4.1.4 Evaluation Metrics. We evaluate the performance of the predictors in terms of absolute error (RMSE) and Absolute Relative Improvement (ARI) as well as feature importance in RFs.

Root Mean Square Error (RMSE): If $\widehat{P}$ is an estimator for P, then $RMSE(\widehat{P}) = \sqrt{MSE(\widehat{P})} = \sqrt{E((P-\widehat{P})^2)}$, in dB. We report $RMSE$ for each predictor at different levels of granularity, namely: (i) per cID (ii), per LTE TA (in NYC and LA), (iii) over all data (Campus).

Absolute Relative Improvement (ARI): This captures the improvement of each predictor over the variance in the data: $ARI = 1 - (1/|\mathrm{C}|)\sum_{i\in\mathrm{C}}(MSE_i/Var_i)$, where |C| is the number of the different cells in the dataset, and Var_i is cell i's variance.

Mean Decrease Impurity (MDI), a.k.a. Gini Importance: It captures how often a feature is used to perform splits in RFs. It is defined as the total decrease in node impurity, weighted by the probability of reaching that node (approx. by the proportion of samples reaching that node), averaged over all trees in the ensemble [23].

4.2 Results

4.2.1 Feature Importance.

a. Campus dataset*:* We train one RFs model per cID for the set of features $\mathbf{x} = (l_j^x, l_j^y, d, h, ||\vec{l}_{\mathrm{BS}} - \vec{l}_j||_2, out, dev)$. Results w.r.t. MDI are shown on Fig. 3. We observe that, in cells with high data density and low dispersion, the most important are the time features (d, h) w.r.t. to MDI. An example of such a cell is x204 (depicted in Fig. 1(a)), which has $SDD = 325$, density=0.66 points/m^2 and its MDI is shown in Fig. 3(a). Feature importance for dev and out are close to zero, which is expected because of the small number of devices in the Campus dataset. For more dispersed and less dense cells, such as cell x355 ($SDD = 573, 0.116N/m^2$, map in Fig. 1(b)), the location features (l_j^x, l_j^y) have higher MDI; results are omitted.

b. NYC and LA datasets*:* In this case, $freq_{dl}$ is available and the datasets contain thousands of cells. We start with a RFs model per LTE TA. As a representative example, we report the feature importance, in Fig. 3(b), for the LTE TA of a major mobile network carrier (MNCarrier-1) located in NYC Midtown Manhattan and already depicted in Fig. 1(c)-1(d). The most important features turn out to be the spatial features (l_j^x, l_j^y) as well as the cell cID and dev. This is because the data are sparser and the whole LTE TA is served by geographically adjacent or overlapping cells.

We also investigated whether we should train a separate RFs per cID, or cID should be used as one of the features in a single RFs. For a representative urban LTE TA (Manhattan Midtown), in Fig. 4(a) we calculate the $RMSE$ for two cases: (i) when cID is used as a feature in a single RFs per LTE TA and (ii) when a separate RFs model is produced per cell. Interestingly, the prediction is better when cID is utilized as a feature. Given the sparsity of the data and the high overlap of the cells, RFs benefit from the features of the additional measurements. Manhattan Midtown has a cells density of 238 per km^2 (see Table 3): the cell size does not exceed the size of a few blocks or sometimes there are multiple cells within a skyscraper. On the contrary, for the suburban LA dataset, where the cells are not so densely deployed, a unique RFs model per cell performs better than RFs per LTE TA, as shown in Fig. 4(c). In the Campus dataset (lower density than NYC), the RFs model per cID did better than using as a feature in a single RFs model for the entire LTE TA. Similar results and findings were observed for the rest of cells and TAs, but are omitted due to space constraints. In general, RFs trained per cID is usually a better option, but cID should be used as a feature in urban areas with high cells density.

Table 4: Campus dataset: Comparing Predictors per cell

	Cell Characteristics					$RMSE$ (dB)

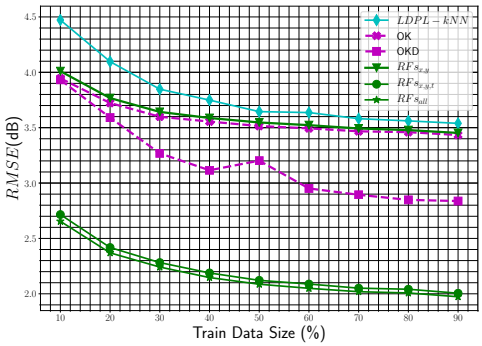
4.2.2 Comparing RSRP Predictors. We compare against baselines, both geospatial interpolation (OK and OKD) and model-driven (LDPL-knn and LDPL-hom).

a. Campus dataset*:* Table 4 reports the $RMSE$ for all predictors for each cell in the Campus dataset, for the default 70-30% split.



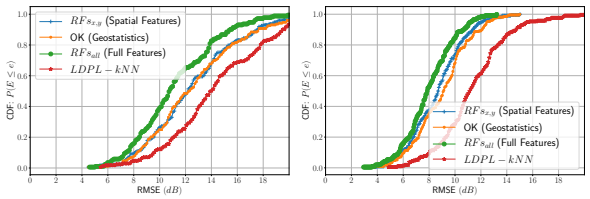


Figure 5: Campus dataset: *RMSE* **vs. Training Size. Our methodology (RFs with more than spatial features, *i.e.,* $RFs_{x,y,t}$, RFs_{all}) significantly improves the RMSE-cost tradeoff: it can reduce** *RMSE* **by 17% for the same number of measurements compared to state-of-the-art data-driven predictors(OKD);** ***or*** **it can achieve the lowest error possible by OKD (≃ 2.8dB) with 10% instead of 90% (and 80% reduction) of the measurements.**

Fig. 7 compares all methods, calculating *RMSE* over the entire Campus dataset, instead of per cell. We can see that our RFs-based predictors ($RFs_{x,y,t}$, RFs_{all}) outperform model (LDPL) and other data-driven (OK, OKD) predictors.

Fig. 5 shows the *RMSE* as a function of the training size (as % of all measurements in the dataset). First, the performance of OK and $RFs_{x,y}$ is almost identical, as it can be seen for *RMSE* over all measurements (Fig. 5 and Fig. 7) and *RMSE* per cell (Table 4). This result can be explained by the fact that both predictors are essentially a weighted average of their nearby measurements, although they achieve that in a different way: OK finds the weights by solving an optimization problem while $RFs_{x,y}$ uses multiple decision trees and data splits. Second and more importantly, considering additional features can significantly reduce the error. For the Campus dataset, when time features $\mathbf{t} = (d, h)$ are added, $RFs_{x,y,t}$ significantly outperforms OKD: it decreases *RMSE* from 0.7 up to 1.2 dB. Alternatively, in terms of training size, $RFs_{x,y,t}$ needs only 10% of the data for training, in order to achieve OKD's lowest error (≃ 2.8dB) with 90% of the measurement data for training. Our methodology achieves the lowest error of state-of-the-art geospatial predictors with 80% less measurements. The absolute relative improvement of $RFs_{x,y,t}$ compared to OKD is 17%, shown in Fig. 7(b).

b. NYC and LA datasets*:* Fig. 6 shows the error for two different LTE TAs, namely for NYC Manhattan Midtown (urban) and for southern LA (suburban), where RFs have been trained per *cID*. CDFs of the error per *cID* of the same LTE TA are plotted for different predictors. Again, OK performance is very close to $RFs_{x,y}$, because they both exploit spatial features. However, RFs_{all} with the rich set of features improves by approx. 2dB over the baselines for the 90th percentile, in both LTE TAs. Interestingly, the feature *dev* is important, which is expected since this data, has heterogeneous devices reporting RSRP.

There are multiple reasons why RFs_{all} outperform geospatial interpolation predictors. The mean and variance of RSRP depend on time and location and the complex propagation environment. RFs can easily capture these dimensions instead of modeling a priori every single aspect. For example, $RFs_{x,y,t}$ predicts a time-varying value for the measurements at the same location in Fig. 1(a), while $RFs_{x,y}$ or OK/OKD produce just a flat line over time. OK also

(a) NYC Manhattan Midtown (b) LA Southern Suburb

Figure 6: NYC and LA datasets**: CDFs for** *RMSE* **per** *cID* **for two different LTE TAs, for the same major MNCarrier-1.** RFs_{all} **offer 2dB gain over the baselines for the 90th percentile.**

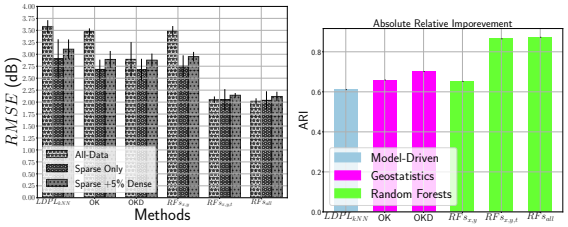

Figure 7: Comparison of all predictors over the entire Campus dataset**. Left (a)** $RMSE(dB)$ **under various scenarios, Right (b) ARI over all data points. Our Approaches ($RFs_{x,y,t}$, RFs_{all}) outperform prior art in all scenarios.**

relies on some assumptions (same mean over space, semivariogram depending only on the distance between two locations), which do not hold for RSRP. Even hybrid geospatial techniques (OKD) cannot naturally incorporate additional features (*e.g.,* time, device type, *etc.*). Finally, RFs significantly outperform propagation models, except for a few areas with limited number of measurements.

4.2.3 Location density and overfitting. In the Campus dataset, we observed that a significant fraction of the data comes from a few locations, *i.e.,* from grad students' home and work, which begs the question whether this leads to overfitting. We investigated this question and found that our RFs predictors neither get a performance boost nor overfit. To that end, we utilize HDBSCAN [7], a state-of-the-art clustering algorithm, to identify very dense (spatially) clusters of measurements (cluster size 5% of the cell's data). We refer to data from those locations as "dense"; we remove them and we refer to the remaining ones as "sparse-only" data. Fig. 7(a) reports the *RMSE* of different methods when training and testing is based on (i) all-data, (ii) sparse-only data and (iii) sparse-only data with a 5% randomly sampled from the dense data. It can be clearly seen that our $RFs_{x,y,t}$ and RFs_{all} have similar performance in all scenarios and consistently outperform baselines (similarly in cell-by-cell basis; results omitted). Please note that OK and LDPL-knn's errors slightly decrease for "sparse-only"; OK cannot handle repeated locations and LDPL-knn may overfit.

5 CONCLUSION

We developed a machine learning framework for cellular signal strength prediction, which is important for creating signal maps in a cost-efficient way, crucial for future 5G and IoT deployments. We used the powerful tool of random forests, which we adapted in this context by evaluating different features. The datasets under study are the largest used in this context and provide unique insight into city-wide signal map prediction. Future work includes a hybrid ML-propagation model to harvest the diversity of both worlds.

ABSTRACT

Social media provides the government with novel methods to improve regulation. One leading case has been the use of Yelp reviews to target food safety inspections. While previous research on data from Seattle finds that Yelp reviews can predict unhygienic establishments, we provide a more cautionary perspective. First, we show that prior results are sensitive to what we call "Extreme Imbalanced Sampling": *extreme* because the dataset was restricted from roughly 13k inspections to a sample of only 612 inspections with only extremely high or low inspection scores, and *imbalanced* by not accounting for class imbalance in the population. We show that extreme imbalanced sampling is responsible for claims about the power of Yelp information in the original classification setup. Second, a re-analysis that utilizes the full dataset of 13k inspections and models the full inspection score (regression instead of classification) shows that (a) Yelp information has lower predictive power than prior inspection history and (b) Yelp reviews do not significantly improve predictions, given existing information about restaurants and inspection history. Contrary to prior claims, Yelp reviews do not appear to aid regulatory targeting. Third, this case study highlights critical issues when using social media for predictive models in governance and corroborates recent calls for greater transparency and reproducibility in machine learning.

1 INTRODUCTION

Governments are increasingly exploring predictive approaches with large-scale datasets to improve regulation. Data mining approaches have witnessed great success across domains such as inferring wealth in a country using mobile phone records [5] or satellite images [31] or inferring migration stocks using both social media data like Facebook and survey data [53]. Social media datasets like Twitter have the potential to provide an additional signal of future, offline outcomes of interest as illustrated by predicting electoral outcomes [16], health outcomes [12], and many others [40].

Increasingly, government usage has expanded to leverage social media data for predictive governance [34]. Police departments have mined Facebook and Twitter for investigation and predictive policing [48]. Municipal service departments have used social media to forecast the need for municipal services, such as filling potholes [1]. Governments have used traffic complaints on Twitter to shape transportation planning [51]. One of the leading examples has been the case of food safety [14, 19, 23, 33, 44, 46, 47]. Health departments from major cities, including New York, Las Vegas, Boston, and Chicago, have, for instance, used Yelp and Twitter terms, such as "sick" and "vomit," to allocate enforcement and investigatory resources.

While governments have experimented with such novel data uses, researchers have begun to examine the reliability of such approaches. A prominent example is that of Google Flu Trends. Google Flu Trends was initially advertised as using search terms to forecast influenza epidemics, beating early detection of the Centers for Disease Control and Prevention (CDC) [18]. But researchers showed that the algorithm was prone to substantial overfitting [36]. As put in *Science*, big data "does not mean that one can ignore measurement and construct validity and reliability" [36].

Our article makes three contributions. First, we revisit the seminal case of food safety. Earlier work showed that the use of social media may import private biases into public enforcement [2, 11]. We show here instead that the leading case of social media data use for food safety [33] has substantial methodological shortcomings: (a) changing the prediction problem to predict only extremely hygienic and extremely unhygienic establishments and (b) failing to assess the impact of class imbalance in the population. We call this a case of "extreme imbalanced sampling." We show that a single, seemingly minor correction – drawing a random sample of hygienic establishments (as opposed to using the nonrandom order in the original dataset, which overrepresents the same establishments) – causes the originally reported results to disappear. This analysis follows other social media studies documenting classification results that are overoptimistic [9] or limited in their data sampling approaches [52].

Second, we conduct a comprehensive analysis, by using the full dataset of about 13k inspections, rather than the subset of approximately 612 inspections originally analyzed. We find that (a) Yelp reviews provide substantially less predictive power than inspection history already possessed by the health department, and (b) Yelp reviews do not significantly improve predictions, given existing information about restaurants and inspection history.

Third, we discuss some of the implications both for machine learning and government use of social media. Most importantly,

our paper points to emerging recognition of a replication crisis in machine learning [27, 49]. Methodological flubs can easily occur inadvertently with complex methods, and we highlight that the implications are severe when it comes to public policy. News outlets, including *NPR*, the *New York Times*, *Forbes*, and *Newsweek*, quickly touted the idea of food safety targeting based on social media. And private industry may have an incentive to promote use cases before thorough vetting. Yelp's CEO, for instance, proclaimed that Yelp could "beat gold standard healthcare measures" [50]. Our evidence shows that much more thought needs to be given for ethical and reliable use by government of social media [21].

Our article proceeds as follows. In Section 2, we describe the Seattle restaurant dataset that led to provocative claims that Yelp could "clean up the restaurant industry" [3]. In Section 3, we assess the original analysis that purported to show that Yelp reviews could be used to predict unhygienic establishments. We highlight how a single, minor modification – random rather than non-random sampling of the majority class – invalidates the claim that Yelp terms are more informative than inspection history. In Section 4, we conduct a more comprehensive analysis that (a) makes use of all of the data (13k as opposed to 612 inspections), (b) uses all of the information in inspection outcomes (regression vs. classification), and (c) uses word embeddings to exploit review terms [42]. In Section 5, we discuss the more general implications for replication in machine learning and government use of social media data.

2 THE SEATTLE RESTAURANT DATASET

The prediction problem considered throughout this work is to infer the inspection penalty status of a restaurant (either in terms of a restaurant's raw inspection score or classifying restaurants as unhygienic if above a certain score threshold [33]) given features created based on the restaurant, online Yelp reviews, or past inspection history. This prediction problem can be framed as either a classification problem if one sets a threshold for defining "unhygienic" restaurants or a regression problem if one aims to predict the actual prediction score. We will use the terms penalty score and inspection score interchangeably throughout this work.

Data: We utilize the Yelp and inspection dataset compiled in earlier work [33], which we summarize here. In Seattle, food safety inspectors conduct routine inspections one to two times a year per establishment, resulting in an inspection score based on health code violations. The data contain about 13k inspections covering 1,756 Seattle restaurants with 152k Yelp reviews from 2006 to 2013. Yelp reviews are collected for the preceding period of time between inspections (or six months earlier when no prior inspection existed). Review data is concatenated as a text string.[1]

Features: We evaluate three categories of features for predicting a restaurant's sanitation level: restaurant-fixed features (cuisine and location), inspection history features, and features derived from Yelp for the preceding inspection period (e.g., average rating, review text). We list these features in Table 1. Inspection history includes information derived from an establishment's past inspection record (e.g., average past inspection history or normalized metrics).[2] The principal question is whether Yelp reviews help predict sanitation.

Table 1: Features for prediction. Inspection history includes an establishment's previous penalty score and an average measure across previous inspections. Cuisine indicates type of food offered, and ZIP code denotes restaurant's location. Yelp features we consider include ratings, review counts, and then the review text itself using a TF-IDF or word embedding representation. The negative review count feature is referred to as non-positive review count in [33].

Feature Name	Feature Category
inspection history	Inspection
cuisine	Restaurant
zip code	Restaurant
avrg. rating	Yelp
negative review count	Yelp
review count	Yelp
review text	Yelp

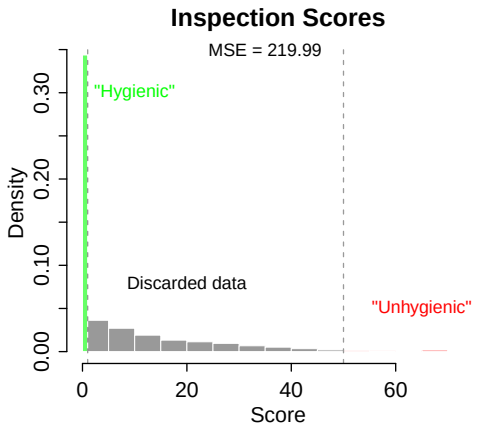

Figure 1: Distribution of inspection scores, with vertical lines indicating cutoffs for "unhygienic" restaurants (red) with scores above 50 and "hygienic" restaurants (green) with scores of 0. This figure shows how the prior analysis sampled from the extremes of the distribution.

Prior Analysis: Prior analysis of this data attempted to classify "hygienic" and "unhygienic" restaurants. First, all features were calculated on the full dataset of approximately 13k observations and outcomes were labeled as "unhygienic" if the inspection score was greater than 50.[3] Figure 1 displays the outcome distribution, showing highly skewed scores. Only 306 restaurants, 2.3% of the sample, are labeled as "unhygienic," resulting in an extremely imbalanced setting for classification. Second, because of this class imbalance, 306 "hygienic" restaurants with no violation history

[1] See https://www3.cs.stonybrook.edu/~junkang/hygiene/. We are not able to observe different reviews or reviewers. While there are other data quality issues, such as duplicated review texts, we do not address these issues here for comparability.

[2] While cuisine information is technically derived from Yelp data, we denote this as a restaurant category because this information is not derived from user-input. It is common for health agencies to retain information about cuisine.

[3] While the original paper describes the labels as a non-strict inequality, the implementation code uses a strict inequality (see line 720 of train_model.py). The original analysis also assessed performance at other thresholds, but mainly focused on the 50 point threshold as that with highest accuracy (see Figure 3 and Table 1 in [33]).

were (non-randomly) selected from the majority class.[4] We discuss below the effects of this non-random selection. Figure 1 shows that 34% of restaurants receive scores of 0 and the prior analysis discards 63% of restaurants receiving scores between 0 and 50.

Third, the prior analysis trained ℓ_1-regularized support vector machines (SVMs), with a constant C parameter, for each feature separately, evaluating results via 10-fold cross-validation on the dataset of 612 observations. By only evaluating predictive performance on this dataset of 612 observations, predictive performance may be overstated compared to performance on the full population of 13k inspections. The top left panel of Figure 3 presents accuracy statistics as reported in the original paper.[5] Because unigrams and bigrams from Yelp reviews outperformed inspection history, the study concluded that Yelp reviews can aid in targeting food safety inspections. We obtained the original code and successfully replicate the results in the top right panel of Figure 3. Minor differences likely stem from different train/test splits, as random seeds were not originally set.

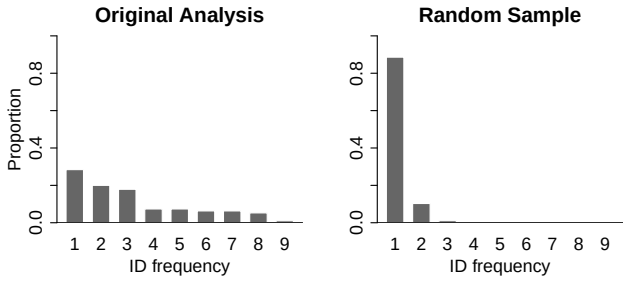

Figure 2: Histogram of counts of occurrences for a unique hygienic restaurant (i.e. defined by inspection scores of 0) in the original analysis (left panel) and under one instance of a random sample of 306 hygienic restaurants (right panel). This panel shows that by selecting observations in the non-random order of the dataset (sorted by restaurant ID), the hygienic sample overrepresents specific establishments compared to a sample one would expect under random sampling.

3 EXTREME IMBALANCED SAMPLING

We now explain the methodological challenges in the prior analysis. First, rather than predicting hygienic and non-hygienic restaurants with a particular cutoff for classification, the prior analysis dramatically simplified the prediction problem. Hygienic restaurants were those with inspection scores of 0 violations[6] (green in Figure 1) and unhygienic restaurants were those with over 50 violation points (red in Figure 1). In other words, the analysis sampled extreme end points, making the prediction substantially easier. Consider an educational analogy: instead of predicting the full grade range for students, it is akin to classifying straight-A students versus drop-out students, discarding the majority of students in the mid-range.

Moreover, hygienic restaurants were not randomly selected from the 4,571 hygienic observations. Instead, they were selected based on (non-random) order in the dataset, which was sorted by restaurant and cuisine type. As a result, hygienic establishments in the training data overrepresent the *same* restaurants and cuisines, as illustrated in Figure 2. As can be seen from that Figure, 72% of training observations represent multiple inspections for the same establishment (left panel), which would be expected for only 12% of training observations under random sampling[7] (right panel illustrates one random sample instance). This is problematic because terms unique to a restaurant (e.g., "café", "Chipotle") may result in overfitting. To continue the educational analogy, it would be akin to predicting grades for each school year, but rather than randomly sampling training data, repeatedly selecting the same students observed over multiple school years.

Second, instead of implementing methods to account for class imbalance using undersampling [15] or oversampling [8], the study reported accuracy only on the extreme balanced sample of 612 observations. By not reporting results on the full held-out dataset, results were likely overly optimistic, particularly in light of non-random sampling of hygienic restaurants noted above. Jointly, we refer to this problem as one of "extreme imbalanced sampling," and consider two minor modifications to illustrate the consequences of these methodological choices.

Random Sample of Hygienic Establishments: First, we consider the consequence of over-representing the same restaurants in the hygienic training sample. We randomly sample 306 hygienic restaurants (i.e. restaurants with scores of 0) and fit the same SVM models. We report mean accuracy results across 5 different datasets created with a random sample of hygienic restaurants. Contrary to the prior analysis, we find that inspection history has *higher* predictive performance than Yelp review features as shown in the bottom left panel of Figure 3. Indeed, this simple modification reduces the predictive power of Yelp review substantially: unigrams and bigrams drop from 83% reported accuracy to 69% reported accuracy, compared to 71% accuracy of inspection history, suggesting that the original results were due to overfitting.

Full Imbalanced Dataset: Next, we consider the consequence of not taking into consideration the imbalanced nature of this dataset by only reporting results on the sample of 612 inspections. Instead, we evaluate predictive performance on the full population of 13k inspections (via 10-fold cross-validation), accounting for class imbalance [30]. We implement undersampling on the training data, and report class averaged accuracy results on the test data.[8] The lower right panel of Figure 3 illustrates results. Inspection history alone achieves higher relative performance (67% class-averaged accuracy) than all other features. The (class-averaged) accuracy for unigrams and bigrams drops to 62%. Moreover, the overall predictive performance is substantially lower than what previous results suggested.

[4] As described in the original paper [33]: "For restaurants with "hygienic" labels, we only consider those without violation, as there are enough number of such restaurants to keep balanced distribution between two classes".
[5] See Table 1 in [33].
[6] There is one observation with a score of -1 that is treated as an inspection score of 0.
[7] We simulate random draws of hygienic restaurants and compute the mean number of duplicates across 10k draws.
[8] The class averaged accuracy represents a class-specific measure of accuracy calculated as $:= \frac{1}{2} \cdot \left(\frac{TP}{TP+FN} + \frac{TN}{TN+FP} \right)$, where TP denotes true-positives, FN denotes false-negatives, TN denotes true-negatives, and FP denotes false-positives. Note that in settings with exact (or approximately) class balance that accuracy is exactly (or approximately) the same as class averaged accuracy.

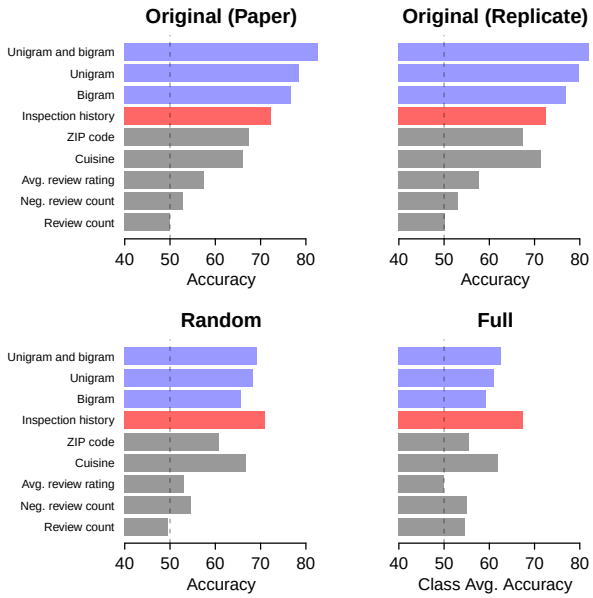

Figure 3: Predictive performance of Yelp review words (blue) and inspection history (red) in prior analysis (top left), replication (top right), random sample of hygienic restaurants (bottom left), and the full imbalanced dataset (bottom right). The figure shows that the relative performance of Yelp reviews depends entirely on a non-random and unrepresentative sample. The vertical dashed line represents baseline accuracy of 50%.

The fact that these two minor modifications reverse the core claim of the original paper is sobering. Higher levels of accuracy with predictive targeting could be achieved exclusively with data already possessed by the health department. The bottom panels of Figure 3 also show that predictive performance degrades when the hygienic class is chosen in random order and/or the full dataset is evaluated.

4 A RE-ANALYSIS

We now re-analyze this dataset from a regression perspective, to more closely align with the actual prediction problem of modeling inspection scores (without discarding data), and offer an alternative interpretation of the relative usefulness of inspection features versus online Yelp features. We view this re-analysis as a step forward in understanding the ability to predict an establishment's future inspection performance.

4.1 Data, Features, and Model

First, we reduce the dataset to routine (unannounced) inspections, by matching the Seattle Restaurant Dataset to data from the public health department. This removes (a) return inspections, which are triggered by poor performance in routine inspections, and typically occur a month after the routine inspection, and (b) educational inspections, which are unscored.[9] This leaves us with 12,613 observations.

Second, for comparability, we use largely the same feature set. Minor modifications are that we (a) construct cuisine features that indicate if a restaurant is denoted by a particular cuisine category, (b) do not normalize inspection scores,[10] (c) use the raw average rating score as opposed to further processing this score, and (d) use the raw previous penalty score instead of discretizing scores. The more substantial change is that we address sparseness of Yelp review text by leveraging word embedding `doc2vec` [37], instead of raw unigrams and bigrams. We apply a standard text cleaning process[11] that converts text to lower case and tokenizes all words. Results for embeddings created using the `doc2vec` parameters `vector_size=100`, `window=5`, and `min_count=3` are reported for the remainder of this paper.[12]

Third, rather than discarding information in inspection scores by discretization at an arbitrary cutoff, we evaluate each feature's prediction performance in a regression set-up to predict the full inspection score. We evaluate a Random Forest (RF) model [7], which is suitable for capturing higher-order interactions.[13] We report results across a 10-fold cross-validation set-up, where we select hyperparameters via 3-fold cross-validation on each training data portion.[14] Model parameters are selected via a randomized search for quicker run-time with textual features,[15] but we note comparable model performances between random versus grid search implementation on all the other features.[16]

4.2 Evaluation of Inspection, Restaurant, and Yelp-derived Features

Consistent with the earlier study, Figure 4 presents the predictive performance for each of the features individually. The baseline prediction is the mean inspection score from training observations used to predict on testing observations. The dashed vertical line represents the mean performance across the 10-folds for this baseline classifier. For each of the features, we plot densities of mean-squared-error (MSE) across the 10 folds in gray, with the vertical dash representing mean MSE. Figure 4 shows that inspection history achieves the lowest MSE (i.e., the highest predictive performance). Yelp features outside of the review text (review count, non-positive review count, average review reading) perform poorly.

[9] There are 2 observations in the original dataset that do not have corresponding inspection IDs in our dataset, which we drop. We also set one observation with an inspection score of -1 to 0.

[10] Inspection history features here will include the following fields provided in the original dataset: `inspection_average_prev_penalty_scores` and `inspection_prev_penalty_score`.

[11] In the `gensim` library in Python, we use `gensim.utils.simple_preprocess()`.

[12] We vary the hyperparameter settings when training a `doc2vec` model and observe comparable prediction performance across the range of hyperparameters considered. See [35] for more technical details on hyperparameter parameters in `doc2vec`.

[13] Technically inspection penalty scores are integers but RF computes averages in subsamples of the model resulting in fractional numbers. We evaluate the raw predictions from RF and avoid rounding.

[14] We consider the following search range for each hyperparameter parameter: `max_features = [None, 0.25, 0.5, 0.75]`, `max_depth = [None, 5, 10]`, `min_samples_leaf = [0.0005, 0.01, 0.05, 0.1]`, `min_samples_split = [2, 5, 10]`, and `n_estimators = [100, 200, 500]`

[16] http://scikit-learn.org/stable/modules/generated/sklearn.model_selection.GridSearchCV.html

Figure 4: Predictive performance of restaurant-, inspection- or Yelp-derived features as measured by mean squared error (MSE) in regression problem. Results are based on 10-fold cross-validation set-up (presented as densities, with means in vertical lines), fitting a RF regression model with hyperparameter tuning. Yelp review (blue) indicates word embedding representation of review content.

We observe only modest performance of Yelp reviews, providing less predictive power than inspection history and about the same as ZIP code.

4.3 Marginal Value of Yelp Features

While Figure 4 considered features individually, we now compare the performance of a "full" model consisting of inspection-, restaurant-, and Yelp-derived features, versus a "non-Yelp" model to evaluate the marginal value of Yelp. A full model with all features considered in Figure 4 yields a mean MSE of 185.70, while a non-Yelp model (excluding Yelp review, ratings, and review counts) yields a comparable mean MSE of 183.61, with a non-significant p-value of 0.984 from a paired Wilcoxon signed rank one-sided test for whether the additional Yelp features improve the fit. These results indicate that Yelp features do not significantly improve predictions, given existing information available about restaurants and inspection history. Table 2 illustrates the marginal value of Yelp reviews given different feature sets. Yelp adds predictive value only in instances where the features are extremely limited (e.g., only ZIP code). The bottom four rows show that with any realistic feature set (e.g., inspection history and cuisine), Yelp reviews do not statistically (and substantively) improve predictive performance.

4.4 Limitations

We note several limitations to our analysis. First, as in the prior analysis, our review information is aggregated. It may be important to treat each user's review as a separate block of text instead of a concatenated text field across the inspection period. That said, review information is already exceedingly sparse, so accounting for specific reviews may be challenging. Second, it is possible that more refined feature extraction from text (e.g., sentence encoding) would improve the predictive performance of Yelp reviews or that some alternative feature representation of the review text would be useful.[17] The prior analysis used raw unigrams and bigrams, which we also found lacking in predictive power. Third, while we have followed the original setup of evaluating performance by cross-validation, a more appropriate evaluation should take into account that the use case involves forecasting *future* sanitation [32]. Understanding how algorithms generalize temporally has been raised in other contexts such as inferring economic conditions in a country [6]. In our setting, a more appropriate model may involve early detection prediction to trigger an early inspection [55]. Fourth, alternative datasets or features, such as the length of time a restaurant has been open, might provide a better signal of a restaurant's future hygienic conditions.

Table 2: This table evaluates the additional predictive value of the Yelp review text given different subsets of other features such as ZIP code, cuisine, or inspection history. We observe that Yelp's additional predictive value is minimal. We report p-values from a paired Wilcoxon signed rank test, testing whether the difference in MSE without versus with the Yelp text features across the same test folds is greater than 0. */** indicate statistical significance at 0.05 and 0.01.

Features included			Mean Squared Error		
ZIP	Cuisine	Inspection history	Without Yelp review text	With Yelp review text	p-value
			222.13	209.93	0.003**
✓			211.30	203.27	0.003**
	✓		198.50	204.13	0.996
		✓	192.00	189.12	0.004**

✓	✓	✓	183.61	185.61	0.988

5 DISCUSSION

While web and social media data offer tantalizing possibilities for governance, we have shown that one of the most celebrated cases for "reinventing food safety" overstates the utility of Yelp reviews. While this may be no fault of the authors – indeed the original authors generously offered replication code, data, and comments to help assess the methodology – the popular susceptibility to "big data hubris" has considerable ethical and policy implications. As mentioned above, health departments in Boston, Las Vegas, Chicago, and New York City each adopted techniques for targeting based on Yelp or Twitter, and much more serious work needs to be conducted to validate and assess these methods for policy adoption. We here highlight three particular implications.

5.1 Replication and Transparency

Our study corroborates that the replication crisis that has affected the social sciences and biomedicine [10, 29] may also affect the machine learning community [15, 39]. Only 6% of papers at top artificial intelligence conferences made code available [22]. As data and methods become more complex, unarticulated researcher "degrees of freedom" expand. Here, such discretionary choices included: the

[17] For observations on the consequences of pre-processing for topic modeling, see [13].

feature set, feature representation (e.g., TF-IDF weighting of word terms), data cleaning, software version, hyperparameter tuning (the kernel, C, and γ in the original SVM setup), the penalty threshold, and selection of majority class from an ordered dataset. The original authors deserve much credit to providing the replication data. But even with the exact data in hand, we were unable to replicate the findings after three months of efforts. Only after the code was generously shared did it become clear that classification was limited to ≈600 restaurants with extreme imbalanced and non-random sampling. Moreover, while we were able to perform a "direct replication," this uncovered substantial methodological problems.

Our evidence hence underscores recent calls for more general reproducibility (or "conceptual replication") in machine learning [15, 20, 38]. More generally, our findings highlight the importance of recent projects in machine learning to promote transparency and replication , such as including code with conference submissions and details on the trained model [43], automating hyperparameter searching [4], developing open source software and computational infrastructure for reproducibility [41, 49], and providing datasheets for detailed dataset information [17].

We also note that another form of transparency is relevant in the law and policy context, namely surrounding the role of private industry sponsorship. When private data is used for public purposes, a greater obligation of transparency may attach. Yelp, for instance, sponsored a predictive tournament for health scores in Boston [19], posing a potential conflict of interest. Recall Yelp's CEO statement that Yelp could "beat gold standard healthcare measures." Disclosure both of sponsorship, data, and methodology would help ensure that these findings can be externally validated when private data enters public enforcement.

5.2 Machine and Policy Translation

Our results also show that much work remains to be done for machine learning to be translated into policy. First, notwithstanding wide media coverage of how Yelp could solve food safety, we show that the prediction is much more difficult than previously appreciated. As Table 2 shows, predictive power of *any* features is not very high. By definition, health authorities already retain rich administrative data on inspection history and restaurant meta-information, and Table 2 confirms that with any reasonable baseline set of features, Yelp reviews add no statistically significant predictive power.

Second, machine learning scholars need to understand the substantive policy setting of a prediction problem. For instance, when the prediction problem is defined as a classification problem, cutoff points should be policy-relevant. The 50-point cutoff, predicting only the most extreme 2.3% of the sample, does not accord to any meaningful quantity in Seattle. As a policy matter, Seattle (and King County) mandate (i) a return inspection when more than 35 points for critical violations are assessed and (ii) a shutdown of the restaurant when more than 90 critical violation points are assessed. The prior analysis neither distinguished between critical and non-critical violations nor paid attention to these substantive thresholds. Converting a regression to classification problem must be done with care and attention to the substantive setting [28], particularly when discretization can discard meaningful information.

Third, applying this technique in policy has to grapple with the fact that Yelp reviews reflect the digital divide. In Seattle and King County, for instance, Yelp has a much higher penetration in areas with lower minority presence, higher educational attainment, and lower unemployment rates [26]. When reviews themselves are of an unrepresentative sample of restaurants, there are considerable ethical concerns about the distributive implications for adopting food safety enforcement based on such data. For a similar example, Boston's StreetBump application, which used smartphone accelerometer and GPS data to trigger service requests for potholes, initially deployed more public resources to wealthier areas where smartphone penetration was higher [11]. None of these concerns are explored in work proposing to use social media to target inspections and thus, these concerns warrant much greater attention.

Last, scholars may also need to contemplate what "predictive accuracy" means in a given context. One of the predominant substantive concerns in food safety enforcement has been that inspection stringency may be largely driven by the differences across inspectors [24, 25]. If so, targeting based on predictive scores may contravene rather than support policy goals: more inspection resources would simply be deployed to where inspections are already the most stringent [26].

5.3 Class Imbalance

For classification problems, class imbalance is a common concern [45, 54]. The prior study exacerbated this concern by engaging in extreme imbalanced sampling. But the fact that accuracy statistics were only presented on the sample of ≈600 restaurants may illustrate a more pervasive challenge in machine learning: while it may be desirable to train a classifier on a balanced sample (e.g., via undersampling or oversampling), class imbalance in the population must be accounted for when assessing model performance. This can clearly be seen in the bottom two panels of Figure 3, where class-averaged accuracy from the population appears much worse than the originally reported 82% accuracy statistic. This concern is particularly acute in the policy setting. Food safety predictions, for instance, necessarily must be conducted on the population of restaurants.

6 CONCLUSION

We have shown in this work that one of the most widely cited examples of machine learning with social media for public policy suffers from considerable concerns about replicability. We close by noting that the original authors are not to be blamed: they advanced a novel hypothesis and amassed new data to test it. Given the large number of researcher degrees of freedom, any researcher may inadvertently introduce methodological problems in one of hundreds of lines of code. Yet the case also illustrates the profound challenges of the replication crisis given researcher degrees of freedom in machine learning. We believe that the ethical concerns with such applications are compounded when applied to law and public policy, heightening the importance of recent calls for improving the replication, transparency, and validation of methods in the machine learning community.

ABSTRACT

In this paper, we address the keyphrase extraction problem as sequence labeling and propose a model that jointly exploits the complementary strengths of Conditional Random Fields that capture label dependencies through a transition parameter matrix consisting of the transition probabilities from one label to the neighboring label, and Bidirectional Long Short Term Memory networks that capture hidden semantics in text through the long distance dependencies. Our results on three datasets of scholarly documents show that the proposed model substantially outperforms strong baselines and previous approaches for keyphrase extraction.

1 INTRODUCTION

Keyphrase extraction is a key natural language processing task aimed at automatically extracting descriptive phrases or words from a document [17]. Keyphrases (also referred as keywords) provide a brief summary of the content of a document. The importance of keyphrases has been widely recognized in many downstream applications such as query formulation, document clustering, classification, recommendation, indexing, and summarization [16, 21, 38].

Most of the existing works on automatic keyphrase extraction focus on supervised and unsupervised approaches. The unsupervised approaches use ranking techniques to rank phrases based on the aggregated "informativeness" scores of the individual words comprising a phrase. Graph-based ranking algorithms that are applied to the word graph representation of a document are the most prevalent in this category. To construct the graph, each candidate word in a document (i.e., a word with certain part-of-speech tags) is mapped to a node and connecting edges represent the association patterns among the candidate words. The scores of individual words are estimated using various graph centrality measures such as PageRank [10, 12, 27, 34, 41].

The supervised approaches use binary classification to label candidate phrases positively (as keyphrases) or negatively (as non-keyphrases), based on a set of linguistic and statistical features such as *tf-idf*, part of speech (POS) tags, and the position of phrases in documents. Supervised keyphrase extraction allows for expressive feature design and is reported to often outperform unsupervised methods [6, 23]. Two major limitations of these supervised approaches are: (1) they classify the labels of each candidate phrase independently, while completely ignoring the dependencies that could potentially exist between neighboring labels; and (2) they do not incorporate the hidden semantics in the input text.

More recently, Gollapalli et al. [13] formulated keyphrase extraction as sequence labeling and showed that using linear-chain Conditional Random Fields can improve the performance over baseline models for this task. However, the approach in [13] does not explicitly take into account the long-term dependencies and semantic relationships hidden in text. Figure 1 shows examples of long-term dependency patterns and semantic relationships hidden in text from a research paper published in the ACM KDD conference, e.g., the phrase "we describe" is followed by (and indicative of) keyphrases, whereas the terms "Conditional Random Field" and "discriminatively-trained model" are semantically related. We posit that a deep understanding of the text is required in order to correctly identify keyphrases for a document.

To this end, we address keyphrase extraction as a sequence labeling problem, using *research papers* as a case study, and precisely aim to capture both the semantics of document contexts as well as the dependencies among the labels of neighboring words in order to overcome the limitations in previous approaches. Specifically, we explore a neural learning model, called Bi-LSTM-CRF, that combines a bi-directional Long Short-Term Memory (Bi-LSTM) layer to model the sequential text data with a Conditional Random Field (CRF) layer to model dependencies in the output [19, 30]. The result of this extraction task will aid indexing of documents in scholarly document collections, and hence, will lead to improved organization, search, retrieval, and recommendation of scientific documents. In summary, our contributions are as follows:

- We explore a neural learning model for keyphrase extraction from scholarly documents that combines the complementary strengths of Bi-LSTM and CRF. In the combined model, the input and output layers are not directly connected as in CRF, but instead a Bi-LSTM layer is inserted between them to exploit the long term dependencies in the text.

A Unified Approach for **Schema Matching**, **Coreference** and **Canonicalization**
by Michael L. Wick, Khashayar Rohanimanesh, Karl Schultz and Andrew McCallum

The automatic consolidation of database records from many heterogeneous sources into a single repository requires solving several *information integration* tasks. Although tasks such as **coreference**, **schema matching**, and **canonicalization** are closely related, they are most commonly studied in isolation. Systems that do tackle *multiple integration problems* traditionally solve each independently, allowing errors to propagate from one task to another. *In this paper, we describe* a *discriminatively-trained model* that reasons about **schema matching**, **coreference**, and **canonicalization** jointly. [...]

Author-annotated keyphrases: *Data Integration, Coreference, Schema Matching, Canonicalization, Conditional Random Field, Weighted Logic*

Figure 1: The title and abstract of a paper by Wick et al. (2008) and the author-input keyphrases for the paper. Cyan bold phrases represent the gold-standard (author-annotated) keyphrases for the document. Red italic phrases represent long-term dependency patterns or semantic relationships with the gold-standard keyphrases.

- We conduct a thorough evaluation to examine the role of each layer in the model. To our knowledge, there is no study that demonstrates an ablation experiment that compares, with this clarity, the role of input dependencies and label dependencies in keyphrase extraction from research papers.
- We show empirically on three datasets of research papers that the Bi-LSTM-CRF model outperforms strong baselines and previous works on the keyphrase extraction task.
- We investigate the performance of Bi-LSTM-CRF at document and sentence level and show that a document level model that captures a broader context is more accurate than a sentence level model. To our knowledge, this has not been addressed before, especially, not on a large scale dataset as we do in this paper.

In the next section, we describe related work on keyphrase extraction. We then introduce the neural learning model in Section 3, followed by Section 4 that presents our evaluation setup. Finally, we discuss our experimental results in Section 5 before we conclude the paper and touch on future directions in Section 6.

2 RELATED WORK

Keyphrase extraction has been the focus of many studies. These studies generally adopt a two phase approach. In the first phase, candidate words or phrases are extracted from the text using heuristics such as POS patterns for words or *n*-grams [20]. In the second phase, the candidate phrases are predicted as keyphrases or non-keyphrases, using both supervised and unsupervised approaches. In the supervised approaches, the prediction is done based on a selection of features, e.g., POS tags, *tf-idf* scores, and position information, used in conjunction with machine learning classifiers [11, 20, 36, 39]. Traditional features were also combined with features extracted from external sources such as WordNet and Wikipedia [29, 32] or from various neighborhoods, e.g., a document's citation network or a webpage's hyper-link network [5, 6, 22].

Unsupervised approaches include phrase scoring methods based on measures such as *tf-idf* and topic proportions [3, 28, 46], graph-based ranking using centrality measures [15, 34, 41], and keyphrase selection from topics detected using topic modeling [25, 40]. In this context, several extensions of PageRank and personalized PageRank have been proposed that make use of a document's citation network [12] or that bias the random walk based on the words' positions in text [10] or the words' topic distribution [27]. In order to add semantic relatedness between the words in a word graph, Martinez-Romo et al. [31] used information from WordNet.

The best performing SemEval 2010 system used term frequency thresholds to filter out phrases that are unlikely to be keyphrases, where the thresholds were estimated from the data [9]. The candidate phrases were ranked using the *tf-idf* model in conjunction with a boosting factor which aims at reducing the bias towards single word terms. Danesh et al. [8] computed an initial weight for each phrase based on a combination of the *tf-idf* score and the first position of a phrase in a document. Phrases and their initial weights were then incorporated into a graph-based algorithm, which produces the final ranking of keyphrases. Adar and Datta [1] extracted keyphrases by mining abbreviations from scientific literature and built a semantic hierarchical keyphrase database. Many of the above approaches, both supervised and unsupervised, are compared and analyzed in a survey by Hasan and Ng [17].

Neural networks have started to be incorporated into models for keyphrase extraction. For example, Wang et al. [42] investigate word embeddings to measure the relatedness between words in graph-based models. A Recurrent Neural Network (RNN) based approach is proposed by Zhang et al. [45] to identify keyphrases in Twitter data. The model addresses the problem as sequence labeling for very short text, where a joint-layer RNN is used to capture the semantic dependencies in the input sequence, but does not address the dependencies in the labels. In our work, we capture the flow of scientific writing and the dependencies between keyphrases and the other words in the text that may not necessarily exist between hashtags and the text of the tweets. Augenstein and Søgaard [2] treated keyphrase extraction as a multi-task learning problem and applied RNNs to classify keyphrase boundaries. Inspired from work in machine translation, Meng et al. [33] focused on keyphrase generation (rather than keyphrase extraction) and addressed it as a sequence to sequence learning problem with a copying mechanism, where the sequence of words in a document is used to generate a sequence of keyphrases. An Encoder-Decoder RNN, originally proposed by Cho et al. [7], was used to generate the keyphrase sequences. A variation of the model, which performs better than the Encoder-Decoder RNN, includes a copying mechanism to identify keyphrases that occur rarely in the text. Unlike Meng et al. [33], we focus on keyphrase extraction, i.e., extracting only words that are present in text, and not keyphrase generation, which outputs words that may or may not be present in text. We use the Encoder-Decoder RNN with the copying mechanism as one of our baselines.

Sequence labeling models for keyphrase extraction have shown promising results in recent studies [4, 13, 44]. For example, Gollapalli et al. [13] trained Conditional Random Fields (CRFs) to extract keyphrases from scholarly documents, using features such as *tf-idf*

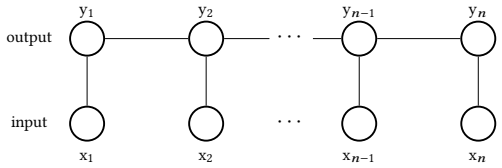

Figure 2: Layers in a CRF network.

and POS tags to predict a label for each token position in a document as being a keyphrase token (**KP**) or not (**Non-KP**). This CRF model is able to capture the dependencies in previous and future tags in the label sequence, however, the semantic dependencies in the input sequence, i.e., the text, are not incorporated.

Recently, a sequence labeling framework that takes into consideration both types of dependencies has been explored on a variety of NLP tasks such as part-of-speech tagging, noun phrase chunking, and named entity recognition [19, 26, 30]. This framework combines a bidirectional LSTM (Bi-LSTM) network as the first layer to capture sequential text dependencies with a second CRF layer to capture label dependencies. In our work, we identify the limitations of each independent model (Bi-LSTM and CRF) and explore their combination on keyphrase extraction from scholarly documents. To our knowledge, in the context of keyphrase extraction from scholarly documents, we are the first to simultaneously capture the semantics of document contexts and long-range dependencies in text by modeling the sequential text data as well as the dependencies among the labels of neighboring words.

3 METHODOLOGY

In this section, we formulate keyphrase extraction as a sequence labeling task and present the details of the Bi-LSTM-CRF model and its constituent components, CRF and Bi-LSTM.

3.1 Problem Formulation

Keyphrase extraction can be formulated as a sequence labeling task as follows: Given an input sequence $\mathbf{x} = \{\mathbf{x}_1, \cdots, \mathbf{x}_n\}$, where each $\mathbf{x}_i$ represents the input vector of the i^{th} word, predict a sequence of labels $\mathbf{y} = \{y_1, \cdots, y_n\}$, one label for each word in the input, where each label y_i is **KP** (keyphrase word) or **Non-KP** (not keyphrase word). The sequence labeling formulation of our task takes into account the correlations between neighboring labels and allows to *jointly* decode the best sequence of labels for the input sequence, rather than decoding each label independently.

3.2 Conditional Random Fields

Conditional Random Field (CRF) introduced by Lafferty et al. [24] has been successfully used in many sequence labeling tasks and we use it here to jointly model the sequence of labels for our keyphrase extraction task. The conditional probability distribution over the label sequence $\mathbf{y}$ given $\mathbf{x}$ defined by CRF has the form:

$$p(\mathbf{y}|\mathbf{x}; \mathbf{W}, \mathbf{b}) \propto \exp\left(\sum_{i=1}^{n} \mathbf{W}^T_{y_{i-1}, y_i} \mathbf{x}_i + \mathbf{b}_{y_{i-1}, y_i}\right)$$

where $\mathbf{W}_{y_{i-1}, y_i}$ and $\mathbf{b}_{y_{i-1}, y_i}$ are model parameters (weight vector and bias) corresponding to the neighboring labels (y_{i-1}, y_i).

For training a CRF model, we estimate model parameters $\mathbf{W}$ and $\mathbf{b}$ from a training dataset $\mathcal{D} = \{(\mathbf{x}^{(j)}, \mathbf{y}^{(j)})\}_{j=1}^{N}$ by maximizing the log-likelihood given by:

$$L(\mathbf{W}, \mathbf{b}) = \sum_{j=1}^{N} \log p(\mathbf{y}^{(j)}|\mathbf{x}^{(j)}; \mathbf{W}, \mathbf{b})$$

To find the best sequence path during decoding, the optimal sequence $\mathbf{y}$ that maximizes the likelihood, is computed using the Viterbi decoding:

$$\mathbf{y}^* = \text{argmax}_{y \in \mathcal{Y}(\mathbf{x})} p(\mathbf{y}|\mathbf{x}; \mathbf{W}, \mathbf{b})$$

Figure 2 depicts the layout of a simple CRF network. As shown in the figure, nodes in the output layer are connected, enabling the model to capture dependencies in the sequence of labels.

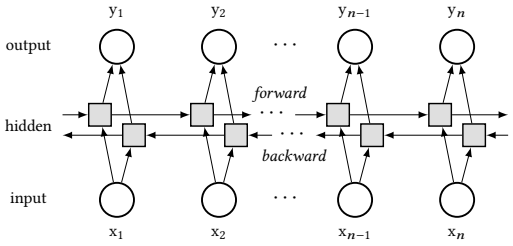

Figure 3: Layers in a Bi-LSTM network.

3.3 Bi-LSTM

Long Short Term Memory networks (LSTMs) are a special type of Recurrent Neural Networks (RNNs) and are designed to overcome the gradient vanishing problem of RNNs. In particular, LSTMs have additional memory cells, which store memory from long distance terms [18]. Because LSTMs are capable of preserving information over previous inputs of a sequence into the current input state, they have been a natural choice for applications involving temporal and sequence data such as speech recognition, language modeling and translation [14, 35]. The structure of an LSTM includes an input layer, a hidden layer and an output layer. An LSTM unit at time t consists of sub-unit-inputs ($\mathbf{i}_t$), output ($\mathbf{o}_t$), forget gates ($\mathbf{f}_t$) and memory cell ($\mathbf{c}_t$). The updates at time t are then:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}^{(i)}\mathbf{h}_{t-1} + \mathbf{U}^{(i)}\mathbf{x}_t + \mathbf{b}^{(i)}) \\
\mathbf{f}_t &= \sigma(\mathbf{W}^{(f)}\mathbf{h}_{t-1} + \mathbf{U}^{(f)}\mathbf{x}_t + \mathbf{b}^{(f)}) \\
\mathbf{o}_t &= \sigma(\mathbf{W}^{(o)}\mathbf{h}_{t-1} + \mathbf{U}^{(o)}\mathbf{x}_t + \mathbf{b}^{(o)}) \\
\tilde{\mathbf{c}}_t &= \tanh(\mathbf{W}^{(c)}\mathbf{h}_{t-1} + \mathbf{U}^{(c)}\mathbf{x}_t + \mathbf{b}^{(c)}) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{(t-1)} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}$$

Here, σ is the element-wise logistic sigmoid function and $\odot$ is the Hadamard product; $\mathbf{x}_t$ is the input vector at time t, i.e., the word embedding in our case, and $\mathbf{h}_t$ is the hidden state that stores sequential information up to time t. $\mathbf{W}$, $\mathbf{U}$, and $\mathbf{b}$ are model parameters to be estimated during training.

In a forward LSTM network, the hidden state $\mathbf{h}_t$ stores information only from the past. To capture the flow of information both ways, we use a bi-directional LSTM network, which consists of a forward hidden layer and a backward hidden layer. Figure 3 shows the structure of a Bi-LSTM network. Here, the nodes in the hidden layer are connected which is how long distance information is maintained in the matrix weights.

Table 1: Dataset statistics.

Statistics	Training	Validation	Testing		
	kp527k	**kp20k-v**	**kp20k**	**WWW**	**KDD**
Number of documents	527,830	20,000	20,000	1,330	755
Number of sentences	4,686,986	176,930	177,278	12,288	7,768
Number of tokens in total	78,441,075	2,948,609	2,971,668	200,704	132,728
Number of tokens in keyphrases	5,458,743	205,586	207,073	12,181	6,119
Number of keyphrases	2,806,381	106,181	105,523	6,405	3,093

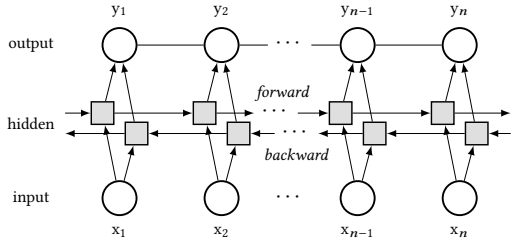

Figure 4: Layers in a Bi-LSTM-CRF network.

3.4 Bi-LSTM-CRF

In order to build a sequence labeling model that incorporates long distance information over a sequence of input as well as information on the output sequence, we combine a Bi-LSTM network with a CRF network. The network architecture is shown in Figure 4. As shown in the figure, the first layer of the model is a Bi-LSTM network with the purpose of capturing the semantics of the input text sequence. The output of the Bi-LSTM layer is passed to a CRF layer that produces a probability distribution over the tag sequence using the dependencies among labels of the entire sequence. In order to find the best sequence of labels for an input sequence, the Viterbi algorithm is used.

4 EVALUATION SETTING

To evaluate the performance of our proposed model, we conduct a wide range of experiments. In this section, we describe the datasets used for training and evaluation, discuss hyper-parameters, baselines and the evaluation measures.

4.1 Datasets

We use three different datasets of scientific documents for our evaluation purpose. The first dataset was made available by Meng et al. [33] and was collected by crawling the metadata of papers from several online digital libraries such as ACM, WebofScience, and Wiley. The dataset contains metadata for 567, 830 papers with a clear split as train, validation, and test sets provided by the authors, as follows: 527, 830 were used for model training, 20, 000 were used for parameter tuning, and the remaining 20, 000 were used for model evaluation. We refer to these sets as **kp527k**, **kp20k-validation** (or **kp20k-v**), and **kp20k-test** (or simply **kp20k**), respectively.

The second and third datasets were made available by Gollapalli and Caragea [12] and were compiled from the CiteSeerX digital library. These datasets contain metadata for research papers from the proceedings of two top-tier data mining and machine learning conferences, i.e., the ACM Conference on Knowledge Discovery and Data Mining (referred as **KDD**) and the World Wide Web Conference (referred as **WWW**).

The metadata of each paper from all three datasets above consist of titles, abstracts, and author-assigned keyphrases. The title and abstract of each paper are used to extract keyphrases, whereas the author-input keyphrases are used as gold-standard for evaluation. In experiments, for all models, we use **kp527k** for model training, **kp20k-validation** for parameter tuning, and **kp20k**, **KDD**, and **WWW** as three independent test sets for model evaluation. Note that we removed from **KDD** and **WWW** the entries that occur also in **kp527k-train** and **kp20k-validation** to avoid the overlap between train, validation, and test sets. Table **??** shows the statistics of these datasets.

4.2 Implementation Details

Since we use a sequence labeling formulation of the keyphrase extraction problem, the abstract/keyphrases data pairs are converted such that each document is a sequence of word tokens, each with a positive (**KP**) label if it occurs in a keyphrase, or with a negative (**Non-KP**) label, otherwise (consistent with [13]). We train four network models: Bi-LSTM-CRF, CRF, Bi-LSTM, and LSTM. Each sentence from a document is passed to a network as the input sequence. To evaluate performance and runtime differences, we also train Bi-LSTM-CRF models with the entire document as the input sequence (instead of each sentence at a time).

We use word embeddings as input to the above four models. The word embeddings are initialized with 100-dimension Glove pre-trained embedding vectors [37]. For all models, we use a single 100-dimension hidden layer. The LSTM, Bi-LSTM, and Bi-LSTM-CRF are optimized during training using stochastic gradient descent with learning rate $\eta_t = \frac{\eta_0}{1+\rho_t}$, where initial learning rate $\eta_0 = 10^{-2}$ and decay ratio $\rho_t = 0.5$. Gradient clipping of 5.0 is used to prevent the gradient from overflows during back-propagation. In addition, we use dropout to avoid over-fitting. We select the model with the best F1 score on the validation set, **kp20k-validation**.

Our implementation of the network models is based on a modified version of the implementation developed by [26].[1] Publicly available implementations were used for the other baselines [33].[2]

4.3 Baselines and Evaluation Measures

We contrast the Bi-LSTM-CRF network with three baselines: CRF, forward LSTM, and Bi-LSTM, and several previous models: copy-RNN [33], KEA [11], *Tf-Idf*, TextRank [34] and SingleRank [41].

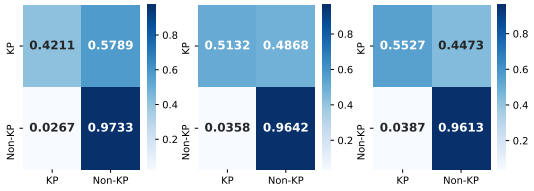
[2] https://github.com/memray/seq2seq-keyphrase

Table 2: Results (Pr, Re, F1) of Bi-LSTM-CRF in an ablation experiment on the kp20k, WWW, and KDD datasets.

Method	kp20k			WWW			KDD		
	Pr%	Re%	F1%	Pr%	Re%	F1%	Pr%	Re%	F1%
Bi-LSTM-CRF	64.19	24.66	**35.63**	64.33	28.43	**39.43**	**57.83**	31.85	**41.08**
CRF	**66.67**	10.04	17.46	**64.89**	22.11	32.98	55.76	18.69	27.99
Bi-LSTM	9.41	76.24	16.75	9.53	**76.76**	16.96	8.15	**75.93**	14.71
LSTM	9.41	**78.43**	16.81	9.51	75.71	16.90	8.13	75.38	14.68

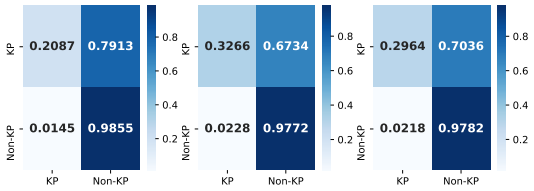
Consistent with previous works, we evaluate the predictions of each model against the author-input keyphrases, which are available with each document, i.e., the gold standard, and report Precision, Recall, and F1-score. For model comparison in the next section, we focus the discussion of our results in terms of the F1-score, which is the harmonic mean of Precision and Recall.

5 RESULTS AND OBSERVATIONS



We now describe the evaluation performance of the Bi-LSTM-CRF model for extracting keyphrases from research papers.

5.1 Performance of Bi-LSTM-CRF for Keyphrase Extraction



First, we evaluate the performance of Bi-LSTM-CRF in an ablation experiment to determine the role played by each component in extracting keyphrases from research papers. Specifically, we compare the Bi-LSTM-CRF model with a bidirectional LSTM, a forward LSTM, and a CRF model (by removing one component at a time from the full Bi-LSTM-CRF model).

Table 2 shows the results of this comparison. As can be seen from the table, Bi-LSTM-CRF consistently achieves the best results on all three datasets in terms of the F1-score. For example, on the **kp20k** dataset, Bi-LSTM-CRF achieves an F1-score of 35.63%, whereas CRF and Bi-LSTM achieve an F1-score of 17.46% and 16.75%, respectively. Interestingly, removing the Bi-LSTM component and using only a CRF model, we notice a steep drop in recall on all three datasets. For example, on **kp20k**, Bi-LSTM-CRF achieves a recall of 24.66%, whereas CRF alone achieves a recall of only 10.04%. This result demonstrates that leveraging the long distance semantic dependencies from text through the Bi-LSTM component of the full model is beneficial for correctly extracting a larger fraction of gold keyphrases. The CRF model alone generally achieves a similar or small increase in precision compared with the Bi-LSTM-CRF model. For example, on **WWW**, the precision values of Bi-LSTM-CRF and CRF are 64.33% and 64.89%, respectively, whereas on the **kp20k** dataset, these values are 64.19% and 66.67%, respectively.

On the other hand, removing the CRF component and using only an LSTM model (either bidirectional or forward LSTM) yields a consistent and substantial improvement in recall on all datasets over both CRF and Bi-LSTM-CRF at the expense of a dramatic drop in precision, consistently across all datasets (see Table 2). That is, on **kp20k**, the precision drops from 64.19% (achieved by Bi-LSTM-CRF) to an unacceptable value of 9.41% (obtained by LSTM alone), whereas the recall increases from 24.66% to 78.43%, obtained by Bi-LSTM-CRF and LSTM, respectively. This result indicates that LSTM is powerful in capturing the deep semantics of the text, and is

(a) Bi-LSTM-CRF

(b) CRF

Figure 5: Keyphrase extraction confusion matrices on kp20k (left), WWW (middle), and KDD (right) (results reported at word-level). The darker the blue on the main diagonal, the more accurate the model is.

able to achieve a high recall. This result also indicates that the CRF component of the full Bi-LSTM-CRF model successfully captures the label dependencies among the output labels for identifying keyphrases and contributes the most towards the full model's precision. Thus, exploiting dependencies in both the textual content of a document and the sequence of labels through the combination of an LSTM model with a CRF model yields improved results over CRF and LSTM models alone, quantified by a much larger F1-score.

Table 2 shows also that the performance of bidirectional-LSTM is very similar to that of forward LSTM. Intuitively, this makes sense since, in scientific papers, often dependencies occur in a forward fashion, e.g., patterns such as "we propose/study/explore/describe" precede keyphrases.

Moreover, from Table 2, we can also see that the performance on the **WWW** and **KDD** datasets is higher than that on the **kp20k** dataset. The lower performance on **kp20k** could be due to a larger spectrum of venues, author writing styles and author keyphrase annotations, whereas **WWW** and **KDD** are specialized datasets of papers from the data mining and machine learning communities.

Figures 5a and 5b show the confusion matrices of Bi-LSTM-CRF and CRF, on all three datasets. Each matrix is represented as a heat map, i.e., the darker the color, the higher the value at that position. An accuracy of 100% will be represented by a matrix with dark blue blocks on the main diagonal and white blocks off diagonal. As can be seen from the figures, the Bi-LSTM-CRF model that incorporates

Table 3: Comparison of Bi-LSTM-CRF with previous approaches on kp20k, WWW, and KDD datasets.

Method	kp20k			WWW			KDD		
	Pr%	Re%	F1%	Pr%	Re%	F1%	Pr%	Re%	F1%
Bi-LSTM-CRF	**64.19**	24.66	**35.63**	**64.33**	**28.43**	**39.43**	**57.83**	**31.85**	**41.08**
copyRNN @5	27.71	**41.79**	33.29	11.47	14.72	12.89	8.59	11.8	9.94
Tf-Idf @5	8.97	13.49	10.77	8.90	10.00	9.40	8.30	10.20	9.20
TextRank @5	15.29	23.01	18.37	5.80	7.10	6.20	5.10	6.50	5.60
SingleRank @5	8.42	12.70	10.14	8.80	10.90	9.50	7.70	10.30	8.60
KEA	15.14	22.78	18.19	13.57	15.25	13.86	11.39	14.50	12.42

dependencies in both the input and output, is more accurate (and thus, has a lower percentage of mis-labeled keyphrases) showed by darker cells corresponding to the **KP-KP** entry in all matrices.

5.2 Baseline Comparisons

Second, we compare the performance of Bi-LSTM-CRF with existing state-of-the-art models including supervised, unsupervised as well as deep learning models. The unsupervised models are Tf-Idf, TextRank [34], and SingleRank [41]. The supervised model is KEA[3] [43], and the deep learning model is the recently proposed copyRNN[4] [33], which is a sequence to sequence learning model based on an RNN Encoder-Decoder framework [7], combined with a copying mechanism. The Bi-LSTM-CRF, copyRNN, and KEA models are all trained on the **kp527k** dataset. For the unsupervised models and the sequence to sequence learning model, we report the performance at top 5 predicted keyphrases since top-5 showed highest performance in previous works for these models.

Table 3 shows the results of this comparison. The Bi-LSTM-CRF model outperforms all baselines in terms of the F1-score, on all three datasets. More notably, Bi-LSTM-CRF outperforms the copyRNN model in precision on all datasets, yet is slightly worse in the recall score on the **kp20k** dataset. For example, on the **kp20k**, Bi-LSTM-CRF achieves an F1-score of 35.63% as compared with 33.29% achieved by copyRNN. The precision increases from 27.71% (obtained by copyRNN) to 64.19% (obtained by Bi-LSTM-CRF) at the expense of a drop in recall from 41.79% (obtained by copyRNN) to 24.66% (obtained by Bi-LSTM-CRF).

This result is consistent with our findings in the previous section regarding the role of CRF in improving precision. Although both models use variants of RNNs to capture the semantics of the input sequence, by integrating the learning of phrasal structure into the model itself, via the CRF layer, we get higher performance than applying beam search to a decoded sequence after the learning phase, as is done in the copyRNN model.

5.3 Sentence vs. Document Level Input

Third, we conduct an experiment to examine the effect of the type of input sequence used to the models. Specifically, we compare the model where the input sequence consists of the entire document with the model where the input sequence consists of each sentence.

[3]http://www.nzdl.org/Kea/Download/Kea-4.0.zip
[4]https://github.com/memray/seq2seq-keyphrase

Table 4: Comparison results for document ("doc") vs. sentence ("sent") level for Bi-LSTM-CRF on the kp20k dataset.

Method		Pr%	Re%	F1%
Bi-LSTM-CRF	doc	**67.30**	**30.32**	**41.81**
	sent	64.19	24.66	35.63

Table 4 shows the results of this comparison for document vs. sentence level Bi-LSTM-CRF, on the **kp20k** dataset. As can be seen from the table, the performance of the Bi-LSTM-CRF that takes as input the entire content (all sentences at once) is higher than that of the Bi-LSTM-CRF that takes as input each sentence at a time. Precisely, precision, recall, and F1 values for the document-level Bi-LSTM-CRF show improvement by up to 6% over the sentence-level Bi-LSTM-CRF. This is likely due to the increased information captured by the LSTM layer (through the larger context) when using the entire content as opposed to each sentence.

A common drawback with increasing input sequence length for a recurrent neural network is that computing the gradients during back-propagation takes longer, which in turn increases the time it takes to train the model. For example, in our setting, training the Bi-LSTM-CRF model on the **kp527k** dataset at the document level took on average 22.1 hours for only five epochs, where the average input sequence size is 147 tokens, whereas when training Bi-LSTM-CRF using the sentence-level, it took only 2.7 hours, where the average number of tokens in a sentence is 16.

6 CONCLUSIONS

In this paper, we formulated the keyphrase extraction task as sequence labeling and proposed to use a Bi-LSTM-CRF model that incorporates dependencies among both the input and output sequences. To our knowledge, this is the first work to propose a neural network based sequence labeling model for keyphrase extraction from scholarly documents. The model takes advantage of the ability of Bi-LSTM to capture long distance semantic information from the input sequence and the ability of CRF to capture dependencies from the label sequence. Experimental results on three datasets showed that the proposed Bi-LSTM-CRF model that takes into account both of these dependencies play an important role in the keyphrase extraction performance.

As future work, it would be interesting to integrate the relationships between documents such as those available from a citation network. Another interesting direction would be to extend keyphrase extraction approaches to other scholarly domains.

ABSTRACT

Although deep learning models trained on electronic health records (EHR) data have shown state-of-the-art performance in many predictive clinical tasks, the discovery of adversarial examples (i.e., input data that are engineered to cause misclassification) has exposed vulnerabilities with lab and imaging data. We specifically consider adversarial examples with longitudinal EHR data, an area that has not been previously examined because of the challenges with temporal high-dimensional and sparse features. We propose Longitudinal AdVersarial Attack (LAVA), a saliency score based adversarial example using a method that requires a minimal number of perturbations and that automatically minimizes the likelihood of detection. Features are selected and modified by jointly modeling a saliency map and attention mechanism. Experimental results with longitudinal EHR data show that LAVA can substantially reduce model performance for attention-based target models (from AUPR = 0.5 to AUPR = 0.08).

1 INTRODUCTION

Electronic health record (EHR) data from millions of patients are now routinely collected across diverse healthcare systems and physician practices, that can be represented as a longitudinal patient-level history of diagnoses, laboratory test results, and medication prescriptions orders, procedure orders, among other events and accompanied by demographic and other features. Deep learning models trained on these data are yielding high levels of performance for many clinical tasks such as diagnostic classification [15], disease detection [5], risk prediction [24]. In some instances, the performance of these models exceed the capabilities of experienced physicians in head-to-head comparisons [2]. However, the discovery of "adversarial examples" has exposed vulnerabilities in deep learning models across various application domains [9]. The connected EHR systems are under risk of adversarial attacks for a number of reasons including manipulations of pharmaceutical and device approvals, medical reimbursement decisions, etc [7]. As a major means of adversarial attacks, the "adversarial examples" are crafted to cause diagnostic errors via perturbation of EHR data, and further trigger significant consequences in treatment or other patient outcomes. Therefore, the risks from adversarial attacks need to be mitigated. Ultimately, a good understanding of such adversarial examples on longitudinal EHR can help patients and EHR administrators to proactively prevent the high-risk attacks to their records.

Adversarial examples have received much attention in computer vision [13, 19, 21] and natural language processing [12, 29], but relatively little work has been done with a focus on EHR data. Finlayson et al. [7] demonstrated vulnerability of convolutional neural network models trained with medical imaging datasets, replicating prior work on imaging from other industries. Sun et al. [26] proposed a recurrent neural network (RNN) based time-preferential minimum attack model to identify susceptible locations in clinical time series data focused on real-valued continuous variables such as vital sign and lab measurements. Despite all these efforts, adversarial attacks on longitudinal EHR data on neural network models is still fairly open. More generally, challenges to devising adversarial examples for longitudinal EHR data include:

- *High-dimensional, discrete and sparse feature space*: Unlike most other domains such as image and audio waveform, EHR data are characterized by high-dimensional, discrete, and extremely sparse feature space. As many as 80% to 90% of the 10,000 or more

features (i.e., diagnosis, medication, and procedure codes) have non-null values less than 1% of the time. Thus, existing crafting algorithms for continuous or dense data cannot be directly applied because they assume perturbations were broadly spread over the entire feature space.

- *Feature significance and relevance*: Each medical code differs in clinical significance and relevance to prediction tasks. For example, diagnostic codes for fever and heart failure inform the different level of risks in terms of morbidity and mortality risks. Perturbation of critical features such as heart failure could be readily detected even though they are the most effective attacks.
- *Temporal significance*: Patients' health conditions evolve over time. The temporality encoded in time-stamped medical events reveals important information on impending patient health conditions, with differential significance on prediction outcomes. For example, more recent events are likely to have a stronger influence on the prediction result. Thus adversarial attacks on more recent events are more likely to be detected.

To address these challenges, we propose LAVA (**L**ongitudinal **A**d**V**ersarial **A**ttack), a saliency score based method for discrete and sequential EHR data. LAVA introduces a minimal number of perturbations while also avoiding the selection of features and clinical encounters whose modifications are highly likely to be detected. This is achieved by jointly modeling the saliency map and attention mechanism. We specifically propose LAVA with the following technical contributions.

- *Efficient crafting with a bidirectional saliency map*: We proposed a new bidirectional saliency map that searches candidate features from both (+/−) altering directions simultaneously.
- *Low detectability with an attention mechanism*: LAVA automatically avoids choosing features that have high relevance to the prediction targets. This is achieved via a dual-level attention mechanism that can highlight and avoid important visits and important features within those visits.

In experimental modeling with real-world data show that LAVA substantially reduces performance (i.e., area under the precision-recall curve or AUPR) for the white-box[1] type of attention-based target models from 0.5 to 0.08, and achieves comparable performance reductions for other gray-box[2] target models, while providing minimal to non-detectable perturbations.

2 RELATED WORK

Adversarial examples can be crafted in different ways and categorized by the norm they use. In general, L_p-norm, $\|\cdot\|_p$ measures the distance between an original input $\mathbf{x}$ and the corresponding adversarial example $\tilde{\mathbf{x}}$. The choice of L_p (e.g., L_0, L_1, L_2, or L_∞) is related to the problem domain. Goodfellow et al. [9] proposed the Fast Gradient Sign Method (FGSM), a widely used method that generates untargeted adversarial examples optimized under the L_∞ norm. FGSM works by adding perturbations of size ϵ to the direction of increasing loss function $J(\theta, \mathbf{x}, y)$ used to train the model F with the model parameters θ, the input $\mathbf{x}$, and the target y. Kurakin et al. [14] proposed an iterative variant of FGSM called Projected Gradient Descent (PGD), which shows better generalization and performance for most cases. PGD is a universal adversary among first-order approaches [17]. Moosavi Dezfooli et al. [20] proposed an approach that uses a directional derivative to find a distance from the input data point in the feature space to the decision boundary, crafting adversarial examples that minimize perturbations.Papernot et al. [22] proposed Jacobian-based Saliency Map Approach (JSMA) that finds a feature that has the highest overall impact on leading a classifier to an aimed wrong class label at each iteration under the L_0 (or L_1 according to the termination condition) norm constraint.

L_∞ norm constrained approaches (e.g., FGSM and PGD) add perturbations to each dimension of the entire feature space; thus, it is difficult to apply these methods directly to EHR data given the sparseness of the feature space, where non-zero values are rare. We show the perturbation distribution generated by PGD from EHR data in Section 5. For both the discrete and sparse feature space we selected L_0 or L_1 as the options for the target domain, where the proposed method LAVA is optimized under L1 objective.

3 BACKGROUND

3.1 Jacobian-based Saliency Map

The Jacobian-based Saliency Map Approach (JSMA) [22] finds a feature that has the highest overall impact on leading a classifier to a targeted wrong class label at each iteration. Given $F : \mathbb{R}^d \mapsto \mathbb{R}^s$, a neural network that maps an input vector $\mathbf{x} \in \mathbb{R}^d$ to probabilities over s classes, x_k is the k-th element of the input vector $\mathbf{x}$, and F_r is the model output probability for the class r w.r.t. the input $\mathbf{x}$, the Jacobian matrix of the model is computed as the forward derivative of the neural network, where the element at the k-th column and the r-th row is denoted as $\mathbf{J}_{rk}$, is given by $\mathbf{J}_{rk} = \frac{\partial F_r}{\partial x_k}$. Assuming that t is the target class that an adversary wants the neural network model incorrectly classify the input $\mathbf{x}$ into, a *target class saliency* A_k and an *overall non-target classes saliency* B_k for feature k are given by

$$A_k = \mathbf{J}_{tk} = \frac{\partial F_t}{\partial x_k}, \quad B_k = \sum\nolimits_{r \neq t} \mathbf{J}_{rk} = \sum\nolimits_{r \neq t} \frac{\partial F_r}{\partial x_k}. \tag{1}$$

We can then construct a saliency map $S(\mathbf{x}, t)$ based on A_k and B_k to search candidate features. The JSMA is applicable to craft adversarial example from EHR data since it perturbs one feature at each iteration. However, it only searches along one direction (i.e., either increasing or decreasing) and thus is not adequately efficient given the very high feature space in EHR data.

3.2 Neural Attention Mechanism

The attention mechanism is increasingly used to understand what part of spatial or temporal information contributes most in predicting target values. It is widely used applications for computer vision [18, 28], natural language processing [1, 11], and speech recognition [6]. When introduced to EHR modeling, attention weights indicate the degree to which past clinical events predict disease onsets or future events [3, 16]. Choi et al. [4] proposed a model architecture with a dual-level attention mechanism, RETAIN, which calculates attention weights at the visit and feature (embedding) levels to compose the context vector for the final predictions. In this current

[1]White-box means both training data and the model architecture are available to the attackers.
[2]Gray-box refers to the setting where model architectures are unknown but training data are available to the attackers.

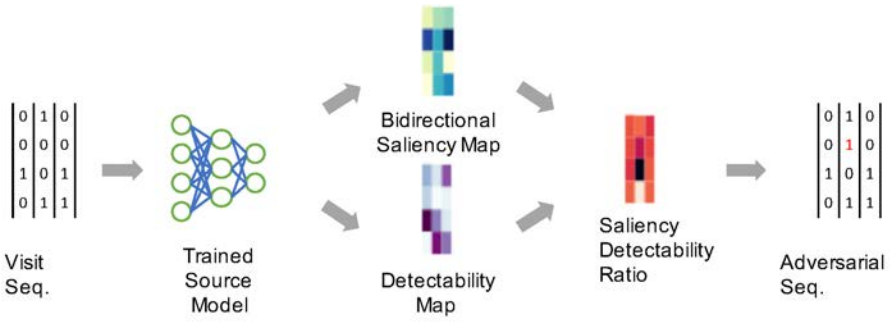

Figure 1: Crafting iteration of LAVA. LAVA balances the effectiveness of the attack through the bidirectional saliency and the detectability of the attack over longitudinal EHR data. Given a trained model and an input visit sequence of a patient, LAVA calculate both the bidirectional saliency score and the detectability cost for each feature at each visit. LAVA increases or decreases the binary feature value that has the highest saliency-to-detectability ratio at a specific visit. This procedure is iteratively performed until it satisfies stopping criteria.

work, we have adopted the RETAIN architecture to capture both visit and feature level significance and use this information to estimate the likelihood of perturbations to be discovered by a target model or defender.

4 LAVA: LONGITUDINAL ADVERSARIAL ATTACK

Given longitudinal EHR data from N patients, denote $\mathbf{x}^{(n)}$ as the clinical trajectory of patient n, which is characterized by a sequence of T^n hospital visits. Then $\mathbf{x}^{(n)}$ can be formulated as given by Eq. 2.

$$\mathbf{x}^{(n)} = \left\{\mathbf{x}_1^{(n)}, \mathbf{x}_2^{(n)}, \dots \mathbf{x}_{T^n}^{(n)}\right\} \tag{2}$$

where $\mathbf{x}_i^{(n)} \in \mathbb{R}^d$ denotes the concatenation of medical codes (often binary encoded) of the i-th visit made by patient n. In the following, we omit the superscript (n) to reduce clutter (e.g., represent $\mathbf{x}^{(n)}$ as $\mathbf{x}$, and $\mathbf{x}_i^{(n)}$ as $\mathbf{x}_i$). We also denote $x_{i,k}$ as the k-th dimension of the i-th visit $\mathbf{x}_i$ for a patient. Then, for a given patient records $\mathbf{x}$, a trained model F, and an original label $y = F(\mathbf{x})$, crafting adversarial example from longitudinal EHR requires finding a perturbation $\delta_\mathbf{x}$:

$$\underset{\delta_\mathbf{x}}{\operatorname{argmin}} \|\delta_\mathbf{x}\|_p \quad \text{s.t. } F(\mathbf{x} + \delta_\mathbf{x}) = \tilde{y} \neq y \tag{3}$$

The resulting adversarial example $\tilde{\mathbf{x}} = \mathbf{x} + \delta_\mathbf{x} = \{\tilde{\mathbf{x}}_1, \tilde{\mathbf{x}}_2, \dots \tilde{\mathbf{x}}_T\}$ can have $\tilde{\mathbf{x}}_i \neq \mathbf{x}_i$ and $\tilde{x}_{i,k} \neq x_{i,k}$ for any k-th feature in any i-th visit.

4.1 Overview

We propose LAVA as an adversarial examples crafting method for discrete and sequential EHR data. LAVA iteratively searches features from selected clinical visits that are suitable as adversarial examples as defined by a higher ratio of the sensitivity to fool a given model over the likelihood of the attack being detected. LAVA executes the following sequential procedure.

- Computes the **bidirectional saliency score** of each feature at each visit for perturbation to measure suitability as an adversarial example.
- Computes the **detectability cost**, which is the likelihood that modification to a feature will be detected.
- Calculates the **saliency-to-detectability ratio** to determine which feature at a specific visit is optimal to be perturbed.

This procedure is iteratively performed until it satisfies stopping criteria. Figure 1 depicts the overall process pipeline for an iteration of LAVA, and the details of each step are described in the following sections.

4.2 Bidirectional Saliency Score

To find the most prominent feature that contributes to the current classification result, we propose the *bidirectional saliency score* that rearranges and combines the computation of increasing and decreasing saliency map [22] with a minimal additional computational cost. We first derive a bidirectional saliency map for non-sequential data first, then extend it to sequential data.

Non-sequential Data. Given (1), the bidirectional saliency map $S(\mathbf{x}, t)$ for the input $\mathbf{x}$ and the target label t is given by (4).

$$S(\mathbf{x}, t)[k] = \operatorname{sgn}(B_k) \min(0, A_k B_k) \tag{4}$$

Here a positive valued $A_k B_k$ indicates two possible cases: both A_k and B_k are either positive or negative simultaneously, such that feature x_k has the impact on the probabilities of target class and non-target classes toward the same direction (e.g., increase or decrease). To avoid this ambiguity, we limit $A_k B_k$ to negative values only where the feature x_k has opposing directional effect on the target class and on the non-target classes. When this condition arises, a saliency score has a sign that is opposite to the sign of B_k but same as the sign of A_k since the resulting value of $\min(0, A_k B_k)$ is always negative. Consequently, this single bidirectional saliency map $S[k]$, omitting $\mathbf{x}$ and t, indicates which direction of perturbation on the k-th dimension of the input feature leads to a higher probability that the input is classified as the target class t with its relative strength given by the value of $S[k]$.

Sequential Data. For sequential data such as the longitudinal EHR sequence in our study, we firstly represent it as Eq. 2, then we adopt a RETAIN architecture [4], an RNN-based attention model,

to be the source model for crafting adversarial examples, and extend the bidirectional saliency method to handle sequential data. In particular, we extend the forward derivative, the Jacobian matrix whose element is given by $\mathbf{J}_{rk}$ in Section 3, to a sequential input for a recurrent neural network. Computing the forward derivative through a recurrent neural network is straightforward; any recurrent connections can be unrolled and transformed into a directed acyclic graph (DAG), and the partial derivatives of output with respect to input at each visit on the unrolled computational graph can easily be taken [8]. Thus, a Jacobian matrix can be computed for each visit, and they can be represented together as a tensor form with an additional time axis. Consequently, each element of the forward derivative and the corresponding target and non-target saliency are formulated as (5)–(7).

$$\mathbf{J}_{rik} = \frac{\partial F_r}{\partial x_{i,k}} \tag{5}$$

$$A_{ik} = \mathbf{J}_{tik} = \frac{\partial F_t}{\partial x_{i,k}} \tag{6}$$

$$B_{ik} = \sum\nolimits_{r \neq t} \mathbf{J}_{rik} = \sum\nolimits_{r \neq t} \frac{\partial F_r}{\partial x_{i,k}} \tag{7}$$

where $x_{i,k}$ is the k-th coordinate of the input vector at time i. As a result, a bidirectional saliency score map where each element is a score for each k-th feature at each i-th input $\mathbf{x}_i$ of a sequential input $\mathbf{x}$ can be obtained simply by (8).

$$S[i,k] = \operatorname{sgn}(B_{ik}) \min(0, A_{ik} B_{ik}) \tag{8}$$

Assuming that each visit vector $\mathbf{x}_i$ is a binary vector where each $x_{i,k}$ can have only either 1 or 0, we apply a restriction that a feature valued at 0 will not decrease and valued at 1 will not increase. Thus the bidirectional saliency score for sequential data is given by (9).

$$S[i,k] = \begin{cases} \max(0, \operatorname{sgn}(B_{ik}) \min(0, A_{ik} B_{ik})), & \text{if } x_{i,k} = 0 \\ \min(0, \operatorname{sgn}(B_{ik}) \min(0, A_{ik} B_{ik})), & \text{if } x_{i,k} = 1 \end{cases}. \tag{9}$$

4.3 Detectability Cost

We formulate the *detectability cost* using the attention mechanism to measure the imperceptibility of perturbations where the lower cost indicates the lower chance that a perturbation will be detected. The attention mechanism is a widely used technique to pay more 'attention' to features influential on model decisions; significant changes in the amount of 'attention' on each event reflect either a critical event has been newly added or an existing important event has been removed. In particular, the impact of each $x_{i,k}$ on the final classification result is measured from the two-level attention weights by (10) following the derivation from [4]:

$$w_{ik} = \alpha_i \mathbf{W}(\boldsymbol{\beta}_i \odot \mathbf{W}_{\text{emb}}[:,k]) \tag{10}$$

where α_i is the attention weight on the i-th visit, $\boldsymbol{\beta}_i$ is an attention weight vector for all features $x_{i,k}$ of the i-th visit, $\mathbf{W}$ is the output weight matrix, $\mathbf{W}_{\text{emb}}$ is the weight matrix at the embedding layer, and $\odot$ denotes element-wise multiplication. Here we assume that an input vector $\mathbf{x}_i$ at time i is a binary vector. Similar to the computation of the saliency score in the previous section, the forward derivative of each w_{jl} with respect to each input feature $x_{i,k}$ can be obtained from the unrolled computational graph. Then, we define the detectability cost by

$$D[i,k] = \sum_{j,l} \frac{\partial w_{jl}}{\partial x_{i,k}} \tag{11}$$

which captures the overall amount of change of the impact by all features and all visits when the feature $x_{i,k}$ is perturbed.

4.4 Saliency-to-Detectability Ratio

Last, we calculate *Saliency-to-Detectability Ratio* (*SDR*) at each iteration, which is defined as a ratio between the normalized saliency score and the normalized detectability cost as given by (12)–(13).

$$SDR[i,k] = \frac{\hat{S}_{ik}}{\hat{D}_{ik}} \tag{12}$$

where

$$\hat{S}_{ik} = \frac{S_{ik}}{\max_{j,l} \left|S_{jl}\right|}, \quad \hat{D}_{ik} = \frac{D_{ik}}{\max_{j,l} \left|D_{jl}\right|}. \tag{13}$$

Consequently, the feature $x_{i,k}$ that has the maximum value of $SDR[i,k]$ is perturbed in the direction of the sign of $SDR[i,k]$ at each iteration. To conclude, we summarize the pseudo code of LAVA in Algorithm 1. The source code of LAVA is publicly available at https://github.com/ast0414/lava

Algorithm 1 LAVA (Longitudinal AdVersarial Attack)

F is a trained model, $\mathbf{x}$ is an input sequence, $\tilde{\mathbf{x}}$ is a crafted adversarial sequence, t is a target class/label, and M is the maximum number of distortions

Table 1: Descriptive statistics of EHR dataset

# total patients	30,742	Avg. # visits per patient	18.68
# case patients	3,409	Max. # visits per patient	246
# total visits	574,108	Avg. # codes per visit	3.27
# unique codes	17,081	Max. # codes per visit	47

Table 2: Model performances on the clean test set

Model	AUROC	AUPR	F1 Score	Accuracy
RETAIN-WHITE	0.851	0.495	0.465	0.821
RETAIN-GRAY	0.849	0.493	0.461	0.817
RNN	0.837	0.456	0.444	0.809
MLP	0.821	0.388	0.426	0.797

5 EXPERIMENTS

In this section, we evaluated the sequences with adversarial examples using different types of neural network models.

5.1 Setup

Data. We conducted all experiments using EHR data provided by Sutter Health. The dataset was originally constructed for a heart failure (HF) onset prediction study that consists of 30K patients (age 50-89) including 3K HF case patients chosen by a set of criteria described by Gurwitz et al. [10], Vijayakrishnan et al. [27] and 27K control patients matched by a set of criteria described by Choi et al. [5]. Patients data over an 18 month period were used in this study. The summary statistics of the data is described in Table 1.

Source model. To craft adversarial examples, we used the RETAIN [4] architecture with two independent GRU layers, each of which includes 128 hidden units and embedding layer of 128 dimensions.

Target models. To evaluate multiple aspects of the crafted adversarial examples, we considered the following white-box and gray-box target models. The white-box target model is identical to the source model that crafts adversarial examples. The gray-box models are ones with different architectures and/or different hyperparameters while they are trained using the same train data as the source model.

- *RETAIN-WHITE*: Pure white-box attack was evaluated on the exact same architecture and trained parameters as the source model.
- *RETAIN-GRAY*: A RETAIN model with a different set of hyperparameters was trained and evaluated on attacks. It has 256 hidden units for each GRU layer for visit and feature attention, and an embedding layer of 256 dimensions was used.
- *RNN*: An RNN model without attention mechanism. It includes two GRU layers, each consisting of 128 hidden units, and an embedding layer of 128 dimensions.
- *MLP*: A multi-layer perceptron (MLP) model that was trained on aggregated feature vectors where a patient is represented by a single vector without temporal information. Then, the crafted sequential adversarial examples were also aggregated for each patient and passed into the trained MLP. The MLP model consists of three hidden layers, each of which consists of 128 hidden units.

Baseline methods. We compare LAVA with the following crafting algorithms.

- LAVA *w/o detectability*: We used non-penalized saliency scores only to find a candidate feature at each iteration. In other words, this algorithm is equivalent to LAVA where the detectability costs for all feature over the visits are equal to one.
- *PGD*: Adversarial examples were crafted by Projected Gradient Descent [13], where we set the step size as 1 and limit feature space as binary.
- *Random*: At each iteration, a visit was randomly selected from the sequence of visits, and a feature, a medical code, was chosen also randomly to be perturbed.

Implementation details. All models were implemented using PyTorch 0.3 [23] and trained with a system equipped with Intel Xeon E5-2683v4 CPU, 756GB RAM, and Nvidia Tesla P100 GPU. We used Stochastic Gradient Descent (SGD) with momentum [25] for optimization. The momentum value was set to 0.9. The initial learning rate was set to 0.01 and was reduced by a factor of 10 once the learning stagnated.

5.2 Attack Evaluation

As a contrast, we first show how these target models perform on unperturbed data. Table 2 shows that all models achieved accurate predictions of a future HF diagnosis when using unperturbed test data. Figure 2 compares the performance of different craft algorithms by the extent to which they reduce prediction performance as defined by the Area Under Precision-Recall curve (AUPR).

- For attention based target models such as RETAIN-WHITE and RETAIN-GRAY, LAVA achieved the best performance drop and was able to beat the state-of-the-art gradient-based method, PGD, after 12 iterations.
- For some models (e.g., RNN and MLP) and during early iterations of attention models, LAVA caused less AUPR drop than LAVA w/o detectability, the non-penalized saliency score method. This is due to the fact that saliency score methods often perturbed the most critical feature, while LAVA avoids such perturbation. During interactive attack and defense, perturbing most critical features will again be easily caught. While LAVA address this concern, it still achieved good AUPR drops.
- Although PGD showed good performances in some settings, it perturbs a large number of features (1,650 per visit in our experiment) even in the first iteration. While LAVA is cost-sensitive, it only perturbs one feature at a time.
- Moreover, the random perturbations barely have any influence on the performance for all settings.

5.3 Perturbation Analysis

We evaluated the perturbations made by each algorithm to determine effectiveness and the ease of detection (i.e., from the EHR system perspective that is a target of an adversarial attack). Figure 3 shows how the perturbations in the adversarial examples crafted by each algorithm are distributed over the visit and feature

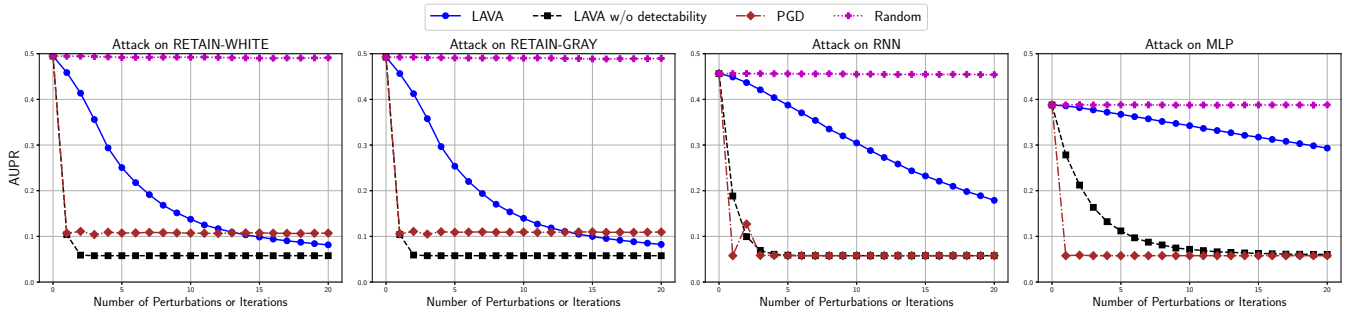

Figure 2: Comparison of the different types of attack on each target model.

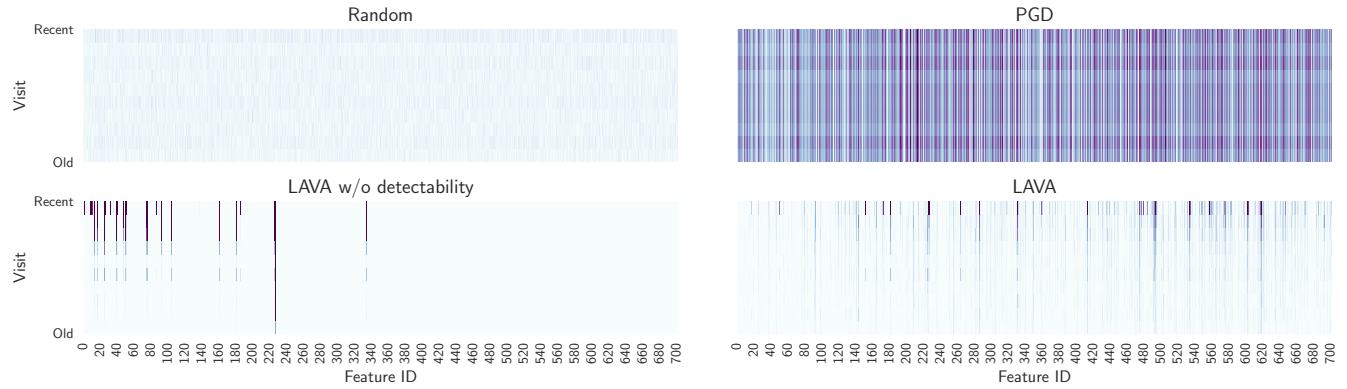

Figure 3: Comparison of perturbations by the different types of attack. The x-axis represents features ordered by feature ID. The y-axis represents visits in chronological order from the bottom to the top. Each heatmap depicts how the adversarial perturbations by each algorithm are distributed over the visits and features in the sequential EHR data. The white color means no perturbation and the darker color represents the more perturbations.

dimension of the test sequential EHR data. Random attacks spread perturbations over the entire visit and feature space, but each perturbation holds no meaningful attraction for the models since it was crafted in a purely random manner. PGD attacks also crafted perturbations over the entire space and are densely distributed, influencing almost every feature in every visit. PGD attacks would be easily discovered by a defender (e.g., an administrator of the EHR system that might be human or machine). Moreover, PGD attacks may be treated as a system malfunction since it may seem the data themselves are scrambled. On the contrary, the perturbations in the adversarial examples crafted using non-penalized saliency scores are concentrated on a few certain features in relatively recent visits. Thus, the administrator of a machine learning based EHR system can monitor and pay attention to only those particular features to make provisions against potential adversarial attacks by non-penalized saliency methods. Adversarial examples crafted by LAVA have perturbations spread wider than those made by the algorithm without detectability costs although the recent visits are still highlighted slightly more than the others. Hence, the administrator may need to monitor the system more carefully to figure out the existence of adversarial attacks; otherwise, it might be misunderstood for random noises that are naturally inherent in the data. In conclusion, it is shown that LAVA crafted the adversarial examples for sequential EHR data, where it is difficult to detect their existence in terms of the distribution of the perturbations over both visit and feature spaces.

6 CONCLUSION

In this work, we propose LAVA to craft adversarial examples on longitudinal EHR data. We compared the attack result by LAVA with other attacks. It is shown that the adversarial examples crafted by LAVA perform effective attacks toward white-box and gray-box target models. Moreover, it is also shown that the adversarial examples crafted by LAVA are relatively well spread over the visits and the feature space; it would be more difficult to detect such attacks generated by LAVA than other attacks. As future work, we plan to design and compare different defense mechanisms to provide better guidance on how to alleviate the adversarial attacks on longitudinal EHR data.

ABSTRACT

Story timeline summarization is widely used by analysts, law enforcement agencies, and policymakers for content presentation, story-telling, and other data-driven decision-making applications. Recent advancements in web technologies have rendered social media sites such as Twitter and Facebook as a viable platform for discovering evolving stories and trending events for story timeline summarization. However, a timeline summarization structure that models complex evolving stories by tracking event evolution to identify different themes of a story and generate a coherent structure that is easy for users to understand is yet to be explored. In this paper, we propose StoryGraph, a novel graph timeline summarization structure that is capable of identifying the different themes of a story. By using high penalty metrics that leverage user network communities, temporal proximity, and the semantic context of the events, we construct coherent paths and generate structural timeline summaries to tell the story of how events evolve over time. We performed experiments on real-world datasets to show the prowess of StoryGraph. StoryGraph outperforms existing models and produces accurate timeline summarizations. As a key finding, we discover that user network communities increase coherence leading to the generation of consistent summary structures.

1 INTRODUCTION

With the increasing explosion of Web 2.0 technologies, social media sites such as Twitter, Facebook and Weibo have provided a vast continuous supply of diverse information content [2, 4, 14, 16]. These sites provide functionalities for users to share and broadcast information on fashion trends, political debates, breaking news and other issues of interests [8, 17, 18, 28]. However, with the overwhelming amount of information generated from social media, it has become difficult for news analysts, law enforcement agencies and policymakers to obtain a summarative perspective of the large amount of information on trending topics, news stories and events.

A prevailing solution is to organize and present stories in a summarization timeline for easy comprehension [1, 14, 16, 23, 28]. This provides a better understanding of how events evolve throughout the life cycle of a story [8, 16, 23, 28], as well as reveal the flow and evolution of the various themes that make up a story. Such summaries help users to understand the general information of the story in a more concise and logical manner [14, 16].

Motivating Example. Figure 1 is a graph illustrating a story of the popular *"Black Lives Matter"* protest from Aug. to Nov. 2014 in the US. Each distinct colour represents a theme in the story graph. For example: all the green nodes represent related events that evolved in *Ferguson Missouri*; all orange coloured nodes are events related to the *shooting of Michael Brown*. Each node in this graph (i.e. the StoryGraph proposed in this paper) represents an event σ, and a connection between two events represents an event evolution in the story. For example, the path $\sigma_2 \rightarrow \sigma_{16}$ tells the story of the events that emerged from the *Ferguson Missouri protests* leading to the *formation of the Ferguson Committee*. As shown in Fig.1, it is of no doubt that modeling the evolutionary connections between events into a summarization timeline structure can help users to learn the main information quickly. However, developing such comprehensive summarization from the massive volume of social media posts inundated with spam and diverse range of events is like *"finding a needle in a haystack"* [9, 14, 28, 29].

In the attempts to solve timeline summarization problems, Traditional Document Summarization (TDS) [12, 21, 25] has been extensively studied with increasing popularity in many domains [6, 12]. In these lines of research [16, 21, 25, 30], the objective is to provide a curative summary of documents, news reports and articles over a period of time to tell the story of how events evolve. Despite the successes in developing novel TDS techniques to generate timeline summaries, TDS approaches are however not effective in

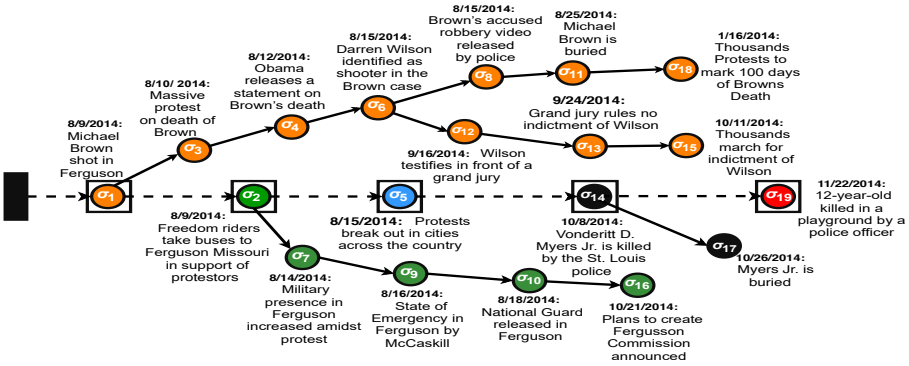

Figure 1: The StoryGraph of the *Black Lives Matter* protests from August to November 2014

handling data from social media sites such as Twitter for timeline summarization due to a number of reasons.

First and foremost, traditional documents such as news reports are well written, proof read by professionals and usually have a writing structure (i.e headlines, paragraphs, body, etc) which provides important cues for summarization [11, 22]. Tweets, on the other hand are highly unstructured. Secondly, tweets are very short, and often do not provide sufficient statistical information and context for robust similarity measures [10]. Furthermore, with the daily massive volume of tweets swamped with spam, it has become increasingly difficult to sort through the hundreds of breaking news events on Twitter and track their evolution to generate timeline summaries [11, 22]. These properties of Twitter data do not only make it difficult to apply TDS techniques, but also manifest a new research challenge for event storyline summarization.

Recent works [9, 14, 28, 29] have attempted to solve the timeline summarization problem using social media. However these models suffer from two main limitations. 1) Their output structures are usually flat timeline structures which are unable to capture the different themes in a larger story. For example, stories like the *"Black Lives Matter"* protest in Fig.1 have different themes that make up the bigger story. A flat timeline structure will connect node σ_6 to σ_7. However, these two event evolutions are totally different and have no logical connection even though they are part of the *"Black Lives Matter"* protest story. 2) The flat timeline models are incapable of presenting the complex evolution relationships between events thus resulting in incomprehensible story summaries devoid of any logical connection between the events.

Developing models to resolve these limitations will aid in the generation of comprehensible story timeline structures. Addressing these problems is non-trivial as it requires the construction of summarization timeline structures with coherent paths, while maintaining logical consistency. This will help users to understand the story in a more concise and logical manner.

To achieve this goal, we propose a novel summarization framework called StoryGraph. Given a set of tweets from the Twitter stream, StoryGraph uses an information propagation based algorithm [4, 5] to detect and extract events with high coherence from online communities in Twitter. Once these events are extracted, we carefully design high penalty metrics using temporal proximity of events, semantic contents, and user community membership. Using Fig.1 as an example, our solution identifies nodes (events) $\sigma_1, \sigma_2, \sigma_5, \sigma_{14}$ and σ_{19} as the starting events of the main themes in the story. StoryGraph further uses coherence and topic drifting metrics to build coherent timeline paths in the summary structure such that each path provides a comprehensive evolution of events related to a specific theme in the story.

While storyline summarization using social media has been attempted in previous works, to the best our knowledge, this is the first work that proposes a comprehensible summarization timeline structure that leverages: user communities, textual content and temporal metrics to model the event evolution relationships and present event summary as a graph. StoryGraph is able to identify the different aspects of a story as the story evolves.

Our main contributions can be summarized as:

- We formally define and formulate a novel graph timeline summarization structure that is capable of identifying and representing the different themes of a story.
- We design high penalty metrics to capture evolving events in communities to construct coherent paths in our summarization structure.
- We develop StoryGraph, a comprehensive summarization framework to generate summaries to tell the story of how events evolve over time. We perform extensive experiments on real-world datasets to show the prowess of our methods.

2 NOTATION AND PROBLEM DEFINITION

In this paper, we focus on timeline summarization of evolving stories using information spreading on Twitter. It is however worth mentioning that the models and formulations can be extended to other social networks such as Sina Weibo and Facebook.

We model the Twitter follower network as a graph $G_N = \langle V_N, \mathbf{E}_N \rangle$, where $V_N = \{u_1, u_2, ..., u_n\}$ represents a set of n Twitter users, and $\mathbf{E}_N \subseteq V_N \times V_N$ is the set of directed edges, and an edge $u_i \rightarrow u_j$, denotes that user u_j is a follower of user u_i on Twitter. As users post tweets, information propagates from one user to another in the network. We represent the tweet stream containing tweets as $\mathcal{D} = \{d_1, d_2, ..., d_m\}$, from which we seek to extract event set $\Sigma = \{\sigma_1, \sigma_2, ..., \sigma_k\}$ in a given time period $T_s - T_f$. Each event σ_i can be represented as $(\mathbb{W}_i, \tau_i)$, where $T_s \leq \tau_i \leq T_f$ is the timestamp of σ_i and $\mathbb{W}_i = \{w_1, w_2, ..., w_{|\mathbb{W}_i|}\}$ is the event lexis comprising of a set of words. We aim to construct a story graph to represent the development of the events in Σ.

To clearly present our problem, we firstly define some key concepts that are crucial to the proposed StoryGraph framework.

Story: A story consists of a set of events that revolve around a particular subject or concept during a specific period of time. An example of a story is the *"US presidential election"*, *"Black Lives Matter"* protest, etc. A story usually has different topic themes.
Topic Theme: A topic theme is a specific aspect/subject of a story. For example in Fig. 1, conversations about *Michael Brown* (i.e., $\sigma_1 \rightarrow \sigma_{15}, \sigma_{18}$) is one topic theme in the story graph.
Event: An event is an incident that occurs at a specific time [30], represented as $\sigma_i = (\mathbb{W}_i, \tau_i)$.

Thus, we have the hierarchy: Story →Topic Theme → Event.

More formally, we present the following definitions. Let $Sim(\sigma_i, \sigma_j)$ be a metric that returns the similarity of two events σ_i, σ_j.

*Definition 2.1 (**Related Events**).* Given a user-specified threshold $\lambda \in [0, 1]$ two events σ_i, σ_j are *related* iff. $Sim(\sigma_i, \sigma_j) \geq \lambda$. □

In our story graph, a group of related events form a topic theme. A topic theme can be thought of as the subject of a cluster of related events in the story graph.

*Definition 2.2 (**Topic Theme**).* A topic theme ϑ is a distribution of words generated by a set of *related* events. □

Intuitively, a set of related events $\Sigma' = \{\sigma_1, \sigma_2, ..., \sigma_{k'}\}$ belong to the same topic theme, and share similar words distribution.

*Definition 2.3 (**Topic Theme Node**).* Given $\Sigma' = \{\sigma_1, \sigma_2, ..., \sigma_{k'}\}$ of temporally ordered related events, the *topic theme node* is the first event σ_1 in Σ'. □

A topic theme node initiates a theme in the story graph. From Fig.1, *shooting of Michael Brown* (σ_1), is the topic theme node of the topic theme *Michael Brown*. Also, the other topic theme nodes in the story graph are $\sigma_2, \sigma_5, \sigma_{14}$ and σ_{19}.

*Definition 2.4 (**Topic Theme Path** ψ).* Given a set of related events $\Sigma' = \{\sigma_1, \sigma_2, ..., \sigma_{k'}\}$, a topic theme path is a sequence of directed edges from the topic theme node σ_1 to all events in Σ'. □

Figure 1 shows the three topic theme paths that can be found in the story graph. A topic theme path is said to be *coherent* if every pair of consecutive events are related.

*Definition 2.5 (**Coherent Score** Γ).* The coherence score of a topic theme path is a measure of the theme consistency [25] along its path of related events $\Sigma' = \{\sigma_1, \sigma_2, ..., \sigma_{k'}\}$, and is given by:

$$\Gamma(\sigma_1, \sigma_2, ..., \sigma_{k'}) = \frac{1}{|k' - 1|} \sum_{i=1}^{|k'-1|} Sim(\sigma_i, \sigma_{i+1}). \quad \square$$

*Definition 2.6 (**Timeline Path**).* A timeline path is a temporally ordered sequence of topic theme nodes in a story graph. □

A timeline path connects different topic themes in a story graph. Thus, given any evolving story, a timeline path shows the various distinct topic themes that make up the story. For example, in Fig. 1, the timeline path is: $\sigma_1 \rightarrow \sigma_2 \rightarrow \sigma_5 \rightarrow \sigma_{14} \rightarrow \sigma_{19}$.

We proceed to define a story graph in Definition 2.7, following the definition of all relevant concepts.

*Definition 2.7 (**Story Graph**).* A story graph is a directed graph $\mathbf{G} = (\Sigma^G, E)$, with a set of nodes $\Sigma^G \subseteq \Sigma = \{\sigma_1, \sigma_2, ..., \sigma_k\}$ and edge set E. The node set Σ^G of a story graph is such that $\Sigma^G = \Sigma^G_T \cup \Sigma^G_E$, and $\Sigma^G_T \cap \Sigma^G_E = \emptyset$, where Σ^G_T represents the set of topic theme nodes and Σ^G_E represents the set of event evolutions. A directed edge $\sigma_i \rightarrow \sigma_j$ from node σ_i to σ_j indicates a temporal and/or a semantic relationship between two events s.t $\forall\, \sigma_i \rightarrow \sigma_j \in E, \tau_i < \tau_j$. The edge set $E \in \mathbf{G}$ is such that $E \subseteq \Sigma^G \times \Sigma^G \setminus \left(\Sigma^G_E \times \Sigma^G_T\right)$. □

Our goal is to develop a comprehensive and coherence structure that can capture the event evolution of the various themes of a bigger story. Stories contain different topic themes that evolve as new events emerge [14, 16]. For any given story, we expect our solution to identify the main topic themes and capture how the events on each topic theme evolve. For example, given the *"Black Lives Matter"* protest (Refer to Fig.1), we expect our timeline summarization structure to identify the Fergusson protest (node σ_2) as a topic theme node and capture the series of aftermath related events (nodes $\sigma_7, \sigma_9, \sigma_{10}, \sigma_{16}$). The StoryGaph proposed in this paper presents a structural timeline summarization of events evolution on a general story as shown in Fig.1

*Definition 2.8 (**Problem Statement**).* Given a tweet stream $\mathcal{D} = \{d_1, d_2, ..., d_m\}$ containing tweets published by users in the Twitter follower network $G_N = \langle V_N, \mathbf{E}_N \rangle$ over a period $T_s - T_f$, the goal of this paper is to construct a StoryGraph $\mathbf{G} = (\Sigma^G, E)$ using the event set $\Sigma = \{\sigma_1, \sigma_2, ..., \sigma_k\}$ extracted from the Tweets such that all the topic theme paths are coherent. □

3 STORY GRAPH CONSTRUCTION

In Fig. 2 is an overview of our StoryGraph framework. The framework accepts tweets over a period and the follower network relationships as input. Recall, that structural timeline summarization involves two main steps [16, 30]: 1) extracting candidate events, and 2) using the events to build a comprehensive summarization structure. To achieve this, StoryGraph constructs propagation trees and leverages bursty tree detection [5] to extract events with high coherent word-distribution from online communities. These events are used as conduits for generating our structural timeline summaries. The next subsections present details of the steps.

3.1 Event Extraction from Communities

The goal here is to extract events from the online Twitter communities. To achieve this goal, we adopt and extend SensorTree [5], an event detection method capable of extracting coherent events using burst from online communities.

Given a set of tweets over a time period as input, we construct propagation trees [4] which effectively capture information diffusion among users in a community. The trees represent communities of online social media users who are discussing events of interest. The nodes of the trees are users in the community and the edges represent the adoption of information among users in a community.

We incorporate user community membership as a feature to increase the confidence of finding topic themes of related events for our StoryGraph construction. This enriches our feature set and helps to overcome limitations posed by relying solely on text (tweet content) [5, 26].

We design a feature vector to help us get our desired output.

*Definition 3.1 (**Event Feature Vector**).* Given an extracted event σ, its event feature vector is a tuple, $\overrightarrow{\sigma} = (U_l, \mathbb{W}, \tau)$, where:

- U_l is a list of the community membership in which the event was detected;
- $\mathbb{W}$ is a word distribution describing the event;
- τ is the timestamp indicating when the event was detected.

□

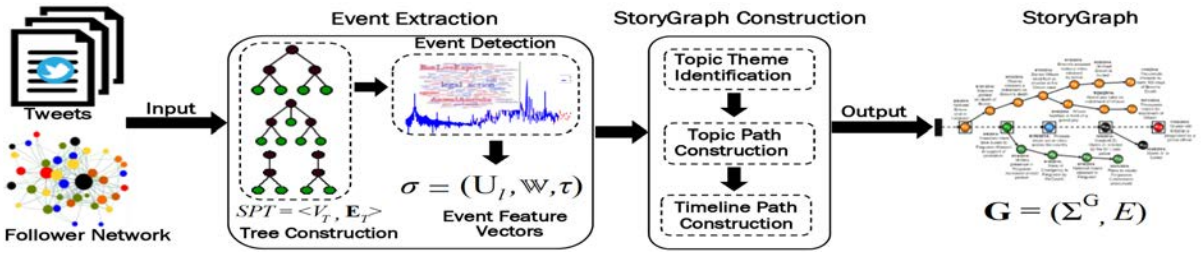

Figure 2: Framework Overview of StoryGraph

The event feature vector $\vec{\sigma}$ provides a feature rich vector that covers user community relationships, textual and temporal information on extracted events.

Given a set of tweets $\mathcal{D} = \{d_1, d_2, ..., d_m\}$ published during a given time period $T_s - T_f$, we construct semantic propagation trees [5], $SPT = \langle V_T, \mathbf{E}_T \rangle$, where $V_T = \{(u_i, [(c_i, t_i)]) \,|\, u_i \in V_T, [(c_i, t_i)] = [(c_{i_1}, t_{i_1}), (c_{i_2}, t_{i_2}) \cdots (c_{i_Q}, t_{i_Q})]\}$ represents users u_i, the contents c_i and the timestamps t_i of their posts, and the edge set is $\mathbf{E}_T = \{(u_i, [(c_i, t_i)]) \rightarrow (u_j, [(c_j, t_j)]) \,|\, u_i \rightarrow u_j \in \mathbf{E}, t_{i_1} \leq t_{j_1}\}$. We set the time window $\top = 60min$, once the burst threshold ϕ is obtained in any tree, an event description model using tensor decomposition [3] outputs word distribution and parses it into $\vec{\sigma}$. We query the node list of the community in which the event was detected to output the event feature vector $\vec{\sigma} = (U_l, \mathbb{W}, \tau)$ for that event.

The **EventExtract** block (Algorithm 1, lines 1-10) shows the pseudocode for extracting events and obtaining the event feature vector. Line 9 outputs a candidate event set $\Sigma = \{\sigma_1, \sigma_2, ..., \sigma_k\}$ which is represented by their corresponding event feature set vector $\vec{\sum} = \{\vec{\sigma_1}, \vec{\sigma_2}, ..., \vec{\sigma_k}\}$ to build a story graph. The event feature set vector $\vec{\sum}$ holds the features vectors of all the events extracted.

Algorithm 1 StoryGraph Algorithm

Input: tweets stream $\mathcal{D} = \{d_1, d_2, \ldots, d_m\}$ over $T_s - T_f$; G_N

Output: StoryGraph, $\mathbf{G} = (\Sigma^G, E)$.

1: **EventExtract:** Initialize $\mathcal{D} = \{d_1, d_2, \ldots, d_m\}$
2: → Sort $\mathcal{D}$ in temporal order
3: → Construct $SPT = \langle \boldsymbol{\mathcal{V}}_T, \mathbf{E}_T \rangle$ using extended [5]
4: → Vary $\top$ to optimum threshold and compute burst score
5: → Extract detected event set $\Sigma = \{\sigma_1, \ldots, \sigma_k\}$
6: **for** $\sigma_i \in \Sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_k\}$ **do**
7: *Generate tensorized feature word-distribution* $\mathbb{W}$ [3]
8: *Extract* $\vec{\sigma} = (U_l, \mathbb{W}, \tau)$
9: *Query* $\Sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_k\}$, $\vec{\sum} = \{\vec{\sigma_1}, \vec{\sigma_2}, \ldots, \vec{\sigma_k}\}$
10: **end for**
11: **SGConstruct** : Load $\vec{\sum} = \{\vec{\sigma_1}, \vec{\sigma_2}, \ldots, \vec{\sigma_k}\}$
12: → Sort $\Sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_k\}$ in temporal order s.t. $\tau_i \leq \tau_j$
13: → Set $\sigma_1 \in \Sigma$ as first topic theme node $\vartheta \in \Sigma_T^G$
14: **for** $\vec{\sigma} \in \vec{\sum} = \{\vec{\sigma_1}, \vec{\sigma_2}, \ldots, \vec{\sigma_k}\}$ **do**
15: *Compute* $F_{Rel}(\vec{\vartheta}, \vec{\sigma})$
16: **if** $F_{Rel}(\vec{\vartheta}, \vec{\sigma}) > \lambda$
→ Append and update $\vec{\sigma}$ with $\vec{\vartheta}$
→ *Check* **Node Merge Criterion** *to merge* (Definition 3.2)
→ Compute *PC* (Eqn. 3) *to append new child node* and update Σ_E^G
17: **else**
Set σ *as new topic theme node* and update Σ_T^G
18: **end for**
19: → *Align topic theme nodes* Σ_T^G *on time line path in chronological order*
20: **return** $\mathbf{G} = (\Sigma^G, E)$.

3.2 StoryGraph Construction

The input for our story graph construction phase **SGConstruct** (i.e, Algorithm 1, lines 11-20) is $\vec{\sum}$. To construct the story graph, we sort the candidate events feature vectors $\vec{\sigma_1}, \vec{\sigma_2}, ..., \vec{\sigma_k}$ using increasing temporal ordering such that $\tau_i \leq \tau_j$. The first event in $\vec{\sum}$ is chosen as the first topic theme node. For every incoming node, we apply a dual-component metric to detect its topic theme.

Topic Theme Identification: As described earlier, every candidate event has its own event feature vector $\vec{\sigma}$. To quantify the relatedness between an incoming event and the existing topic theme, we compute the feature relatedness F_{Rel}, between the topic theme feature vector $\vec{\vartheta}$ and the feature vector of the incoming event $\vec{\sigma}$. The feature relatedness F_{Rel} is given by:

$$F_{Rel}\left(\vec{\vartheta}, \vec{\sigma}\right) = \frac{1}{2}\left[D_{KL}(\mathbb{W}^{\vec{\vartheta}}||A) + D_{KL}(\mathbb{W}^{\vec{\sigma}}||A)\right] \times \frac{2U_l^c}{U_l^{\vec{\vartheta}} + U_l^{\vec{\sigma}}} \quad (1)$$

where $A = \frac{1}{2}(\mathbb{W}^{\vec{\sigma}} + \mathbb{W}^{\vec{\vartheta}})$ is the average of the two word distributions, and D_{KL} :

$$D_{KL}(\mathbb{W}||A) = \sum_{w \in |\mathbb{W}|} p(w|\mathbb{W}) \log \frac{p(w|\mathbb{W})}{p(w|A)} \quad (2)$$

is the *Kullback-Leibler* divergence [13] which measures distribution divergence of A from $\mathbb{W}$. U_l^c is the number of the common users in the community user list of $U_l^{\vec{\vartheta}}$ and $U_l^{\vec{\sigma}}$.

Equation 1 has two parts. The first part measures the text semantic similarity to determine if an event belongs to a particular topic theme. We utilized the *Jenson-Shannon divergence (JSD)* [19] to measure relatedness directly in $F_{Rel}(\vec{\vartheta}, \vec{\sigma})$ instead of $D_{KL}(\vec{\vartheta}||\vec{\sigma})$, because the *JSD* is a symmetrical and smoothed. The second part of the equation uses the *Sørensen-Dice coefficient* [27] to measure the community similarity between the incoming event and the topic theme community. We apply this dual-component criteria because the use of only textual content is not always reliable [7, 26]. Using community membership increases the confidence of obtaining coherence. The intuition here is that users in the same community have similar interest and are likely to have discussions on the same topic theme.

Equation 1 (F_{Rel}) is used to determine whether an incoming candidate event should be added to an existing topic theme node or not. If the relatedness $F_{Rel} \geq \lambda$, we can add the event to the related topic theme. Once we determine which topic theme an incoming event belongs to, we update the topic theme feature vector $\vec{\vartheta}$. Consequently, a topic theme vector becomes the summation of all the related event feature vectors. For example, given an existing topic theme with

topic theme feature vector $\overrightarrow{\vartheta_i} = \{(U_l^1, \mathbb{W}_1, \tau_1), ..., (U_l^k, \mathbb{W}_k, \tau_k)\}$. Using F_{Rel}, if an incoming event with feature vector $\overrightarrow{\sigma_j} = (U_l^j, \mathbb{W}_j, \tau_j)$ is found to be related to $\overrightarrow{\vartheta_i}$, then we append and update $\overrightarrow{\vartheta_i}$ with $\overrightarrow{\sigma_j}$. If the $F_{Rel} \geq \lambda$ criterion is not met, we create a new topic theme vector $\overrightarrow{\vartheta_j}$ with $\overrightarrow{\sigma_j}$ as the topic theme node.

Constructing the Topic Theme Path: After a candidate event has been identified to be related to a topic theme, the next step is to connect the candidate event to an existing node in the topic theme path of the related topic theme. One of our objectives is to reduce redundancy or duplication of events presented in the story graph. Thus we seek to merge nodes that discuss the same event. If two events are the same we merge their event feature vector as one event using the following criterion.

*Definition 3.2 (**Node Merge Criterion**).* Given a topic path ψ with a set of nodes $\sigma_1, \sigma_2, ..., \sigma_{k''}$, the merge operation combines an incoming node with an existing event in the topic theme path if: i) $\cos(\overrightarrow{\sigma}_i, \overrightarrow{\sigma}_j) = \frac{\mathbb{W}^i \cdot \mathbb{W}^j}{|\mathbb{W}^i| \cdot |\mathbb{W}^j|} \geq \beta$ (i.e., refers to the same event), where $\cos(\overrightarrow{\sigma}_i, \overrightarrow{\sigma}_j)$ is the similarity between the two word distributions, ii) and the two events occur within $\tau_j - \tau_i < \theta$. □

We set $\theta = 24hrs$. If a candidate event does not overlap with an existing node in the topic theme path, we find its parent node by computing the parent-child propensity score, *PC* in Equation 3. We design a matrix that stores the *PC* score. The *PC* score is the pairwise comparison of the incoming candidate event (potential child node) σ_i and the existing nodes (potential parent nodes) in the topic theme path. Given an incoming node σ_i that is related to $\overrightarrow{\vartheta_i}$ (i.e. has passed the F_{Rel} threshold test), and a potential parent node σ_j in the topic theme path, The *PC* score is given by:

$$PC(\sigma_i, \sigma_j) = ComSim \cdot t_d \cdot \Gamma \tag{3}$$

where $ComSim = \frac{|U_l^c|}{|U_l^{\overrightarrow{\sigma_j}}| + |U_l^{\overrightarrow{\sigma_i}}| - |U_l^c|}$ is the community similarity between the event child node and the potential parent node, the temporal distance score t_d:

$t_d(\tau_i, \tau_j) = \begin{cases} \frac{1}{(\tau_j - \tau_i)}, & \forall \tau_j - \tau_i > 0 \\ 0, & otherwise \end{cases}$ measures the time proximity between the two nodes. A bigger t_d score increases the possibility that a candidate event is connected to a parent. The third component of the *PC* score is the topic path coherence $\Gamma(\sigma_1, \sigma_2, ..., \sigma_{k'}) = \frac{1}{|k'|} \sum_{i=1}^{|k'|-1} \cos(\overrightarrow{\sigma}_i, \overrightarrow{\sigma}_j)$ measuring the theme consistency [29] along the theme path. For the candidate pair with the highest score in *PC* score matrix, we create an edge from the parent node to the incoming node in the topic theme path. The topic nodes are then aligned in chronological order in the story graph.

4 EXPERIMENTS

We present a detailed description of how the experiments were conducted, evaluated as well as the results obtained in comparison with existing state-of-the-art models.

4.1 Datasets and System Settings

We use four different and geographically diverse real world Twitter data sets for our experiments. Table 1 shows the information on our datasets[1]. With the exception of the FP-Datasets that was provided by the D2DCRC[2], all other datasets used in the work as well as the user follower network were crawled through the Twitter API.

We implemented and conducted all experiments using Python 3.2 and 3.6 on a Windows machine with 8GB Memory and a 64-bit Linux virtual machine with 6GB memory all running on an Intel(R) Core(TM) i5-4310m CPU 2.70Ghz processor.

Table 1: Dataset Description

Data sets	No. of Tweets	Network Size (No. of Nodes)
FP	200,756	12,243,427
USGH	100,000	854,626
Live Exports	3,200,000	8,202,053
USJM	5,200,000	13,202,724

4.2 Gold Standard Records (GSR)

To construct a GSR for evaluation, we search through popular news portals every day and record reported civil unrest events as ground truth. Each GSR entry represents a reported protest event with attributes such as protest event date, headline description, event summary, and news source. An event is recorded if more than three major news outlets cover a story on it. Table 2 shows sample entries in the GSR. As a preprocessing step, we remove stopwords and manually select keywords tokens to obtain a GSR keywords distribution which summarizes the real-word event. For every GSR summary, we expect the summarization models to produce some word token that matches the GSR summary.

4.3 Baseline and Comparison Methods

To evaluate the performance of our methods, we compare our solution to the following models:

1. TwitInfo [20]: explores and tracks events by aggregating tweets about the event using a peak detection algorithm.

2. ConnectingDots [25]: presents a chain structure that finds hidden connections to link coherent news articles together.

3. EventGraph [30]: uses a similarity threshold to calculate connection strength for event pairs to generate an event graph.

4. LDA+Temporal Ordering: We build a single LDA [6] topic model over the datasets and temporally order the events into a timeline chain as a baseline model. This method exemplifies the naive approach to solving the timeline structure summarization problem.

It is worth mentioning that ConnectingDots [25] and EventGraph [30] were originally designed to handle news articles. To level the playground for a fair comparison we build topical tweet clusters using the methods in [24]. These clusters are used as representative news articles. We then follow strictly the authors implementation in their published work and selected the parameter settings that yield the best results. Comparing our methods with ConnectingDots [25] and EventGraph [30] will help us further assess how models that are designed to handle news articles for summarization perform with Twitter data.

4.4 Performance Evaluation

In the first part, we evaluate the quality of the abstractive summaries generated using Recall-Oriented Understudy for Gisting Evaluation (ROGUE) metric [15] which has been demonstrated to be the most consistent with human judgement and effective for evaluating such

[1] data description available at https://github.com/vanslerry/dataDescription

Table 2: Sample coded GSR event entries by news analysts

Event ID	Date	Headline Description Summary	News Sources
FP-548662	2/05/2017	Freeport to reduce Indonesian Mining Activities	Kompass, Republica, Jarkarta Post
USGM-204201	28/03/2018	Thousands fill the streets to protest new Ghana-US defence deal	Joy News, TV3, GhanaWeb
Live Exports	18/06/2018	Protesters in Adelaide rally against live animals exports	ABC, News, Advertiser

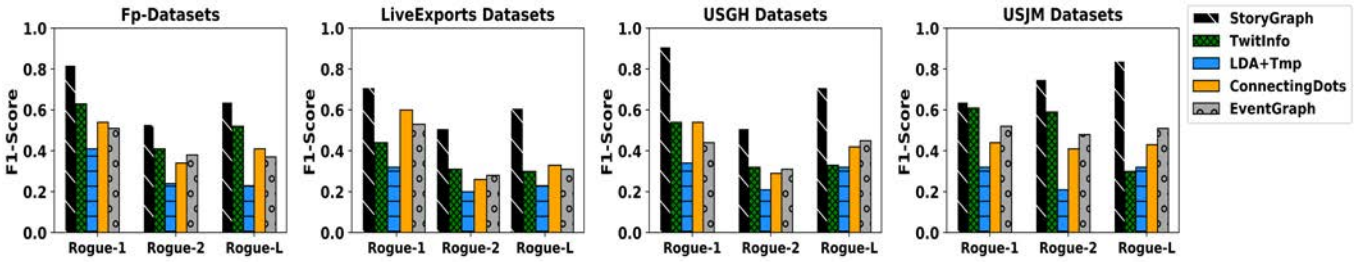

Figure 3: F1-Score on all Datasets

summaries. ROGUE measures the degree of overlap of the model's output with the ground truth. We use ROGUE-1, ROGUE-2 and ROGUE-L. For a fair comparison, we vary the vocabulary $\mathbb{W}$ size of output of the individual models, using $\mathbb{W} = 10, 20, 30, 40, 50$, to reduce bias on models that rely on word frequencies.

In the second part, we evaluate the output of the summarization structures generated by measuring the coherence between nodes in a topic path. This is achieved by computing the distance between the word vectors of the node-pairs which is given by: $C_T(\hat{c_i}, \hat{c_j}) = 1 - \frac{\hat{c_i} \cdot \hat{c_j}}{|\hat{c_i}|^2 + |\hat{c_j}|^2 - \hat{c_i} \cdot \hat{c_j}}$, where are c_i and c_j are the word vector pairs whose coherence is to be determined. This metric also indirectly measures the validity of an edge between two nodes in a path.

5 RESULTS AND DISCUSSIONS

Summary Quality: We compare the ROUGE-1, ROGUE-2 and ROGUE-L metric results of StoryGraph with 4 other comparison models. Due to space limitation, we present the averaged ROGUE metrics performance of all the model across the four datasets in Table 3. StoryGraph outperforms the comparison models in almost all cases followed by TwitInfo. LDA+Temporal is seen to be trailing in all cases. This observation is reasonable since building a single topic model over the tweet datasets will produce words distributions which are not focused on a specific subject. Even though ConnectingDots [25] and EventGraph [30] outperforms the naive approach, these models do not perform well in most cases.

Table 3: Averaged Performance comparison on all datasets

Model	ROGUE- 1		ROGUE-2		ROGUE-L	
	Precision	Recall	Precision	Recall	Precision	Recall
ConnectingDots	0.443	0.592	0.142	0.154	0.372	0.354
LDA+Temporal	0.332	0.425	0.021	0.023	0.121	0.263
EventGraph	0.522	0.53	0.258	0.253	0.254	0.248
TwitInfo	0.551	0.621	0.292	0.281	**0.513**	0.462
StoryGraph	**0.781**	**0.872**	**0.432**	**0.392**	0.503	**0.572**

This observation further affirms the claims that traditional document summarization (TDS) techniques do not perform well with Twitter data due to the unique properties of Twitter data [8, 11, 22]. We further show the F1-scores across the 4 datasets in Fig.3. StoryGraph achieves the best performance across the datasets. Recall that, StoryGraph incorporates user communities in extracting event summaries. The use of community structure contributes to this good performance. From earlier work in [4, 7], using community structure helps to extract event summaries that are coherent with fewer word intrusions. The reason is that conversations in user communities are usually focused on specific subjects of interests. Hence, there are fewer word intrusions from conversations that are not related to the topic of discussion in the community.

Structure Coherence: We evaluate three different timeline and story generation structures. A Complex Graph Structure (CGS) [30], Flat Timeline (FT) [25] and our Storygraph (SG) structure. The goal is to find out which structure presents the general information of the story in a more coherent and logical manner. We utilize the FP datasets since we have the complete evolution of events in the GSR. We present the results on the evaluation metrics in Fig.4. StoryGraph (SG) achieves the best structure coherence, followed by flat timeline (FT). Complex graph (CGS) is observed to be trailing behind in this section. While this is surprising, the possible explanation that Eventgraph [30] presents a graph structure which models the complex relationships between events in the graph. Thus, if all the nodes in the graph share some similar keywords, edges are created between them. This results in complex structures with low theme inconsistency among node pairs. A good summary structure should be simple while at the same time having the capability to model complex relationships between events, which is exactly what StoryGraph provides.

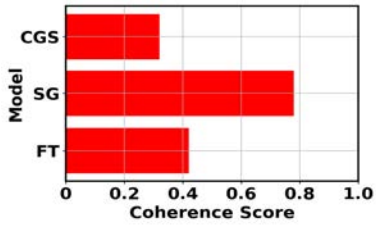

Figure 4: Coherence Comparison in Structural Summaries

6 CONCLUSION

In this paper, we have presented StoryGaph, a timeline graph summarization framework for telling the story of events that evolve over time. We formulate a novel graph timeline summarization structure capable of identifying the different themes of a story using high penalty metrics. StoryGraph constructs coherent paths to track event evolution and generates comprehensive story summaries to

tell the story of how events evolve over time. Experimental results show that StoryGraph outperforms existing models.

ABSTRACT

In the last decade drug overdose deaths reached staggering proportions in the US. Besides the raw yearly deaths count that is worrisome *per se*, an alarming picture comes from the steep acceleration of such rate that increased by 21% from 2015 to 2016. While traditional public health surveillance suffers from its own biases and limitations, digital epidemiology offers a new lens to extract signals from Web and Social Media that might be complementary to official statistics. In this paper we present a computational approach to identify a digital cohort that might provide an updated and complementary view on the opioid crisis. We introduce an information retrieval algorithm suitable to identify relevant subspaces of discussion on social media, for mining data from users showing explicit interest in discussions about opioid consumption in Reddit. Moreover, despite the pseudonymous nature of the user base, almost 1.5 million users were geolocated at the US state level, resembling the census population distribution with a good agreement. A measure of prevalence of interest in opiate consumption has been estimated at the state level, producing a novel indicator with information that is not entirely encoded in the standard surveillance. Finally, we further provide a domain specific vocabulary containing informal lexicon and street nomenclature extracted by user-generated content that can be used by researchers and practitioners to implement novel digital public health surveillance methodologies for supporting policy makers in fighting the opioid epidemic.

1 INTRODUCTION

The opioid crisis emerged in the US from the interplay of several determinants and evolved over time through three major phases: from the abuse of drug prescriptions of late 80's [26], to heroin injecting users soaring in 2010 [31] and the very recent rise of synthetic opioids flooding the drug market [23]. The rate of overdose deaths involving opioids shows heterogeneous geographical patterns ranging from 4.9 per 100,000 inhabitants in Texas to 43.4 in West Virginia in 2016 [45]. Unfortunately, despite the effort of national agencies in monitoring the phenomenon, state-level estimates suffer biases due to unequal coverage of the surveillance system as well as intrinsic biases in counting overdose deaths that lead to low specificity of drugs involved [17, 25, 41]. Besides drug overdose maps, opioid prescription maps are provided on yearly basis by the Centers for Disease Control and Prevention (CDC), showing heterogeneous patterns also due to different prescribing policies implemented by individual states. In this perspective, the gold standard represented by official surveillance statistics has to be carefully considered in the light of the known biases of the reported numbers and estimates. A complementary way to investigate these phenomena is by field studies, through ethnographic approaches and structured interviews: sadly these methods require an exceptional effort in order to gather insights from firsthand users [28] or subjects under opioid substitution maintenance treatment [47], and are often limited to small sample sizes ranging from tens to hundreds of individuals. In this context, a digital epidemiology approach [42] aimed at integrating and complementing existing knowledge about the opioid crisis gathering information with a bottom-up unsolicited approach might be extremely valuable.

In recent years, Social Media changed the way drug users share information about opiates, give online warnings and avoid potentially toxic drug batches [21], pointing at "Reddit: the front page of Internet" [39] as a promising digital source of information. Reddit is a social content aggregation website, the 5th most popular website in the US (`Alexa.com`, Fall 2018), on which users can post, comment and vote content. It is structured in cross-referenced yet independent sub-communities (i.e. *subreddits*), centered around a variety of topics ranging from science to drugs and porn [30]. Reddit is constantly growing, with a total of almost 800 million comments in the year 2016 and almost a billion comments in the year 2017. Given the ease to register with a "throwaway" account, Reddit is often used to discuss topics otherwise considered socially unacceptable or unsuitable for the mainstream; users can actively engage with others, talking uninhibitedly about personal experiences [27], receiving back social support and even life-saving tips from sub-communities of peers [21]. However, navigating such massive platforms and finding areas of specific interest is usually cumbersome since topics

are self-organized bottom-up through users' interactions, leaving the users to find relevant topics by word of mouth or using a basic search feature.

The main contributions of this work are summarized as follows:

- Design a general purpose information retrieval algorithm able to identify regions of interest when conducting epidemiological surveillance and monitoring on social media
- Provide an open domain specific vocabulary related to opiates discussions
- Demonstrate how information disclosed by Reddit users can be used to estimate their geographical location
- Identify a novel digital cohort of individuals addressing in a pseudonymous fashion health related topics
- Provide prevalence maps of interest in opiates consumption

2 RELATED WORK

Digital epidemiology [42], also referred to as *digital disease detection* [4] and *infodemiology* [13], broadly includes the use of the Internet and digital technologies for collecting and processing health information, both in aggregate form for public health surveillance or from individuals for personal health monitoring. Data from a so called *digital cohort* might be collected with active participation of individuals, as in the case of participatory epidemiology [14], but might also be collected passively, e.g. from Social Media, as a byproduct of platforms designed for different purposes. Participatory systems have been implemented through the use of Web platforms [35] and signals collected from such systems have been shown to be useful for epidemic forecasting [49]. Data collected from the Web and Social Media have also shown to be useful for monitoring different infectious diseases [3, 5, 9, 22, 46].

Reddit has already proven to be suitable for a variety of research purposes, ranging from the study of user engagement and interactions between highly related communities [18, 48] to post-election political analyses [1]. Also, it has been useful to study the impact of linguistic differences in news titles [20] and to explore recent web-related issues such as hate speech [43] or cyberbullying [38] as well as health related issues like mental illness [8], also providing insights about the opioid epidemics [36]. It is worth to notice that since the platform is collectively generated by the users as in most Social Media, there is not a blueprint of Reddit to perimeter the area under study, and only few attempts tried to overcome this issue extracting meaningful maps or suitable embedding spaces [29, 34].

We approach the problem of selecting subreddits that are relevant for a specific topic as an information retrieval (IR) problem, where it is possible to retrieve topic-specific documents by expressing a limited set of known keywords. Language models [10, 37, 44] tackle this problem using a probabilistic approach with the idea that words that are relevant for a given topic would be more likely to appear in a relevant document. While language modeling is not a common approach for ranking documents collected from Social Media due to the inherent sparsity of the documents – e.g. for Twitter, more elaborated IR approaches are needed to resolve the sparsity of short texts for tweets [33] – subreddits, on the other hand, can be seen as very rich documents from which topic-specific word distributions can be built.

The set of keywords expressed by the user may not include some yet unknown terms that are relevant to the topic but very specific to the language models of the documents, pointing the necessity of query expansion techniques. Relevance feedback [40] and pseudo-relevance feedback [6] are common approaches for query expansion; many of these approaches use human judgment to manually select a subset of the top retrieved documents, and use them to expand the query. More recently, word embeddings [24] have been used to expand the query with terms that are semantically similar to the query terms. Techniques that are based on language modeling might incorporate term proximity information [12] to address the automatic query expansion problem, or use an approach based on Information Theory, exploiting the *Kullback-Leibler distance* for query reweighing [7] and for training local word embeddings [11].

3 DATASET AND DATA PREPARATION

A dataset [1] containing the list of all submissions and comments published in Reddit since 2007 is publicly available online [2] and is maintained monthly by adding recent entries. The dataset is not 100% complete and it contains some gaps [15], but these are very small for the years 2016 and 2017 (around 1% missing data per month). We use the union of all submissions and comments from years 2016 and 2017, for a total of 1,980,497,553 entries. Only subreddits with at least 100 entries were selected, resulting in a set of 1,973,863,886 entries with 74,810 distinct subreddits and 15,747,502 distinct users. The text of each entry is parsed and tagged using the spaCy NLP library [2] v1.9.0. For the part-of-speech tagging, a greedy averaged perceptron model was used [19]. Finally, lemmatization is applied to each POS tag; the English lemmatization data is taken from WordNet [32] and lookup tables are taken from Lexiconista [3]. After all terms are lemmatized, we select those that appear at least 100 times in the corpus, resulting in a vocabulary of 762,746 lemmas.

4 IDENTIFYING RELEVANT DOCUMENTS VIA DOCUMENT RANKING AND QUERY EXPANSION

As discussed in Section 2, the wealth of information contained in Reddit data is not readily available and has to be thoroughly mined. In this section we describe an iterative methodology of semi-automatic retrieval of documents in heterogeneous corpora, in which human intervention is as little as possible. It is worth to stress that the approach is general and fully unsupervised. However, we added a human-in-the-loop to include domain expert knowledge in the process and reach better results. On the other hand, a domain expert alone without the aid of the algorithmic pipeline for document ranking and query expansion would have been hopeless in navigating the Reddit world by hand. The steps are summarized in Algorithm 1. We start with a small set of keywords Q provided by the user, or *query* in the following. At each iteration, we select documents which are both relevant to the query and informative, and enrich the *query* terms set until we arrive to a stable list of documents and query terms. While this methodology works well on Reddit in the domain of topics related to the opioid epidemics

[1] https://files.pushshift.io/reddit/
[2] https://spacy.io/
[3] http://www.lexiconista.com/datasets/lemmatization/

(see Section 4.1), it is also sufficiently general to be used for other information retrieval tasks and might be valuable for different epidemiological research questions.

Algorithm 1: IR steps for document ranking

Input: Corpus C, query Q
Parameters: n, m, α
Initialize the vocabulary $\mathbf{V}$;
foreach *word* $w \in \boldsymbol{V}$ **do**
  calculate $p_C(w)$;
  foreach *document* $d \in C$ **do**
    calculate $p_d(w)$;
$Q_{new} \leftarrow Q$;
$K_{new} \leftarrow \emptyset$;
repeat
  $Q \leftarrow Q_{new}$;
  $K \leftarrow K_{new}$;
  $R_d \leftarrow$ Rank documents using score$(d \mid Q, C)$ (Eq. 2);
  $K_{new} \leftarrow$ top n documents in R_d;
  $R_w \leftarrow$ Rank terms using score$(w \mid K_{new})$ (Eq. 3);
  $Q_{candidate} \leftarrow$ top m terms from R_w;
  $Q_{new} \leftarrow$ manual selection of terms in $Q \cup Q_{candidate}$;
until $Q = Q_{new}$ *and* $K = K_{new}$;
Output: R_d, R_w

First, we create a general vocabulary $\mathbf{V}$ by collecting terms from the entire corpus in a bag-of-words fashion. We compute the probability of occurrence of a term w in the entire corpus C as the ratio $p_C(w) = f_C(w)/\sum_w f_C(w)$ between its raw count $f_C(w)$ in the corpus and the total number of words in the corpus. Let us also define the regularized marginal probability of occurrence of term w in a document d as

$$p_d(w) = \frac{f_d(w)}{\sum_w f_d(w) + \alpha} + p_C(w). \tag{1}$$

where $f_d(w)$ is the count of w in d. In case of corpora with very heterogeneous document sizes, the regularization term α is added to control "the size" of the language model of the documents (small documents will result in small marginal probabilities). In our experiments, we use $\alpha = 10^4$, so documents with total number of words lower than 10^4 have "flattened" probabilities in their language model. Adding $p_C(w)$ to the marginal probability of w reduces the impact of words that are rare or not present in a document, and only words that are more likely to appear in the document will impact the document ranking. The use of these two regularization terms (α and $p_C(w)$) are effective in low-count scenarios and have a small impact for words with high probability in the document or in case of documents with large language model.

With the intuition that a document will result to be relevant in the context of the query if it contains query terms more likely to appear in the document than in the general corpus, we evaluate

$$\text{score}(d \mid Q, C) = KLD_Q(p_d, p_C) = \sum_{w \in Q} p_d(w) log \frac{p_d(w)}{p_C(w)} \tag{2}$$

which is the total contribution of the query terms in the *Kullback-Leibler divergence* between the document and the whole corpus C. We consider the top n documents ranked by relevance as measured by Eq. (2) as the *set of relevant documents* K. Once n is chosen (and thus K is obtained), in order to enrich the query terms Q we assign a score to each term based on the logarithm of the likelihood ratio

$$\text{score}(w \mid K) = \sum_{k \in K} log \frac{p_k(w) + p_C(w)}{p_C(w)}. \tag{3}$$

Whenever the the maximum likelihood estimate $p_k(w)$ of a term in a relevant document is higher than its estimate in the general context $p_C(w)$ – i.e. the term is more informative in the document than in the general context – the contribution to the score will be high and positive. Conversely, whenever a term is less likely to appear in the document than in general context, its contribution to the score will be smaller, highlighting that the term is common or not relevant to the context. Considering the top m terms ranked by Eq. (3), a subset of previously unknown relevant terms is added to Q with the supervision of an expert. With the newly enriched set of query terms, the entire pipeline can be iteratively evaluated until convergence, reached if no new documents are added to the top n documents and no new relevant terms among the top m can be added to Q. These steps are summarized in Algorithm 1, and the document ranking resulting from the last iteration of the algorithm is used to select the most relevant documents.

4.1 Opioid related subreddits

Our assumption is that authors who post content in a subreddit related to a particular topic are *interested* in that topic. Therefore we consider all authors participating in threads on subreddits related to opioid consumption as those *interested* in the topic, and we discover such subreddits by applying the algorithm described in Section 4.1. After data preparation steps described in Section 3, starting from a list of opiates related keywords q = `[fentanyl, oxycodone, suboxone, morphine]` we extract the top $n = 10$ subreddits: `[suboxone, fentanyl, Opiatewithdrawal, TarkovTrading, heroinaddiction, ChronicPainPlayhouse, OpiatesRecovery, opiates, Methadone, PoppyTea]`. We then proceed with the iterative procedure of query enrichment and document ranking, considering as relevant terms only opioid drug names, i.e. chemical names (e.g. *oxycodone*), brand names (e.g. *Percocet*) and street slang (e.g. *percs*), disregarding drugs that might be abused together with opiates (like benzodiazepines) but are not in the opiates domain. The final set of *opioid related subreddits* used in this paper is K = `[fentanyl, suboxone, Opiatewithdrawal, Methadone, opiates, pillhead, lean, ChronicPainPlayhouse, heroinaddiction, OpiatesRecovery]`. All the 37,009 users who posted on such subreddits in 2016 or 2017 are then considered as interested in opiates. Figure 1 (top) shows the final ranking score for the subreddits, plotted against their size in terms of number of words.

4.2 Opioid specific vocabulary

When applied to Reddit, the query expansion approach is particularly useful in revealing how a topic is discussed on subreddits. Given the large user base of Reddit and the tendency of the users in employing slang and street names alongside proper drug names,

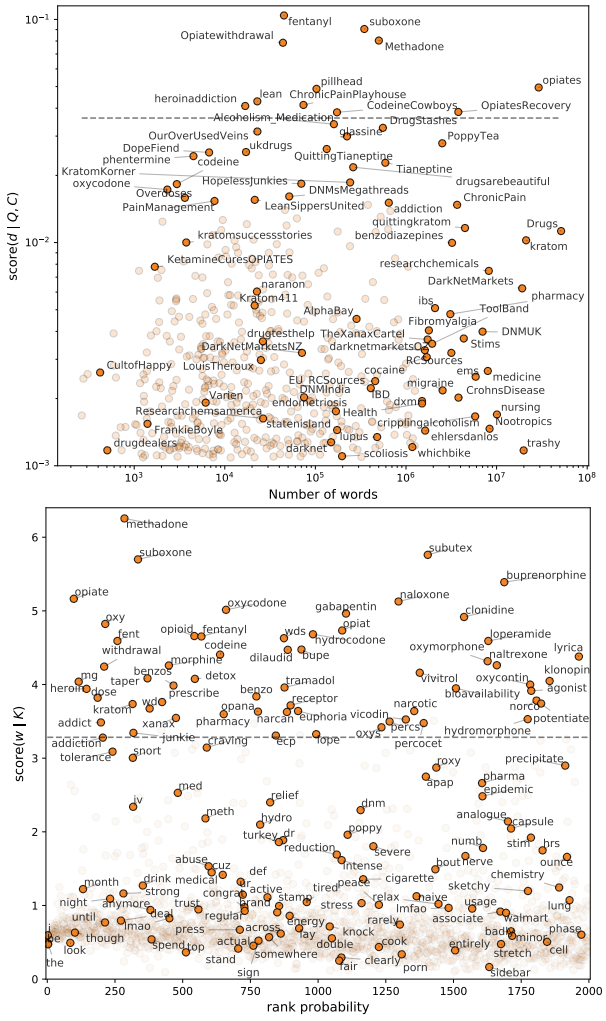

Figure 1: *Opiates subreddits* (top): individual subreddits are shown in a coordinate space of the number of words in the subreddit and the final ranking score. The subreddits above the dashed line are those selected as K opiates related subreddits. *Opiates vocabulary* (bottom): Top 2,000 terms sorted by rank probability of term in the set K. Terms above the dashed line were selected as query term candidates in the last step of the subreddit retrieval algorithm.

this method is very helpful in acknowledging alternative names of drugs, like *sub* for *suboxone* and *bth* for *black tar heroin*.

As a byproduct of the proposed methodology applied to the opiates domain, we extracted a topic-specific vocabulary by weighting each term of the vocabulary with Eq. 3. Very specific opioid-related terms (i.e. with high probability in opiates subreddits and low probability in the whole corpus) have large positive values of $score(w \mid K)$, as shown in Figure 1 (bottom), while stop-words and common terms have small score values. A total of 2,616 terms out of the original 762,746 (0.3%) have score higher than 1. The full list of vocabulary terms ranked by score is available for research purposes [4].

5 GEOLOCATING USERS ON REDDIT

Reddit does not provide any explicit information about users' location, therefore we apply three methodologies to assign a location to users. Finally, we merge the mappings in a single user-location matching.

1. Self reporting via regular expression: Reddit users often declare geographical information about themselves in submission or comment texts. We selected all texts containing the expression `'I live in'` (3,337,850 instances in 2016 and 2017) and extracted candidate expressions from the text that follows, to identify which ones represented US states and cities. We started with a set of US cities from the GeoNames database [5] with population higher than 20k, and selected only the candidate expressions that included both the city name and the state (e.g. 'Newark, California' or 'Newark, CA') to avoid confusion with cities with same name (e.g. 'Newark, New Jersey'). Once the US state for these expressions were assigned and removed from the candidate expressions, we proceeded to all US cities with population higher than 200k, selecting expressions with the name of the city and their variants (e.g. 'New York', 'Big Apple'). After assigning the corresponding US state for these expressions and removing them from the candidates, we proceeded to select the expressions with a state name on it (e.g. 'Alabama', 'California'). Among the initial set of candidate expressions, 886,919 (27%) had a state associated to it. By removing inconsistent self reporting (13,374 users who reported more than one US state) we geolocated 378,898 distinct users.

2. Self reporting via *user flairs*: In Reddit, *user flairs* are attributes (usually selected by the users) that are attached to their submissions or comments in a specific subreddit. In some subreddits flairs might be limited to a set of geographical locations (countries, states, cities and city neighborhoods), meaning that users should identify themselves with one of these locations. A user selecting a location flair is therefore considered equivalent to a user self reporting its location. We mapped the users participating in subreddits with location flairs referring to US states to their *flaired* positions. Using this approach, we mapped 206,125 users to the 51 US states (including District of Columbia) by selecting the most common among the position flairs expressed by a user.

3. Posting on subreddits specific to locations: Reddit includes subreddits discussing topics specific to geographical locations (e.g. `r/Alabama` or `r/Seattle`). The subreddit `r/LocationReddits` keeps a curated list of these local subreddits. We collected from the page corresponding to North America[6] the mappings of 2,844 subreddits to 51 US states. By assuming that a user who posts comments in one of these subreddits is likely to live that location, we estimated the position of 1,198,096 authors.

After retrieving US states positions using the three methods above, we found that about 12% of mapped users expressed multiple locations. In order to uniquely map authors and states, for location flairs and LocationReddits sources we assigned each author a unique

[4] https://github.com/ISIFoundation/WWW19OpiatesAbuseSocialMedia
[5] http://www.geonames.org/
[6] https://www.reddit.com/r/LocationReddits/wiki/faq/northamerica

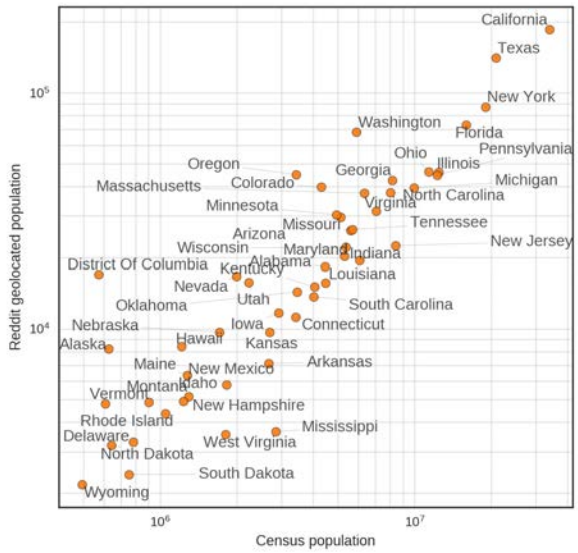

Figure 2: *Reddit geolocated population*: scatter plot of the number of geolocated Reddit users and census population.

location, it being the most frequent among the ones expressed by the author. We discarded authors whose most frequent location was not unique. This resulted in 194,008 authors retrieved via location flairs (5.9% loss) and 1,077,516 via LocationReddits (1.4% loss).

We evaluated Pearson's r correlation between the log of the 2000 US Census population and the log of the population assigned to the same US states using the three methodologies. Results are in good agreement for all sources, with r= 0.85, 0.91 and 0.86 for respectively User flairs, Regular expression and LocationReddits, and all p-values below 1e-12.

Finally, we merged the information from all three sources in a unique location for each author. We considered the regular expression technique to be the most reliable due to its unambiguous self reporting nature, resulting in the highest correlation with census data. We proceeded in the merging process by first assigning the authors their regular expression location, if present. If missing, we assigned them their position from the joint information of location flairs and LocationReddits by summing the occurrences of locations expressed in the two sources and verifying the uniqueness of the most frequent location. Although some approaches have been proposed to geolocate users using language models [16], we rely on a conservative approach with the aim of reducing misclassification, considering only explicit geographical information directly provided by the authors. The full set of users geolocated using the above methodology consists of 1,408,388 users, with state representativeness in the order of 5.5 Reddit users per thousand U.S. residents (median value among all U.S. states). Although we acknowledge a potential bias due to heterogeneities in Reddit population coverage and users demographics, the number of Reddit users has good linear correlation of r = 0.89 and p-value below 1e-12 with census population (Figure 2).

Region	Division	Opiates authors	Reddit authors	Interest prevalence
Northeast	Middle Atlantic	1,186	154,418	768.05
Northeast	New England	455	69,132	658.16
Midwest	East North Central	1,082	172,902	625.79
Midwest	West North Central	424	92,931	456.25
South	East South Central	457	63,269	722.31
South	South Atlantic	1,656	242,470	682.97
South	West South Central	1,079	177,856	606.67
West	Mountain	793	119,742	662.26
West	Pacific	1,894	315,668	599.10

Table 1: *Interest prevalence by US regional division*: number of opiates authors, total number of authors, and interest prevalence per 100,000 individuals measured on Reddit.

6 PREVALENCE OF INTEREST IN OPIATES

Conversations in opiates related subreddits branch off in many topics, mostly regarding opiates usage, dosages, interactions with other substances, safe practices and withdrawal, usually with a personal perspective. Users share their health and addiction status and provide support among each other. In general, they share a common and firsthand interest in opiates experiences. Thus, the number of authors participating in the conversations in opiates related subreddits (as identified in Section 4) is not to be considered as a crude number of opiates users and addicts but it is rather to be considered as a proxy of users personally interested in opiates in the broadest sense.

Using the geographical information of Reddit population estimated in Section 5 and having identified the opiates authors in Section 4.1, we were able to evaluate the *opiates interest prevalence* at the US state level as the fraction of geolocated users engaged in opiates subreddits and the total estimated population.

We mapped to US states the 9,026 geolocated users who posted in opioid related subreddits, equivalent to 24% of the opiates authors, for a mean interest prevalence of 636 per 100,000 Reddit users (CDC data for 2016 reported an age-adjusted rate of overdose deaths of 19.8 per 100,000 , and opioid prescription rate of 66.5 prescriptions dispensed per 100 persons). The areas of greater interest according to our estimates is the South Region (Table 1), with high prevalence for Mississippi, Arkansas, Louisiana and the highest measured value of 1,180 interested users per 100,000 population in West Virginia (Figure 3, green map). Middle Atlantic and New England states like Pennsylvania, New Jersey and Rhode Island are also largely involved, showing high interest rates ranging between 850 to 900 individuals per 100,000. In line with official statistics about drugs overdose deaths, West North Central states are those with the lowest interest rate measured on Reddit, ranging from 341 per 100,000 in Nebraska to 510 per 100,000 in Minnesota.

We confronted the estimated interest prevalence with official statistics from the Centers for Disease Control and Prevention [7] grasping different angles of the opioid crisis. In particular we focused

[7] https://www.cdc.gov/drugoverdose/data/index.html

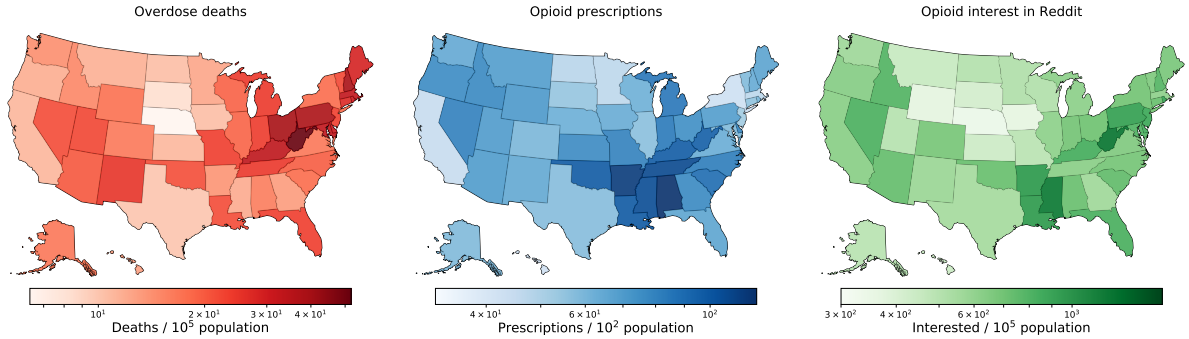

Figure 3: *US states distribution maps:* choropleth maps representing the overdose deaths rate for 2016 (red), the opioid prescription rate for 2016 (blue), the opioid interest rate in Reddit for 2016 and 2017 (green).

on opioid drug overdose deaths rates and retail opioid prescribing rates, both regarding 2016 (the most recent available dataset at the time of writing), shown in Figure 3 in red and blue respectively. These two phenomena seem fairly uncorrelated, with a Pearson's correlation of 0.068 (p-value of 0.637). It is worth to stress that those "gold-standard" data are the only ones provided by CDC that allows for comparisons between different states: although the counting of drugs overdose deaths includes every drug and is not broken down by drug type, state-level estimates of opiate-related overdose deaths are affected by heterogeneities in the surveillance system. On the other hand, official statistics about prescribing rates that includes both appropriate prescriptions and drug abuse are affected by different prescription policies in place at different states.

The interest prevalence shows fairly high positive linear correlations with CDC rates, respectively r = 0.45 (p-value = 8.4e-04) with the opioid overdose deaths rate and r = 0.506 (p-value = 1.6e-04) with the retail opioid prescribing rate. These correlations suggest that the signal of interest in opiates measured on Reddit partially explains the observed phenomena around opioid epidemics measured by the standard surveillance system. Moreover, we trained a linear regression model to fit the estimated prevalence using drug overdose death rates and prescriptions rates as features and predicted new values of interest prevalence, resulting in an higher correlation of r = 0.655 (p-value = 1.7e-07) with the estimated interest prevalence. This result confirms that we are sensing a broad signal, tied to drug overdose deaths and opioid prescriptions but probably accounting for more complex aspects of the phenomenon.

Leveraging the geolocated cohort, we also evaluated the temporal variation of interest prevalence between 2016 and 2017 broken down by state. According to Figure 4, the interest prevalence decreased only in 8 states while in general we observe that in areas with a good coverage of opiates-related users (namely, California, Texas, New York, Florida), the interest prevalence increased by 10% to 20%. It is worth to stress that, at the time of writing, no official data about 2017 drug overdose deaths and associated trends are available, highlighting the tremendous potential of a digital epidemiology approach to gather timely insights about hard-to-reach information of health-related topics at the population level.

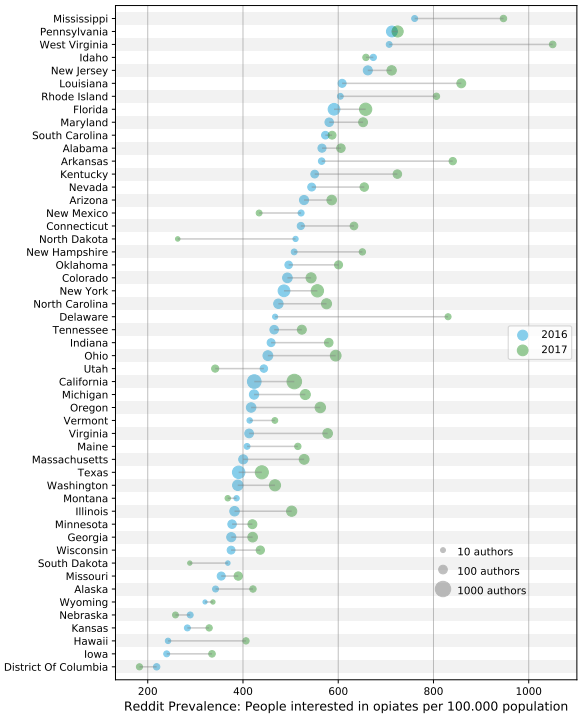

Figure 4: *Opioids interest prevalence:* number of Reddit authors per 100,000 Reddit population. Prevalence values for years 2016 and 2017 are reported on the x-axis. The size of the bubbles is proportional to the number of Reddit authors.

7 CONCLUSION

This study provides an analysis of Reddit content related to personal opiates abuse in the period of 2016 and 2017. Starting from almost 2 billion posts over 74k distinct subreddits, we applied a general information retrieval algorithm to identify specific subreddits of interest thus selecting 37,009 users that show an explicit interest in the topic. 1.5 million pseudonymous Reddit users were geolocated at US state level by looking at the content they generated in the platform. The number of mapped users for each state are in good agreement with census data, with some differences in terms of coverage. Such cohort might represent a biased yet valuable digital

observatory on several social, political and health-related topics. The prevalence of opiates interest extracted with the presented approach shows a complementary perspective to official surveillance, and its geographical heterogeneity partially encodes signals from opioid prescribing rates and drug overdose deaths.

ABSTRACT

Data cleaning and preparation has been a long-standing challenge in data science to avoid incorrect results and misleading conclusions obtained from dirty data. For a given dataset and a given machine learning-based task, a plethora of data preprocessing techniques and alternative data curation strategies may lead to dramatically different outputs with unequal quality performance. Most current work on data cleaning and automated machine learning, however, focus on developing either cleaning algorithms or user-guided systems or

argue to rely on a principled method to select the sequence of data preprocessing steps that can lead to the optimal quality performance of. In this paper, we propose Learn2Clean, a method based on Q-Learning, a model-free reinforcement learning technique that selects, for a given dataset, a ML model, and a quality performance metric, the optimal sequence of tasks for preprocessing the data such that the quality of the ML model result is maximized. As a preliminary validation of our approach in the context of Web data analytics, we present some promising results on data preparation for clustering, regression, and classification on real-world data.

1 INTRODUCTION

Through the use of data mining, statistics, and machine learning, data scientists and researchers can discover relevant patterns and gain crucial and actionable knowledge from data. In the context of Web data analytics, it is necessary to extract, transform, and structure the data and also adapt the data volume, data format, and distributional characteristics in order to better suit the underlying assumptions and constraints of statistical machine learning (ML) models so that they can be effectively applied to the preprocessed input data. It is essential to detect glitches (aka data quality problems) [2] because erroneous data limit the performance of statistical methods and cause misleading results [3, 11].

Web Data can be big, noisy, unreliable, highly imbalanced, heterogeneous, and evolve over time [6]. In practice, Web data analytics can suffer from a wide range of data anomalies such as missing values, inconsistencies, outlying data, duplicates, etc. The results of classification, clustering or predictive models obtained from the data that were preprocessed inappropriately are misleading and can cause inadequate decision-making. To mitigate the impact of data anomalies and thus provide high quality analytical results, a first necessary step is to preprocess data appropriately.

Data preprocessing has been acknowledged as a primary sequence of tasks to correct the negative effects and bias that data anomalies may produce on output results as demonstrated in various contexts [9, 12]. Common data preprocessing tasks mainly include: data extraction and formatting, selection of features, data normalization, treatment of missing values and outliers, deduplication, inconsistency detection (wrt some rules and constraints), data replacement, and pattern enforcement. Although there is a vast number of data preprocessing methods available to achieve these tasks in the context of Web mining [12–16], the selection and orchestration of the sequence of tasks often remains *ad hoc*, difficult, and with no guarantee that it is optimal. An important question is: How do we actually measure the quality of data preprocessing for a given analytics task? This is a challenging problem with combinatorial issues if we consider the infinite "curation space" with hundreds of possible techniques, each with various parameter settings, and multiple possibilities in the combination and the ordering of the cleaning tasks, and even worse when we consider multiple iterations of certain tasks.

For example, in the context of Web usage data mining, data characterizing the interaction of Internet-users with Web sites are collected and analyzed in order to provide personalized Web-pages or enhance search engines. To prepare such data before analysis, one may define a preprocessing strategy that starts with a distance-based deduplication for Web user and session identification, then the removal of outliers, and ends with a regression-based imputation of missing values; another expert may use a totally different sequence of methods with another ordering and add the re-iteration of outlier detection and removal. Ultimately, the two preprocessed datasets may be so different that the conclusions from classification or clustering results may also differ radically. Similarly in the context of Web content mining, the information presented on Web

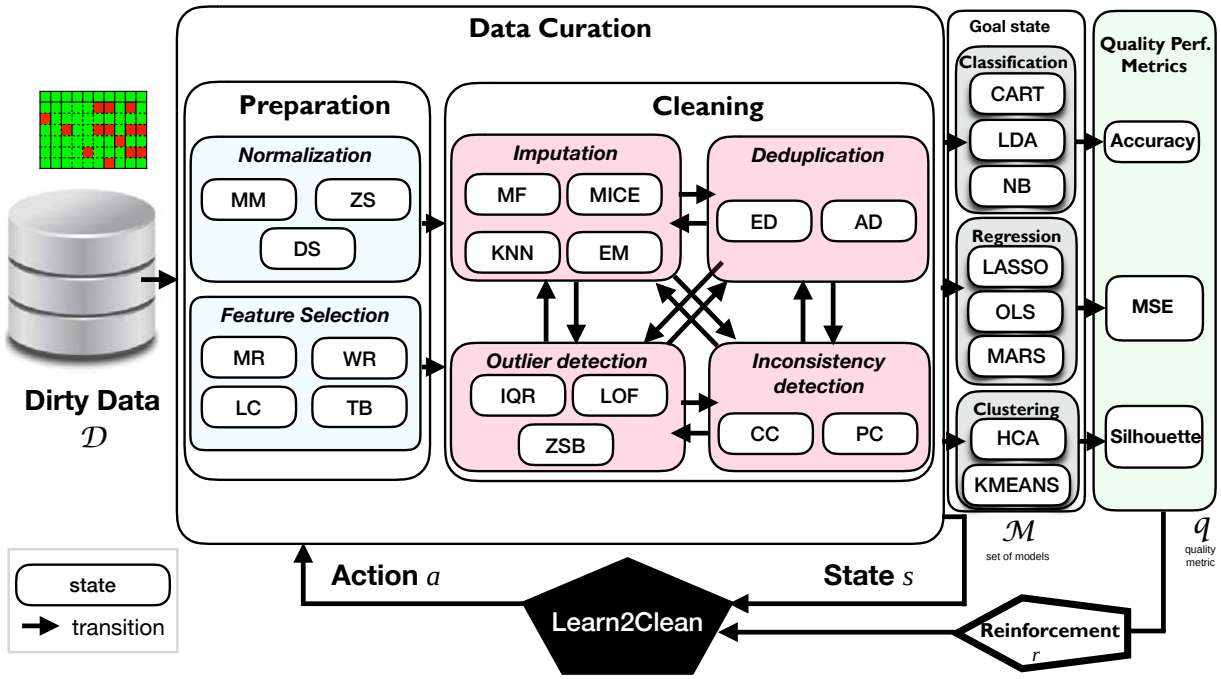

Figure 1: Learn2Clean Architecture

pages combining text and multimedia content is used for page classification, page summarization, entity extraction, and semantic processing. The data need to be filtered because many objects present on Web pages are not relevant with the stated objectives (e.g., digital marketing or advertising). Text content by itself is noisy: for example, sentences contain many words that have a poor influence on the semantic content and various strategies for text preprocessing, Web content cleaning and transformation into feature vectors may lead to very different mining results.

There are several methods that optimize single data cleaning operations based on downstream accuracy metrics (see [18] for a survey) and also recent approaches such as [17], data transformation learning [22], and AutoML line of work [19, 20] in the area of automated machine learning. However, the problem of selecting the optimal data preprocessing pipeline has been understudied.

The focus of our work is first to study the impact of various sequences of data preprocessing methods on the output results of some representative ML models; second, we propose a novel method that learns by reinforcement the sequence of tasks that can optimize a preselected quality performance metric for the considered ML model. In our study, we consider the following tasks of (1) selecting features, (2) normalizing data, dealing with (3) missing values and (4) outliers, (5) deduplicating, and (6) consistency checking, since these methods are the most frequently used for preparing data.

2 OVERVIEW OF LEARN2CLEAN

Our overall approach can be summarized in Figure 1. We consider a ML pipeline with a particular goal such as classification, regression or clustering. The ML pipeline includes: (i) the data $\mathcal{D}$; (ii) the feature set $\mathcal{X}$; (iii) the learning algorithm $\mathcal{M}$, along with the objective function $\mathcal{L}$ that maximize a quality performance metric q; and, possibly, (iv) its (trained) parameters $\mathbf{w}$. The ML pipeline can thus be formalized in terms of a space $\Theta = (\mathcal{D}, \mathcal{X}, \mathcal{M}, \mathbf{w})$. Input data preprocessing is strongly dependent on the given practical scenario. For example, additional constraints while preprocessing the data have to be considered to conform the data with the ML model requirements (e.g., normalization, discretization, deduplication, missing value imputation, extreme values replacement, etc.). Typically, these constraints can be nevertheless accounted for in the definition of the optimal curation strategy. In particular, we characterize them by assuming that $\mathcal{D}'$ is the dataset resulting from a sequence of data modifications in the space of all possible data cleaning transformations of $\mathcal{D}$ such as $D' \in \Phi(\mathcal{D})$ with $\Phi(\mathcal{D}) = \{\phi(\mathcal{D}) | \forall \phi\}$. The problem can be formalized as follows:

Given a ML pipeline $\theta \in \Theta$ and the data sets resulting from all preprocessing alternatives $\Phi(\mathcal{D})$, the goal of preprocessing can be characterized in terms of an objective function $\mathscr{P}_q \in \mathbb{R}$ which evaluates how effective the preprocessing alternative D' is with respect to a given quality metric q. The result of the optimal preprocessing strategy can be thus given as:

$$D^\star = \underset{D' \in \Phi(\mathcal{D})}{\operatorname{argmax}} \mathscr{P}_q(D', \mathcal{X}, \mathcal{M}, \mathbf{w}). \quad (1)$$

More intuitively, the problem we address is the following: *Given a dataset as input $\mathcal{D}$, a ML pipeline θ to apply to the input dataset, a quality performance metric q, and the space of all possible data preparation and cleaning strategies $\Phi(\mathcal{D})$: Find the dataset D' in $\Phi(\mathcal{D})$ that maximizes the quality metric q.*

To solve this problem, we propose Learn2Clean a system based on Q-learning that learns in an on-line fashion with interleaving learning and execution. The intuition is the following. In the early

stages of execution, when little is known, it is important to explore and try some data curation actions when their consequences on the output quality performance of the given ML model are still unknown. Rewards are given when the quality performance improves. Later on, the system may want to almost always choose the action that gets highest rewards; when there is little information to be gained, the value of learning can be negligible. This is modeled with a Q-learning function that assigns a probability of being chosen for each possible action in a given state such that it should tend to choose actions with higher Q-values, but should sometimes select lower Q-value actions.

3 Q-LEARNING

Q-learning [10] is a form of model-free reinforcement learning, where the system only needs to know what state exists next and what actions are possible in each state. An estimated value Q-value is assigned to each state. When the system visits a state and receives a reward, the Q-value of that state is updated accordingly such as:

$$Q(s,a) = R(s,a) + \gamma max_{a'} Q(s',a') \tag{2}$$

where the value of taking action a in state s is the immediate reward denoted $R(s,a)$ for the state-action pair (s,a), plus the value of the best possible state-action pair for the successor state. The γ parameter has a range of 0 to 1 ($0 \leq \gamma < 1$). If γ is closer to zero, the system will tend to consider only immediate rewards. If it is closer to 1, the system will consider future rewards with greater weight, willing to delay the reward. We can use Eq. (2) to update the Q-value of a state-action pair as a reward r' is observed:

$$Q_{t+1}(s,a) = r' + \gamma max_{a'} Q(s',a'). \tag{3}$$

r' is the reinforcement received when the system selected the a action in the state s to move to the state s'. In our context, we represent data preprocessing and curation strategy as a graph: each state is a node representing a preparation or cleaning task that generates a "cleaner" version of the original dirty dataset. A sequence of tasks is represented by a link between two nodes (i.e., between a cleaning task and the next cleaning task). In the architecture presented in Figure 1, we can start with any normalization method as a task (e.g., ZS, MM, SM or DS) or feature selection method (e.g., CFS, WR, LC)[1], and move to the next task choosing one method amongst the ones proposed either for deduplication, inconsistency checking, outlier detection or imputation, until the system reaches the goal state. We define the goal state and a particular quality metric we want to maximize denoted $G(q)$. For example, as shown in Figure 2, the goal state for a LASSO regression applied to the input dataset is the state of preprocessing that minimizes the mean squared error, MSE. To reach this node as a goal, we associate a reward value to each link between nodes. The nodes that lead immediately to the goal node have an instant reward of r_{max}. There may be no link between nodes (encoded as -1 in the Reward R-matrix represented in Figure 2). In this example, particular cleaning paths can be avoided or task precedence can be enforced: e.g., after normalization, there is feature selection, then imputation (either using MICE or KNN), and then outlier detection (either with LOF or IQR), and again imputation. This figure represents a particular graph instantiation of Learn2Clean architecture presented in Figure 1. The final goal

[1] Acronyms of the methods are described in Section 3.1.

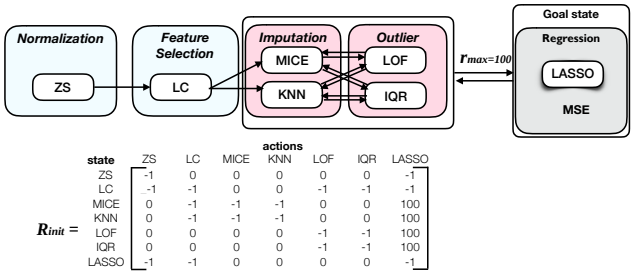

Figure 2: Simplified example of state-action graph with initial reward matrix.

state is ML model-dependent since the dataset should be prepared and curated with respect to the specific requirements of the ML model considered for the analysis. The goal state in the example of Figure 2 is reached after a maximum number of 100 iterations when LASSO regression is executed after either imputation or outlier detection such that MSE (the considered quality performance metric) is minimal.

Reinforcement via reward. The reinforcement function provides, for each new state s' reached from state s, a signal r' that can be a reward or punishment, this signal takes the value $\{-1\}$ when the state s is not linked to the new state s' or a value in $[0,1]$, which is used by the update function in Eq. (3) to adjust the Q-value function associated with the state-action pair. The reward r' is computed as follows:

$$r' = \beta(Norm(s,q_m) - Norm(s',q'_m)) \tag{4}$$

where $Norm(s,q_m)$, $Norm(s',q'_m)$ are the normalized quality metric values q and q' in [0,1] for the considered ML model m and

$$\beta = \begin{cases} -r_{max} & if\, Norm(s,q_m) - Norm(s',q'_m) < 0 \\ r_{max} & if\, Norm(s,q_m) - Norm(s',q'_m) > 0 \end{cases}$$

with r_{max}, the user-defined maximum reward value. This penalizes the next data curation task when it provides a lower quality performance metric compared to the ones obtained after the current cleaning task.

Selection of the next curation tasks. The probability of selecting the highest Q-value action should increase over time and this can be defined by the Boltzmann distribution as follows:

$$P(a|s) = \frac{e^{Q(s,a)/k}}{\sum_j e^{Q(s,a_j)/k}}. \tag{5}$$

The k parameter (often referred to as temperature) controls the probability of selecting non-optimal actions. If k is large, all actions will be selected fairly uniformly. If k is close to zero, the best action will always be chosen. We begin with k large and gradually decrease it over time. Each edge contains an instant reward value, as shown in the initial reward matrix R_{init} given as example in Figure 2.

Learn2Clean will learn through experience in an unsupervised way. It will explore from state to state until it reaches the goal. Each exploration consists of the system moving from the initial state to the goal state. Each time, it arrives at the goal state, the program goes to the next exploration. Learn2CLean algorithm is given in Algorithm 1 where the system learns from experience. Each exploration is equivalent to one training session. In each training

session, the system explores the curation graph (represented by matrix R), receives the reward (if any) until it reaches the goal state (lines 6–8). The purpose of the training is to enhance the decision of the system, represented by matrix Q to get more training results in a more optimized matrix Q. In this case, if the matrix Q has been enhanced, instead of exploring around, and going back and forth to the same tasks, the system will find the fastest route to the goal state.

Algorithm 1 Learn2CLean Algorithm

```
1. INPUT γ and reward matrix R
2.        ML model m, quality metric q
3. Initialize Q matrix
4. FOR each exploration
5.     Select the initial state
..     Apply the corresponding curation method to generate
..     a "cleaner" dataset, and apply m to it
6.     WHILE {goal G(m,q) has not been reached}
7.         Select one among all possible actions with prob.
..             in Eq.(5) for the current state
8.         Using this possible action, move to the next state
9.         Get max Q-value for this next state based on all
..             possible actions
10.        Compute Eq.(2)
11.        Set the next state as the current state.
12.    END_WHILE
13. RETURN the list of actions with highest Q-values and
..         optimal quality metric and the final curated dataset
```

The algorithm finds the actions with the highest reward values recorded in matrix Q (lines 9–10) and returns the sequence of states from the initial state to the goal state where the quality metric is optimal (either minimized for regression MSE or maximized for classification accuracy or clustering silhouette) and the ultimately cleaned dataset to be used for the considered ML model (line 13).

Why Q-learning? In model-based reinforcement methods, the model learns the transition probability $T(s_1|(s_0, a))$ from the pair of current state s_0 and action a to the next state s_1. However, model-based algorithms become impractical as the state space and action space grows, which is typically the case with the space of data cleaning strategies. Moreover, the transition probability and the dynamics of the system is not given a priori. These are the reasons why model-free algorithms are more adequate for our problem. We choose Q-Learning instead of other model-free reinforcement learning methods (like Monte-Carlo or SARSA methods) because Q-learning will not wait until the end of the episode (i.e., cleaning task) to update the expected future reward estimation, it will only wait until the next time step to update the value estimates and may not use the same policy to choose the next action. This makes it agile and performant compared to other model-free reinforcement learning methods.

3.1 Data preprocessing methods

As shown in Figure 1, various types of representative preprocessing techniques were used in our study with the long-term goal to provide an extensible library for data cleaning and preparation.

- **Normalization**. Three methods were applied to numerical data: min-max (MM), Z-score (ZS), and decimal scale normalization (DS);
- **Feature selection**. Four methods were tested to select an optimal set of features, namely: based on a user-defined acceptable ratio of missing values (MR), removing collinear features (LC), using a wrapper subset evaluator (WR) [8], and a tree-based classifier for feature selection (TB);
- **Imputation**. Four imputation methods were used to impute missing values: two distance-based imputation methods: *Expectation-Maximization* (EM), *K-NN* [1], Multiple Imputation by Chained Equations (*MICE*) [5], and replacement by the most frequent value (MF);
- **Outlier detection**. Outliers were detected using three methods including: a statistic-based approach, Inter Quartile Range (IQR), the Z-score-based method (ZSB) [7], and a density-based approach (Local Outlier Factor, LOF) [4]. Outliers were replaced using one of the previous imputation methods;
- **Deduplication**. Exact duplicate (ED) and approximate duplicate (AD) detection methods were used. In the later case, various comparison functions were used to measure the similarity distance between pairs of records to detect duplicates based on the user-defined threshold (e.g., Jaro-Winkler or Levenshtein distance);
- **Consistency checking**. Two methods based on constraint discovery and checking (CC) and pattern checking (PC) were used to identify inconsistencies.

3.2 ML Models and Quality Performance

Our goal is to study the impact of data preprocessing pipeline selection and how it can affect the output results of statistical ML methods. In particular for Web usage data analysis, we considered the following ML models and corresponding quality performance metrics.

- **Clustering**. We used two clustering methods: HCA (Hierarchical Clustering) and K-means with silhouette metric to evaluate the quality of the clustering as $silhouette = (b(i) - a(i))/max\{a(i), b(i)\}$ with $a(i)$ the average distance between i and all other data within the same cluster and $b(i)$ the smallest average distance of i to all points in any other cluster, of which i is not a member;
- **Regression**. We used three regression methods: LASSO (Least Absolute Shrinkage and Selection Operator), OLS (Ordinary Least Squares Regression), and MARS (Multivariate Adaptive Regression Splines) and as quality metrics, we used MSE (Mean Squared Error) to measure the robustness of regression as $MSE = \sum_{i=1}^{N}(Y_i - \hat{Y}_i)^2/N$; and
- **Classification**. We used three classification methods: LDA (Linear Discriminant Analysis), NB (Naive Bayes), and CART (Classification and Regression Trees) with accuracy metric as $accuracy = (TP + TN)/(TP + TN + FP + FN)$ with TN and FN true and false negatives and TP and FP true and false positives respectively in the classification result.

Our approach is not limitative and other ML models, quality metrics or preprocessing methods could be added and used by Learn2CLean.

4 EXPERIMENTS

We have performed preliminary experiments to compare the preprocessing alternatives (described in Section 3.1) for the classification, regression, and clustering methods (described in Section 3.2) using real-world datasets from Kaggle[2] repository as shown in Table 1.

All methods and Learn2CLean are implemented in Python (Jupyter Notebook 5.5, Python 3.6.5). Source code and datasets used in our study are available at: https://github.com/LaureBerti/Learn2Clean.

Table 1: Real-world datasets

Datasets	[#]Att.	[#]Rows	Clustering	Regression	Classification
Google Play Store Apps	13	10.8k	X		X
Google Play Store Users	5	64.3k	X		
House Prices	81	1.46k	X	X	X

4.1 Compared Methods

We have compared the results of data preprocessing strategy returned by Learn2CLean to four types of data cleaning: (1) random selection (*RAND*) of a sequence of one (or none) curation task from each block of possible actions for normalization, feature selection, imputation, outlier, duplicate and inconsistency detection and removal (as depicted in Figure 1) with no particular order; (2) manual cleaning by a human expert in Data Science (*DS_EXP*); (3) one automated ML approach (*AUTO*) obtained by MLBox[3] including cleaning and preprocessing; and (4) *NO-PRE* when no data preparation/curation is achieved. In particular, we have compared the quality metrics of the ML models applied to the preprocessed datasets obtained from these various preparation strategies, respectively MSE for regression, accuracy for classification, and silhouette for clustering[4]. In the case of random preprocessing, we averaged the results in terms of quality and time over the total number of execution runs.

We used default parameter settings for all the ML models with no particular hyper-parameter optimization and future work will be to integrate this important aspect and provide an in-depth experimental analysis and a fair comparison with other AutoML approaches [20] (such as AutoSklearn[5]). In these approaches, the user has to predefine the pipeline of default preprocessing methods to be used for feature selection (e.g., drift thresholding for MLBox or variance thresholding for AutoSklearn) and imputation techniques (e.g., One-Hot encoding for AutoSklearn). They do not include approximate duplicate or inconsistency detection/correction. Feature preprocessing is a single transformer which implements, for example, feature selection or transformation of features into a different space (i.e., PCA). The AutoML preprocessors do not test and select the optimal preprocessing method for a given dataset and their core added-value is on hyper-parameter optimization of the ML models.

In average, it takes 1.55 seconds for Learn2CLean to enumerate all possible cleaning strategies given the 19x19 Q-matrix for the 18 possible preprocessing methods. Then, each strategy as a sequence of curation tasks is executed with a duration depending on the dataset size, the number of glitches to detect and correct, and the time complexity of each task. Ultimately, the strategy with best quality metric is selected by Learn2CLean. In the last columns, Table 2 presents the pipeline of curation selected by Learn2CLean and the overall execution time.

4.2 Clustering

Clustering analysis was performed using K-Means (KMEANS) and Hierarchical clustering (HCA) methods. The number of clusters that maximizes the silhouette for each clustering method was automatically selected to perform the clustering. Table 2 presents the silhouette measures obtained by KMEANS and HCA applied to the Learn2CLean-preprocessed vs no-preprocessing, random, manually, and AutoML curated datasets. We can observe that Learn2CLean and *AUTO* show the best silhouette values for the three datasets, close or better to what an expert would obtain in reasonable time: less than one minute for Google Play Store Apps dataset and from 15 to 40 seconds for the other datasets.

4.3 Classification

For classification, the observations were split into a training and test set where 70% of data was used for training and 30% for testing. The model was fit to the training set, and the fitted model was used to predict the responses for the observations in the testing set. Classification methods cannot be executed and accuracy cannot be computed in presence of missing values, which is the case for House Prices dataset where 3 variables have from 80% to 99% missing values (MiscFeature, Fence, PoolQC). The classification methods require first feature selection based on the ratio of missing values for example, then imputation for other missing values, and another feature selection to avoid collinearity. Consequently, *RAND* and *NO-PRE* are not applicable (NA) and *DS_EXP* curation is the best strategy for this dataset because the preprocessing pipeline is quite complex with reiteration of feature selection methods before and after handling missing values. For this set of experiments, we initialized the Q-matrix of Learn2CLean to avoid re-iteration of methods from the same block. In other words, feature selection methods are mutually exclusive in the same pipeline; similarly only one imputation method can be applied. This explains the relatively low accuracy of Learn2CLean in this case and the need of expertise. However, for Google Play Store Apps classification, *AUTO* and Learn2CLean the best accuracy values for NB and and LDA respectively; not surprisingly, *NO-PRE* and *RAND* give the worst accuracy values.

	LASSO (MSE)	> 1	> 1	0.165	0.138	**1.44E-12**	KNN→ZSB→LASSO	24.2
	MARS (MSE)	0.175	0.192	**0.163**	NA	0.231	IQR→MICE→MARS	134.5
	OLS (MSE)	> 1	> 1	0.176	0.137	**2.20E-25**	KNN→ZSB→OLS	45.1

4.4 Regression

For LASSO and OLS regression, we can observe that Learn2CLean has the lowest MSE for House Prices dataset and it outperfoms the other curation approaches. For *RAND* and *NO-PRE*, MSE values are not reliable (>1) because of high collinearity of the dataset variables.

In conclusion, the results of our limited set of experiments is promising and has opened several directions for research and improvements of Learn2CLean algorithm and the experimental set-up. In particular, we plan further experiments with semi-synthetic data where noise injection is carefully controlled in order to study more complex and intricate distributions of various glitch types and patterns [3] (combining duplicates, inconsistencies, missing and outlying values) and their impact on the robustness of our approach. We also plan to combine AutoML hyper-optimization with Learn2CLean extended library of preprocessing methods and Q-learning based selection of the best preparation strategy.

5 CONCLUSIONS

We proposed an approach based on Q-learning that identifies the optimal data preprocessing strategies for representative ML models applied to various real-world datasets. To the best of our knowledge, Learn2CLean is the first approach that leverages reinforcement learning for data preparation. Although there is no universally adequate data preprocessing procedure, we were able to learn hidden features for selecting the optimal data preprocessing for a given dataset and a given ML task. Our preliminary results show that an instantiation of the proposed framework based on Q-Learning is efficient and a promising direction for automating data curation. As future work, we plan to explore a wider spectrum of datasets from diverse applications of Web content extraction and mining, and extend the set of data preprocessing and ML methods to test Learn2CLean in a wider range of settings.

ABSTRACT

Most network embedding algorithms consist in measuring co-occurrences of nodes via random walks then learning the embeddings using Skip-Gram with Negative Sampling. While it has proven to be a relevant choice, there are alternatives, such as GloVe, which has not been investigated yet for network embedding. Even though SGNS better handles non co-occurrence than GloVe, it has a worse time-complexity. In this paper, we propose a matrix factorization approach for network embedding, inspired by GloVe, that better handles non co-occurrence with a competitive time-complexity. We also show how to extend this model to deal with networks where nodes are documents, by simultaneously learning word, node and document representations. Quantitative evaluations show that our model achieves state-of-the-art performance, while not being so sensitive to the choice of hyper-parameters. Qualitatively speaking, we show how our model helps exploring a network of documents by generating complementary network-oriented and content-oriented keywords.

1 INTRODUCTION

Networks are ubiquitous. The Web is a large-scale network of resources, social media help developing broad online social networks [6], the scientific literature forms a vast network of documents, from which one can derive a network of co-authors [16], *etc.* Understanding and exploring these networks involves solving tasks like node classification or link prediction. Efficiently solving these tasks via machine learning requires meaningful representations of the nodes.

The usual approach is to learn node representations using techniques originally devised for word embedding, based on the distributional hypothesis [13]. The analogy between word embedding and network embedding makes sense, because of the similarities in some of the statistical properties of networks and language [11]. DeepWalk [11], arguably the most popular network embedding algorithm, consists in extracting sequences of nodes, akin to sentences, via truncated random walks and then learning node representations based on the Skip-Gram model [9], using the hierarchical softmax approximation. Node2Vec [5] builds on DeepWalk and suggests another strategy for extracting node sequences via biased truncated random walks. It learns the node representations based on the Skip-Gram model, using the negative sampling approximation (SGNS). Metapath2vec [3] adapts DeepWalk to heterogeneous networks. Other variants based on SGNS are generalized into a common frame in [12].

Dealing with large-scale networks requires low-complexity algorithms. An issue with these algorithms is that SGNS scales linearly in the size of the corpus of node sequences. GloVe [10], the main alternative of SGNS, hasn't been investigated yet for network embedding, even though it scales sub-linearly in the size of the corpus. Still, GloVe is limited in the sense that it ignores non co-occurrence, as opposed to SGNS, which could result in less relevant node representations.

In this paper, we address these two issues and propose a matrix factorization approach for network embedding, inspired by GloVe. Our contributions are the following:

- we present a general model for network embedding, that consists in factorizing a thresholded co-occurrence matrix. By formulating a regression problem on all positive entries and randomly sampled zero entries, this model can take both co-occurrence and non co-occurrence into account, while preserving a competitive time complexity;
- we show how to extend this general model to networks of documents, by jointly learning word, document and node representations;
- we quantitatively assess the performance of the general model on well-known networks, against recent baselines. Not only we show that it outperforms GloVe by a very large margin on several datasets, but we also show that it outperforms on-par with recent network embedding algorithms;
- we quantitatively and qualitatively show that our model brings interesting innovation to deal with network of short

documents. We show how to leverage the extension of our model to explore such networks by suggesting keywords.

The rest of the paper is organized as follows. In Section 2 we survey related work. We present in details our general model, discuss its relationship to other models, and show how to deal with networks of short documents by incorporating text into the model in Section 3. Next, in Section 4, we present a thorough experimental study, where we assess the performance of our model following the usual evaluation protocol on a node classification task for well-known networks. We also discuss hyper-parameter sensitivity, and evaluate, quantitatively speaking, the extended model for networks of documents. In Section 5, we present a case study that illustrates the recommendation of keywords with the extended model. Lastly, we conclude this paper and provide future directions in Section 6.

The code for both our model and the evaluation procedure are made publicly available[1].

2 RELATED WORK

The quality and informativeness of data representation greatly influence the performance of machine learning algorithms. For this reason, a lot of efforts are devoted to devising new ways of learning representations [1]. Word embedding, *i.e.*, the task of learning representations of words, is tightly connected to the task of learning representations of nodes, *i.e.* network embedding. In this section, we first cover important works related to word embedding and then survey recent developments in network embedding.

2.1 Word Embedding

The distributional hypothesis is the basis for word embedding. It states that distributional similarity and meaning similarity are correlated, which allows learning representation of words based on the contexts in which they occur, the context of a word being co-occurring words [13]. Co-occurrences are observed by sliding a window over a large corpus.

The Skip-Gram [9] model learns word representations by maximizing the log-likelihood of a multiset of co-occurring word pairs, C:

$$\sum_{(w_i, w_j) \in C} \log p(w_j|w_i). \tag{1}$$

The conditional probability is given by the softmax function, parameterized by the word vectors:

$$p(w_j|w_i) = \frac{e^{u_i \cdot v_j}}{\sum_W e^{u_i \cdot v_w}}. \tag{2}$$

This formulation is impractical because of the cost of computing the denominator. For this reason, two variants are introduced in [9]. Skip-Gram with Hierarchical Softmax (SGHS) uses a binary tree to approximate $p(w_j|w_i)$ and speed-up learning. Skip-gram with Negative Sampling (SGNS) redefines $p(w_j|w_i)$ to make it easier to compute:

$$p(w_j|w_i) = \frac{1}{1 + e^{-u_i \cdot v_j}} = \sigma(u_j \cdot v_j). \tag{3}$$

[1] https://github.com/brochier/gvnr

The objective becomes maximizing the following log-likelihood:

$$\sum_{(w_i, w_j) \in C} \Big(\log \sigma(w_j \cdot w_i) + \sum_{k=1}^{K} \mathbb{E}_{w_k \sim q(w_k)} \big[\log \sigma(-w_k \cdot w_i) \big] \Big). \tag{4}$$

It boils down to a classification task that consists in distinguishing the pairs of co-occurring words in C from random pairs of words, *i.e.* the negative samples. For each $(w_i, w_j) \in C$, K negative samples (w_i, w_k) are drawn, with $q(w_k) \propto \text{frequency}(w_k)^{\frac{3}{4}}$.

The GloVe [10] model learns word representations by factorizing the word-word co-occurrence matrix. Its objective is minimizing the reconstruction error, only for positive entries of X:

$$\sum_{i=1}^{n} \sum_{j=1}^{n} f(x_{ij}) \big(u_i \cdot v_j + b_i^U + b_j^V - \log(x_{ij}) \big)^2, \tag{5}$$

where $f(x_{ij})$ is the following weighting function, that notably reduces the importance of rare co-occurrences and filter-out zero entries:

$$f(x_{ij}) = \begin{cases} \big(x/x_{\max}\big)^{\frac{3}{4}} & \text{if } x < x_{\max}, \\ 1 & \text{otherwise.} \end{cases} \tag{6}$$

The authors show that the distribution of x_{ij} follows a power-law and that the time complexity of GloVe is $O(|C|^{\frac{1}{\alpha}})$, α being the exponent of the power-law. Because α is usually larger than 1 for text, $\frac{1}{\alpha}$ becomes smaller than 1. Hence, this model has a better time complexity than Skip-gram with Negative Sampling, which runs in $O(|C|)$.

In [8], Levy and Goldberg note that the introduction of a bias for each target/context word adds an extra degree of freedom to the GloVe model as compared to the Skip-gram model.

2.2 Network Embedding

Even though the distributional hypothesis originated in linguistics and is naturally leveraged for word embedding, Perozzi *et al.* establish the connection with network embedding. To do so, they show that the frequency at which nodes appear in short random walks follows a power-law distribution, like the frequency of words in language [11].

They propose DeepWalk, that consists in applying skip-gram with hierarchical softmax on a corpus of node sequences, deemed equivalent to sentences, generated with truncated random walks [11]. For some specific tasks, the representations learned with DeepWalk offer large performance improvements. Thus, many subsequent works focus on modifying or extending DeepWalk. Node2vec replaces random walks with biased random walks, in order to better balance the exploration-exploitation trade-off, arguing that the added flexibility in exploring neighborhoods helps learning richer representations [5]. Dong *et al.* address the heterogeneous network representation learning problem. They propose Metapath2vec [3], a modification of DeepWalk based on meta-path-based random walks to generate sequences of heterogeneous nodes. They also suggest learning the representation with negative sampling instead of hierarchical softmax. In [18], Yang *et al.* prove that skip-gram with hierarchical softmax can be equivalently formulated as a matrix factorization problem. They then propose Text-Associated DeepWalk (TADW), to deal with networks of documents. TADW consist

Table 1: Notations.

Notation	Definition
n	Number of nodes.
d	Embedding dimension.
C	Corpus of co-occurring nodes.

$X \in \mathbb{R}^{n \times n}$	Co-occurrence matrix.
n_i	Number of nodes that co-occur with node i.

in constraining the factorization problem, with a pre-computed representation of documents via LSA [2].

Qiu *et al.* [12] provide the theoretical connections between Skip-Gram based network embedding algorithms and the theory of graph Laplacian. This allows them to unify DeepWalk, LINE [15] (which they prove to be a special case of DeepWalk), PTE and Node2Vec, all with with negative sampling, into the matrix factorization framework.

3 MODEL FORMULATION

In this section, we present our model, *GVNR* (Global Vectors for Node Representation), to learn node representations, taking into account both co-occurrence and non co-occurrence. We formulate a factorization problem on the thresholded co-occurrence matrix. More specifically, we formulate this problem so that the reconstruction error is measured on all the positive entries and some randomly sampled zero entries. We begin by listing the set of notations we use in Table 1, next we describe the matrix to factorize and then formulate the factorization problem. Eventually, we discuss the relationship to other models.

3.1 Description of the Matrix to Factorize

We observed node co-occurrences in truncated random walks [11]. Then, for each node j visited within q steps, with $q \leq l$, from a node i, we increase X_{ij} by $\frac{1}{q}$ [10]. Thus, we construct a weighted co-occurrence matrix, so that distant co-occurrences are increasingly downweighted. The matrix obtained with this procedure is approximately proportional to the weighted sum of the l first of the adjacency matrix: $\sum_{i=1}^{l} \frac{1}{i} A^i$. However, this sum is likely to give a denser co-occurrence matrix because unlikely and distant co-occurrences will lead to coefficients close to zero. On the contrary, the truncated random walk is likely to estimate these coefficients as exactly zero. Because we consider coefficients close to zero as noise, we're not interested in calculating them, and can computationally benefit from a sparser matrix. For the same reason, we zero-out coefficients that are less than a threshold $x_{\min}$, assuming they are irrelevant.

3.2 Formulation of the Factorization Problem

We formulate a factorization problem on X, measuring the error only for positive coefficients and a fraction of randomly sampled zero coefficients. Note that we measure the error w.r.t the logarithm, which help compress the range of values in X [10]. Because the matrix is already thresholded, we assume all the remaining positive entries have the same importance, thus we don't weight the least-square objective:

$$\underset{U,V,b^U,b^V}{\operatorname{argmin}} \sum_{i=1}^{n} \sum_{j=1}^{n} s(x_{ij}) \Big(u_i \cdot v_j + b_i^U + b_j^V - \log(c + x_{ij}) \Big)^2. \quad (7)$$

The constant $c \in]0; 1]$ allows for smoothing X while making the logarithm negative when $x_{ij} = 0$. The function s effectively selects the coefficients considered for measuring the reconstruction error:

$$s(x_{ij}) = \begin{cases} 1 & \text{if } x_{ij} > 0, \\ m_i & \text{else, with } m_i \sim \text{Bernoulli}(\alpha_i). \end{cases} \quad (8)$$

It takes the value 1 for all positive coefficients of X, while for zero coefficients, its value is given by a Bernoulli random variable, m_i, with a node-specific parameter α_i. Denoting the proportion of positive coefficient on the i$^{\text{th}}$ row of X by p_i, α_i is calculated in terms of the odd-ratio:

$$\alpha_i = \begin{cases} k \times \frac{p_i}{1-p_i} & \text{if } p_i \leq (k+1)^{-1}, \\ 1 & \text{else} \end{cases} \quad (9)$$

where $k > 0$ is an hyper-parameter that controls the proportion of zero coefficients incorporated into the calculation of the reconstruction error, akin to the number of negative samples in SGNS. The larger k, the more importance is given to pushing away vectors of non co-occurring nodes.

3.3 Relationship to Other Models

This objective function bears a resemblance to the objective of GloVe, still the two are quite different. As stated by the equation 5, GloVe performs a weighted least-square regression on the raw co-occurrence matrix. Although the authors of GloVe claim that rare co-occurrences are noisy and carry less information than the more frequent ones, this objective function still takes them into account (with a proportionally smaller weight, according to the equation 6). Our model has a stronger interpretation of this claim, by zeroing out rare co-occurrences, and weighting equally all the others. In addition, while all zero coefficients are ignored in GloVe due to the definition of f in equation 6, we incorporate a fraction of them, proportional to the quantity of positive coefficients. That constitutes an additional set of constraints we think should lead to better representations. Lastly, thresholding X helps us eliminating noise while drastically sparsifying it, since x_{ij} follows a power law [10, 11].

The complexity of Skip-Gram based algorithms, implemented with the procedure described in [9], is linear in the size of the multiset of pairs of co-occurring nodes, *i.e.* $O(|C|)$. Based on the proof given in [10], the complexity of our model is $O(|C|^{\frac{1}{\alpha}})$, where α is the exponent of the power law that models x_{ij}. For the networks studied in this paper, we observe a mean value for $\frac{1}{\alpha}$ of 0.79.

3.4 Extension to Networks of Documents

Lastly, we show how to extend the general model under the name *GVNR-t*, to deal with networks where nodes are text documents.

Assuming word order is negligible for documents [2], we can model a text as a bag of words and thus represent it by a vector $\delta \in \mathbb{N}^{+m}$, m being the size of the vocabulary. We can further

Table 2: General properties of the studied networks.

	$\|V\|$	$\|E\|$	# labels	weighted	multi-label
Citation 1	2,708	10,556	7	no	no
Citation 2	3,312	9,226	6	no	no
Co-authorship	5,021	29,856	5	yes	no
Protein	3,890	76,584	50	no	yes
Language	4,777	184,812	40	yes	yes

assume that the meaning of a text can be captured by averaging the representations of its words [7]. Therefore, with $W \in \mathbb{R}^{m \times d}$ a word embedding matrix, rather than learning the the context-vector of a node as explained previously, we define it as the average of the representations of the words it contains:

$$\underset{U,V,b^U,b^V}{\operatorname{argmin}} \sum_{i=1}^{n}\sum_{j=1}^{n} s(x_{ij})\Big(u_i \cdot \frac{\delta_j\, W}{|\delta_j|_1} + b_i^U + b_j^V - \log(c + x_{ij})\Big)^2, \quad (10)$$

where δ_j is the bag of words representation of text associated to the node j, and $|\delta_j|_1$ is the number of words in it. Thus, the model jointly learns node and word representations, that in turn allows representing documents.

4 QUANTITATIVE EVALUATION

A common task in network analysis is node classification. Following the experimental designs in recent works [12, 18], we assess the quality of the representations learned with *GVNR* by using them as input of a linear classifier to solve multi-class and multi-label classification tasks.

4.1 Networks

To show the versatility of *GVNR*, we consider five networks of various nature:

- Two citations networks: Citation (1) and Citation (2), extracted respectively from Cora and Citeseer[2]; each node is an article and is labelled with a conference.
- A co-authorship network extracted from DBLP[3]; each node is an author labelled with a domain of expertise[4] and each edge is weighted according to the number of common publications.
- A protein-protein interaction (PPI) network [14] which is a subgraph of the PPI network for Homo Sapiens. Each node is associated to several labels that represent biological states.
- A language network that describes collocated words observed in the first 10^8 bytes of the English Wikipedia[5] (as of March, 2006); each node is associated to multiple labels, which are the potential part-of-speech tags identified with the Stanford POS tagger [17].

The general properties of these five networks are reported in Table 2.

[3]https://dblp.uni-trier.de/
[4]https://static.aminer.org/lab-datasets/expertfinding/
[5]http://mattmahoney.net/dc/text.html

4.2 Tasks and Evaluation Metrics

For each network, we consider a classification task and evaluate the performance of a linear classifier, namely a logistic regression, using node representations as input. We use the LIBLINEAR implementation [4], without regularization, for a fair comparison between different representations. For each network, we train and evaluate the classifier by cross-validation, with varying split ratios.

More precisely, we consider a multi-class classification problem for the citation and co-authorship networks and measure the overall accuracy of the one-vs-all logistic regression. We consider a multi-label classification problem for the protein-protein and the language networks and measure the F_1 score of the one-vs-all logistic regression, following the procedure described in [12].

4.3 Compared Representations

We run $\gamma = 80$ random walks per node of length $t = 40$ and apply a sliding window of size $l = 5$ to generate a multiset of co-occurring nodes and then learn representation with $d = 80$ with four algorithms:

- DeepWalk: we report the results with the hierarchical softmax approximation.
- GloVe: we report the results with $x_{\max} = 10$.
- NetMF: we report the results with the small-scale implementation provided by the authors, with $k = 10$ negative samples.
- *GVNR*: we report the results with $c = 1$, $x_{\min} = 1$ and $k = 1$ and discuss their impact in the next sub-section.

4.4 Result Analysis

Tables 3 to 7 detail the accuracy measures. The classifier performs well with the representations learned by *GVNR*, achieving similar or better results w.r.t the representations learned with DeepWalk and NetMF. Still, there is one exception concerning the language network, where the classifier performs best with the representation learned with GloVe. We sum up our findings in two points:

(1) *GVNR* always achieves a good performance, while there is more variance in the performance of the baselines. For instance, NetMF is largely outperformed by the others on the language network, GloVe is also significantly outperformed on the co-authorship network, while DeepWalk struggles to learn good representations from the citation (2) network.
(2) Thresholding always improves the performance of *GVNR*. As an example, its leads to an average gain of 9.4 accuracy on the co-authorship network.

Interestingly, GloVe produces the best results on the language network. The average number of neighbors is 38.7 for this network which makes it the denser network.

4.5 Impact of the Hyper-Parameters

Figure 1 shows the sensitivity, in terms of accuracy, of *GVNR* to its hyper-parameters, namely, the threshold $x_{\min}$, the shifting constant c, the window length l, and the sampling proportion k. We only report the results for the citation (1) network since their are similar across the considered networks. We see that c has little impact on the accuracy. In practice, we found *GVNR* performs best across the

Table 3: Accuracy on the citation (1) network.

	% of training data				
	10%	20%	30%	40%	50%
GloVe	57.7	62.4	69.5	72.8	73.8

DeepWalk	41.3	52.5	54.5	55.5	56.0
GVNR ($x_{\min} = 1$)	45.6	**55.6**	**57.3**	**58.7**	**59.0**

Table 5: Accuracy on the co-authorship network.

	% of training data				
	10%	20%	30%	40%	50%
GloVe	41.0	42.1	43.7	46.4	51.2
GVNR ($x_{\min} = 0$)	60.3	64.6	67.4	67.1	68.2
NetMF	60.7	66.2	70.1	72.1	72.8
DeepWalk	**75.4**	**77.2**	**77.3**	**75.9**	**79.3**
GVNR ($x_{\min} = 1$)	74.7	75.3	76.3	73.8	74.6

Table 6: F_1 score on the language network.

	% of training data				
	10%	20%	30%	40%	50%
GloVe	**34.0**	**44.1**	**46.7**	**47.7**	**48.6**
GVNR ($x_{\min} = 0$)	31.7	40.7	43.2	44.7	45.1
NetMF	27.5	33.5	36.2	37.7	38.7
DeepWalk	33.6	43.6	46.2	47.6	48.2
GVNR ($x_{\min} = 1$)	32.2	41.7	44.0	45.2	46.1

datasets with $c = 1$. It seems that the model performs best with a threshold value between 1 and 5. Setting $x_{\min} > 0$ clearly improves the performance. In general, we observed that $k = 1$ constantly brings an improvements over $k = 0$, but higher values only brings a boost for high training ratios. Finally, the accuracy increases along with the window size l, with few improvements above $l = 5$.

4.6 Additional Results with Text

We now report additional results when taking into account the text information, associated to the nodes of the citation networks, *i.e.* titles and abstracts. We consider three ways of learning text-aware representations: TADW [18], the representations learned with DeepWalk concatenated with the LSA representation of the texts, and *GVNR-t*. We report the results for TADW with 20 iterations and 4 iterations for *GVNR-t*.

Table 7: F_1 score on the protein-protein network.

	% of training data				
	10%	20%	30%	40%	50%
GloVe	11.8	13.8	15.6	17.3	19.1
GVNR ($x_{\min} = 0$)	10.7	13.3	15.0	16.7	18.1
NetMF	10.2	11.7	13.5	14.7	16.1
DeepWalk	**12.2**	**13.9**	**16.2**	**17.8**	**19.6**
GVNR ($x_{\min} = 1$)	11.7	13.3	15.8	17.6	19.2

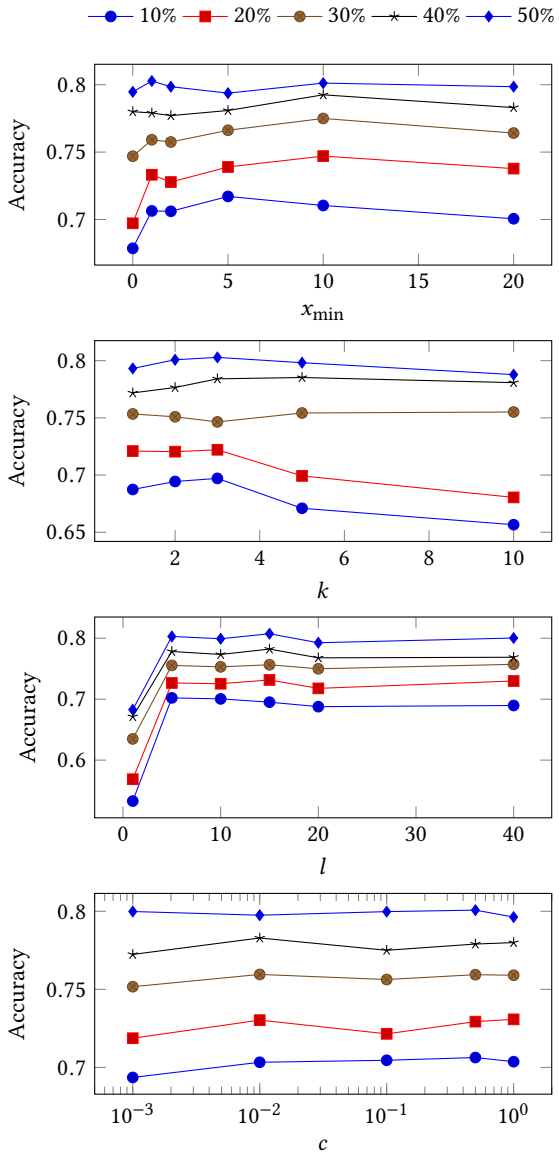

Figure 1: Sensitivity of *GVNR* to the hyper-parameters $x_{\min}$, k, l and c on the citation (1) network.

Tables 8 and 9 report the accuracies. *GVNR-t* shows interesting improvements over the simple concatenation of text and graph features and the reference baseline in the field, TADW. This motivates the study of the word representations learned by *GVNR-t* and the interplay between the node and document representations.

5 CASE STUDY

To showcase the usefulness of learning jointly word, node and document representation, we apply *GVNR-t* to full DBLP network that consists in 1,397,240 documents and 3,021,489 citation relationships. After computing X, we threshold it with $x_{\min} = 20$, which divides the density of $X_{(ij)}$ by 50. For the learning phase, we keep the same settings as before, that is $d = 80$, $k = 1$, $c = 1$, $l = 5$. Note that we apply a standard pre-processing, that consists in merging recurrent phrases, as suggested in [9]. Computing X and estimating U and W, the node and word representations takes about 8 hours on a single machine with 32 cores and 192 GB of RAM.

Our aim is to show that we can measure the similarity, on the one hand, between word and node representations, and, on the other hand, between word and document representations, to extract sets of complementary keywords.

Tables 10 and 11 show 2 randomly selected papers for which we computed the 5 closest word embeddings w_k to, respectively, (i) the node representation u and (ii) its content representation v. First, we note that the keywords are all relevant, even though none of them actually appear in the documents. Then, we see that words close to the node representation are more general, giving a broad view of the studied topic, whereas words close to the document representation are more specialized and provide a more fine-grained perception. We suspect that the network topology, mostly influencing U, helps locating a node in its broader context, while the content of documents, mostly influencing W, helps in selecting some very specific keywords. In future work, we would like to investigate further the quality of the learned representations for a wider range of recommendation tasks.

Table 10: Keyword recommendation by selecting the closest word embeddings w_k to both embeddings u (node) and v (content) of an input document (1).

Closest words to v (content)	*company, consumer brand, today highly competitive, data cleaning, consumer heterogeneity*

6 CONCLUSION

In this paper, we presented *GVNR*, a matrix factorization based method for network embedding, that better handles non co-occurrence than GloVe. We further extended this model to incorporate textual content associated with the nodes to learn meaningful representations of words and documents. We showed that *GVNR* performs state-of-the-art results on a wide range of networks and can provide recommendations based on the distance between words, documents and graph embeddings. In future works we would like to explore further the relations between the word embeddings learned with *GVNR-t* and traditional word embeddings learned with GloVe or Skip-Gram. More particularly, we would like to study whether *GVNR-t* could help learning better word embeddings from small structured corpora.

ABSTRACT

At the core of many important machine learning problems faced by online streaming services is a need to model how users interact with the content they are served. Unfortunately, there are no public datasets currently available that enable researchers to explore this topic. In order to spur that research, we release the Music Streaming Sessions Dataset (MSSD), which consists of 160 million listening sessions and associated user actions. Furthermore, we provide audio features and metadata for the approximately 3.7 million unique tracks referred to in the logs. This is the largest collection of such track metadata currently available to the public. This dataset enables research on important problems including how to model user listening and interaction behaviour in streaming, as well as Music Information Retrieval (MIR), and session-based sequential recommendations. Additionally, a subset of sessions were collected using a uniformly random recommendation setting, enabling their use for counterfactual evaluation of such sequential recommendations. Finally, we provide an analysis of user behavior and suggest further research problems which can be addressed using the dataset.

KEYWORDS

music streaming; user sessions; dataset; user interactions

1 INTRODUCTION

A long-standing and central challenge for online services is to understand and model how users behave [18]. For web search and online advertising, this has led to a large body of work on click modeling, most of which would not have been possible without access to publicly available click logs [8]. Modeling user behaviour is similarly important to streaming services [17, 19], but to the best of our knowledge there are no user interaction datasets currently available to the public. This is particularly limiting when it comes to designing recommender systems, where the use of implicit feedback is often critical [14].

Motivated by the paucity of user interaction logs in streaming, we release the Music Streaming Sessions Dataset (MSSD), which consists of over 160 million listening sessions with associated user interaction information. In addition, we provide audio features and metadata for the approximately 3.7 million unique tracks referred to in the logs, making this the largest collection of such track metadata currently available to the public. A useful characteristic of the dataset is that a subset of the sessions contained in the log were obtained using a uniformly random shuffle, enabling research on counterfactual methods. Lastly, we provide snapshots of the playlists from which this subset of sessions was streamed.

By providing the sequences of track plays, the smaller pools of tracks which were available for recommendation during the session, and the probabilities each of those tracks had of being played next, we allow this dataset to be used as a test-bed for sequential recommendation research, and in particular with counterfactual approaches to the problem. The rise of counterfactual methods [4] dramatically improved the speed of experimentation for online services, however there is still very little data available to academic researchers in that area, and no data at all for the specific problem of sequential recommendation.

One of the main ambitions of this dataset release is to enable public research on two central challenges facing music streaming services, namely understanding when a user will 1) skip a track, and 2) move from one listening context to another. Related to this dataset we therefore also organized a skip prediction machine learning challenge for the 2019 WSDM Cup. More generally, we expect that this dataset will spur further research in the area of Music Information Retrieval (MIR), where it will function as a partial expansion of the Million Song Dataset (MSD) [3]. For the first time we provide a dataset that links track audio features with user listening behaviour. Finally, sequentially recommending items for users is of particular importance to music streaming services but also to other types of services, such as news or e-commerce, for example in next-basket recommendation. We believe the underlying solutions for these cases would be comparable to those for music.

Our contributions are therefore threefold: (1) we provide the only dataset of streaming logs and interactions currently available to the public in Section 3; (2) we provide an analysis of the logs in Section 4; and (3) we identify important research questions that can be addressed using this dataset in Section 5.

2 RELATED WORK

Click log releases have played a key role in allowing the development of sophisticated click models for web search and advertising applications, with companies including Microsoft, Yahoo, Yandex, and Criteo all providing such logs to the academic research community. An overview of the click modeling literature, and available datasets is provided in [8].

In the context of recommender systems there are fewer such interaction logs available. Instead, recommender systems datasets have tended to contain explicit ratings [2, 9, 11]. Some streaming logs containing user interactions have been released, for example the XING dataset which was part of the 2016 Recsys Challenge [1].

https://doi.org/10.1145/3308558.3313641

However, this dataset was in the field of job recommendations and is no longer publicly available.

There are several music listening histories datasets, most of which were crawled from from social media such as last.fm or twitter, however none of these datasets contain user interactions beyond what songs were listened to [5, 12, 15–17]. Similarly, the kkbox dataset from the 2018 WSDM Cup challenge provides listening logs [7], but these logs are not timestamped, nor do they provide user interactions beyond what tracks were listened to. Thus, although there are some music listening logs, crucially none of these contain information about how users interacted with the tracks they listened to, showing instead only what tracks users were exposed to.

An important feature of our dataset is that a subset of the sessions contained in the logs were collected from users experiencing a uniformly random shuffle function. This allows our dataset to be used in connection with so-called counterfactual methods. These have the potential to allow offline evaluations of new algorithms while only requiring some randomization of the deployed algorithm's output [4]. If the cost of randomizing the deployed algorithm's output is not too great, this can provide a practical way of obtaining results that are potentially as reliable as those obtained from A/B testing, but without requiring the variants being tested to be production ready [10]. This can allow tests of new algorithms to be carried out more quickly and efficiently than what is currently possible. To the best of our knowledge there are no other public datasets except the counterfactual test-bed from [13]. Our dataset distinguishes itself since it is focused on the novel problem of applying counterfactual methods to sequential recommendations. Counterfactual evaluation of sequenced recommendations provides an interesting challenge since a naive approach would suffer from a growth in the propensities exponential in the length of the sequence.

3 THE MUSIC STREAMING SESSIONS DATASET

The MSSD consists of 160 million streaming sessions with associated user interactions, audio features and metadata describing the tracks streamed during the sessions, and snapshots of the playlists listened to during the sessions. The dataset is hosted at http://research.spotify.com/datasets/music-streaming-sessions together with a set of tools for working with the dataset.

The streaming sessions are stored in a log, where each row of the log contains a session id, a timestamp, contextual information about the stream, the track and context id's, and the timing and type of user interactions within the stream. A schema for the log is provided in Table 1. Each session is defined to be a period of listening with no more than 60 seconds of inactivity between consecutive tracks. Additionally for this dataset we set a cut off of at most 20 tracks per session as part of our privacy strategy. Sessions included in the dataset are sampled uniformly at random from eligible listening sessions on the contexts included in the dataset over an 8 week period. We exclude sessions that include tracks which did not meet a minimum popularity threshold. The sessions in this dataset are sampled from radio, personalized recommendation mixes, the user's own collections, and 100 of the most popular playlists on a major music streaming service. The logs therefore contain a mix of listening sessions based on user's personally curated collections; expertly curated playlists; contextual, but non-personalized recommendations; and finally, personalized recommendations.

For each track contained in the sessions, we provide audio features and metadata describing the track. This part of our dataset can be regarded as a partial update and expansion of the Million Song Dataset (MSD) [3]. We provide approximately 3.7 million tracks, and many new features not included in the Million Song Dataset. These include features like acousticness, a measure of confidence that the track is acoustic; downbeats, estimated timestamps for the downbeats in a track; and valence, a measure of how positive a track sounds. The schema for the track features is provided in Table 2, features which did not exist in the Million Song Dataset are bolded. More detailed descriptions of the features are available in [3] and on our dataset website.

3.1 Uniform Random shuffle subset

As noted earlier, counterfactual methods have the potential to allow offline evaluations of new algorithms if the deployed algorithm's output is randomized and the propensities are known [4]. The standard shuffle function used during streaming on our service is not uniformly random, however we have collected and labelled a subset of the sessions contained in this log using a uniformly random shuffle.

With this dataset we focus on the novel problem of applying counterfactual methods to sequential recommendations. Shuffled listening sessions provide a nice means of collecting randomized observations, without seriously harming the user's experience since the user already expects a somewhat random experience. However good and bad sequences of tracks can still be distinguished by a variety of session level and track play level metrics such as session length and skip rate.

For each session using the uniformly random shuffle function we include snapshots of the tracks contained in the playlist and their positions in the playlists. This allows us to use the logs and playlist snapshots for counterfactual evaluations of sequential recommendations as outlined in Section 3.1.

4 DATASET ANALYSIS

Here we provide summary statistics and figures for the dataset, highlight some of its properties, and explore implications for future user modeling efforts. The logs detail how users behave in terms of two particularly important forms of implicit feedback: user skip behavior, and their context switch behavior, i.e. when users change from one listening context or playlist to another.

4.1 Summary Statistics

The dataset consists of 160 million sessions with lengths varying between 10 to 20 interactions. Recall that a session is defined as a period of listening interrupted by no more than 60 seconds between consecutive playbacks. Sessions shorter than this limit are excluded to try to increase the amount of information available early in sessions to predict a user's interactions later in the session. Recall that longer sessions are excluded as part of our privacy strategy. Figure 1 shows that the proportion of sessions of a given length decreases steadily with increasing length, although sessions of

Table 1: Schema for the interaction log

Column name	Column description	Example value
session id	unique session identifier	57 _55129e3f-29bf-4ef6-aa72-d140333eac9c
session position	position of track within session	18

length 20 are much more common since sessions that were longer are capped at this length.

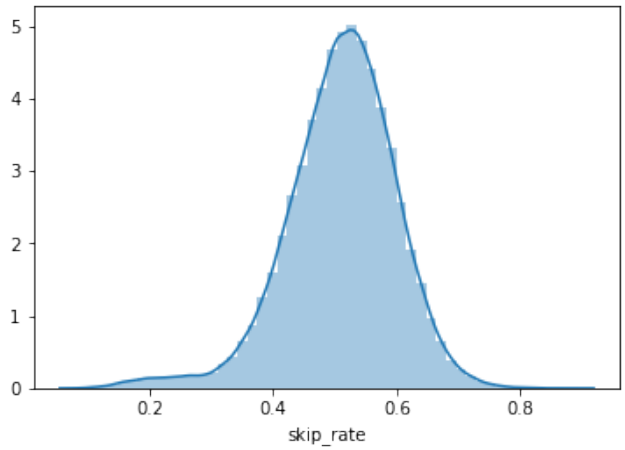

Figure 2: Distribution of skip rate across tracks

4.2 User Interactions

We begin by exploring user skip behavior. In this dataset we provide a variety of different skip definitions, for this analysis we use the skip _1 threshold. The distribution of skip rates across tracks is given in Figure 3.

In general, skip rates are higher for longer sessions, as shown in Figure 3. However, whereas skip rates are higher for longer sessions, skip rates are not substantially higher earlier in sessions, remaining relatively constant at a non-skip rate between 34% and 35% for all session positions.

Whereas it might be expected that a user explicitly selecting a song would lead to a low probability of that song being skipped, we see from Figure 4 that the reason for a track starting that is most

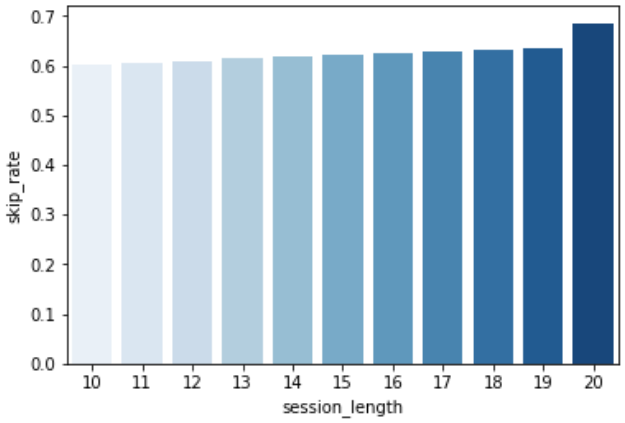

Figure 3: Session length against skip rate

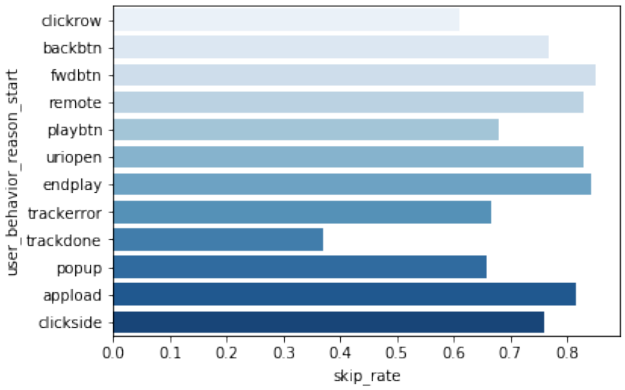

Figure 4: Skip rate against reason for start of playback

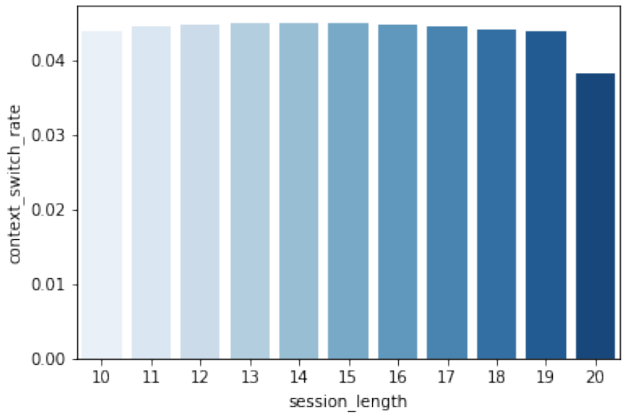

Figure 5: Session length against context switch rate

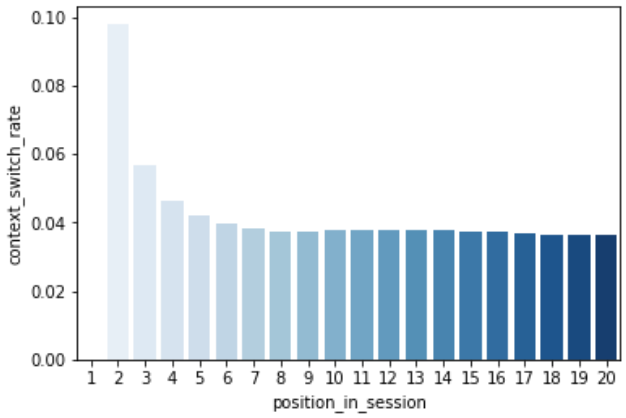

Figure 6: Session position against context switch rate

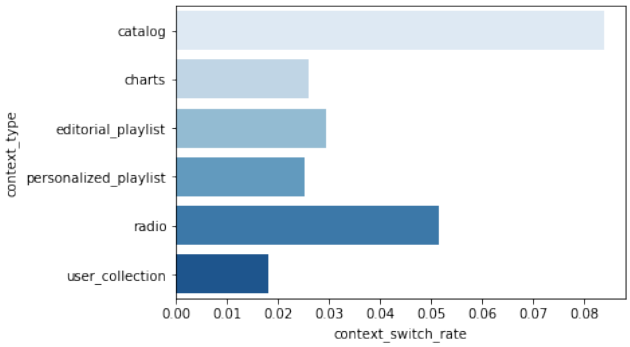

Figure 7: Context switch rate against source context

closely associated with a track not being skipped is that the previous track was listened to completion. This may be partly explained by the fact that although a user who explicitly selected a song wanted to listen to that track, a user who is in a so-called lean-back listening mode, is even less likely to skip. A deeper analysis of such listening modes is an interesting challenge for MIR researchers.

Whereas skip rates are highly correlated with session length, this is less obviously the case for the context switch rate, as shown in Figure 5, with the exception of sessions of length 20, which due to the cutoff include potentially longer sessions. Here we see a substantially lower context switch rate, possibly reflecting extreme lean-back sessions, such as sleep playlists. Despite this, we see in Figure 6 that context switches are much more likely at the beginning of a session. Finally, we see in Figure 7 that the likelihood of a user switching context depends heavily on the source context. Understanding the causes and directions of users context switches is an important challenge for music streaming services.

4.3 Track Features

Figure 8 shows the distributions of feature values across tracks for selected audio features. The distributions for the remaining audio features are included on the dataset website. Features display dramatically different distributions, with a feature like instrumentalness bimodal and highly skewed, with most tracks having a very low value indicating an extremely low probability estimate

of the track being an instrumental track, and relatively few tracks displaying a high estimated probability of being instrumental.

Such a large number of audio features and the variations in their distribution could inspire future research on understanding how user consumption is linked with content level features. While most user engagement studies in the past have looked at patterns across recommended items, jointly performing such analysis on content features would make for an interesting insightful discussion.

5 FURTHER RESEARCH PROBLEMS

While we have highlighted issues around user interactions with a sequential recommender, specifically predicting user interactions (skips) and context switches, the released dataset allows us to go beyond these problems, and can serve as a benchmark dataset for researchers interested in various other research areas. Here we list a few key potential research areas.

1. Session based Sequential Recommendations
While most machine learning techniques focus on either item recommendation or even set recommendations aimed at increasing instantaneous user satisfaction, we believe that this dataset will enable researchers to propose novel techniques aimed at optimizing user sessions, and more long term satisfaction.

2. User Intervention in Automated Systems
For each session, the dataset provides user interaction with each track, which opens up interesting problems around human interventions with automated systems. Indeed, the user might begin by relying on the recommender system to suggest content, but at some point decide to intervene, either slightly (e.g. only skip a track) or to a larger extent (e.g. stop using the recommender system and move to their own playlist). As we develop advanced automated systems, we need to understand user reactions to them and comprehend, predict and leverage user interventions, in an attempt to not only reduce the need for further interventions but also to optimize the system more efficiently.

3. Offline Evaluation of Recommender Systems
Metrics and reward models of machine learning systems relies heavily on user feedback. The detailed per item meta-data allows researchers to develop advanced evaluation metrics and reward functions for systems to learn from.

4. User Journeys
The session level data enables research on carefully constructing user journeys not only in the general space of recommendation items, but also in the space of user moods. Indeed, research on music therapy has highlighted the impact of positive music [6], and this dataset enables researchers to develop carefully crafted user journeys to affect user moods.

5. Proactive Recommendations
Anticipating user actions and interventions allows machine learning systems to be proactive in recommendations. So far, research on proactive recommendations has been conducted in the industry by researchers having access to large scale user interaction logs. We hope the dataset enables academic researchers to conduct research on proactive systems.

6. Counterfactual Evaluation
Most major web companies rely on large scale A/B tests for model development and iteration. Counterfactual estimation of metrics has recently enabled researchers to make offline predictions of online metrics. We advocate the use of counterfactual estimation techniques for unbiased offline evaluation of systems using our dataset. Compared to A/B tests, offline evaluation allows multiple models to be evaluated on the same log, without the need to be run online. Effectively, counterfactual estimation techniques make it possible to run many A/B tests simultaneously, leading to substantial increase in experimentation agility. Developing good ounterfactual estimators for sequential recommendations is an open research problem for which this dataset can function as a test bed.

Owing to the heterogeneous data released as part of this dataset (user sessions, audio featres, user contexts, etc), we envision myriad future use-cases of this dataset, beyond the six broader areas highlighted above.

6 CONCLUSION

The problems of understanding, modeling and predicting how users interact with content on streaming services has until now been understudied, mainly because of a lack of access to data. With the paper, we provide the only dataset of streaming logs and user interactions currently available to the research community.

With this dataset we address two key problems facing streaming services, namely how to predict user skips and context switches. We provide an analysis of the dataset in terms of these problems. In particular, we illustrated that skip behavior in a session is correlated with prior skip behavior within that session. We believe that a thorough investigation of these forms of user behavior is an important future research challenge.

Finally, we identify other important research questions that can be addressed using the dataset. We believe that the task of providing session-based sequential recommendations is of particular importance, due to the need for fast learning from limited user-based information when onboarding new users.

While the dataset enables new types research directions, compromises were made for privacy and commercial reasons. An interesting future extension of this dataset would be to provide more precision on the skip information than the currently bucketed times. That level of information could allow to predict moments in the track where skips are most likely to occur, which could be of great value for generative and interactive music models.

ABSTRACT

Over the last decade, the illegal distribution of child sexual abuse imagery (CSAI) has transformed alongside the rise of online sharing platforms. In this paper, we present the first longitudinal measurement study of CSAI distribution online and the threat it poses to society's ability to combat child sexual abuse. Our results illustrate that CSAI has grown exponentially—to nearly 1 million detected events per month—exceeding the capabilities of independent clearinghouses and law enforcement to take action. In order to scale CSAI protections moving forward, we discuss techniques for automating detection and response by using recent advancements in machine learning.

KEYWORDS

child sexual abuse; child exploitation; online abuse

1 INTRODUCTION

Child sexual abuse is a horrific crime affecting an estimated 9–19.7% of girls and 3–7.9% of boys [2, 31, 38]. These children endure indecent exposure, forced intercourse, and sex trafficking [33]. Even after escaping abusers, victims face immediate and lasting consequences such as a heightened risk of depression, substance abuse, and suicide [5, 23].

Compounding the enormity of this situation, in the last decade, child sexual abuse imagery (CSAI) has evolved to leverage online sharing platforms as a tool for distributing abusive videos and images. The children depicted are re-victimized every time the content is accessed. According to the Internet Watch Foundation, which reviews reports of CSAI in the United Kingdom, 53% of CSAI images depict the abuse of children under the age of ten and 28% of CSAI images involve rape and sexual torture [20].

Platform operators including Google, Microsoft, Facebook, and Twitter have responded by proactively blocking attempts to access, share, or distribute CSAI [1, 9, 28, 32]. This involves scanning user-generated content using fingerprints of known abusive images [29] and reporting all incidents, as required by law, to independent clearinghouses that then manually process and action reports. Likewise, law enforcement actively disrupts criminal communities and web forums that foster child sexual abuse [16]. For example, law enforcement agencies dismantled the W0nderland Club, an online network of 300 participants who shared over 750,000 photos of child sexual abuse taken of 1,236 children [4].

Despite intense scrutiny into CSAI on the part of researchers and law enforcement, the broad scale of the problem and the effectiveness of current solutions for protecting online sharing platforms remains unknown. We address this gap by conducting the first longitudinal measurement study of CSAI distribution across the Internet. In collaboration with the National Center for Missing and Exploited Children (NCMEC)—the United States clearinghouse for all CSAI content detected by the public and online sharing platforms in the region—we examine metadata associated with 23.4M incidents of CSAI from 1998–2017. Our study captures the exponential growth of detected CSAI content, the expanding international scope of abuse, and the evolution of the technologies and mediums used to create and distribute CSAI content online.

Overall, our analysis reveals that online sharing platforms have accelerated the pace of CSAI content creation and distribution to a breaking point where NCMEC's manual review capabilities and law enforcement investigations no longer scale. To cope with the current volume of nearly one million CSAI reports per month, we argue there is a pressing need for these institutions and processes to

leverage technological advancements to automate CSAI detection and response. We outline promising directions, such as extensive use of deep-learning, that address pain points highlighted in our measurement findings.

In summary, the key insights of this study are:

CSAI reports are growing exponentially. Of 23.4M reports of CSAI, 9.6M (40%) occurred in 2017 alone. The ability of clearing houses to manually investigate each incident cannot scale to this volume of reports absent automated prioritization, labeling, and clustering.

Protecting against CSAI requires coordinated, global action. Ten years ago, 70% of CSAI reports reflected abuse in the Americas. Today, 68% of reports relate to abuse in Asia, 19% the Americas, 6% Europe, and 7% Africa.

New CSAI content is constantly emerging. 84% of detected CSAI images and 91% of videos are reported only once. The specter of potential false negatives due to unknown abusive imagery requires moving from the existing, decades old blacklist-based approaches to algorithms that recognize the nature of CSAI content.

Criminals readily adopt new technologies. Over the years, distribution vectors have changed from email and FTP, to peer-to-peer, and now Tor and resurgent chat and messaging apps. Protections must keep pace with advancements in both distribution channels and digital mediums

2 CHILD SAFETY LAWS & REPORTING

Before diving into our study, we briefly outline the laws in the United States surrounding child sexual abuse imagery (CSAI) and the process that the public and companies use to report abuse to the National Center for Missing and Exploited Children (NCMEC) [30]. These reports form the basis of our study.

2.1 Reporting requirements

CSAI refers to any visual depiction of sexually explicit content involving a minor under the age of 18. United States law prohibits the distribution, production, receipt, and possession of any such material (see generally 18 U.S. Code §2251, 2252). Furthermore, any United States-based electronic service provider (ESP) must report any apparent CSAI to the CyberTipline operated by NCMEC [30].

We note that similar laws exist in 82 countries around the world such as the 1978 Protection of Children Act [13] and the 1988 Criminal Justice Act [14] in UK. Many countries also have CSAI clearing houses—including Canada with the Canadian Centre for Child Protection [12] and United Kingdom with the Internet Watch Foundation [18].

Our study focuses on NCMEC reports as NCMEC is by far the largest clearing house in the world: In 2016 NCMEC received 8.2 million CSAI reports, compared to 39,714 for the Centre for Child Protection [6] and roughly 105,000 for the Internet Watch Foundation during the same period [20]. The large volume gap between NCMEC and the other entities is due to the fact that many large US companies report all material detected on their platforms to NCMEC, with NCMEC routing reports to the correct law enforcement agency.

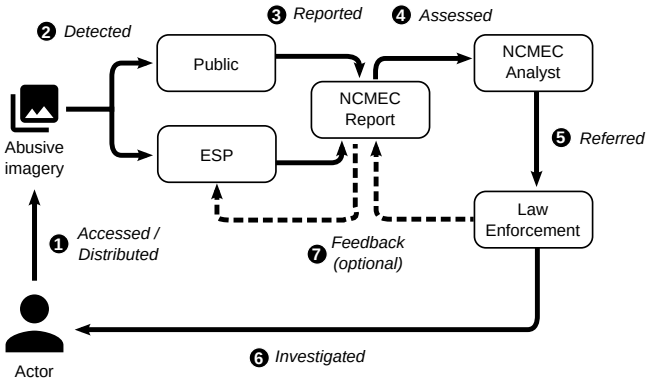

Figure 1: Life cycle of a CSAI report. Upon detection of an actor distributing or accessing abusive imagery, the public or an ESP report the activity to NCMEC. A NCMEC analyst reviews the report and refers actionable leads to law enforcement.

2.2 Life cycle of a NCMEC report

NCMEC's CyberTipline was first launched in 1998 and has since served as a clearing house that coordinates between the public, ESPs, and law enforcement. We provide a rough breakdown of the life cycle of a NCMEC report in Figure 1. Reports first stem from a public entity observing an abusive actor accessing or distributing CSAI material, or by an ESP detecting such activities on their service. Automated detection tools currently include, among others, Microsoft's PhotoDNA for images [29] and Google's CSAI Match for videos [42]. Both tool leverage a variation of the local-sensitive hashing algorithm [10] to not only detect known bad content but also slightly modified versions that abusers produce in an attempt to avoid detection. These CSAI detection technologies are deployed by many companies including Google, Microsoft, Facebook, and Twitter [1, 9, 28, 32].

Once NCMEC receives a report of suspected CSAI, an analyst reviews, augments, and deconflicts the report. As part of this, the analyst manually characterizes the type of incident and the distribution channel involved. The analyst also infers the likely location of the abusive actor and victim, using among multiple factors, the IP address embedded in each abuse report. Ultimately, the analyst assesses the priority of the report for law enforcement referral.

NCMEC refers all US cases to United States state or federal law enforcement. For those reports related to abusive actors or victims outside the United States, NCMEC works with Interpol, Europol, and national police forces. These agencies then investigate reports, take action when appropriate, and may provide optional feedback to NCMEC (and through NCMEC potentially to ESPs) on the outcome. During our study we found out that fewer than 3% of all NCMEC reports have such optional feedback. This precludes any detailed analysis on the actionability of reports.

3 DATASET

Our study builds on a snapshot of anonymized metadata associated with the 23,494,983 NCMEC reports related to suspected CSAI that NCMEC received from March 1, 1998 when the CyberTipline was

created till September 30, 2017. As mentioned earlier these reports come from the US public and many US ESPs. In this section, we provide an overview of the data used through the study and discuss inherent limitations that might bias our study.

3.1 Metadata per Report

Every report consists of at least a timestamp for when NCMEC received the report, the content reported as well as optional metadata such as the IP address of the uploader. As reports have evolved since 1998, more recent reports contain more details. Here are the key metadata fields we use throughout this study:

Source. Reports originate from one of two sources: the public, or electronic service providers (ESPs). For privacy reason, our metadata is limited to these coarse groupings; researchers involved in the study never obtained access to detailed information on reporting entities.

File hashes. Starting in 2013, report metadata contains an MD5 hash of every image, video, and other file attached to the reports. We note that more recent reports include a PhotoDNA hash (discussed in Section 2) and other local sensitive hash, but we did not use these due to the lack of historical coverage.

File format. Starting in 2013, NCMEC's staff began tracking and annotating CSAI content present in each report into one of three file formats: images, videos, and other (e.g., PDFs, HTML). In total, reports reference 20,568,240 abusive images, 2,335,536 abusive videos, and 337,575 other files.

Distribution vector. When possible, NCMEC's staff will annotate each report with a distribution vector. A majority of CSAI distribution vectors are either URLs (90.5%) or unidentifiable due to insufficient report details (8.5%). Other vectors in the remaining 1% of reports include IRC channels, email messages, chat applications, P2P websites, and Tor. We discuss these in further detail in Section 4.

Country. When possible, NCMEC's staff will annotate each report with a country representing either the victim or the abusive actor accessing or distributing content. We note this location information is overloaded: it can reflect the server where CSAI is hosted, the location of the person accessing the CSAI, or even the suspected location of a victim. As such, we are cautious when drawing conclusions about global CSAI trends.

3.2 Limitations

Our dataset is skewed towards US ESPs that proactively scan content using automated tools. As such, our findings likely underestimate the volume of CSAI content that actors access or distribute online. Furthermore, our data is skewed towards the market share of reporting ESPs; for example, China is entirely absent from our dataset. For confidentiality reasons, we are unable to share the identities of any of the ESPs involved or the relative volumes of CSAI reports they contribute. Despite these limitations, we believe that our large-scale dataset provides the first portrait of the evolution of CSAI online and the challenges faced by clearing houses and law enforcement. We discuss these challenges later in Section 5.

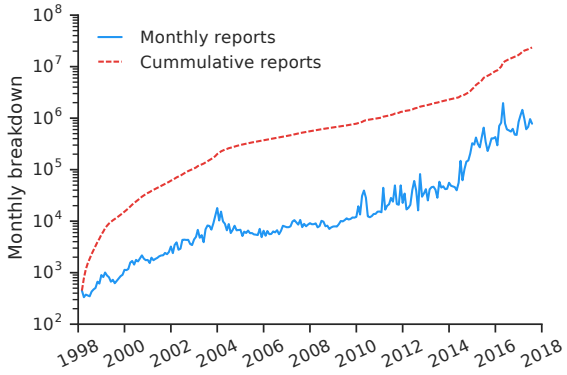

Figure 2: Monthly volume of CSAI reports (log scale) received by NCMEC since the creation of the CyberTipline in 1998. An exponential increase in report volume has lead to 9.6M reports in the last year alone.

3.3 Ethics

Working with CSAI reports presents significant ethical hurdles. Due to the sensitivity and legal protections surrounding reports, the researchers involved in this work never had direct access to reports, or even the metadata of reports. We constructed all measurements based of a report's schema, which were then executed by NCMEC's staff on their infrastructure after vetting by NCMEC's leadership. Additionally, to avoid re-victimizing the children involved in cases reported to NCMEC, and to avoid adding additional burdens to NCMEC's staff, we avoided any reprocessing of old reports. This also precludes analyzing images to understand the nature of abuse, the age of victims, or the uniqueness of the content beyond the hashes present in a report's metadata.

4 ANALYSIS

Our longitudinal measurement study surfaces how reports of CSAI have grown exponentially in parallel with online sharing platforms. In particular, we highlight the global nature of abuse, the adaptation of abusers to new technologies and mediums, and the frequent appearance of new content. Our measurements underscore the challenges of scaling manual review and law enforcement as a response to this threat.

4.1 Exponential Report Growth

Since the founding of the CyberTipline, NCMEC's report volume has grown a median of 51% year-over-year as shown in Figure 2. In aggregate, the public and ESPs have reported over 23.4M suspected incidents of CSAI. Over 9.6M reports (40%) occurred in the year 2017 alone—nearly 1 million per month. For contrast, NCMEC received only 565,000 reports (2.4%) in its first ten years of operation.

A major contributor to the observed exponential growth is the rise of proactive, automated detection efforts by ESPs, as shown in Figure 3. In July, 2009, for the first time the number of reports generated by ESPs exceeded that of the number of public reports. This coincides with the release of Microsoft's PhotoDNA tool (discussed in Section 2). Since then, reporting by ESPs increased an

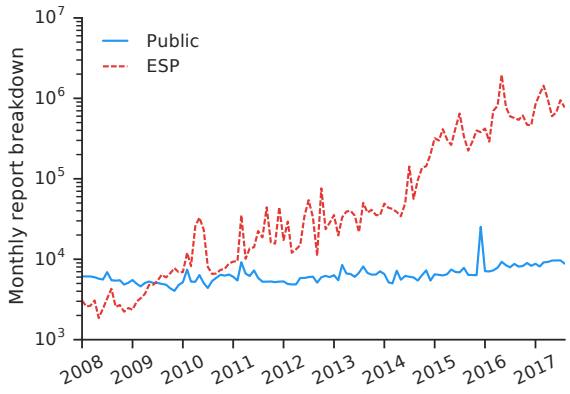

Figure 3: Breakdown of CSAI reports by the public and ESPs. Since 2009, an exponential growth in proactive, automated reporting has overtaken the public as the primary source of reports.

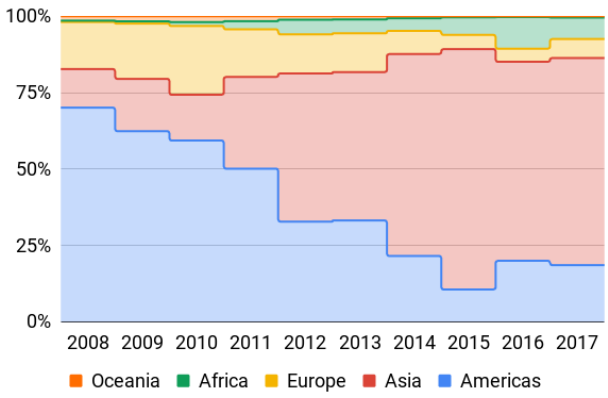

Figure 4: Annual breakdown of CSAI reports by geographic region. NCMEC has transformed from a regional reporting body to a global clearing house of CSAI reports.

average of 101% year-over-year, likely due to increasing user bases and an influx of user-generated content. While automated detection solutions help ESPs scale their protections, law enforcement and NCMEC analysts currently contend with the deluge of reports in a non-automated fashion as they are required to manually reviews the reports.

4.2 Global Threat

Over the last ten years, NCMEC has transformed from a regional reporting body—with 70% of reports related to victims or abusive entities in the Americas and 54% from the United States—to a worldwide clearing house with 68% of its reports relating to Asia, 19% to Americas, 6% to Europe, 7% to Africa, and 0.04% Oceania (Figure 4). Consequently, combating CSAI increasingly requires broad international cooperation with law enforcement.

Table 1: Top 10 countries flagged in reports. To account for population, we also consider the volume of reports per 1000 estimated Internet users for each country.

Country	Reports	Frac. reports	Normalized per 1K capita
India	3,880,235	24.1%	11.9
Indonesia	1,743,362	10.8%	31.0
Thailand	1,706,055	10.6%	63.8
Mexico	1,243,028	7.7%	17.8
Bangladesh	985,347	6.1%	40.5
United States	792,957	4.9%	3.3
Brazil	719,704	4.5%	6.0
Vietnam	701,315	4.3%	14.1
Algeria	631,190	3.9%	41.8
Pakistan	567,850	3.5%	15.8

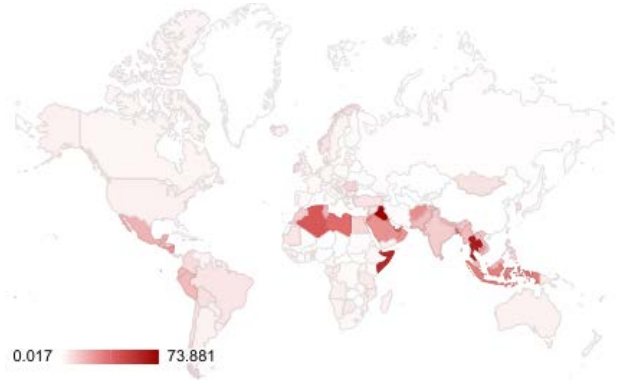

Figure 5: Estimated volume of CSAI reports per one thousand Internet users. South-East Asia, the Middle East, and North Africa have the highest incident rates.

We provide a breakdown of reports by the top 10 locations of victims and abusive entities (when discernible by analysts) in Table 1. As this information is often based on the IP address for abusive entities, we caution it may include VPNs or proxies that skew geographic distributions. We find that India, Indonesia, and Thailand account for roughly 37% of all reports. Both Indonesia and Thailand lack a legal definition for "child pornography" and do not require ISP reporting [18], potentially contributing to CSAI in the region.

As the populations of the top 10 countries differ by an order of magnitude, we also estimate the volume of reports per 1,000 Internet users (based on the International Telecommunication Union Internet penetration estimates for 2015 [19]). After this normalization, the top three countries involved in CSAI include Iraq, Thailand, and Somalia. Both Iraq and Somalia lack any laws related to child sexual exploitation [18]. We visualize these normalized rates across the globe in Figure 5, excluding countries with fewer than 500 reports. We observe higher incident rates of CSAI involvement in South-East Asia, the Middle East, and North Africa. A multitude of

Figure 6: Evolution of technologies involved in the distribution of CSAI. For example, 25% of all CSAI found on FTP servers was reported in 2001. Conversely, 42% of CSAI content distributed via Tor was reported in 2016. Our findings illustrate how technologies other than URL hosting fall in and out of favor over time.

factors likely play a role in this, including the lack of criminalization [18], the presence of sexual exploitation in conflict zones [8], and entrenched commercial production [22].

4.3 Proliferation of Contexts

As technologies for communicating and sharing over the Internet have shifted, CSAI distribution has evolved in kind (Figure 6). While over 91% of reports since 1998 reference a URL, the minority of other reports provide a lens into how distribution channels fall in and out of favor over time. For example, prior to 2004, abusive entities relied on FTP and email attachments before a rise in peer-to-peer technology. In recent years, we find some sophisticated abusers have adopted Tor (likely to avoid law enforcement authorities), while less sophisticated abusers have favored the convenience of chatroom and messaging apps. One other notable trend is the rise of gaming communities in the last 2–3 years (where children are likely to be participants), both as an enticement platform and as a distribution mechanism. While the overall volume of reports in these mediums is small (possibly due to a lack of ESP monitoring), our data illustrates the broad cooperation necessary among Internet services to tackle CSAI and the adaptability of abusers to new platforms.

4.4 Rise of Videos

In conjunction with video-capable smartphones and the availability of higher bandwidth, we find that CSAI video sharing has dramatically increased from under 1,000 reports per month in 2013 to over 2 million reports per month (Figure 7). In the last year alone, NCMEC observed a 379% year-over-year growth in reported CSAI videos, compared to an 18% increase in CSAI images. In contrast, other reports, such as HTML or PDFs, have remained largely stable over the years at 6,000 reports per month.

This exponential growth of video sharing highlights the necessity for online sharing platforms to develop robust and scalable detection. In particular there is an urgent need for platforms to agree on a standard for video fingerprinting, with Microsoft's PhotoDNA being designed for individual images. At present, ESPs use in-house technologies to flag CSAI videos. Additionally, the size and volume of videos poses a challenge for clearing houses to store and index content. With the advent of virtual and augmented reality, scaling will only increase as a future challenge.

4.5 Uniqueness & Lifetime of Imagery

CSAI content is constantly being transformed and created. Using each reported content's (non-PhotoDNA) hash as an indicator of uniqueness, we find that the public and ESPs report 84% of images and 91% of videos only a single time. Outliers exist, with reports flagging a single image that resurfaced 491,200 times and a single video that resurfaced 5,876 times. Our results illustrate the challenge of identifying new CSAI purely from approximate histograms of previously flagged images; algorithms instead need a deeper understanding of the abusive nature of CSAI content.

Re-distributed content offers an estimate of the lifetime of CSAI. Here, we calculate the elapsed time between the first and last report of CSAI for all hashes reported more than once (Figure 8). We caution this is strictly an underestimate. We find the median lifetime of an image was 257 days, while 10% of images resurfaced over the course of three years. For videos, which just recently emerged as a popular CSAI medium, the median lifetime was 210 days while 10% of videos resurfaced over the course of 1.5 years. Other media is skewed towards long-lived file bundles, where 70% of files resurfaced over the course of 3 years. These findings suggest that once CSAI content is uploaded to the Internet, it continues to resurface, with multiple months elapsing between attempts at distribution.

5 DISCUSSION

Our measurements highlight how the rapid adoption of the latest advancements in Internet platforms and digital mediums allows abusers to create and distribute CSAI across the Internet at an exponential rate. This exponential growth currently threatens our society's ability to combat online child abuse as the rate at which abusive content emerges vastly outpaces the processing capabilities of clearing houses and law enforcement agencies.

At its core this imbalance between abusers and defenders stems from the fact that the development of detection and processing technologies substantially lags behind the development of content creation and sharing capabilities. This section discuss the key technological directions that need to be pursued to reverse this trend.

Scaling the review process. For NCMEC and other clearing houses, a significant amount of time and human labor is spent processing, aggregating, and de-duplicating reports. Recent advancements in deep learning offer the opportunity to scale the review process by

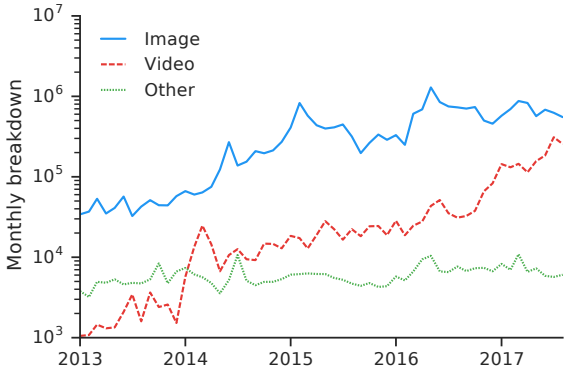

Figure 7: Volume of images, videos, and other file types reported each month since annotations appeared in our dataset in 2013. Simplified video sharing and recording has lead to a 379% increase in CSAI videos in 2017 alone.

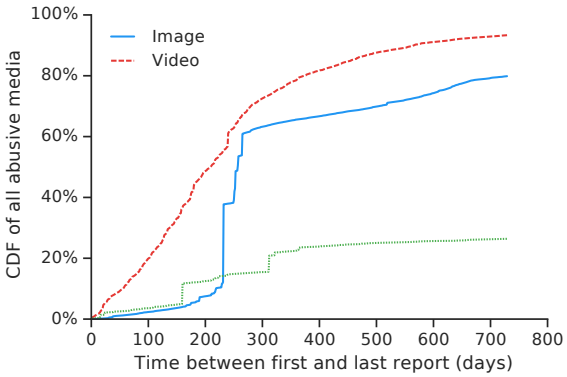

Figure 8: Time elapsed between the first and last report of a unique CSAI hash. We find that a median image has an observed lifetime of 257 days, while videos have a lifetime of 210 days.

automatically grouping reports that have content in common. In particular, two types of clustering could help:

- **Scene clustering:** Content retrieval techniques [11, 27, 41] can be used to group reports coming form various ESP by looking for reports that have similar images/videos that are potentially from the same scene.
- **Facial clustering:** Another possibility involves leveraging facial recognition [7, 15, 37] to find reports that contains the same child or perpetrator. A key challenge here is that traditionally models, including the latest ones based on triplet-loss, have struggled with children's faces because due to less defined facial traits. This represents a challenge both for facial recognition and identifying key attributes such as gender or approximate age.

Scaling the investigation process. A key challenge for law enforcement is prioritizing the reports which are most likely to lead to an arrest. Deep learning techniques can potentially help with prioritization by automatically detecting which content is the most "actionable" from an investigation standpoint. In particular:

- **Facial detection:** Recent progress in facial detection [21, 26] and gender or age prediction [25, 34] lend themselves to automatically reporting the number of victims or perpetrators found in an image. Additionally, it may be possible to extend these technologies to also report if an image contains blurred faces or if identifying features such as hair and eye color are present.
- **Scene information:** Image classifiers can automatically report objects that are present in a scene [39, 40], an image's environment [35, 45], and potentially identify landmarks that will help locate the region where an abusive image originated [43].

Detecting new content. Microsoft's PhotoDNA, originally developed in 2009, is a specialized version of minhashing that fingerprints images based on the histogram of grid-segmented images [29]. This technique is resilient to image transformations related to scale, color, or angle, but is incapable of detecting new CSAI images that have yet to be flagged during manual review. Likewise, the technique does not currently scale to videos. A critical direction here is to develop new algorithms that automatically identify CSAI material based on an image's subject matter. Any such algorithm should work seamlessly across digital mediums, including images and videos.

Reducing reviewer burden. Human analysts currently play a critical role in reviewing CSAI images and videos, both to identify victims, but also to confirm the abusive nature of content. Finding ways to reduce the burden and emotional toll of this task—even through non-technical means—is more pressing than ever given the exponential increase in the amount of content undergoing review.

6 RELATED WORK

Prior investigations of the distribution of CSAI online have largely focused on criminal sharing in peer-to-peer networks. Bissias *et al.* studied roughly 300,000 CSAI torrents and found that, despite law enforcement actions against criminals sharing CSAI, torrents had a survival rate of over 60% even after four years [3]. Our metrics also show a long lifetime of CSAI content: images and videos resurfaced over the course of nearly a year. Other research has tried to estimate the number of criminals accessing CSAI based off of unique IP addresses tied to torrent requests [44], though such metrics are susceptible to DHCP churn from residential machines. In terms of detection and disruption, research has focused either on flagging queries for CSAI content based on known keywords [24, 36] or on targeting major seeders to prevent further distribution [17]. Given the frequency of content shared outside of torrents—our dataset of 23.4M reports included only 8,900 torrents—solutions beyond peer-to-peer networks are critical.

7 CONCLUSION

In this paper, we showed how CSAI on the Internet has outpaced the capabilities of independent clearinghouse analysts and law enforcement to respond. In 2017 alone, NCMEC received 9.6M reports of CSAI, compared to roughly 10,000 reports a year when NCMEC first started in 1998. This exponential growth and the frequency of unique images requires re-imagining CSAI defenses away from

fingerprint-based detection and manual review. Instead, we argued that researchers need to develop algorithms that automatically detect CSAI content, cluster images and videos of victims, and ultimately surface identifying features to help law enforcement. The cost of human review also requires both technical and non-technical solutions that reduce the emotional toll of examining CSAI content. Absent new protections, society will be unable to adequately protect victims of child sexual abuse.

ABSTRACT

Societal-scale data is playing an increasingly prominent role in social science research; examples from research on geopolitical events include questions on how emergency events impact the diffusion of information or how new policies change patterns of social interaction. Such research often draws critical inferences from observing how an exogenous event changes meaningful metrics like network degree or network entropy. However, as we show in this work, standard estimation methodologies make systematically incorrect inferences when the event also changes the sparsity of the data.

To address this issue, we provide a general framework for inferring changes in social metrics when dealing with non-stationary sparsity. We propose a plug-in correction that can be applied to any estimator, including several recently proposed procedures. Using both simulated and real data, we demonstrate that the correction significantly improves the accuracy of the estimated change under a variety of plausible data generating processes. In particular, using a large dataset of calls from Afghanistan, we show that whereas traditional methods substantially overestimate the impact of a violent event on social diversity, the plug-in correction reveals the true response to be much more modest.

1 INTRODUCTION

Over the past decade, the increasing availability of societal-scale data has led to new approaches to social science research[5, 11, 24, 38]. In this literature, one common strain of analysis studies the human response to important geo-political events, using digital trace data as a lens into that response. For instance, [36] shows how to rapidly detect an earthquake from Twitter behaviour, [3] uses mobile phone data to study collective response to several different types of emergencies, and [39] studies rumors on social media following an oil spill, to cite just a few examples.

A common methodological challenge in such research is the issue of *sampling sparsity*: where the likelihood of observing any given edge in the social graph during a given period may be low and lead to inaccurate estimates of an individual-level properties. This problem is well-known and there is a rich body of work[19, 32, 35, 41, 43, 46] in both theory and application considering how to better estimate in the presence of sparsity. However, additional and previously unconsidered issues arise when this sparsity may vary over time: we call this property *dynamic sampling sparsity*.

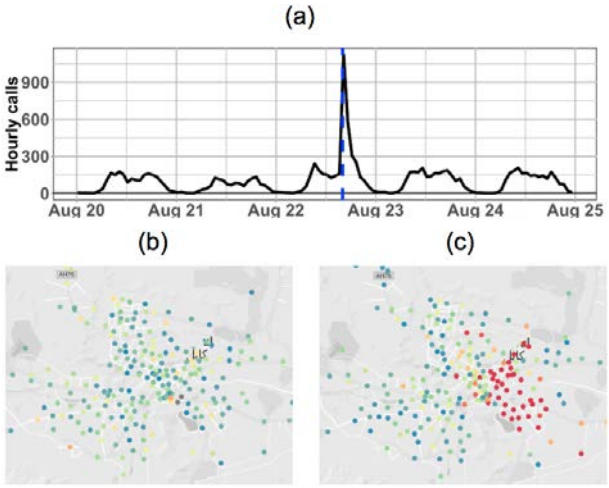

Figure 1: Illustrating variations in sparsity through analysis of call records during a bomb attack in a major city. Graph (a) shows how the hourly call volume of one of the impacted cell towers experiences a very noticeable surge during the emergency. This is also apparent when mapping the tower-level call volume (b) one hour before and (c) one hour after the bombing. The color of each tower represents how abnormally high the call volume is: with red representing call volumes over 5 standard deviations from the mean.

While dynamic sampling sparsity appears in many scenarios, analyzing the impact of emergency events provides a particularly illustrative example. Almost without fail, emergencies produce an immediate spike in transaction log activity (indeed, this spike often serves as the basis for emergency event detection and prediction[8, 18, 22, 36, 50]). However, this means that the sparsity of the social networks decreases at precisely the most confounding time: in the immediate aftermath of the event. An example of the abrupt change in sparsity conditions, derived from anonymized mobile phone data from Afghanistan, in the wake of a serious emergency can be seen in Figure 1. Understanding how important metrics of mobility and social diversity are impacted by such an emergency event, without being misled by the increased volume of communication, now becomes a serious challenge.

Our contribution: This paper shows how dynamic sampling sparsity of digital trace data can systematically bias downstream statistical inferences, and proposes a plug-in correction (namely, a fix that can be applied as a pre-processing step for any existing estimator) to address this problem. In particular:

- We develop a general framework to show why existing methods will systematically produce spurious discoveries. We use this framework to derive a simple statistical correction.
- We benchmark against several state of the art estimators using both real-world and simulated data, under a range of dynamic sparsity conditions. We show that our correction reliably outperforms or matches these methods under all conditions.

The rest of the paper is organized as follows. Section 2 provides necessary technical background and discusses related work. Section 3 introduces a general framework to model the problem and proves that existing methods are biased. We construct a simple plug-in correction to existing estimators that is unbiased. This correction is then put to the test in section 4, where we test its performance on both real-life and synthetic examples and then examine how this alters the conclusions of a sociological analysis. Finally, in Section 5 we discuss the pertinence of our investigation to the broader computational social science community, noting that this problem extends to many scenarios outside of emergency event analysis, and suggest further questions of both practical and statistical relevance.

2 BACKGROUND AND RELATED WORK

2.1 Measuring social phenomena with societal-scale digital trace data

A common approach to current computational social science research involves the analysis of summary statistics that are derived from societal-scale digital trace data. Though the methods we propose apply to a great many such statistics, we begin by introducing a few common metrics which will serve as a running example in the analysis that follows.

The first set of metrics summarize network structure, a generic class of metrics equally applicable to the Twitter re-tweet graph, the DBLP citation network, or a mobile phone network. Specifically, we consider **network degree** (which captures the number of unique connections of each node in the network, also called degree centrality) and **network entropy** (a measure of the dispersion of each individual's network). For any graph, let the number of interactions between node i and node j during a given time period t be $c_{ij}(t)$, and the total volume of i's interactions $c_i(t) = \sum_j c_{ij}(t)$. Degree $D_i(t)$ and network entropy $H_i(t)$ of node i during period t are defined as,

$$D_i(t) = \left|\{j \mid c_{ij}(t) > 0\}\right| \text{ and } H_i(t) = -\sum_j \frac{c_{ij(t)}}{c_i(t)} \log \frac{c_{ij}(t)}{c_i(t)} \quad (1)$$

A second set of metrics, most relevant in networks with geomarkers, capture the characteristic travel distance or diversity of locations visited. Common examples of metrics here include **location entropy** [51] (defined similarly to the network entropy, but over the distribution of locations visited rather than individuals called) for diversity and **radius of gyration** [16] for travel distance.

These network- and location-related metrics have been used in hundreds of papers on dozens of different datasets. For instance, entropy and degree have proven informative in inference tasks ranging from estimating regional unemployment from Twitter usage[25] to predicting wealth from cell-phone records [4, 10]. Related papers show similar results for mobility metrics [6, 15, 30]. In addition to proving useful on this range of societal-scale social networks, several forms of entropy have shown usefulness in aiding visualization of the DBLP citation network[37].

2.2 Estimators and Bias

As the sheer scale of data available increases, it is important to note the growing problem of sparsity. Metrics that require large number of samples from the distribution may be confounded when the number of samples (for instance, the volume of communication) is much smaller than the support size of the distribution (e.g., the number of individuals in the true distribution). This necessitates the use of **estimator** functions that approximate the true underlying metric. Since we are interested in the predictive accuracy of the estimator, we focus mainly on its bias and variance (Equation (2)), the former of which underlies the problem discussed in this paper.

Definition 2.1. Let $\hat{\theta}(Y)$ be an estimator of true parameter θ^* using the data Y. The *bias* and *variance* of $\hat{\theta}$ is defined as,

$$bias(\hat{\theta}) = E[\hat{\theta}] - \theta^*, \quad var(\hat{\theta}) = E[(\hat{\theta} - E[\hat{\theta}])^2]. \quad (2)$$

Note that the expectation E[.] is over the randomness of data.

It is important to note that many key social metrics, including all of those defined in Section 2.1, have serious issues with bias when being estimated. Network degree and any entropy based metric have no unbiased estimator[29]. Obtaining an unbiased estimator for the radius of gyration, since it is related to the standard deviation of locations visited, is known to be a hard problem[47].

2.3 Inferring changes

Detecting and quantifying the impact of an exogenous geopolitical event on a social metric of interest (either over time or across locations) can provide important insight into how such events impact the behavior of larger populations. Examples in the literature include using anomalies detected in social media [20, 23] and mobile phone data [22, 50] to infer the severity and location of damage from natural disasters, or the impact of employment shocks [40]. Many of these difference detection techniques transfer smoothly across data-sets: techniques first applied to social media and communications data can be adapted to a data set as dissimilar as credit card transactions[9].

Non-parametric paired tests are used to detect if there is a systematic change in the mean of a metric of interest, say X, over the same population before and after an event or a treatment. For example, the Wilcoxon signed-rank test takes the paired difference of X before and after an event, ranks them in the order of magnitude and then uses the rank and the sign of the difference (discarding the actual magnitude of difference to avoid the effect of heavy-tail noise) to determine whether a change occurred. However, such tests (implicitly) assume that the bias in measuring in X is the same before and after the event. The proportion of times a paired test detects a change when there is no actual change (null hypothesis) is called the *type I error rate* (α) and when the underlying value did indeed change this proportion is called the *power* (β).

Why bias matters: In contrast to the assumptions of the paired tests, the bias in estimating quantities like entropy depend on the sparsity of the observed distribution. Since the sparsity levels can differ widely before and after an event, the bias in the measurement of entropy will also be different. Therefore, when we take a paired difference, we are not only measuring the change, but also an additional *unknown bias* term that is difficult to isolate. Even when there is no change in entropy, a systematic bias due to dynamic sampling sparsity can lead to a consistently increased rate of type I errors. This is discussed more formally in Section 3. The implications of dynamic sparsity on bias and consequently on the outcome of change detection is discussed Section 3.1. We systematically study this effect for state-of-the-art entropy and support size estimators in Section 4.

2.4 Related work

Estimating the support size, entropy and general symmetric functions[1] of discrete distributions when the number of observations is much smaller than the support size of the distribution is a fundamental problem that has been very well-studied [2, 13, 14, 17]. It is still an active area of research in statistics, information theory as well as computer science [1, 21, 26–28, 31, 34, 41–43, 45, 46, 48, 49]. While this research has improved state-of-the-art estimators, the primary focus has been on estimating a function on a single distribution, rather than the issue of varying sparsity across the network and over time — which are crucial in the applications of interest.

To give a concrete example, the optimal number of samples needed to estimate the entropy of a discrete distribution within ϵ-error is $\Theta\left(\frac{S}{\log S}\frac{1}{\epsilon}\right)$, where S is the support size of the distribution[2] [21]. In practice, we do not have the luxury of soliciting more samples to meet this bound and consequently the estimation of entropy per individual in a network will incur some non-negligible bias. As we will see in Section 4.1, this can lead to systematic inference errors in a way that falls outside of this body of statistical literature.

In contrast to the situation in the statistical literature, the issue of dynamic sparsity arises when analyzing social graphs. This has been an issue in particular when looking at mobility since key metrics like radius of gyration and location entropy have issues with estimator bias. Using a more densely sampled signal that is normally not available, one work[51] showed a systematic underestimation of mobility metrics using call networks that was greater for individuals making few calls. This has also been previously seen in [33] which found that while key locations were generally well inferred, functions like location entropy or radius of gyration likewise had similarly unbalanced issues with bias. However neither of these works offered general solutions to the problem. Heuristics such as dividing a biased metric by the number of communications[7] have no guarantees in improving accuracy: whether they mitigate or aggravate the problem is entirely dependent on the underlying distributions, functions and sample sparsities. A recent work[44] has analyzed the specific bias induced on location metrics by the location-varying tower density and provided correction specially designed for their specific application setting.

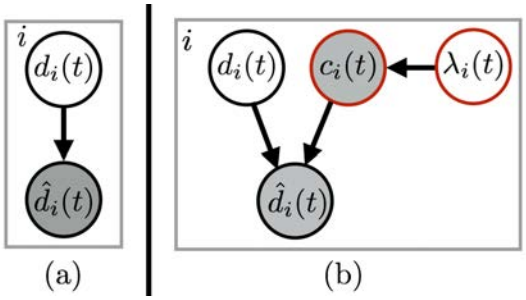

Figure 2: Generative model for the data for a single period of time (a) when sparsity is stationary, and (b) when sparsity is non-stationary.

3 THEORY: DYNAMIC SAMPLING SPARSITY

In the case where sparsity is stationary, the number of samples observed before and after an event is the same on average. The generative model for the observed data is as shown in Figure 2(a), where $d_i(t)$ denotes the true distribution and $\hat{d}_i(t)$ denotes the *observed distribution* for an individual i. However, as motivated in the introduction, the sampling rate or *sparsity is not stationary* (Figure 1). In this section, we describe a general framework to capture the observation model in the setting of dynamic sparsity.

Let $c \sim \text{Poi}(\lambda)$ denote a random variable drawn according to Poisson distribution with rate parameter λ. At time t, let $\lambda_i(t)$ be the rate of sampling for individual i and $c_i(t) \sim \text{Poi}(\lambda_i(t))$ denote the number of samples observed for an individual i. So, we get to observe the empirical distribution $\hat{d}_i(t)$, which is obtained by drawing $c_i(t)$ samples from the true distribution $d_i(t)$. This generative model is illustrated in Figure 2(b).

Let f be the functional (e.g: entropy) we are interested in computing on the distribution d. Let $\hat{f}_i := g\left(\hat{d}_i(t), c_i(t)\right)$ denote the estimator of f for individual i. We note that this estimator is not only dependent on the true underlying distribution $d_i(t)$, but also the sampling rate $\lambda_i(t)$. Therefore, the bias in estimating f_i at time t is also affected by the sampling sparsity, that is,

$$\text{bias}(\hat{f}_i(t)) = \text{E}(\hat{f}_i(t)) - f_i(t) =: B(d_i(t), \lambda_i(t)). \tag{3}$$

Since the sparsity is not stationary, that is, $\lambda_i(\text{after}) \neq \lambda_i(\text{before})$, the *bias itself is not stationary*. Even when $d_i(a) = d_i(b)$, the change in sparsity leads to a systematically increased type-I error rate in

[1] A function over a discrete distribution is said to by a *symmetric function* if it remains invariant to relabeling of domain symbols.
[2] The notation $h(n) = \Theta(g(n))$ means that h is bounded both above and below by g asymptotically.

classical tests like Wilcoxon signed-rank test for detecting change in f as we discuss next.

3.1 Analysis of existing methods

We are interested in detecting and quantifying the difference in f of the distribution $d(t)$ before and after an event. For each individual i, let the difference be denoted by, $\delta_i := f(d_i(a)) - f(d_i(b))$, where a and b stand for *after* and *before* respectively. However, we do not get see the distribution d_i itself, and instead we get to observe $\hat{d}_i$ which has c_i samples from the true distribution d_i. Given an estimator $\hat{f}_i$, the intuitive way to use it to find the difference δ_i is to estimate on the before and after distributions seperately and then take the difference. This gives us the estimator for the change $\hat{\delta}_i := \hat{f}_i(\hat{d}_i(a)) - \hat{f}_i(\hat{d}_i(b))$, where $\hat{f}_i(\hat{d}_i(t))$ denotes the estimate of f on the observed distribution $\hat{d}_i(t)$. Using Equation (3), the expected difference can then be written as,

$$\mathrm{E}(\hat{\delta}_i) = \delta_i + B(d_i(a), \lambda_i(a)) - B(d_i(b), \lambda_i(b)). \tag{4}$$

Under the null hypothesis, the underlying distributions remain the same before and after, i.e, $d_i(a) = d_i(b)$. Therefore, under the null, $\delta_i = 0$. When we test for change, we want to control α (the chance of declaring a change when the null is true). If sparsity was stationary, i.e $\lambda_i(b) = \lambda_i(a)$, the mean of the difference would be zero since bias would cancel when we take paired differences (Equation (4)). However, since the observed distribution also depends on the non-stationary rate parameter $\lambda_i(t)$, the mean of paired difference is not zero under the null. For $\mathrm{E}(\hat{\delta}_i)$ to be zero under the null hypothesis, we need the following to hold, for all $d_i(a), \lambda_i(a)$ and $\lambda_i(b)$,

$$B(d_i(a), \lambda_i(a)) = B(d_i(a), \lambda_i(b)). \tag{5}$$

For functions like entropy, which do not have unbiased estimators [29], such a condition would never hold for any non-trivial distribution d_i and estimator $\hat{f}_i$. This leads to a systematically increased type-I error rate under classic tests like Wilcoxon signed-rank test as illustrated in Figure 3.

3.2 Correction by downsampling

We propose downsampling the observed distributions to same number of samples before estimating f as a plug-in solution to avoid this problem in change detection tests.

Let $c_i^{\min} := \min\{c_i(a), c_i(b)\}$, and $\widetilde{d}_i(a, l)$ and $\widetilde{d}_i(b, l)$ be obtained by drawing $l \le c_i^{\min}$ samples from $\hat{d}_i(a)$ and $\hat{d}_i(b)$ respectively. The downsampling-corrected version of estimator $\hat{f}_i$ for difference is then defined as follows:

$$\tilde{\delta}_i := \mathrm{E}\left(\hat{f}(\widetilde{d}_i(a, l))\right) - \mathrm{E}\left(\hat{f}(\widetilde{d}_i(b, l))\right), \tag{6}$$

where the expectation is over the randomness of drawing $\widetilde{d}_i \sim \hat{d}_i$. In practice this can be approximated by averaging over a few random re-samplings. Downsampling ensures that under the null hypothesis, the bias in estimating f is same for before and after and hence it cancels out when we take paired difference. The situation where the null hypothesis is false is significantly harder to analyze but the performance of the proposed correction in this case is explored empirically in Section 4.2.

4 EMPIRICAL ANALYSIS

To verify the pertinence of this problem in real-life analysis we perform a number of empirical studies. In all of these we focus on

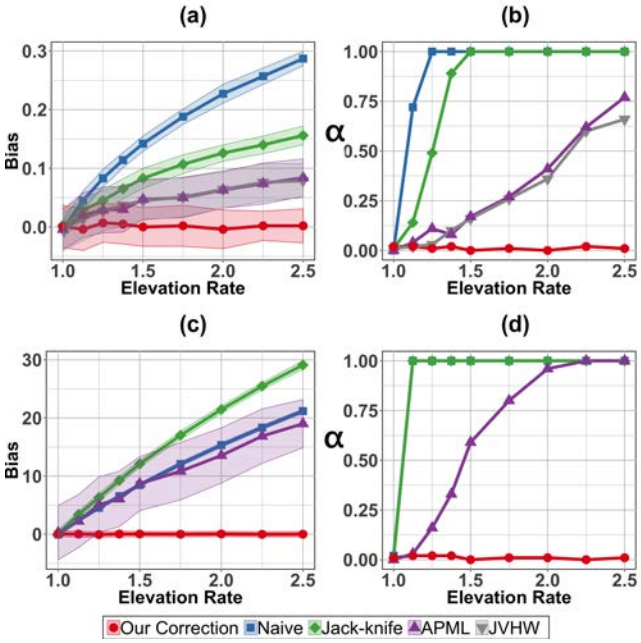

Figure 3: Comparison of how the (a) bias and (b) type-I error rate (α) for estimating difference in entropy increases with more variation in sparsity. (c) and (d) show the same for network degree. The bands in (a) and (c) show the variance in estimates of the average difference.

inferring the change in two metrics: social entropy and network degree. We pick these two since they are both socially informative as well as ubiquitously available over many different types of social graphs. We are interested in how estimates in the change of these metrics are impacted by the variation in sparsity, which we quantify as the *elevation rate* r.

$$\text{Elevation Rate, } r := \frac{\lambda(\text{after})}{\lambda(\text{before})}.$$

We compare the performance of the following four estimators:

(1) **Naive-Estimator**: This simply computes the metric by treating the empirical distribution as the true distribution.
(2) **Jackknifed naive**[12]: This is the naive estimator with a jackknife heuristic that averages the naive estimate over all distribution generated by removing one sample from the empirical distribution.
(3) **JVHW**[21]: This estimator combines an unbiased estimator for the best polynomial approximation of the function being estimated in the non-smooth region with a bias-corrected estimate on the smooth region.
(4) **APML**[31]: Approximate Profile Maximum Likelihood Estimator is a computationally efficient approximation of the profile maximum likelihood [1] which maximizes the probability of the observed profile (multiplicities of the symbols observed ignoring the label).

Note that JVHW is only applicable to entropy and not network degree. We compare these estimators to their *corrected* variants, where we downsample the data (as described in Section 3.2) before running these estimators. We found the results broadly similar across the corrected version of these four methods. In the interest

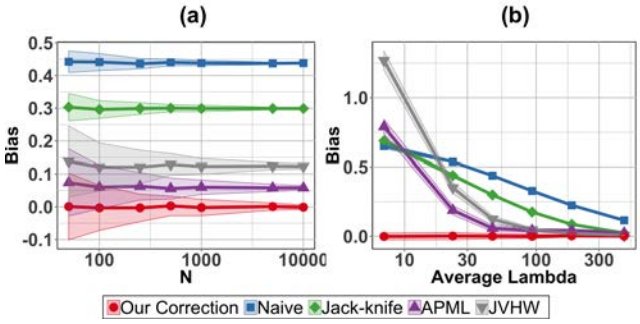

Figure 4: Analysis of how (a) varying the number of individuals N and (b) average sparsity impacts entropy bias. Both experiments are run on synthetic data generated from the Dirichlet distribution with elevation rate $r = 2$. The former only improves the variance while the latter decreases bias as the average sparsity drops (as calling rate increases).

of clarity we only show one corrected estimator per graph: the JVHW-correction for entropy and the jack-knifed correction for network degree.

In all of these experiments we ask two questions. Firstly, what is the bias in the estimated difference for each estimator under different values of elevation rate r? Secondly, how does this translate into type-I and type II errors? The first question is simply done by computing the average predicted change and comparing it to the actual average change. The second question is studied by applying a Wilcoxon signed-rank test to the estimated differences with a desired α of 0.01.

4.1 Natural experiments with real-world data

In the first set of experiment we use a country-wide CDR dataset collected over 6 months in Afghanistan. This data comprises data for millions of callers and since our interest concerns changes in specific groups of individuals we restricted this to calls from a set of $N = 1000$ individuals determined to be living near a specific tower in a major city. We take the empirical distribution generated by 6 months of data (with a median of 500 calls per individual) as being sufficiently well sampled to approximate the true social distributions $\{d_i\}$'s and call rates $\{\lambda'_i\}$'s.We take the empirical call rates for six months and scale them down to the equivalent rate for a week $\lambda_i = \frac{7}{180}\lambda'_i$. We then assign before and after distributions to be identically $d_i(a) = d_i(b) = d_i$ and $\lambda_i(a) = \lambda_i$ but we multiply the second calling rate by the elevation rate: $\lambda_i(b) = r\lambda_i$. We repeat 100 trials where we sample using these distributions and λ's as in Figure 2(b) and compare the estimated difference between the metric average of sets a and b. We run the Wilcoxon signed-rank test and check if it detects a change. Since the distributions are the same, ideally we would like to estimate that there is no difference. Figure 3 shows the results for social entropy and network degree: though the same trend is present in both. We clearly see that all the methods that do not correct for varying sparsity, including cutting-edge estimation techniques like JVHW and APML, reveal substantial issues with bias at even modest elevation rates which get progressively worse as the rate increases. In contrast, our corrected method consistently returns the correct result no matter the level of imbalance in sparsity.

4.2 Synthetic tests

While experiments on real data are essential to proving the practical concerns around the sampling problem they only provide a fixed set of conditions to experiment with. For this reason we created a synthetic test suite that would allow us to compare our methods against baselines on a variety of distributions and at a significantly more granular level. This allows us to directly set $d_i(a)$ and $d_i(b)$ to both explore different distributions and also be significantly different. As such we can compute the bias of estimators when $E[\delta_i] \neq 0$ as well as for the null case where $E[\delta_i] = 0$.

The experiment then proceeds similarly to section 4.2: with the exception that λ_i and $d_i(a)$ are drawn randomly from a prior distribution. λ_i is consistently distributed by a log-normal with mean of 50 while we perform separate experiments where the $d_i(a)$ are drawn from a distribution of either Dirichlet (with Dirichlet parameter $\alpha_D = 1.0$), geometric (with average probability of success $p = 0.9$) or uniform distributions. For the case where we wish $E[\delta_i] \neq 0$, we additionally alter the parameter of $d_i(a)$ by some fixed amount to generate $d_i(b)$.

We note that the existing methods will have substantial bias in the null case no matter how large the population N is, as shown in Figure 4(a). The variance decreases as a function N, but not the bias. We set $N = 1000$ for the remainder of our synthetic experiments. Figure 4(b) shows that decreasing the sparsity, or equivalently increasing the observation rate λ, of course helps all methods: though as previously noted this is rarely possible in practice.

We investigate how the estimators perform in the case of both no change and some change: a subset of our results are shown in Figure 5. Our results for the null case reinforce our conclusions in Section 4.1: there is considerable variance between the different distributions and uncorrected metrics but our correction consistently return an accurate estimate (Figure 5(a—d)). This illustrates the difficulty of the problem when not accounting for variable sparsity: a non-corrected method that seems to work on one distribution may entirely fail on another. We also record how often the Wilcoxon singed-rank test records a true positive as a function of the actual average difference. We see that the elevation rate has induced an asymmetric change in non-corrected methods and hence worse discovery rates when the true change in entropy is negative. On the other hand, the corrected method is reliable through-out (Figure 5(e—h)). Even in a situation where a given uncorrected method perform well (notably, the APML method is fairly robust in the uniform scenario for both network degree and entropy), the corrected method has comparable or better sensitivity while outperforming it in all other situations. This provides strong evidence that the plug-in correction is an improvement also in the case where there is a difference.

4.3 Analysis of sociological events

In this section, we highlight the relevance of this problem to computation social science by demonstrating how it can alter the conclusion of a real analysis. Recalling the call dataset described in Section 4.1, we cross-referenced calls made in that set with the time and location of a serious bomb attack and generated a set of 220 individuals who appear to live in the vicinity of this attack. Our goal is now to analyze how the average network entropy changes

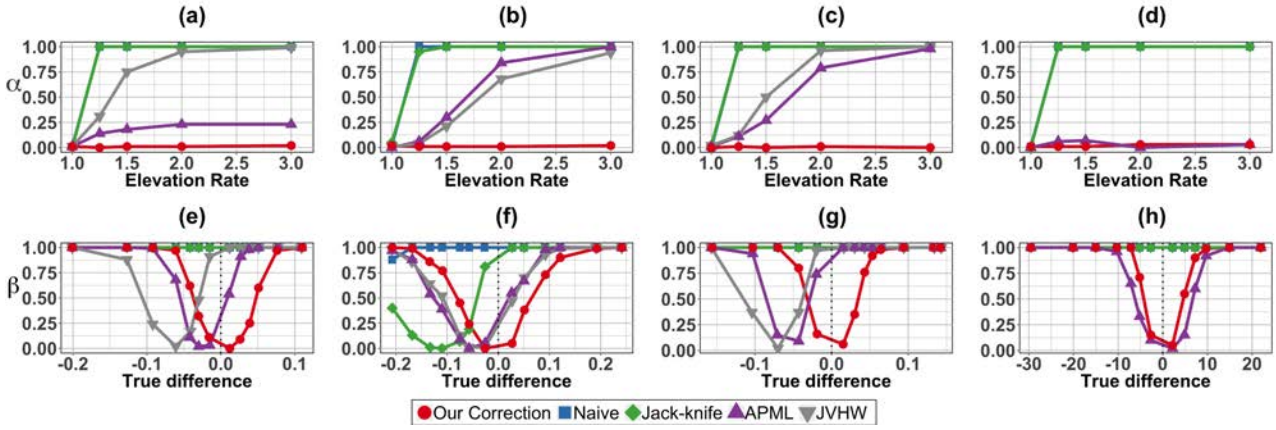

Figure 5: Panels (a)-(c): Experiments showing type-I error rates (α) for entropy change for the uniform, geometric and dirichlet scenarios respectively. Panel (d): Type-I error rate for network degree under the uniform scenario. Panels (e)-(g): Power (β) for entropy change detection at an elevation rate of 3 for the uniform, geometric and dirichlet scenarios respectively (h): Power for network degree under the uniform scenario and elevation rate of 3.

in the immediate aftermath of this emergency. For each 24-hour period in our date range we take the difference with respect to the same period one week before. For example the 24-hour period starting on August 22nd 10am is paired with the 24-hour period starting on August 15th 10am, the one starting at August 22nd 11am is paired with that starting on August 15th 11am etc. We then compare how different methods infer changes based on these differences: our results are shown in Figure 6. While both the basic methods and our correction to JVHW method detect an increase during the emergency period, the uncorrected methods detect anywhere from twice to three times as much of a change. Moreover, the corrected method finds only one 24-hour period to be statistically significantly different: while the other methods declare almost the entire period to show a significant increase in network-entropy.

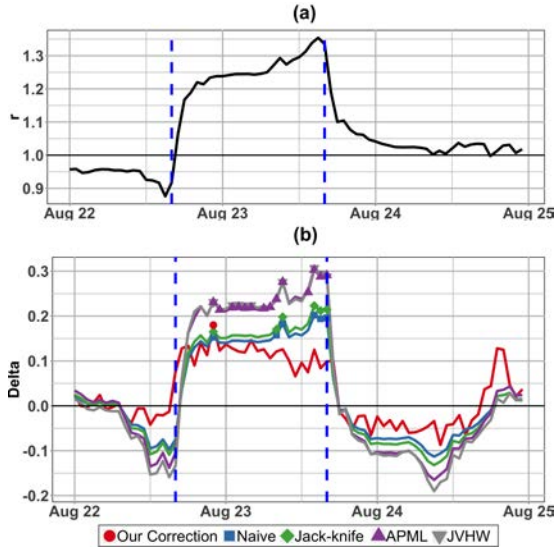

Figure 6: Analysis of (b) how different methods infer the change in network entropy in (a) the presence of varying sampling sparsity caused by a violent event. The period between the dotted blue lines indicate when the sliding window contains the bomb blast period. Marked points in (b) indicate a statistically significant difference between this 24-hour period and the same 24-hour period one week prior.

5 CONCLUSION

This paper explains and formalizes the concept of *dynamic sampling sparsity*, and highlights why it is such an important problem for estimation and change detection. Our statistical framework shows that failing to account for varying sparsity in the data frequently leads to systematic errors in the downstream statistical analysis. We demonstrate the severity of this issue through experiments on both real social graph datasets and comprehensive synthetic tests.

While we motivated this problem by considering the real-world problem of understanding the impact of emergency events, we note that this problem of varying sparsity is significantly broader. Indeed the issue would likely arise when comparing average values of social metrics (whose bias gets influenced by sampling sparsity) between two different populations with different sampling sparsity rates. Examples in the literature include comparing the structure of social networks in urban locations with that of provincial villages [10], or wealthy provinces to a poorer ones [11, 25]. Our empirical results show that it is very hard to determine ahead of time how much a specific scenario will be affected: the impact is a complex function of the different sparsity rates, the underlying distributions and the estimators themselves. The correction we develop can help avoid such errors in arbitrary environments.

A broader implication of the results in this paper is that great care is needed when performing empirical analysis on societal-scale datasets with non-stationary sampling sparsity. Many common distributional tests fail when two distributions are generated from different sparsity regimes. Rather than applying one-off fixes to each such biased metric, more research is needed into optimal statistical detection, estimation and inference tools for large-scale heterogeneous and sparse datasets.

ABSTRACT

Generative Adversarial Networks (GAN) have not only achieved a big success in various generation tasks such as images, but also boosted the accuracy of classification tasks by generating additional labeled data, which is called *data augmentation*. In this paper, we propose a Rating Augmentation framework with GAN, named RAGAN, aiming to alleviate the *data sparsity problem* in *collaborative filtering* (CF), eventually improving recommendation accuracy significantly. We identify a unique challenge that arises when applying GAN to CF for rating augmentation: naive RAGAN tends to generate values *biased towards high ratings*. Then, we propose a refined version of RAGAN, named RAGAN^{BT}, which addresses this challenge successfully. Via our extensive experiments, we validate that our RAGAN^{BT} is really effective to solve the data sparsity problem, thereby providing existing CF models with great improvement in accuracy under various situations such as basic top-N recommendation, long-tail item recommendation, and recommendation to cold-start users.

1 INTRODUCTION

In recommender systems, *collaborative filtering* (CF) is one of the most widely used frameworks. The aim of CF is to generate a personalized item recommendation to a user based on her prior preference. Users' past preferences are typically presented in the form of a user-item *rating matrix*, where each cell value contain a rating given by a user for an item, mostly within a specific range (e.g., [1, 5]). However, the majority of entries in a rating matrix are missing: this *data sparsity problem* [13] is a universal obstacle to most CF methods, making them difficult to capture true relationships between users and items, thereby causing unsatisfactory accuracy in recommendation. To mitigate such a problem, most studies try to acquire additional information from social/trust networks among users [24] and auxiliary content of items [32]. However, their methods are applicable only when such additional data is available. The goal of this work is to investigate a generic solution to alleviate the sparsity issue in the context of pure CFs, i.e., a recommendation task given with only the user-item interaction data.

Recently, Goodfellow et al. [9] proposed the *Generative Adversarial Networks* (GAN), which learn to generate samples that mimic the distribution of the training data. Through an adversarial process between a *generative model* G and a *discriminator model* D, G learns to capture the data distribution in order to generate *synthetic but realistic* data. GAN has been very successful in image generation [25], and has gained popularity in performing other tasks, such as natural language generation [35] and music generation [7]. In addition, GAN's impressive ability to generate synthetic but realistic data has been used to improve the accuracy of a classification task, where the synthetic data is used as additional training data, which is called *data augmentation* [1, 2]. For example, [8] synthesized images labeled with Liver Lesion using GAN, resulting in 7% increase in terms of accuracy in Liver Lesion classification.

Motivated by such a success of data augmentation with GAN, this paper explores the *use of GAN for relieving the data sparsity problem in CF* under the context of data augmentation. We expect that using GAN to augment plausible ratings to a rating matrix would help CF models to provide more accurate recommendation by learning the augmented rating matrix, rather than the original one. Along this line, we propose a novel Rating Augmentation framework based on GAN, named RAGAN. RAGAN first trains GAN by using the observed ratings in a rating matrix as a training data, and

then makes its G generate plausible ratings for unobserved user-item interactions, which are to be augmented in the original rating matrix. Finally, conventional CF models can be trained by using the augmented rating matrix to produce final recommendations.

When applying this idea of data augmentation by GAN to the field of CF, we face a unique challenge that comes from the inherent *selection bias* of the rating data. We observed that only a small fraction (i.e., 10−17%) of ratings are low values (i.e., 1 or 2) and the rest are high values (i.e., 3, 4, or 5) from four real-life datasets used in our experiments, which has been also noticed in other studies [6, 12]. This might be because people have a tendency to select (and thus to rate) the items likely to give high satisfaction to them, and to disregard those items likely to result in low satisfaction (i.e., selection bias [6]). If GAN learns from the original rating matrix skewed to such high ratings, it would also generate *high ratings for most unobserved entries* in the matrix. However, this augmentation result seems not satisfactory since the majority of unobserved entries are likely to indicate users' negative preferences; in other words, users would not give a rating to those items that they are not interested in. If CF models are trained with such a *biased* augmented rating matrix, they would show poor recommendation accuracy since they fail to capture users' true preferences. We will demonstrate this phenomenon clearly through our experiments.

Towards this challenge, we propose RAGAN$^{\text{BT}}$, a refined version of RAGAN, which takes users' *negative items* (i.e., the items having users' negative preferences) additionally into account when training GAN, in order to avoid G from being biased towards high ratings in rating augmentation. Here, we formulate the problem of identifying such negative items as the well-known *one-class collaborative filtering* (OCCF) [23, 34] that infers the interestingness (or uninterestingness) of every user-item pair. By training GAN with the identified negative items as an additional source together with the original rating matrix, RAGAN$^{\text{BT}}$ successfully avoids the bias towards high ratings, and thus could generate the plausible ratings that better reflect the characteristics of unrated items. As a result, by augmenting the plausible ratings to the rating matrix, RAGAN$^{\text{BT}}$ solves the data sparsity problem, thereby contributing towards significant improvements of accuracy in CF.

In order to validate the effectiveness of our RAGAN$^{\text{BT}}$, we conduct extensive experiments using four real-world datasets. Notably, the results demonstrate that the key idea behind RAGAN$^{\text{BT}}$ (i.e., involving negative items in training GAN) is quite effective in generating more realistic ratings, leading to higher recommendation accuracy. The results also demonstrate that our RAGAN$^{\text{BT}}$ consistently and universally outperforms the state-of-the-art CF models not only under basic top-N recommendations, but also under more-difficult situations: (1) long-tail item recommendations and (2) recommendations to cold-start users. We believe our RAGAN$^{\text{BT}}$ sheds a light on the practical adoption of GAN for alleviating the data sparsity problem, which has been a universal obstacle to accuracy improvement in recommender systems.

2 PRELIMINARIES

Let two sets be denoted as $U = \{u_1, u_2, .., u_m\}$ and $I = \{i_1, i_2 ..., i_n\}$, where U consists of m users and I contains a set of n items. I_u is defined as a set of items that a user u has rated. A corresponding m-by-n rating matrix is $\mathbb{R}$, each entry r_{ui} is a rating on item i given by user u, and the ratings are within a specific range (e.g., [1, 5]). We denote $\mathbf{r_u}$ and $\mathbf{r_i}$ as rating vectors of user u and item i, respectively.

Given complicated real-world data, the *Generative Adversarial Network* (GAN) allows for a novel training method for generative models. GAN is made up of two models (neural networks in general), where one is a generative model, G, and the other is a discriminative model, D. The training process is a minimax game between G and D (i.e., $\min_G \max_D \mathcal{L}_{GAN}$): G tries to increase the error rate of D by generating seemingly authentic data, while D tries to accurately distinguish whether the data has come from the ground truth (i.e., real data) or from G. Formally, the objective function is:

$$\mathcal{L}_{GAN} = \mathbb{E}_{\mathbf{x}\sim p_{data}}[\log D(\mathbf{x})] - \mathbb{E}_{\hat{\mathbf{x}}\sim p_G}[\log(D(\hat{\mathbf{x}}))], \qquad (1)$$

where $\mathbf{x}$ is a ground-truth data from the data distribution p_{data} while $\hat{\mathbf{x}}$ is a synthetic data from the model distribution p_G, typically derived by $\hat{\mathbf{x}} = \text{G}(\mathbf{z})$ where $\mathbf{z}$ is a random noise vector. D$(\cdot)$ indicates the estimated probability of its input being a ground truth [4].

3 RAGAN

The main idea of this paper is to train GAN with the rating data, generate plausible ratings, and augment the generated values in the rating matrix. This section illustrates a basic solution to this objective, called RAGAN (rating augmentation framework based on GAN). As a first step, we need to train GAN by using the rating data. In this context, there exist several recently proposed GANs that could be proper candidates for our framework, such as IRGAN [33], GraphGAN [31], and CFGAN [3], all of which focus on recommendation tasks. Among them, we note that both IRGAN and GraphGAN can only learn from users' implicit feedback data, and expanding these methods to also learn from explicit ratings (i.e., the degree of satisfaction) and generate such data is non-trivial. In contrast, CFGAN can be easily extended to learn from and generate the rating data, even though it was also proposed to perform CF based on implicit feedback dataset. For this reason, our GAN for rating data is based on CFGAN.

Formally, $\mathcal{L}_{GAN}$ in our work is defined as:

$$\begin{aligned}\mathcal{L}_{GAN} &= \mathbb{E}_{\mathbf{x}\sim P_{data}}[lnD(\mathbf{x}|c)] - \mathbb{E}_{\hat{\mathbf{x}}\sim P_G}[lnD(\hat{\mathbf{x}}|c)] \\ &= \frac{1}{m}\Big(\Sigma_u lnD(\mathbf{r_u}|\mathbf{r_u}) - \Sigma_u lnD(\hat{\mathbf{r}}_\mathbf{u} \odot \mathbf{e_u}|\mathbf{r_u})\Big), \qquad (2)\end{aligned}$$

where $\hat{\mathbf{r}}_\mathbf{u}$ is an n-dimensional rating vector generated by G corresponding to a user u and $\mathbf{r_u}$ is her real rating vector (i.e., ground truth). $\hat{\mathbf{r}}_\mathbf{u}$ is derived by $\hat{\mathbf{r}}_\mathbf{u} = G(\{\mathbf{z}, \mathbf{r_u}\})$ where {} indicates the concatenation of two vectors inside. From the viewpoint of *conditional GAN*[22], $\mathbf{r_u}$ corresponds to a user u's specific condition; our G generates output conditioned by $\mathbf{r_u}$. Likewise, conditioned by $\mathbf{r_u}$, D outputs a single scalar value representing the probability that its input came from the real rating data, rather than from G. Both G and D are represented by neural networks. $\mathbf{e_u}$ is an n-dimensional indicator vector specifying whether user u has given a rating to item i (e_{u_i}=1) or not (e_{u_i}=0), and $\odot$ stands for element-wise multiplication. $\mathbf{e_u}$ is used to mask G's output $\hat{\mathbf{r}}_\mathbf{u}$ by multiplying it with $\mathbf{e_u}$, and thus the model parameters are learned based solely on the observed ratings and will be used later to generate potential (yet unobserved) user-item ratings.

We employ the *stochastic gradient descent* (*and ascent*) with mini-batch and back-propagation to train our G (and D). We update the model parameters of G and D alternately, keeping one fixed when

Table 1: Accuracy with/without RAGAN (P@5)

	ML100K	Ciao	Watcha	ML1M
AutoRec	.0696	.0191	.0272	.0727
RAGAN+AutoRec	.0543	.0150	.0210	.0805
SVD	.0976	.0128	.0384	.0419
RAGAN+SVD	.1016	.0125	.0321	.0444
ItemKNN	.0326	.0079	.0071	.0362
RAGAN+ItemKNN	.0339	.0079	.0049	.0297

the other is being trained. After training of GAN is completed, we feed $\mathbf{z}$[1] and $\mathbf{r_u}$ for G to generate a dense rating vector $\hat{\mathbf{r}}_\mathbf{u}$, which contains predicted ratings on all the items for user u. Among all the predicted ratings, we collect element j in $\hat{\mathbf{r}}_\mathbf{u}$ where $j \in I \setminus I_u$, i.e., the predicted ratings only for the unrated items, and augment the original rating matrix $\mathbb{R}$ with those ratings.

4 RAGAN^{BT}

4.1 Motivation

We first point out a unique challenge of treating biases in RAGAN. We note that the ratings in our datasets are skewed towards high ratings (i.e., 3, 4, or 5 that implies *positive preferences*), coinciding with the results in other studies [6, 12]. This is mainly because people tend to choose (thus, to give ratings to) only the items that they are likely to love, and never to give ratings to those items that do not attract their interest. We claim that this *selection bias* is the main reason to make GAN trained to generate the values for unobserved entries *biased towards high ratings*. As a result, the CF models learning the rating matrix augmented with such biased ratings would fail to capture users' true preferences.

In order to make the above challenge clearer, we conducted preliminary experiments with four real-world datasets. We compare two *precisions* of top-5 recommendations performed by CF methods: one obtained by learning from the original rating matrix and the other from the rating matrix augmented with the synthetic ratings generated by RAGAN. As CF methods, we employ ItemKNN [27], SVD [16] and AutoRec [28], which are very popular ones among memory-based methods, MF-based models, and DNN-based models, respectively.

As shown in Table 1, the effect of the rating augmentation does not seem that positive: RAGAN did not help improve the accuracy in all cases and even worsened it in some cases. We analyzed the results and found the reason as shown Figure 1. First, in the original rating matrix, we observe severe *imbalance* between low (i.e., 1 or 2) and high (i.e., 3, 4, or 5) ratings from all the datasets: only a small fraction (i.e., 10–17%) of ratings are 1 and 2 which indicate negative preferences, and the rest are 3, 4, and 5 which indicate positive preferences. Since RAGAN is trained with the data biased to those high ratings, it generates mostly high ratings as in Figure 1. We note, however, this result is quite far from the reality: the majority of unobserved entries would imply users' negative preferences since users would not give a rating to those items that they are not interested in [6, 13]. Consequently, the CF methods learning the augmented matrix having unrealistic ratings could not provide accuracy improvement as shown in Table 1.

[1]In practice, however, we did not use the random noise vector $\mathbf{z}$ as done in [3].

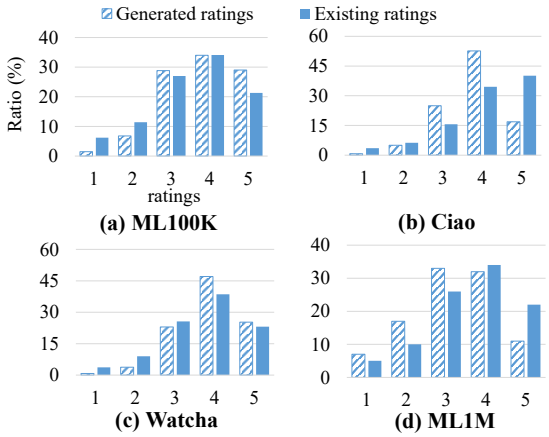

Figure 1: Rating distributions.

4.2 Overview of RAGAN^{BT}

A challenge then arises: how can we prevent GAN from being biased towards high ratings, thus generating realistic ratings for accurate CF? As a solution to this challenge, we now propose RAGAN^{BT}: a refined RAGAN with *bias treatment*. Figure 2 shows an overview of our RAGAN^{BT}, composed of the following three steps: first, we identify the *negative items* for users in a rating matrix (Figure 2(a)); we add low ratings to the negative items and use the newly added ratings along with the original ratings to train GAN (Figure 2(b)); finally, G in the trained GAN generates future ratings, which are to be augmented in the rating matrix (Figure 2(c)). We will elaborate the details of each step in the following sections.

4.3 Finding Negative Items

If user u's rating on item i is missing in a rating matrix, it will be due to one of the following reasons [11, 21, 29]:

- **lack of awareness**: u might prefer i, but was not aware of the existence of i. So, u could not rate i.
- **lack of interest**: u was aware of the existence of i, but was not interested in i because u has a low preference on i. So, u did not buy i, thus not rating i.

Obviously, a user's negative items would be her items unrated due to the latter reason. Along this line, our goal is to capture a user's interest on her unrated items and to select the items on which she has low interest. To this end, we employ the *one-class collaborative filtering* (OCCF) framework [23] following several recent work [13, 17, 19, 20]: The *implicit feedback* of a user does not always indicate her eventual preference on items represented by ratings, but naturally implies her interest on items *before using them* [10, 13, 23]; therefore, OCCF can be seen as a task of analyzing a user's interest on her unrated items and then finding top-N items that are likely to be of interest to her. Note that we have the goal *opposite* to that of OCCF: while the goal in OCCF is to find the items *most interesting* to a user, our goal is to find the items *least interesting* to her.

There have been numerous OCCF methods proposed; for example, BPR [26], FISM [14], and CDAE [34]. Among them, we employ Collaborative Denoising Auto-Encoder (CDAE), which is a DNN-based latent factor model and has shown a state-of-the-art accuracy

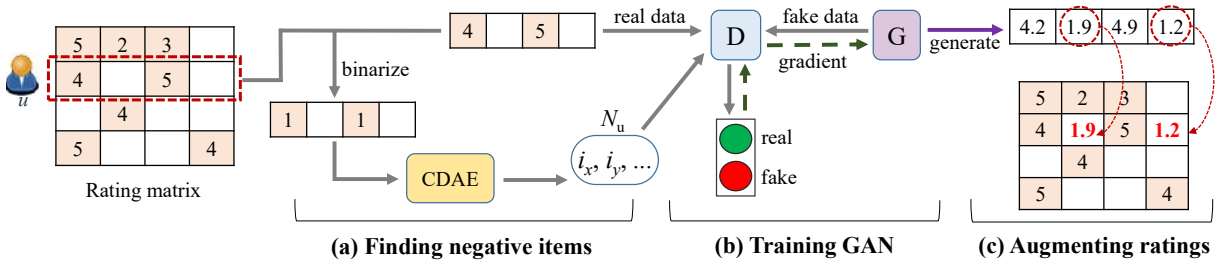

Figure 2: Overview of our proposed RAGAN^{BT}.

under OCCF setting. CDAE's input is a sparse implicit feedback vector of a user u, $\mathbf{r}_\mathbf{u}^\mathbf{b}$ (i.e., u's binarized ratings). This vector is first corrupted by masking noise: formally, the corrupted input vector, $\tilde{\mathbf{r}}_\mathbf{u}^\mathbf{b}$, is drawn by making some fraction (chosen at random for each user) of observed entries of $\mathbf{r}_\mathbf{u}^\mathbf{b}$ 0. Then, fed with $\tilde{\mathbf{r}}_\mathbf{u}^\mathbf{b}$, CDAE maps it to the hidden layer as $\mathbf{h} = \sigma(W_1^T \tilde{\mathbf{r}}_\mathbf{u}^\mathbf{b} + \mathbf{V_u} + \mathbf{b_1})$ where $\mathbf{V_u}$ is user u's latent feature vector. Finally, it tries to reconstruct the initial input (i.e., not corrupted one) by $\hat{\mathbf{r}}_\mathbf{u}^\mathbf{b} = \sigma(W_2\mathbf{h} + \mathbf{b_2})$. The model parameters of CDAE (i.e., W_1, b_1, W_2, b_2, and V) are learned by optimizing the objective function in the following:

$$\arg\min_{\psi} \frac{1}{m} \sum_{u=1}^{m} \mathbb{E}_{p(\tilde{\mathbf{r}}_\mathbf{u}^\mathbf{b} | \mathbf{r}_\mathbf{u}^\mathbf{b})} [\ell(\mathbf{r}_\mathbf{u}^\mathbf{b}, \hat{\mathbf{r}}_\mathbf{u}^\mathbf{b})] + \Omega(\psi), \tag{3}$$

where $\ell(\cdot)$ is a loss function and $\Omega(\cdot)$ is a term for so-called L2 regularization. While $\ell(\cdot)$ can be either square loss or logistic loss, we choose square loss that provides better empirical results in our work. We use ψ to denote a collection of all edge weights (W_1 and W_2) and biases ($\mathbf{b_1}$ and $\mathbf{b_2}$) in the network.

After ψ is learned, CDAE is fed with $\mathbf{r}_\mathbf{u}^\mathbf{b}$, and then reconstructs a *dense vector* that contains predicted scores of interestingness on all *unrated* items for user u. We now define a user u's *negative items*, N_u, as the bottom S percent of unrated items whose predicted scores of interestingness are the lowest [13].

4.4 Training GAN with Negative Items

We now present how we leverage those negative items to GAN's learning process. Our goal is to prevent G from being biased towards high ratings. To this end, we add a *low rating* for the negative items to $\mathbf{r_u}$ which is fed to D, as a new ground truth vector that G tries to mimic. By doing so, G would try to generate not only high ratings on the observed entries in $\mathbf{r_u}$ but also low ratings on the identified negative items in order to deceive D. Thus, we expect that G will no longer be biased towards high ratings, being able to learn users' positive and negative preferences *together in a balanced way*.

Let δ denote a low rating to be added. There are three choices for δ assigned to $\mathbf{r_u}$: 0, 1, and 2. Assigning ratings of 0 (i.e., $\delta = 0$) poses strong implication that a user does not like the negative items at all, while assigning ratings of 2 (i.e., $\delta = 2$) indicates a less severe uninterestingness towards the negative items. For each user u given, we add ratings of δ for N_u to u's real rating vector $\mathbf{r_u}$ (i.e., $r_{uj} \leftarrow \delta$, $\forall j \in N_u$), and then the imputed $\mathbf{r_u}$ is fed with D as a ground truth vector that G tries to mimic.

4.5 Recommendation

Once the training of GAN is complete, we feed G with $\mathbf{z}$ and $\mathbf{c_u}$ to generate plausible ratings. Then, we fill all missing entries in $\mathbb{R}$ with those generated ratings. We denote this augmented rating matrix as $\mathbb{R}'$. Finally, any CF models such as ItemKNN, SVD, and AutoRec can be trained to predict the preferences on the unobserved entries in $\mathbb{R}$ in their own way by using $\mathbb{R}'$ as training data. Finally, for each user, we pick the top-N items having the highest predicted preferences for recommendation.

5 EVALUATION

5.1 Experimental Settings

For evaluation, we used four real-world datasets of Watcha[2], Ciao [30], Movielens 100K, and Movielens 1M[3] (shortly, ML100K and ML1M). Table 2 summarizes their detailed statistics. For each dataset, we randomly select 80% of ratings for training data and the rest 20% for testing. In addition, we again set aside 20% of the training data for validation in order to use it for tuning hyper-parameters, such as the number of hidden layers and hidden nodes in G and D. Among the ratings in the test and validation sets, we only consider the ratings of 5 as our ground truth [5, 18]. Also, we employed four popular accuracy metrics: *precision* (P@N), *recall* (R@N), *normalized discounted cumulative gain* (G@N), and *mean reciprocal rank* (M@N). We set N as 5 and 20[4].

Table 2: Statistics of datasets

Datasets	# users	# items	# ratings	Sparsity
Ciao	996	1,927	18,648	98.72%
Watcha	1,391	1,927	101,073	96.98%
ML100K	943	1,682	100,000	93.69%
ML1M	6,039	3,883	1,000,209	95.72%

5.2 Experimental Results and Analyses

5.2.1 Q1: Effectiveness of our idea of bias treatment. Our key contribution is to address a unique challenge arises when data augmentation by GAN is applied to CF, and to suggest RAGAN^{BT}, a solution to this challenge. To show the effectiveness of this solution in rating augmentation, we visualize the accuracies of ItemKNN, SVD, and AutoRec that learn from two different rating matrices: (1) $\mathbb{R}'$ augmented by RAGAN and (2) $\mathbb{R}'$ augmented by RAGAN^{BT}.

Figure 3 reports the learning curves provided by each method *A+B* where *A* indicates a rating augmentation method and *B* does a CF model. We observe that RAGAN^{BT} makes great improvements in accuracy for all three CF models: for instance, RAGAN^{BT}+AutoRec

[2]http://watcha.net
[3]https://grouplens.org/datasets/movielens/
[4]Throughout the paper, however, we report the result of P@5 due to space limitations. We observed that the results of the other metrics exhibited very similar tendency.

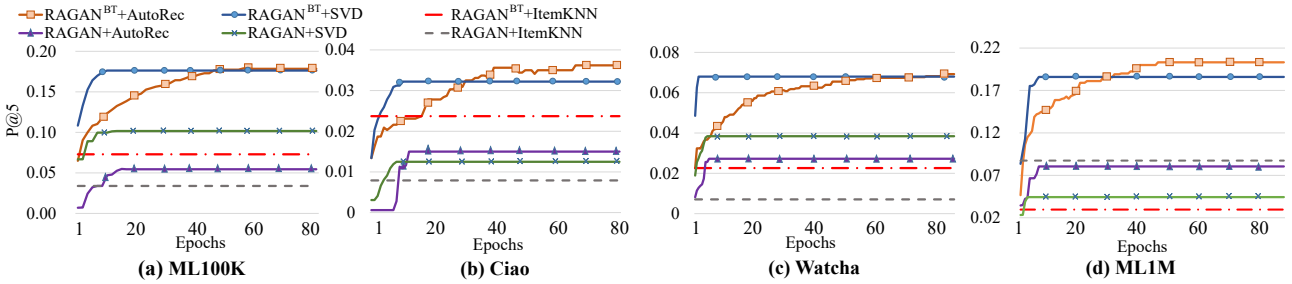

Figure 3: Learning curves (P@5).

provides up to 141.3% improvement, compared to RAGAN+AutoRec on Ciao and up to 228.5% on ML100K. This great improvement is mainly because RAGAN^{BT} generates plausible ratings by treating successfully the bias towards high ratings, thereby alleviating the data sparsity problem by augmenting those ratings.

Figure 4 reports the distributions of ratings generated by RAGAN^{BT}. Compared to the distribution of ratings generated by naive RAGAN, which is shown in Figure 1, most of generated ratings for unrated items are shown lower than or equal to 2. This result coincides with the observation that people tend to have low preferences on most of their unrated items [6, 13]. As a result, RAGAN^{BT} helps CF models to better understand users' true preferences, thereby improving the accuracy of top-N recommendation significantly.

5.2.2 Q2: Accuracy of RAGAN^{BT} according to varying hyper-parameters. This subsection investigates the impact of the following key hyper-parameters, which are unique in our RAGAN^{BT} framework: (1) the portion of negative items, S, for bias treatment and (2) which value to use as δ. Here, we employ SVD as our CF model. The results on Ciao and ML1M are shown only due to limited space.

Figure 5 reports the experimental results, where the three graphs in each figure represent the P@5 value over varying S when δ is given to negative items with 0, 1, and 2, respectively. We observe that the proposed framework works well when δ is 0 and 1. We also observe that when S reaches sufficiently large number (e.g., 25%), the accuracy of RAGAN^{BT} converges and does not change much after that point. These results show that setting S as a value moderately larger than 25% ensures CF models to understand users' positive and negative preferences in a balanced way, owing to our bias treatment. Thus, in the following experiments, we fix $\delta = 0$ and $S = 25$, and then compare it with the state-of-the-art methods.

5.2.3 Q3: Comparisons with state-of-the-arts. We now compare the accuracy of RAGAN^{BT} with those of the state-of-the-art top-N recommenders. Notably, we performed the comparisons not only under basic top-N recommendation, but also under the following two more-difficult settings: (1) long-tail items (i.e., items having a few ratings) recommendation and (2) recommendation to cold-start users (i.e., users giving a few ratings) [13]. To set up the first situation, we divided all items, by their popularity, into *top-head* items[5] that involve 30% of all ratings and *long-tail* items that are the rest. Then, we recommended only long-tail items to users. To create the second setting, we randomly selected 200 users as cold-start users. Then, we also randomly selected five ratings for each

[5] 140, 107, 101, and 202 items are included as the *top-head* items in Ciao, Watcha, ML100K, and ML1M, respectively.

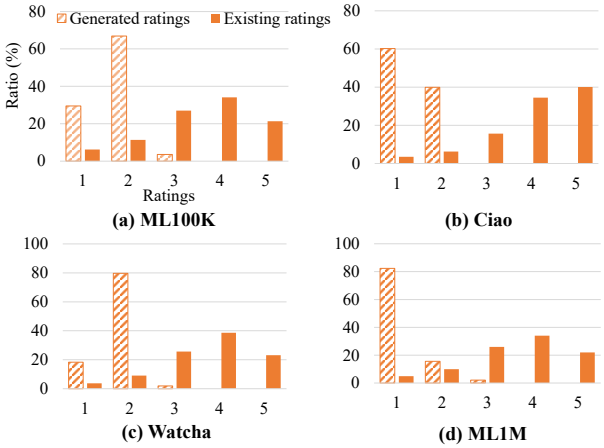

Figure 4: Rating distributions.

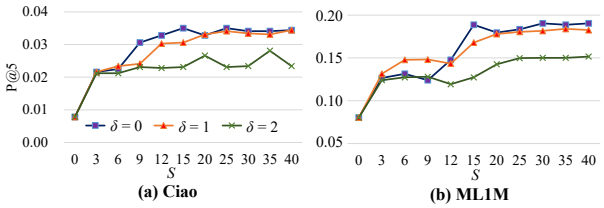

Figure 5: Impact of key hyper-parameters (P@5).

cold-start user and discarded the rest of her ratings. We finally recommended items to the cold-start users only.

Next, we introduce our competitors: (1) ItemPop, the simplest non-personalized method that ranks items based on the descending order of popularity; (2) ItemKNN, a popular neighborhood based method [27]; (3) SVD, a standard MF-based model along with user and item bias terms [16]; (4) SVD++, a combined idea of an MF and a neighborhood based method by approximating similarities among items via MF model [15]; (5) AutoRec, an autoencoder based, non-linear latent factor model [28]. Furthermore, we include two models that employ the *zero rating imputation*: PureSVD [5] and Zero-Injection [13]. Notably, Zero-Injection is the most similar to ours: both Zero-Injection and ours find a set of negative items, but after then Zero-Injection runs SVD to directly produce recommendations while our RAGAN^{BT} runs GAN to generate ratings to be imputed. PureSVD is also similar to ours: it regards *all unrated items* as negative ones and imputes zeros to them before running SVD.

Table 3: Accuracy comparisons with the state-of-the-art CF methods (P@5)

Datasets	Ciao			ML100K			Watcha			ML1M		
Situations	Basic	Long-tail	Cold-start	Basic	Long-tail	Cold-start	Basic	Long-tail	Cold-start	Basic	Long-tail	Cold-start
ItemPop	.0209	.0050	.0185	.0685	.0210	.0390	.0256	.0088	.0244	.1071	.0322	.0498
ItemKNN	.0079	.0075	.0064	.0326	.0262	.0159	.0087	.0071	.0099	.0362	.0199	.0284
SVD	.0128	.0072	.0164	.0976	.0312	.0431	.0384	.0204	.0221	.0419	.0155	.0390
SVD++	.0197	.0063	.0174	.0910	.0297	.0455	.0324	.0207	.0240	.0755	.0256	.0520
PureSVD	.0278	.0131	.0185	.1466	.0753	.0572	.0573	.0377	.0290	.1483	.0923	.0620
AutoRec	.0191	.0078	.0174	.0696	.0324	.0440	.0272	.0212	.0242	.0727	.0231	.0511
Zero-Injection	.0347	.0197	.0256	.1429	.0617	.0601	.0672	.0389	.0255	.1856	.0926	.0600
RAGAN^{BT}+ItemKNN	.0237	.0206	.0231	.0729	.0637	.0573	.0369	.0288	.0346	.1035	.0346	.0610
RAGAN^{BT}+SVD	**.0366**	.0197	.0256	.1762	.0880	.0660	.0680	.0423	**.0350**	.1860	**.0997**	**.0780**
RAGAN^{BT}+AutoRec	.0362	**.0267**	**.0277**	**.1784**	**.0884**	**.0670**	**.0701**	**.0426**	.0330	**.2032**	.0957	.0680

Table 3 reports the comparison results. Overall, we see that AutoRec and SVD along with our RAGAN^{BT} significantly outperform all the other competitors. In particular, we beat PureSVD and Zero-Injection, which have shown the best accuracy among all CF models, by a wide margin: the average of relative improvements of our RAGAN^{BT}+AutoRec over Zero-Injection is 15.8%. We note that PureSVD and Zero-Injection can be considered as simplified versions of our work: they assign 0 ratings to all the unrated items (PureSVD) or to carefully chosen negative items (Zero-Injection), and then run SVD to produce recommendation without GAN for further imputation. However, their important drawback is that they do not take users' *personalized preferences* on items into account, just adding the *same zero* ratings to all (PurSVD) and some (Zero-Injection) unrated items. In contrast, we exploit GAN so as to generate more realistic and personalized ratings carefully. Our experimental results indeed verify the effectiveness of our RAGAN^{BT} over the two competitors: it successfully relieves the data sparsity problem by carefully generating plausible ratings, rather than simply imputing zero ratings as PureSVD and Zero-Injection did.

Another notable point is that RAGAN^{BT} is more successful under the long-tail and cold-start settings, which are more-difficult situations than basic top-N recommendation. More specifically, RAGAN^{BT}+AutoRec performs well under the long-tail setting on Ciao (35.5% improved, compared to the best performer among our competitors) and ML100K (17.3% improved), and RAGAN^{BT}+SVD performs well under the cold-start setting on Watcha (20.7% improved) and ML1M (25.8% improved). It can be a very promising result since those difficult situations are very common in most real-world recommender systems. Therefore, our RAGAN^{BT} could be a good choice for those situations suffering from lots of cold-start users and long-tail items.

5.2.4 Q4: Execution time analysis. Lastly, we analyzed our proposed RAGAN^{BT} in terms of the execution time. Specifically, we measured each time consumed by (1) finding negative items with CDAE, (2) augmenting ratings with GAN, and (3) recommending items with AutoRec, which has achieved higher accuracy than SVD and ItemKNN. Here, we used a single machine equipped with an i9 7700K Intel CPU, 64GB RAM, and NVIDIA TITAN XP GPU. The results are summarized in Table 4. For the largest dataset (i.e., ML1M), total time required is about 6,891 seconds: each epoch of CDAE takes around 8 seconds, and needs 150 epochs to sample appropriate negative items for each user; each epoch of GAN takes approximately 12.5 seconds, and needs 450 epochs to generate plausible ratings; finally, AutoRec needs 100 epochs to get satisfactory accuracy where each epoch takes about 1 second. Note that the total execution time consumed by SVD++, which is one of our baselines, is around 5,078 seconds. In summary, we see that our framework augments plausible ratings and provides high-quality recommendations within a reasonable time. This is because, even though our RAGAN^{BT} involves three procedures of model training, all of them are based on neural networks whose training can be easily parallelized by fast GPU.

Table 4: Execution time (s)

	Total	Finding negative items (**CDAE**)	Augmenting ratings (**GAN**)	Recommending items (**AutoRec**)
Ciao	1,062.76	123.49	927.11	6.08
Watcha	2,060.70	222.69	1,827.21	10.80
ML100K	2,500.42	382.08	2,102.03	16.31
ML1M	6,891.66	1,164.88	5,623.58	103.20

6 CONCLUSIONS

In this paper, we have presented RAGAN, a novel rating augmentation framework based on GAN, to relieve the data sparsity problem in CF. Then, we have identified a challenge of treating the biases to high ratings that GAN faces when learning from the rating data. We have proposed RAGAN^{BT}, which successfully addresses the challenge by involving negative items when training GAN. From our comprehensive experiments, we have demonstrated that RAGAN^{BT} significantly improves the accuracies of existing CF methods, making them outperform the existing state-of-the-art CF methods, not only under basic top-N recommendations but also under more-difficult situations of long-tail item recommendations and recommendations to cold-start users.

ABSTRACT

Online donation platforms, such as DonorsChoose, GlobalGiving, or CrowdFunder, enable donors to financially support entities in need. In a typical scenario, after a fundraiser submits a request specifying her need, donors contribute financially to help raise the target amount within a pre-specified timeframe. While the goal of such platforms is to counterbalance societal inequalities, biased donation trends might exacerbate the unfair distribution of resources to those in need. Prior research has looked at the impact of biased data, models, or human behavior on inequality in different socio-technical systems, while largely ignoring the *choice architecture*, in which the funding decisions are made.

In this paper, we focus on (i) quantifying inequality in the project funding in online donation platforms, and (ii) understanding the impact of platform design on donors' behavior in magnifying those inequalities. To this end, we borrow decomposable measures of income inequality from economics, and apply it to identify candidate factors contributing to inequality on the DonorsChoose website. Analyzing longitudinal changes in the website design, we show how the platform design impacts the relative contribution of the different factors. Our work motivates the need for a careful investigation of the impact of choice architectures on user decisions, in donation platforms in particular, and in online platforms more generally.

1 INTRODUCTION

Online donation platforms, such as DonorsChoose, Chuffed, GlobalGiving, CrowdFunder or Facebook fundraising, provide effective platforms for connecting donors to entities in need of financial support. In a typical scenario, after a recipient submits a request specifying her need, donors can contribute financially to help raise the target amount within a pre-specified timeframe. The core mission of such platforms is to counter existing social inequalities. Biased donor behavior, however, may skew the distribution of donations towards or against certain recipients, exacerbating some of these inequalities as a result. Consider DonorsChoose.org, a platform where US-based school teachers can create funding requests to support the educational needs of their classrooms. Since public schools in the US are primarily supported by local taxes [24], schools located in poor neighborhoods are often severely underfunded. If the donors have a preference to donate to schools in their own region, the funding inequality combined with biased donation behavior could lead to a *rich get richer* effect, where wealthy schools easily receive additional funding in the form of online donations, while schools in poor neighborhoods remain impoverished [25].

At first glance, such biased outcomes may seem to be the sole artifact of donors' preferences rather than that of the platform mediating donations. After all, donors are rational beings, and the donation platforms offer them full freedom of choice. However, drawing on a rich body of work in behavioral economics, we argue that the platform can indeed play an important role in shaping donors' behavior without limiting their choices: Donation websites present requests within a *choice architecture* [33], influencing donors' decision-making and *nudging* them towards choosing certain alternatives. Examples of nudges [32] on DonorsChoose include the *default* ranking strategy used in project listings, *decision making aids* such as search filters, or the *selection of project attributes* disclosed to the donors. The main conceptual contribution of our work is to draw attention to the power of nudges in socio-technical systems, while our empirical contributions focus particularly on online donation platforms.

Prior research works have looked at how different factors impact long-term retention of donors [1] or the project financial success [14, 16, 34]. The likelihood of funding has also been shown to be influenced by the language used in project descriptions [22], the gender of teachers [26], the social media activity associated with the project [20], or the amount of early donations [29]. However, our work highlights that the way a platform presents its users with choices will have significant impact on their donation decisions.

We, therefore, advocate for a careful investigation of choice architectures and the ethics of their impact on guiding user decisions. What we focus on in this paper more specifically, is how the choice architecture of the website might nudge donors towards choosing projects with certain attributes, and as a result, contribute to inequality in donations along the dimension of these attributes.

As our first contribution, we quantify the inequality in project funding and attribute portions of the inequality to different project characteristics (Note that in highly empirical applications, it is difficult to reason about causal effects without making strong assumptions about the data generating process, which limits the practicality of causal estimation approaches). Our approach to this task emerges from its similarity to the problem of quantifying income inequality, specifically to measure the contribution of characteristics such as gender or race to wage inequality. This problem has been studied in economics using decomposable inequality indices [4, 23], whose *additive decomposability property* helps factor out the influence of individual differences. We borrow one of such measures called 'Generalized Entropy' to find the contribution of different project characteristics to the overall inequality in funding.

Our second contribution revolves around *understanding how platform design choices affect donor behavior*. This idea is related to the existing literature on nudges [27, 32] and choice architectures [19, 28, 33] in behavioral economics. Research in these areas investigates how people's choices depend on how information is presented to them. This framing applies to our scenario: we are interested in learning whether the way a donation platform presents project information influences how donors choose projects with specific attributes. We face two challenges when attempting this goal.
First, once we pick a design element whose influence we want to measure, we have to make sure all other elements of the platform environment are fixed, including other website elements as well as donor characteristics. Second, while it is feasible to imagine running active experiments (i.e., A/B testing) by the platform, such an approach raises a lot of ethical concerns in a setting where people's decisions are nudged, and the outcomes influence future real-world financial success of others [3]. To overcome these issues, we analyze longitudinal changes in DonorsChoose platform design, and we estimate the average impact of a design change by comparing the observations right before and after it was first introduced. This way, we are able to quantify the influence of individual website design elements on project selection rates from historical donation data, while avoiding manipulation of future donations.

We run the inequality analysis on the data released by DonorsChoose in 2016, which provides over ten years worth of project and donation information, revealing two interesting findings. First, school location (zip code) is a factor largely contributing to funding inequality. Further analysis confirms that this is because (i) the majority of money is donated within-state (i.e., donors tend to give to their local projects), and (ii) the bulk of donations come from a handful of wealthier states, such as California or New York. Second, we find that the poverty level of the school does not contribute much to funding inequality – projects from high-poverty facilities have equal success rates as those from low-poverty ones, despite research showing that people consciously prefer charitable giving to be need-based [10].

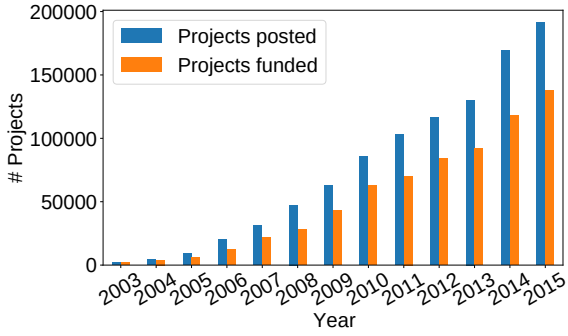

Figure 1: Number of projects posted per year (along with the number of projects successfully funded).

Our longitudinal analysis shows that it is possible to enhance the impact of school location or poverty level in influencing the project selection rates, via changes in the platform design. In the process, we highlight that even though donation platforms are perceived as neutral facilitators of interactions between the donors and the requestors, they do have an active role to play. We envision our work to pave the way for future studies aiming to employ nudges effectively to improve platform-specific goals, such as to maximize total amount of donations, or to ensure the social and ethical requirements of online altruism, such as bringing in fairness in the distribution of donations across projects.

2 DONORSCHOOSE.ORG DATASET

`DonorsChoose.org` is a popular donation platform where teachers from schools in the United States can request donations for their classroom projects. Such requests range from buying books or tools for specialized experiments, funding of excursions, all the way to replacing wore-down basic classroom equipment. Teachers do not receive money directly; DonorsChoose purchases all the requested resources and ships them directly to the schools [13]. Teachers on average request $561.57, with the median request being $413.67[1].

When choosing the projects, donors can select projects based on attributes such as the school location (zip code, city, state), main focus subject of the project (e.g., Math and Science, Health and Sports, Literacy and Language), or requested resources (e.g., Books, Computers and Tablets, Food, Clothing and Hygiene etc.). However, if a project does not raise its target amount by a certain deadline, it receives no funding, and the donors need to reallocate the donated money to other projects. While implementing this 'all-or-nothing' rule has been shown to have certain positive effects on donations, like increasing the overall amount of donations [35], there are projects that fail to receive funding as a result.

To identify the magnitude of such unsuccessful projects, in this work, we analyze the dataset publicly released by DonorsChoose in 2016 [12], which contains information about all projects posted on the platform starting from 2002 until the dataset's release date. During this period, DonorsChoose helped raise over $500M from over 5M donors. There were over 1M projects created by around 500K teachers from over 70K different schools. The dataset contains many project attributes, such as details about the teacher, requested

[1]The median amount is not round because of factors such as sales tax.

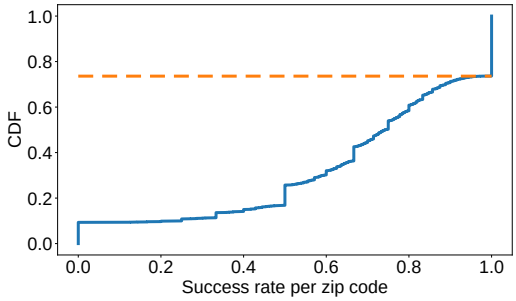

Figure 2: CDF of project success rates across different zip codes. The distribution is highly unequal. Around 26% zip codes have 100% success rate (shown as the dashed line), whereas the success rate is much lower in other zip codes.

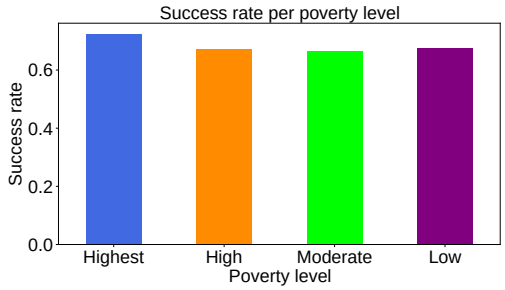

Figure 3: Distribution of project success rates across 4 poverty levels. The distribution is relatively equal.

resources, and the textual description of the request. The dataset also contains donation data, including donation date, amount donated, and location of the donor (state and city; while the zip codes of donors are anonymized for privacy reasons). Since the dataset covers only a part of 2002 and 2016, we remove these two years from our analysis and focus on projects posted from 2003 to 2015.

Figure 1 shows that the number of projects on the platform has been steadily growing, yet a significant number of projects fail to get funded each year. The data reveals that on average 29.79% of projects fail every year. These failure rates are unlikely to be the result of some projects being low-quality or fraudulent since all the projects posted on the website are vetted and verified by DonorsChoose. The platform also decided to fund all active projects after getting Ripple's generous $29M donation in early 2018 [6]. We can thus conclude that all projects on DonorsChoose are worthy of getting funded, and it is important to understand the factors contributing to the inequality of success rates across projects, to ensure that the failure rates do not adversely affect certain types of projects or schools. This problem is the focus of the next section.

3 MEASURING INEQUALITY IN DONATIONS

In this section, we propose a methodology based on the well-studied concept of inequality measurement in economics, to identify whether a given feature (or attribute) contributes to inequality in projects' chances of success. The proposed method allows us to quantify the inequality contributions *without the need for making any assumptions about the data generating process.*

For a fixed choice architecture, let features $X_1, \cdots, X_k$ characterize a project, and Y denote its success (with $Y = 1$ meaning that the project is successfully funded). We have access to observational data of the form $D = \{\langle (x_1^i, \cdots, x_K^i), y_i \rangle\}_{i=1}^N$ sampled i.i.d. from a joint distribution F. Then, we can utilize D to decide whether feature X_k contributes to the inequality across Y values. Note that we use upper case letters to denote random variables and lower case letters to denote in-sample realizations.

3.1 Decomposable Measures of Inequality

We propose to measure inequality using an *additively decomposable index of inequality* (namely, *generalized entropy*) for the vector $(y_1, \cdots, y_N)$. We then estimate the impact of a feature X_k by decomposing the total inequality according to X_k feature values.

We begin with an overview of inequality measurement. Measures of inequality quantify the degree of inequality in a distribution of resources or benefits over a population. More precisely, given a distribution/vector $\mathbf{y} = (y_1, \cdots, y_N) \in \mathbb{R}^n_{\geq 0}$, an inequality measure, $I : \bigcup_{n=1}^{\infty} \mathbb{R}^n_{\geq 0} \to \mathbb{R}_{\geq 0}$, maps any distribution/vector $\mathbf{y}$ to a non-negative real number $I(\mathbf{y})$. A distribution $\mathbf{y}$ is considered more equal than $\mathbf{y}'$ if and only if $I(\mathbf{y}) < I(\mathbf{y}')$. A long established line of work in economics offers an axiomatic characterization for inequality indices. Virtually all commonly-used inequality indices satisfy axioms such as Anonymity, Population invariance, Transfer principle, Zero-Normalization [30].

Additive decomposability is a structural property of some inequality measures requiring that for *any* partition G of the population into groups, the measure, $I(\mathbf{y})$, can be expressed as the sum of a *"within-group component"* $I^G_\omega(\mathbf{y})$ (a weighted sum of subgroup inequality levels) and a *"between-group component"* $I^G_\beta(\mathbf{y})$ (computed by assigning to each element in a subgroup $g \in G$ the subgroup's mean benefit μ_g): [2]

$$I(\mathbf{y}) = I_\omega(\mathbf{y}) + I_\beta(\mathbf{y}).$$

Following [30], we focus on a family of inequality indices called *generalized entropy indices* that satisfy additive decomposability. For a constant $\alpha \neq 0, 1$, the generalized entropy is defined as follows:

$$\mathcal{E}^\alpha(y_1, y_2, \cdots, y_n) = \frac{1}{n\alpha(\alpha-1)} \sum_{i=1}^{n} \left[\left(\frac{y_i}{\mu} \right)^\alpha - 1 \right]. \quad (1)$$

One can interpret generalized entropy as a measure of information theoretic *redundancy* in data. Given a partition G of the population, generalized entropy can be additively decomposed: Suppose subgroup $g \in G$ consists of n_g individuals with the benefit vector $\mathbf{y}^g = (y_1^g, \cdots, y_{n_g}^g)$ and mean benefit μ_g. Generalized Entropy can be decomposed as follows:

$$\mathcal{E}^\alpha(y_1, y_2, \cdots, y_n) = \sum_{g=1}^{|G|} \frac{n_g}{n} \left(\frac{\mu_g}{\mu} \right)^\alpha \mathcal{E}^\alpha(\mathbf{y}^g) + \sum_{g=1}^{|G|} \frac{n_g}{n\alpha(\alpha-1)} \left[\left(\frac{\mu_g}{\mu} \right)^\alpha - 1 \right]$$

[2] When the partition G in reference to is clear from the context, we drop the superscript G to simplify notation.

Feature	School Location	Amount Requested	Matching Donations	Resource Type	School Type	Primary Focus Subj.	Secondary Focus Subject	Secondary Focus Area	Primary Focus Area	Teacher Prefix	Poverty Level	Teacher Cred.	Grade Level
Normalized Inequality Contribution	0.1372	0.07198	0.02048	0.01399	0.0034	0.00307	0.00291	0.00208	0.0016	0.00108	0.00093	0.00087	0.00058

Table 1: The contribution of different features to inequality in donations. School location has the highest contribution, whereas poverty level has low contribution.

3.2 Measuring Feature Contribution through Inequality Decomposition

We propose estimating the impact of a feature X_k on Y through the following procedure:

(1) Partition the population (i.e., the set of all projects) into groups G, according to the value of the feature X_k. For instance, suppose X_k represents a teacher's gender, taking two different values. G partitions the projects into two groups, those with male teachers and those with female teachers.
(2) Compute and return $I_\beta^G(\mathbf{y})/I(\mathbf{y})$ as the impact of X_k on Y.

Note that just because there is a higher between-group component in decomposition according to feature X_k when compared to the decomposition according to X_j does not necessarily mean that feature X_k has more *causal* impact on Y when compared to X_j. Why are we focusing on inequality decomposition then?

3.3 Relationship with Causal Inference

Traditionally, in order to understand the impact of a set of explanatory variables (in our case, $X_1, \cdots, X_K$) on a target variable of interest (in our case, Y), econometricians begin by specifying an "explanatory model" (e.g., a simple regression model). Such a model carefully specifies a counterfactual in order to examine the influence of each supposedly causal factor on the target. In the process of developing such a model, econometricians must make several important choices, including which explanatory variables belong in the model, what functional form should the regression function take (i.e. logarithms, quadratic, etc.), and what the error distribution looks like. These choices are usually guided by domain expertise. For instance, consider a simple regression (which is one of the most commonly used methods in empirical studies): We assume $Y = U + \beta_0 + \sum_{k=1}^{K} \beta_k X_k$ where U is the error/noise term. Provided that this functional form is correctly specified, and that standard assumptions such as exogenous covariates hold, we can use OLS methods to estimate the coefficients. These estimates then serve as the measure of the causal impact of each attribute on the target variable: the parameter β_k measures the increase in Y attributable to one unit of change in X_k, keeping all the other covariates fixed.

Unfortunately, the above approach is restrictive in many empirical applications. First and foremost, this is because the modeling step can be cumbersome, and conclusions made through explanatory models are often sensitive to model specification [9]. Given these issues, here we base our analysis on an alternative tool, namely, measurement of inequality. [9] have indeed established a strong connection between the two methods under certain conditions. Assuming that the model is correctly specified (e.g., the data is indeed generated through the assumed linear model), they show that the impacts estimated by OLS and those derived by inequality decomposition are closely related. For the precise expressions, see equation (22) in [9]. In summary, our decomposition approach allows us to measure feature influence without the need for strong assumptions on the data generating process, and is better suited for discrete variables.

4 IMPACT OF CHOICE ARCHITECTURE ON DONATION INEQUALITY

Using the proposed methodology, in this section, we utilize observational data from DonorsChoose to identify the features contributing to inequality in projects' chances of success.

4.1 What's Behind Inequality in Donations?

Table 1 illustrates our proposal on the DonorsChoose data corresponding to the year 2015[3]. Note that the contributions of school location (in terms of zip codes), amount requested, resource type (the type of resource that was requested), and matching donations (whether the amount donated by individual donors to a project are going to be matched by larger corporate donation) are deemed high, whereas the contribution of poverty level is low. Throughout the rest of this section, we narrow down our attention to two of these features: school location and poverty level.

Figure 2 shows the CDF of project success rates across different zip codes. As evident from the figure, zip code has a high contribution to inequality. For around 26% of the zip codes, all the projects were funded, whereas for other zip codes, the percentage of funded projects varied anywhere between 50% to 90%. Figure 3 shows the distribution of project success across different poverty levels (schools in DonorsChoose are classified into four poverty categories: Highest, High, Moderate, and Low, depending on how many students come from low-income families). As evident from the figure, the project success rates are similar across different poverty levels, explaining the low value of inequality contribution for this feature.

4.2 Behavioral Mechanisms Underlying the Inequality Contributions

We suspect that the high inequality contribution of school location is in part due to the donors' preference to donate locally, that is, to donate to schools in their own zip code, city or state. The dataset does not contain donors' zipcode (due to privacy considerations), but our analysis at the city and state level indeed reveals a strong

[3] As mentioned earlier, the DonorsChoose dataset consists of project funding information of multiple years. To exclude external factors such as the amount of traffic to the website, large fundraising activities in specific years, or varied amounts of matching donations from our analysis, we focus on the projects posted on a particular year.

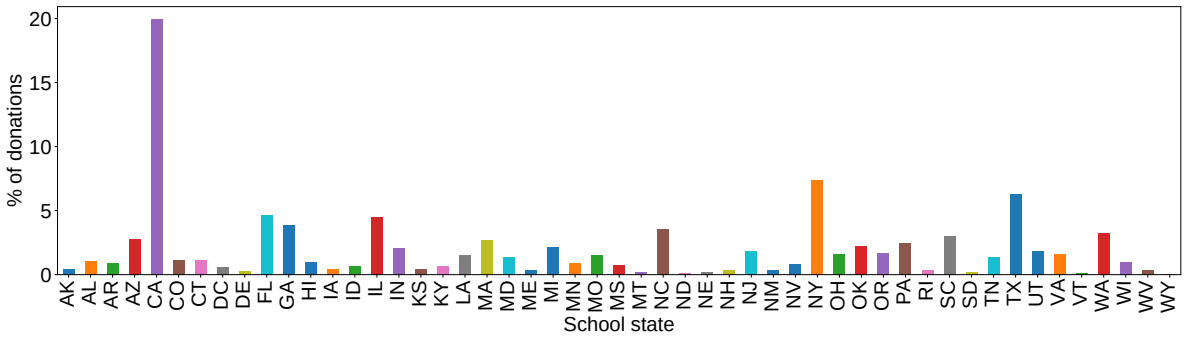

Figure 4: Percentage of donations going to different school states. There is huge disparity in the donation distribution.

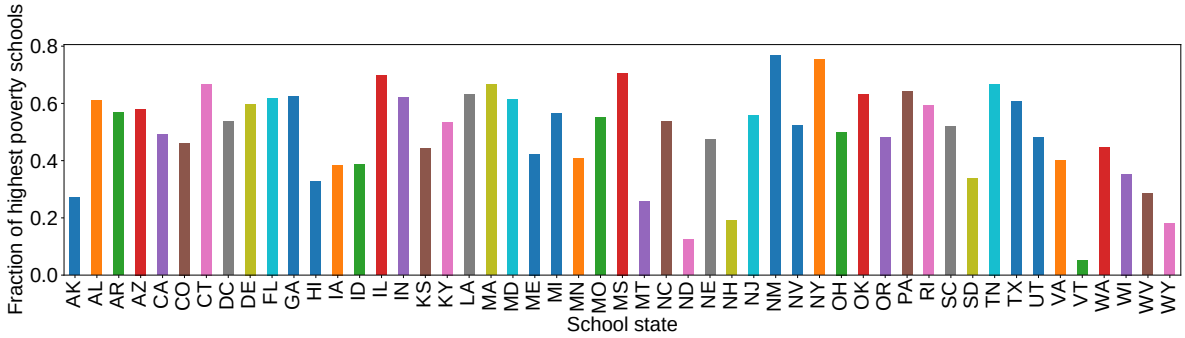

Figure 5: Fraction of schools belonging to highest poverty level in different states. Donation distribution in Figure 4 does not correlate with the school poverty level distribution.

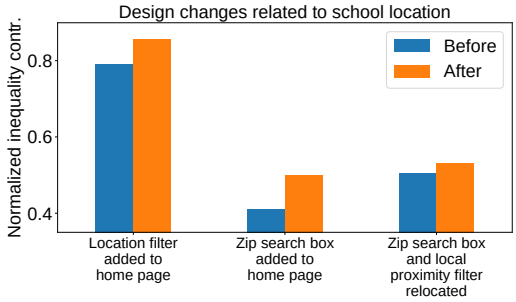
tendency of donors to fund local projects: almost 80% of the total amount of funding is donated within the same state, and around 20% of the total amount is donated within the same city as the donor's. Only 20% of the total donations are made to schools outside donors' states. This tendency, combined with the fact that the amount of total donation varies widely across states (see Figure 4), explains the high inequality contribution of the school location. As we will discuss in Section 4.3, the locality bias might be further encouraged by the presence of certain nudges on the website (e.g., the option to search projects by location). This is despite the fact that the donation distribution in presence of the location bias does not correlate with the distribution of highest poverty schools in different states (see Figure 5), which are in higher need of economic support.

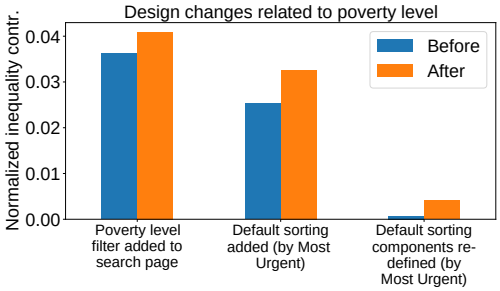
From a moral standpoint and to alleviate current social injustice, one may argue that the schools with higher economic need are more deserving of receiving donations, and the website should nudge the donations in their favor. To put it more formally, it may be desirable (ethically and socially) to reduce the contribution of location, but increase the contribution of school's poverty level to how donations are distributed. Next, we show evidence that choice architecture and nudges indeed impact contribution of these factors.

4.3 Evidence on the Impact of Nudges



To gain insights on the impact of choice architecture and nudges on inequality in different projects' chances of success, we identify the time points, throughout the years, when a new website design was introduced in DonorsChoose, using snapshots from 'The Internet Archive' (`web.archive.org`). Then, utilizing the longitudinal donation data, we analyze the effect of these interventions.

To this end, prior works have proposed *Regression Discontinuity Designs* (RDDs) [2, 11, 17, 21]—a quasi-experimental design that reasons about the causal effects of interventions by identifying a threshold above or below which an intervention is assigned. We follow this methodology by comparing the projects *before* and *after* a new design feature is introduced. (The intuition is that other conditions (e.g., the project and donor pool) are likely to be very similar right before and after each intervention.) More specifically, let $(x_1, ..., x_k)$ specify the features that impact a project's success (e.g., *school location* or *poverty level*) and t_0 the timestamp when a new design feature is introduced. Let y specify whether a project is successful or not. We fit the following model to the data consisting of projects introduced right before and right after the design change of interest:



$$y = a_0 + a_1 x_1 + ... + a_k x_k + I(t > t_0)(b_0 + b_1 x_1 + ... + b_k x_k). \quad (2)$$

The estimated coefficients $b_1, ..., b_k$ specify if the intervention has impacted the importance of feature $x_1, .., x_k$ on the success of a project. Unfortunately for our data set, linear regression is not a good fit—making the conclusions from the RDD design unreliable.

To circumvent the issue, we measure the impact of each design change on donors' behavior via another quasi-experimental design: we estimate the average impact of the change by comparing the

(a)

(b)

Figure 6: Changes in the inequality contribution of school location and poverty level before and after certain design changes were introduced in DonorsChoose website.

inequality contribution of different features right before and after it was first introduced. Again, the intuition is that other conditions are likely to be very similar right before and after each intervention. Therefore, comparing the inequality contribution after the intervention (treatment group) to that before the treatment (control group) will deliver the local treatment effect.

Next, we look at several nudges directly related to the school location, introduced in DonorsChoose website at different times:

- **2004:** Location filter was added to the homepage and the project search page. We expect this to increase the contribution of school location. Figure 6a confirms this.
- **2012:** Added 'projects near me' filter to the homepage. We expect this to increase the contribution of school location. Figure 6a further confirms this.
- **2015:** Location search box was added to both home and search pages. We expect this to increase the contribution of school location, and this is indeed consistent with what we observe in Figure 6a.

We now look at several nudges directly related to the school poverty level:

- **2005:** Filter "High level of poverty" was added. We expect this to increase the contribution of poverty level to inequality (i.e., poor schools now have more chance of getting funds). This is what we observe in Figure 6b.
- **2008:** "Most Urgent" criteria became the default ranking of search results (urgency = highest poverty + lowest cost + fewest days left). We expect this to increase the contribution of poverty level. This is consistent with our observation in Figure 6b.
- **2012:** "Most Urgent" criteria was redefined (to highest poverty + closest to finish line). We expect this to increase the contribution of poverty level. This is consistent with what we observe in Figure 6b.

These results show the potential of choice architecture to impact donors' behavior, and we believe that by carefully designing the nudges, the platform can influence the selection rates of projects of different poverty levels and locations in a socially desirable way.

5 CONCLUSION AND FUTURE DIRECTIONS

Recently, there has been a lot of focus on biases in human behavior [7, 22, 26] as well as in algorithmic models [5, 8, 15], and their impacts on different socio-technical systems. Our work sheds light on the power of choice architecture and nudges in shaping the user behavior in online platforms, thus contributing to the observed biases. We conducted an in-depth analysis of the donation platform – DonorsChoose.org, by utilizing longitudinal empirical data. In this process, our work takes an important first step towards adapting nudge frameworks to the social and ethical requirements of online altruism. Many interesting directions remain open for future work:

How can donations be fairly distributed across projects?
To answer this question, we need to first carefully specify a measure of *need* for different projects, which may depend on factors such as the poverty level of the school district, the funding target, project urgency, and others. Given an inter-project-comparable measure of need, one can define fairness as follows: projects with the same level of need should have a similar likelihood of success. Our findings illustrate that the choice architecture can influence project selection rates, and the platform can potentially explore different ways to achieve a fair distribution of donations using nudges.

Ethics of nudges
There has already been much debate about whether and when the use of nudges is ethical [18]. Some refer to nudges as a form of paternalism and restriction of choice and agency, whereas others refer to it as libertarian paternalism – a way of positively influencing people without limiting their freedom of choice [31]. We believe such a discussion should be informed by the context in which nudges are employed. While we did not attempt to tackle these issues in this paper, there are deep ethical concerns that arise when discussing nudges in the context of online charity platforms: For instance, does the goal of promoting more deserving (but less attractive) projects justify the use of the nudges? To what extent? We leave these and many other questions for future work.

ABSTRACT

Consumers today face too many reviews to read when shopping online. Presenting the most helpful reviews, instead of all, to them will greatly ease purchase decision making. Most of the existing studies on review helpfulness prediction focused on domains with rich labels, not suitable for domains with insufficient labels. In response, we explore a multi-domain approach that learns domain relationships to help the task by transferring knowledge from data-rich domains to data-deficient domains. To better model domain differences, our approach gates multi-granularity embeddings in a Neural Network (NN) based transfer learning framework to reflect the domain-variant importance of words. Extensive experiments empirically demonstrate that our model outperforms the state-of-the-art baselines and NN-based methods without gating on this task. Our approach facilitates more effective knowledge transfer between domains, especially when the target domain dataset is small. Meanwhile, the domain relationship and domain-specific embedding gating are insightful and interpretable.

1 INTRODUCTION

Product reviews, primarily text, provide important information for consumers to make purchase decisions. Hence, it makes great business sense to quantify the quality of reviews and present consumers useful reviews in an informative manner. In fact, major E-commerce websites like Amazon.com encourage users to rate whether a review is helpful or not. However, most reviews do not have helpfulness scores or votes. Fewer than 20% of the reviews in Amazon Review Dataset [20] have 5+ votes while only 0.44% have 100+ votes. In addition, the review voting itself may be biased [5, 8]. It is thus interesting yet important to automatically infer the helpfulness score of any review.

Recently, there are growing interests from both the academia and the industry on such *review helpfulness prediction task* [17, 19, 30, 31]. Pioneering work hypothesizes that helpfulness is an underlying property of the text, and uses handcrafted linguistic feature to study it [17, 19, 30, 31]. Unfortunately, most of them focus on domains with rich labels, and may not be practical for domains with insufficient data. For example, the "Electronics" domain from the Amazon Review Dataset has more than 354k labeled reviews, while "Watches" has less than 10k [30]. To alleviate, we study Transfer Learning (TL) for review helpfulness prediction. Specifically, we propose a multi-domain approach that transfers knowledge from multiple data-rich domains to data-deficient domains. Inspired by the remarkable performance and efficiency of Convolutional Neural Networks (CNNs) on many tasks in natural language processing [6, 13], we adopt CNNs to prove the concept of our TL framework for the task. Our proposed framework is a multi-domain gated NN model based on two important observations below (arranged in the order of the data processing flow.)

First, while embeddings of words are equally used downstream in previous applications of CNNs in NLP, actually different words have different and domain-dependent impacts to review helpfulness. For example, the top aspect extracted by the model in [30] for "Watches" domain is "Warranty" whereas "Portablity" for "Electronics" domain, implying that words related to "Warranty" are

important to "Watches," while words related to "Portability" are important to "Electronics." Hence, we introduce the *word-level gating* mechanism to weight embeddedings[1].

Although gating mechanisms have been used in RNNs [7, 26, 29], our gating method is complimentary for being word- and domain-specific, i.e., one gate weight for one word in one domain. Our gating mechanism can help selectively memorize the input representations of the words and scores the relevance/importance of such representations in different domains, to provide insightful word-level interpretations for the TL prediction results. Meanwhile, to the best of our knowledge, our gating mechanism is the first to study cross-domain word-level importance.

Second, domain difference is indeed a pending problem in review analysis, as agreed by previous work [6, 17, 30]. When transferring knowledge, not all domains are helpful to a target domain. We propose multi-domain relationship learning to exploit cross domain relationships to properly transfer knowledge from *related* domains with sufficient labeled data to domains with limited reviews. It is worth noting that, existing studies on this task only focus on a single product category or largely ignore the inner correlations between different domains [6]. Previous work show some features are domain-specific while others can be shared. For example, image quality features are only useful for cameras [30], while semantic features and argument-based features are applicable for all domains [17, 31]. While there are some common practices to transfer knowledge between domains [21, 32], such as using a shared NN. We urge *domain correlations* to be established before the knowledge can be transferred properly for review helpfulness prediction, otherwise, transferring the knowledge from a wrong source domain may backfire. We thus provide a holistic solution to both domain correlation learning and knowledge transfer by incorporating domain relationship learning in our framework.

Furthermore, we propose to enrich the word representation in a vanilla CNN by considering cross-domain *character-* and *aspect-level* representations. Character-level representations are notably beneficial for alleviating the out-of-vocabulary problem [2, 14], while aspect distribution provides another semantic view on words [30].

In all, our model explores cross-domain word representations, multi-domain word gating, and multi-domain relationship learning to help the task. As shown in Figure 1, our network has four types of layers: (1) shared embedding layers, (2) gating layers, (3) convolutional layers, and (4) output layers with relationship learning. Experimental results show that our final model can correctly tap into domain correlations and facilitate the knowledge transfer between correlated domains. In all, we summarize our contributions following the network architecture (left to right in Figure 1) below:

- **Rich word representations:** We study CNN for review helpfulness prediction task, and further enrich our word representations by incorporating multi-granularity information, i.e., character-, word-, and aspect- based embeddings;
- **Domain specific gating layer:** We proposed a novel domain-specific gating mechanism to learn/interpret the important/non-important words in reviews and to boost model performance.
- **Cross-domain relationship learning:** We are the first to study cross-domain relationship learning for the task and show that the cross-domain correlations learned are insightful and beneficial for the task;
- **Evaluation:** Extensive experiments show that our model significantly outperforms the state of the art and can transfer knowledge to help target domain with limited data.

[1]The gates are applied over all three types of representations (i.e., character-, word-, and aspect-based) for all words and weights are domain-specific.

2 RELATED WORK

Review helpfulness prediction is a task close to but *different from sentiment analysis* [16]. The goal of sentiment analysis is to detect the emotion behind an opinion, whereas review helpfulness aims to identify helpful information like reasoning etc., regardless of the emotion nor the opinion [17, 31].

Recent studies on review helpfulness prediction extract handcrafted features from the review text. For example, semantic features used in [31] and [19], aspect features in [30] and argument-based features in [17]. These methods require prior knowledge and human effort in feature engineering and may not be robust for new domains. CNNs with the ability to extract deep features, have demonstrated remarkable performance over many NLP tasks, for its high-efficiency and comparable performance to Recurrent Neural Networks (RNNs) [13]. Our initial study shows that vanilla RNN [27] does not outperform our CNN models. It echoes the finding that RNNs are more robust but do not guarantee to have better results than CNNs [33]. Thus, we employ CNNs for our task. Since character-level representations are notably beneficial for alleviating the out-of-vocabulary [14] problem, while aspect distribution provides another semantic view on words [30], we further enrich our word representation by adding character- and aspect-based representations.

Unlike a single domain model, our work focuses on leveraging reviews from multiple domains. As a word may play different importance on different domains, we consider to weight word representations by adding word-level gates. Note that some gating mechanisms have been used in RNNs [7, 10]. The work in [15] explored contextual word attentions in different tasks. Different from these studies, our word-level gates are domain-specific and help further differentiate important and non-important words in different domains.

It is common that some domains have rich user reviews while other domains may not. To help domains with limited data, we study cross-domain learning, i.e., transfer learning (TL) [22] or multi-task learning (MTL) [36] for this task. There are generally two lines of studies for TL. The first is supervised domain adaptation, which assumes enough labeled data from source domains and also a little labeled data from a target domain [9]. The second assumes having labeled data from source domains only and some unlabeled data from a target domain [3, 35]. Our study belongs to the first line of work. Typical method in this line is to find a shared feature space which can reduce the divergence between the distributions of the source and target domains [1, 28]. In this work, we adapt CNN model to learn shared feature representations.

With the popularity of deep learning, a great amount of Neural Network (NN) based methods are proposed for TL [6, 11, 12, 34]. A typical framework is to use a shared NN to learn shared features for

both source and target domains [21, 32]. Another approach is to use both a shared NN and domain-specific NNs to derive shared and domain-specific features [18]. A multi-domain relationship learning method is introduced in [37], to uncover the relationship between domains. Inspired by this, we adopt the relationship learning in our gated multi-domain framework to help model the correlation between different domains. Experiments show that the multi-domain relationship learning method indeed helps capture the correlations between different domains and can further boost our model's performance by better leveraging knowledge from correlated domains. We have also visualized the learned domain correlations and find them insightful.

3 MODEL

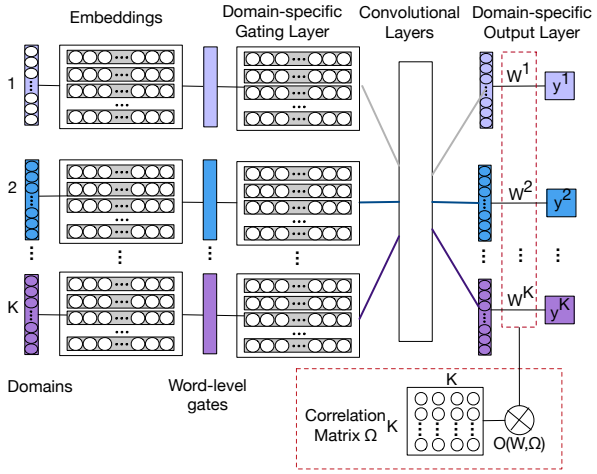

Figure 1: Proposed multi-domain gated CNN model. Note that the embedding and convolutional layers are shared across domains, while the gating and output layers are domain-specific. U and $W^{(\cdot)}$ are shared and domain-specific output layers, respectively. The parameter Ω models domain correlations.

Review helpfulness prediction is defined as a regression task to predict the helpfulness score given a text review [31]. The ground truth of helpfulness is determined using the "a of b approach": a of b users think the review is helpful.

In this work, we consider a *cross-domain review helpfulness prediction task* given labeled reviews from multiple source domains and a target domain. We seek to transfer knowledge from data-rich source domains to a target domain. For a review $\mathbf{X}^k$, our goal is to predict its helpfulness score y^k, where $k \in [0..K]$ is the domain label indicating which domain the data instance is from.

As shown in Fig. 1, Our proposed multi-domain gated CNN has four components: embedding layers, gating layers, convolutional layers, and output layers with relationship learning. Embedding and convolutional layers are shared across domains, while other layers are domain-specific.

3.1 Shared embedding layers

Our word embeddings contain word-level, character-level, and aspect-level representations.

3.1.1 Word and Character Representations. A review $\mathbf{X}$ consists of a sequence of words, i.e., $\mathbf{X} = [x_1, x_2, \ldots, x_m]$. Following the model in [13], for words in a review $\mathbf{X}$, we first lookup their embeddings $(\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_m)$ from an embedding matrix $E \in \mathbb{R}^{|V| \times D}$ where $|V|$ is vocabulary size and D is embedding dimension, and $\mathbf{e}_i \in \mathbb{R}^{D \times 1}$. This word embedding matrix is then fed into a convolutional neural network to obtain an output representation. This is a typical *word embedding* based model.

In many applications, such as text classification [4] and machine reading comprehension [25], it is beneficial to enrich word embeddings with subword information. Inspired by that, we consider to use a character embedding layer to obtain *character embeddings* to enrich word representations. Specifically, the characters of the i-th word x_i are embedded into vectors and then fed into another convolutional neural network to obtain a fixed-sized vector $\texttt{CharEmb}(x_i)$.

3.1.2 Aspect Representations. A recent work in [30] shows that extracting the aspect/topic distribution from the raw textual contents does help the task of review helpfulness prediction. The reason is that many helpful reviews tend to mention certain aspects, like "brand," "functionality," or "price," of a product. Inspired by this, we enrich our word representations by aspect distributions. We adopt the generative model in [30] to learn aspect-word distributions $\Phi \in \mathbb{R}^{|V| \times A}$, where A is aspect size and $|V|$ is the size of vocabulary. Note, aspect representations learned are shared across domains.

A word-aspect representation Φ' is obtained by row-wise normalization of the matrix Φ. Then for each word x_i in input review $\mathbf{X}$, we obtain aspect representation by looking up the matrix Φ' to get $\Phi'_i \in \mathbb{R}^{A \times 1}$.

3.1.3 Putting all three embeddings together. In all, for an input review $\mathbf{X}$, we obtain its representation as:

$$\mathbf{e}_X = [\mathbf{e}'_1, \mathbf{e}'_2, \ldots, \mathbf{e}'_m], \tag{1}$$

$$\mathbf{e}'_i = \mathbf{e}_i \oplus \texttt{CharEmb}(x_i) \oplus \Phi'_i, \quad \forall i \in [1..m], \tag{2}$$

where $\mathbf{e}_i$, $\texttt{CharEmb}(x_i)$, and Φ'_i are word-, character-, and aspect-representations respectively, and $\oplus$ is a stacking operator. Note that m (=100 in this paper) is the sentence length limit. Sentences shorter than m words will be padded with zeros, while those longer than m words will be truncated.

3.2 Domain-specific gating layers

It is intuitive that given a domain, some words play more important roles to the helpfulness of reviews. For example, "warranty" words are more important for "Watches" domain than other domains, and descriptive or semantic words (such as "great battery life" or "versatile function") are more informative than general background words like "phone" in "Cellphone" domain [30]. Hence, we propose to weight the input word embeddings by a multi-domain gating mechanism. Specifically, the input word representations are first transformed with a weighting matrix $\mathbf{V}_g$ and concatenate with a domain-specific embedding $\mathbf{V}_k$ for domain k. The final output is then fed into a fully connected layer to obtain final word-level gates.

More specifically, for each input word x_i, we learn its weight g_i through the gating mechanism. And for input $\mathbf{X} = [x_1, \ldots, x_m]$, we obtain its representation $\mathbf{e'}_X$ as:

$$\mathbf{e}_X = [\mathbf{e}'_1, \mathbf{e}'_2, \ldots, e'_m], \tag{3}$$

$$g_i = \texttt{FC}(\mathbf{V}_g^\top \mathbf{e}'_i \oplus \mathbf{V}_k), \quad \forall i \in [1..m], \tag{4}$$

$$\mathbf{e'}_X = [g_1\mathbf{e}'_1, g_2\mathbf{e}'_2, \ldots, g_m\mathbf{e}'_m], \tag{5}$$

where $\mathbf{V}_g$ is a transform matrix, $\mathbf{V}_k$ is domain-specific weights, and FC represents fully connected layers with sigmoid activations. The same weight g_i is applied to all dimensions of the embedding $\mathbf{e}'_i$ for word x_i.

3.3 Shared convolutional layers

Next, we stack a 2-D convolutional layer and a 2-D max-pooling layer on the matrix $\mathbf{e}'_X$ to obtain the hidden representation h_X. Multiple filters are used, where for each, we obtain a hidden representation h_f. All these representations are concatenated to form the final representation h_X.

$$h_f = \texttt{CNN}\Big(\mathbf{e}'_X, \text{filterSize} = \big(f, D, C\big)\Big),$$
$$h_X = h_2 \oplus h_3 \oplus h_4 \oplus h_5. \tag{6}$$

where $f \in \{2, 3, 4, 5\}$ is window size, D is embedding dimension, C is channel size, and $\texttt{CNN}(\cdot)$ represents a convolution layer followed by a max-pooling layer [2]. We refer our base model as Embedding-Gated CNN (EG-CNN).

3.4 Domain-specific output layers

If all the domains are homogeneous, we can build an unified model for our task to optimize the following objective:

$$l = \sum_k \sum_{\mathbf{X}^k \in \mathcal{D}^k} \left(\mathbf{U}^\top \texttt{EG-CNN}\left(\mathbf{X}^k\right) - y^k\right)^2 + l_{reg}, \tag{7}$$

where $\mathbf{U}$ is the output layer weights, $\mathbf{X}^k$ is a review in the set $\mathcal{D}^k$ containing all reviews from domain k, y^k is the corresponding label, l_{reg} is a regularization term.

However, *domains are not homogeneous.* The formulation in Eqn. (7) is limited because it does not take domain differences into consideration. To utilize cross-domain knowledge, we convert the method above to a multi-domain setting where besides the shared output layer $\mathbf{U} \in \mathbb{R}^{P\times 1}$, we add a domain-specific output layer $\mathbf{W}_k$ for each domain k. Assuming $\mathbf{W}_k \in \mathbb{R}^{P\times 1}$, where P is output layer size, we have $\mathbf{W} = [\mathbf{W}_1, \mathbf{W}_2, \ldots, \mathbf{W}_K]$. Unlike a unified model to learn universal feature representation, our *cross-domain relationship learning* approach has two output layers $\mathbf{U}$ and $\mathbf{W}$ to model domain *commonalities* and *differences* respectively.

Following matrix-variate distribution setting in [37], we assume:

$$\mathbf{W} = q(W) \prod_{i=1}^{K} \mathcal{N}\left(W_i \mid \mathbf{0}_P, \epsilon_i^2 \mathbf{I}_P\right), \tag{8}$$

$$q(W) = \mathcal{MN}_{P\times K}\Big(W \mid \mathbf{0}_{P\times K}, \mathbf{I}_P \times \Omega\Big), \tag{9}$$

where $\mathcal{N}(\cdot \mid A, B)$ and $\mathcal{MN}(\cdot \mid A, B)$ are normal distribution and matrix-variate normal distribution with A as mean and B as variance/covariance matrix respectively, $\mathbf{0}$. is a zero vector/matrix, $\mathbf{I}_P$ is identity matrix. The covariance matrix $\Omega \in \mathbb{R}^{K\times K}$ models domain correlations, where $\Omega_{i,j}$ is the correlation between domains i and j.

As shown in [37], the above formulas are resolved to optimize the trace of the matrix product $\text{tr}(\mathbf{W}\Omega^{-1}\mathbf{W}^\top)$. Hence, our objective can be defined as follows:

$$\begin{aligned} l \quad = \quad & \sum_k \sum_{X^k \in \mathcal{D}^k} ((\mathbf{U} + \mathbf{W_k})^\top \texttt{EG-CNN}(\mathbf{X}^k) - y^k)^2 + \\ & \lambda_1 \text{tr}(\mathbf{W}\Omega^{-1}\mathbf{W}^\top) + \lambda_2 l_{reg}, \\ \text{s.t.} \quad & \Omega \succeq 0, \quad \text{tr}(\Omega) = 1. \end{aligned} \tag{10}$$

where $\text{tr}(\cdot)$ gets the trace of a matrix, l_{reg} is a regularization term, λ_1 and λ_2 are weight coefficients. To minimize the trace term $\text{tr}(\mathbf{W}\Omega^{-1}\mathbf{W}^\top)$, when domain i and domain j are close, i.e., $\mathbf{W}_i$ is close to $\mathbf{W}_j$, the model tends to learn a large $\Omega_{i,j}$. And when domain i and j are distant, the model tends to learn a small $\Omega_{i,j}$.

3.5 The final model

In all, our final model has four types of layers: embedding layers, gating layers, convolutional layers, and output layers. In the output layers, we consider learning domain correlations in the multi-domain setting. Note that, if we set the correlation matrix Ω as an identity matrix (no domain correlation) and $\mathbf{U} = \mathbf{0}$ (no shared output layer), the multi-domain setting is degenerated to a fully-shared setting in [21]. The limitation of the fully-shared setting is that it ignores domain relationships. However, in practice, we may think that reviews from some domains (e.g., the domain "Electronics") are helpful to the task on other domains (e.g., "home" and "cellphones") but not all. With our model, we seek to automatically capture such domain relationships and use that information to help boost model performance.

4 INFERENCE

Let $\boldsymbol{\theta}$ be the model parameters in our model. It is not easy to optimize the objective function in Eqn. (10) with respect to Ω, $\mathbf{W}$, $\mathbf{U}$, and $\boldsymbol{\theta}$. Alternatively, we use a stochastic alternating method [37] to first optimize $\boldsymbol{\theta}$, $\mathbf{W}$, and $\mathbf{U}$ through fixing Ω, and then optimize Ω by fixing $\boldsymbol{\theta}$, $\mathbf{W}$, and $\mathbf{U}$. The procedure is repeated within a given iteration or until the convergence criterion is met.

Optimizing $\mathbf{W}$, $\mathbf{U}$ *and* $\boldsymbol{\theta}$. While Ω is fixed, the objective function is convex. We can use gradient descent method to optimize $\mathbf{W}$, $\mathbf{U}$, and $\boldsymbol{\theta}$ jointly. The gradients can be computed by back propagation method with details in [24].

Optimizing Ω. With the fixed $\mathbf{W}$, $\mathbf{U}$, and $\boldsymbol{\theta}$, our objective is to optimize $\mathbf{min_\Omega\ tr(W\Omega^{-1}W^\top)}$ with regard to $\Omega \succeq \mathbf{0}$ and $\mathbf{tr(\Omega) = 1}$.

According to [37], the convex problem above has a closed-form solution: $\Omega = \frac{(\mathbf{W}^\top\mathbf{W})^{\frac{1}{2}}}{\text{tr}\left((\mathbf{W}^\top\mathbf{W})^{\frac{1}{2}}\right)}$. If $\mathbf{W_i}$ and $\mathbf{W_j}$ are close, $\mathbf{\Omega_{i,j}}$ will be be large. $\mathbf{W^\top W}$ is a symmetric matrix, whose square root can be computed by singular-value decomposition (SVD).

[2] Our gated TL framework can work with any sentence representation model, where CNN layer here is chosen as an example to prove the concept for the task.

5 EXPERIMENTS

We use reviews from 5 different categories/domains from the public Amazon Review Dataset [20] in the experiments. The 5 categories are: watches, Phones, Outdoor, Home, and Electronics, each with 9k, 18k, 73k, 219k, 354k data instances respectively. The 5 categories are chosen in accordance with the practices of previous work on this topic [6, 30, 31].

In our model, we initialize the lookup table $\mathbf{E}$ with pre-train word embeddings from *GloVe* [23] by setting $\boldsymbol{D = 100}$. For aspect representation, we adopt the settings from [30] to set the aspect size to 100. For the convolutional layer, the activation function is ReLU, the channel size is set to 128. The output layer size of $\mathbf{U}$ and $\mathbf{W}_{\boldsymbol{k}}$ are 128, i.e., $\boldsymbol{P = 128}$. We use data from five domains, hence $\boldsymbol{K = 5}$. AdaGrad is used with an initial learning rate of 0.08.

Following the previous work on helpfulness prediction, all experiment results are evaluated in the *Pearson correlation coefficient* between the predicted helpfulness score and the ground truth score. The ground truth scores are computed by "a of b approach", indicating the percentage of consumers thinking a review as useful.

5.1 EG-CNN vs. the state of the art and vanilla CNNs without gating

We first compare EG-CNN, i.e., our full base model with rich word representations and domain-specific gates, against those based on traditional linguistic features. Following [31], five baselines use handcrafted features "STR", "UGR", "LIWC", "INQ" and aspect-based features "ASP" [30]", respectively, are established. We further consider two fusional baselines with ensemble linguistic features: Fusion_1 with "STR", "UGR", "LIWC", and "INQ" features [31] and Fusion_2 with additional "ASP" features [30]. Different vanilla CNN-based models without gating are also compared to examine the effectiveness of different embeddings and domain-specific gates: CNN - the vanilla CNN model in [13], $\text{CNN}_{\boldsymbol{c}}$ - the vanilla CNN model with additional character-based representation used in [6].

Table 1: Performance of EG-CNN variants and linguistic feature baselines in Pearson correlation coefficient. † and ‡ mean the method outperforms the best baseline with $\boldsymbol{p < 0.05}$ and $\boldsymbol{p < 0.1}$ by the Student's paired t-test in terms of prediction errors respectively.

		Watches	Phones	Outdoor	Home	Elec.
Baselines	STR	0.276	0.349	0.277	0.222	0.338
	UGR	0.425	0.466	0.412	0.309	0.355
	LIWC	0.378	0.464	0.382	0.331	0.400
	INQ.	0.403	0.506	0.419	0.366	0.405
	ASP	0.406	0.437	0.385	0.283	0.406
	Fusion_1	0.488	0.539	0.497	0.432	0.484
	Fusion_2	0.493	0.550	0.501	0.436	0.491
CNNs without gating	CNN	0.480	0.562	0.501	0.459	0.524
	$\text{CNN}_{\boldsymbol{c}}$	0.495	0.566	0.511	0.464	0.521
Our method	EG-CNN	$\mathbf{0.515}^\dagger$	$\mathbf{0.585}^\dagger$	$\mathbf{0.555}^\dagger$	$\mathbf{0.541}^\dagger$	$\mathbf{0.544}^\ddagger$

Table 1 shows several interesting observations that validate our motives behind this work. First, even the vanilla CNN outperforms the baselines, indicating the expressive superiority of NN-extracted features over handcrafted features. Second, increasing the level of embedding yields better performance as vanilla CNN is outperformed by $\text{CNN}_{\boldsymbol{c}}$. In all cases, EG-CNN outperforms all the CNN variants, which shows the importance of adding aspect-based representations and the gating mechanism of our model. Last, EG-CNN consistently outperforms all the baselines. This further shows the advantage of our base model, i.e., EG-CNN, for the task.

5.2 Our full model with domain relationships

To evaluate the effectiveness of our domain relationship learning, we compare our proposed full model against the following baselines:

- Source-only (Src-only): EG-CNN model that does not consider target data. We use the largest domain 'Elec.' as source.
- Target-only (Tgt-only): EG-CNN model that does not consider source data, it is equivalent to train our model on each domain individually by setting $\mathbf{W = 0}$.
- Fully-Shared transfer learning model (FS): a variant of our full model by setting $\mathbf{U = 0}$, which is identical to the fully-shared TL model in [21] except that our base model is EG-CNN with rich word representations;
- Transfer Learning with Adversarial loss (TL_{adv}): a recently proposed TL model for the task with adversarial loss [6], which is extended from [18]. For fair comparison, the base model used in TL_{adv} is also replaced with EG-CNN.
- Our full model (Ours): our final model with both $\mathbf{U}$ and $\mathbf{W}$ in a domain relationship learning setting.

Table 2: Comparisons between our model and TL models

		Watches	Phones	Outdoor	Home	Elec.
Baselines	Src-only	0.481	0.502	0.501	0.445	0.544
	Tgt-only	0.515	0.585	0.555	0.541	0.544
	FS	0.522	0.580	0.551	0.518	0.534
	TL_{adv}	0.525	0.588	0.556	0.541	0.545
	Ours	$\mathbf{0.535}^\dagger$	$\mathbf{0.592}^\ddagger$	$\mathbf{0.561}^\dagger$	**0.544**	**0.548**

According to results in Table 2, Tgt-only outperforms Src-only, which is intuitive as source domains are close to but different from the target domain. On all product domains, our model consistently achieves better results than Src-only, Tgt-only, FS, and $\text{TL}_{\boldsymbol{adv}}$, supporting the effectiveness and benefit of multi-domain relationship learning. The improvement is greater on domains with fewer labeled data, e.g., the "Watches" domain which has the least number of reviews and where our model shows the most improvement.

Interestingly, the FS model performs much worse than the Tgt-only model in the "Home" domain. This might be justified by the potential domain shift, under which the FS model may not perform better than the Tgt-only model. Because some domains are more related while some others are more different, incorporating data from those less related can hardly help, especially when the target domain (such as "Home") has sufficient data for the Tgt-only model to perform well enough.

The domain correlations presented in Figure 2 provides further evidence into this. The "Home" domain is positively correlated with the two smallest domains, "Watches" and "Phones," and negatively correlated with two other data-rich domains, "Outdoor" and "Electronics." When relevant domains have much less data than

uncorrelated domains, the FS model will cause non-ideal transfer of knowledge, just like what we have seen on the "Home" domain. On a separate note, our model is more robust that it outperforms all the baselines, thanks to our model's ability to learn domain correlations and leverage knowledge from the right domains.

5.3 Is more data equal to more knowledge?

We study whether more data equals to more knowledge by varying the amount of source or target data available. A transfer learning setting from the largest domain "Electronics" to a target domain "Phones" is used as a case study.

Table 3: Performances w.r.t. different amounts of target data.

% of Phone Data	25%	50%	75%	100%
# of Reviews	19.7k	39.4k	59.2k	78.9k
Target-only	0.453	0.532	0.564	0.585
Our full model	0.481	0.544	0.575	0.594
Improvement	6.2%	2.3%	2.0%	1.5%

We study how performance changes along with different amounts (1/4, 1/2, 3/4, and 100% of all, data pre-scrambled) of reviews from the target domain used in the case study. The performances of both our full model and the Tgt-only model are presented in Table 3. Our model has the most advantage (6.2%) over Tgt-only model when only 25% of target domain data is used. The more target data involved in training, the smaller the advantage is. When all of the target domain data is used, the advantage shrinks to 1.5%. It suggests that our model helps more when the target domain is more data-deficient. The reason behind is that the task on target domain benefits little from the knowledge transferred from other domain when target domain data itself is enough to train a good model.

5.4 Domain relationships

We lastly examine the *domain correlation* Ω learned by our model. The correlation matrix is a 5×5 matrix where each value indicating the correlation between two domains. As in Figure 2, domain correlation learned is reasonable. For example, domain "Phone" is close to "Home" and "Elec.," but not so close to "Watch" and "Outdoor."

	Watch	Phone	Outdoor	Home	Elec.
Watch	1	-0.096	-0.41	0.128	-0.008
Phone	-0.096	1	-0.089	0.166	0.206
Outdoor	-0.41	-0.089	1	-0.2	-0.014
Home	0.128	0.166	-0.2	1	-0.279
Elec.	-0.008	0.206	-0.014	-0.279	1

Figure 2: An illustration on domain correlation. A redder cell represents a closer domain relationship between the two domains.

5.5 Interpretability of embedding gates

To examine the word-level gates in our proposed model, we visualize the gate weights learned in Figure 3. We randomly choose one sentence from the review text from the 'Watch' domain and plot a gray-scale heat map according to the gate weights learned for the words. The weights, ranging from 0 (unimportant) to 1 (important), are placed under each word. The redder a cell is, the closer a word's weight is to 1.

i	be	really	disappoint	in	this	product	i
0.2517	0.2405	0.4392	0.5086	0.4541	0.2902	0.3993	0.2517
have	a	watch	that	i	could	not	get
0.4271	0.3001	0.3395	0.336	0.2517	0.4097	0.3348	0.4114
the	pin	all	the	way	back	in	purchase
0.3385	0.3949	0.3814	0.3385	0.4131	0.4975	0.4541	0.4106
this	hope	to	resolve	the	problem	the	pin
0.2902	0.5286	0.3529	0.6678	0.3385	0.5587	0.3385	0.3949
bit	bent	and	could	not	handle	the	task
0.5564	0.5617	0.3673	0.4097	0.3348	0.5445	0.3385	0.5777

Figure 3: An visualization of word-level gate weights, ranging from 0 (unimportant) to 1 (important) from a review sample in the 'Watch' domain. The redder a cell is, the closer a word's weight is to 1.

The example in Figure 3 is very interpretable. Stop words, e.g., "i", "be"[3], and "the", and general background words, such as "product" and "watch" in the "Watches" domain, have small weights, whereas sentiment words and adjectives are assigned with large weights, such as "disappoint," "careful," and "error." In summary, we find that the word-level gate weights learned are helpful for improving model performance and provide insightful word-level interpretations for the prediction.

Furthermore, we visualize the top important and non-important words indicated by the word-level gates learned by our model in all the five domains in Table 4. First, important words and non-important words are easily distinguishable. For example in the "Watch" domain, important words include words related to opinions like "angry" and "disappointment," or aspects like "warranty." And non-important words contain stop words like "i," "be," and some words that do not carry specific meanings like "le" and "de." Similarly in other domains, we find the top important words are far more meaningful than the unimportant words.

Table 4: Top important/unimportant words in five domains.

Domain	Top Important Words
Watch	cut-out,flimsier,unsuccesfully,angry,warranty,disappointment
Phone	unplayable,retransmit,equipped,trouble-free,screen,well-protected
Outdoor	bizzare,wired,niggles,slumberland,stuggle,double-a,right-angle
Home	unsuccesfully,bizzare,button-down,stone-age,creasing,wierd,home
Elec.	units,superiores,unsuccesfully,know-nothing,exterior,checkable
Domain	**Top Unimportant Words**
Watch	le,de,como,i,bonito,be,monte,hoy,ser,in,the,alta,-,um,mil,monte
Phone	para,le,por,la,eso,todo,mudo,como,hace,gran,the,-,musica,casa
Outdoor	ha,hoy,de,le,an,como,the,um,despues,ecuador,6,-,vinal,mas,this,km
Home	mi,por,ser,ha,lo,como,eso,nah,the,quart,doubly,para,alta,estas,fue
Elec.	high,optional,fiber,play,an,this,meter,is,playing,inch,-,mb,the,ha

Second, in general, each domain has its own set of important words. For example,"warranty" in "Watches," and "trouble-free" and "screen" in "Phones." And the top 10 important words in "Watches" domain differ from those in "Phones." Interestingly, some words are important across different domains. For example, "unsuccessfully"

[3] All the words in our model are lemmatized.

is important to "Watches," "Home,", and "Electronics" domains, and "bizzare" is important to "Outdoor" and "Home" domains.

Last but not least, almost all of the top 10 unimportant words are hard to make sense of, e.g. words like "de," "le," and "lo." We find some background words like "fiber," "meter," and "play" are regarded as unimportant for "Electronics". This is also intuitive as the high occurrences of these words in "Electronics" domain makes them less important.

To summarize, the multi-domain word-level gates are interpretable and provide us an insight into the important and unimportant words in different domains. And such word-level gates can help boost model performance.

6 CONCLUSION

In this work, we tackle the review helpfulness prediction in a cross domain transfer learning framework. We built our base model on EG-CNN with word-, character- and aspect-based representations. On top of this model, domain-specific gates and domain relationships were learned to better transfer knowledge across domains. Extensive experiments showed that our model significantly outperforms the state of the art, and the domain relationships and embedding gates learned are insightful.

ABSTRACT

We present collaborative similarity embedding (CSE), a unified framework that exploits comprehensive collaborative relations available in a user-item bipartite graph for representation learning and recommendation. In the proposed framework, we differentiate two types of proximity relations: direct proximity and k-th order neighborhood proximity. While learning from the former exploits direct user-item associations observable from the graph, learning from the latter makes use of implicit associations such as user-user similarities and item-item similarities, which can provide valuable information especially when the graph is sparse. Moreover, for improving scalability and flexibility, we propose a sampling technique that is specifically designed to capture the two types of proximity relations. Extensive experiments on eight benchmark datasets show that CSE yields significantly better performance than state-of-the-art recommendation methods.

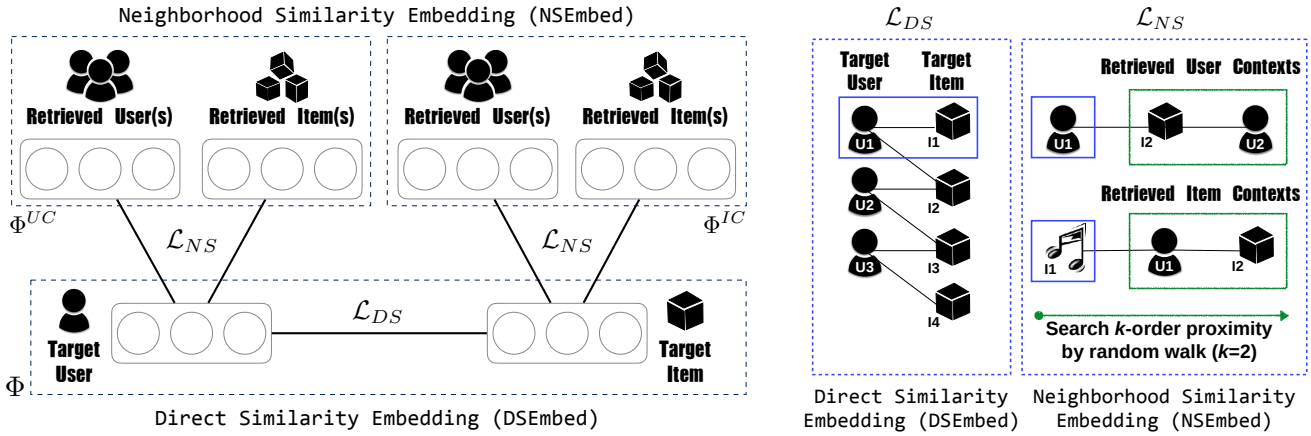
1 INTRODUCTION

Collaborative filtering (CF) is a common yet powerful approach for generating user recommendations that takes the advantage of the collective wisdom from all users [10]. Many CF-based recommendation algorithms have been shown to work well across various domains and been used in many real-world applications [21]. The core idea of model-based CF algorithms is to learn low-dimensional representations of users and items from either explicit user-item associations such as user-item ratings or implicit feedback such as playcounts and dwell time. This can be done by training a rating-based model with matrix completion to learn from observed user-item associations (either explicit or implicit feedback) to predict associations that are unobserved [1, 4, 8, 9, 11–15, 20, 28]. In addition to this rating-based approach, ranking-based methods have been proposed based on optimizing ranking loss; the ranking-based methods [15, 19, 25–27] have been found more suitable for implicit feedback. However, many existing model-based CF algorithms leverage only the user-item associations available in a given user-item bipartite graph. Thus, when the available user-item associations are sparse, these algorithms may not work well.



It has been noted that it is possible to mine from a user-item bipartite graph other types of collaborative relations, such as user-user and item-item similarities, since users and items can be indirectly connected in the graph. By taking random walks on the graph, it also exploits higher-order proximity among users and items. Using item-item similarities in the learning process has been firstly studied by Liang *et al.* [13], who propose to jointly decompose the user-item interaction matrix and the item-item co-occurrence matrix with shared item latent factors. Hsieh *et al.* [8] propose to learn a joint metric space to encode both user preferences and user-user and item-item similarities. A recent work presented by Yu *et al.* [27] shows that jointly modeling user-item, user-user, and item-item relations outperforms competing methods that consider only user-item relations. In [6, 16], the higher-order proximity has been shown useful in graph embedding methods. In general, exploiting additional collaborative relations shows promise in learning better representations of vertexes in an information graph.

We note that these prior arts [6, 8, 13, 27] share the same core idea: using some specific methods to sample auxiliary information from a graph to augment the data for representation learning. However, there is a lack of a unified and efficient model that generalizes the underlying computation and aims at recommendation problems. For example, Liang *et al.* [13] consider only the item-item similarities but no other collaborative relations; Yu *et al.* [27] consider only ranking-based loss functions but not rating-based ones. Higher-order proximity is exploited in [5, 6, 16], which however deal with the general graph embedding problem not the recommendation one. Moreover, the model presented by [8] fails to manage large-scale user-item associations [23].

To address this discrepancy, we present *collaborative similarity embedding* (CSE), a unified representation learning framework for collaborative recommender systems with the aim of modeling

(a) The bottom part depicts the direct similarity embedding module for user-item associations, whereas the upper left (right) part corresponds to modeling user-user (item-item, respectively) similarity with the neighborhood similarity embedding module. An optimization step includes a sampled pair of a user and an item in DSEmbed and multiple high-order relation pairs in NSEmbed.

(b) The left part shows that a target user-item pair (U1-I1) can be directly sampled from the observed edges for DSEmbed; the right part shows that for U1 (or I1), a 2-step random walk is applied to obtain the contexts used in the NSEmbed module.

Figure 1: An overview of the proposed CSE framework

the direct and in-direct edges of user-item interactions in a simple and effective way. CSE involves a *direct similarity* embedding module for modeling user-item associations as well as a *neighborhood similarity* embedding module for modeling user-user and item-item similarities. The former module provides the flexibility to implement various types of modeling techniques for user-item associations, whereas the later module models user-user and item-item relations via k-order neighborhood proximity. To simultaneously manage the two modules, we introduce *triplet embedding* into the proposed framework to ideally model user-user, item-item clustering and user-item relations in a single and joint-learning model, while most prior arts use only one or two embedding mappings in their methods. Moreover, the two sub-modules are fused by a carefully designed sampling technique for scalability and flexibility. The space complexity and time of convergence are both only linear with respect to the number of observed user-item associations. In addition, with the proposed sampling techniques, CSE provides the flexibility to shape different relation distributions in its optimization.

Extensive experiments were conducted on eight recommendation datasets. We compare the performance of CSE with classic methods such as matrix factorization (MF) and Bayesian personalized ranking (BPR) [19], recent methods that incorporate user-user and/or item-item relations [8, 13, 27], as well as several general graph embedding methods [5, 16]. The evaluation shows that CSE outperforms the competing methods for seven out of the eight datasets. Our framework advances the state-of-the-art recommendation algorithms along the following four dimensions.

(1) The CSE serves as a generalized framework that models comprehensive pairwise relations among users and items with a unified function in a simple and effective manner.
(2) The proposed sampling technique enables the suitability of CSE for large-scale user-item recommendations.
(3) We report extensive experiments over eight recommendation datasets covering different user-item interaction types, levels of data sparsity, and data sizes, demonstrating the robustness, efficiency, and effectiveness of our framework.
(4) For reproducibility, we share the source code of CSE online at a GitHub repo,[1] by which the learning process can be done within an hour for each dataset performed in this work.

2 PROPOSED CSE FRAMEWORK

Problem Formulation. A recommender system provides a list of ranked items to users based on their historical interactions with items. Let U and I denote the sets of users and items, respectively. User-item associations can be presented as a bipartite graph $G = (V, E)$, where $V = \{v_1, \ldots, v_{|V|}\} = U \cup I$, and E represents the set of observed user-item associations. Note that for explicit rating data, the weights of the user-item preference edges can be positive real numbers, whereas for implicit interactions, the bipartite graph becomes a binary graph. The goal of the CSE framework is to obtain an embedding matrix $\Phi \in \mathbb{R}^{|V| \times d}$ that maps each user and item into a d-dimensional embedding vector for item recommendation; that is, with the learned embedding matrix Φ, for a user $v_i \in U$, the proposed framework generates the top-N recommended items via computing the similarity between the embedding vector of the

[1] https://github.com/cnclabs/proNet-core

user, i.e., Φ_{v_i}, and those of all items, i.e., Φ_{v_j} for all $v_j \in I$, where Φ_{v_x} denotes the row vector for vertex $v_x \in V$ from matrix Φ.

Framework Overview. Figure 1 provides an overview of CSE. In the figure, CSE consists of two similarity embedding modules: a direct similarity embedding (DSEmbed) module to model user-item associations, and a neighborhood similarity embedding (NSEmbed) module to model user-user and item-item similarities. The DSEmbed model provides the flexibility to implement two mainstream types of modeling techniques: rating-based and ranking-based models to preserve direct proximity of user-item associations; NSEmbed, in turn, models user-user and item-item relations using the contexts within a k-step random walk, as shown in Fig. 1(b), to preserve k-order neighborhood proximity between users and items. To minimize the sum of the losses from DSEmbed and NSEmbed modules, which are denoted as $\mathcal{L}_{DS}$ and $\mathcal{L}_{NS}$ respectively, the objective function of the proposed framework is designed as

$$\mathcal{L} = \mathcal{L}_{DS} + \lambda \mathcal{L}_{NS},$$

where λ controls the balance between the two losses. The rationale behind this design is that $\mathcal{L}_{DS}$ controls the optimization of the embedding vectors towards preserving direct user-item associations, and $\mathcal{L}_{NS}$ encourages users/items sharing similar neighbors to be close to one another in the learned embedding space.

2.1 Direct Similarity Embedding (DSEmbed) Module

Definition 2.1. **(Direct Proximity)** Given a bipartite graph $G = (V, E)$, the *direct proximity* between a user $v_i \in U$ and an item $v_j \in I$ is represented by the presence of an edge $(v_i, v_j) \in E$ between these two vertices. If there is no edge between user v_i and item v_j, then their direct proximity is defined as 0.

The DSEmbed module is designed to model the direct proximity of the user-item associations defined in Definition 2.1. For a rating-based approach, the objective is to find the embedding matrix Φ that maximizes the log-likelihood function of observed user-item pairs:

$$\begin{aligned} &\arg\max_{\Phi} \sum_{(v_i, v_j) \in E} \log p(v_i, v_j|\Phi) \\ &= \arg\min_{\Phi} \sum_{(v_i, v_j) \in E} -\log p(v_i, v_j|\Phi). \end{aligned} \tag{1}$$

In contrast, a ranking-based approach cares more about whether we can predict stronger association between a 'positive' user-item pair $(v_i, v_j) \in E$ than a 'negative' user-item pair $(v_i, v_k) \in \bar{E}$ [19], where $\bar{E}$ denotes the set of edges for all the unobserved user-item associations. This can be approached by maximizing the log-likelihood function of observed user-item pairs over unobserved user-item pairs for each user:

$$\begin{aligned} &\arg\max_{\Phi} \sum_{(v_i, v_j, v_k)} \log p(v_j >_i v_k|\Phi) \\ &= \arg\min_{\Phi} \sum_{(v_i, v_j, v_k)} -\log p(v_j >_i v_k|\Phi), \end{aligned} \tag{2}$$

where $v_i \in U$ and $v_j, v_k \in I$, and $>_i$ indicates that user v_i prefers item v_j over item v_k. In the above two equations, $p(v_i, v_j|\Phi)$ and $p(v_j >_i v_k|\Phi)$ is calculated by

$$p(v_i, v_j|\Phi) = \sigma\left(\Phi_{v_i} \cdot \Phi_{v_j}\right),$$

and

$$p(v_j >_i v_k|\Phi) = \sigma\left(\Phi_{v_i} \cdot \Phi_{v_j} - \Phi_{v_i} \cdot \Phi_{v_k}\right),$$

respectively, and $\sigma(\cdot)$ denotes the sigmoid function.

2.2 Neighborhood Similarity Embedding (NSEmbed) Module

Definition 2.2. **(k-Order Neighborhood Proximity)** Given a bipartite graph $G = (V, E)$ representing the observed user-item associations of the set of users and items in $V = U \cup I$, the *k-order neighborhood proximity* of a pair of users (or items) is defined as the similarity between their neighborhood network structures retrieved by k-step random walks. Mathematically speaking, given the k-order neighborhood structures of a pair of users (or items), $v_i, v_j \in U$ (or $v_i, v_j \in I$, respectively), which are denoted as two sets of neighbor nodes N_{v_i} and N_{v_j}, with $|N_{v_i}| = |N_{v_j}| = k$, the k-order neighborhood proximity between v_i and v_j is decided by the similarity between these two sets N_{v_i} and N_{v_j}. If there are no shared neighbors between v_i and v_j, the neighborhood proximity between them is 0.

The NSEmbed module is designed to model k-order neighborhood proximity for capturing user-user and item-item similarities. Given a set of neighborhood relations for users (or items) $S_U = \{(v_i, v_j)|\ \forall v_i \in U, v_j \in N_{v_i}\}$ (or $S_I = \{(v_i, v_j)|\ \forall v_i \in I, v_j \in N_{v_i}\}$, respectively), the NSEmbed module seeks a set of embedding matrices $\Phi, \Phi^{UC}, \Phi^{IC} \in \mathbb{R}^{|V| \times d}$ that maximizes the likelihood of all pairs in S_U (or S_I, respectively), where Φ is a *vertex mapping matrix* akin to that used in the DSEmbed module, and Φ^{UC} and Φ^{IC} are two *context mapping matrices*. Note that each vertex (representing a user or an item) plays two roles for modeling the neighborhood proximity: 1) the vertex itself and 2) the context of other vertices [2, 6, 16, 22, 29]. With this design, the embedding vectors of vertices that share similar contexts are thus closely located in the learned vector space. Therefore, the maximization of the likelihood function can be defined as

$$\begin{aligned} \arg\max_{\Phi, \Phi^{UC}, \Phi^{IC}} \quad & \textstyle\prod_{(v_i, v_j) \in S_U} p(v_j|v_i; \Phi; \Phi^{UC}) \\ & + \textstyle\prod_{(v_i, v_j) \in S_I} p(v_j|v_i; \Phi; \Phi^{IC}). \end{aligned}$$

Similar to Eqs. (1) and (2), the above objective function becomes

$$\begin{aligned} \arg\min_{\Phi, \Phi^{UC}, \Phi^{IC}} \quad & \textstyle\sum_{(v_i, v_j) \in S_U} -\log p(v_j|v_i; \Phi; \Phi^{UC}) \\ & + \textstyle\sum_{(v_i, v_j) \in S_I} -\log p(v_j|v_i; \Phi; \Phi^{IC}), \end{aligned} \tag{3}$$

where

$$p(v_j|v_i; \Theta) = \begin{cases} \sigma\left(\Phi_{v_i} \cdot \Phi^{UC}_{v_j}\right) & \text{if } v_i \in U, \\ \sigma\left(\Phi_{v_i} \cdot \Phi^{IC}_{v_j}\right) & \text{if } v_i \in I. \end{cases} \tag{4}$$

It is worth mentioning that most prior arts use only one or two embedding mappings; while the former approach fails to consider high-order neighbors (e.g., [3, 7, 12, 22, 24]), the later one cannot model user-user, item-item, and user-item relations simultaneously (e.g., [1, 2, 6, 16, 17, 29]). Our designed triplet embedding solution

(i.e., $\Theta = \{\Phi, \Phi^{UC}, \Phi^{UC}\}$) can ideally model user-user, item-item clustering and user-item relations in a joint-learning model.

2.3 Sampling-based Expectation Loss

In order to minimize the above objective functions, we need to go through all the pairs in E for Eq. (1), E and $\bar{E}$ for Eq. (2), and S_U and S_I for Eq. (3), to compute all the pairwise losses. This is not feasible in real-world recommendation scenarios as the complexity is $O(|V| \times |V|)$. To address this, we propose a sampling technique to work in tandem with the above two modules to enhance CSE's scalability and flexibility in learning user and item representations from large-scale datasets.

In CSE, the DSEmbed and NSEmbed modules are fused with the shareable data sampling technique described below. For each parameter update, we first sample an observed user-item pair $(v_i, v_j) \in E$, as shown as U1 and I1 in Fig. 1(b), where $v_i \in U$ and $v_j \in I$. Then, we search for the k-order neighborhood structures of user v_i and item v_j via the k-step random walks. To improve computational efficiency, we use negative sampling [22]. Consequently, for a rating-based approach (see Eq. (1)), the expected sampled loss of the DSEmbed module can be re-written as

$$\mathcal{L}_{DS} = \mathbb{E}_{(v_i,v_j)\sim E}\left[-\log p(v_i, v_j|\Phi)\right] + \sum_{M} \mathbb{E}_{(v_k,v_h)\sim \bar{E}}\left[\log p(v_k, v_h|\Phi)\right], \quad (5)$$

where M denotes the number of negative pairs adopted. For a ranking-based approach (see Eq. (2)), the DSEmbed module can be re-written as

$$\mathcal{L}_{DS} = \mathbb{E}_{(v_i,v_k)\sim \bar{E}}\left[\mathbb{E}_{(v_i,v_j)\sim E}\left[-\log p(v_j >_i v_k|\Phi)\right] | v_i\right]. \quad (6)$$

Note that for the ranking-based approach, there is no need to explicitly include M negative sample pairs as this kind of method naturally involves negative pairs from $\bar{E}$. Similarly, given a user or an item vertex v_i, its k-order neighborhood structure N_{v_i} is composed of nodes in the k-step random walks surfing on G, $\mathcal{W}_{v_i} = (\mathcal{W}^0_{v_i}, \mathcal{W}^1_{v_i}, \mathcal{W}^2_{v_i}, \ldots, \mathcal{W}^k_{v_i})$, where the vertex for $\mathcal{W}^j_{v_i}$ is randomly chosen from the neighbors of the vertex v given $\mathcal{W}^{j-1}_{v_i} = v$ and $\mathcal{W}^0_{v_i} = v_i$. The expected sampled loss of the NSEmbed module can be re-written as

$$\begin{aligned}\mathcal{L}_{NS} = {} & \mathbb{E}_{(v_i,v_j)\sim S_U}\left[-\log p(v_j|v_i;\Phi;\Phi^{UC})\right] + \sum_{M}\mathbb{E}_{(v_i,v_j)\sim \bar{E}}\left[\log p(v_j|v_i;\Phi;\Phi^{UC})\right] + \\ & \mathbb{E}_{(v_i,v_j)\sim S_I}\left[-\log p(v_j|v_i;\Phi;\Phi^{IC})\right] + \sum_{M}\mathbb{E}_{(v_i,v_j)\sim \bar{E}}\left[\log p(v_j|v_i;\Phi;\Phi^{IC})\right]. \end{aligned} \quad (7)$$

Since $\mathcal{L}_{DS}$ and $\mathcal{L}_{NS}$ are described in a sampling-based expectation form, CSE provides the flexibility for accommodating arbitrary distributions of positive and negative data. In the following experiments, we produce the positive data according to primitive edges distribution of given user-item graph. As to negative sampling, we propose to directly sample the negative data from whole data collection instead of unobserved data collection.

Dataset	#Users	#Items	#Edges	Edge type

Table 1: Statistics of the datasets considered in our experiments.

2.4 Optimization

In the optimization stage, we use asynchronous stochastic gradient descent (ASGD) [18] to efficiently update the parameters in parallel. The model parameters are composed of the three embedding matrices $\Theta = \{\Phi, \Phi^{UC}, \Phi^{IC}\}$, each having the size $O(|V|d)$. They are updated with learning rate α according to

$$\Theta \leftarrow \Theta - \alpha\left(\frac{\partial \mathcal{L}_{DS}}{\partial \Theta} + \lambda\left(\frac{\partial \mathcal{L}_{NS}}{\partial \Theta}\right) - \lambda_V \|\Phi\|\right), \quad (8)$$

where λ_V is a hyper-parameter for reducing the risk of overfitting.

3 EXPERIMENT

3.1 Settings

3.1.1 Datasets and Preprocessing. To examine the capability and scalability of the CSE framework, we conducted experiments on eight publicly available real-world datasets that vary in terms of domain, size, and density, as shown in Table 1. For each of the datasets, we discarded the users who have less than ten associated interactions with items. In addition, we converted each data into implicit feedback:[2] 1) for 5-star rating datasets, we transformed ratings higher than or equal to 3.5 to 1 and the rest to 0; 2) for count-based datasets, we transformed counts higher than or equal to 3 to 1 and the rest to 0; 3) for the CiteULike dataset, no transformation was conducted as it is already a binary preference dataset.

3.1.2 Baseline Algorithms. We compare the performance of our model with the following eight baseline methods: 1) POP, a naive popularity model that ranks the items by their degrees, 2) DeepWalk [16], a classic algorithm of network embedding, 3) WALS [9], a weighted rating-based factorization model, 4) ranking-based factorization models: BPR [19], WARP [25], and K-OS [26], 5) BiNE [5], a network embedding model specialized for bipartite networks, and 6) recent advanced models considering user-user/item-item relations: coFactor [13], CML [8] and WalkRanker [27]. Note that except for POP, the embedding vectors for users and items learned by these competitors as well as by our method can be directly used for item recommendations. Additionally, while CML adopts Euclidean distance as the scoring function, all other methods including ours utilize the dot product to calculate the score of a pair of user-item embedding vectors. The experiments for WALS and

[2]Note that in real-world scenarios, most feedback is not explicit but implicit [19]; we here converted the datasets into implicit feedback as most of the recent developed methods focus on dealing with such type of data. However, our method is not limited to binary preference since the presented sampling technique has the flexibility to manage arbitrary weighted edge distributions and rating estimation is also allowed in the proposed RATE-CSE.

Table 2: Recommendation performance. The † symbol indicates the best performing method among all the baseline methods; '*' and '%Improv.' denote statistical significance at $p < 0.01$ with a paired t-test and the percentage improvement of the proposed method, respectively, with respect to the best performing baseline.

BPR were conducted using the matrix factorization library QMF,[3] and those for WARP and K-OS were conducted using LightFM;[4] for coFactor, CML, and WalkRanker, we used the code provided by the respective authors.

3.1.3 Experimental Setup. For all the experiments, the dimension of embedding vectors was fixed to 100; the values of the hyper-parameters for the compared method were decided via implementing a grid search over different settings, and the combination that leads to the best performance was picked.

For our model, the learning rate α was set to 0.1, λ_V was set to 0.025; the hyper-parameter λ was set to 0.05 and 0.1 for rating-based CSE and ranking-based CSE, respectively, and k was set to 2 as the default value. The sensitivity of CSE parameters are additionally reported. For each dataset, the sample time for convergence depends on the number of non-zero user-item interaction edges and is set to $80 \times |E|$. Sensitivity analysis for k and λ and convergence analysis are later provided in the section for convergence analyses.

3.2 Results

3.2.1 Recommendation Performance Comparison. The results for the ten baseline methods along with the proposed method are listed in Table 2, where RATE-CSE and RANK-CSE denote two versions of our method that employ respectively rating-based and ranking-based loss functions for user-item associations. Note that the best results are always indicated by the bold font, and for coFactor and BiNE we report only part of the experimental results on Frappe and CiteULike because of resource limitations.[5] DeepWalk is not suitable for user-item recommendation as it make the users apart from items in the embedding space. In addition, observe that BiNE does not perform well in our experiments; such a result is due to the fact that BiNE is a general network embedding model and thus does not incorporate the regularizer in their objective function, which is however an important factor for the robustness of recommendation performance. Comparing the performance of the other baseline methods, we observe that the performance of WALS, WARP

[5]While the memory usage of coFactor implementation is $O(|V|^2)$, BiNE's requires extensive computational time, e.g., more than 24 hours to learn the embedding for the large dataset, Movielens-Latest.

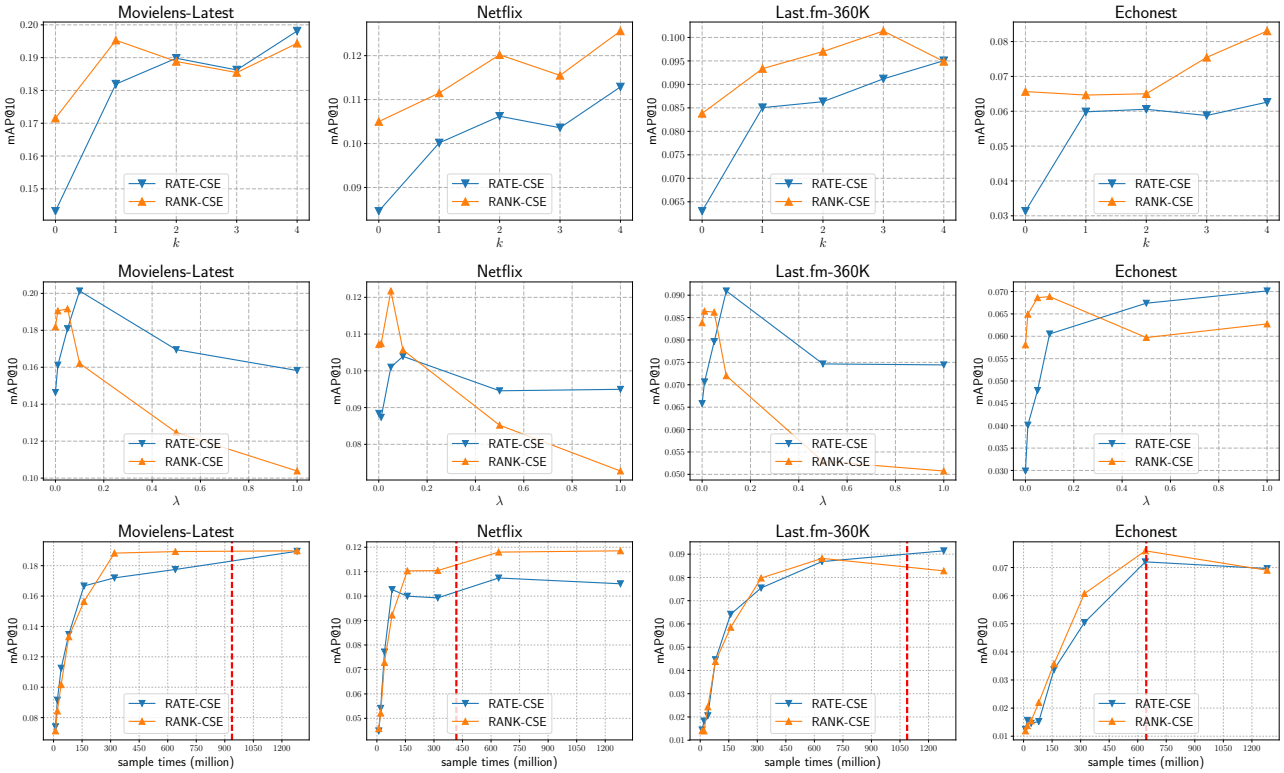

Figure 2: Sensitivity and convergence analyses

and K-OS is very competitive. That is, these methods achieve the top performance among all the baselines on several datasets. The performance of WalkRanker and CML, on the other hand, seems satisfactory only on two rather small datasets.

We observe that our method achieves the best results in terms of both Recall@10 and mAP@10 for most datasets. Moreover, RANK-CSE generally outperforms RATE-CSE in the experiments, reconfirming that using a ranking-based loss is indeed better for datasets with binary implicit feedbacks [19, 25, 26]. Specifically, except for Frappe, RATE-CSE or RANK-CSE achieves significantly much better performance than the best performing baseline methods.

3.2.2 Parameter Sensitivity and Convergence Analyses. Figure 2 shows the sensitivity tests on two hyper-parameters k and λ in the first and second rows, respectively, and those of the convergence analysis based on sample times in the third row.[6] We first observe that increasing the order k of modeling neighborhood proximity between users or items improves the performance in general. The optimal value of k is data dependent and has to be empirically tuned considering the trade-off between accuracy and time/space complexity. In general, a larger k leads to better result, and from our experience, the result would reach a plateau when k is sufficiently large (e.g., when $k > 3$). The second row of Figure 2 shows how the balancing parameter λ affects performance: RANK-CSE obtains better performance with a value around 0.05, while RATE-CSE performs well with a value around 0.1. Finally, we empirically show that the required total sample times for convergence is linear with respect to $|E|$ as illustrated in the third row, where the vertical dash line indicates the boundary of $|E| \times 80$ as we applied to the previous recommendation experiment. As the training time depends linearly on the sample times, it can be said that both RATE-CSE and RANK-CSE converge with less than a constant multiple of $|E|$ sample times. This demonstrates the nice scalability of CSE.

[6]Note that due to space limits, we report the results for the four largest datasets only.

4 CONCLUSION

We present CSE, a unified representation learning framework that exploits comprehensive collaborative relations available in a user-item bipartite graph for recommender systems. Two types of proximity relations are modeled by the proposed DSEmbed and NSEmbed modules. Moreover, we propose a sampling technique to enhance the scalability and flexibility of the model. Experimental results show that CSE yields superior recommendation performance over a wide aange of datasets with different sizes, densities, and types than many state-of-the-art recommendation methods.

ABSTRACT

In graphs with rich texts, incorporating textual information with structural information would benefit constructing expressive graph embeddings. Among various graph embedding models, random walk (RW)-based is one of the most popular and successful groups. However, it is challenged by two issues when applied on graphs with rich texts: (i) *sampling efficiency*: deriving from the training objective of RW-based models (e.g., DeepWalk and node2vec), we show that RW-based models are likely to generate large amounts of redundant training samples due to three main drawbacks. (ii) *text utilization*: these models have difficulty in dealing with zero-shot scenarios where graph embedding models have to infer graph structures directly from texts. To solve these problems, we propose a novel framework, namely Text-driven Graph Embedding with Pairs Sampling (TGE-PS). TGE-PS uses Pairs Sampling (PS) to improve the sampling strategy of RW, being able to reduce ∼99% training samples while preserving competitive performance. TGE-PS uses Text-driven Graph Embedding (TGE), an inductive graph embedding approach, to generate node embeddings from texts. Since each node contains rich texts, TGE is able to generate high-quality embeddings and provide reasonable predictions on existence of links to unseen nodes. We evaluate TGE-PS on several real-world datasets, and experiment results demonstrate that TGE-PS produces state-of-the-art results on both traditional and zero-shot link prediction tasks.

1 INTRODUCTION

Graph provides a fundamental tool to represent interconnected entities (e.g., articles, diseases) and their attributes (e.g., entity description). Graphs with rich text information are ubiquitous in many fields [18], and there is often a strong dependency between graph structure and text structure in these graphs. Textural information may also expose structural information [56]. Hence, it is promising to better utilize textual information in graphs.

Graph embedding is famous for its efficient representations for entities in graphs [16, 38]. A series of models are proposed to maximize edge reconstruction probability with different proximities [5], e.g., LINE [45], DeepWalk [42] and node2vec [17]. Although these models are widely used in mapping nodes to low-dimensional dense vectors, they are not well designed for graphs with rich text information. To solve this problem, models like DDRW [26], GENE [8], PPNE [25] and Tri-DNR [40] focus on preserving vertex labels. Especially, TADW [53], CANE [47] and Paper2Vec [14] are proposed to utilize textural information with effectiveness in many scenarios.

However, these graph embedding models still need to resolve two issues. The first issue is *sampling efficiency*. The optimization goals of these models can be summarized as maximizing pairwise node similarity, thus the number of training node pairs is critical to training time and can be used as a metric of sampling efficiency. These models usually use edges as training node pairs directly like LINE, or sample training sequences using random walk (RW) and extract node pairs within a specific shortest distance like DeepWalk and node2vec. RW generalizes the idea of directly sampling edges and shows better experimental performance under similar settings. However, our theoretical and empirical analyses show that RW samples redundant node pairs which severely lags efficiency.

The second issue is *text utilization*. Text utilization models like TADW and CANE mainly rely on training node embeddings (NE)

and text embeddings (TE) together (denoted as NE+TE). In zero-shot settings, where link existence with previously unseen nodes is to be predicted and the only reliable information is texts attributed to nodes , humans can make inference by assuming textual connections even if he has little prior knowledge about this field. However, NE+TE is incapable of dealing with this scenario due to two drawbacks: (i) it requires both NE and TE to generate high-quality representations, but NE is missing for unseen nodes, and (ii) even if it uses only TE part to predict, empirical results show that it may be no better than simple text matching. This reveals that NE+TE does not utilize text information sufficiently.

In this paper, we propose a novel Text-driven Graph Embedding with Pairs Sampling (TGE-PS) framework. TGE-PS uses Pairs Sampling (PS) to efficiently generate training samples, and uses Text-driven Graph Embedding (TGE) to produce final node representations. We theoretically analyze the redundant sample phenomenon of RW from three perspectives , and propose PS to improve sampling efficiency. PS samples center-neighbor node pairs directly from central node's neighborhood. Our experiment results on 6 datasets show that PS produces competitive or even better results in link prediction task with much fewer training samples (saving ~99% samples) compared with RW. In embedding stage, we propose inductive TGE method. TGE incorporates text information with structure information and encodes character- and word-level embeddings into node embeddings while following graph structure. Since node embeddings are generated from text embedding in TGE, they can be applied to zero-shot scenarios. The comparison between TGE-PS and other strong baseline models shows that TGE-PS produces remarkably good results in traditional and zero-shot link prediction tasks.

2 RELATED WORKS

Recent years have witnessed various graph embedding models with applications in link prediction[2, 27, 30], node classification[21, 44, 46, 54], clustering[3, 12], recommendation [50, 51, 55], knowledge graph [4], etc. These graph embedding models can be categorized into three classes, factorization-based, random walk (RW)-based, and deep learning-based[5, 16]. Factorization-based models focus on the connections among nodes and using matrix factorization (MF) to learn the low-rank representations of nodes [1, 6, 39, 53]. TADW [53] uses MF to decompose the transition matrix with textual information incorporated. RW-based models explore the neighborhood of each node through sampling paths, and thus can maintain local structural information in node embeddings. Among RW-based models, DeepWalk [42] and node2vec [17] are the most representative, and DeepWalk can be regarded as a special case of node2vec. Deep learning-based models mainly use deep representation learning techniques to improve the quality of node embeddings [7, 20, 47, 48].

There are also models that do not belong to these three classes. LINE [45] proposes to train graph embeddings through first-order and second-order proximities and is efficient in large-scale networks. Besides, LINE claims to preserve both local and global network structures. GraphGAN [49] adopts GAN [15] framework to learn the underlying true connectivity distribution implicitly. The generator produces "fake edges" while the discriminator tries to tell generated node pairs from ground truth. It also proposes Graph Softmax to boost its efficiency in training.

Among graph embedding models, RW-based models present robust and remarkable performance on various datasets. The training of RW-based models have two phases, the sampling phase and the optimization phase. Different sampling policies are proposed to generate high-quality node sequences to explore the neighborhoods of certain nodes. Especially, DeepWalk adopts the simplest policy where each node is generated only depending on its predecessor, while node2vec adopts a biased policy to trade off between Breadth-first Sampling (BFS) and Depth-first Sampling (DFS). After obtaining sufficient node sequences, RW-based models use Skip-Gram [33, 35] model to maximize the log-probability of observing a network neighborhood for a node conditioned on its feature representation. However, we concern the sampling strategies of RW-based models have intrinsic drawbacks, which we discuss in Section 3.2.2.

For graphs with rich texts, many models are proposed to incorporate textual information with structural information. TADW [53] incorporates text features under the framework of matrix factorization. CANE [47] uses convolutional neural networks and mutual attention mechanism to learn text embeddings, which are interacted with node embeddings via vector inner product. These models encode structural information and textual information into two separate embedding spaces and generate final node representations from the interactions between these two spaces. Paper2Vec [14] pre-trains node embeddings with text embeddings in Skip-gram model, and then the node embeddings are trained with node2vec. STNE [29] "self-translates" sequences of text embeddings into sequences of node embeddings. All the above models rely on known connections to generate graph embeddings, thus are not applicable to zero-shot scenarios. Although some previous works [13, 22, 52] discuss graph representation learning in zero-shot setting, they do not solve the same problem as we do.

When processing texts in zero-shot scenarios, it is common to encounter out-of-vocabulary words. In NLP field, character-level embeddings have proven success like Neural Machine Translation [9, 23, 28] and Named Entity Recognition [31, 43]. These models are based on a hybrid of character- and word-level embeddings, thus can automatically capture patterns in the sub-word level and present advantages in dealing with unseen words.

3 TEXT-DRIVEN GRAPH EMBEDDING WITH PAIRS SAMPLING FRAMEWORK

In this section, we firstly give definitions of notions, and then introduce PS and TGE separately. We show the architecture of TGE-PS in Fig. 1, with fully-connected and lookup layers omitted.

3.1 Definitions

Let $G = (V, E)$ be the given graph and $f : V \to \mathbb{R}^n$ be the mapping function from the node set to the n-dimensional embedding space. We denote the central and context embeddings of node v_i as $\mathbf{e}_i = f(v_i)$ and $\mathbf{e}'_i = f'(v_i)$, and the trainable parameters as θ. We define the distance $\mathcal{L}(u, v)$ between u and v as the length of the shortest path between them. And we define node v_i's o-neighborhood $\mathcal{N}_i^o$ as a set of nodes within a given distance o from v_i, $\mathcal{N}^o(v_i) = \{v_j \in$

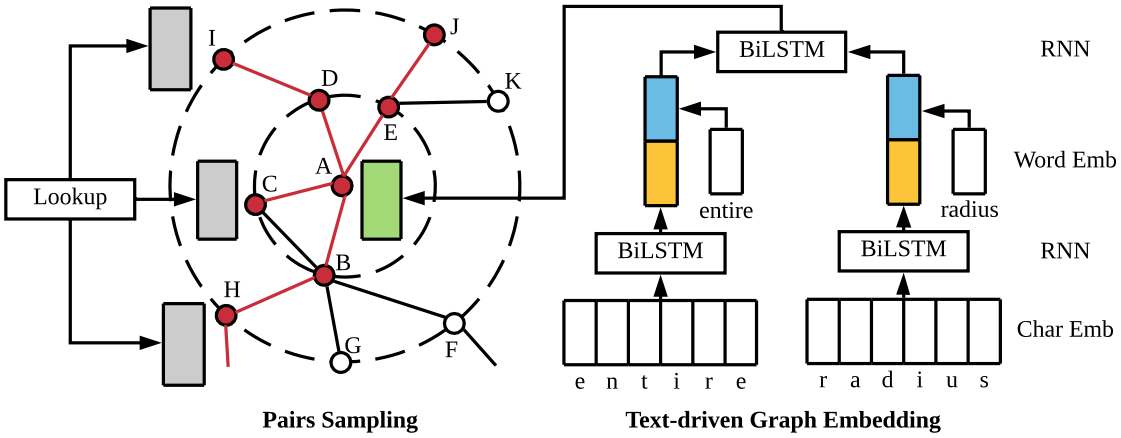

Figure 1: Model architecture of TGE-PS. *Note:* Circles represent nodes and colored boxes represent embeddings. Blue boxes represent word-level embeddings, yellow boxes represent character-based word embeddings, green boxes represent central embeddings and gray boxes represent neighbor embeddings. The sampled nodes and paths are colored as red.

$V|\text{dist}(v_i, v_j) \leq o\}$. For every node v_i, we call one node v_j^o as an o-th order neighbor of v_i when the distance between v_i and v_j is o.

3.2 Pairs Sampling Method

3.2.1 Revisit Random Walk. Since DeepWalk can be regarded as a special case of node2vec [17, 42], our discussion mainly focuses on node2vec. The objective of node2vec is to maximize the log-probability of observing the o-neighborhood $\mathcal{N}_i^o$ of a node v_i as in Eq. (1), and following conditional independence assumption of SkipGram, node2vec changes its objective to maximize the log-probability of all center-neighbor node pairs as in Eq. (2). Following symmetry in feature space assumption, the conditional probability of a node pair is defined as in Eq. (4), where $\tau_{i,j}$ is the abbreviation of the score function $\tau(v_i, v_j)$. It is worth noting that, the score function $\tau_{i,j}$ is asymmetric since the input v_j is conditioned on the other input v_i. With Eq. (2) and Eq. (4), the objective becomes Eq. (3), where Z_i denotes the normalizing term, and each window has size $2k$. Z_i is usually approximated by hierarchical softmax or negative sampling in training. And we mainly focus on the scoring terms $\sum_i \sum_j \tau_{i,j}$.

$$\max_\theta \sum_{v_i \in V} \log Pr(\mathcal{N}_i^o | v_i) \tag{1}$$

$$= \max_\theta \sum_{v_i \in V} \sum_{v_j \in \mathcal{N}_i^k} \log Pr(v_j | v_i) \tag{2}$$

$$= \max_\theta \sum_{v_i \in V} \Big(\sum_{v_j \in \mathcal{N}_i^k} \tau_{i,j} \Big) - |\mathcal{N}_i^k| \log Z_i \tag{3}$$

$$Pr(v_j | v_i) = \frac{\exp(\tau_{i,j})}{\sum_{v_k \in V} \exp(\tau_{i,k})} \tag{4}$$

From the training perspective, node2vec defines the inner product of a central embedding and a context embedding to represent the score function, i.e., $\mathbf{e}_j'^\top \mathbf{e}_i$. The training objective of the scoring terms becomes Eq. (5), where s denote a node sequence, S is the set of all sequences, ω_i^s is the abbreviation of the window function $\omega(v_i, s)$ which denotes the nodes within the window of v_i when v_i appears in s and j' denotes the position of v_j in s. We transform Eq. (5) to Eq. (6) and Eq. (7), where T denotes the sampling time of RW starting from v_i, T_i denotes the amount of sequences where v_i is not the starting point, $T_{j|i}$ denotes the amount of v_j appearing in N_i^k when v_i appears in sequence s. It is worth noting that, each node serves as the starting point in T sequences, and each node also appears in the sequences starting from the other nodes. Thus, there are $T + T_i$ windows centering at v_i to be optimized in the sequences. α_i is the ratio of v_i being more "important" than the other nodes, e.g., bridge nodes are likely to be sampled more frequently, and these nodes have larger α. $\beta_{j|i}$ is the probability of v_j sampled in the neighborhood $\mathcal{N}_i^o$ of v_i. Since there are $T + T_i$ windows centering at v_i, there are $2k(T + T_i)$ center-neighbor node pairs. Thus $2k(T + T_i) = \sum_{v_j \in N_i^k} T_{j|i}$, and $\beta_{\cdot|i}$ reflects the distribution of the neighbor nodes appearing in training samples. Till now, we get the ideal training objective of RW regardless of the sampling strategies. In another word, any RW policies will converge to Eq. (7) when the amount of sampled sequences approaches infinity.

$$\max_\theta \sum_{v_i \in V} \sum_{s \in S} \sum_{v_{j'} \in \omega_i^s} \mathbf{e}_{j'}'^\top \mathbf{e}_i \tag{5}$$

$$= \max_\theta \sum_{v_i \in V} (T + T_i) \Big(\sum_{v_j \in \mathcal{N}_i^k} \frac{T_{j|i}}{2k(T + T_i)} \mathbf{e}_{j'}'^\top \mathbf{e}_i \Big) \tag{6}$$

$$= \max_\theta T \sum_{v_i \in V} (1 + \alpha_i) \Big(\sum_{v_j \in \mathcal{N}_i^k} \beta_{j|i} \mathbf{e}_{j'}'^\top \mathbf{e}_i \Big) \tag{7}$$

3.2.2 Inefficiency of Random Walk. We introduce the sampling strategy of node2vec at first. For every node v_i in the graph, node2vec simulates a random walk with length L. During the sampling process, given previous node t and current node v, the next node x is sampled from the following distribution:

$$Pr(x|v) = \begin{cases} \frac{p_{vx}}{Z} & \text{if } (v, x) \in E \\ 0 & \text{otherwise} \end{cases}$$

where p_{vx} is the unnormalized transition probability from nodes v to x, and Z is the normalizing term. The unnormalized transition probability p_{vx} is set to be $\alpha(t, x; p, q) \cdot w_{vx}$, where $\alpha(t, x; p, q)$ is a function of $\text{dist}(t, x)$, w_{vx} denotes the edge weight of (v, x),

$\text{dist}(t, x)$ denotes the shortest path length between t and x, p and q control the searching strategy of random walks. Without loss of generality, we take $w_{vx} = 1$.

DeepWalk can be regarded as a special case of node2vec when $p = q = 1$. TADW has proved that DeepWalk is reconstructing the transition matrix M. Induced from this conclusion, we view node2vec as reconstructing a biased transition matrix M'. Thus in DeepWalk, $\beta_{j|i}$ in Eq. (7) are actually the non-zero elements of the i-th row of M in DeepWalk, or the i-th row of M' in node2vec. The sampling strategy of node2vec is an exploration of neighborhoods with second-order Markov Property. We analyze the inefficiency of RW in 3 aspects.

Biased Objective. Comparing Eq. (3) and (7), we find node2vec is biased from its log-probability objective since the neighborhoods N_i^k are weighted by different α_i. α_i can be regarded as an "importance ratio", given the previously mentioned bridge nodes example. Hence node2vec introduces a prior distribution implicitly, making its training objective biased from its proposal. If we follow Eq. (1) strictly, α should be all zero and we should only sample each neighborhood T time, which can reduce a lot of training samples.

Interconnected Neighbors. The target of node embedding is to encode structural information in an embedding space. It is a free lunch to assume when optimize a central node v_i, its neighbor nodes $v_j \in N_i^k$ have already been trained and the context embedding $\mathbf{e}'_j$ have already been encoded with the structural information of v_j respectively after training RW for some time, otherwise, the target of node embedding becomes ill-posed and can never be achieved. Thus center-neighbor connections are much more important than neighbor-neighbor connections, and the neighbor-neighbor connections within one neighborhood will become the center-neighbor connections of other neighborhoods. With these observations, we concern RW is less efficient since it results in lots of neighbor-neighbor connections when training central nodes. Therefore, adopting a stronger assumption that alleviates variance of distribution $\beta_{\cdot|i}$ is still possible to produce good results while decreases sampling complexity.

Revisiting Nodes. DeepWalk has the first-order Markov property since it only remembers the current node. node2vec is second-order Markov since it remembers the current node and the previous node. When the window size is larger than the Markov order, RW cannot prevent from revisiting a previously visited neighbor node. The worst case is revisiting the central node itself, because that introduces self-loops and doubles the training time of the central node. In ideal cases, revisiting is equivalent to approximate the transition matrix, where $\beta_{j|i} = M_{i,j}$, $\tau_{i,j} = \beta_{j|i}\mathbf{e}'^{\top}_j \mathbf{e}_i$. Since $\beta_{j|i}$ is a constant determined by the graph structure, the node embeddings $\mathbf{e}_i$ and $\mathbf{e}'_j$ are approximating $\tau_{i,j}/\beta_{j|i}$, where $\tau_{i,j}$ is the unormalized probability. The ideal sample complexity of a neighborhood N_i^k is determined by the minimal sampling probability $\beta_{j*|i}$, by assuming every node in the neighborhood N_i^k gets sufficient training samples. For simplicity, we say the sample complexity of N_i^k is $O(1/\beta_{j*|i})$. And this complexity must be greater than $O(|N_i^k|)$ since $\beta_{j*|i} \le 1/|N_i^k|$. This means any distribution β over N_i^k results in a higher sample complexity than uniform distribution $\beta_{\cdot|i} = 1/|N_i^k|$.

3.2.3 Method Introduction. The intuition of Pairs Sampling (PS) has three points: as for the **biased objective** problem, it is desirable to sample each neighborhood with same time; as for the **interconnected neighbors** problem, it is desirable to sample center-neighbor pairs directly from a neighborhood; as for the **revisiting nodes** problem, it is promising to introduce higher-order Markov property.

To obtain the training node pairs set $\mathcal{P}$, we sample the neighbor nodes in the neighborhood of v_i in the following process:

1. Add all first-order neighbor nodes of v_i into N_i^O.
2. If $O > 1$, for every v_j^o $(1 \le o \le O-1)$, sample a next-order neighbor node v_k^{o+1} from the following distribution:

$$Pr(v_k^{o+1}|v_j^o) = \begin{cases} \frac{1}{Z_j} & \text{if } (v_j^o, v_k^{o+1}) \in E \text{ and } \mathcal{L}(v_i, v_k^{o+1}) = o+1 \\ 0 & \text{otherwise.} \end{cases}$$

   where Z_j is the number of $o+1$-order neighbors connected to v_j^o. The sampled v_k^{o+1} is added into N_i^O.
3. For each neighbor node v_j^o, add node pair (v_i, v_j^o) into pairs set $\mathcal{P}$.
4. Repeat for N times.

We take the graph in Fig. 1 as an example to illustrate how PS works. In this graph, A is the central node, with dashed circles indicating the neighbors of the same order. We color sampled neighbors as red circles and leave the others as white ones. Following the aforementioned process, first-order neighbors $\{B, C, D, E\}$ are all sampled. H is sampled from $\{F, G, H\}$ as the successor of B. I is sampled as the successor of D. J is sampled from $\{J, K\}$ as the successor of E. Unsampled nodes are ignored in the next iteration of sampling, only sampled nodes in this order can be used to generate the next-order samples, e.g., H continues searching while F stops. By now PS samples a set of node pairs $\{(X, A)\}|X \in \{B, C, D, E, H, I, J\}\}$.

By restricting the max order of neighbors and the number of successors for each node to be at most 1, we successfully set an upper bound for the total number of node pairs. In fact, under the same training objective, pairs sampled by different sampling strategies will converge to different distributions of α and β. Theoretical optimal distributions are so far too complex to compute, but we show empirically that pairs sampled by Pairs Sampling can yield competitive results as RW-based does.

3.3 Text-driven Embedding Model

3.3.1 Intuition. Previous graph embedding models focus on generating graph embeddings from only structural information (denoted as NE) or incorporating text attributes with structural information (denoted as NE+TE). NE+TE models can be regarded as encoding structural information into an NE space and encoding textual information into a TE space. Even though complicated interactions are explored between these two spaces, we concern the textual information has not been fully utilized, and propose to generate graph embeddings from text embeddings (denoted as TE2NE). TE2NE is more suitable for large graphs with strong text dependency. A large-scale graph with rich texts may contain million- to billion-level nodes, where the number of nodes is much larger than the number of words. Besides, TE2NE can also apply to zero-shot scenarios, since no explicit NE is required in inference. Therefore,

we propose the Text-driven Graph Embedding (TGE) method that makes the most of textual information by projecting textual information into the NE space. To model the text, we adopt bidirectional LSTM (BiLSTM) [31] for its success in Nature Language Processing field [34, 36]. To deal with out-of-vocabulary words in unseen nodes, we adopt character-level embeddings. Character-level embeddings have proven success in NLP tasks [9, 31]. The advantages of character-level embeddings over word-level embeddings are summarized by [9]. Hence, we adopt character-level embeddings in addition to word-level embeddings.

3.3.2 Generating Embeddings. We denote the set of words as $\mathcal{D}^w$, the set of characters as $\mathcal{D}^c$ and text of node v_i to be $t_i = \{w_{ij}, 1 \le j \le |t_i|\}$, where $w_{ij} \in \mathcal{D}^w$ and $|t_i|$ is the length of t_i. Each word w_{ij} contains characters as $w_{ij} = \{c_{ijk}, 1 \le k \le |w_{ij}|\}$, where $c_{ijk} \in \mathcal{D}^c$ and $|w_{ij}|$ is the length of w_{ij}. We denote character- and word-level embedding vectors as $\mathbf{e}^c$ and $\mathbf{e}^w$ respectively.

We start by generating embedding of node v_i. We feed the sequence of character embeddings $\mathbf{e}^c_{ij,1:|w_{ij}|}$ into character-level BiLSTM and obtain a character-based word embedding $\mathbf{e}^{w'}_{ij}$ as in Eq. (8). The character-based word embedding is concatenated with the corresponding word embedding $\mathbf{e}^w_{ij}$ and fed into the word-level BiLSTM layer as in Eq. (9).

$$\mathbf{e}^{w'}_{ij} = \text{BiLSTM}^c(\mathbf{e}^c_{ij,1:|w_{ij}|}) \quad (8)$$

$$\mathbf{e}_i = \tanh(W\text{BiLSTM}^w([\mathbf{e}^w_{i,1:|T_i|}; \mathbf{e}^{w'}_{i,1:|T_i|}]) + b) \quad (9)$$

Now we obtain the text-based node embedding $\mathbf{e}_i$ of node v_i. We also set up a lookup layer which embeds v_i into *dim*-dimensional structure-based vector $\mathbf{e}'_i$ that is used to help train $\mathbf{e}_i$, and outputs $\mathbf{e}_i$ as the embedding vector of v_i.

3.3.3 Training. The training objective is Eq. (1). To reduce computation complexity, we define the loss function to be

$$\mathcal{L}_{\text{sim}}(v_i, v_j) = -\log(\sigma(\mathbf{e}'^{\top}_j \mathbf{e}_i)) - \sum_{v_k \sim P(v)}^{N_{\text{neg}}} \log(\sigma(-\mathbf{e}'^{\top}_k \mathbf{e}_i))$$

where $\mathbf{e}_i$, $\mathbf{e}'_j$ and $\mathbf{e}'_k$ denotes embeddings of the central node, the neighbor node in a pair, and the randomly sampled negative node, N_{neg} denotes the number of negative samples [35], σ denotes the sigmoid function and $P(v) \propto d_v^{3/4}$ denotes the distribution of nodes when sampling negative samples, where d_v is the degree of v.

We also apply L_2-regularization on parameters and embeddings We use AdaGrad optimizer [11] to minimize the loss.

4 EXPERIMENTS

4.1 Datasets

To verify the effectiveness and efficiency of PS, we conduct a series of experiments over 6 datasets. We list their details in Tab. 1, where $|V|$ and $|E|$ refer to number of nodes and edges, respectively. In practice, we keep all nodes and $p\%$ edges of the dataset *Data* for training and denote this setting as *Data@p%*. Before conducting our experiments, we pre-process texts including lowering all characters, removing stop words and discarding punctuations.

Table 1: Details of Datasets

Datasets	$\|V\|$	$\|E\|$	Type
Cora [32]	2,211	5,214	Citation Graph
Facebook [24]	4,039	88,234	Social Network
Zhihu [47]	10,000	43,894	Q&A Datasets
AstroPh [24]	18,772	198,110	Co-work Network
HepTh [24]	27,400	352,542	Citation Graph
SNOMED [10, 37]	391,892	2,047,749	Health Terminology

4.2 Baselines

We evaluate our model against several graph embedding models: **LINE** [45], **DeepWalk** [42] **node2vec** [17], **CANE** [47], **Paper2Vec** [14] and **STNE** [29]. Since all listed models are not capable of fitting in zero-shot scenarios. Therefore, we design a rule-based embedding method, **Text Matching**, which represents each node as the average vector of pre-trained word embeddings from Glove [41] for every word in the text. The performance of Text Matching reflects the dependency between graph and text structure.

4.3 Evaluation Metrics

In evaluation, we sample an unobserved link (v_c, v_p) and a non-exist link (v_c, v_n) as the positive and negative samples for each node v_c, respectively. we adopt AUC (Area Under Curve) [19] as the metric in two different ways: we use the a portion of pairs to train a logistic regression classifier, use the trained classifier to infer the connectivity of another set of pairs and compute the final AUC score as $\mathbf{AUC_{LR}}$; we directly compute the times of $\mathbf{e}_c^{\top}\mathbf{e}_p > \mathbf{e}_c^{\top}\mathbf{e}_n$ as $\mathbf{AUC_{pair}}$, similar to that in [30]. We report the results of all experiments in two columns, which represent AUC_{LR} and AUC_{pair} respectively.

4.4 Experiments of Pairs Sampling

4.4.1 Theoretical Analysis. Firstly, we compute the sample complexity of each method. Given the number of nodes $|V|$, average degree $\bar{d}$, walk length L, window size W and walk time T in RW, and max order O and sampling time N in PS, the number of sample pairs under RW and PS are $(2L - W - 1)WT|V|$ and $NO\bar{d}|V|$, and the ratio of them r is $\frac{(2L-W-1)WT}{NO\bar{d}}$. We compute the ratio of node pairs with fine-tuned parameters in Tab. 2. Note that real ratios will be larger for that the number of pairs sampled by PS is actually no greater than $NO\bar{d}|V|$. From results in Tab. 2, we can see that PS can significantly reduce the training samples (reducing ~99% samples) compared with RW. Note that r is often much larger in sparse networks like Cora, Zhihu and SNOMED. In graphs with small average degree, RW often conducts DFS-like walks and encounter leaf nodes, which results in frequent revisiting behaviors and hence more redundant samples.

Table 2: Ratios of Different Datasets

Datasets	$\|V\|$	$\|E\|$	$\bar{d}$	r
Cora@50%	2,211	2,607	2.33	183.60
Cora@100%	2,211	5,214	4.42	140.46
Facebook@50%	4,039	44,117	21.84	36.17
Zhihu@50%	10,000	21,947	4.28	369.16
AstroPh@50%	18,772	99,054	10.56	55.40
HepTh@50%	27,400	176,271	12.86	99.79
SNOMED@20%	391,892	409,550	2.09	409.36

4.4.2 Link Prediction. We evaluate PS against RW on 6 datasets listed in Section 4.1. We use PS and RW to generate training sets, and train node embeddings respectively. Results in Tab. 3 show that PS outperforms RW on almost all datasets. This indicate that even if PS adopts stronger assumptions for efficiency consideration, it still proves to be a competitive alternative to RW.

Table 3: Link Prediction Results of RW and PS

Datasets	Random Walk		Pairs Sampling	
	AUC_{LR}	AUC_{pair}	AUC_{LR}	AUC_{pair}
Cora@50%	0.9200	0.9293	**0.9272**	**0.9394**
Facebook@50%	0.9921	0.9892	**0.9922**	**0.9911**
Zhihu@50%	0.8659	**0.9144**	**0.8673**	0.9136
AstroPh@50%	0.9788	0.9768	**0.9795**	**0.9789**
HepTh@50%	0.9741	0.9648	**0.9743**	**0.9730**
SNOMED@20%	0.9350	0.9396	**0.9359**	**0.9402**

4.5 Experiments of TGE-PS

4.5.1 Link Prediction. We evaluate TGE-PS against all baseline models on SNOMED and HepTh respectively. The results are shown in Tab. 4, where "-" refers to results of failed experiments. From Tab. 4, we have following observations:

- TGE-PS outperforms all baseline models on both datasets. Incorporating textual information with structural information helps constructing expressive graph embeddings. Improvements of TGE-PS over PS and Paper2Vec over node2vec strongly support this point. Only preserving structural information like LINE or textual information like Text Matching both presents limitations.
- The improvements of TGE-PS are quite different on the two graphs. Recall that we use the text description of concepts in SNOMED and the whole abstract in HepTh, we owe this to that SNOMED has stronger text dependency than HepTh. The performance of Text Matching in SNOMED supports this point. Similar difference of improvements also appears between Paper2Vec and node2vec.

Table 4: Link Prediction Results of Different Models

Model	**SNOMED**@20%		**HepTh**@50%	
	AUC_{LR}	AUC_{pair}	AUC_{LR}	AUC_{pair}
LINE	0.6461	0.6985	0.7883	0.7520
DeepWalk	0.9164	0.9258	0.9711	0.9573
node2vec	0.9350	0.9396	0.9741	0.9648
Text Matching	0.8954	0.8717	0.7057	0.5700
TADW	-	-	0.8866	0.8977
CANE	0.9613	0.9544	0.9785	0.9388
Paper2Vec	0.9581	0.9604	0.9745	0.9748
STNE	-	-	0.9651	0.9572
PS	0.9359	0.9402	0.9758	0.9716
TGE-PS	**0.9721**	**0.9621**	**0.9793**	**0.9752**

It is also worth noting that not all models are capable of dealing with large graphs: TADW requires pre-loading the whole adjacent matrix with $O(|V|^2)$ complexity; the training speed of STNE is extremely slow on astronomical number of walks generated in SNOMED. We also try to conduct experiments on GraphGAN in link prediction task, but they fail on both datasets due to OOM. On the contrary, our TGE-PS performs well in handling large graphs.

4.5.2 Zero-Shot Experiments. Unlike common link prediction scenarios, where each node embedding is trained at least once before inference, zero-shot scenarios require prediction on link existence with unseen nodes. Zero-shot scenarios are common in real-world applications. For example, when updating medical terminology graphs like SNOMED, terms of newly found diseases will be added into existing databases, and it is possible for a human to infer link existence by text information with high accuracy even if he is not an expert in this field. Therefore, zero-shot scenario in fact reflects whether the model incorporates text information by capturing important message and potential connections or simply matching literal similarities.

We conduct zero-shot experiments on SNOMED and HepTh where 0.5% of the nodes and related edges are removed from the graph. Embeddings of these nodes will be generated by trained models directly and used for evaluation. As we stated in previous sections, zero-shot scenarios are not widely studied and most current models are incapable of generating embeddings for unseen nodes. However, to better study this problem, we manage to conduct experiments on a variant of CANE with only averaged TE part , which we denote as CANE (TE): We also conduct ablation experiments on zero-shot scenarios to analyze the influence of character- and word-level embeddings. In ablation experiments, we either replace $[\mathbf{e}^w; \mathbf{e}^{w'}]$ with $\mathbf{e}^{w'}$ (w/o word), or replace $[\mathbf{e}^w; \mathbf{e}^{w'}]$ with $\mathbf{e}^w$ (w/o char). High AUC scores in Tab. 5 indicate TGE-PS is practical and reliable in zero-shot scenarios. Besides, we have following observations:

- Word-level embeddings are essential in embedding nodes. This is not surprising given that there are much more words (100,471 in SNOMED and 72,083 in HepTh) than characters (88 in SNOMED and 59 in HepTh, mostly English characters and numbers). Besides, when words are often composed of sub-words as in SNOMED, the improvements of character-level embeddings are apparently higher.
- Using Text Matching as a baseline, TGE-PS presents larger promotion on HepTh than SNOMED. Unlike terms in SNOMED, texts in HepTh are abstracts of papers, which have longer average length. In this case, BiLSTM shows its advantages over naive matching methods in processing long texts.

Table 5: Zero-Shot Experiment Results

Model	SNOMED		HepTh	
	AUC_{LR}	AUC_{pair}	AUC_{LR}	AUC_{pair}
Text Matching	0.9059	0.8813	0.5934	0.6250
CANE (TE)	0.5271	0.5344	0.6036	0.5288
TGE-PS (w/o word)	0.5000	0.5003	0.5000	0.5037
TGE-PS (w/o char)	0.9701	0.9786	0.8979	**0.9485**
TGE-PS	**0.9760**	**0.9811**	**0.8990**	**0.9485**

ABSTRACT

Natural Language Generation (NLG), as an important part of Natural Language Processing (NLP), has begun to take full advantage of recent advances in language models. Based on recurrent neural networks (RNNs), NLG has made ground breaking improvement and is widely applied in many tasks. RNNs typically learn a joint probability of words, and the additional information is usually fed to RNN's hidden layer using implicit vector representations. Still, there exists some problem unsolved. Standard RNN is not applicable when we need to impose *hard constraints* on the language generation tasks: for example, standard RNNs cannot guarantee designated word(s) to appear in a target sentence to generate. In this paper, we propose a Backward-or-Forward Generative Adversarial Nets model (BoFGAN) to address this problem. Starting from a particular given word, a generative model at every time step generates a new *preceding* or *subsequent* word conditioned on the generated sequence so far until both sides reach an end. To train the generator, we first model it as a stochastic policy using Reinforcement Learning; then we employ a discriminator to evaluate the quality of a complete sequence as the end reward; and lastly, we apply Monte Carlo (MC) search to estimate the long-term return and update the generator via policy gradient. Experimental results demonstrate the effectiveness and rationality of our proposed BoFGAN model.

1 INTRODUCTION

Natural Language Generation (NLG) is the process of producing high-quality texts from some underlying representation of key information. NLG is an important task in Natural Language Processing, and it is also a critical step in many applications, such as machine translation [1, 33], dialogue systems [36, 38], stylistic writing [6, 17, 35], storytelling [16, 37], and abstractive summarization [7, 28], etc. The task can be roughly divided into 2 steps: content determination and sentence structuring. Content determination involves choices of what semantic information to convey, which is closely related to the specific application and/or scenario. Although contents may vary, the way for sentence structuring of natural languages is similar even given different applications/scenarios. Thus, it is likely to propose a general framework to generate texts from given contents. There are three dominant approaches for sentence generation architectures: human-crafted templates [19, 27], grammar-based systems [3], statistical data-driven approaches [2, 20, 21, 26].

Template-based method is widely used in industry systems to generate articles by filling the templates with correct terms. It allows full control over the quality of the output, but it is quite labor-intensive, and rigid. It is only applicable when the application domains are small and variation is expected to be restricted. *Grammar*-based system is more flexible than template-based ones. However, the complexity and difficulty to design and to use these systems make them less popular. Recently, *statistical* approaches gain more attention in research work powered by deep learning. In particular, deep neural networks (DNNs) lead the way since they can learn dense, low-dimensional, and distributed representations at a more abstract level for sentence generation.

It is well-suited to get rid of hand-crafted templates and rules by capturing grammatical and semantic generalisations in a fixed size vector [18, 22, 25]. Thereinto, recurrent neural networks (RNNs) [21], a prevailing class of language models, has achieved notable successes in sequential modeling. It projects histories into a low-dimensional space and propagates the projection through the sequence to build up the implicit relations among the sequence. Compared to the standard *n*-gram model, RNNs can represent sequences of varying lengths, while avoiding both data sparseness and an explosion of parameter numbers.

There is a prominent drawback for RNNs: once the model is learned, the model generates autonomously. Standard RNN is not directly applicable when we need to impose *hard constraints* on the language generation tasks. In other words, for example, standard RNNs cannot guarantee designated word(s) to "explicitly appear" in the generated sentence. The designated word is the hard-constraint for sentence generation. The need for constrained generation is real.

Templates and grammar based systems are inflexible since different scenarios require different templates and grammars: the given word may not match any slots/templates. Existing language models, such as RNNs, can learn the joint probability of a sentence with an additional information. With a given word information fed into the hidden layer, RNN can generate a sentence semantically correlated with the word, but there is no policy to guarantee the word will appear.

Mou *et al.* [23] proposed a backward and forward language model (B/F LM) to tackle the problem. Given a specific word, the model generates previous words and subsequent words simultaneously or asynchronously. That is to say, once the generation direction is determined, the generation process will be executed until the end of the direction. A more natural way is that given the constraint word, we generate sentences incrementally, i.e., from words to word groups (e.g., phrases), from word groups to larger phrases, and from phrases to sentences. Such a process is to some extent analogous to human cognitions about natural language generation [8].

Here is a motivating case. Given a word "*convolutional*" and the target sequence is "*word order for text categorization with convolutional neural networks*", the B/F language model firstly generate backward words (*"with", "categorization", "text", "for", "order", "word"*) and then (*"neural", "networks"*). However, the entire sequence consists of two parts using *"with"* between *"word order for text categorization"* and *"convolutional neural networks"*. It is difficult to derive the first part from the single word *"convolutional"* since the word itself contains little information while it is more feasible to do so from the phrase *"convolutional neural networks"*.

In this paper, we propose a novel framework to tackle the problem of imposing hard constraints on sentence generation. Rather than *pre-defined* backward and then forward direction to generate words, we leave the choice to the model itself. The generative model is treated as an agent of Reinforcement Learning (RL): the state is the generated tokens so far and the action is the combination of what the next token is and which direction (backward, or forward) to generate it. We consider the generation procedure as a sequential decision making process: at each time, it decides to generate either a preceding or a subsequent word conditioned on generated tokens. One side will stop "growing" when it has generated the $\langle eos \rangle$ token. The reward is given by a discriminator, which evaluates the generated sequences and feeds the evaluation back to guide the learning of the generative model. Since the gradients can not pass back to the generator when the output is discrete, we follow SeqGAN [39] and regard the generative model as a stochastic parametrized policy. We employ Monte Carlo (MC) search to approximate the state-action value and directly train the policy via policy gradient. Theoretically, our model guarantees a sentence with a designated constraint word. The model does not plan a whole sentence with merely a single word in the first place; itself decides backward or forward to generate words, it has the chance to generate words into phrases, and to generate phrases into sentences.

Our contributions are as follows: we propose a novel *backward-or-forward* model with gradual information enrichment to generate a sentence given hard-constraints. The model generates text pieces to eliminate uncertainty and finally organize them into a complete sentence. We formulate the model under a Generative Adversarial Network framework and a backward/forward sequential decision making process. The model constructs sentences in a hierarchial generation process, from words to "phrases" and to sentences.

2 RELATED WORK

2.1 RNN and Sequence-to-Sequence

An RNN is widely used in language modeling, which is capable of capturing sequential dependency. It consists of an input layer, a hidden layer and an output layer. At each time t, a word is mapped to a fixed dimensional vector as an input x_t, which is called word embedding. The hidden state vector h_t depends on its previous hidden state h_{t-1} and the input vector x_t. The output layer predicts the generated word y_t from a vocabulary using a $softmax$ function. The formulas are as follows:

$$h_t = \text{RNN}(x_t, h_{t-1})$$

$$y_t = \text{softmax}(W_{out} h_t)$$

The vanilla RNN has the gradient vanishing or explosion problem. To solve this problem, Graves and Schmidhuber [10] proposed long short term memory (LSTM) unit, which contains a memory cell and three kinds of gates controlling what information is retained or forgotten.

Character-level RNN language model [32] has been applied to various generation tasks at early times. Later, a text-to-text NLG framework named sequence-to-sequence (Seq2Seq) [33] plays an important role in language generation. It combines the subtasks (i.e., content determination and sentence structuring) together through an encoder-decoder framework. The encoder encodes the source sentence into a fixed-size vector, acting as the content decision. The decoder decodes the vector to the target sentence, acting as the sentence realisation. The vector passed from encoder to decoder is an underlying representation of the content information of the generated sentence. LSTM-based RNN can be used as the encoder and the decoder.

2.2 B/F Language Model

The standard RNNs or LSTMs are able to formulate language models but they cannot deal with language models with constraints.

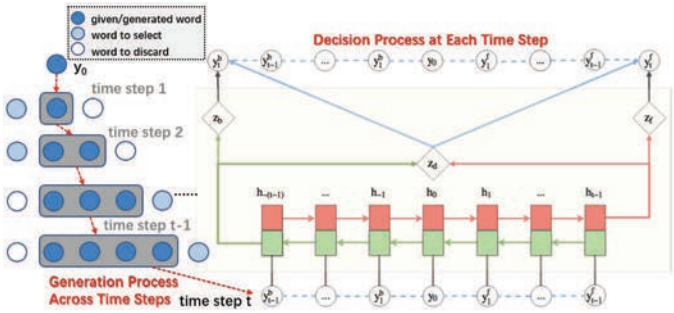

Figure 1: BoFGAN sequence generation at time step t: G_θ would generate the next two tokens conditioned on the previously generated sequence $Y_{0:t-1}$. Note that the red flow is forward h_f propagation, and the green flow is the backward h_b propagation. The diamonds are softmax layers: z_d represents the confidence for direction, and z_f, z_b choose the next token. Across time steps, the model repeats the process incrementally, starting from the constraint word, until the whole sentence is completed by $\langle eos \rangle$'s.

Under the scenarios that constraints exist, the B/F language model, introduced by [23], is a new language model towards the generation of constrained natural language. Given a specific word, the model generates preceding words and subsequent words simultaneously or asynchronously. In the simultaneous setting (syn-B/F model), there is a shared RNN sequence which emits words in the backward and forward directions at the same time. The backward language model and the forward language model share the same input layer and hidden layer. In the asynchronous setting (asyn-B/F model), the model generates the backward sequence firstly, which is then fed to another RNN to generate the forward sequence.

For both settings, the B/F language model pre-defines the directions to generate the sequence while we are seeking for a more flexible model that decides which direction to generate according to the current status and changes the generation strategies from time to time, dynamically.

2.3 GAN and SeqGAN

Generative adversarial networks (GAN) proposed by [9] is a state-of-the-art generative model, which has been successfully applied in generating picture samples [5, 11]. GAN includes a discriminator D classifying the given data as real or fake, and a generator G generating almost real data to confuse D. G and D finally reach a Nash equilibrium, which can be regarded as a win-win situation. However, problems arise when applying GAN in sequential language generation.

Originally, GAN is defined in real number domain for continuous conditions. G is updated via the gradient loss from D. In general, it makes sense only when we slightly change the synthetic data which is continuous, such as pixel values. When GAN generates discrete tokens, the slightly changed data may not have corresponding tokens from the vocabulary. Besides, we can only evaluate the quality of a sentence when it is completely generated. To this end, Yu *et al.* [39] proposed a model named SeqGAN considering the generation procedure as a sequential decision making process, where the generator is an agent of Reinforcement Learning (RL) and the discriminator is used to score the generated sequence and feedback the reward. They employ Monte Carol (MC) search to approximate the state-action value and train the policy via the policy gradient.

However, the GAN and SeqGAN models cannot deal with constrained information so that we can not guarantee the designated word will appear in the generated sentence.

3 BOFGAN

In this part, we introduce our proposed *Backward-or-Forward GAN* (BoFGAN) model in details. The model consists of two parts: a generator and a discriminator. The generator is an RL agent to generate a sentence from a given token. Starting from a single word, each time it needs to make two choices: where to put the new word and what the new word is. The generation process will reach an end when both sides have met an $\langle eos \rangle$ token or the sequence length exceeds limits. In other words, the state is the tokens generated so far, and the actions consist of 1) the position and 2) selection of the new word. Since it is hard to evaluate an incomplete sequence with an appropriate reward for each step, we also employ MC search to approximate the action value function and evaluate the complete sequence using a discriminator. We treat the agent's behaviour as a stochastic parameterized policy and train it using policy gradient method. The discriminator is trained to evaluate how likely a sequence is from real data or not by learning from real-world data and synthetic data from the generator. The generator and discriminator are trained to improve each other iteratively in an adversarial way.

3.1 Generator

G_θ is the θ-parameterized generative model. Γ is the vocabulary of candidate words plus the empty token ε. y_0 is the **hard-constraint** word, i.e., the start token given to the generator in the beginning and is required to exist in the generated sentence.

At timestep t, the state s_{t-1} is the previously generated sequence $Y_{0:t-1} = (y^b_{t-1}, y^b_{t-2}, ..., y^b_1, \mathbf{y_0}, y^f_1, ..., y^f_{t-2}, y^f_{t-1})$, where $y^f_i, y^b_i \in \Gamma$. The action a_t is to separately append new tokens (y^b_t, y^f_t) to two ends of $Y_{0:t-1}$, i.e., the next state s_t means $Y_{0:t} = (y^b_t, y^b_{t-1}, y^b_{t-2}, \ldots, y^b_1, y_0, y^f_1, \ldots, y^f_{t-2}, y^f_{t-1}, y^f_t)$. For the *backward or forward* language modeling, at least one of (y^b_t, y^f_t) is ε because the G_θ is allowed to append one valid word to the sequence at each timestep of generation.

To generate two tokens at a time, we use the bi-directional RNN [29] to model the policy $G_\theta(y^b_t, y^f_t | Y_{0:t-1})$. The bi-RNN maps $X_{0:t-1} = (x_{-t+1}, x_{-t+2}, ..., x_{-1}, x_0, x_1, ..., x_{t-1})$, the input embedding representation of $Y_{0:t-1}$, into two sequences of hidden state, by using the update function g recursively:

$$h_{0:t-1} = (\{h^b_{-t+1}, h^f_{-t+1}\}, \ldots, \{h^b_0, h^f_0\}, \ldots, \{h^b_{t-1}, h^f_{t-1}\})$$

$$\begin{aligned} h^f_i &= g_f(h^f_{i-1}, x_i) \\ h^b_i &= g_b(h^b_{i+1}, x_i) \end{aligned} \tag{1}$$

where h^f_{-t} and h^b_t, the initial vectors to feed into the hidden layer, are both zero vectors. Note that we allow the subscripts be negative for convenience and each subscript stands for the relative position to y_0. g_f and g_b are implemented by LSTM cells, since LSTM cells can faster converge and eliminate the problem of vanishing or exploding gradients in sequence via self-regularization [10].

Generator's action actually consists of two parts: 1) the position and 2) the selection of the new token, thus, we use three output units to parameterize the policy.

$$\begin{aligned} z_d &= \text{softmax}\left(b_d + W_d h\right) \\ z_f &= \text{softmax}\left(b_f + W_f h^f_{t-1}\right) \\ z_b &= \text{softmax}\left(b_b + W_b h^b_{-t+1}\right) \end{aligned} \tag{2}$$

where W_d, W_f, W_b are weight matrics and b_d, b_f, b_b are bias vectors. h is the concatenation of h^f_{t-1} and h^b_{-t+1}. z_d is a two-dimension vector to control the preference for which direction to append newly generated tokens, and z_f, z_b are used to represent the output token distribution separately:

$$\begin{aligned} p\left(y^f_t | Y_{0:t-1}\right) &= z_{d0} \cdot z_f \\ p\left(y^b_t | Y_{0:t-1}\right) &= z_{d1} \cdot z_b \end{aligned} \tag{3}$$

Note that

$$\sum_{y^f_t \in \Gamma} p\left(y^f_t | Y_{0:t-1}\right) + \sum_{y^b_t \in \Gamma} p\left(y^b_t | Y_{0:t-1}\right) = 1.$$

At timestamp t, the generator would only sample one word from $p\left(y | Y_{0:t-1}\right)$. If one side has obtained $\langle eos \rangle$ token, the corresponding direction of z_d would be forced to be 0 and the other to be 1. When both sides reach an end or the total length goes beyond the limit, the generation is terminated. The whole generation process is shown in Figure 1.

3.2 Discriminator

D_ϕ is the ϕ-parameterized discriminative model. It is a binary classifier that takes a sequence as the input and outputs a probability indicating how likely the input is generated by humans. Deep learning methods have been widely used in the task of text classification and achieves good performance, especially using the convolutional neural network (CNN)-based methods [12, 13, 15]. CNN is similar to the n-gram model to some degree as the filter window can be seen as the n-gram method. The use of convolution layer and pooling layer can largely reduce the number of parameters and extracts high-level information of text at the same time. We follow SeqGAN [39] and choose the same architectures as our discriminator.

The overall classification framework is based on CNN. The input sequence is represented as:

$$x_{1:T} = x_1 \oplus x_2 \oplus \cdots \oplus x_T$$

where $\oplus$ is the concatenation operator and $x_t \in \mathbb{R}^k$ is the k-dimensional word embedding corresponding to the t-th word in the sequence. The convolutional operation is then applied to a window size of m words with a kernel $w \in \mathbb{R}^{m \times k}$. We can use multiple kernels to extract different features and the window size varies when needed. Each feature map can be denoted as:

$$\mathbf{c} = [c_1, c_2, \cdots, c_{T-m+1}]$$

where

$$c_i = f(w \cdot x_{i:i+m-1} + b)$$

Here f is a non-linear function and $b \in \mathbb{R}$ is a bias term. Then, a max-over-time operation is applied to the feature map getting the most important feature $\tilde{c} = max\{\mathbf{c}\}$

We add highway networks [31] after the pooling operation. At last, we apply a fully connected layer to distinguish whether the input sequence is from human or not. The loss function is the cross entropy between the ground truth label and the classifier output.

3.3 BoFGAN via Policy Gradient

To guide the learning of the generator, we establish an adversarial reinforcement architecture. The key idea of the system is to encourage the G_θ to generate a semantically coherent and grammatically correct sentence with a constraint word. In other words, our objectives are that 1) the generated sequence includes the designated constraint word, and 2) is indistinguishable from human generated sentences.

We construct a bi-directionally growing generator. On one hand, the model guarantees that the constraint word will appear; on the other hand, it splits the whole generation task into sub-tasks, i.e., from words to word groups (e.g., phrases), from text pieces to sentences, making each sub-task easier than the task to generate a sentence as a whole. The process is quite similar to human cognitions [8].

We employ a discriminator to assess the quality of the generated sentence in the end. If the synthetic sentence gets a high probability from D_ϕ, that means the sentence is good enough to fool the discriminator and shows the effectiveness of the generator. However, it exists a problem applying traditional GAN to our model: it has difficulty to pass back the gradient to G_θ due to the discrete output. Thus, we adopt the policy gradient method to train the generator, and we use MC search to estimate the action-value function and the discriminator to provide the reward.

To improve the authority of the discriminator, we periodically re-train the discriminator by feeding real-world data and synthetic data generated by the upgraded Generator G_θ. The objective of the discriminative model is to minimize the cross entropy of the classification:

$$\min_\phi -\mathbb{E}_{Y \sim p_{\text{data}}}\left[\log D_\phi(Y)\right] - \mathbb{E}_{Y \sim G_\theta}\left[\log\left(1 - D_\phi(Y)\right)\right] \tag{4}$$

Each time when we obtain an upgraded discriminator D_ϕ, we continue the improvement of Generator G_θ. The objectives of G_θ is to maximize the state value of state s_0.

$$\begin{aligned} J(\theta) &= V_\theta(s_0) \\ &= \mathbb{E}\left[Q_\theta(s_0, a)\right] \\ &= \sum_{y^b_1, y^f_1 \in \Gamma} G_\theta\left(y^b_1, y^f_1 | s_0\right) \cdot Q^{G_\theta}_{D_\phi}\left(s_0, y^b_1, y^f_1\right) \end{aligned} \tag{5}$$

$V_\theta(s_0)$ is the state value of s_0, $Q_\theta(s_0, a)$ is the action value function, and the $Q^{G_\theta}_{D_\phi}\left(s_0, y^b_1, y^f_1\right)$ is the approximation of $Q_\theta\left(s_0, y^b_1, y^f_1\right)$

obtained from MC Search. Since there is no intermediate reward, we utilize the discriminator to provide the reward for the complete sequence, apply MC search with a roll-out policy G_β to sample the rest of the sequence, and estimate action value function with the empirical mean return. Note that, to improve the accuracy, we set β the same as θ.

To reduce variance, we run the roll-out policy for N times to get a batch of samples. Starting from sequence $Y_{0:t}$, the sampled sequences are represented as

$$\{Y_{0:T}^1, ..., Y_{0:T}^N\} = \mathrm{MC}^{G_\beta}(Y_{0:t}; N)$$

Thus, the $Q_{D_\phi}^{G_\theta}(s_{t-1}, y_t^b, y_t^f)$ can be written as:

$$Q_{D_\phi}^{G_\theta}(s_{t-1}, y_t^b, y_t^f) = \begin{cases} \frac{1}{N}\sum_{n=1}^{N} D_\phi(Y_{0:T}^n),\ Y_{0:T}^n \in \mathrm{MC}^{G_\beta}(Y_{0:t}; N) & \text{for } t < T \\ D_\phi(Y_{0:T}) & \text{for } t = T \end{cases} \tag{6}$$

We use policy gradient method to update G_θ. Following [34], the gradient of $J(\theta)$ can be derived as:

$$\nabla_\theta J(\theta) = \mathbb{E}_{s_{t-1}\sim G_\theta}\Big[\sum_{y_t^b, y_t^f \in \Gamma} \nabla_\theta G_\theta(y_t^b, y_t^f | s_{t-1}) \cdot Q_{D_\phi}^{G_\theta}(s_{t-1}, y_t^b, y_t^f)\Big] \tag{7}$$

Thus, the equation above can be unbiasedly estimated using likelihood ratios as:

$$\begin{aligned} \nabla_\theta J(\theta) &\simeq \frac{1}{T}\sum_{t=1}^{T}\sum_{y_t^b, y_t^f \in \Gamma} \nabla_\theta G_\theta(y_t^b, y_t^f | s_{t-1}) \cdot Q_{D_\phi}^{G_\theta}(s_{t-1}, y_t^b, y_t^f) \\ &= \frac{1}{T}\sum_{t=1}^{T}\sum_{y_t^b, y_t^f \in \Gamma} G_\theta(y_t^b, y_t^f | s_{t-1}) \nabla_\theta \log G_\theta(y_t^b, y_t^f | s_{t-1}) \cdot Q_{D_\phi}^{G_\theta}(s_{t-1}, y_t^b, y_t^f) \\ &= \frac{1}{T}\sum_{t=1}^{T} \mathbb{E}_{(y_t^b, y_t^f)\sim G_\theta(y_t^b, y_t^f | s_{t-1})}\Big[\nabla_\theta \log G_\theta(y_t^b, y_t^f | s_{t-1}) \cdot Q_{D_\phi}^{G_\theta}(s_{t-1}, y_t^b, y_t^f)\Big] \end{aligned} \tag{8}$$

For brevity, we omit several details of derivations. We can approximate the expected value with sampled means, thus, we can update the parameters θ as:

$$\theta \leftarrow \theta + \alpha \nabla_\theta J(\theta),$$

where α is learning rate. We can adopt gradient algorithms such as Adam [14] here.

To sum up, we first pretrain the generator and the discriminator. Then the generator and discriminator are trained alternately. For the discriminator, positive samples are from human generated sequences and negative samples are synthetic sequences generated by the generator. We need to periodically re-train the discriminator for several times as we get synthetic data of higher quality from the improved generator. In turn, the generator needs to be re-trained after we obtain an upgraded discriminator. In the end, the discriminator and the generator can both get improved.

4 EXPERIMENT

We conduct experiments to evaluate the effectiveness and to understand the inherent mechanism of BoFGAN.

4.1 Experimental Setups

Data and Pre-processing. We implement our experiments over the the Westbury Lab Wikipedia Corpus [30]. We carry out the data pre-processing, including data selection and data cleaning. First, we split the paragraphs into sentences and replace some entities with designated symbols, such as numbers, name mentions, temperature and so on. Since extremely short sentences are less meaningful, we extract one million sentences of length between 5 and 10 tokens as dataset $Data_1$, and one million sentences of length between 10 and 20 tokens as dataset $Data_2$. Both vocabulary sizes are set as 30,000, and the words out of vocabulary ($\leq$ 25 occurrences) were grouped as a single token, ⟨UNK⟩. Then we remove those sentences with more than three ⟨UNK⟩'s. Both $Data_1$ and $Data_2$ have 900,000 sentences, including 800,000 samples for training, and 100,000 for testing.

Baselines. We compare our model with traditional RNN language models as one of our baselines. Since standard RNNs can only generate sequence in one direction, it cannot handle our task scenario if a constraint word occurs in the middle of the target sentence. Therefore, for RNNs, we test the performance of **Forward-RNN** (F-RNN), starting from the constraint word, as well as the performance of **Backward-RNN** (B-RNN), ending by the constraint word. RNN is capable to deal with sequential generation in only one direction. We also include the B/F language models with RNNs. As mentioned above, B/F language model is designed for the same scenario as ours: to generate a sentence with the hard constraint word. The **asyn-B/F** language model is the best method as reported in [23].

In the pre-training process, asyn-BF language model is splitted into two part: the forward one and the backward one, each of which is trained as normal RNN language models. We feed the first word of each sentence as the start token, and the forward sequence reconstructs the original sentence. For the backward one, we reverse the sequence and train in the same way. The pretraining loss of asyn-BF is as:

$$-\frac{1}{M}\sum_{i=1}^{M}\left[\log p_f(Y_{1:T}|y_0) + \log p_b(Y_{T-1:0}|y_T)\right] \tag{9}$$

where p_f and p_b are the probability of forward generation and backward generation, and M is the batch size.

Implementation. Since BoFGAN is implemented based on the bi-directional architecture, thus, we use the same pretraining method mentioned above for the generator G_θ. At each time step, it actually acts like a bi-directional RNN if we ignore the direction decision layer z_d. After pretraining, the generator is preliminarily able to generate the start or end token for a sequence. As for the softmax layer of z_d, we leave it for next training stage.

We use LSTM architectures in both our generator and asyn-B/F language model. Actually, most of the RNN variants, such as the GRU [4] and soft attention mechanism [1], can also be applied. We adopt Adam gradient algorithms [14] for all the stochastic optimization, including the training of generator and discriminator. Adam is computationally efficient, has low memory cost, requires little tuning, and is invariant to diagonal rescaling of the gradients.

Evaluation Metric. Since our model is not learned by joint probability of word estimation during generation, it is infeasible to

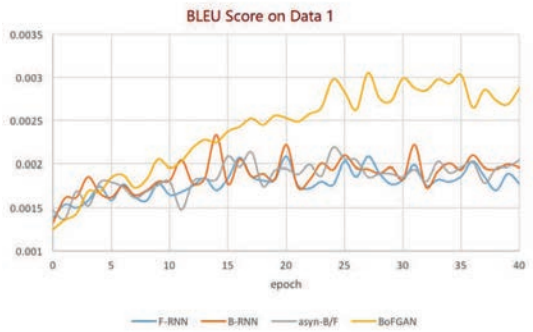

Figure 2: BLEU score curves on dataset $Data_1$

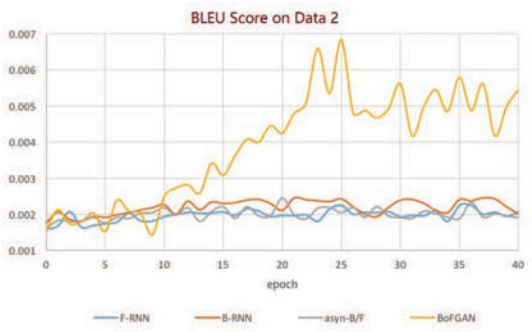

Figure 3: BLEU score curves on dataset $Data_2$

Table 1: Evaluation scores of different groups, measured in terms of BLEU evaluations.

Methods	BLEU of $Data_1$	BLEU of $Data_2$
F-RNN	1.82	2.04
B-RNN	1.96	2.37
asyn-B/F	1.84	2.02
BoFGAN	**2.83**	**4.73**

evaluate with *perplexity* as other language model studies do. *BLEU* is an algorithm to evaluate the quality of generation by comparing the overlap between the generated texts and the target references from humans [24]. BLEU is calculated by taking the geometric mean of the N-gram precision scores and then multiply the result by an exponential brevity penalty factor. Readers may refer to [24] for details. In this work, we regard all target sentences with the constraint word as references for BLEU calculation. N is set to 4 combining BLEU-1 to BLEU-4.

4.2 Experimental Results

The BLEU performance of all methods is provided in Table 1, measuring the overlap between the generated sentences and the targeted sentences as references. For each method, we use the best model in training stage to generate candidate samples and calculate their BLEU score. We can see that BoFGAN shows apparent advantages over other methods. BoFGAN outperforms baselines both on dataset $Data_1$ and $Data_2$, and it shows much larger gap in $Data_2$, which is trained to generate longer sentences. As mentioned above, when a sentence is longer, it is more likely to contain complex structures. This situation means that it would be more favorable for BoFGAN to perform its stronger capability. There is not so much difference among three baselines, since they are all based on the same RNN language model. Note that Forward RNN and Backward RNN has a "prior" knowledge because they are aware of the position of the constraint word (at the beginning or the end). Besides, they can only generate sequence in one way. Thus, if they are fed with a constraint word at a random position of the target sentence, they would perform much worse than BoFGAN and asyn-BF model.

In Figures 2-3, we show the learning curves, which strongly illustrate the effectiveness of BoFGAN. In the pretraining period—from epoch 0 to 10—BoFGAN is even slightly weaker than baselines since parameters of BoFGAN are not fully trained. In the training stage, i.e., from epoch 11 to 40, BoFGAN quickly outperforms baselines and enlarges the gap gradually, which demonstrates the effectiveness.

5 CONCLUSION

In this paper, we proposed a BoFGAN model for hard-constrained natural language generation. The model consists of two parts: a generator treated as a stochastic policy in reinforcement learning, and a discriminator to give a reward. Given the constraint word, we can generate a complete sentence containing it. The generation process is innovative. Starting from the given word, 1) which direction to generate and 2) what is the next token to generate are conditioned on previously generated words so far. Thus, we can form a word group (e.g., a phrase) from individual words and form a sentence from the word groups (or phrases).

Experimental results show that BoFGAN outperforms other baselines using BLEU scores. The generation process enlightens us another perspective of natural language generation paradigm: not only sequential, but also *backward-or-forward*. We will investigate how to organize multiple inconsecutive constraint words with our proposed model.

ABSTRACT

With the rapid growth of cloud service systems and their increasing complexity, service failures become unavoidable. Outages, which are critical service failures, could dramatically degrade system availability and impact user experience. To minimize service downtime and ensure high system availability, we develop an intelligent outage management approach, called AirAlert, which can forecast the occurrence of outages before they actually happen and diagnose the root cause after they indeed occur. AirAlert works as a global watcher for the entire cloud system, which collects all alerting signals, detects dependency among signals and proactively predicts outages that may happen anywhere in the whole cloud system. We analyze the relationships between outages and alerting signals by leveraging Bayesian network and predict outages using a robust gradient boosting tree based classification method. The proposed outage management approach is evaluated using the outage dataset collected from a Microsoft cloud system and the results confirm the effectiveness of the proposed approach.

1 INTRODUCTION

A typical cloud system is a system of systems, providing different services such as networking, storage, computation, security and management. Cloud providers, such as Microsoft, Amazon, Google, and IBM, aim at fast delivery of computing resources in a dynamically scalable and virtualized manner [3, 25]. Many cloud services could be hosted in a cloud system and each service itself is a large and complex system that consists of many components. Failures would happen in a complicated system due to frequent updates of components, changes in operation environment, online repairs, and mobility of devices, [10, 12, 27]. Failures could dramatically degrade system availability and lead to bad user experience. To manage failures, various system monitors and alerting tools are deployed at different places of a cloud service system to detect if a service performs well or not.

In cloud systems, outages are critical system failures that can lead to system unavailability. When an outage is detected, the management tool is expected to automatically notify, mitigate, and diagnose the outage. In literature, there is a large amount of work on predicting and diagnosing failures in a large and complex system such as a data center, grid system, and defense system [14, 15, 20, 30]. Such an ability can help prevent potential disasters and minimize damages caused by system unavailability. However, they only consider a single system and ignore the related systems that could have an impact on the prediction results. In this work, we are interested in predicting and diagnosing outages of a cloud system. A typical cloud system contains many sub-systems (i.e., services), each of which consists of many interconnected components. Each component has its own monitors that regularly check the runtime status of the component. Signals from components reflect different aspects of system health status, such as individual cloud resource, node/data center traffic volume, response latency, temperature, and power consumption. While component-level alerting signals are useful, it is important to have a global watcher for the entire cloud system which understands the topology, resiliency models and dependencies of the system. After connecting all the signals, the global watcher can proactively monitor and correlate service health issues across the whole system without manually defined rules.

In our work, we propose an intelligent outage management tool, called AirAlert, as a global watcher of the whole cloud system. AirAlert collects all alerting signals across the whole cloud system, and utilizes them to diagnose and predict outages. The outages we

try to predict come from two levels: component-level and service-level. These two concepts are hierarchical, where service-level outage consists of various corresponding component-level outages. The service-level outage prediction can help locate the suspicious behavior in the general system, also, locating which component is responsible for the outage can better alleviate the cost of diagnosing and debugging. To diagnose where outages come from, we adopt a Bayesian network approach and investigate dependency relationships between signals and outages. We also construct predictive models to achieve robust outage prediction.

In our work, we are investigating a large-scale Microsoft cloud system. As there are a large number of altering signals, it is hard to know beforehand the dependencies among the signals and their relationships with outages. Therefore, a comprehensive global watcher, specially designed for diagnosing and alerting failures, is needed. In our approach, Bayesian network is used to build the signal dependencies from historical failure statistics. For outage prediction, many algorithms can be used for constructing a prediction model, such as time-series forecasting method (e.g., auto-regressive moving average), rule-based methods (e.g., frequent event set mining [6, 24]), and supervised machine learning methods [8, 17]. However, traditional methods are not capable of handling outage prediction in a cloud service system as they ignore interactions among different system components. There are several challenges in constructing an effective predictive model. The foremost one is that we have very imbalanced datasets due to the limited number of outage cases. Therefore, we apply sampling techniques to preprocess the data and then use the gradient boosting tree based classification method for robust model construction.

Our approach has been evaluated using a set of outage data collected from the Microsoft cloud system over an one year period. We compare the AirAlert approach against other methods and obtain good performance in outage prediction. Also, we show that AirAlert can help outage diagnosis and present several real-world cases.

The contributions of the paper are as follows:

- We propose an outage prediction and diagnosis approach for a cloud service system. Our model takes into consideration multiple related services and components in the cloud system.
- We can infer causal relationships among outages and alerting signals, which can help us understand where the outage is from and which components work cooperatively.
- We can predict whether a component or service will have an outage in the near future, which would potentially help engineering teams alleviate the influence of outages as quickly as possible.
- We have evaluated the proposed approach using an one-year outage dataset collected from a Microsoft cloud system, and the results confirm the effectiveness of the proposed approach.

The remaining sections of this paper are organized as follows. Section 2 describes the related work of the study. Section 3 presents the proposed outage prediction and diagnosis approach and Section 4 describes the experiments. Section 5 concludes our work.

2 RELATED WORK

Failures occurred in online systems could degrade system performance and impact user experience. They are often defined as 'an event that occurs when the delivered service deviates from correct service' [1]. Traditional work on failure management for online systems deals with failures after they have happened. Recently, there are increasing efforts on proactively predicting failures to prevent potential disasters or minimize damages [20]. For internet service provider networks, there are intensive work on failure predictions (e.g., [11, 13, 21, 22]). For example, in [30], switch failures in data center networks are predicted using signals reflecting switch system current status and data containing curated historical hardware failure cases. Input signals of the predictive model are mostly system event logs, such as changes in configuration, interface, device working mode and operational maintenance. Similarly, in [9], network failures in data centers are predicted using data recording network errors related to device and link failures. There are also many studies on investigating the failure characteristics [19, 23, 29] of high performance computing systems (HPCs). In [18], failures occurred in a 350-node cluster system is predicted using various system reliability, availability and service ability (RAS) logs containing health related events. In [7], a failure prediction framework for HPCs is designed by exploring correlations among failures and forecasting the time-between-failure. In [26], a Bayesian network based fault diagnosis tool is developed for managing a defense system-of-systems (SoS), which collects signals from a sensor, network, command and control systems. Bayesian network is used to find the root causes of system failures by using the network topology of the whole SoS. In our work, we use the Bayesian network to find the relationships among alerting signals and outages of cloud systems and then we use XGBoost model for prediction.

The work in [10] studies proactive failure management for cloud systems. It uses Bayesian models and decision trees to proactively predict failure dynamics. Failures are regarded as abnormal signals detected by monitors and failure prediction is tackled from an anomaly detection point of view. Different from their works which focus on predicting failures based on raw signals, our work uses the failure signals from monitors (which we call, *alerting signals*) to predict critical failures (which we call, *outages*). In current real-time system, outage prediction is an important issue that bothers many systems. The reason lies in several aspects: outages are critical system failures that could lead to severe consequences; outages occur without a significant alerting signals pattern, which makes it harder to predict; and the scope of impacting signals is a complex process to define.

3 PROPOSED APPROACH

In this section, we introduce our proposed approach, which is called AirAlert. We first give definitions for our task. Then, we introduce the Bayesian network for generating relationships between alerting signals and outages as well as the gradient boosting tree classification method for outage prediction.

3.1 Definitions

Alerting Signal A single alerting signal A^i can be represented by $A^i = [A^i_1, A^i_2, ..., A^i_T]$, where each component A^i_t indicates the

strength of this signal at time $t \in (1, T)$. For all alerting signals, we denote a multivariate time series of length T as $A = [A_1, A_2, ..., A_T]' \in \mathbb{R}^{D \times T}$ for all signals, where for each $t \in \{1, 2, ..., T\}$, and $A_t = [A_t^1, A_t^2, ..., A_t^D] \in \mathbb{R}^D$ represents the observations of all the alerting signals at time t.

Outage Sequence The outage sequence is a binary time series of length T as $O = (O_1, O_2, ..., O_T) \in \mathbb{R}^T$, where for each $t \in \{1, 2, ..., T\}$, $O_t \in \{1, 0\}$ indicating whether an outage happens at time t or not.

Outage Prediction. Outage prediction at time t is a classification task. We want to maximize the probability $Pr(O_t|\boldsymbol{\mathcal{A}}_t)$, which is predicting accuracy of O_t given the input feature $\boldsymbol{\mathcal{A}}_t$. The input feature $\boldsymbol{\mathcal{A}}_t = [A_t^1, A_t^2, ..., A_t^m]$ are the m alerting signals used for prediction, where $m \leq D$.

3.2 Bayesian network for outage diagnosis

A cloud system is an online system of systems, where the occurrence of an outage is associated with a combination of alerting signals. For example, if a particular web application encounters an outage, it is normally resulted from multiple failures occurred in different services such as networking, hardware and DNS server, rather than from one single failure of the web application component . To be more specific, when several alerting signals are observed, the chance of having an outage depends on all alerting signals. However, it is hard to enumerate all possible combinations of alerting signals and determine which set of signals is related to an outage. To better model the problem, we used a Bayesian network inference method to detect the relationship between alerting signals and outages. Here, we use the FCI-algorithm [5] to infer our Bayesian network. The fundamental idea of FCI algorithm is to build a directed acyclic graph (DAG), where each node X_i represents an alerting signal or an outage based on the causal Markov assumption. The FCI algorithm can be used for the connectivity inference and orientation determination. In this paper, we use it to generate the connectivity between the alerting signals and outages rather than infer the direction.

In our method, the conditional dependence between the alerting signal and outage given a set of other alerting signals are obtained by calculating the Pearson correlation. The influence of the conditional signals needs to be regressed out first. Then, the Fisher's z-transform is performed as in [5]. For example, given the time series sequence of an alerting signal A_i and an outage O_i, and the conditional set only contains the alerting signal A_{i_2}, the correlation between A_i and O_i given A_{i_2} is:

$$\begin{aligned} r &= \frac{cov(A_i|A_{i_2}, O_i|A_{i_2})}{\sigma_{A_i|A_{i_2}}\sigma_{O_i|A_{i_2}}} \\ &= \frac{\sum_{t=1}^{T}(A_{i|i2} - \bar{A}_{i|i2})(O_{i|i2} - \bar{O}_{i|i2})}{\sqrt{\sum_{t=1}^{T}(A_{i|i2} - \bar{A}_{i|i2})^2}\sqrt{\sum_{t=1}^{T}(O_{i|i2} - \bar{O}_{i|i2})^2}}. \end{aligned} \tag{1}$$

Then, Fisher-z transform is used as follows to generate the score for testing the significance of the correlation value:

$$z = \frac{1}{2}\ln(\frac{1+r}{1-r}). \tag{2}$$

z is the correlation score for the alerting signal A_i and outage O_i give A_{i_2}. The significant test of z is then used to check whether the independence assumption can be accepted that A_i is independent of O_i given A_{i_2}.

The FCI-algorithm is an approximation method to obtain the network structure by calculating conditional dependence. It adopts a recursive inference process and uses the Fisher-z conditional independence test to capture all the independence possibilities among all alerting signals and outages. A bootstrap method for stable result generation is used here [16]. After using FCI-algorithm, the skeleton of the causal network among alerting signals and outages can be obtained. In our work, the Bayesian network mainly works as a diagnositic tool to infer the relationship between the alerting signals and the outage. We can also use it to select the most relevant features and feed them as the inputs of the outage prediction model.

3.3 Gradient boosting tree for outage prediction

In practical online systems, conventionally outage prediction is performed using rule-based methods [20]. Despite the complex pattern of outage, each component or service only focuses on their own alerting signals. For each component or service, engineers will simply set up a monitor to predict outage by examining whether the strength of the alerting signal exceeds a certain threshold θ:

$$P(t) = \begin{cases} 1 & \text{if} A_t > \theta \\ 0 & \text{otherwise} \end{cases}, \tag{3}$$

where A_t is the observation of alerting signals reported from a certain component at time t, and the value of θ for each team is set based on human knowledge. Such rule-based outage prediction method is normally effective for in-system outages, as this type of outages only caused by malfunction of a component .

In cloud systems, outages are often caused by cross-service malfunctions simultaneously. Thus, using a single signal of a component or service will not be very effective. As a result, we use the alerting signals A_t at time t as the input feature for outage prediction. At a certain time slot t, several alerting signals $\boldsymbol{\mathcal{A}}_t$ will be collected to predict whether the outage will happen at this time. To construct a robust predictor, we use the gradient boosting tree based model (XGBoost) [4]. XGBoost is fundamentally a regression tree that has the same decision rule as the decision tree model. But the model ensembles a set of classification and regression trees (CART). In the CART tree, each node is one of the alerting signals. The prediction result is the sum of scores predicted by K decision trees, as:

$$\hat{y}_t = \sum_{k=1}^{K} f_k(\boldsymbol{\mathcal{A}}_t), f_k \in F \tag{4}$$

where $f_k(\cdot)$ is the score from the kth tree, F is the function space containing all regression trees, and $\hat{y}_t$ contains prediction results at time t. The XGBoost is optimized to achieve the best prediction results by minimizing the following loss:

$$\mathcal{L} = \sum_{t=1}^{T} l(y_t, \hat{y}_t) + \lambda \sum_{k=1}^{K} \Omega(||f_k||) \tag{5}$$

where the first term $\sum_{t=1}^{T} l(y_t, \hat{y}_t)$ is the summation of cross-entropy loss measuring whether the classification model and features can

well perform for the prediction task across all timestamp. The second term $\lambda \sum_{k=1}^{K} \Omega(||f_k||)$ penalizes the tree boosting parameters f_k in the model as described in [28].

4 EXPERIMENTS

In this section, we carry out extensive experiments using data collected from six representative services across tens of data centers over one year period from the Microsoft cloud system. Due to the privacy policy of Microsoft, we deliberately masked sensitive data throughout this paper. We first show the results of predicting outages at component and service levels, where AirAlert has two prediction modes: AirAlert Related and AirAlert Full. In the AirAlert Related mode, only outage dependent signals found in the Bayesian network are used for prediction, while in the AirAlert Full mode all signals are used for prediction. Then, we give case studies to show how our work can help to diagnose outages and find which team to handle the outage.

4.1 Outage prediction

In this subsection we investigate the performance of predicting the component-level outages and also the service-level outages. These experiments aim at investigating the performance of our method for predicting outages of different complex levels. The component-level outage is the outage coming from a specific component . As a service would contain multiple components, the service-level outage is more complicated and heterogeneous.

4.1.1 Experiment Setups. The investigated component-level outages come from three most representative components: the Storage Location, Physical Networking and Storage Streaming component. The service-level outages come from three most representative services: the Web Application, Cloud Network and the Microsoft Cloud System Operation Service. We evaluate the method by collecting outages over one year period from tens of data centers. We acquired data at the time step of one hour and obtained over 8,000 samples in total (24hrs*365days). The period that the data covered only has a very small number of outages. For evaluation, we choose the service and component outages that occurred frequently in the last year (that is why we choose three most representative services/components). For other services/components, which rarely have any outages happened, there is no sufficient data to construct a predictive model. As we only have a limited number of outages , classification methods would suffer from the imbalanced data problem. To better deal with the imbalanced data, the **SMOTE** [2] over-sampling strategy is used for generating the training data from system database so that the positive and negative samples in the training phase can be balanced.

Given alerting signals across the cloud system, we predict whether a component or service outage will happen. We use precision, recall and F1 as the evaluation metrics. Five different outage prediction methods are compared, which are:

- Simple Spike: This is a rule-based outage prediction method as described in Equation 3, where the threshold θ is predefined by domain knowledge and could vary across different components or services . If the strength of the alerting signal is larger than θ, an outage will happen.
- Support Vector Machine (SVM): SVM is commonly used in classification problems. In this experiment, all the alerting signals are served as input features for the SVM classifier with linear kernel.
- Penalized Logistic Regression (PLR): PLR is commonly used in feature selection and prediction with the introduction of sparse constraints. In this experiment, all alerting signals are used as input features for the PLR model.
- AirAlert Related: It first applies the Bayesian network method to find the most relevant alerting signals for outage prediction, which are signals in the Bayesian network directly connected to the outage. Then, we use these selected signals for outage prediction using the Xgboost classification method.
- AirAlert Full: It is based on the XGBoost classifier. Different from 'AirAlert Related', this approach uses all alerting signals as input features.

AirAlert Related and AirAlert Full are two modes of our method. Users can choose which mode they want to use based on their needs. When they want to use all signals for prediction, they can choose the full mode. However, for the dataset with limited number of samples but large number of signals, full mode would easily return an overfitted model. Therefore, we provide the AirAlert Related mode, where only the signals selected by Bayesian network are fed into the gradient boosting tree model.

4.1.2 Results. The results for the component-level and service-level prediction are shown in Table 1 and 2 respectively.

Table 1 shows the outage prediction results at the component-level. Here, we select three most representative and frequently occurred component-level outages for performance evaluation, which are related to Storage Location, Physical Networking and Storage Streaming. All five different prediction methods are compared in terms of precision, recall and F1. We can see that their performance results are quite similar. Simple spike, which is a straightforward rule-based outage prediction method, can achieve 100% recall in some cases for component-level outage prediction. We will later show its performance in predicting service-level outages, which are more complex and involving many heterogeneous signals. Unlike other methods using the whole feature set for prediction, AirAlert Related only uses the Bayesian network selected features. With reduced feature set size, the performance can be still maintained. This observation shows that Bayesian network can help us find the most representative and dependent alerting signals. Other signals which are not found to be highly related to outages in the network would not significantly improve the performance.

Table 2 shows the outage prediction results at the service level. Again, three most representative and frequently happened outages are selected, which are from Website Application, Cloud network and Microsoft Cloud System Operation. Different from the results in Table 1, we can see that the performance of different prediction methods varies greatly. Among them, Simple Spike obtains very low precision and recall. This is because the service-level outage is more complex than the component-level outage and simple rule-based method cannot work for complicated cases. The outage from a single service can be heterogeneous. For example, outages coming

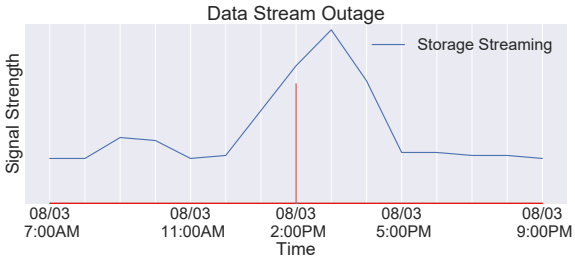
Table 1: Comparison of different methods for component-level outage prediction.

	Outage (Storage Location)			Outage (Physical Networking)			Outage (Storage Streaming)		
	Precision	Recall	F1-score	Precision	Recall	F1-score	Precision	Recall	F1-score
Simple Spike	61.65	100.00	76.28	73.71	67.71	70.58	61.52	100.00	76.18
PLR	70.02	92.71	79,78	67.72	83.33	74.72	63.23	91.67	74.84
SVM	65.65	95.83	77.92	63.13	88.54	73.71	58.62	88.64	70.57
AirAlert Related	65.31	100.00	79.01	63.33	98.95	77.25	62.34	100.00	76.80
AirAlert Full	71.11	100.00	83.17	69.07	100.00	81.71	63.75	98.99	77.86

Table 2: Comparison of different methods for service-level outage prediction.

	Outage (Website Application)			Outage (Cloud Network)			Outage (Microsoft Cloud System Operation)		
	Precision	Recall	F1-score	Precision	Recall	F1-score	Precision	Recall	F1-score
Simple Spike	5.73	11.83	7.72	4.47	67.74	8.39	7.27	29.03	11.63
PLR	61.18	54.17	57.46	26.27	60.52	36.64	20.36	35.17	25.79
SVM	66.41	88.54	75.89	6.89	88.42	12.78	26.90	22.50	24.50
AirAlert Related	92.18	85.63	88.78	62.08	47.65	53.92	72.40	77.96	75.08
AirAlert Full	82.75	76.74	79.63	75.93	67.07	71.22	72.59	50.15	59.32

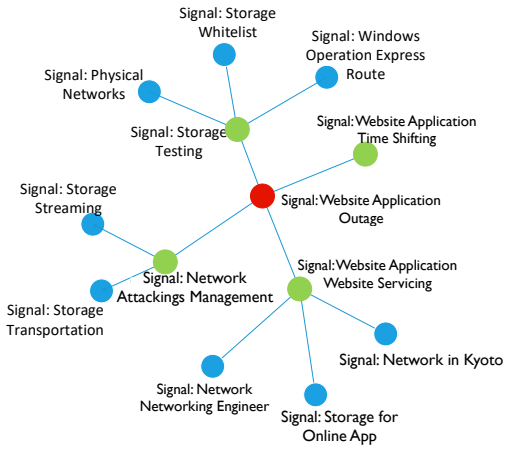
from the "website application" service may result from network or hardware failures.



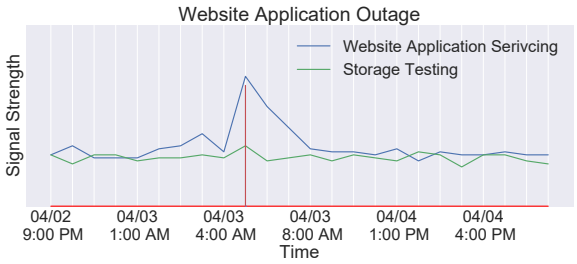
From Table 2 we can further observe that different from Simple Spike, PLR and SVM, AirAlert Related and AirAlert Full have more stable results across different outages. This observation tells us that XGBoost is more robust than others. Consistent with Table 1, the performance of AirAlert Related using Bayesian network selected features has similar performance as AirAlet Full, which uses the whole dataset. More specifically, for the first and the third outage, using related alerting signals about 10% gain in both precision and recall can be achieved. With the help of the Bayesian network, not only the most relevant alerting signals can be identified but also the most predictive features can be detected. The most relevant signals are the ones which would directly lead to outages, while the most predictive features are the ones which contribute to the predictive model the most.

4.2 Outage diagnosis

4.2.1 Cases for outage diagnosis. As mentioned in the previous section, Bayesian network can specify the root cause of outages by calculating the conditional dependence. Here, we would like to give two examples of Bayesian network results. Fig. 1 and Fig. 2 show component-level and service-level outage diagnosis results, respectively. In Fig. 1, subplot (a) contains the Bayesian network for diagnosing relevant alerting signals for the outage called 'Data Stream Outage'. In the graph, the studied outage is in red; its directly linked nodes are in green; and the two-hop neighbours are in blue. This figure shows that the 'Storage Streaming component signal' and the 'Storage Trouble Guide component signal' are most relevant to the occurrence of the 'Data Stream Outage'. When we look up records saved in the Microsoft cloud system, we find that engineer team manually diagnosed the causes of the Data Stream outage



(a) Bayesian network for 'Data Stream Outage'.



(b) Time series of the 'Storage Streaming' Signal.

Figure 1: Diagnosis results for a component-level outage named 'Data Stream Outage'.

(a) Bayesian network for 'Web Application Outage'.

(b) Time series of the 'Web Application Services' and 'Storage Testing' Signals.

Figure 2: Diagnosis results for a service-level outage named 'Web Application Outage'.

based on their knowledge. They found that the Storage Streaming signal is the top first cause, which is consistent with our findings from Bayesian network. Fig. 1 (b) presents the time-series change for alerting signals, where there was one 'Data Stream Outage' happened at 2:00 PM Aug 3rd. At that time, the related 'Storage Streaming signal' rose significantly, showing the findings in the Bayesian network are quite reasonable.

In Fig. 2, we show an example of diagnosing a service-level outage, called 'Web Application Service Outage'. Fig. 2 (a) tells us how the alerting signals are related to this service-level outage. Comparing Fig. 2 (a) with Fig. 1 (a), we can see that Fig. 2 (a) has more interconnected nodes, which indicate that the service-level outage is more complex than component-level outages and thus has more relevant alerting signals across the system. The signals that directly linked to the 'Website Application Service Outage' are 'Storage testing signal', 'Web Application Time Rotation signal', 'Network attacking Management signal' and 'Web Application Website Servicing signal'. From the records of the Microsoft cloud system, The engineering team has manually identified a large number of Web Application Service outages that are related to 'Web Application Website Servicing', which matches our results well. In Figure 2 (b), we also show the changes of some alerting signals over time, where one 'Web Application Service Outage' happened at 5:00 AM April 3rd. At that time, both 'Web Application Website Servicing signal' and 'Storage testing signal' had a significant jump, which is consistent with the observation in Figure 2 (a). These two examples show that our work on Bayesian network can be a useful outage diagnosis tool that helps the engineering team locate the root cause of outages.

4.2.2 Cases for outage assignment. In a real cloud system, determining which team to handle each outage is a non-trivial task. If we correctly predict the outage to be the 'TeamA Outage', the system will automatically assign the *TeamA* team to handle this outage. Here, we would like to give two examples to show the potential of using our method to assign outages. In these examples, the cloud system first wrongly assigns an outage to a team and then reassigns the outage to the correct team sometime later. However, AirAlert correctly predicted which part of the cloud would have the outage and indicated the correct responsible team who should handle it. There are two instances of the 'Location Servicing Outage' happened on June 7th at 16:00 and July 19th at 16:50, respectively. When we look at the operation record in the Microsoft cloud system, this outage was first assigned to the 'Windows Cloud System Live Site' team and then transferred to the 'Location Servicing' team. If we use our prediction and diagnosis approach, we find that we can correctly predict in advance that an outage would happen in 'Location Servicing Outage'. From the Bayesian network diagnosis results, we can find alerting signals related to 'Location Servicing Outage'. By investigating the time series changes of those related signals, we can see that they increased obviously before these two instances of 'Location Servicing Outage'.

5 CONCLUSION

In this paper, we studied the outage diagnosis and prediction problem in cloud systems. We proposed an intelligent outage management method called AirAlert. In contrast to the previous work focusing on dealing with failures in a single service, we work on outages that would come from many parts of the whole cloud system, which is a system of systems. AirAlert works as a global watcher of the cloud system by collecting alerting signals across the whole system. The dependence relationships among the alerting signals and outages are discovered based on the Bayesian network method. AirAlert can diagnose where the outages come from to help us identify the root causes of outages. For outage prediction, we use the gradient boosting tree based model and compare the results from both component-level and service-level outage predictions. To the best of our knowledge, this is the first work that uses alerting signals across the whole cloud system to diagnose and predict outages coming from different levels.

ABSTRACT

Team composition is a central factor in determining the effectiveness of a team. In this paper, we present a large-scale study on the effect of team composition on multiple measures of team effectiveness. We use a dataset from the largest multiplayer online battle arena (MOBA) game, Honor of Kings, with 96 million matches involving 100 million players. We measure team effectiveness based on team performance (whether a team is going to win), team tenacity (whether a team is going to surrender), and team rapport (whether a team uses abusive language). Our results confirm the importance of team diversity with respect to player roles, and show that diversity has varying effects on team effectiveness: although diverse teams perform well and show tenacity in adversity, they are more likely to abuse when losing than less diverse teams. Our study also contributes to the situation vs. personality debate and show that abusive players tend to choose the leading role and players do not become more abusive when taking such roles.

1 INTRODUCTION

The increasing complexity and scale of tasks in modern society require individuals to work together as a team [13, 40]. Crucial to the effectiveness of a team are the individuals in the team, i.e., team composition. Extensive prior research has studied team roles to analyze team composition [6, 7, 30, 31, 36, 38]. The most influential work is Belbin's team role framework, also known as Belbin Team Inventory. A central hypothesis in Belbin's framework is that balance in team roles is associated with team performance. Belbin [7] defines nine roles[1], and finds that teams with certain role combinations result in poor performance, even if they are formed by members with the sharpest mind and the most experience. However, team roles are usually implicit in real life and it is difficult to identify such nine roles in most contexts.

Another challenge in studying the effect of team composition on team effectiveness arises from the definition of *effectiveness*. Team performance is the most straightforward definition and has been studied in a battery of studies [10, 13, 15, 35]. Example measures of team performance include the impact of published papers from a team [40], winning a sports game [4, 24], etc. However, the effectiveness of a team can also be reflected by the tenacity in face of adversity, and the rapport between team members [9]. The effect of team composition likely depends on the definition of team effectiveness. Therefore, it is important to understand the effect of team composition on the effectiveness of teams in multiple measures.

To address these two challenges, we identify multiplayer online battle arena (MOBA) as an ideal testbed and provide a large-scale study on the effect of team compositions on multiple measures of team effectiveness. We use a dataset from Honor of Kings, the largest MOBA game in the world. This platform is ideal for studying the effect of team composition for three reasons. First, there are defined roles in the game and players choose their roles to form a team. Given that there are five players in each team, we are able to enumerate all possible team compositions. We also have information about the characteristics of each role. Second, the popularity of Honor of Kings leads to digital traces of hundreds of millions of players in hundreds of millions of games. These detailed game records allow us to explore the notion of team "effectiveness" beyond the simple measure of team performance, winning or losing. For instance, we study the effect of team composition on abusive language use, which reflects the rapport in a team. This research question naturally connects to the literature on toxic behavior in online communities and gaming [11, 12, 26]. Finally, we have access to the past history of players for capturing their background and experience. Historical information enables us to investigate questions in the "situation vs. personality" debate [16, 22]: how much of our behavior is determined by fixed personality traits or by the specific situation at hand? We will explore this question in the context of toxic behavior in online gaming.

Organization and paper highlights. In this paper, we conduct a large-scale study on the effect of team composition in the context of online gaming, particularly, in Honor of Kings. Our dataset comes

from this popular MOBA game in China, and includes 96 million games and 100 million players in total. We provide details of the dataset and character roles in §2.

We quantitatively study the effect of team composition on three distinct definitions of team effectiveness: (§3) team performance — whether a team is going to win — is directly based on the result/goal in a game and is the most common measure in prior studies; (§4) team tenacity — whether a team is going to surrender — indicates a team's resilience to adversity and is understudied in existing literature as most studies only look at individual tenacity or perseverance [5, 19]; (§5) toxic behavior, i.e., abusive language use, reflects the rapport in a team and is extracted from the activities during a game.

Our results on team effectiveness confirm the theory that balance in team roles is important for effective teams. We find that diverse teams are more likely to win. Furthermore, diverse teams are less likely to surrender, indicating a higher level of tenacity. Note that the likelihood to surrender does not correlate with winning rate for commonly used team compositions. However, we observe diverging effects on abusive language use: diverse teams are more likely to abuse when losing, but are less likely to abuse when winning.

In addition to exploring the effect of team composition, we investigate individual-level abusive language use to understand how teamwork influences individuals and shed light on the "situation vs. personality" debate [16, 22]. We find that players who choose assassins (the leading role) are more likely to abuse. We further demonstrate that the reason is that abusive players are more likely to choose assassins, instead of the alternative explanation that a player becomes more abusive when playing assassins. Finally, we present related work in §6 and offer our concluding thoughts in §7. A detailed version with additional analysis and prediction experiments can be found on arXiv: https://arxiv.org/abs/1902.06432.

Role	Description	Freq.(%)
warrior	Warriors have a large pool of health and considerable damage; they often undertake the stress from enemies in side lanes.	27.1
mage	Mages have heavy spell damage, but a small pool of health; they often take the middle lane and prepare to assist teammates.	25.8
marksman	Marksmen have a small pool of heath but can cause heavy damage; they need protection and may need time to grow.	25.7
assassin	Assassins are explosive and control the pace, but the health pool is often small; they are usually the leading role in a team.	11.5
support	Supports always aid teammates; they absorb damage while disrupting opponents by stunning and displacing them.	9.9

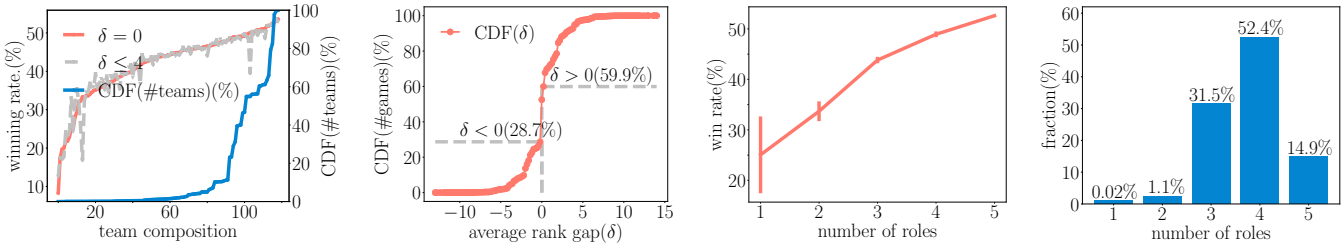
2 DATASET

Our dataset is provided by Tencent[2] and comes from a multiplayer online battle arena (MOBA) game: Honor of Kings, the most profitable game in the world. Similar to many other MOBA games such as Dota2 and League of Legends, Honor of Kings involves two teams to battle with each other. Each team consists of five players and the success of a team depends on the chemistry and collaboration between the five team members. The main motivation of our study is that players are expected to take certain roles when they select characters. These roles are designed to complement each other and "good" teams usually require particular compositions of roles. In this paper, we aim to explore the effect of team composition on different measures of team effectiveness.



There are multiple types of games in Honor of Kings. *Ranked games* are used to estimate a player's rank level in the game; while the other games are for practice or for fun. Since players care much less about unranked games than ranked games, all of our analyses are based on ranked games. Unranked games are only used to analyze players' role preferences.

Dataset description. Our dataset is derived from daily logs spanning three weeks in August, 2017. Specifically, we first randomly sample 20K games in each day of the third week, thereby obtaining 140K games and 1.3M players participating in these games. Among them, there are 78K ranked games. We then retrieve all the games involving any of these 1.3M players in the first two weeks to obtain player information. In total, we obtain 95.6M games and 100.2M players. Among these games, there are 54.4M *ranked games* on which most analyses in §3, §4, and §5 are based. In those analytical settings, we do not need historical information of every player in a team. There are several exceptions where we need historical statistics of every team member, so we use games in the third week in those cases and will point out in the text.

The log of each game includes its start time, end time, result (which team wins), gaming stats recorded when the game ends, and text messages in the chat room with abusive labels. See overall statistics of the dataset in Table 1.

Team roles. There are five roles in Honor of Kings: warrior ( ), mage ( ), marksman ( ), assassin ( ), and support ( ). A team is

[2]Honor of Kings is developed and published by Tencent, which is one of the largest Internet companies and also the largest game service provider in China.

(a) Sorted winning rate of different team compositions.

(b) Distribution of rank gap (δ) between two teams.

(c) Winning rate vs. team diversity (rank gap $\delta = 0$).

(d) Frequency of teams vs. team diversity.

Figure 1: Team composition and winning rates. In Fig. 1a, x-value corresponds to the index of a team composition, and is sorted by winning rate. The CDF of #teams shows the cumulative distribution in #teams according to the order in the x-axis. Fig. 1b shows the distribution of the rank gap between two teams. Fig. 1c shows that a diverse team with more role categories is more likely to win (error bars represent standard errors). Fig. 1d shows that most teams are rationale and cover at least 3 roles.

composed of different roles depending on players' choices. Henceforth, we use five icons to represent a team composition, e.g., (🛡, 🗡, 🗡, 🏹, 🏹) stands for a team with one warrior, two mages, two assassins, and no marksman or support. In total, there exist 126 team compositions. Table 2 presents the characteristics and frequency of each role. Table 3 shows several role combinations with its winning rate and frequency. We can clearly see that team compositions are not used equally by players: single roles and role combinations both vary greatly in frequency.

3 TEAM COMPOSITION AND WINNING

We first investigate the effect of team composition on whether a team wins or not, a direct measure of team performance. Although the matching system in Honor of Kings is designed to balance the ability of two teams, we observe that the winning rate of most team compositions is significantly lower than 50%, indicating that some role combinations cannot effectively work with each other.

Although two teams are with similar "skills", there exist winning and losing team compositions (Fig. 1a). Since we have 126 different team compositions in total, it is straightforward to estimate the *winning rate* of each team composition using the fraction of winning games, $\frac{\#\text{winning games}}{\#\text{games}}$. Fig. 1a shows that the winning rate of different team compositions spans a wide range, from 8.3% to 53.6%. It seems that some team compositions are doomed to lose. In addition, the figure also shows the cumulative distribution of #teams for each team composition, suggesting that most losing teams do not occur frequently. Notice that a similar plot will also be made for surrendering and abusing and we will see that the CDFs present very different shapes.

The fluctuation of winning rate between different team compositions among all games may not due to the effect of team compositions; another possible explanation is the ability of individual players: only relatively bad players choose certain bad team compositions. Although a matching system is designed to balance the ability of the players in two teams, it is difficult to always make sure that two teams exactly have the same ability. Fig. 1b shows the distribution of the rank level gap (δ) between two teams [3]. To calculate δ, we sum up the individual rank level in a team, and subtract the result of losing team from that of winning team. By

[3]Rank level indicates a player's gaming skill and ranges from 0 to 26.

Team compositions	Win rate	Used frequency(%)
team compositions with the highest winning rate		
🗡-✙ – ✙ – ✙ – ✙	53.6%	0.3
🏹 – 🗡 – ✙ – ✙ – ✙	53.2%	2.0
🏹 – 🗡-✙ – ✙ – 🛡	52.6%	14.9
team compositions with the lowest winning rate		
🗡 – 🗡 – ✙ – ✙ – ✙	19.7%	3.1×10^{-3}
🏹 – 🏹 – 🏹 – 🏹 – 🏹	17.4%	2.2×10^{-2}
🗡 – ✙ – ✙ – ✙ – ✙	8.3%	7.0×10^{-4}
team compositions that are most used		
🏹 – 🗡 – ✙ – ✙ – 🛡	52.6%	14.9
🗡 – ✙ – ✙ – 🛡 – 🛡	52.0%	13.3
🏹 – 🗡 – ✙ – 🛡 – 🛡	48.5%	11.6

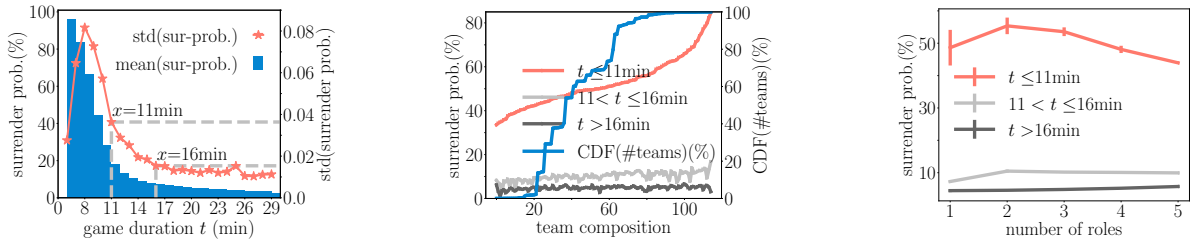


Table 3: Example team compositions and winning rates.

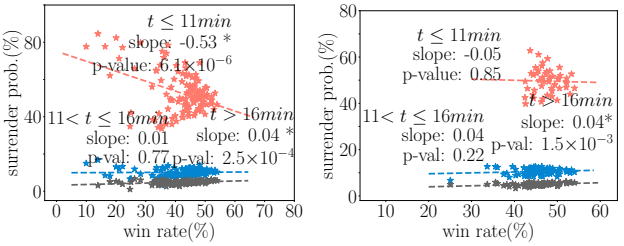
the effect of the matching system, the rank gaps in over 90% games are relatively small (within ±5). These minor gaps, however, are still associated with a significant difference in winning rate: only 28.7% games end up with the winning of the lower ranked team. Therefore, to demonstrate the influence of team compositions on winning rates and to exclude the ability factor, we control the rank gap between teams in Fig. 1a: we focus on games with $\delta = 0$ (red plots) and $\delta \leq 4$ (gray plots) respectively.

To further illustrate winning and losing team compositions, we present team compositions with the highest (lowest) winning rate in Table 3 (controlling the rank gap $\delta = 0$). Upon a careful examination, these losing teams do not often occur, reflected also by the cumulative distribution curve in Fig. 1a. In total, the bottom 90 losing team compositions only take 11.1% of all teams. This suggests that most players choose a reasonable team composition. However, the last three rows in Table 3 show that the most common team compositions still vary in winning rates, from 48.5% to 52.6%.



Diverse teams tend to perform well (Fig. 1c, 1d). An observation that stands out in Table 3 is that teams with the highest winning rate consist of more role categories than teams with the lowest winning rate. For instance, support (✙) or assassin (🏹) dominates the two compositions with the lowest winning rate, while all the top winning teams have at least four roles.

We further explore this observation by examining how winning rate changes as the number of roles in a team grows (Fig. 1c). We

(a) Surrender probability vs. game duration. (b) Surrender prob. vs. team composition. (c) Surrender prob. vs. team diversity.

Figure 2: Team composition and surrender probability. Fig. 2a shows the mean and standard deviation of surrender probability across team compositions conditioned on game duration. Fig. 2b shows that team compositions have varying surrender probabilities in games that end within 11 minutes, but have similar ones in longer games. Fig. 2c shows that diverse teams are less likely to surrender in early games (error bars represent standard errors).

(a) All team compositions. (b) Frequent team compositions.

Figure 3: Surrender probability vs. winning rate. In both figures, each dot denotes a team composition with its x-value for winning rate and y-value for surrender probability. Fig. 3a shows results for all team compositions. Fig. 3b shows the results after removing infrequent compositions, where surrender is not correlated with winning rate.

find that diverse team compositions are much more likely to win. One explanation is that these roles are designed to complement each other and teams with too few roles have weaknesses to be exploited. For instance, a team with no mage (🔧) or marksman (🎯) cannot cause sufficient damage in a game. Fig. 1d shows that most teams are employing at least three role categories, which is consistent with the observation in Fig. 1a that the losing team compositions on the left are not usually used.

4 TEAM COMPOSITION AND SURRENDER

As nothing worth achieving is going to be easy, tenacity is an important characteristic of an effective team. In the context of Honor of Kings, team tenacity can be reflected by not surrendering easily. The surrendering procedure is as follows: a player can propose to surrender and if at least four of five team members agree, the team will surrender as a whole and lose immediately. In this section, we examine the effect of team composition on team tenacity.

Surrender probability varies across team compositions in early games (Fig. 2a, 2b). Similar to winning, surrender happens at the end of a game. But surrender requires extra careful analysis because surrender may not always reflect team tenacity in Honor of Kings. For example, when the opponents are destroying the team base and all team members are killed, it is time to move on and surrender is simply a sign of "game over". Therefore, it is necessary to distinguish surrender in different game stages.

We examine the mean and the standard deviation of surrender probability across team compositions conditioned on game duration in Fig. 2a. We make two observations. First, the surrender probability monotonically decreases as game duration increases, partly because a team is only allowed to surrender starting from the 6th minute and games end in 6-8 minutes mostly because a team surrenders. Second, the standard deviation across team compositions first increases and then decreases as game duration increases, indicating that in late games every team surrenders with similar probability to signal game over. Based on Fig. 2a, we define three game stages: *early games* ($t \leq 11$), where the surrender probability has great mean and great std; *late games* ($t > 16$), where the surrender probability has small mean and small std; *middle games* ($11 < t \leq 16$), the middle part.

Having established the three types of games, we hypothesize that surrender in early games is the most indicative of team tenacity and varies across team compositions, while surrender in middle and late games is more of a formality and should not depend on team compositions. To study that, we sort team compositions by surrender probability in early games in Fig. 2b. According to the same order, we show the surrender probability in middle games and late games, as well as the cumulative distribution function of #teams. Consistent with our hypothesis, the surrender probability of different team compositions span a wide range from 33.6% to 84.6% in early games, but is pretty stable in middle games and late games. The CDF of #teams presents a different shape from that in Fig. 1a: commonly used team compositions are neither the most tenacious nor the least tenacious.

Diverse teams tend to be tenacious (Fig. 2c). Role diversity influences surrender probability in early games, especially when the number of roles is large. It seems that diverse teams with five roles are the most tenacious in early games. In comparison, the influence on middle and late games is minimal.

A weak team can still be tenacious (Fig. 3). We have shown that diverse teams tend to both perform well and show tenacity in adversity. One concern is that these two measures are correlated and tenacity is simply a side effect of team strength (winning). This hypothesis suggests that winning team compositions should be less likely to surrender. To further understand this issue, we study the correlation between surrender probability and winning rate for different team compositions. Fig. 3a shows that there is indeed a negative correlation between winning rate and surrender

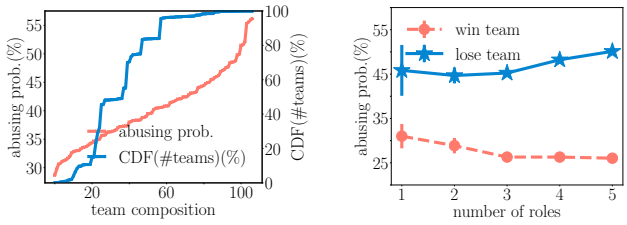
probability in early games, while little correlation in middle and late games. However, it seems that the correlation between winning rate and surrender probability in early games is dominated by a few outliers with very low winning rates. Given that we know that these teams only take a small fraction of all games in §3, we filter infrequent team compositions that appear less than 10,000 times and find that in the remaining team compositions (98.7% of all teams), surrender probability is not correlated with winning rate in all game stages (Fig. 3b), suggesting that team tenacity is almost independent of team strength/performance.

5 TEAM COMPOSITION AND ABUSIVE LANGUAGE USE

Our final measure of team effectiveness is concerned with the rapport in a team during the game. We use abusive language use to capture the rapport. Toxic behavior in online communities and gaming has received significant interests from our research community recently [11, 12, 26]. Here we provide the first systematic study on the effect of team composition on team-level abusive language use.

5.1 Team-level Abusive Language Use

Team compositions vary in abusing probability (Fig. 4a). In our dataset, we have a label of whether a message uses abusive language for all text messages based on a dictionary-based method officially used by Tencent. A team abuses if any player in that team abuses. For each team composition, we define *abusing probability* as the fraction of games that this team composition abuses.



We find that similar to winning and surrendering, team compositions vary in abusing probability, ranging from 28.7% to 56.2%. The cumulative distribution function of #teams looks much more similar to surrendering in Fig. 2b than winning in Fig. 1a: most commonly used team compositions are neither the most nor the least abusive. We will investigate further the interaction of individual-level abusing and team-level abusing in §5.2.

Losing teams are more likely to abuse. We hypothesize that losing teams are more likely to abuse because winning usually brings positive team morale, while losing leads to frustration and dissatisfaction [26]. This is indeed the case, as we examine the correlation between abusing probability and winning rate by the same way in Fig. 3: the slope of abusing probability with respect to winning rate is -0.41 (p-value is 5.2×10^{-4}, and we omit the figure due to the space limitation). Therefore, it is important to distinguish abusing probability between winning teams and losing teams.

Diverse teams tend to abuse more when losing and abuse less when winning (Fig. 4b). We further explore the effect of role diversity on team-level abusing. We observe different trends in winning teams and losing teams. When a team wins, team diversity is associated with low abusing probability; but it becomes the other way around if a team loses.

5.2 Individual-level Abusive Language Use

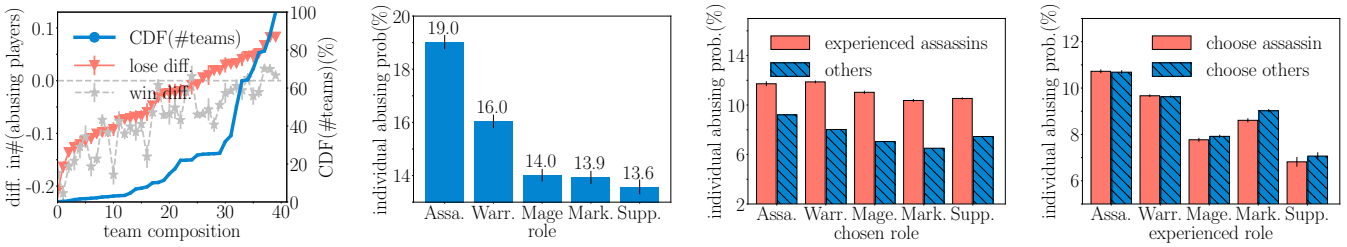
Different from winning and surrendering, abusive language use is an individual behavior. It provides a great opportunity to understand the effect of team composition on individual behavior and shed light on the "situation vs. personality" debate [16, 22].

(a) Sorted abusing probability. **(b) Abusing probability. vs. team diversity.**

Figure 4: Team composition and abusive language use. Fig. 4a presents sorted abusing probability for different team compositions and its corresponding cumulative distribution function in #teams. In Fig. 4b, x-axis represents #roles in a team, and y-axis represents team-level abusing probability.

Note that we conduct this part of experiments on players who have played at least 20 games to ensure sufficient samples for statistics.

A team does not equal the sum of individuals (Fig. 5a). We define individual abusing probability based on the fraction of games that a player abuses in. Because of linearity of expectation, the total number of expected abusing players in a team is simply the sum of each player's abusing probability:



$$\mathbb{E}(\#\text{abusing players in a team}) = \sum_{v \in \texttt{team}} P_{\texttt{abuse}}(v) \qquad (1)$$

where $P_{\texttt{abuse}}$ is estimated separately when a player wins or loses because abusing is associated with losing. This expectation is only valid if all players act independently in a team, but studies on teamwork have shown that a team does not equal the sum of individuals [7]. Therefore, we examine the discrepancy between observed and expected values to understand how team composition influences individual players. This analysis is done on games in the third week since it requires historical information of every team member.

Figure 5a shows the difference between the observed and the expected values for winning and losing teams, where *win/lose diff.* refers to the disparity between the observed and the expected number of abusing players($\mathbb{O}$(#abusing players) − $\mathbb{E}$(#abusing players)). For most team compositions, the difference is not zero, indicating that individuals abuse differently depending on team compositions. In particular, in the most commonly used teams (when the CDF grows quickly on the right of the plot), individuals are more likely to abuse than expected when losing.

Players who prefer leading roles are more abusive (Fig. 5b, 5c, 5d). There always exists a leader or a major contributor in a team. In Honor of Kings, assassins usually take this role in a team because of their explosiveness: assassins can carry the team and control game pace. A failed assassin may lead the team to lose.

Fig. 5b shows that assassins are more likely to abuse than other roles. We call this the "abusive assassin" phenomenon. One natural question arises: are assassins more abusive because abusive players tend to choose assassins, or players become more abusive when choosing assassins? To answer this question, we compare the abusing probability of the same roles chosen by different players and the same player choosing different roles. We define the *experienced role* for a player if that player chooses a role frequently, i.e., playing in more than 50% of games. This procedure identifies experienced

(a) Observed #abusing players – expected values. **(b) Abusing probability vs. roles.** **(c) Abusing probability of the same roles by different players.** **(d) Abusing probability of the same player with different roles.**

Figure 5: Fig. 5a shows the difference between the observed number of abusing players and the expected value based on individual abusing probability. The right three figures investigate the "abusive" assassin phenomenon. Fig. 5b shows individual abusive probability grouped by roles. Fig. 5c compares the abusing probability of players who usually play assassins with those who usually play other roles, grouped by their chosen role. Fig. 5d compares the abusing probability when a player choose assassin with when the same player chooses other roles, grouped by his experienced role. Error bars represent standard errors.

assassin players, experienced warrior players, etc. Fig. 5c presents the abusing probability of experienced assassin players when they choose each role (the same player choosing different roles). We observe that these experienced assassin players are much more likely to abuse than other players no matter what role they choose.

Fig. 5d examines the alternative hypothesis: players become more abusive when choosing assassins. We compare the same player's abusing probability when they choose assassins with choosing other roles, grouped by their experienced roles. We find that players do not become more abusive when choosing assassins. If anything, experienced mages and experienced marksmen are actually more abusive when they choose roles other than assassins.

Overall, our results in Honor of Kings support the hypothesis that abusive players tend to choose assassins, the leading role in a team, and players do not become abusive when choosing assassins.

6 RELATED WORK

Team formation. Researchers from the data mining community have formulated the problem of team formulation as a constrained optimization problem based on each individual's skills and their social networks [2, 3, 27, 28]. For instance, Li et al. [28] study a family of problems in team enhancement including team member replacement, team expansion, and team shrinkage.

Social/team roles. Digitalization of human traces have increasingly made implicit social/team roles explicit and enabled large-scale study on theories of social/team roles [6–8, 14, 41], e.g., Yang et al. [42] study how social roles influence the process of online information diffusion. In the context of gaming, Stetina et al. [37] examined problematic gaming behavior and depressive tendencies among people who play different types of online games.

Online gaming. Many researchers have recognized that online gaming can serve as a platform for studying individual/team behavior and communities [18, 24], where players not only develop individual skills but also coordinate and communicate with others [17, 20, 21, 29, 39]. Among our three measures of effectiveness, team performance is the most heavily studied topic, e.g., Pobiedina et al. [33, 34] explore factors that influence player's performance in Dota 2. and Agarwala and Pearce [1] demonstrate that different role combinations may affect team performance. Furthermore, gamification can also play an important role in education and scientific discovery [23, 32]. In addition to these exciting opportunities, online gaming leads to issues such as addiction and depression [25, 37].

7 CONCLUSION

In this paper, we study the effect of team composition in the largest MOBA game: Honor of Kings. We quantitatively show the varying effects of team composition on team performance (winning), tenacity (surrender), and rapport (abusive language use): although diverse teams tend to perform well and show tenacity in adversity, they are more likely to abuse when losing. The double-edged influence of team diversity suggests the importance of balancing team composition. We further examine how team composition influences individual behavior in abusive language use. In addition to showing that a team is not the sum of independent individuals, we contribute to the "situation vs. personality" debate and show that assassins abuse more because abusive players tend to choose assassins instead of players becoming abusive when choosing assassins. Our work suggests that the gaming environment may be improved by adjusting team matching and preventing players from using team compositions that correlate with increased abusive language use.

Limitations. Although we control for roles in our analyses, our study is observational and can be strengthened with experimental studies. However, experimental studies on team compositions are non-trivial because of the great number of possible combinations. Our notion of diversity is limited by our lack of access to users' demographic information. Despite that Honor of Kings is the largest MOBA game, the selection bias in our data and specifics of the game design may limit the generalizability of our findings.

Future directions. Several promising directions arise from our work. It remains challenging to develop a holistic model that captures the interaction between individual members, learns novel representations for role combinations, and makes accurate predictions for effectiveness metrics to validate and deeply understand our findings in this paper. Furthermore, although MOBA games provide an ideal environment for understanding the effect of team composition, it is important to generalize our findings in other scenarios, e.g., with implicit roles beyond gaming.
